Abstract

In clinical trials, the primary efficacy endpoint often corresponds to a so-called "composite endpoint". Composite endpoints combine several events of interest within a single outcome variable. Thereby it is intended to enlarge the expected effect size and thereby increase the power of the study. However, composite endpoints also come along with serious challenges and problems. On the one hand, composite endpoints may lead to difficulties during the planning phase of a trial with respect to the sample size calculation, as the expected clinical effect of an intervention on the composite endpoint depends on the effects on its single components and their correlations. This may lead to wrong assumptions on the sample size needed. Too optimistic assumptions on the expected effect may lead to an underpowered of the trial, whereas a too conservatively estimated effect results in an unnecessarily high sample size. On the other hand, the interpretation of composite endpoints may be difficult, as the observed effect of the composite does not necessarily reflect the effects of the single components. Therefore the demonstration of the clinical efficacy of a new intervention by exclusively evaluating the composite endpoint may be misleading. The present paper summarizes results and recommendations of the latest research addressing the above mentioned problems in the planning, analysis and interpretation of clinical trials with composite endpoints, thereby providing a practical guidance for users.

Key words: Composite endpoint; Competing risks; Multiple testing; Time-to-event; Adaptive designs

Core tip: When planning a clinical trial with a composite primary endpoint: (1) Be aware of planning uncertainties when calculating the sample size and incorporate them in an adequate way; (2) Include a multiple testing strategy for an improved interpretation of the study results; (3) Take into account competing risks when analyzing the individual components of a composite endpoint; and (4) Analyze subsequent events in an adequate multi-stage model.

RATIONALE FOR USING COMPOSITE ENDPOINTS

Clinical trials often focus on event variables as primary efficacy endpoints. In cardiology, "death" is often considered as the outcome of primary interest. However, clinically most relevant event types like "death" may be rare in many clinical conditions under investigation[1]. For example, due to the beneficial effects of modern treatments, patients with cardiovascular events like acute myocardial infarction experience a low mortality in the following years. Therefore, the assessment of differences in the survival curves of several treatment options may be difficult[2]. Using a rare event as primary endpoint results in the need of large sample sizes, a prolonged follow-up, and consequently an increased financial support, which often is not available. Thus, a "relevant and important treatment benefit" as claimed by the ICH E9 Guideline[3] cannot always be achieved by evaluating a single event endpoint, especially if this event type occurs with a low frequency[4]. By combining several types of events in a composite endpoint, the number of expected events is increased thereby intending an enlarged overall treatment effect. In the field of cardiovascular research, apart from death, clinical events like "non-fatal myocardial infarction", "non-fatal stroke", or "cardiovascular hospital admissions" also are of clinical interest and thus included into composite endpoints.

Most often, the composite endpoint is defined as a time-to-first-event variable, where different event types are counted as target events. In some applications, where the time period until the occurrence of an event is not of interest, composite endpoints can also be defined as binary event variables.

In summary, by using composite endpoints the required sample size is usually reduced and the study duration is shortened. Thereby, the use of composite endpoints very often is the only way to realize clinical trials investigating special interventions of interest.

Another important reason to use composite endpoints is when the effect of a new intervention may only be adequately assessed by considering several event variables. For example, atherosclerosis may result in a variety of clinical complications, and a single event endpoint therefore might not be sufficient for an adequate clinical evaluation[5]. Instead of formulating a multiple testing problem for several primary event endpoints, which always results in a loss of power, the ICH E9 Guideline[3] states that a composite outcome "addresses the multiplicity problem without requiring adjustment to the type I error".

CHALLENGES OF USING COMPOSITE ENDPOINTS

Planning and interpreting clinical trials with composite endpoints

Apart from the advantages of composite endpoints as outlined above, there also exist some serious problems and challenges.

In the planning stage of a clinical trial with a composite primary endpoint, calculation of the power may be particularly difficult as the assumed effect of the intervention depends on the effect sizes of the single components and their correlations. However, the level of evidence for these quantities may be low in many applications, as good historical data do not always exist. This complicates the choice of valid parameter assumptions in the planning phase of a study.

Analyzing and interpreting clinical trials with composite endpoints can be challenging as the composite effect as a "net measure" does not necessarily reflect the influence of the new intervention on the individual components[6,7]. Even in case a statistically significant and clinically relevant effect in the composite endpoint is observed, it may happen that the effects for some components are of very different magnitude or even point in opposite directions. As the efficacy of a treatment is usually judged on the composite effect alone, these situations may result in serious misinterpretations. This especially is a problem in case the composite endpoint consists of components of different clinical relevance and the less relevant endpoints refer to the larger effect sizes. The CPMP Guideline "Points to Consider on Multiplicity Issues"[8] therefore recommends to combine only components, which are expected to show effects of similar magnitude and with the same direction. This recommendation, however, may not be realistic in clinical practice. Even in thoroughly planned clinical studies, the initial assumptions about the underlying effect sizes can be wrong. Furthermore, the choice of the components must primarily be guided by their clinical relevance, and similar effects for all relevant event types cannot be expected in many cases.

Competing risks as a source of bias

The individual components of a composite endpoint usually define competing risks. In the presence of competing risks, the event rate of a specific event type also depends on the rates of all competing events[9]. For this reason, the event rates cannot be interpreted without simultaneously reporting all competing event rates. To illustrate this concept, assume that a novel therapeutic intervention in patients with cardiovascular disease is associated with a "one year mortality" of 0.3 as compared to 0.5 in the control group. Within the same group of patients, the rate for a "non-fatal myocardial infarction" might be 0.4 in the treatment group but only 0.2 in the control. If the death rates would not have been reported, one might come to the wrong conclusion that the control is superior to the treatment group with respect to "non-fatal myocardial infarction". When looking at the death rates, however, it becomes evident that the lower rate of "non-fatal myocardial infarction" in the control could exclusively be due to the fact that many patients had died before experiencing a (non-fatal) myocardial infarction. Ignoring the competing event scenario therefore may lead to a serious misinterpretation of treatment efficacy.

Therefore, methods taking into account competing events must be applied whenever the components of a composite endpoint are separately analyzed[5,8].

Follow-up beyond the first event

Composite time-to-first-event variables only take into account the first occurring event. This of course does not imply that there are no other subsequent events of interest occurring later. However, in the time to first event analysis these later events are not investigated, thereby leading to a loss of information.

On the other hand, an adequate and meaningful analysis of subsequent events may be a complex and difficult task, as-once a primary event has occurred the risk for all following events usually changes. For the latter reason models only focusing on a certain type of event, but not taking into account whether other events have occurred before, will yield biased results.

An unbiased approach to evaluate subsequent events would be to use more complex multistate models, which investigate all transition hazards between different subsequent event types[9]. The complexity of these models may be very high, and in order to get estimates with reasonable accuracy of all transition probabilities, the required sample size soon becomes unrealistically large. Therefore, for the confirmatory analysis of the composite and its components the time-to-first-event approach should usually be preferred. However, a descriptive presentation of the absolute numbers of all observed events should be provided in addition, keeping in mind that a correct interpretation of these results may be difficult.

NEW BIOMETRICAL METHODS FOR THE INTERPRETATION OF COMPOSITE ENDPOINTS

Overcoming uncertainties in sample size calculation

The standard approach to take account of planning uncertainties is the use of group-sequential or adaptive study designs. These designs allow stopping a trial at an interim stage due to an early demonstration of efficacy or due to futility. Whereas for group-sequential designs the number of interim analyses and the corresponding time points must be strictly planned in advance, adaptive designs additionally allow to change design parameters within an ongoing trial while still controlling the type I error rate.

A standard group-sequential design with one interim analysis (*e.g.*, after inclusion of 50% of the total study population) only offers two options-either to stop the study at interim or to continue the study until the full number of patients specified in the planning stage has been recruited[10-12].

In contrast, when using an adaptive design with one interim analysis, the sample size for the second stage can be recalculated based on the observed treatment effect at interim. If the observed effect at interim is large but not yet significant, only a small sample size for the second stage is needed, whereas the additionally required sample size is large, if the effect observed at interim is small. Moreover, it is possible to incorporate predefined stopping-for-futility rules in such designs, allowing to stop the study early with the acceptance of the null hypothesis whenever, on the basis of the interim data, the primary study goal becomes unrealistic. Thereby the number of patients being exposed to an ineffective treatment can be limited, and time and financial resources can be saved.

Another way to deal with uncertainties in the study planning assumptions is to use a more flexible power approach for sample size calculation. While the classical power is defined as the probability to reject the null hypothesis under a fixed parameter constellation of the alternative hypothesis, Rauch *et al*[13] proposed a so-called "expected power", which is defined as a weighted average over the classical power for different parameter constellations. Thereby, parameter constellations assumed to be more realistic in the planning stage of a study are assigned a higher weight, whereas other, less realistic assumptions are down-weighted. If there is no preexisting evidence available at all, equal weights for all possible parameter constellations might be assigned. The weights, which are defined by prior distributions, thus reflect the level of evidence or uncertainty in the planning stage. Calculating the sample size based on the "expected power" therefore defines a more robust approach in the common case of uncertain planning assumptions. The "expected power" can also be interpreted as a semi-Bayesian power approach[14].

Improving the interpretation of study results

The interpretation of study results may become difficult as the effect of the intervention under investigation on the composite endpoint does not necessarily reflect its effects on the single components. A possible solution of this problem would be to incorporate the (most important) components within the confirmatory test strategy by a multiple testing problem. However, this approach might seem to be contradictory as one main rationale for the use of a composite endpoint was to avoid multiplicity. A multiple testing problem always comes along with a certain loss in power resulting in an increase in sample size. The aim therefore is to create an adequate compromise by a multiple testing procedure, which mainly focuses on the composite endpoint but additionally gives some confirmatory evidence (at least) on the most important components.

In the literature, there exist a variety of either simple but also of more sophisticated multiple testing procedures, which can be applied to evaluate composite endpoints and their components. Simple applicable multiple testing strategies include the Bonferroni-Holm approach[15] or the sequential testing approach for hierarchically ordered hypotheses[16]. The application of at least a simple multiple testing strategy, which allow to address the components in a confirmatory way, is generally recommended. Even, if the trial is powered to

assess only the composite endpoint, these methods often allow a gain in information without increasing the sample size[17].

There also exist a variety of more sophisticated multiple testing procedures, which can be applied to provide sufficient power for the composite as well as for the (most relevant) components. So called "sequentially-rejective methods" represent extensions of the simple approaches outlined above. The underlying idea is to use an optimal splitting of the global significance level to test the individual hypotheses corresponding to the composite and the components. By "recovering" local levels of rejected hypotheses, the power loss due to multiplicity can be limited. Moreover, the test hypotheses for the components may be formulated less strictly than for the composite. For example, if the treatment under investigation already exhibits a significant and relevant effect on the composite, it might be sufficient to demonstrate in addition that the most relevant component is not adversely affected.

The application of sequentially-rejective multiple testing strategies in the evaluation of composite endpoints and their components has to be combined with the methodology for competing risks in order to provide an unbiased analysis and to prevent misinterpretations[18,19].

These methods can be further improved, if the correlation between the test statistics is taken into account. As an event referring to a single component always corresponds to an event in the composite endpoint, the test statistic of the composite and its components are usually highly correlated. By incorporating the information of the underlying correlation, the local significance levels of a multiple testing problem can be chosen less stringent, and the power loss often can be markedly decreased. These two approaches have been investigated recently by Rauch *et al*[20,21].

A completely different approach to improve the interpretation of clinical trials with composite endpoints is to use a weighted combined effect measure, which assigns higher weights to the more important components with the intention that an opposite effect in a relevant component (*e.g.*, "death") is less likely to be masked by a large effect in a component of secondary importance (*e.g.*, "cardiovascular hospital admission"). Recently, Pocock *et al*[22] and Buyse[23] proposed two similar combined effect measures, referred as the "win ratio" and the "proportion in favor of treatment", respectively. Both approaches are based on the same idea: All components are ordered with respect to their clinical relevance. The individual patients are compared between the groups. Based on the component of primary importance, for each comparison the patient with the "better" outcome is determined. In case no unique "winner" can be determined with respect to the most relevant component (*e.g.*, due to censoring, missing values or due to equal performance of both patients), the comparison will be based on the component of secondary importance and so on. This approach intends a higher weighting of the more relevant components, but also allows incorporating subsequent events.

Although this approach appears to be attractive in general, it also has some deficiencies. On the one hand, it can be shown that the weights, which are assigned to the single components, depend on the follow-up and the censoring distribution[24]. Moreover the weights are not standardized, that means they do not sum up to 1. As a consequence, the combined effect measure is not comparable between various studies as required-for example-within the context of meta-analyses. A small effect in the combined measure might thus be due to small effects in the components, but also could be explained by an unfavorable censoring distribution. Therefore, it cannot generally be deduced that these two approaches provide a gain in interpretation.

CONCLUSION

The use of a composite endpoint as primary efficacy variable can provide major advantages compared to a single event endpoint, if the event of primary interest is rare. However, care has to be taken when planning, analyzing and interpreting clinical trials with a composite endpoint as the primary efficacy outcome. The current statistical literature provides a variety of methods to overcome typical challenges arising from the use of composite endpoints thereby strengthening the interpretation of the results of clinical trials and avoiding serious misinterpretations. Now, the time has come to routinely incorporate these new methods into clinical trial applications.

Abstract

Over the last decades, cardiac magnetic resonance (CMR) has transformed from a research tool to a widely used diagnostic method in clinical cardiology. This method can now make useful, unique contributions to the work-up of patients with ischemic and non-ischemic heart disease. Advantages of CMR, compared to other imaging methods, include very high resolution imaging with a spatial resolution up to 0.5 mm × 0.5 mm in plane, a large array of different imaging sequences to provide *in vivo* tissue characterization, and radiation-free imaging. The present manuscript highlights the relevance of CMR in the current clinical practice and new perspectives in cardiology.

Key words: Cardiac magnetic resonance; Gadolinium enhancement; Myocarditis; Myocardial; Cardiomyopathy

Core tip: The present manuscript highlights the relevance of cardiac magnetic resonance in the current clinical practice and new perspectives in cardiology.

INTRODUCTION

Over the last decades, cardiac magnetic resonance (CMR) has transformed from a research tool to a widely used diagnostic method in clinical practice. While other imaging modalities like echocardiography and cardiac computed tomography depend solely on tissue density, the most important feature that CMR affords to the diagnostic toolset of the clinic cardiologist, is its ability to provide with a very-high spatial resolution, up to 0.5 mm × 0.5 mm in plane, a large array of different imaging sequences in order to assess *in-vivo* tissue characterization, in addition to radiation-free imaging. These imaging sequences investigate the presence of protons in different chemical environments, thereby allowing conclusions on the presence of fat, water (edema), blood or myocardium among other tissues. The addition of a contrast agent enhances the diagnostic capabilities to assess perfusion, fibrosis and necrosis as well as identify thrombus. Exploiting these different imaging sequences, in addition to the capability of performing high spatial resolution imaging in any desired imaging plane in 3-dimention (3D)

space, CMR provides what could be also called "*in-vivo* pathology". Therefore, this has led to substantial progress in the assessment of patients with ischemic and non-ischemic heart disease[1].

ISCHEMIC HEART DISEASE

Acute ischemic disease

After the development of electrocardiographic-triggered fast CMR imaging using gradient-echo sequences, the late gadolinium enhancement (LGE) imaging technique opened new horizons for CMR at the beginning of the century[2-4]. The method exploits the fact that gadolinium-based contrast agents have a much higher volume of distribution in necrotic and fibrotic tissue, when the cardiomyocytes have lost their cell wall integrity or have been replaced by collagen. Late enhancement imaging therefore allows for an assessment of viability with unprecedented image contrast and very-high spatial resolution. Clinical applications included the detection, when the diagnosis is unclear, the differences between acute myocardial infarction (AMI) and chronic ischemic cardiomyopathy[5,6]. The assessment of viability predicts functional recovery in acute myocardial infarction based on the transmural extent of the necrosis[7].

The use of CMR in this setting was subsequently enhanced by the development of water-sensitive T2-STIR sequences, allows the assessment of tissue edema. Of note, since only acute infarction has edema, the combination with LGE imaging, T2-STIR helps to differentiate acute from chronic myocardial infarction[6,8,9]. The edematous tissue in AMI is thought to reflect the area-at-risk, allowing for quantitative assessment of salvaged myocardium after reperfusion therapy[10-12]. This can be measured as the difference between edematous tissue minus necrotic tissue, where the latter is seen on LGE.

Microvascular obstruction (MVO) as a consequence of ischemia and reperfusion injury in AMI is reliably detected with first-pass perfusion imaging or the LGE sequence applied early after contrast injection. The presence of MVO is an independent predictor of adverse outcome, independent of infarct size and left ventricular systolic function[13,14]. Severe microvascular injury can be complicated by reperfusion hemorrhage, which again can be visualized and also quantified with a specific CMR sequence (T2*-weighted imaging)[15]. It is currently unclear whether hemorrhage has independent prognostic effects beyond MVO, since insufficient sample size and flaws in study design, limited most of the clinical studies trying to address this question.

Chronic ischemic disease

Newer imaging approaches are emerging to fine-tune risk assessment in chronic ischemic heart disease, and help, for example, with patient's selection for implantable cardioverter-defibrillators (ICD) implantation. Several authors have shown that the peri-infarct zone between chronic infarction tissue and healthy myocardium displays an intermediate contrast signal. The extent of this "grey-zone" has been associated with ventricular arrhythmia and major adverse cardiac events, probably due to electrical re-entry circuits being located in this area[16]. Prospective studies are under way to assess, whether advanced tissue characteristics such as the LGE grey-zone would be helpful to better select patients for ICD implantation, thereby switching selection criteria from the current left ventricular systolic function to a tissue characteristic. Hence, an improved patient's selection could be of tremendous help, allowing for better selection of patients at higher risk, and also avoiding potentially unnecessary ICD implantations.

In stable coronary artery disease, CMR perfusion imaging with and without stress agents (predominantly adenosine) can detect myocardial ischemia with high accuracy. Depending on the reference standard, it has been reported a sensitivity and specificity of about 90% and 70%-90%, respectively, for the detection of myocardial ischemia[17,18]. Advantages of CMR in this setting include a higher spatial resolution than nuclear imaging methods, allowing the diagnosis of sub-endocardial perfusion defects and microvascular disease[19]. Research efforts are under way to detect ischemia without using contrast agents. Indeed, blood-oxygen-level-dependent (BOLD) sequences are able to create image contrast-based on the tissue's oxygen content in the brain, and initial reports have suggested that modified BOLD sequences could also be applied in the heart[20,21]. This approach, once developed to a clinically applicable tool, promises to revolutionize the ischemia detection field by measuring myocardial oxygen directly, and moving away from perfusion as a surrogate marker.

NON-ISCHEMIC HEART DISEASE

Cardiac magnetic resonance has allowed significant progress in understanding of non-ischemic cardiomyopathies. Beyond accurate assessment of ventricular volume and function, tissue characterization using T1, T2, T2*, perfusion and contrast-enhanced sequences allows for comprehensive tissue characterization as a non-invasive pathology[22-24]. This further contributes to identify the etiology of heart failure, and initial studies have started to identify CMR-based tissue characteristics as prognostic markers[25-28]. In fact, CMR is now the reference diagnostic tool to diagnose myocarditis, as recommended by the Lake Louise consensus criteria[29]. Importantly, T2-weighted imaging identifies edema as a marker of inflammation in acute/active disease, and late gadolinium enhancement is typically present in a "patchy", thus, a non-ischemic pattern. Of note, the combined imaging sequences yield a diagnostic power to assess myocarditis with a sensitivity of 76% and specificity of 96%[30]. Noteworthy, patients with LGE in myocarditis have a worse prognosis than patients

without LGE[31]. Moreover, infiltrative cardiomyopathies such as amyloidosis are reliably diagnosed based on their typical pattern of signal change on T2 and LGE, usually involving the entire myocardium as an organ[32]. The diagnostic power of CMR is especially well exploited in iron deposition disease like thalassemia and hemochromatosis. In fact, CMR can semi-quantitatively assess iron deposition by measuring the T2* value of myocardium. The latter highly correlates with myocardial iron content[33,34]. Furthermore, it is of prognostic value as can be used to monitor the effect of iron chelation therapy, let's say, to start, titrate or finish iron chelation therapy.

THE FUTURE OF CMR

Cardiac magnetic resonance is still a relatively "young" imaging technique, and new technical developments are continuously entering the clinical arena. While current imaging sequences mostly provide a contrast suited for visual analysis, imaging methods that quantitatively map T1, T2 and T2* characteristics are under evaluation[35]. Moving away from qualitative assessment to semi-quantitative or quantitative image analysis will allow increased diagnostic accuracy and reduced observer bias, as well as improve inter-study variability. Normal values will have to be established for different field strengths, and differences in sequence programming between different CMR vendors as a source of variability of normal values will have to be addressed. Eventually, advanced tissue characterization with mapping sequences could reduce (but probably not eliminate) the dependence on gadolinium-based contrast agent. New imaging sequences that apply self-triggering may eliminate the need for electrocardiographic tracing and breath-hold maneuvers[36], further increasing patient comfort and reduce scan time.

CONCLUSION

Cardiac magnetic resonance has become a basic diagnostic tool in cardiovascular medicine. The next decade will be marked by clinical trials investigating the prognostic value of the detailed imaging findings that can be obtained today, and may guide therapy and improve patient prognosis.

Abstract

In recent years attention has been raised to the fact of increased morbidity and mortality between women who suffer from coronary disease. The identification of the so called Yentl Syndrome has emerged the deeper investigation of the true incidence of coronary disease in women and its outcomes. In this review an effort has been undertaken to understand the interaction of coronary disease and female gender after the implementation of newer therapeutic interventional and pharmaceutics' approaches of the modern era.

Key words: Yentl syndrome; Women coronary disease; Acute coronary syndromes; Female gender; Invasive treatment

Core tip: Coronary disease although remains a leading cause of morbidity and mortality in women, is however underestimated mainly because of the protective role of estrogens that results in lower rates of the disease until the age of mid-fifty. In this review detailed information about the prevalence and the consequences of the disease in women are quoted as well as evidence concerning the results of invasive treatment and use of modern drug therapy.

INTRODUCTION

Coronary artery disease (CAD) constitutes a form of modern epidemic, as it still remains the leading cause of mortality and morbidity in the ageing western societies[1]. The prevalence of CAD in the general population varies, depending on age and sex. In terms of age, there is a trend of more incidents in older ages. Concerning sex, until the age of 60 years old, the predicted probability of having an acute myocardial infarction (AMI) is by

far higher in men than in women (60.6% *vs* 33.0%, respectively)[1]. Therefore, CAD is widely believed to be a man's disease, although it accounts for more deaths in women at the age of 35 years than breast cancer (Table 1)[2]. This has been mainly attributed to the protective role of estrogens in the cardiovascular system as they enhance vascular function, reduce the inflammatory response, increase metabolism and insulin sensitivity and finally promote cardiac myocyte and stem cell survival[3]. As a consequence, female hormones may partially account for women's longevity observed in randomized control trials, where women with CAD are older than men and have more co-morbidities such as diabetes, hypertension and chronic kidney disease[4,5]. At menopause, the lack of the protective effect of estrogens leads to a 10-fold increase in the prevalence of CAD in women compared to a 4.6 fold increase in men of the same age[6]. Finally, by the 7th decade of life the increasing rate of CAD among women results in similar rates of the disease among the two genders, although lifestyle factors seem to have a different impact on clinical outcome between gender[1,7,8].

Due to the above mentioned characteristics of the female gender, and the fact that the majority of trials more often enroll younger patients, the representation of women in clinical trials was until recently relatively low, approximately 30% (Table 2)[9,10]. Even in one of the largest contemporary trials designed to compare outcomes between invasive and conservative pharmacological treatment in patients with stable CAD, the COURAGE trial (Clinical Outcomes Utilizing Revascularization and AGgressive Drug Evaluation), men encountered for approximately 85% of the study group[11]. As a result, women suffering from CAD are handled diagnostically and therapeutically based on conclusions drawn mainly from male populations. This observation underscores the need for a more gender focused approach both in every day clinical practice but also in large scale trials. The purpose of the present review is to explore the available data depicting the best strategies to recognise and treat CAD in women.

WOMEN AND SYMPTOM PRESENTATION

It has been demonstrated that women tend to present for chest pain evaluation in the emergency room at a greater rate compared to men (4.0 million visits for women *vs* 2.4 million visits for men). However, women tend to present with less typical symptoms, such as fatigue (70.7%), sleep disturbance (47.8%) and shortness of breath (42.1%)[12], back pain, indigestion, weakness, nausea/vomiting, dyspnoea and weakness[13,14]. At an older age, with more co-morbidities including diabetes, peripheral vascular disease, chronic kidney disease and hypertension[15]. A great amount of literature explored this phenomenon giving rise to large scale clinical trials which resulted in the identification of three paradoxes with regard to female sex and CAD manifestation[13]. (1) Women have disproportionately lower burden of atherosclerosis and obstructive CAD compared with the extent of angina they complain for; (2) Compared to men, women have less severe CAD despite the fact that they are older with a greater risk factor burden; and (3) Even though CAD is less evident in women, as illustrated by invasive diagnostic imaging modalities, females still have a more adverse prognosis compared to men.

Another parameter of great importance is the increasing prevalence of the cardiac X syndrome or coronary microvascular dysfunction among women of post-menopausal age. It is evident that almost 40% of the operated coronary angiographies reveal non obstructive atherosclerosis although patients present with anginal symptoms and positive exercise training results[16]. A large proportion out of 30% of these findings is attributed to coronary microvascular dysfunction as no other identifiable

Table 2 Women are considerably underrepresented in clinical trials[9]

cause can be found. The most interesting aspect of this group of patients is the fact that it is consisted in its great proportion (almost 70%) of post-menopausal women[17]. In contrast to the findings of earlier studies that microvascular angina does not affect long term prognosis[18], it is evident nowadays from a large retrospective analysis of 11223 patients referred for coronary angiography with stable angina, that patients with non-obstructive CAD consolidate a further increase in the risk of coronary events and of all-cause mortality (HR = 1.85; 95%CI: 1.51-2.28; and 1.52; 95%CI: 1.24-1.88, respectively)[19].

Thus, women are frequently a clinical challenge for the cardiologist and their symptom misinterpretation may lead to the wrong diagnosis and treatment with potentially unfavourable consequences. Symptom evaluation and recognition in women is a matter of great importance, since it has been shown that when typical symptoms accompany an acute coronary syndrome (ACS) there is no difference in the disease diagnosis between women and men[20]. Moreover, when prodromal symptoms are recognised in women before an ACS, women have better survival in comparison to men[21].

WOMEN AND TREATMENT STRATEGIES

Not only diagnostic evaluation of women may be misleading, but also the appropriate treatment selection can be difficult. It was already recognized in 1991 that women suffering from CAD had less chances to be introduced either in coronary angiography or percutaneous coronary intervention (15.4% of women *vs* 27.3% of men, $P < 0.001$)[22]. This approach was demonstrated even in cases were admission symptoms were more prominent in women than in men[23]. Unlike men, women were submitted less frequently to any diagnostic or therapeutic intervention creating in this way dissimilarity on curing procedures. This alarming fact was described by Bernadine Healy, the first woman director of National Health Institute in United States, as the Yentl syndrome named after the Jewish heroine of Isaac Singer, who was masqueraded as a boy in order to be educated in the Talmud philosophy. Healy concluded that when a woman has been shown to have extensive CAD, like men, only then she gets the appropriate treatment[24]. Since, a plethora of studies examined gender differences in order to provide the best treatment options for women.

WOMEN AND PERCUTANEOUS CORONARY INTERVENTION

One of the first studies comparing the impact of percutaneous coronary interventions (PCI) with bare metal stent (BMS) implantation between females and males, revealed that women had 50% more chance of death in comparison to men after adjustment for age, co-morbidities, and extend of coronary atherosclerosis[25]. However, in the same analysis, after final adjustment for Body Surface Area, mortality rates were similar between the two genders, although a slighter increased rate of stroke, vascular complications and repeat in-hospital revascularization was observed in women[25]. Similar results were reported in a retrospective analysis from Mayo Clinic investigating 18885 consecutive, patients who underwent PCI between 1979 and 1995 (early group) and between 1996 and 2004 (late group)[26]. The results indicated no difference in terms of 30-d mortality, while after adjustment for baseline risk factors, again there was no difference observed in short or long term mortality between the two genders (Figures 1 and 2)[26]. The study indicated that between the two groups a decrease in 30 d mortality was observed in both genders during the 25-year follow up period.

A retrospective study from Rotterdam investigated the outcomes of Sirolimus Eluting Stents, Pacliataxel Eluting Stents and BMS in women[27]. In this study, even though women had worse baseline characteristics compared to men, no differences in 3-year outcomes were detected between males and females.

A recent meta-analysis, which included 43904 patients (26.3% women) in 26 trials, assessed the safety and

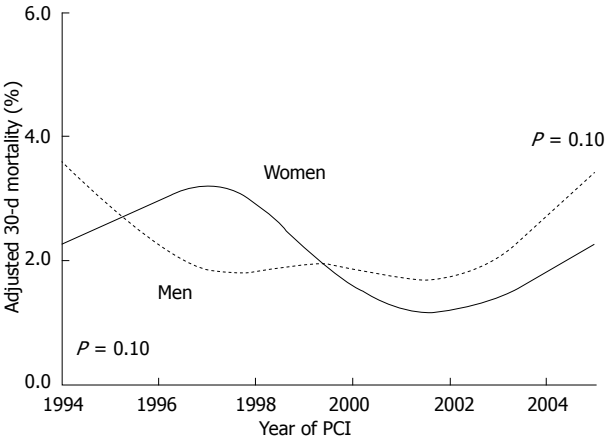

Figure 1 Mayo clinic percutaneous coronary interventions registry: 12798 pts adjusted 30-d mortality after percutaneous coronary interventions[26].

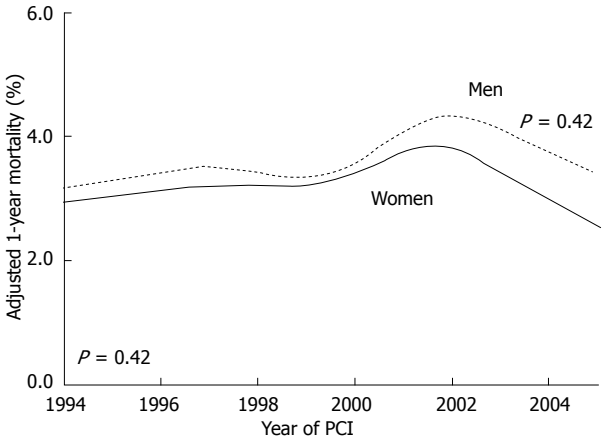

Figure 2 Mayo clinic percutaneous coronary interventions registry: 12798 pts Adjusted 1-year mortality after percutaneous coronary interventions[26].

efficacy of DES in women[28]. The study showed that DES implantation in women was more effective and safe than BMS implantation. Furthermore, it was observed that 2nd and 3rd generation DES, such as everolimus-eluting Xience and Promus stents, zotarolimus-eluting Endeavor and Resolute stents, biolimus-eluting Biomatrix and Nobori stents, and sirolimus-eluting Yukon stents, were associated with an improved safety profile compared with early-generation DES[28]. These results suggest that women undergoing PCI may benefit more when DES and moreover newer generation DES are used.

An interesting meta-analysis was designed in order to evaluate whether female gender is an independent risk factor for repeated coronary revascularization after PCI. The results indicated that although female sex increases the short term rate of repeated revascularization after PCI the long term rate was the same between the two genders clarifying the fact that even for this parameter female gender is not an independent risk factor[29].

Bleeding complications at the point of vascular puncture, hematomas and retroperitoneal bleedings are decreased in the current era. This is mainly due to introduction of less aggressive anticoagulant regimens, adjustment of heparin dose according to body mass index and smaller size catheters. However, women still continue to be at 1.5 to 4 times greater risk for bleeding in comparison to men (Table 3)[30]. Reduced Body Surface Area, altered pharmacokinetics and diminished drug metabolism are the main aspects of female gender that attribute mostly in these higher bleeding rates.

Newer anticoagulant agents were recently introduced in clinical practice raising expectations for further bleeding risk reduction. In order to evaluate this hypothesis, novel studies were contacted to evaluate the action of direct thrombin inhibitor bivalirudin (ANGIOX®) in both genders who suffered from moderate and high-risk ACS[31]. Out of 7789 patients submitted to PCI, 2561 received heparin and Ⅱb-Ⅲa glycoprotein inhibitor, 2609 received bivalirudin in combination to Ⅱb-Ⅲa glycoprotein inhibitor and 2619 received bivalirudin solely. The group of patient to receive bivalirudin in comparison to the group of patient receiving heparin in combination to Ⅱb-Ⅲa glycoprotein inhibitor displayed the same degree of ischemic events but with a lesser degree of major bleeding (4% *vs* 7%, $P < 0.0001$)[31]. Interestingly, bivalirudin alone decreased the variance of bleeding between the two genders, but it did not completely eliminate it.

In order to achieve decreased bleeding rates in women, the idea of radial approach during intervention was implemented into clinical practice. However, due to women's smaller vessel size and lower pain threshold it was revealed that 14% of women were finally switched to femoral approach in contrast to 1.7% of men[32]. In the same study however, during 299 radial interventions in women no major bleeding was observed, whereas in 601 femoral intervention, 25 major bleedings where recorded ($P = 0.0008$). In addition, radial approach was related with a lower rate of minor bleeding (6.4% *vs* 39.4% $P = 0.00001$). These favourable results indicate that radial approach during PCI in women is safer in terms of bleeding, even though there are more difficulties to initiate the procedure through the particular access site.

WOMEN AND CORONARY ARTERY BY-PASS GRAFTING

In the past, women submitted to CABG were shown to have higher perioperative morbidity and mortality compared to men[33-35]. These first results raised the issue of CABG safety in women and initiated the conduction of several newer trials. Indeed, over 20 trials investigated the impact of CABG in women compared to men. A recent meta-analysis confirmed that women experience higher mortality rates in comparison to men in terms of short-, mid- and long-term follow-up with the higher mortality recorded in the short-term period[36]. Several explanations for this observation have been proposed such as the delayed reference of women to CABG when

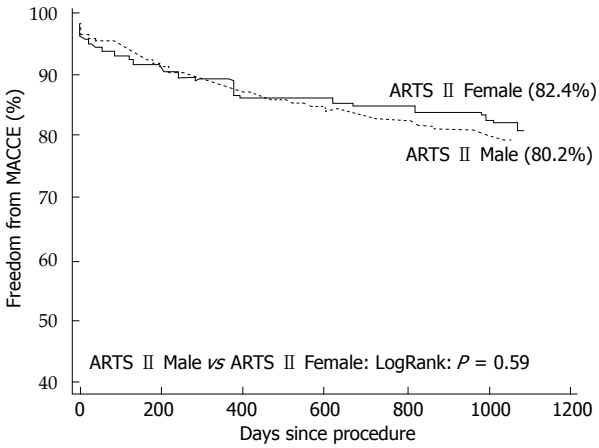

Figure 3 Freedom from major adverse cardiac and cerebrovascular events after percutaneous coronary intervention in Arterial Revascularization Therapies Study-Part Ⅱ[41].

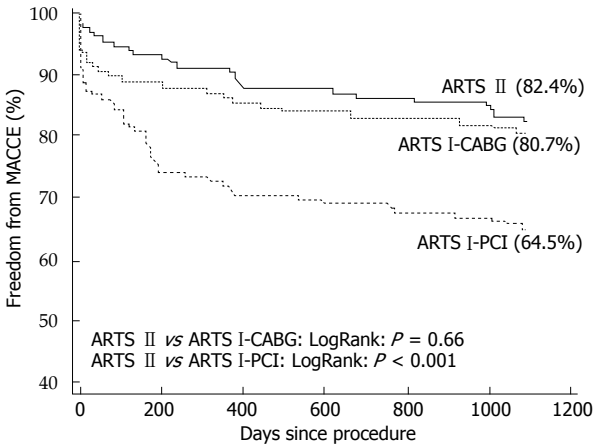

Figure 4 Freedom from major adverse cardiac and cerebrovascular events after coronary artery by-pass grafting and percutaneous coronary intervention with bare metal stent and sirolimus eluting stent implantation in women[41].

CAD extends to a greater degree, the smaller size of women coronary vessels that creates technical issues to the surgeon or finally the limited use of left internal mammary artery in women[37-39].

Arterial Revascularization Therapies Study Part I (ARTS I) was one of the first studies to compare CABG and PCI in women. The study demonstrated that for a total of 1205 patients there was no significant difference in terms of death, stroke, or myocardial infarction between the two genders. However, stenting was ascossiated to a greater need for repeated revascularization[40,41].

Newer studies in the Drug Eluting Stent (DES) era sought to further investigate the effect of gender on PCI and CABG outcomes. The multicenter randomized study Arterial Revascularization Therapies Study-Part Ⅱ (ARTS Ⅱ) was designed to evaluate the outcomes of Sirolimus Eluting Stent implantation in comparison to BMS implantation and Coronary Artery Bypass Grafting (CABG) in patients with multivessel CAD[41]. In ARTS Ⅱ, although women tended to have more risk factors compared to men, they experienced the same rate of adverse events with men at 30 d, one year and three years after Sirolimus Eluting Stent implantation (Figure 3)[37]. Additionally, it was observed that both genders had a more favorable clinical outcome with Sirolimus Eluting Stents compared with BMS but similar to CABG (Figure 4)[41].

These results could potentially institute PCI as the first choice treatment in women with multivessel disease.

WOMEN AND ACUTE CORONARY SYNDROMES

The vast majority of women, about 60%, experience an acute coronary syndrome (ACS) or sudden cardiac death as the first manifestation of the disease[42]. The initial results comparing gender differences in patients with ACS were presented in the pre-thrombolytic era, where a 28% mortality rate was demonstrated in women compared to a 16% mortality among men[43]. Women also experienced a 3 fold higher rate of reinfarction. In the following years, the introduction of thrombolysis decreased the total mortality rates in the general population. However,

a discrepancy was still evident between the two genders (30 d unadjusted mortality rate was 13.1% in women and 4.8% in men)[44]. Newer, large scale studies were undertaken in order to re-evaluate these results in the modern era of invasive approach to ACS. One of the largest trials investigating these aspects enrolled 78254 patients (39% women) with AMI in 420 United States hospitals from 2001 to 2006[45]. The results reconfirmed the data observed in previous trials. The study showed that women with ACS are older, with more comorbidities such as hypertension, diabetes, and metabolic syndrome and tend to present less often with ST-elevation AMI[46-48]. Adjusted analysis revealed no differences in terms of mortality between the two genders for ACS, but in the subgroup of ST Elevation Myocardial Infarction (STEMI) there was a statistically significant and almost double proportion of mortality in women (10.2% women *vs* 5.5% men, $P < 0.0001$). An important conclusion from this trial was the fact that women received less often aspirin and b-blockers and were less often treated in an invasive manner with percutaneous transluminal coronary angioplasty.

This approach was also noticed in an earlier contacted study in Minnesota (46% less chances of invasive approach) as well as in a in a Swiss national registry where the rate of women introduced in PCI was significantly lower than men (OR = 0.70; 95%CI: 0.64 to 0.76)[15,48].

These observations raised the question of whether physicians prefer more conservative strategies because women have higher mortality rates with invasive procedures or whether women are less willing to undergo such a procedure. PRimary Angioplasty in patients transferred from General community hospitals to specialized PTCA Units with or without Emergency thrombolysis 1 and 2 studies evaluated 520 patients with STEMI treated with thrombolytics and 530 patients treated with primary PCI. Women treated with thrombolytics had almost two fold higher mortality than women treated with primary PCI ($P = 0.043$)[49]. Therefore, although patient demographic data were not adjusted to body mass index, which could have an effect on the unadjusted doses of streptokinase used, it can be concluded that primary PCI to treat women with AMI is superior to a more conservative approach. Similar results were demonstrated in the Global Utilization of Streptokinase and TPA for Occluded Coronary Arteries Ⅱ-B and in a sub-analysis of the Primary Angioplasty in Myocardial Infarction trial comparing newer thrombolytic agents *vs* PCI[50,51]. More recent studies showed that mortality and major adverse cardiac events, though higher among women with primary PCI in unadjusted analyses, are comparable in both genders after adjusting for age, hypertension, smoking, diabetes mellitus, stent diameter, and time between symptoms onset and ambulance arrival[52-55]. A meta-analysis that included 8 trials and almost 10115 patients, demonstrated that low-risk women with ACS may benefit from a more conservative approach. However, males and high-risk females with ACS treated with an invasive strategy have similar clinical outcome in terms of death, MI, or rehospitalisation for ACS[56].

CONCLUSION

It has been consistently shown that women who are suffering from CAD usually present with less typical symptoms, at an older ager and with more co-morbidities compared with men. Therefore, they constitute a high risk group that potentially poses a diagnostic and therapeutic challenge. However, it seems that in the modern era, where sophisticated interventional and surgical techniques have emerged, women significantly benefit from an early invasive approach provided an intense medical monitoring is implemented.

Abstract

Helicobacter pylori (*H. pylori*) is a known pathogen implicated in genesis of gastritis, peptic ulcer disease, gastric carcinoma and gastric lymphoma. Beyond the stomach, the organism has also been implicated in the causation of immune thrombocytopenia and iron deficiency anemia. Although an area of active clinical research, the role of this gram negative organism in causation of atherosclerosis and coronary artery disease (CAD) remains enigmatic. CAD is a multifactorial disease which results from the atherosclerosis involving coronary arteries. The major risk factors include age, diabetes mellitus, smoking, hypertension and dyslipidemia. The risk of coronary artery disease is believed to increase with chronic inflammation. Various organisms like Chlamydia and Helicobacter have been suspected to have a role in genesis of atherosclerosis *via* causation of chronic inflammation. This paper focuses on available evidence to ascertain if the role of *H. pylori* in CAD causation has been proven beyond doubt and if eradication may reduce the risk of CAD or improve outcomes in these patients.

Key words: Extra gastric; Coronary artery disease; *Helicobacter pylori*; Atherosclerosis; Inflammation

Core tip: Coronary artery disease (CAD) is a multifactorial disease and inflammation plays an important role in Atherogenesis. *Helicobacter pylori* (*H. pylori*) is speculated to be one organism which may incite the inflammatory response thereby predisposing infected individuals to CAD. This paper looks at clinical evidence in relation to *H. pylori* infection and CAD and also examines the evidence of effects of eradication of *H. pylori* on CAD and its risk factors.

Sharma V, Aggarwal A. *Helicobacter pylori*: Does it add to risk of coronary artery disease. *World J Cardiol* 2015; 7(1): 19-25 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i1/19.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i1.19

INTRODUCTION

Helicobacter pylori (H. pylori), first identified by Marshall and Warren in 1982, is a ubiquitous gram negative bacterium. A mixture of serendipity and diligent research lifted the veil off this enigmatic organism which was first

thought to be Campylobacter like. The Easter holidays of 1982 had ensured that the culture plates were not destroyed after 48 h of absence of growth and led on to the discovery of *H. pylori*[1]. However, it was after much perusal that the scientific community accepted the bacterium-ulcer-cancer dogma eventually culminating in the 2005 Nobel Prize[2]. Over years it has become clear that this bacterium is responsible for many disease other than the gastric diseases. In the stomach *H. pylori* is implicated in the causation of chronic gastritis, peptic ulcer (gastro-duodenal), gastric MALTOMA (mucosa associated lymphoid tissue lymphoma) and gastric adenocarcinoma. It is also associated with certain extra-gastric disorders like immune thrombocytopenia and iron deficiency anaemia[3,4]. Although the role of these in causation of gastric injury has emerged in recent times, the role of *H. pylori* and its virulence factors in causation of atherosclerosis and coronary artery disease is not entirely clear as yet. The present review will focus on the relationship between this bacterium and the coronary artery disease

THE BACTERIUM

H. pylori have an inherent ability to survive in the gastric epithelium where they reside in the mucous layer and remain protected from the gastric acid. Urease, an enzyme abundantly present in this flagellate organism, helps create an alkaline environment to help in survival in the otherwise acidic environment. While most infected individuals remain unaffected, others develop a myriad of clinical manifestations ranging from gastritis to gastric cancer. What fuels and drives the pathogenesis of these varied clinical spectrums is not completely understood. While it is estimated that around half the world's population harbours infection with *H. pylori*, only a fraction of the infected manifest with the implicated diseases. The various factors implicated in disease causation following infection by *H. pylori* include both the bacterial virulence factors and the host response to the infection. The bacterial virulence factors include BabA (bacterial binding and inflammation), lipopolysaccharide (interaction with toll-like receptors and mediation of inflammation), Cag pathogenicity island (heightened inflammatory response to infection) and vacA toxin (impaired host responses). The host responses which affect the outcome of infection include interleukin (IL)-1β (certain polymorphisms associated with carcinogenesis), activation of nuclear factor (NF)-κB, IL-8 levels, recruitment of neutrophils, macrophages and oxidative injury and TH1 cell response may all mediate tissue injury and reaction to *H. pylori* infection.

CORONARY ARTERY DISEASE: A MULTIFACTORIAL DISEASE

Coronary artery disease (CAD) is a multifactorial disease manifesting in a number of clinical presentations including angina, myocardial infarction and heart failure. The CAD is primarily a result of coronary atherosclerosis for which a multitude of risk factors are implicated including hyperlipidemia, smoking, diabetes mellitus, lack of physical activity, male gender, increasing age, obesity amongst others[5]. There is a growing acknowledgement of inflammatory factors including C-reactive protein in prediction of increased risk of CAD[6]. *H. pylori* has also been implicated by some to have a role in predisposition to cardiac risk and causation of CAD. Indeed, in a polymerase chain reaction (PCR) based study for detection of *H. pylori* in the coronary plaques of patients who underwent coronary artery bypass grafting (CABG), 29.5% patients had a detectable *H. pylori* on PCR. Also there was serological evidence of infection in 53.3% of these 105 patients[7]. Therefore the infection by *H. pylori* may play a role in plaque rupture and causation of ischemic heart disease. Interestingly, cytotoxin asso-ciated gene A (Cag-A) may also play a role in the path-ogenesis of CAD as results of one study suggest that anti-Cag-A antibody titres were higher in patients with CAD vis-à-vis normal subjects. Also patients with anti-Cag-A positivity had more severe lesions of CAD[8]. It is believed that the chronic inflammation associated with chronic infections may result in progressive atherosclerotic disease eventually manifesting as CAD[9].

CAD AND *H. PYLORI*

Epidemiological evidence

A number of reports have evaluated the role of *H. pylori* in causation of CAD. In a report on 120 patients who underwent coronary angiography, the prevalence of serologically detectable evidence of *H. pylori* infection was more in patients with angiographically documented CAD (> 50% stenosis in at least one coronary artery). The evidence of infection was found in 70% patients with single vessel disease, 76.3% patients with double vessel disease but only in 50% individuals with no CAD[10]. Coronary artery calcium is believed to be a marker of atherosclerosis and its progression a predictor of CAD events. The correlation of coronary artery calcium (CAC) with various pathogens is conflicting. In a report on 201 asymptomatic subjects, the antibodies to heat shock protein 65 correlated with CAC score as also with evidence of *H. pylori* infection[11]. Another large study from South Korea which evaluated 2029 individuals for *H. pylori* antibody and coronary artery calcification score found that *H. pylori* seropositivity was different amongst those with and those without CAC[12]. This association was more evident in patients with early coronary atherosclerosis[12]. However another report about presence of *H. pylori* infection in a large cohort of individuals who underwent repeat CAC assessment, the presence of *H. pylori* infection (IgG to *H. pylori*) did not correlate with development or progression of CAC[13]. In a report comparing patients with CAD and healthy controls, sero-positivity for *H. pylori* infection was significantly higher

Table 1 Recent reports on association of *Helicobacter pylori* infection with coronary artery disease

Ref.	Population (number of subjects)	Diagnosis of CAD	Association between *H. pylori* infection and CAD
Shmuely *et al*[23]	CAD (173) *vs* Controls (123)	Myocardial Perfusion imaging	Yes No association with Cag-A
Vafaeimanesh *et al*[10]	CAD (62) *vs* Controls (58)	Angiographic	Yes
Laek *et al*[13]	5744 individuals, Age 45-84 yr, average follow-up of 2.4 yr	Newly detectable coronary artery calcium (CAC)	No correlation with CAC development
Mundkur *et al*[18]	CAD and controls (433 each) from South Asians	Angiography	None
Padmavati *et al*[24]	Acute myocardial infarction *vs* Controls	ECG, enzymes	None
Tewari *et al*[15]	200 CAD cases and controls	ECG, treatment records	Yes
Grdanoska *et al*[25]	Acute coronary syndrome (64), CAD (53), controls (35)	ECG, enzymes	Yes
Grub *et al*[26]	Controls (30), CAD (52) and CAD with rheumatic diseases (67)	Patients referred for CABG	None
Park *et al*[12]	2029 subjects	CAC	Yes
Al-Ghamdi *et al*[27]	CAD (50) and controls (15)	ECG, angiography	Yes
Azarkar *et al*[28]	Controls (78) and myocardial infarction (73)	ECG, enzymes	Yes
Khodaii *et al*[29]	Myocardial infarction (500) and controls (500)	ECG, enzymes	Yes Cag-A positivity also correlates with CAD

CAD: Coronary artery disease; Cag-A: Cytotoxin associated gene A; ECG: Electrocardiography; CAC: Coronary artery calcium; CABG: Coronary artery by-pass grafting; *H. pylori*: *Helicobacter pylori*.

in patients of CAD (59%) vis-à-vis the healthy controls (39%)[14]. Similar reports from India also corroborate that *H. pylori* sero-positivity was much higher in patients with CAD when compared with asymptomatic controls[15-17]. Few reports have indicated, to the contrary, that there is no significant association between *H. pylori* infection and CAD. In a report from Asian Indian families which evaluated role of multiple pathogens in causation of CAD, while CMV infection appeared to elevate the risk of CAD infection with *H. pylori* did not increase the risk[18]. In a large Japanese study to assess seroprevalence of *H. pylori* in CAD and asymptomatic controls no significant differences were detected between the two groups[19]. However when a subgroup of patients younger than 55 years was analysed the seroprevalence of *H. pylori* antibody was higher in cases than controls (58.7% and 43.3%, respectively)[19]. Another report about incidence of CAD in elderly individuals who were assessed for *H. pylori* infection at baseline and followed up for 10 years indicated that *H. pylori* positivity was not associated with increased incidence of CAD[20]. As described previously, PCR based studies of the coronary plaque have been done and have detected *H. pylori* DNA in them. In a controlled study of atheromatous plaques of 46 patients who underwent CABG, 22 (47.8%) showed *H. pylori* DNA while none of the controls who underwent coronary artery biopsy had PCR detectable *H. pylori*[21]. Aortic biopsies from areas free of atheromatous plaque have also been reported to be positive in a significant number of patients with CAD but none of the controls[22]. Table 1 summarises the recent studies reporting about association of *H. pylori* with CAD.

CAG-A AND CAD

As previously mentioned, role of Cag-A has also been evaluated as a predisposing factor for occurrence of coronary artery disease[8]. In a study of cardiac peptides including Brain Natriuretic Peptide in 103 patients with non-ST elevation myocardial infarction and their relation with *H. pylori* infection, it was found that individuals infected with Cag-A positive strains of *H. pylori* had higher levels of BNP in the serum[30]. BNP is a marker of heart failure and may predict a more serious course of the disease thereby suggesting that *H. pylori* infection with Cag-A positive strains may lead to an adverse outcome. Interestingly, IL-6 levels were also found to correlate with the Cag-A status. This suggests that the inflammatory response to Cag-A positive *H. pylori* may mediate atherogeneis in a subgroup of patients with CAD[30]. However other reports indicate that Cag-A positivity does not vary significantly between angiographically positive and negative group of individuals. In a report of 112 consecutive individuals who underwent coronary angiography, the Cag-A positivity did not affect the severity of CAD[31]. In a large study including 505 patients with CAD and 1025 matched controls, neither the prevalence of *H. pylori* infection was increased in the diseased subjects nor did the presence of Cag-A positive strains predict higher likelihood of CAD[32]. In a large population based report on 685 individuals, merely the presence of infection by *H. pylori* did not correlate with serum markers of inflammation. However those seropositive for Cag-A positive strains had increased values of common carotid artery intima-media thickness and the risk of atherosclerosis was enhanced by CRP positivity[33]. Another report also indicated that Cag-A positive strains appeared to raise the risk of CAD while merely the presence of *H. pylori* infection was not significantly different between cases and controls[34]. An

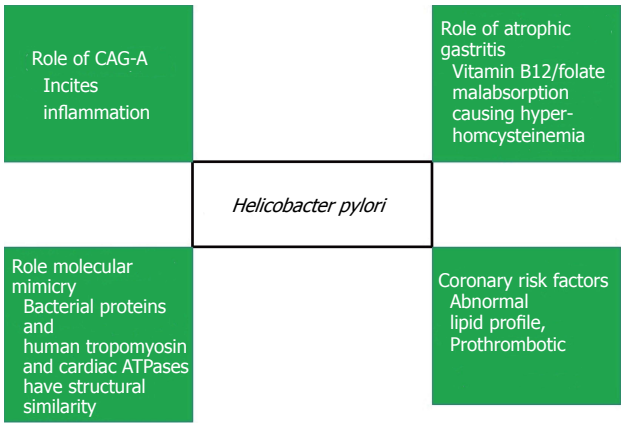

Figure 1 Postulated mechanisms of Atherogenesis in *Helicobacter pylori* infection.

interesting study reported about sero-prevalence of anti-Cag-A antibodies across a spectrum of presentations which included controls, stable and unstable angina and found that anti-Cag A titres were significantly higher in patients with unstable angina[35].

MECHANISMS BEHIND ATHEROGENESIS

One report has studied the association of atrophic gastritis with CAD. Atrophic gastritis is believed to be the end result of chronic gastric inflammation including that related to *H. pylori* infection. Decrease in serum pepsinogen I and a low Pepsinogen I / Ⅱ ratio points to the diagnosis of atrophic gastritis. In this intriguing report based on a population based study, Senmaru *et al*[36] reported that prevalence of CAD was higher in the patients having atrophic gastritis (5.8%) when compared with individuals not having atrophic gastritis (2.8%). Atrophic gastritis may result in malabsorption of Vitamin B12 and Folate and result in increased homocysteine levels. Hyper-homocysteinemia is a recognised risk factor for CAD[37]. One report has also suggested structural homology between bacterial proteins and human tropomyosin and cardiac ATPases thereby providing insight into molecular mechanism involved in the cardiac injury due to anti-*H. pylori* inflammatory response[30]. *H. pylori* has also been associated with dyslipidemia. In a Japanese study on 6289 subjects, infection with *H. pylori* was associated with low HDL and elevated LDL levels[38]. Other reports have also provided similar evidence[39]. Cag-A positive strains also exhibit elevated levels of highly sensitive CRP, oxidized LDL and apolipoprotein B all of which may participate in the pathogenesis of atherosclerosis[40]. There is also a suggestion that *H. pylori* may have a prothrombotic role which may also increase the associated risk of atherosclerotic diseases. The bacterium may promote aggregation of platelets by binding to the von-Willibrand factor[41]. Infection with *H. pylori* may stimulate an inflammatory response against heat shock protein (hsp60) which may drive a helper T cell (TH1) response and increase the risk of atherosclerosis[42]. The high degree of homology between bacterial and eukaryotic HSP may result in molecular mimicry and collateral immune damage from immune response primarily directed against infectious agents[43]. The host reaction to the *H. pylori* lipopolysaccharide (LPS) may also be a risk factor for atherosclerosis[44]. Figure 1 depicts the predominant mechanisms purported to play a role in genesis of *H. pylori*-related CAD.

EFFECT OF ERADICATION

The prognostic role of *H. pylori* infection has also been assessed in acute CAD. In 433 patients of acute coronary syndrome (ACS) the seroprevalence of *H. pylori* infection was determined using IgG and IgA serology. Those infected with *H. pylori* had an increased risk of short term adverse outcomes during the first month of follow-up[45]. Another report which evaluated role of eight pathogens on occurrence future events in patients diagnosed to have angiographic evidence of CAD. Serological evidence of *H. pylori* infection predicted an increased risk of future events and mortality in these 1018 patients and increase in pathogen burden also affected long term outcome[46]. An interesting study evaluated the role of *H. pylori* eradication on coronary artery lumen reduction in patients who underwent percutaneous intervention for CAD. A higher loss of coronary lumen was noted in those patients who had serological evidence of *H. pylori* infection. Also, eradication of *H. pylori* attenuated this reduction in lumen of the coronary artery vis-à-vis the placebo group[47]. Another report by the same group provides similar findings but it is not clear if the report was based on different patients[48]. This small but elegant study opens debate about possible benefit of *H. pylori* eradication in attenuating further atherosclerotic process which is driven primarily by inflammatory mediators. In a study assessing the effect of *H. pylori* eradication on coronary risk factors in 48 patients, no differences were observed in pre and post-treatment fasting sugars, lipid profile and levels of tissue-plasminogen activator, fibrinogen, plasminogen activator inhibitor-1 and D-dimer levels[49]. However a larger study of 496 patients and reporting about pre and post- *H. pylori* eradication profile, the eradication of *H. pylori* seemed to increase HDL levels and reduce the levels of C reactive protein and those of fibrinogen. This suggests that attenuation of inflammatory response is likely to occur after *H. pylori* eradication[50]. In a report documenting the effects of *H. pylori* eradication on insulin resistance in 159 patients using homeostasis model assessment of insulin resistance, the insulin resistance measured six weeks post-eradication was lower than the baseline. The study also reported changes in lipid profile including an increase in HDL levels and a fall in LDL levels with *H. pylori* eradication[51]. Another report also indicates that the *H. pylori* eradication may increase HDL levels and lead to reduction of CRP levels[52]. Table 2 depicts various studies reporting about the effects of *H. pylori* eradication on CAD and its risk

Table 2 Effect of *Helicobacter pylori* eradication on coronary artery disease

Ref.	Population	Intervention	Results
Kowalski *et al*[47,48]	40 patient with single vessel CAD and *H. pylori* infection	All underwent PTCA and 20 each received eradication or placebo	Attenuated reduction mean coronary artery lumen at 6 mo in those undergoing eradication
Lu *et al*[49]	*H. pylori* positive individuals	Testing of coronary risk factors before and after *H. pylori* eradication	No change in sugar, lipid and fibrinolytic parameters with eradication
Pellicano *et al*[50]	*H. pylori* positive individuals	Testing of coronary risk factors before and after *H. pylori* eradication	Improvement in HDL-C, reduction in CRP and fibrinogen levels. Elevation in BMI and diastolic blood pressure
Gen *et al*[51]	*H. pylori* positive individuals	Testing for insulin resistance, lipid profile and CRP before and after eradication	Improvement in insulin resistance, lipid abnormalities and CRP levels
Kanbay *et al*[52]	*H. pylori* positive individuals	Testing for lipid profile and CRP before and after eradication	Increase in HDL and reduction in CRP with successful eradication

CAD: Coronary artery disease; CRP: C-reactive protein; HDL: High density lipoprotein; PTCA: Percutaneous transluminal coronary angioplasty; *H. pylori*: *Helicobacter pylori*.

factors.

ATHEROGENESIS BEYOND CORONARY ARTERIES

In contrast to CAD, data is scarce on the relation between *H. pylori* infection and stroke. A meta-analysis found that Cag-A-positive *H. pylori* increases the risk of both ischemic stroke and coronary heart disease[53].

A case-control study of 150 patients by Yang *et al*[54] in 2011 does not reveal any strong association between chronic *H. pylori* infection and ischemic stroke. However, another study by Pan[55] suggested lowering of inflammatory markers and decrease in cerebral infarction readmission rates in patients of stroke with positive urease test treated with (conventional therapy + anti- *H. pylori* therapy. Wu *et al*[56] suggested role of increased expression of CD62p on platelets and increase in clotting indexes in pathogenesis of stroke in *H. pylori* positive patients.

A meta-analysis of 13 studies including 4041 participants indicated that positive anti-*H. pylori* IgG, anti-Cag-A IgG and (13)C-urea breath test were significantly associated with increased risk of IS, respectively, and positive anti-Cag-A IgG was more effective for predication of IS risk[57].

But a formal meta-analysis of ten prospective observational studies indicated no strong association between *H. pylori* infection and stroke, neither in those with cytotoxin-associated gene-A-positive infection[58].

All in all, the evidence supporting the role of *H. pylori* in causation of CAD is equivocal and interventions aimed at *H. pylori* eradication have not shown conclusive evidence of benefit in eradicating the organism vis-à-vis cardiovascular outcomes. Perhaps multicentre randomised trials comparing eradication of *H. pylori* in large populations at risk of CAD and then follow-up to deterimine risk of CAD may answer this question.

Abstract

Inflammation and endothelial dysfunction are linked to the pathogenesis of atherosclerotic disease. Recent studies suggest that periodontal infection and the ensuing increase in the levels of inflammatory markers may be associated with myocardial infarction, peripheral vascular disease and cerebrovascular disease. The present article aimed at reviewing contemporary data on the pathophysiology of vascular endothelium and its association with periodontitis in the scenario of cardiovascular disease.

Key words: Endothelium; Vascular; Atherosclerosis; Periodontal diseases; Nitric oxide; Cardiovascular diseases

Core tip: Recent studies underscore the importance of endothelial dysfunction and inflammatory markers for the development of atherosclerotic disease. In addition, the literature suggests a direct association between periodontal and cardiovascular diseases. Nevertheless, more robust intervention studies are required to clarify specific gaps, especially in relation to the biological and clinical effects of periodontal disease on the genesis and progression of atherosclerotic disease.

INTRODUCTION

Cardiovascular disease is still the leading cause of morbidity and mortality worldwide. Nevertheless, as a

result of new and effective strategies to prevent and treat atherosclerosis, the number of deaths associated with cardiovascular events has not increased, and seems to have stabilized in some countries[1].

Because it has regulatory, secretory, metabolic, immunological, and synthesizing properties, the vascular endothelium may be regarded as a heterogeneous and dynamic organ. An imbalance of these properties is linked to the onset of endothelial dysfunction and atherogenesis, and to increased risk of cardiovascular events[2]. Added to that, in the past years, the role of inflammation in the development of atherosclerosis has also been explored. Data from epidemiologic studies confirm the association between high levels of inflammatory markers and the progression of cardiovascular disease[3,4].

Emerging evidence suggests that periodontal infection may be an independent risk factor for myocardial infarction, peripheral vascular disease, and cerebrovascular disease[5,6]. A metanalysis has shown increased incidence of coronary heart disease [relative risk (RR) = 1.14; 95%CI: 1.07-1.21; $P < 0.001$] in patients with periodontal disease even after adjustment for confounding factors such as smoking, diabetes, alcohol intake, obesity, and arterial hypertension, also suggesting a positive correlation between dental loss and coronary artery disease[6]. It should be noted that much of this evidence was generated by observational studies. In this sense, additional studies with more robust designs should be carried out to provide answers regarding the association between periodontal and cardiovascular diseases.

With the aim of furthering the understanding of the relationship between vascular endothelium, periodontal disease, and the process of atherosclerosis, this article will review contemporary data about endothelial pathophysiology and its association with periodontitis in cardiovascular disease. For that, the MEDLINE-PubMed database was searched to retrieve articles published between 1980 and 2014, using the following DeCS terms: "endothelium, vascular"; "atherosclerosis"; "periodontal diseases"; "nitric oxide"; "cardiovascular diseases".

VASCULAR ENDOTHELIUM AND ATHEROSCLEROSIS

Endothelial cells (ECs) form an organ weighing approximately 1 kg; they are distributed along the body (total estimated area: 7000 m^2), and are characterized by heterogeneous structure and function, with phenotypic variation according to their location in different organs, tissues, or blood vessel type[7]. Located at the interface between blood and tissues, the vascular endothelium plays an important role in the cardiovascular system, including regulation of vascular tone (smooth muscle), synthesis and secretion of molecules, and control of homeostasis, coagulation, and inflammatory and atherogenic responses[8].

Atherosclerosis is a progressive disease, characterized by accumulation of lipid particles and fibrous elements on the arterial wall. A more recent concept has introduced the notion that, in addition to the thrombotic process, inflammation and endothelial dysfunction are also directly related to all stages of atherosclerosis. In the undamaged endothelium, ECs resist leukocyte adhesion and aggregation, in addition to promoting fibrinolysis. However, when associated with inflammatory factors, such as periodontal disease, cardiovascular risk factors (smoking, obesity, sedentary lifestyle, dyslipidemia, diabetes) promote changes in endothelial permeability and hence endothelial function[9]. At this initial stage, ECs express adhesion molecules that selectively recruit various leukocyte classes into the tunica intima[10]. Monocytes mature into macrophages, forming foam cells that release cytokines and factors that affect ECs. This process induces migration of smooth muscle cells from the media to the intima and affects metabolism of the arterial extracellular matrix (metalloproteinase), synthesis and release of procoagulant factors, and the bioavailability of nitric oxide (NO)[9]. NO, initially defined by Furchgott *et al*[11] as an "endothelium-derived relaxing factor", is synthesized by the action of an enzyme, endothelial nitric oxide synthase (eNOS), from the amino acid L-arginine. NO plays a fundamental part in endothelial function, promoting smooth muscle relaxation and consequently vasodilatation. In addition, NO supports inhibition of platelet aggregation, smooth muscle cell proliferation, and maintenance of anti-sclerotic effect[12].

The inflammatory process may also contribute to atherosclerotic plaque rupture and thrombosis. Inflammation regulates the fragility of the fibrous cap and the thrombogenicity of the atherosclerotic plaque, influencing collagen metabolism, which provides strength and stability to the cap[13]. Pro-inflammatory cytokines such as C-reactive protein (CRP), fibrinogen, tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), and IL-6 reduce the endothelial expression of NOS[14], increasing endothelial synthesis of NADPH oxidases and promoting endothelial expression of vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), E-selectin and P-selectin[14,15]. As a result, the absence of anti-atherogenic properties in the endothelium increases leukocyte migration and platelet activation to form the atherosclerotic plaque[4].

In this sense, endothelial function and inflammatory markers are important predictors of future cardiovascular events in individuals at risk for atherosclerotic disease.

CELL ADHESION MOLECULES

Cell adhesion molecules (CAMs) are glycoproteins expressed on the cellular surface. CAMs are involved in cell-cell and cell-extracellular matrix binding and encompass immunoglobulins such as ICAM-1 and VCAM-1, as well as the selectin family, including leukocyte-endothelial adhesion molecules (E-selectin), P-selectin and leukocyte-lymphocyte adhesion molecules (L-selectin), integrins, and cadherins[16].

Selectins are expressed on the surface of endothelial

Table 1 Summary of the involvement of pro-inflammatory cytokines and adhesion molecules in atherosclerosis

Pro-inflammatory cytokines and adhesion molecules	Cells involved	Atherogenic effect
C-reactive protein	Adhesion molecules and endothelial cells	Stimulates production of adhesion molecules and chemokines by endothelial cells[14]
Fibrinogen	Platelet, adhesion molecules and smooth muscle	Activates platelet aggregation and promotes the migration and proliferation of smooth muscle[14]
Tumor necrosis factor-alpha	Monocytes, neutrophils and endothelial cells	Activates monocytes, neutrophils and endothelial cells to express adhesion molecules[14]
Interleukin-6	Epithelial cells, fibroblasts and macrophages/monocytes	Is involved in promoting coagulation, which result in the development of atherosclerosis[14]
Interleukin-1β	Macrophages/monocytes	Impedes fibrinolysis, facilitates coagulation and thrombosis[14]
Vascular cell adhesion molecule-1	Endothelial cells	Suggested as potential candidate markers of endothelial dysfunction[19]
Intercellular adhesion molecule-1	Endothelial cells	Implicated in leukocyte recruitment and migration into the vessel wall[19]
Leukocyte-endothelial adhesion molecules	Endothelial cells	Migration of monocytes down into the subendothelial space[16]

cells, leukocytes, and platelets, and their expression in the endothelium is induced by various inflammatory cytokines. In the first phase of leukocyte migration, selectins mediate the capture and transport of circulating leukocytes into the vascular endothelium. In the second phase, leukocytes adhere to the endothelium through the action of ICAM-1 and VCAM-1, migrating into the interstitial tissue space[17].

Soluble forms of CAMs are found in plasma and correlate to endothelial dysfunction[18]. Thus, these markers are associated with biological mechanisms that promote thrombus formation, plaque rupture, and subsequently acute coronary events[19]. The summary of the involvement of pro-inflammatory cytokines and adhesion molecules in atherosclerosis is described in Table 1.

SHEAR STRESS

Even if the multifactorial pathophysiologic nature of atherosclerosis is recognized, special attention should be paid to a specific component in this scenario-shear stress. Shear stress is a biomechanical force determined by blood flow, vessel geometry, and fluid viscosity, aspects modulating the structure and function of the vascular endothelium. The presence of "disturbed" flow-that is, nonlaminar flow-favors atherosclerotic plaque formation. Atherosclerotic plaque development is favored by a combination of cardiovascular risk factors and altered arterial hemodynamics around curvatures, arterial branch ostia and bifurcations[20].

Studies have shown that different types of shear stress correlate with "resistant" or "susceptible" regions in the endothelium during atherogenesis[21]. Pulsatile blood flow triggers many types of hemodynamic, hydrostatic, and cyclic forces that have the ability to influence vascular endothelial physiology[22]. The most susceptible atherosclerotic lesions are associated with certain sites in the proximal branches, bifurcations, and in areas of greater curvature. However, regions with uniform laminar flow are typically more resistant to atherogenic plaque formation[23].

PERIODONTAL DISEASE, INFLAMMATORY MARKERS, AND ENDOTHELIAL DYSFUNCTION

Periodontal disease encompasses two large groups of gum diseases. Gingivitis, which is characterized by inflammation of the gingival margin, is easily reversed with adequate oral hygiene. Periodontitis entails a chronic infectious/inflammatory process involving the supporting tissues of the tooth, including periodontal ligament and alveolar bone. The main consequence of periodontitis is the loss of tooth support structures and tooth loss[24]. Data from different countries show a prevalence of periodontitis reaching up to 50%[25-27]; however, progression is usually slow[28].

Epidemiologic studies provide evidence of an association between periodontitis and cardiovascular disease[6,29]. The biological plausibility for this association is based mainly on the fact that patients with periodontitis present increased levels of CRP, TNF-α, interleukins, and other inflammatory markers, which are associated with endothelial dysfunction and cardiovascular events[30,31]. Most studies employ different inflammatory and endothelial biomarkers, with secondary outcomes, whereas primary outcomes such as death or brain stroke have not yet been evaluated[32-34].

A recent systematic review and metanalysis analyzed the effect of periodontal treatment on cardiovascular risk profile in patients with established periodontitis. The main findings show a significant reduction in CRP (-0.50 mg/dL), IL-6 (-0.48 ng/L), TNF-α (-0.75 pg/mL), fibrinogen (-0.47 g/L) and total cholesterol (-0.11 mmol/L) in the intervention group. In addition, there was improvement of endothelial function and an additional benefit regarding inflammatory markers in patients with traditional cardiovascular risk factors[24]. Investigating the same outcome in a different scenario, another study compared patients with coronary heart disease with or without periodontitis. The results indicate that treatment of periodontal disease promoted a reduction in serum concentrations of CRP, from 2.7 ± 1.9 mg/L to 1.8 ± 0.9 mg/L ($P < 0.05$), and of IL-6, from 2.6 ± 3.4 mg/L to 1.6

Table 2 Summary of the effects of periodontal disease on pro-inflammatory cytokines and adhesion molecules

Pro-inflammatory cytokines and adhesion molecules	Effect of periodontal disease
C-reactive protein	Increased[24]
Fibrinogen	Increased[24]
Tumor necrosis factor-alpha	Increased[24]
Interleukin-6	Increased[24]
Interleukin-1β	Increased[24]
Vascular cell adhesion molecule-1	Increased[30]
Intercellular adhesion molecule-1	Increased[30]
Leukocyte-endothelial adhesion molecules	Increased[30]

± 2.6 mg/L ($P < 0.05$) in patients with periodontitis[32].

In addition to inflammatory markers and adhesion molecules, the measurement of brachial artery flow-mediated dilation (FMD), a technique developed initially in 1992, is also useful to assess the endothelium[35]. This non-invasive technique evaluates the diameter of the brachial artery before and after induced forearm ischemia. A blood pressure cuff is inflated at the distal or proximal section of the arm, and FMD is expressed as the percent change in brachial artery diameter at the end of ischemia. This dilatation is mediated by endothelial release of NO in response to shear stress at the arterial wall[36].

FMD is decreased in individuals with cardiovascular risk factors (diabetes, hypertension, obesity, and smoking, among others) and established atherosclerosis[37]. A study published in 2005 evaluated endothelial function in patients with a diagnosis of severe periodontitis. The main findings following periodontal treatment show significant improvement in FMD, of 9.8% ± 5.7% ($P = 0.003$) as compared to baselines measures, accompanied by a reduction in the levels of CRP from 1.1 ± 0.9 to 0.8 ± 0.8 ($P = 0.026$)[34]. In this sense, evaluation of FMD and cardiovascular disease biomarkers have recently been studied and associated with endothelial dysfunction and occurrence of cardiovascular events[38,39]. The summary of the effects of periodontal disease on pro-inflammatory cytokines and adhesion molecules is depicted in Table 2.

CONCLUSION

The present literature review suggests that periodontal treatment reduces the risk of cardiovascular disease by improving plasma levels of inflammatory markers (CRP, TNF-α, IL), thrombotic markers (fibrinogen) and adhesion molecules (VCAM-1, ICAM-1, P-selectin), in addition to improving endothelial function as assessed by FMD. Future intervention studies are required to further elucidate the association between periodontal and cardiovascular disease, especially in terms of the biological effects of periodontal disease on the atherogenic cascade affecting the vascular endothelium.

Abstract

AIM: To compare the therapeutic efficacy of SAR407899 with the current standard treatment for hypertension [an angiotensin converting enzyme (ACE)-inhibitor and a calcium channel blocker] and compare the frequency and severity of the hypertension-related end-organ damage.

METHODS: Long-term pharmacological characterization of SAR407899 has been performed in two animal models of hypertension, of which one is sensitive to ACE-inhibition and the other is insensitive [deoxycorticosterone acetate (DOCA)]. SAR407899 efficiently lowered high blood pressure and significantly reduced late-stage end organ damage as indicated by improved heart, kidney and endothelial function and reduced heart and kidney fibrosis in both models of chronic hypertension.

RESULTS: Long term treatment with SAR407899 has been well tolerated and dose-dependently reduced elevated blood pressure in both models with no signs of tachyphylaxia. Blood pressure lowering effects and protective effects on hypertension related end organ damage of SAR407899 were superior to ramipril and amlodipine in the DOCA rat. Typical end-organ damage was significantly reduced in the SAR407899-treated animals. Chronic administration of SAR407899 significantly reduced albuminuria in both models. The beneficial effect of SAR407899 was associated with a reduction in leukocyte/macrophage tissue infiltration. The overall protective effect of SAR407899 was superior or comparable to that of ACE-inhibition or calcium

channel blockade. Chronic application of SAR407899 protects against hypertension and hypertension-induced end organ damage, regardless of the pathophysiological mechanism of hypertension.

CONCLUSION: Rho-kinases-inhibition by the SAR407899 represents a new therapeutic option for the treatment of hypertension and its complications.

Key words: Hypertension; End organ damage; Rho-kinase; Angiotensin converting enzyme-inhibition

Core tip: Rho-kinase (ROCK) is considered an important ta-rget in cardiovascular diseases, *e.g.*, hypertension and nephropathy. Currently available treatment only moderately alleviates the progression of chronic kidney diseases. We have identified a novel, potent and selective inhibitor of ROCK (SAR407899) and characterized its effects *in vivo*. The therapeutic efficacy of SAR407899 has been compared to the current standard treatment for hypertension in two animal models of hypertension, one of which is sensitive and the other insensitive (deoxycorticosterone acetate) to angiotensin converting enzyme-inhibition. ROCK-inhibition by SAR407899 may represent a new therapeutic option either as a monotherapy or in combination with existing modern therapeutics for the treatment of hypertension and its complications.

End-organ protection in hypertension by the novel and selective Rho-kinase inhibitor, SAR407899. *World J Cardiol* 2015; 7(1): 31-42 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i1/31.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i1.31

INTRODUCTION

Hypertension increases the risk of target organ damage, including heart hypertrophy, heart ischemia, kidney dysfunction or failure, cerebrovascular events and malfunction of the endothelial tissue[1-5]. The contractile response of smooth muscle tissue is controlled at different levels by a tight balance of pro-contractile and relaxing mechanisms. In particular, it has been persuasively shown that Rho-kinases (ROCK1 and ROCK2) are intimately involved in the transmission of contractile signaling within smooth muscle tissue[6-13]. Upon activation of the small GTPase RhoA by ligand-bound specific GPCRs, ROCKs, the downstream effectors of RhoA, phosphorylate the myosin light chain phosphatase and the myosin regulatory light-chain itself, resulting in a net increase in activated myosin. This promotes smooth muscle contraction and actin cytoskeleton re-organization. Inhibition of ROCKs leads to relaxation of vascular smooth muscle cells and, consequently, to a decrease in blood pressure[7,9,14-20]. Several inhibitors of ROCK (in particular, fasudil and Y27632) have been extensively used to evaluate the role of ROCK in cardiovascular physiology and pathology. In addition, fasudil is used in Japan to treat cerebral vasospasm after focal cerebral ischemia or aneurysmal subarachnoid hemorrhage. However, both inhibitors have a moderate specificity, moderate potency and short duration of action *in vivo* that limit their clinical use. Therefore, the development of a more potent and specific inhibitor with a better pharmacokinetic profile is needed to explore the potential of ROCK inhibition in the therapy of hypertension and its complications. We have identified a novel ROCK-inhibitor, SAR407899, and previously characterized its acute effects *in vitro* and *in vivo*[21]. Here, we describe the long-term effects of SAR407899 treatment in two animal models of hypertension, one being sensitive (Nω-Nitro-L-arginine methyl ester hydrochloride, LNAME) and the other being insensitive [deoxycorticosterone acetate (DOCA)] to angiotensin converting enzyme (ACE)-inhibition. The DOCA-induced hypertension model is characterized by a hypervolemic and low plasma renin status, which promotes resistance to ACE-inhibition, whereas the LNAME model is normovolemic and displays a high renin activity in plasma[22-24]. The results of large clinical trials (IDNT, RENAAL and IRMA-2) revealed that the current standard treatment only modestly (approximately 20%) reduces the progression of chronic kidney diseases. From these data it can be concluded that a simple decrease of blood pressure is not sufficient for kidney protection. Our results indicate that chronic inhibition of the ROCK kinases efficiently controls blood pressure and significantly reduces the frequency and severity of the hypertension-related end organ damage.

MATERIALS AND METHODS

DOCA and LNAME-induced hypertension

Adult male Sprague Dawley rats (190 to 210 g, Harlan Winkelmann, Borchen, Germany), were treated with DOCA-salt or Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) to induce hypertension. To compare the pharma-cological potency of ROCK-inhibition with the current anti-hypertension drugs, the individual blood pressure lowering effect of the respective compounds was measured in spontaneous hypertensive rats (SHR). Oral application of SAR407899 at 3 mg/kg lowered blood pressure in conscious telemetred SHR by 26 ± 4 mmHg (n = 10), which was comparable to the action of amlodipine at 3 mg/kg (blood pressure reduction by 33 ± 8 mmHg, n = 10) and ramipril at 1 mg/kg (blood pressure reduction by 21 ± 7 mmHg, n = 10). Therefore, the animals were divided into the following groups: (1) Control; (2) DOCA or LNAME; (3) DOCA or LNAME + SAR407899 at 3 mg/kg; (4) DOCA or LNAME + SAR407899 at 10 mg/kg;

(5) DOCA or LNAME + ramipril at 1 mg/kg; and (6) DOCA or LNAME + amlodipine at 3 mg/kg. All DOCA-salt treated animals underwent a unilateral nephrectomy, received a subcutaneous injection of DOCA (30 mg/kg; Sigma Chemical, St. Louis, MO, United States) dissolved in sesame oil once a week and 1% NaCl in the drinking water ad libitum. All LNAME groups received 40 mg/kg per day LNAME in the drinking water *ad libitum*. After a 4-wk treatment, the animals were placed into metabolic cages and 24 h-urine samples and blood samples were taken to analyze kidney function. Urinary and plasma creatinine levels were determined using standard kits (Roche diagnostics, Basel, Switzerland) on a Hitachi 912 E analyzer (Hitachi, Mountain View, Calif., United States). Urinary albumin was measured using a standard kit from Progen (Mikroflural, Progen, Heidelberg, Germany) and was normalized to urinary creatinine concentrations. After 5 wk of treatment, measurements of: (1) blood pressure (invasively, two hours after the last treatment); (2) organ weights; and (3) endothelial function were taken. The investigation conforms to the Guide for the Care and Use of Laboratory Animals published by the United States National Institutes of Health (NIH publication no. 85-23, revised 1996).

Invasive blood pressure measurement

The animals were anaesthetized with an intraperitoneal injection of thiopental (0.1 g/mL per 100 g body weight). The common carotid artery was catheterized with a heparinized microcatheter (diameter 1.6 mm, Vycon, France). Blood pressure was measured with a Hugo Sachs hemodynamic system (March-Hugstetten, Germany) using the software Hemodyn.

In vitro vascular and heart function

Assessment of *in vitro* vascular function was performed as described earlier[21,25,26]. Heart function was determined using a Langendorff-setup in the working heart perfusion mode. This technique allows the heart to perform its physiological pumping action, *i.e.*, it performs pressure/volume work. The working heart technique therefore provides a complete analysis of heart function. Heart power is an integrative parameter and is calculated by formula (1):

$$HW\ (J) = 133.3\ [(N/m^2)/mmHg] \times (ALPmean\text{-}PLPmean)\ (mmHg) \times SV\ (m^3) + 0.5 \times 1.004\ (kg/m^3) \times SV\ (m^3) \times \{SV\ (m^3)/[\pi \times r^2\ (m^2) \times ET\ (s)]\}^2 \quad (1)$$

where HW-heart power, ALPmean-afterload pressure, PLPmean-preload pressure, SV-stroke volume, and ET-Ejection time. If not otherwise indicated, chemicals were obtained from Sigma (Deisenhofen, Germany).

RT PCR

Real-time quantitative PCR was performed using the QuantiTect Probe RT-PCR Kit (Qiagen, Hilden, Germany). Each sample was assayed in quadruplicate. For relative quantification of gene expression, the ΔCt method was used with GAPDH as a control. Amplification of the target and housekeeping genes was detected simultaneously using differently fluorescent-labeled Taq Man probes (Col1A1: Rn00801665_g1, CD3: Rn01417941_g1 and CD68: Rn01495634_g1), which were obtained from Applera/Applied Biosystems (Foster City, United States). Amplification linearity of the target and housekeeping genes within the multiplex RT-PCR was assessed by performing RT-PCR reactions with dilutions of the templates. RT-PCR reactions and data acquisition was performed using the iCycler-iQ-Thermocycler (Bio-Rad Laboratories GmbH, Munich, Germany). Relative gene expression was calculated as fold induction *vs* control samples.

Histology

Heart and kidneys underwent a standard fixation procedure and standard haematoxylin-eosin and sirius red staining. The hearts and kidneys were analyzed with regard to incidence and extent of fibrosis, inflammatory events, glomerulosclerosis and tubular atrophy. A semi-quantitative score was assigned to each specimen by an experienced pathologist ranging from 1 (minimal changes) to 4 (marked alterations) at a standard magnification of 4 to 20-fold. All histopathological analyses were performed in a blinded fashion. Anti-podocin staining was performed using anti-podocin antibodies (Sigma-Aldrich, United States).

Statistical analysis

All values are given as the mean and standard error of mean. Normality of the distribution and the homogeneity of variance were checked using the Levene test. For group comparisons, one-way analysis of variance (*ANOVA*) or two-way ANOVA was performed followed by Dunnett's post-hoc test using the SAS version 8.2 software. Differences between groups were considered significant if $P < 0.05$; n represents the number of specimens or animals tested.

The statistical methods of this study were reviewed by and complies to the standard of Sanofi-Aventis GmbH Deutschland.

RESULTS

Effect of SAR407899 on body weight, blood pressure and kidney function

The long-term effects of SAR407899 in DOCA- and LNAME-induced hypertension were compared to those of the current standard anti-hypertensive drugs, namely ramipril (ACE-inhibitor) and amlodipine (calcium channel blocker, CCB). Figure 1 depicts the effects of SAR407899 on body weight of the DOCA- and LNAME-hypertensive animals. Treatment with SAR407899 was well tolerated and showed a significant protective effect on body weight in both hypertensive animal models (Figure 1A and C). Factors involved in the continuous body weight loss are not known and most likely depend on hypertension related end-organ damage,

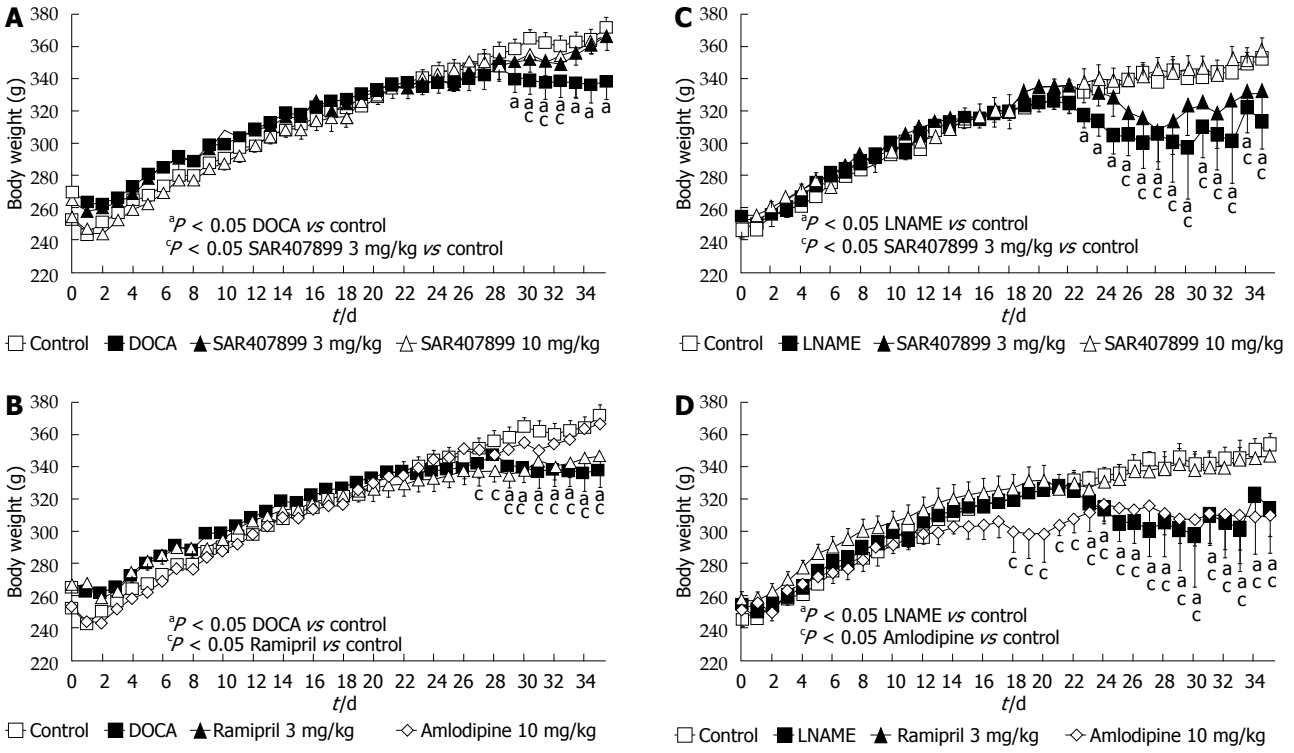

Figure 1 Effect of SAR407899 on body weight in deoxycorticosterone acetate and Nω-Nitro-L-arginine methyl ester hydrochloride hypertensive animals. A and B: Body weight of deoxycorticosterone acetate (DOCA) rats. A significant decrease in body weight was observed after 28 d; A: Effect of SAR407899 at 3 mg/kg and 10 mg/kg on body weight. Both doses protected DOCA rats against body weight loss; B: Effect of ramipril at 1 mg/kg and amlodipine at 3 mg/kg on body weight. Only amlodipine showed protective effects on body weight loss; C and D: Body weight of Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) rats. A significant decrease in body weight was observed after 22 d. C: SAR407899 at 10 mg/kg significantly protected LNAME rats from body weight loss; D: Effect of ramipril at 1 mg/kg and amlodipine at 3 mg/kg on body weight. Only ramipril showed significant protective effects on body weight loss.

including proteinuria. Ramipril showed protective effects on body weight only in the LNAME model (Figure 1D), whereas amlodipine significantly protected the DOCA hypertensive animals from body weight loss (Figure 1B).

Figure 2 demonstrates the effects of SAR407899 (3 mg/kg and 10 mg/kg), ramipril (1 mg/kg) and amlodipine (3 mg/kg) on blood pressure in the DOCA- (Figure 2A) and LNAME-treated rats (Figure 2B). SAR407899 effectively reduced blood pressure in both hypertensive models. Because the DOCA-induced hypertensive model is characterized by hypervolemia and resistance to ACE-inhibition, it was not surprising that ramipril had no significant effect on blood pressure. At the dose employed, amlodipine non-significantly lowered blood pressure in the DOCA rats. In the LNAME rats, all treatments significantly lowered blood pressure. In comparison to amlodipine and ramipril, SAR407899 showed superior blood pressure lowering effects at both doses in the LNAME rats. Thus, only SAR407899 was able to control blood pressure efficiently in both models and was therefore superior to the reference substances.

Kidney function (Figure 2C and D) was assessed by the measurement of albuminuria. In both models, SAR407899 dose-dependently reduced albuminuria. Ramipril significantly reduced albuminuria in only the LNAME model but not in the DOCA model. At the dose administered, amlodipine did not significantly reduce albuminuria in the DOCA or LNAME models. The lack of efficacy of amlodipine has been linked to the inability of CCB's to dilate renal efferent vessels, which is critical for improvement of the renal microcirculation.

Long term treatment effects of SAR407899 on heart and endothelial function

Figure 3 illustrates the effect of SAR407899 and of reference substances on heart function (A and B), measured in isolated Langendorff perfused hearts in the working heart mode and on vessel function *in vitro* (C and D). Hearts of hypertensive the DOCA rats and the LNAME rats were functionally compromised. At an afterload pressure of 40 mmHg (basal afterload), a similar heart performance was found in all groups; however, at higher afterload pressures (60 and 80 mmHg), a significant reduction was found in heart function from the DOCA- and LNAME-treated rats. Long-term treatment with SAR407899 restored heart function in both groups. In contrast, treatment with either amlodipine or ramipril had no significant effect. Endothelial function was found to be severely compromised in the DOCA rats. Figure 3C and D show the effect of SAR407899 and the reference substances on endothelial function. Long-term treatment with SAR407899 improved endothelial function in a dose-dependent manner (Figure 3C). As expected, ramipril had no effect on endothelial function of arteries from the DOCA-induced hypertensive rats (Figure 3D). Amlodipine had similar protective effects

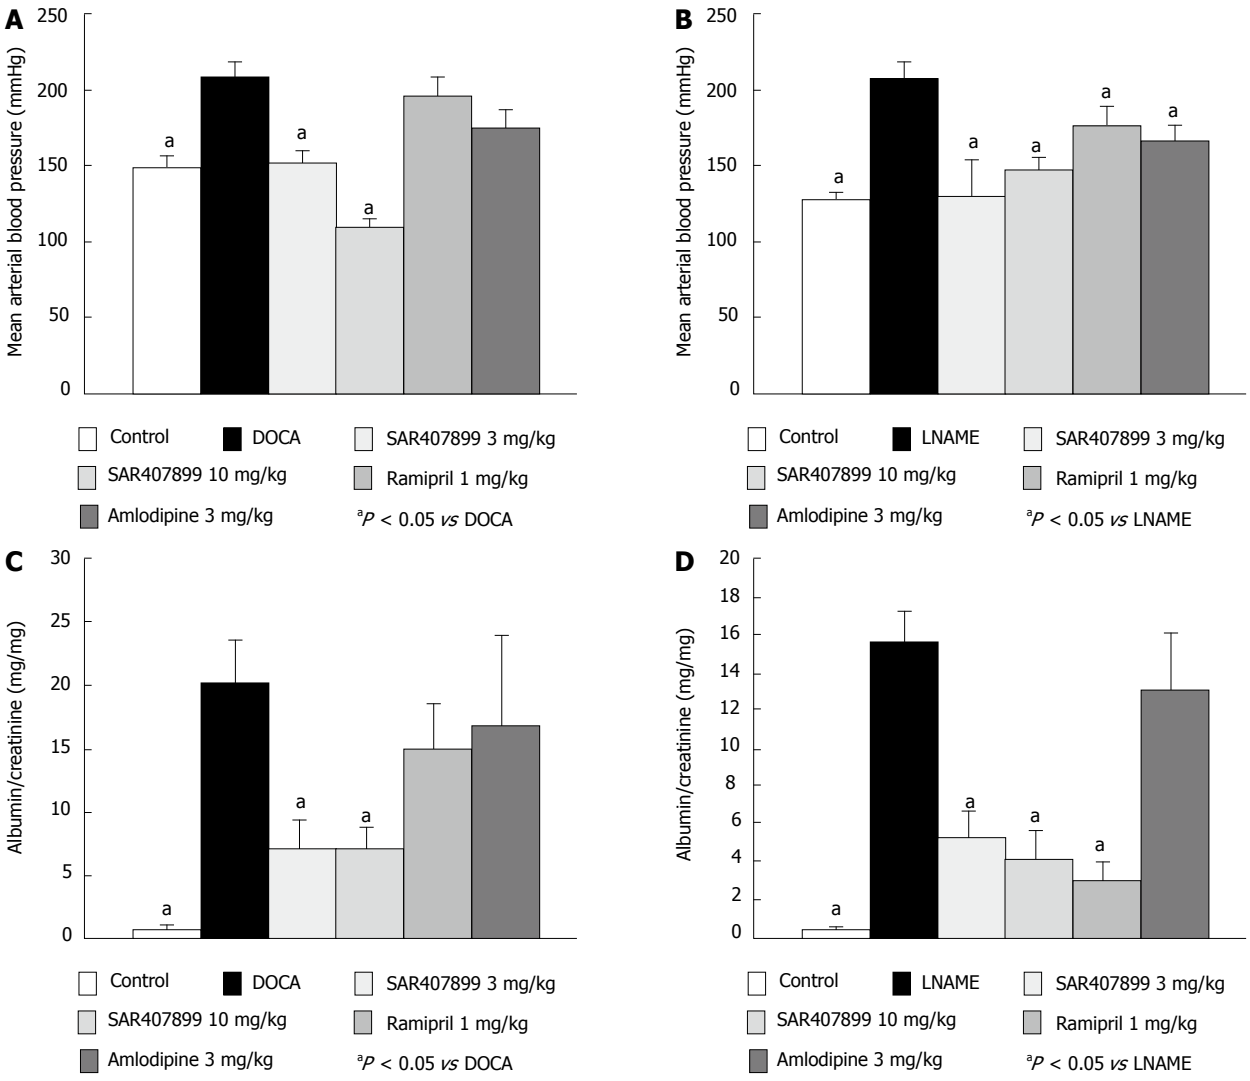

Figure 2 SAR407899 efficiently lowers blood pressure, proteinuria and mortality in hypertensive rats. Invasive measurement of blood pressure in deoxycorticosterone acetate (DOCA) (A) and in Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) (B) rats. At the given dose, SAR407899 showed superior blood pressure lowering effect in comparison to ramipril and amlodipine in both animal models; C and D: Assessment of kidney function in DOCA and LNAME rats. SAR407899 showed significant protective effects on the kidneys in both models, whereas ramipril reduced albuminuria only in the LNAME model. Amlodipine had no therapeutic effect on kidney in either model.

on endothelial function in the DOCA hypertensive rats (Figure 3D). The endothelial function of arteries of the LNAME-treated rats has not been assessed because LNAME exerts a potent and long lasting inhibition of the endothelial nitric oxide synthase.

Effect of SAR407899 on DOCA- and LNAME-induced heart and renal pathology

Histological examination of the hearts of the DOCA- (Figure 4A-F) and LNAME-treated (Figure 4G-L) rats revealed a prominent perivascular fibrosis, massive infiltration of leukocytes into the interstitium and sclerotic changes. Figure 4A-C and 4G-I shows sirius red staining of DOCA- (Figure 4B) and LNAME-(Figure 4H) induced heart fibrosis in comparison to control (Figure 4A and G) and SAR407899 treatment (Figure 4C and I). Figure 4D-F and 4J-L shows haematoxylin eosin staining of DOCA- (Figure 4E) and LNAME-(Figure 4K) induced heart fibrosis in comparison to control (Figure 4D and J) and SAR407899 treatment (Figure 4F and L). In the hearts of the DOCA and LNAME rats, SAR407899 treatment at 10 mg/kg abolished the development of fibrosis (protection with SAR407899 at 3 mg/kg was less pronounced and data not shown). Chronic treatment of the LNAME hypertensive rats with SAR407899 attenuated leukocyte infiltration and perivascular fibrosis. Figure 4M and N summarize heart lesions according to the scoring procedure. The heart lesions of the DOCA rats were significantly reduced by SAR407899 at 10 mg/kg. Both reference compounds showed only marginal non-significant effects on heart lesions (Figure 4M). SAR407899 (at 3 and 10 mg/kg) and ramipril significantly diminished heart lesions in the LNAME-treated rats (Figure 4N). Histological analysis of kidneys from the DOCA- (Figure 5A-F) and LNAME- (Figure 5G-L) treated rats revealed severe

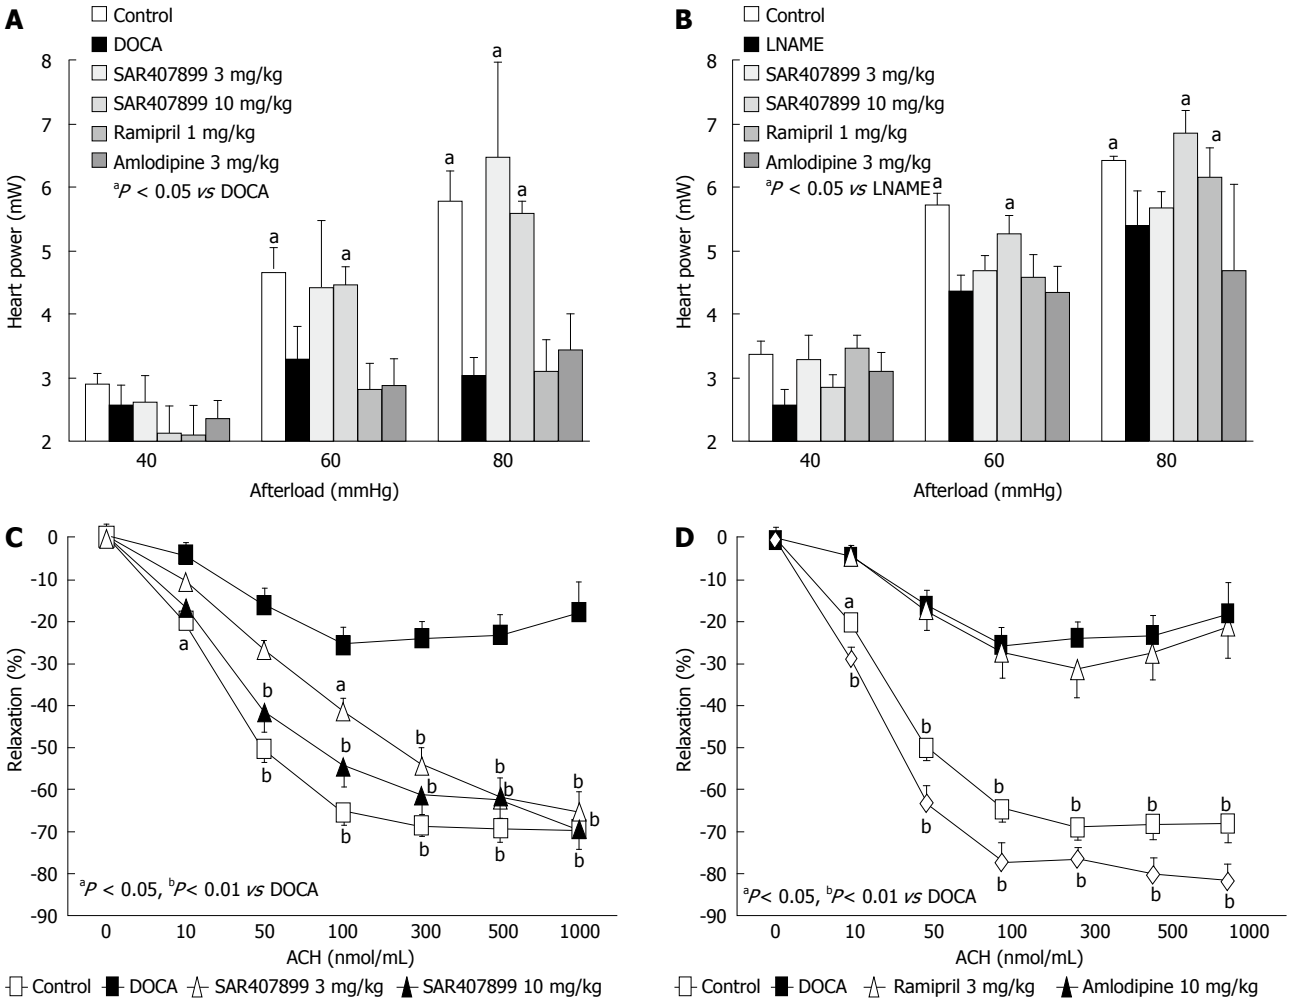

Figure 3 Effect of SAR407899 on heart and endothelial function. Measurement of heart function of isolated hearts of deoxycorticosterone acetate (DOCA) (A) and Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME)-treated rats (B). SAR407899 showed a significant improvement of heart function compared to reference substances at both doses and in both models; C and D: Measurement of endothelial function of aortas of DOCA rats treated with SAR407899 (C) or with reference substances (D). Ramipril treatment had no effect on endothelial function. Long-term treatment with SAR407899 improved endothelial function in a dose-dependent fashion. Amlodipine had similar protective effects as SAR407899.

lesions of glomeruli and tubuli. Figure 5A-C shows haematoxylin eosin staining in kidneys of DOCA- and of LNAME-treated rats (Figure 5G-I). Figure 5D-F shows podocin staining in kidneys of DOCA- and of LNAME-treated rats (Figure 5J-L). In kidneys from the DOCA rats (Figure 5B), severe destruction and sclerotic changes of glomeruli were associated with fibrinous discharges into the capsule, swelling of lobuli and multiple fibrotic events. In comparison to control (Figure 5A), a strong hypertrophy of glomeruli was detectable in the kidneys of the DOCA- treated animals (Figure 5B). Podocin staining (Figure 5D-F)of the DOCA rat kidneys revealed a drastic loss of podocin positive cells (podocytes) upon DOCA treatment (Figure 5E) in comparison to control (Figure 5D). Chronic treatment with SAR407899 attenuated these glomerular (much stronger staining of podocytes), vascular, and interstitial changes (Figure 5F). In contrast to kidneys of control animals (Figure 5G), in the kidneys from the LNAME hypertensive animals (Figure 5H), many changes were detected, including fibrotic changes, infiltration of leukocytes, hypertrophy of glomeruli, marked thickening and inflammation of the vascular wall, hyperplasia and degeneration of tubuli, and tubulointerstitial changes with inflammatory cell infiltration. Again, chronic treatment with SAR407899 attenuated these pathophysiological changes (Figure 5I).

Figure 5K shows the fading of podocin staining upon LNAME treatment indicating that podocin positive cells are damaged. Figure 5J demonstrates podocin staining in control animals. Long-term treatment with SAR407899 attenuated glomerular, vascular, and interstitial changes (Figure 5L). Figure 5M and N summarize kidney lesions according to the scoring procedure. The kidney lesions of the DOCA rats were significantly reduced by SAR407899 at 3 and 10 mg/ kg. Both reference compounds showed only marginal non-significant effects on kidney lesions (Figure 5M). SAR407899 (at 3 and 10 mg/kg) and ramipril significantly diminished kidney lesions in the LNAME-treated rats (Figure 5N). Expression of genes characteristic of fibrosis and leukocyte infiltration of the kidneys of the DOCA- and LNAME-treated rats was measured using RT PCR (Figure 6A-F). The expression of collagen

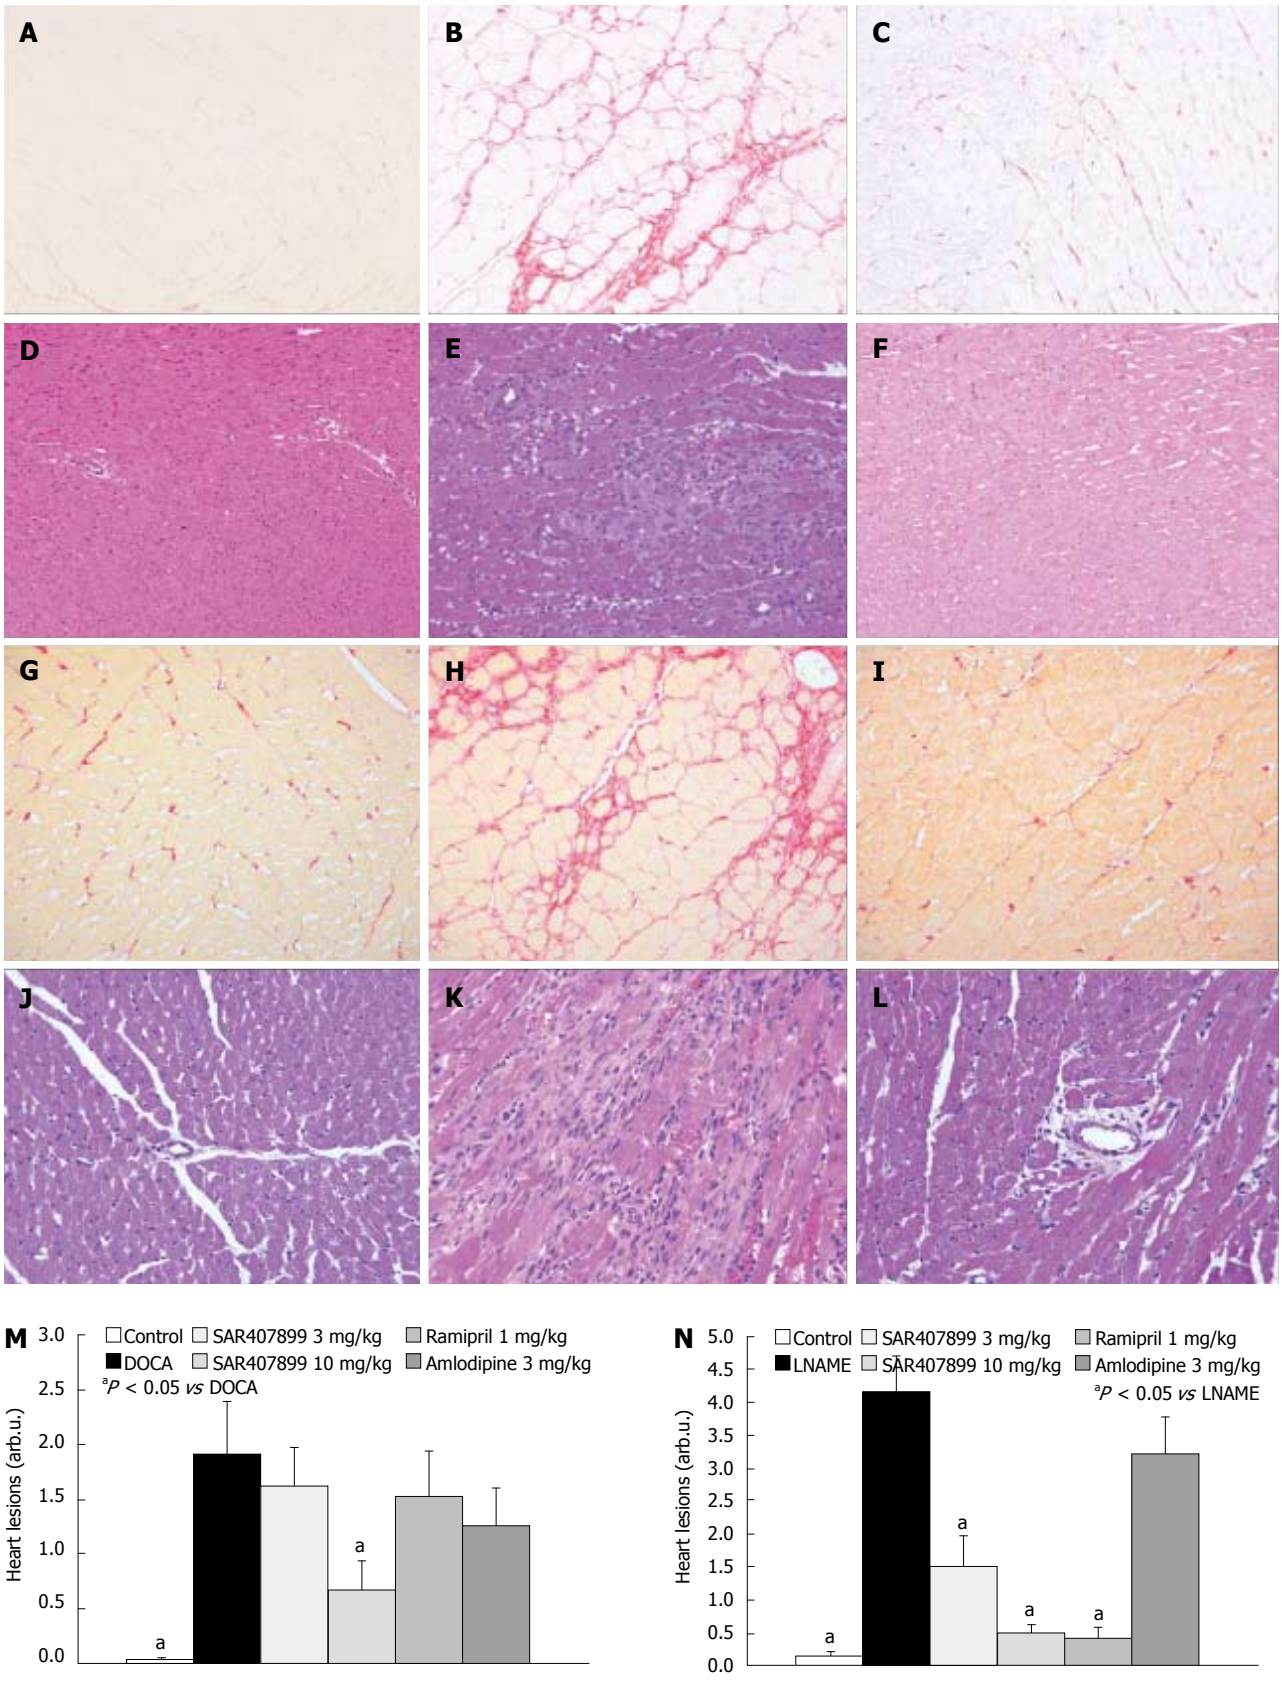

Figure 4 Histological examination of the effect of SAR407899 on the heart. Sirius red staining of hearts of deoxycorticosterone acetate (DOCA) (A-C) and Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) rats (G-I) showed a strong induction of myocardial fibrosis. Upon treatment with SAR407899 at 10 mg/kg, significant protective effects were observed. Haematoxylin eosin staining of hearts of DOCA (D-F) and LNAME rats (J-L) showed perivascular fibrosis, massive infiltration of leukocytes into the interstitium and sclerotic changes. SAR407899 treatment at 10 mg/kg attenuated multifocal fibrosis, perivascular fibrosis and leukocyte infiltration. M and N: Summary of heart lesions and the effect of SAR407899 and reference substances in DOCA (M) and LNAME rats (N). A, D, G, J: Control; B, E: DOCA; H, K: LNAME; C, F, I, L: SAR407899 10 mg/kg.

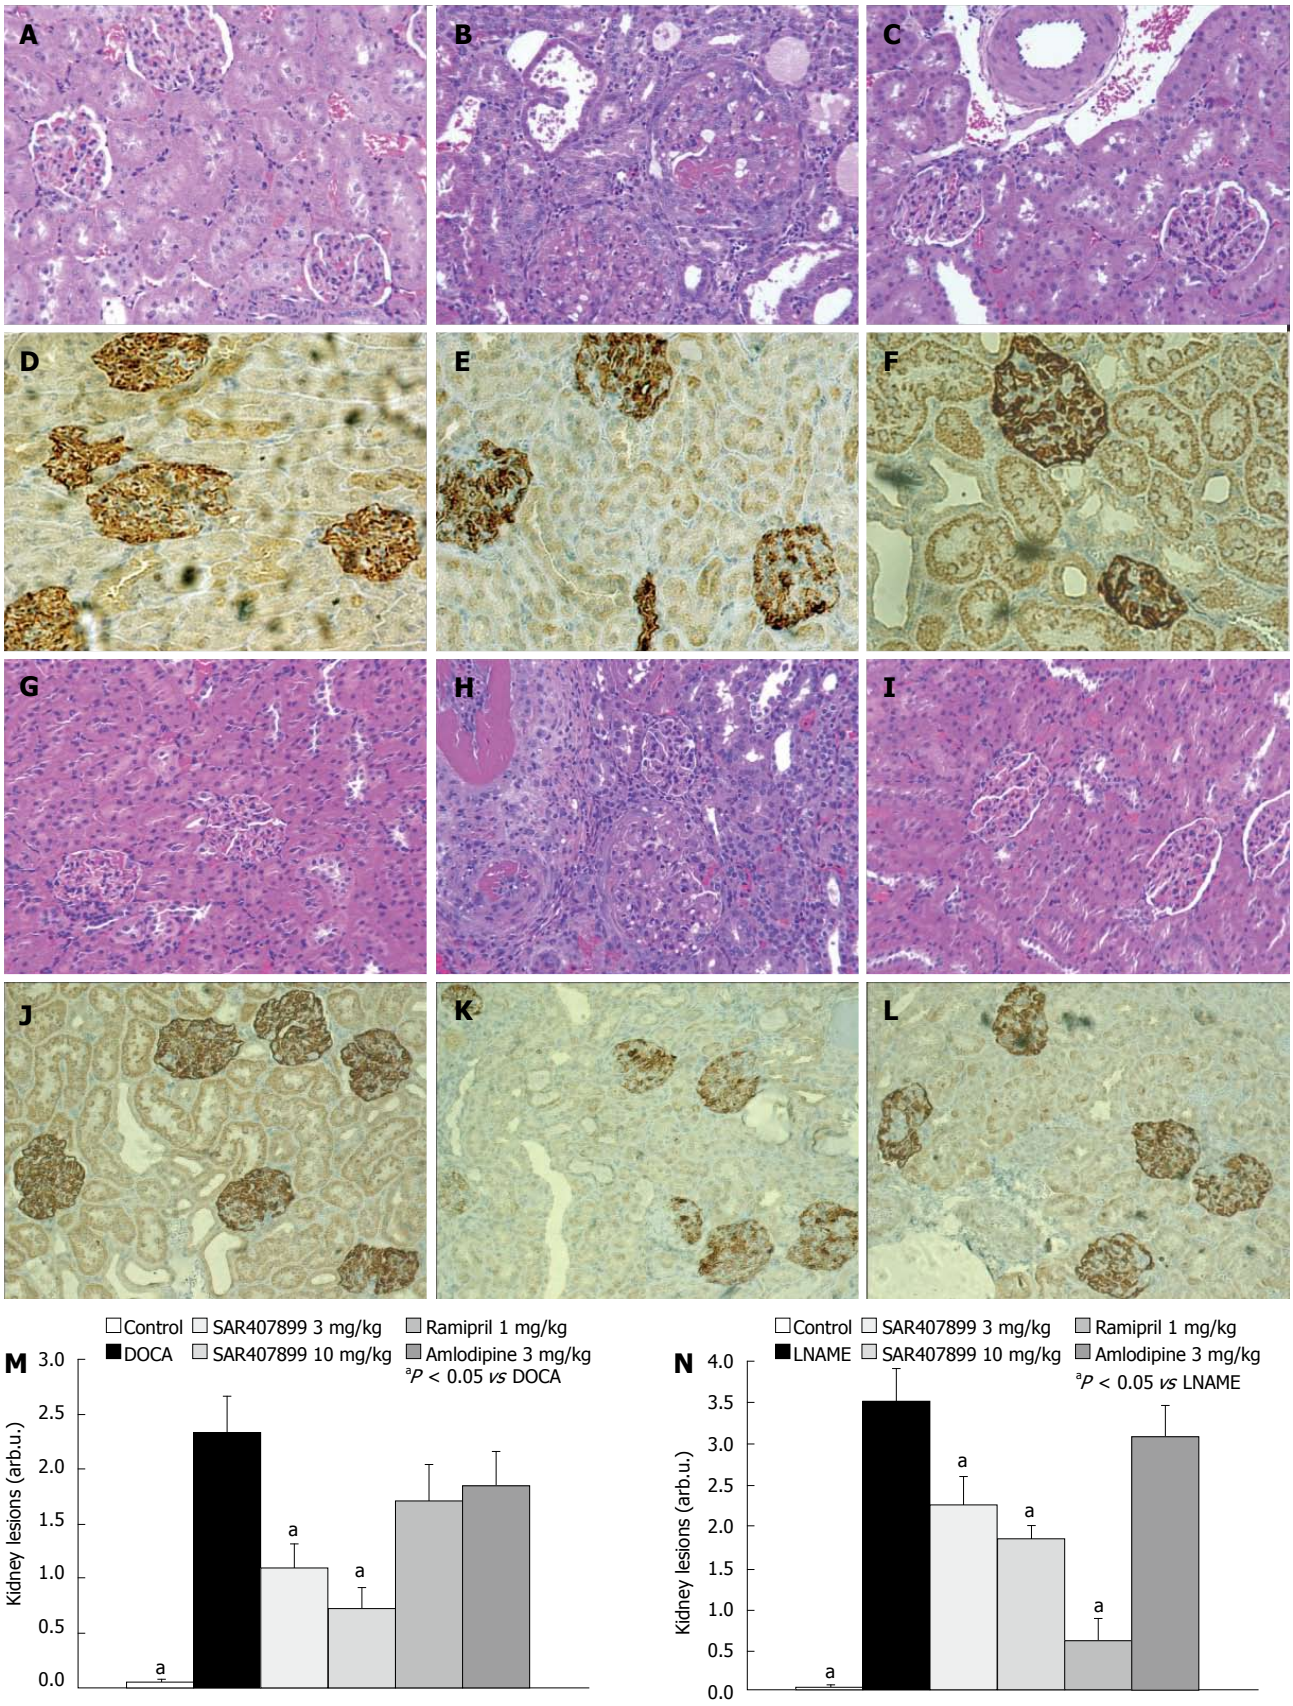

Figure 5 Histological examination of the effect of SAR407899 on the kidney. A-C: Haematoxylin eosin staining of normal glomeruli in control rats (left), sclerotic changes, dilation and hypertrophy of glomeruli of deoxycorticosterone acetate (DOCA) rats (center) and protective effects of SAR407899 at 10 mg/kg (right); D-F: Podocin staining in kidneys. Upon DOCA treatment, massive loss of podocytes can be detected. SAR407899 at 10 mg/kg exerts a protective effect in the kidneys of DOCA rats and rescues podocytes; G-I: Haematoxylin eosin staining of normal glomeruli in control rats (left), severe fibrotic changes, infiltration of leukocytes, and hypertrophy of glomeruli of Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) rats (center), protective effects of SAR407899 at 10 mg/kg (right); J-L: Loss of podocytes upon LNAME treatment. SAR407899 at 10 mg/kg protected against loss of podocytes. Summary of kidney lesions and effect of SAR407899 and reference substances in DOCA (M) and LNAME rats (N). A, D, G, J: Control; B, E: DOCA; H, K: LNAME; C, F, I, L: SAR407899 10 mg/kg.

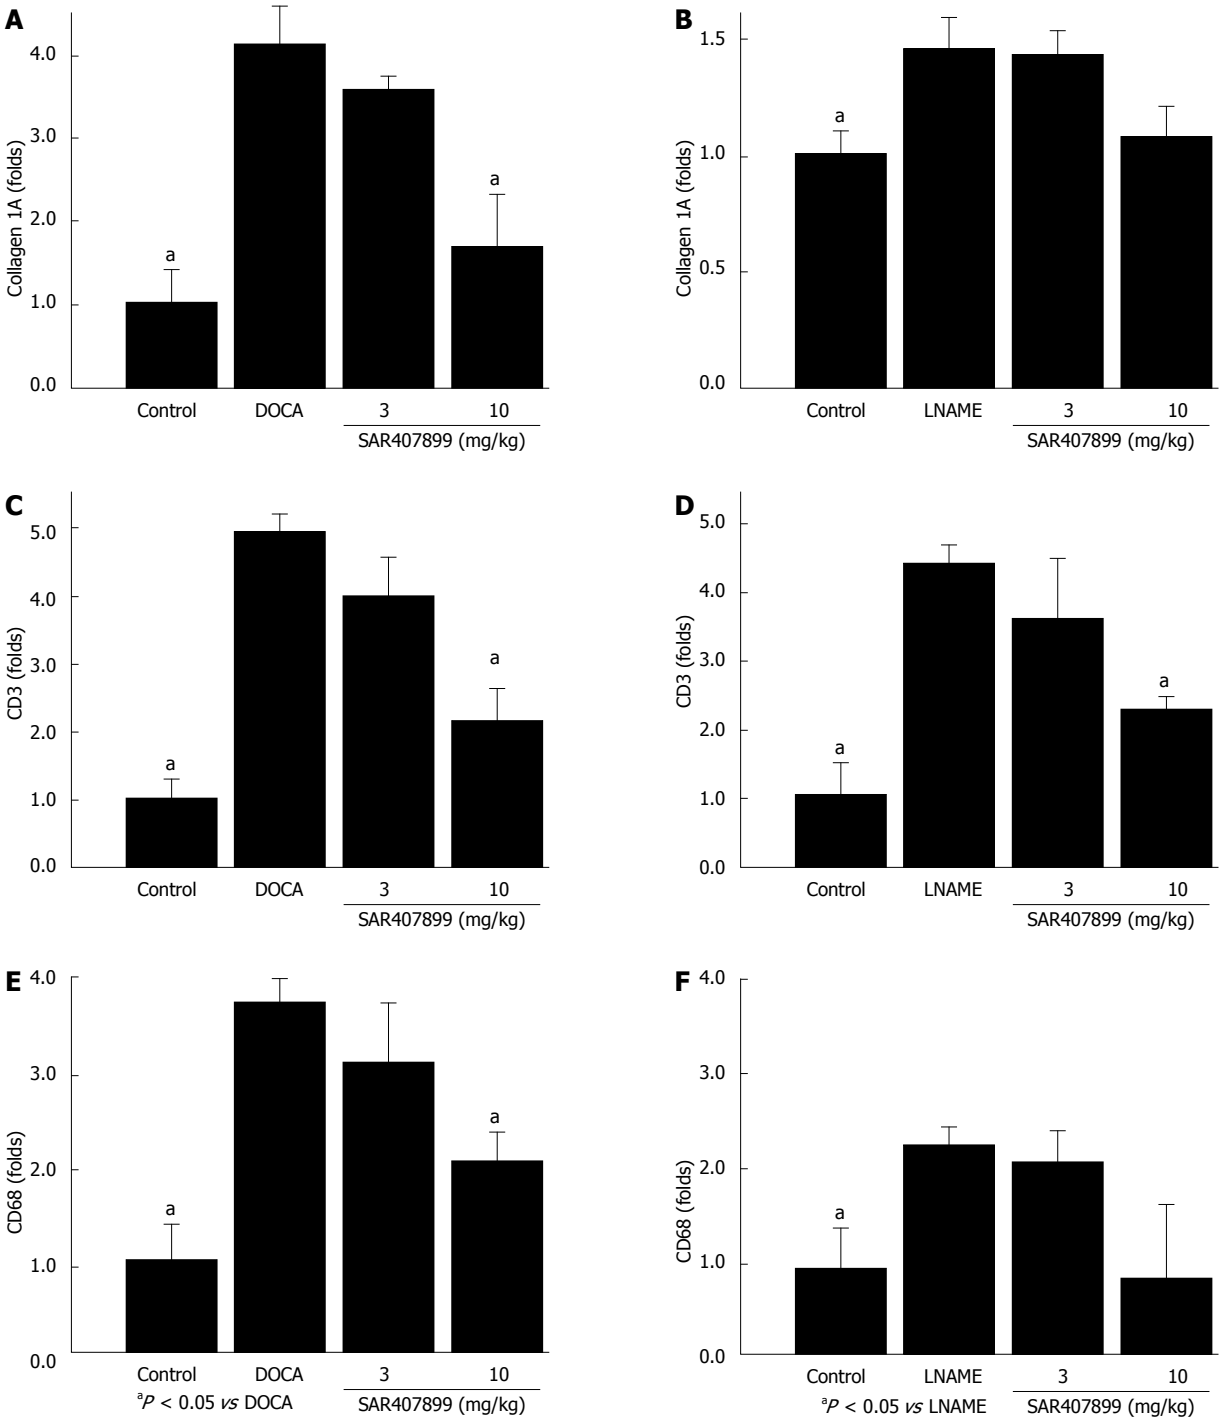

Figure 6 Effect of SAR407899 on the expression of fibrotic and leukocyte genes in the kidney. Determination of collagen, T cell (CD3) and macrophage (CD68) expression in the kidneys of deoxycorticosterone acetate (DOCA) (A, C and E) and Nω-Nitro-L-arginine methyl ester hydrochloride (LNAME) (B, D and F) rats. Expression of collagen was significantly increased upon DOCA and LNAME treatment. Upon DOCA or LNAME treatment, CD3 and CD68 abundance was induced, indicating that leukocytes infiltrated into the kidneys. SAR407899 treatment reduced expression of collagen and leukocyte genes in both models.

was significantly increased upon DOCA and LNAME treatment. SAR407899 at 10 mg/kg significantly reduced collagen expression in the kidneys of the DOCA rats and non-significantly in the kidneys of the LNAME rats (Figure 6A and B). Leukocyte infiltration into kidney tissue was quantified by measuring CD3 (T lymphocytes) and CD68 (macrophages) mRNA abundance in the kidneys of the DOCA and LNAME rats. Upon DOCA or LNAME treatment, both parameters were significantly induced, thus indicating significant leukocyte infiltration. SAR407899 at 10 mg/kg efficiently reduced leukocyte infiltration in the kidneys of the DOCA rats and non-significantly in the kidneys of the LNAME rats (Figure 6E and F), presumably by inhibition of leukocyte migration.

DISCUSSION

It has been generally accepted that RhoA-associated

kinases (ROCK1 and ROCK2) have important functions not only in vascular smooth muscle contractility but also in actin cytoskeleton rearrangement, cell adhesion, cytokinesis and motility in various cell types[7-12,27-31]. Two commercially available ROCK-inhibitors, fasudil and Y27632 were used in the majority of the published *in vitro* and *in vivo* studies. Both compounds were identified in the mid-1980s and were used to elucidate the pathophysiological role of ROCKs in several pathologies. Y27632 was first claimed in a patent in 1988[32,33] as a calcium channel blocker, and fasudil was patented in 1986[34,35], also as a novel calcium channel blocker. Later, discovery of ROCKs[36] led to the identification of these kinases as a direct target of both compounds. However, fasudil and Y27632 possess some unfavorable properties, including limited selectivity and importantly, a short duration of action. The latter might be a reason why fasudil was often administered at high doses, *e.g.*, 30 mg/kg per day or 100 mg/kg per day[37] in *in vivo* animal studies, which increases the probability of non-specific and toxic effects in different organs. In long-term animal studies of hypertension in which fasudil was used at low doses, *e.g.*, 10 mg/kg, no significant blood pressure lowering effect and only a partial renoprotective effect were found[38,39].

SAR407899 is a selective and potent inhibitor of ROCK that has been extensively characterized *in vitro*[21]. Acute treatment of conscious hypertensive animals (SHR, SHR-sp, LNAME or DOCA-salt treated rats) with SAR407899 resulted in a strong and sustained fall in blood pressure[21]. To evaluate the long-term effects of SAR407899, the compound was tested in two models of hypertension, one non-sensitive (DOCA) and the other sensitive (LNAME) to ACE-inhibition. The treatment effects of SAR407899 were compared to two current standard medications for high blood pressure, namely the inhibition of ACE (ramipril) or calcium channels blockade (amlodipine). As expected, treatment with ramipril demonstrated potent blood pressure lowering and end organ protective effects in the LNAME but not in the DOCA hypertension model[24,40,41]. Because the DOCA hypertensive model is characterized by hypervolemia and low plasma renin levels, this model is insensitive to ACE-inhibition[23]. The treatment effects of amlodipine at the given dose were small and non-significant in both models. Our data are in good agreement with several other studies in which amlodipine was found to be ineffective in protecting kidney function and structure in the DOCA rat or less effective than ACE-inhibitors in the LNAME rat[22,42,43]. Even when amlodipine was dosed three times higher, *e.g.*, at 10 mg/kg, no reduction in proteinuria or glomerular damage was found in the DOCA rats, although amlodipine efficiently lowered blood pressure. However, in other models, *e.g.*, in the LNAME rats, treatment with amlodipine showed pronounced protective effects on end organ damage and myocardial protection combined with the efficient blood pressure lowering effect in different rat strains. The lack of efficacy of amlodipine has been further linked to the inability of CCBs to dilate renal efferent vessels to improve renal microcirculation[22,43-47]. Long-term treatment with SAR407899 showed an efficient dose-dependent blood pressure reduction in both models with no signs of tachyphylaxia over the course of 35 d. Blood pressure lowering effects and protective effects on hypertension related end organ damage of SAR407899 were superior to ramipril and amlodipine in the DOCA rat. Typical end-organ damage observed upon chronic LNAME administration (hypertrophy and fibrosis of the heart, fibrosis of the kidney, glomerulosclerosis, tubular degeneration and leukocyte-infiltration) was significantly reduced in the SAR407899-treated animals as supported by histopathological and gene expression analyses. Albuminuria, which is considered the key parameter of kidney damage in general and of glomerular damage in particular, were strongly induced in the DOCA- and LNAME-challenged rats. Chronic administration of SAR407899 significantly reduced albuminuria in both models. Histologically visible improvements should translate into functional benefits (endothelial function and heart contractility) observed upon SAR407899 administration. Indeed, hearts of hypertensive the DOCA or LNAME animals treated with SAR407899 showed a significantly improved heart function (measured as heart power *in vitro*). Moreover, endothelial-dependent relaxation (*in vitro*) was significantly and dose-dependently improved after long-term treatment with SAR407899. Histological scoring and quantitative real time PCR analysis revealed a significant reduction in interstitial fibrosis, as measured by sirius red staining and collagen expression, respectively. SAR407899 treatment significantly reduced tissue expression of CD3 and CD68 (markers of infiltrating leukocytes and macrophages) in both models, which can be explained by the role of ROCKs in cellular migration and cytokinesis through modulation of the cytoskeleton. Similar data were reported by several groups studying the effect of ROCK inhibition on macrophage migration in atherosclerotic plaques[48-50]. Therefore, the beneficial effects of SAR407899 do not depend on only blood pressure control but also the suppression of inflammatory and fibrotic events in the target organs. These data suggest that inhibition of ROCKs could bring clear therapeutic benefit through different mechanisms and is not limited to vasorelaxation only. Recently, other authors stated that potential benefits of ROCK-inhibition, direct or indirect, could be more far-reaching than first thought[13]. Further studies using highly selective, potent, and safe ROCK inhibitors could open new perspectives for ROCK-based therapies in several different clinical indications.

COMMENTS

Background

Large clinical trials have demonstrated that current treatment with angiotensin converting enzyme-inhibitors, Angiotensinreceptor-blockers or calcium channel blockers only modestly reduces the progression of chronic kidney diseases. Hypertension increases the risk of target organ damage, including heart hypertrophy, heart ischemia, kidney dysfunction or failure, cerebrovascular events and malfunction of the endothelial tissue.

Research frontiers

Rho-kinase (ROCK) is considered an important target for a variety of cardiovascular diseases, including hypertension and hypertension-related end-organ damage. Several inhibitors of ROCK have been extensively used to evaluate the role of ROCK in cardiovascular physiology and pathology. However, these inhibitors have a moderate specificity, moderate potency and short duration of action *in vivo* that limit their clinical use. Therefore, the development of a more potent and specific inhibitor with a better pharmacokinetic profile is needed to explore the potential of ROCK inhibition in the therapy of hypertension and its complications.

Innovations and breakthroughs

The authors have identified a novel, potent and selective inhibitor of ROCK (SAR407899) and characterized its long-term effects in two animal models of hypertension.

Applications

ROCK-inhibition by the SAR407899 represents a new therapeutic option for the treatment of hypertension and its complications.

Terminology

Rho-kinases (ROCK1 and ROCK2) are intimately involved in the transmission of contractile signaling within smooth muscle tissue. Upon activation of the small GTPase RhoA by ligand-bound specific GPCRs, ROCKs, the downstream effectors of RhoA, phosphorylate the myosin light chain phosphatase and the myosin regulatory light-chain itself, resulting in a net increase in activated myosin. This promotes smooth muscle contraction and actin cytoskeleton re-organization. Inhibition of ROCKs leads to relaxation of vascular smooth muscle cells and, consequently, to a decrease in blood pressure.

Peer review

This article is particular meaningful for hypertension-related end-organ damage.

Abstract

Cor triatriatum dextrum is an extremely rare congenital heart abnormality in which the right atrium is separated into two chambers by a persistent fibrous membrane. A transvenous approach to place a dual-chamber pacemaker in such patients is technically challenging. We report the first case of a transvenous permanent pacemaker placement in a patient with cor triatriatum dextrum. An 87-year-old woman was diagnosed with paroxysmal atrial fibrillation. She was accidentally found to have cor triatriatum dextrum during the transesophageal echocardiography (TEE) prior to cardioversion. Later during her hospital stay, it was indicated to place a permanant pacemaker due to high grade atrioventricular block. After thorough reviewing TEE imagings, a transvenous catheter-based approach was decided feasible. Patient successfully received a dual chamber pacemaker through left subclavian venous approach. Furthermore in our case, using specially designed pacemaker leads and cautious intra-procedural maneuvering under fluoroscopic guidance ensured procedural success. In summary, a thorough pre-operative evaluation with transesophageal echocardiography is critical for the planning and eventual success of the transvenous placement of right-sided leads.

Key words: Congenital heart defect; Complete heart block; Inter-atrial membrane; Dual-chamber pacemaker

Core tip: Cor triatriatum dextrum is an extremely rare congenital heart abnormality in which the right atrium is separated by a persistent fibrous membrane. This membrane poses a technical challenge for dual-chamber pacemaker placement through the transvenous approach. Here we report the first transvenous pacemaker placement in a patient with cor triatriatum dextrum. A thorough pre-operative evaluation by transesophageal echocardiogram was critical for the planning of transvenous catheter-based right-sided leads placement. Using specially designed pacemaker leads and cautious

intra-procedural maneuvering under fluoroscopic guidance ensured procedural success.

INTRODUCTION

Cardiovascular disease is the leading cause of mortality and mobility according to recent statistics[1]. Adult congenital heart disease has become an important entity in the current cardiology practice due to the advances in pediatric cardiac care and improved survival[2]. Commonly seen congenital heart conditions include septal and valvular defects. Cor triatriatum dextrum is an extremely rare congenital heart anomaly in which the right atrium is separated into two chambers by the persistence of the right sinus venosus valve[3]. It is uncommon to encounter such patients requiring placement of a permanent pacemaker. We report the placement of a dual-chamber pacemaker through the transvenous approach in a patient with cor triatriatum dextrum. To our knowledge, there are no similar reports in the published literature.

CASE REPORT

An 87-year-old woman presented to the hospital with complaints of dyspnea on exertion. She has no significant medical history other than prior cigarette smoking. On her arrival to the emergency room she was found to be in atrial fibrillation with rapid ventricular response. She was treated with heart rate control medications and anticoagulation. A transesophageal echocardiogram (TEE) was performed prior to cardioversion to normal sinus rhythm given poor rate control. This revealed the presence of a well-defined transverse membrane dividing the right atrium (Figure 1) consistent with the diagnosis of cor triatriatum dextrum. Color Doppler evaluation indicated separation of blood flow in the two divisions of the right atrium. However the division of the right atrium by this membrane was not complete. Color Doppler confirmed partial obstruction in the superior portion (Figure 2). The right atrium was enlarged without significant tricuspid regurgitation. An enlarged coronary sinus was noted with a measured diameter of 15.8 mm. Agitated saline injections *via* the left arm showed no saline contrast in the coronary sinus, indicating the absence of a persistent left superior vena cava. In addition, a small atrial septal defect (ASD) (measured diameter 3 mm) with a left to right shunt was demonstrated by color flow Doppler (Figure 3). No thrombus was noted in the left atrium and left atrial appendage. Subsequently the patient was cardioverted to normal sinus rhythm without complication.

During her hospital course, she was found to have Morbitz type Ⅱ AV block along with periods of complete heart block by remote cardiac monitoring station. Considering patient's daily functional capacity predicting reasonable life expectancy, the decision was made to implant a permanent dual-chamber pacemaker. The presence of cor triatriatum dextrum with a membrane partially obstructing the cavity of the right atrium, presented a technical challenge in regards to adequate placement of the right ventricular and right atrial leads *via* the transvenous approach. After obtaining left subclavian venous access, a 6-French St. Jude Medical pacing electrode was inserted *via* a breakaway introducer sheath. The lead was gently guided to the area near the opening of the interatrial membrane. The area was gently probed with the pacing lead until it was seen to dip into the lower atrial area. Care was taken not to cross the ASD with the lead. Once the inner atrial membrane had been crossed, the lead was then advanced and fluoroscopically guided into the right ventricular apex. Once adequate positioning had been determined, the active fixation coil was deployed. *Via* a second breakaway introducer sheath, a Boston Scientific Dextrus active fixation lead was fluoroscopically guided into an area just below the membrane within the right atrial appendage, and the active fixation coil deployed (Figure 4). Each lead was then connected to a Boston Scientific Ingenio dual-chamber pulse generator. *Via* off field telemetry, adequate sensing and pacing levels of the leads were determined. The patient was discharged to home the next day.

DISCUSSION

The prevalence of adult congenital heart disease has increased in the past 10 years and its management has proposed new challenges to current cardiology practice[2]. We presented a case of successful pacemaker lead placement in a patient with non-obstructive cor triatriatum dextrum. Cor triatriatum dextrum is an extremely rare congenital heart abnormality in which the right atrium is separated into two chambers by the persistence of the right sinus venosus valve[3]. The superior chamber receives the venous blood from both vena cava and the inferior chamber is in contact with the tricuspid valve and the right atrial appendage. The size of the communicating orifice between the superior and inferior atrial chambers determines the natural course of cor triatriatum dextrum. If the communicating orifice is small, the patient shows symptoms of congestive heart failure during infancy or childhood and usually requires surgical intervention for survival. If the connection is large and non-obstructive, patient may remain asymptomatic for many years, as in our case. The clinical presentation therefore is somewhat variable. Patients with cor triatriatum dextrum may present with recurrent supraventricular tachycardia, right-side heart failure, or cyanosis in the presence of ASD with right-to-left shunt. In our case, patient presented initially with atrial fibrillation with rapid ventricular response. The disorder can be treated surgically in symptomatic patients by

removing the membrane dividing the atrium.

During normal embryogenesis, the right atrium is formed by two different portions joining together: the right horn of the sinus venosus that forms the smooth posterior portion, and the original embryologic right atrium that forms the trabeculated anterior portion. The connection between these two portions is called sinoatrial orifice. The sinoatrial orifice is sided by two valvular folds that are called the right and left venous valves. During the development of right atrium, the right valve of the right horn of the sinus venosus forms a membranous valve that divides the right atrium in two parts. This valve directs oxygenated venous return from the inferior vena cava across the foramen ovale to the left side of the heart. This membranous valve normally regresses by the 12th week of gestation. Incomplete regression of the superior portion of right venosus valve forms membranes attached to the crista terminalis, while remnant of the inferior portion results in the Eustachian valve of the inferior vena cava, web-like remnant as Chiari network or the Thebesian valve of the coronary sinus. Failure of regression of this membrane causing persistent partition between the venous (smooth) and trabeculated portions of the right atrium

leads to the formation of cor triatriatum dextrum[4].

Cor triatriatum dextrum has been associated with other congenital abnormalities, including ASD, patent foramen ovale, ventricular septal defect, hypoplastic right ventricle, hypoplastic tricuspid valve, and pulmonary atresia[3]. In our case, the presence of a small ASD posed the risk of crossing into the left atrium during manipulation of the lead across the atrial membrane. We also found an enlarged coronary sinus, measured diameter 15.8 mm (normal range 6.6 ± 1.5 mm)[5]. This is likely related to the elevated right atrial pressure. A rare but important congenital vascular anomaly associated with an enlarged coronary sinus is a persistent

left superior vena cava draining into the coronary sinus[6]. To investigate this possibility, an agitated saline injection *via* the left arm was performed during TEE and showed no saline contrast in the coronary sinus, indicating the absence of a persistent left superior vena cava.

Considering the rarity of cor triatriatum dextrum, a patient with such a congenital abnormality who requires a permanent pacemaker is unique. To our knowledge, this is the first reported case of a permanent pacemaker placement through a transvenous approach in a patient with cor triatriatum dextrum. Although it is technically challenging, transvenous catheter-based approach is feasible if the membrane in the right atrium is non-obstructive and caution exercised during the procedure. A thorough pre-operative evaluation by transesophageal echocardiogram was critical for the planning of the transvenous catheter-based right-sided leads placement. Using specially designed pacemaker leads and cautious intra-procedural maneuvering under fluoroscopic guidance ensured procedural success.

COMMENTS

Case characteristics

A 87-year-old woman presented with paroxysmal atrial fibrillation.

Clinical diagnosis

Atrial fibrillation with raid ventricular response, later was also diagnosed with high grade AV block.

Differential diagnosis

Any cause for atrial fibrillation and/or AV block such as hypertension, heart failure *etc*,.

Laboratory diagnosis

Lab test result was unremarkable.

Imaging diagnosis

A transesophageal echocardiogram revealed a rare congenital condition called cor triatriatum dextrum.

Treatment

A permanent pacemaker placement through a transvenous approach.

Related reports

To the knowledge, this is the first reported case of a permanent pacemaker placement through a transvenous approach in a patient with cor triatriatum dextrum.

Term explanation

Cor triatriatum dextrum is an extremely rare congenital heart abnormality in which the right atrium is separated into two chambers by the persistence of the right sinus venosus valve.

Experiences and lessons

Although it is technically challenging, transvenous catheter-based approach for a permanent pacemaker placement is feasible in a patient with cor triatriatum dextrum.

Peer review

It is interesting.

AIM AND SCOPE

World Journal of Cardiology (*World J Cardiol*, *WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJC covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

Abstract

Hypertension is a very prevalent risk factor for cardiovascular disease. The prevalence of resistant hypertension, *i.e.*, uncontrolled hypertension with 3 or more antihypertensive agents including 1 diuretic, is between 5% and 30% in the hypertensive population. The causes of resistant hypertension are multifactorial and include behavioral and biological factors, such as non-adherence to pharmacological treatment. All current treatment guidelines highlight the positive role of physical exercise as a non-pharmacological tool in the treatment of hypertension. This paper draws attention to the possible role of physical exercise as an adjunct non-pharmacological tool in the management of resistant hypertension. A few studies have investigated it, employing different methodologies, and taken together they have shown promising results. In summary, the available evidence suggests that aerobic physical exercise could be a valuable addition to the optimal pharmacological treatment of patients with resistant hypertension.

Key words: Exercise training; Resistant hypertension; Blood pressure; Non-pharmacological; Cardiovascular disease

Core tip: Taken together, the available evidence indicates that, unless there is a contraindication to performing physical exercise, patients with resistant hypertension should be encouraged to engage in regular aerobic physical exercise in addition to the optimal pharmacological treatment.

Ribeiro F, Costa R, Mesquita-Bastos J. Exercise training in the management of patients with resistant hypertension. *World J Cardiol* 2015; 7(2): 47-51 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i2/47.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i2.47

RESISTANT HYPERTENSION

Arterial hypertension (defined as blood pressure > 140/90 mmHg) is the most important risk factor for cardiovascular events and end-stage renal disease[1]. In the general population, arterial hypertension has a prevalence of 30%-45%[1]. The control of blood

pressure is essential to avoid cardiovascular events in primary and secondary prevention[1]. In an important percentage of subjects, arterial hypertension is not controlled (< 140 and 90 mmHg) with a strategy to correct lifestyle behavior and three antihypertensive drugs in high doses, including a diuretic[1,2], and is defined as resistant hypertension. Some authors suggest that resistant hypertension should be diagnosed in those who meet the criteria of blood pressure control with the use of four antihypertensive drugs[2]. Several studies found that the prevalence of resistant hypertension in the hypertensive population is between 5% and 30%[1]. So, it is essential that the diagnosis of resistant hypertension is well defined in order to exclude false resistant hypertension[3]. Normally, arterial hypertension is defined by office blood pressure obtained by an electronic oscillometric device, called casual blood pressure. Ambulatory blood pressure is another way to measure blood pressure. Ambulatory blood pressure is superior to casual blood pressure in the diagnosis[1] and the cardiovascular events prognosis[4,5].

Blood pressure shows circadian rhythm; it is higher in the morning after waking (morning surge), declines during the day and in a more pronounced way during the night with sleeping (nighttime dipping)[6]. In relation to cardiovascular events prognosis, several studies have shown that nighttime blood pressure is superior to daytime blood pressure[4,7]. In patients with resistant hypertension, the absence of nighttime dipping is more prevalent than in patients with nonresistant hypertension and it is associated with higher cardiovascular events[6]. Ambulatory blood pressure also makes the exclusion of the alert reaction (difference between casual blood pressure and day blood pressure determined by ambulatory blood pressure) possible, which is one of the causes of false resistant hypertension or pseudo resistant hypertension[3]. In pseudo resistant hypertension, blood pressure is not controlled in office behavior but has normal values in ambulatory blood pressure. Nonadherence to the prescribed treatment is another cause of false resistant hypertension[5].

Resistant hypertension is associated with higher organ damage and cardiovascular events and a worse renal prognosis[1]. Resistant hypertension can be caused by obesity, excessive alcohol ingestion, high salt intake and obstructive sleep apnea[5]. Secondary hypertension can be the cause of resistant hypertension[8]. Secondary causes of hypertension include hyperaldosteronism, obstructive sleep apnea, renal artery stenosis and pheochromocytoma[9]. Hyperaldosteronism is the most common secondary cause of hypertension; nonetheless, many newly diagnosed hypertensive patients[10] and resistant hypertension patients[11] can have undetected primary aldosteronism. So, in studies looking for the impact of lifestyle changes on blood pressure of patients with resistant hypertension, it is recommended to assess at least the plasma aldosterone-renin ratio even if the serum potassium level is normal[9]. The treatment of arterial hypertension implies changes in lifestyle attitudes, namely regarding exercise habits[8]. Recently, a prospective, blinded, randomized, sham-controlled trial assessing the effect of renal denervation or a sham procedure on ambulatory blood pressure monitoring measurements 6 mo post-randomization failed to demonstrate a benefit of renal artery denervation on reduction in ambulatory blood pressure[12]. However, recently several predictors of blood pressure response in the SYMPLICITY HTN-3 trial were identified, which could at least partially explain the results of the trial[13]; among the predictors are the total number of ablation attempts, baseline office SBP $\geqslant$ 180 mmHg, prescription of an aldosterone antagonist at baseline, and age < 65 years in age[13]. This information is significant for designing future studies in this field.

EXERCISE TRAINING AND RESISTANT HYPERTENSION

The cardioprotective benefits of exercise training in those with cardiovascular diseases include the modification of traditional cardiovascular risk factors, the improvement of exercise tolerance, myocardial and peripheral perfusion, cardiac function, arterial stiffness, autonomic function, endothelial repair, as well as the mitigation of endothelial dysfunction and low-grade vascular wall inflammation, and, most importantly, the reduction of morbidity and mortality[14-25]. Indeed, it is widely accepted that exercise training is a polypill with several beneficial effects, including antihypertensive effects. Indeed, exercise is able to induce a decrease of 5-7 mmHg in systolic blood pressure in patients with hypertension[26]. Nonetheless, the antihypertensive effects of exercise in patients with cardiovascular disease are often underestimated because the analysis is frequently made without assessing the influence of the baseline blood pressure on the effects of exercise training. We showed[17,27] in previous studies that if cardiovascular disease patients with high and low blood pressure at baseline are considered together, an exercise training intervention has no effect on blood pressure. But, if the analysis is conducted dividing patients into two subgroups on the basis of baseline blood pressure (pre-hypertension/hypertension *vs* normotension), exercise training significantly decreases systolic blood pressure[17,27]. An interesting aspect of exercise for patients with hypertension is that they could benefit from the antihypertensive effect of aerobic exercise after just three exercise sessions. Additionally, the duration of the exercise sessions can be as short as 10 min and the intensity of exercise can be relatively low (40% to < 60% VO_2 peak)[26]. The exercise prescription recommendation of the American College of Sports Medicine for those with high blood pressure

is to perform 30 min of continuous or accumulated aerobic exercise of moderate intensity (40%-60% of VO_2 Reserve) per day, on most, preferably all, days of the week[28]. The aerobic exercise could be supplemented by resistance exercise[28].

The management of resistant hypertension includes lifestyle interventions that aim to reduce sodium intake and increase the levels of daily physical activity[29]. Nonetheless, there are few studies evaluating the effects of lifestyle interventions, including physical exercise in patients with resistant hypertension. The potential of aerobic physical exercise as an adjunct non-pharmacological therapeutic tool to manage resistant hypertension was recently addressed in three studies[30-32].

Dimeo *et al*[30] first showed that patients with a reduced responsiveness to medication do not necessarily have reduced responsiveness to non-pharmacological therapies, *i.e.,* aerobic physical exercise, to lower blood pressure. The authors conducted a randomized trial encompassing fifty patients with resistant hypertension on an exercise training program, consisting of walking on a treadmill 3 times per week for 8 to 12 wk. Initially, the duration of the sessions was 30 min (interval training until the fifth week) and then was gradually increased to 30, 32 and 36 min of continuous training. Dimeo *et al*[30] observed a 6 ± 12 and 3 ± 7 mmHg reduction in ambulatory systolic and diastolic daytime ambulatory blood pressure, respectively. More recently, Guimaraes *et al*[31] confirmed these positive results using a different exercise approach. They enrolled 32 patients in a heated water exercise program or to a control group. The heated water exercise program was performed three times per week for 12 wk and consisted of callisthenic exercises (*i.e.*, exercises performed in a rhythmic, systematic way using the body weight for resistance) against water resistance and walking inside a pool with controlled temperature (30℃-32℃). After 12 wk, the exercise program group showed a decrease in 24 h systolic (from 137 ± 23 to 120 ± 12 mmHg) and diastolic blood pressure (from 81 ± 13 to 72 ± 10 mmHg), daytime systolic (from 141 ± 24 to 120 ± 13 mmHg) and diastolic blood pressure (from 84 ± 14 to 73 ± 11 mmHg), and nighttime systolic (from 129 ± 22 to 114 ± 12 mmHg) and diastolic blood pressure (from 74 ± 11 to 66 ± 10 mmHg). This reduction in blood pressure is of great importance as higher ambulatory blood pressure predicts cardiovascular morbidity and mortality in resistant hypertensive patients[33].

Concern for safety must come first in all that prescribe or supervise exercise. Thus, patients with resistant hypertension should consult a physician prior to engagement in exercise training, particularly vigorous intensity exercise[34]. The progression of intensity of aerobic exercise should be gradual to enhance compliance; slow progression of frequency and intensity of resistance exercise is also encouraged to avoid injuries. Isometric exercise is not recommended. In patients with poorly controlled blood pressure, vigorous intensity exercise should be discouraged or postponed until appropriate drug treatment has been instituted and blood pressure lowered[34]. It seems prudent to keep systolic blood pressures at ⩽ 220 mmHg and/or diastolic blood pressures ⩽ 105 mmHg during exercise[35]. It is also important to know that in some patients, β-blockers and diuretics have an adverse impact on thermoregulatory function and could cause hypoglycemia[35,36]. Additionally, patients treated with calcium channel blockers, β-blockers and vasodilators should stop exercise gradually as they have an increased likelihood of hypotension post exercise[35,36]. Hence, it is important to monitor the room temperature during exercise, use the Borg scale as an adjunct to heart rate to monitor exercise intensity, and extend the cool down period.

FUTURE PERSPECTIVES

The above-mentioned results are promising and provide good perspectives for the future. Nonetheless, more studies enrolling a large number of patients are clearly needed to reinforce the role of physical exercise associated with antihypertensive medication in the control of blood pressure in patients with resistant hypertension. Future studies are also warranted to disclose the mechanisms responsible for the positive effects of exercise. Several mechanisms, none of them definitive, have been proposed to explain the benefits of exercise training in these patients, including the decrease of sympathetic and the increase of vagal nerve activity, the improvement of the sensitivity of the baroreceptor reflex, the improvement of endothelial function and arterial stiffness, the decrease in the concentration of rennin, angiotensin Ⅱ and aldosterone, and the reduction of renal sympathetic outflow. These aspects seem to merit close attention in future studies.

Abstract

After myocardial infarction (MI), the heart undergoes extensive myocardial remodeling through the accumulation of fibrous tissue in both the infarcted and noninfarcted myocardium, which distorts tissue structure, increases tissue stiffness, and accounts for ventricular dysfunction. There is growing clinical consensus that exercise training may beneficially alter the course of post-MI myocardial remodeling and improve cardiac function. This review summarizes the present state of knowledge regarding the effect of post-MI exercise training on infarcted hearts. Due to the degree of difficulty to study a viable human heart at both protein and molecular levels, most of the detailed studies have been performed by using animal models. Although there are some negative reports indicating that post-MI exercise may further cause deterioration of the wounded hearts, a growing body of research from both human and animal experiments demonstrates that post-MI exercise may beneficially alter the course of wound healing and improve cardiac function. Furthermore, the improved function is likely due to exercise training-induced mitigation of renin-angiotensin-aldosterone system, improved balance between matrix metalloproteinase-1 and tissue inhibitor of matrix metalloproteinase-1, favorable myosin heavy chain isoform switch, diminished oxidative stress, enhanced antioxidant capacity, improved mitochondrial calcium handling, and boosted myocardial angiogenesis. Additionally, meta-analyses revealed that exercise-based cardiac rehabilitation has proven to be effective, and remains one of the least expensive therapies for both the prevention and treatment of cardiovascular disease, and prevents re-infarction.

Key words: Post-myocardial infarction; Exercise training; Myocardial remodeling; Angiotensin Ⅱ; Fibrosis

Core tip: After myocardial infarction, the heart undergoes extensive myocardial remodeling through the accumulation of fibrous tissue in both the infarcted and noninfarcted myocardium, which distorts tissue structure, increases tissue stiffness, and accounts for ventricular dysfunction. There is growing clinical consensus that exercise training may beneficially alter the course of post-myocardial infarction (MI) myocardial remodeling and improve cardiac function. This review

summarizes the present state of knowledge regarding the effect of post-MI exercise training on infarcted hearts.

INTRODUCTION

Myocardial infarction (MI) is the major cause of heart failure in the adult American population[1]. Annually, 1.5 million Americans suffer from MI, with just over one-third of all cases inflicting serious heart disease and death. Because of this, post-MI treatments have become the major focus of research. There is growing clinical consensus that exercise training may beneficially alter the clinical course of post-MI myocardial remodeling and improve cardiac function[2,3]. Exercise training in post-MI patients with left ventricle (LV) systolic dysfunction has been recommended as a useful adjunct to the existing medical therapy, not only to attain symptomatic and functional improvement but also to prevent the progression of LV dysfunction and its attendant morbidity and mortality[4,5]. Significant improvements in exercise capacity were noted with no major complications in patients with moderate or severe LV dysfunction[4,6,7]. Post-MI training reverses skeletal muscle metabolic derangements[8,9], increases maximal cardiac output[6,10,11] and improves the quality of life in these patients. Exercise training also improves in myocardial perfusion, independent of regressive changes in coronary lesions[12]. The improvement in myocardial blood flow of the infarcted area, even late after acute infarction, may lead to a consistent recovery of both regional and global LV function. Patients with MI experienced an exercise training-induced improvement in myocardial oxygenation and LV function[13].

In recent years, cardiac rehabilitation (CR) has become a multi-disciplinary and multi-faceted intervention aimed at restoring well-being and impeding disease progression in patients with heart disease[14]. This complex intervention involves a variety of therapies, including risk factor education, psychological input, and drug therapy. Nevertheless, international clinical guidelines have consistently identified exercise-based CR as an essential element of therapy.

Despite guidelines recommending the use of CR programs for patients with MI, participation in these programs continues to be low; in fact, it has been reported that only 10% to 20% of patients who survive an acute MI participate in an exercise-based secondary prevention CR program[15]. Indeed, the reason for such low participation is likely multifactorial; additionally, conflicting results regarding the efficacy of experimental research and the absence of large randomized controlled trials with respect to re-infarction likely serve as additional barriers[3]. Therefore, we reviewed the evidence and the mechanisms by which post-MI exercise improves morbidity and mortality, as obtained by means of experimental and clinical studies.

POST-MI LV REMODELING

LV remodeling is the process by which ventricular size, shape, and function are regulated by mechanical, neurohormonal, and genetic factors[16,17]. After acute MI, the abrupt increase in volume overload induces a unique pattern of remodeling in the infarct zone and bordering non-infarct myocardium. The oxygen deprived myocardium experiences a localized inflammatory response *via* neurohormonal activation mediated in part by the migration of neutrophils, monocytes and macrophages[16]. Hypotension and the subsequent decrease in cardiac output stimulate temporary circulatory hemodynamic compensatory mechanisms including increased sympathetic nervous system, renin-angiotensin-aldosterone system (RAAS), and natriuretic peptide activity[18].

The induction of cardiomyocyte hypertrophy is a key process during post-MI remodeling that offsets increased volume over load, attenuates progressive dilation, and stabilizes contractile function; thus, post-MI myocyte hypertrophy initially serves as an adaptive, cardiac-preserving response[7,17]. However, over time, chronic neurohormonal activation, myocardial stretch, RAAS activity, and various paracrine and autocrine factors continue to promote eccentric, pathological hypertrophy, progressively deteriorating LV function to the point of failure. Interestingly, compelling evidence has shown that post-MI exercise favorably influences the course of LV remodeling, which accordingly, has attracted much attention[19].

EFFECT OF POST-MI EXERCISE TRAINING ON RAAS AND MYOCARDIAL REMODELING

Circulating angiotensin Ⅱ (Ang Ⅱ) is markedly increased following MI. Ang Ⅱ is a potent stimulant in pathologic myocardial remodeling both as a circulating hormone and as an autocrine/paracrine mediator produced in response to hemodynamic overload[20]. Ang Ⅱ plays a major role in vasoconstriction and aldosterone release. This peptide also serves as a growth factor and stimulates fibrous tissue formation in various[21-23]. Ang Ⅱ is also generated in the infarcted heart and regulates tissue structure in an autocrine and paracrine manner. All the components for Ang

Ⅱ generation including angiotensinogen, renin, and angiotensin converting enzyme (ACE), are present in the infarcted heart[24,25]. Locally generated AngⅡ stimulates transforming growth factor-β1 (TGF-β1) synthesis, which, in turn, enhances proliferation and collagen generation of myofibroblast, and leads to cardiac fibrosis[26]. Pharmacological intervention with ACE inhibitor or AngII receptor antagonist significantly attenuates cardiac fibrosis, and improves cardiac function and survival[27,28].

Acute physical exercise stimulates renin release and activates renin-angiotensin system[29,30] with an elevation of aldosterone[31], whereas chronic exercise training attenuates renin-angiotensin system at resting condition[32]. A study on patients with MI has demonstrated that the resting plasma AngⅡ reduced by 26% after 4 mo of exercise training[32]. The reduction in plasma AngⅡ was accompanied with 32% reduction in aldosterone, 30% reduction in vasopressin, and 27% reduction in atrial natriuretic peptide. An animal study using a pacing-induced heart failure in rabbits also revealed exercise training-induced attenuation of resting plasma AngⅡ[33].

In a previous study[34], we systematically examined the effect of exercise training on RAAS using a rat-MI model. Rats performed a moderate intensity exercise training on a rodent treadmill 1 wk after MI 5 d/wk for 8 wk at 16 m/min, 50 min per session. Our results showed that exercise training significantly attenuated circulating renin, ACE, AngⅡ, and aldosterone compared with sedentary rats with MI. Rats in exercise groups had similar LV end-diastolic diameters (LVEDd) compared with their sedentary counterparts and tended to have smaller LV end-systolic diameters (LVESd), and percent fractional shortening in exercise rats was significantly higher than in sedentary rats. These findings suggest that exercise training normalizes the circulating RAAS and improves LV function without compromising LV dilation.

In a similar study[35], we further evaluated the effect of post-MI exercise training on myocardial fibrosis, cardiac function, and factors inducing adverse remodeling. For the first time, changes caused by exercise training were investigated in type Ⅰ and Ⅲ collagen, matrix metalloproteinase (MMP-1), tissue inhibitor matrix metalloproteinase (TIMP-1), TGF-β1), AngⅡ receptor type 1 (AT1), and ACE at both gene and protein levels after MI. Our results indicated exercise training significantly attenuated the expression of TIMP-1 at both gene and protein level and improved balance between MMP-1 and TIMP-1 (imbalance between the two appear to be responsible for the increased MMP activity observed in congestive heart failure). Training also lowered expression of AT1 receptor protein and reduced ACE mRNA expression as well as ACE binding. In addition, training significantly decreased collagen content, thereby resulting in attenuated cardiac fibrosis. Lastly, exercise training preserved cardiac function.

AngⅡ receptor blockade has been widely used to alleviate detrimental effects associated with elevated RAAS[36,37]. In a subsequent study[38], we investigated the effect of combined exercise training along with AngII receptor blockade on post-MI ventricular remodeling in rats. Losartan (an AngⅡ receptor antagonist) treatment (20 mg/kg per day) was initiated 1-wk post-MI, and administered *via* gastric gavage for 8 wk. The results indicated significantly decreased levels of TIMP-1 in mRNA and protein expression in both trained and losartan treated groups. Exercise trained groups exhibited attenuated expression of AT1 receptor protein, and decreased ACE binding. These findings revealed that exercise training after MI provided beneficial effects on post-MI cardiac function and LV remodeling by the alteration of specific gene and protein expressions that regulate myocardial fibrosis, whereas the combination of both exercise training and losartan treatment improved the effects[35,38]. Tables 1 and 2 summarize both human and animal studies on post-MI physical training.

EARLY *VS* LATE PHASE POST-MI EXERCISE

Post-MI remodeling has been arbitrarily divided into two phases: the early phase, which lasts up to 72 h, and the late phase, lasting beyond 72 h[17]. Generally, adaptive responses that preserve stroke volume are invoked during the early stage, whereas late remodeling primarily involves hypertrophy and alterations in LV architecture in an attempt to distribute increased wall stresses more evenly. Differences in function between adjacent and remote non-infarcted regions are greatest at one week after anterior MI, and persist for a minimum of six months post-MI[39]; it is during this six-month period that systolic function decreases drastically, as the LV undergoes progressive dilatation, eccentric hypertrophy, and the lengthening of non-infarcted segments[17]. Thus, the question of when to begin exercise and at what intensity has proven elusive. Nevertheless, recent evidence offers novel insights and indeed provides an answer to some questions, although, as quality research often does, asks several more.

To date, several studies in humans reported contradictory effects of training on LV remodeling after MI[4,6,7,40-45]. However, careful inspection of these studies indicate that after small MI, exercise has no detrimental effect[7,41], or even improves[4,43,44,46] LV geometry and function, independent and irrespective of whether exercise was started late (1 year)[4,44] or early (< 2 mo)[7,41,43] after MI. Conversely, in patients with large MI (encompassing 35% to 50% of LV mass), exercise had either no[42], or a beneficial[4]

Table 1 Summary of physical training protocols and outcomes in selected human studies

Ref.	Type of exercise	Exercise intensity	Exercise duration	Exercise frequency	Training period	Assessment	Outcome
Braith *et al*[32] 1999	Treadmill walk	40%-70% of peak oxygen uptake (VO_2)	Started with 10-20 min as tolerated and increased to 30-45 min by the 10th wk	3 times/wk	4 mo	Plasma RAAS	Reduced Resting AngII, Aldosterone, vasopressin, and atrial natriuretic peptide
Myers *et al*[143] 2001	Outdoor walking at an elevation of 3500 ft, in addition to cycling	60%-70% of peak VO_2	Two 1-h sessions of walking, 45 min of cycling	5 times/wk	2 mo	Post-exercise oxygen uptake kinetics	High-intensity training did not result in a faster recovery of oxygen debt
La Rovere *et al*[144] 2002[1]	Graded exercise (cycling, calisthenics)	Adjusted to 75% of the heart rate at peak VO_2	30 min	5 times/wk	1 mo	BRS, LVEF	BRS improved by 26%, while LVEF remained unchanged
Marchionni *et al*[145] 2003[2]	Cycling	70%-85% of max heart rate	1 h	3 times/wk	6 mo	Total work capacity, health-related quality of life	Improved total work capacity and health-related quality of life
Zheng *et al*[146] 2008[1]	Bicycle ergometer	75% of peak heart rate	30 min	3 time/wk	6 mo	HR recovery, time to reach anaerobic threshold, left ventricular end-diastolic	Exercise training prevented ventricular remodeling to a certain extent
Giallauria *et al*[46] 2013	Bicycle ergometer	60%-70% of peak VO_2	30 min	3 times/wk	6 mo	diameter, left ventricular ejection fraction dipyridamole rest gated myocardial perfusion single photon emission computed tomography	Improved peak oxygen consumption, myocardial perfusion and LV function

[1]Exercise was part of a comprehensive secondary prevention program; [2]Combination study consisting of Home and Hospital/group participants. RAAS: Renin-angiotensin-aldosterone system; LVEF: Left ventricular ejection fraction; BRS: Baroreflex sensitivity.

effect on ejection fraction (EF) and LV volumes but only when started late after MI. However, when exercise after large MI is initiated at a time when LV remodeling is still ongoing (3 to 4 mo after MI), the majority of studies reported that exercise has either no[6,7,41], or even a detrimental[40,47] effect on LV volume and EF.

Similarly, experimental research using rat models of MI suggests that exercise initiated late (> 3 wk) after moderate to large MI does not aggravate[45,48], or even blunts[49-51] LV dilation and hypertrophy. Contrarily, exercise started < 1 wk after moderate to large MI resulted in variable outcomes with beneficial[52], no[53,54], or detrimental[55,56] effects on LV remodeling. Therefore, these rodent studies further evidence the concern that early exercise after MI may further exacerbate LV remodeling. Importantly, there are a number of concerns with the methodology of these studies. First, exercise experimental studies conducted late after MI predominately used treadmill running[45,48-50], whereas early exercise studies used swimming[51-55]. Since swimming is not a habitual activity for rats, this type exercise mode may markedly elicit both psychological and physiological stress to the animals, which potentially offsetting the beneficial effects of exercise compared to treadmill running[57,58].

Amazingly, in a recent study of evaluating 8-wk of volunteer exercise, de Waard *et al*[59] reported remarkable data addressing the question of exercise training 24 h after MI. As opposed to most humans, mice like to run, and will do so seemingly endlessly when presented the opportunity. During the first week after induction of MI, recovering mice slowly titrated up their daily running activity, reaching distances similar to their sham-operated counterparts towards the end of the study, thus, suggesting that early post-MI exercise training may have positive effect in post-MI recovery and myocardial remodeling. Authors reported that exercise had no effect on survival, MI size, or LV dimensions, but improved LV fractional shortening from 8% ± 1% to 12% ± 1%, LV dP/dt_{P30} from 5295 ± 207 to 5794 ± 207 mmHg/s, and reduced pulmonary congestion. Additionally, this study also provided novel information regarding myocardial Ca^{2+} handling after MI, debunking the previously held notion that exercise sensitizes myofilaments to the effects of Ca^{2+}[59]. A study from our group[34] systematically examined the timing effect of post-MI exercise training. Rats started exercise training at either 1 wk or 6 wk after MI on a treadmill for 8 wk. Rats in exercise groups had similar LVEDd compared with their sedentary counterparts and tended to have smaller LVESd, and percent fractional shortening (%FS) in exercise rats was significantly higher than

Table 2 Summary of physical training protocols and outcomes in selected animal studies

Ref.	Type of exercise	Exercise intensity	Exercise duration	Exercise frequency	Training period	Assessment	Outcome
Hashimoto *et al*[76] 2004	Treadmill running	10 m/min	60 min	5 d/wk	6 wk	Myosin heavy chain isoforms, cardiac wall measurements	Exercise training resulted in a significant increase of α-MHC expression in both anterior and posterior wall, ensuring a beneficial role in the remodeling of the heart
Xu *et al*[35] 2008	Treadmill running	16 m/min @ 5% grade	50 min	5 d/wk	8 wk	TIMP-1, AT1, ACE, collagen volume fraction, MMP	Early exercise training after MI reduces TIMP-1 expression, improves the balance between MMPs and TIMPs, and mitigates the expressions of ACE and AT1 receptor, thus attenuating myocardial fibrosis and preserving cardiac function
De Waard *et al*[59] 2007	Voluntary treadmill exercise training	N/A	N/A	5 d/wk	8 wk	LV fractional shortening, Ca^{2+} sensitivity, PLB, SERCA	Voluntary exercise improved LV and cardiomyocyte shortening, attenuates global LV dysfunction
Wan *et al*[34] 2007	Treadmill running	16 m/min @ 5% grade	50 min	5 d/wk	8 wk	Echo and RAAS	Exercise training improved cardiac function and attenuated RAAS. Early and late exercise training had similar beneficial results
Xu *et al*[106] 2010	Treadmill running	16 m/min @ 5% grade	50 min	5 d/wk	8 wk	SOD, GPx, MnSOD	Exercise training combined with Ang Ⅱ receptor blockade reduced oxidative stress
Yengo *et al*[147] 2012	Treadmill running	15% grade, speed increased from 13 to 24 m/min	Progressively increased to 60 min	6 d/wk	10 wk	Collagen concentration, non-reducible collagen cross-linking in the RV	Exercise training normalized the observed increase in cross-linking, and favorably modifies heart extracellular matrix

RAAS: Renin-angiotensin-aldosterone system; MHC: Myosin heavy chain; TIMP-1: Tissue inhibitor matrix metalloproteinase; AT1: AngII receptor type 1; ACE: Angiotensin converting enzyme; MMP: Matrix metalloproteinase; SOD: Superoxide dismutase; GPX: Glutathione peroxidase.

in sedentary rats. These finding suggest that exercise training does not cause LV dilation and preserves LV function.

POST-MI EXERCISE AND MYOCARDIAL CONTRACTION

Ca^{2+} handling abnormalities can largely explain depressed myocyte contractility in the remodeled myocardium, whereas abnormalities in myofilament function are less well understood. Previously, it was reported in pigs that impaired pump function three weeks after MI could also be attributed to decreased maximal isometric tension in skinned cardiomyocytes in areas remote from the ischemic border zone; as it turns out, the impairment occurred in the context of increased Ca^{2+} sensitivity of the myofilaments[60]. As a result, the authors attributed the increased post-MI Ca^{2+} sensitivity to reduced protein kinase A-mediated troponin I (TnI) phosphorylation[60]. Similarly, increased myofilament Ca^{2+} sensitivity has also been reported in end-stage human heart failure, mediated by decreased TnI phosphorylation.

Although experimentally challenging, investigators from the de Waard study were able to construct a full pCa-force relationships in isometrically contracting myocytes[59], which differs from previous studies relying on simultaneous measurements of FS% and Ca^{2+} fluorescence in unloaded myocytes to estimate myofilament Ca^{2+} sensitivity. Although a much simpler experimental approach, there are various problems associated with this method. First, maximal developed tension cannot be assessed in unloaded myocytes, and any changes in developed tension are ignored when estimating Ca^{2+} sensitivity. Secondly, basal sarcomere length is much shorter in unloaded myocytes (1.8 *vs* 2.2), and cannot be controlled; therefore, even a slight change in basal sarcomere length would confound the result, which in turn, has prompted investigators to wrongly conclude that exercise increases myofilament sensitivity[51]. Thus, data from de Waard *et al*[59] reveals that voluntary exercise training in mice early after MI normalizes myofilament dysfunction, which likely occurred in response to the exercise-induced improvement in unloaded shortening of isolated intact cardiomyocytes, as the Ca^{2+} transient amplitude was not found to be altered by exercise. Furthermore, basal Ca^{2+} was reduced by exercise, altogether suggesting that exercise decreases myofilament Ca^{2+} sensitivity.

Dysregulation of cardiac β-adrenergic receptor (β-AR) signaling represents another important factor leading to the pathological LV remodeling and the progression to heart failure. In the failing myocardium, adverse changes in β-AR signaling are mainly attributed to β_1-AR downregulation and desensitization/uncoupling of both β_1 and β_2-AR's. It has been reported that exercise after MI increases

β_1-AR, as evidenced by a 48% increase in β_1-AR protein, and a 36% increase in cAMP levels, and improves β-AR signaling[59,61], which in turn, may also contribute to improvement in myocardial contractility in patients with MI.

Myosin heavy chain (MHC) acts as the chemical-mechanical transducer of motion in muscle fibers by converting energy from ATP into the sliding myofilaments[62]. The isoform α-MHC elicits two to three times faster actin-activated ATPase activity and actin filament sliding velocity than the isoform MHC-β[63,64]. Thyroid hormone (TH) has profound effects on the cardiovascular system, and is known to critically regulate the expression of MHC isoforms in the myocardium[65]; in fact, in the absence of TH, the *α-MHC* gene is not transcribed[62]. Triiodothyronine (T_3), the active cellular form of TH, mediates its actions upon binding to thyroid hormone receptors (TRs)[66,67].

After MI, T_3 levels are significantly reduced in patients[68]; similarly, decreased serum concentrations of TH have also been observed in patients with chronic heart failure (CHF), which, in part, attributes to impaired cardiac function[69]. In experimental post-MI rat models, following the decrease of serum T_3, significant downregulation of α-MHC and the concomitant upregulation of MHC-β are observed in the LV non-infarcted myocardium, along with changes in TR isoforms at the mRNA level[68,70,71]. These, in addition to other MI-induced alterations in cardiac phenotype, are thought to further contribute to the progressive nature of LV systolic dysfunction, and have been associated with poor prognosis[62,63,72,73]. Interestingly, endurance exercise has been reported to favorably reverse MHC α- to β-cardiac isoform shifts after MI at both gene and protein levels[74,75], which in turn, may be associated with preserved cardiac functioning, attenuated LV remodeling, and increased myofibril function[76]. Recent evidence by our group[75] indicated that post-MI exercise training significantly increase cardiac expression of α-MHC and decrease cardiac expression of MHC-β without changing serum T_3 levels. Similarly, unpublished data from our group recently revealed that moderate-intensity treadmill exercise training markedly increased TRα-1 and TRβ-1 nine weeks after MI. Thus, it is likely that favorable changes in TH target gene transcription may be due to exercise-dependent upregulation of TR isoforms. Nevertheless, studies with experimental models of LV dysfunction and preliminary clinical investigation of patients with CHF reported that the TH analog 3,5-diiodothyroproionic acid elicits improvements in both systolic and diastolic LV function, accompanied by an increase in cardiac output and improved lipid profile[77]. Thus, it is conceivable that the combination of exercise combined with TH treatment could potentiate beneficial results, and warrants further investigation.

POST-MI OXIDATIVE STRESS AND EXERCISE TRAINING

Reactive oxygen species (ROS) including superoxide (O_2^-), hydroxyl (OH^-), and peroxynitrite ($ONOO^-$), have an unpaired electron[78]. These ROS serve as signaling molecules when in low concentrations; however, they elicit harmful oxidative stress when produced in excess[79]. ROS can directly damage the lipids of cell membranes, proteins and both nuclear and mitochondrial DNA resulting in serious or mortal cellular injury[80]. However, the toxicity associated with the excessive ROS can be prevented by antioxidant defense systems that provide a healthy cellular environment. Living cells have both enzymatic and non-enzymatic defense mechanisms to balance the multitude of oxidative challenges presented to them. The enzymatic antioxidant system includes superoxide dismutase (SOD), catalase and glutathione peroxidase (GPX)[81]. SOD catalyzes the dismutation of superoxide (O_2^-) to hydrogen peroxide (H_2O_2). Catalase and GPX further metabolize H_2O_2 to water and oxygen. The non-enzymatic group includes a variety of biologic molecules, such as vitamins E and C[81,82]. Oxidative stress is enhanced by an unbalance between elevated ROS production and diminished antioxidant system.

Excessive oxidative stress has been observed in the myocardium of patients with CHF[83,84]. Heart failure subsequent to myocardial infarction is associated with oxidative stress in both infarcted and noninfarcted myocardium[83,85,86]. Researchers have identified a membrane-based NAD(P)H oxidase as a major source of O_2^- in the heart[87]. An elevated NAD(P)H oxidase expression has been observed in the infarcted rat heart and the extent of NAD(P)H oxidase elevation is negatively correlated with the deteriorated hemodynamic function and ventricular remodeling of the heart[88]. Furthermore, progressive decrease in antioxidant enzymes, SOD, catalase[89], and glutathione (an antioxidant)[90] has also been observed in the infarcted rat heart. These observations suggest that the impaired antioxidant system and/or augmented ROS promote oxidative stress, contributing to the adverse remodeling and dysfunction of the infarcted heart[91].

There is growing evidence that chronic exercise training adaptively bolsters the activity of protective antioxidant enzymes such as catalase, SOD, GPX[92], glutathione reductase (GR)[93], and antioxidant glutathione content[94,95] in skeletal muscles of healthy animals. Nine-weeks of treadmill training markedly elevated manganese-SOD (Mn-SOD, an isozyme of SOD) activity and its protein content both at rest and after an acute exercise bout in the soleus muscle of rats[96]. In contrast, the muscle Mn-SOD gene expression of untrained rats was significantly decreased after an acute bout of exercise[96]. Exercise

training also resulted in significant increase in SOD activity in the LV of normal rats[97,98]. These findings suggest that muscles have the capacity of responding to training in such a manner as to enhance antioxidant system and reduce the accumulation of ROS resulting from enhanced metabolic activity.

In patients with CHF, exercise training enhanced GPX and catalase activities, and mitigated lipid peroxidation in skeletal muscles[99]. Exercise training also downregulated both gene expression and activity of pro-oxidant NAD(P)H oxidase, and decreased vascular generation of ROS in human arterial tissue[100].

Inconsistent findings have been reported on the effect of post-MI exercise training on ROS and antioxidants. Yamashita *et al*[101] and Brown *et al*[102] reported that exercise training resulted in an increase in myocardial SOD content along with improved recovery from ischemia-reperfusion injury. Others, however, reported that exercise training increased cardioprotection without amplifying myocardial SOD content[103,104] and only certain cardiac antioxidant enzyme activities (*i.e.*, SOD) were enhanced in the exercise trained animals[97,101,105]. The variation in the findings of these studies may be due to the differences in the intensity and duration of exercise regimens. A study from our group[106] demonstrated that exercise training increased MnSOD gene expression after MI regardless of losartan treatment. In addition, exercise training together with losartan treatment remarkably enhanced the enzymatic activity of catalase, suggesting an additive effect of exercise training and Ang Ⅱ receptor blockade treatment. But exercise training did not enhance myocardial glutathione peroxidase activity. Our data also revealed that post-MI exercise training notably attenuated MI-induced elevation of plasma thiobarbituric acid reactive substances (TBARS, a marker of lipid oxidation) although cardiac TBARS was not altered.

It has been documented that Ang Ⅱ stimulates NAD(P)H oxidase activity, which promotes ROS production[107,108]. Thus, exercise training may improve antioxidant capacity and attenuate oxidative stress by attenuating RAAS[35,38,106].

MYOCARDIAL APOPTOSIS AND EXERCISE TRAINING

Loss of cardiomyocytes is an important mechanism in the development of myocardial remodeling and cardiac failure[109]. After MI, apoptotic cardiomyocyte death occurs in the infarcted myocardium as well as the surviving portions of the heart[110,111]. Myocyte apoptosis not only occurs at early phase (7 d) of MI[112,113], but also progresses to late phase (up to 6 mo) in myocardium remote from the area of ischemic damage[114,115], contributing to CHF[116]. ROS have proven to be powerful mediators of myocyte apoptosis[117,118]. Treatment of cardiac myocytes with O_2^- or H_2O_2 induces apoptosis, suggesting a mechanism of ROS as an initial pathogenic event[119]. Enhanced pro-apoptotic Bax expression coexists with oxidative stress and apoptosis in the infarcted heart[120], whereas oxidative stress activates pro-apoptotic enzymes, caspase-9 and caspase-3, resulting in cardiac apoptosis and ventricular dysfunction[117]. *In vivo* studies have demonstrated that long-term treatment with the antioxidants, probucol or pyrrolidine dithiocarbamate, attenuates oxidative stress and myocyte apoptosis within noninfarcted myocardium in rats[121,122].

Siu *et al*[98] demonstrated that endurance training downregulated the expression of caspase and Bax, and upregulated Bcl-2 (an anti-apoptotic gene product) in both skeletal and cardiac muscles of healthy rats. These anti-apoptotic effects were associated with elevated protein content of Mn-SOD. A clinical study also revealed that exercise training attenuated skeletal muscle apoptosis along with improved antioxidant capacity in patients with CHF[99]. Accordingly, the data are consistent with the idea that an increased antioxidant capacity and attenuated oxidative stress from exercise training may be involved in reducing pro-apoptotic genes, suggesting that exercise training may attenuate the extent of apoptosis in muscles. However, the influence of post-MI exercise training in myocardial apoptosis remains to be elucidated.

POST-MI EXERCISE AND CARDIAC ANGIOGENESIS

After myocardial infarction (MI), the adequate growth of new capillaries and arterioles, or angiogenesis, represents a critical process in the development of compensatory hypertrophy in the remaining non-infarcted myocardium[123]. Although compensatory angiogenesis can be observed in both the ischemic and infarcted heart, previous studies have demonstrated that angiogenesis may be inadequate[124,125]; in fact, recent evidence suggests that impaired angiogenesis may lead to maladaptive LV remodeling, promoting the transition from adaptive cardiac hypertrophy to LV dilation and dysfunction[61,126].

Exercise, through increased vascular shear stress, potentiates a powerful angiogenic stimulus[127]. The pro-angiogenic effect of exercise has previously been demonstrated in healthy swine hearts[128]. A study conducted by Leosco *et al*[61] reported that exercise induced a significant increase of capillary density in lateral border and remote zones to the infarct site, but not in the area close to the infarcted site. One of our recent studies (unpublished data) confirms that post-MI exercise training induced about 1.5-fold increase in capillary density in the septum

and left ventricle compared to non-exercised heart, suggesting that exercise promotes capillary growth in non-infarcted areas of severely decompensated hearts.

A number of studies clearly demonstrate that exercise activates vascular endothelial growth factor (VEGF) dependent angiogenic pathways[129-131], which represent critical molecular mechanisms by which exercise triggers angiogenesis[130]. In addition, exercise-induced upregulation of VEGF in patients with heart failure has also been documented[132]. Recently, experimental studies have revealed that exercise reactivates angiogenic signaling by increasing VEGF and eNOS phosphorylation by Akt in the heart, increases coronary vascular network and density, and enhances myocardial blood perfusion. Evidence of endothelial dysfunction in peripheral resistance arteries post-MI has also been observed in both experimental and clinical studies[133,134], which likely contributes to arterial dysfunction[135,136]; in this regard, post-MI exercise has been shown to reverse arterial dysfunction by virtue of restored production of nitric oxide (NO) in the endothelial vessel wall mediated by adaptive changes in eNOS, its activation by Akt, and by reduced NAD(P)H oxidase-generated ROS scavenging of NO[137].

EXERCISE-BASED CR IN PATIENTS WITH HEART DISEASE

Previously, four meta-analyses[138-141] of the effects of exercise-based interventions in patients with coronary heart disease reported a statistically significant benefit in patients receiving exercise therapy compared with usual medical care, with a reduction in total and cardiac morality ranging from 20% to 32%. However, randomized controlled trials (RCT) have generally been small and often of questionable methodological quality, raising concerns that the effect of exercise-based CR may be overestimated. In 2004, Taylor *et al*[142] aimed to update the systematic review of the effects of exercise-based CR in patients with coronary heart disease, addressing previous concerns regarding the applicability of this evidence to routine practice.

For the analysis, over 5000 articles were retrieved from a number of search sources, and only 425 full papers were considered for possible inclusion. Studies were excluded for various reasons including nonrandomized design, inappropriate patient groups, inappropriate intervention, the control group received an exercise intervention, inappropriate outcomes, in adequate follow-up, and preliminary results only available in abstract form. After identification of duplicate publications, only 48 eligible studies remained, and were still of poor methodological quality.

Although exercise-based CR was associated with a significant reduction in all-cause mortality and total cardiac mortality, there was no significant difference with respect to re-infarction[142]. Conversely, a recent meta-analyses conducted in 2011 consisting of 34 RCTs (n = 6111) found that patients randomized to exercise-based CR had a significantly lower risk of re-infarction, cardiac mortality, and all-cause mortality[3]. In a stratified analysis, treatment effects were consistent regardless of study periods, duration of CR, or time beyond the active intervention[3]. Additionally, Exercise-based CR had favorable effects on cardiovascular risk factors, including smoking, blood pressure, body weight, and lipid profile[143].

CONCLUSION

Most of the human and animal studies demonstrated that post-MI physical exercise training results in positive effect on myocardial remodeling. These beneficial effects include improved cardiac function, mitigated interstitial myocardial fibrosis, and enhanced physical capacity. As a result, physical exercise training provides good prognosis and improves the quality of life of MI patients. The current literature revealed the mechanism of physical training-induced improvement in post-MI cardiac remodeling. Physical training attenuates renin[29,30], ACE, Ang Ⅱ, and aldosterone[31,34]. The attenuation of Ang Ⅱ, in turn, reduces cardiac fibrosis[34] and aldosterone secretion[32,34], which may ease MI-induced plasma expansion. Physical training also improves the balance between MMP-1 and TIMP-1, which, in turn, reduces cardiac stiffness *via* regulation of collagen accumulation[38]. Studies show that physical training significantly improves ß-adrenergic receptor, cAMP[59,61], and favorably reverses MHC α- to β-cardiac isoform shifts[74,75], attributing to improvement in myocardial contractility. In addition, post-MI physical training may enhance antioxidant enzyme capacity and attenuate oxidative stress[97,101,105]. It is important to note that the existing studies have only investigated the effects of *endurance* exercise on post-MI remodeling; therefore, the effects of post-MI resistance training have yet to be systematically examined to identify a better exercise mode. Furthermore, although majority of the research has shown that post-MI exercise training improves cardiac remodeling and function, the suitable exercise intensity, duration, and the time to start training are yet to be optimized to provide clinically relevant information regarding the pathophysiology of post-MI recovery through physical training.

Abstract

Transcatheter closure of the left atrial appendage has been developed as an alternative to chronic oral anticoagulation for stroke prevention in patients with atrial fibrillation, and as a primary therapy for patients with contraindications to chronic oral anticoagulation. The promise of this new intervention compared with warfarin has been supported by several, small studies and two pivotal randomized trial with the Watchman Device. The results regarding risk reduction for stroke have been favourable although acute complications were not infrequent. Procedural complications, which are mainly related to transseptal puncture and device implantation, include air embolism, pericardial effusions/tamponade and device embolization. Knowledge of nature, management and prevention of complications should minimize the risk of complications and allow transcatheter left atrial appendage closure to emerge as a therapeutic option for patients with atrial fibrillation at risk for cardioembolic stroke.

Key words: Atrial fibrillation; Stroke prevention; Left atrial appendage; WATCHMAN® device; Complications

Core tip: Left atrial appendage (LAA)-Occlusion was developed as an alternative to chronic anticoagulation therapy in patients with nonvalvular atrial fibrillation. In two large randomized trials the principal concept of LAA-occlusion has been demonstrated to be noninferior to coumadine therapy, in longterm follow up being even superior to oral anticoagulation in terms of efficacy

and some safety issues like bleeding complications. However the procedure is complex and knowledge of nature, management and prevention of complications should minimize the risk of the procedure and allow transcatheter left atrial appendage closure to emerge as a therapeutic option for patients with atrial fibrillation at risk for cardioembolic stroke.

INTRODUCTION

Stroke is one of the leading causes of death and disability worldwide. Approximately 25% of all strokes have a cardioembolic origin. More than 90% of all left atrial thrombi in patients with non-rheumatic atrial fibrillation (AF) originate in the left atrial appendage (LAA)[1,2]. Oral anticoagulation therapy with the vitamin K antagonist warfarin including all its well-known limitations is standard for the prevention[3]. Only about 55% of patients with AF, who are indicated for warfarin therapy, are really treated, however these patients are only about 67% of the time in the therapeutic range[4,5]. Several major recent trials have demonstrated the superiority of the new oral anticoagulants Dabigatran, Rivaroxaban and Apixaban as compared to standard therapy with warfarin[6-8]. Nevertheless, even with these new agents bleeding complications were substantial and in part comparable to that observed with warfarin except for intracranial bleedings being less. A certain amount of patients discontinued drug therapy prematurely for adverse events, mainly gastrointestinal reasons for example in dabigatran patients.

Several studies have been conducted focusing on the development of novel therapeutic tools to prevent AF-related strokes as an alternative to medical treatment. The technique which has arguably shown the most promise is the percutaneous (transcatheter) exclusion of the LAA from systemic circulation.

Three different devices specifically designed for occlusion of the LAA have been clinically evaluated: the Percutaneous LAA Transcatheter Occlusion system (PLAATO®), (ev3, Plymouth, MN), the WATCHMAN® system (Boston Scientific Corp., Natick, MA, United States), and the AMPLATZER® Cardiac Plug (St. Jude Medical, Inc., St. Paul, MN, United States) (Figure 1). Although safety and feasibility of the PLAATO device was demonstrated in several small non-randomized studies, the device was withdrawn from the market for commercial reasons. But even with the PLAATO device we have learned that there are specific complications associated with the implantation procedure such as device embolizations and cardiac tamponade[9-11]. Initial experience with the AMPLATZER® cardiac plug (ACP) has been published recently from a registry containing 132 successfully implanted devices[12]. To date, only the WATCHMAN® device has demonstrated superiority in long term follow up compared with chronic warfarin therapy in randomized, controlled trials[12-14]. In Europe, the latter two systems are approved for implantation, whereas in the United States both systems are under FDA investigation for potential approval. Despite being a lesser invasive procedure (than surgical ligation of the LAA), transcatheter LAA closure has been associated with potentially serious complications due to the necessity of transseptal puncture, manipulation of stiff wires and guide catheters in the left atrium and the release of the device in the LAA.

The following review highlights the potential procedural complications of transcatheter LAA closure with the Watchman-Device and discusses their nature, management and prevention.

IMPLANTATION PROCEDURE

Before starting the procedure transesophageal echocardiography (TEE) has to be performed as the gold standard for thrombus detection within the LAA (Figure 2). Thrombi have been reported to be present in the LAA in 8%-15% of patients with AF lasting greater than 48 h[15]. Understanding the anatomy of the LAA is also critical for procedural safety. To facilitate successful implantation, width and depth of the LAA as well as number and position of different lobes are important to know. Studies have shown that the width of the LAA orifice can vary from 15-35 mm and length from 20-45 mm[16] with various anatomical configurations.

Patient preparation

Implantation of the LAA closure devices should be usually performed under conscious sedation or even general anaesthesia. This is necessary to reduce unintended movement of the patient to avoid perforation of the LA/LAA and for tolerance of TEE, which is crucial for guidance of the procedure with the Watchman-Device. Usually a combination of midazolam and propofol is used, although alternative regimens may be possible. Implantation of the device is performed *via* the right femoral vein through a transseptal puncture with a small sheath in the femoral artery for pressure control or even management of air embolism as outlined below, which might not be mandatory.

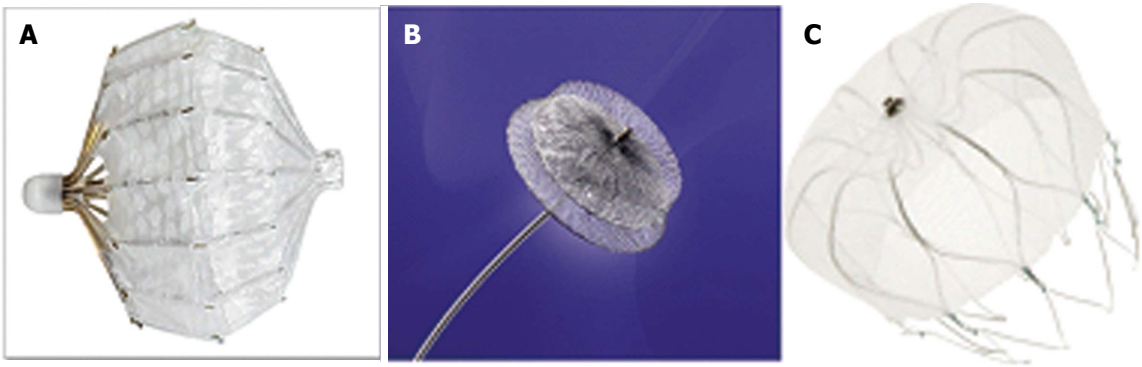

Figure 1 Devices for percutaneous occlusion of the left atrial appendage. A: PIAATO® device; B: Amplatzer® cardiac plug; C: Watchman® device.

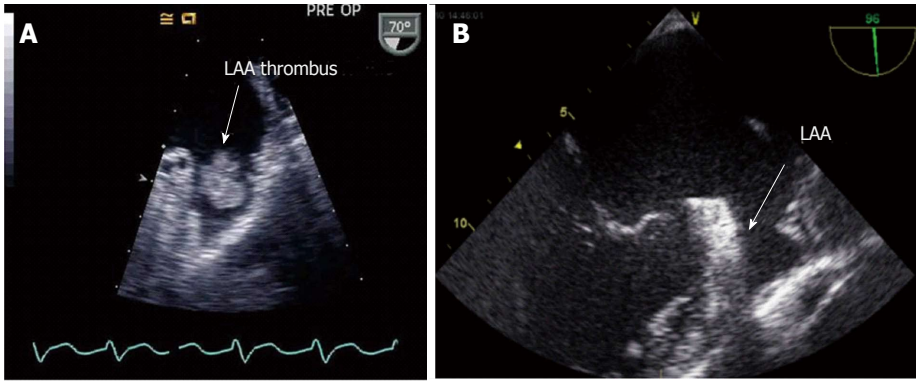

Figure 2 Left atrial appendage. A: With thrombus; B: Without thrombus. LAA: Left atrial appendage.

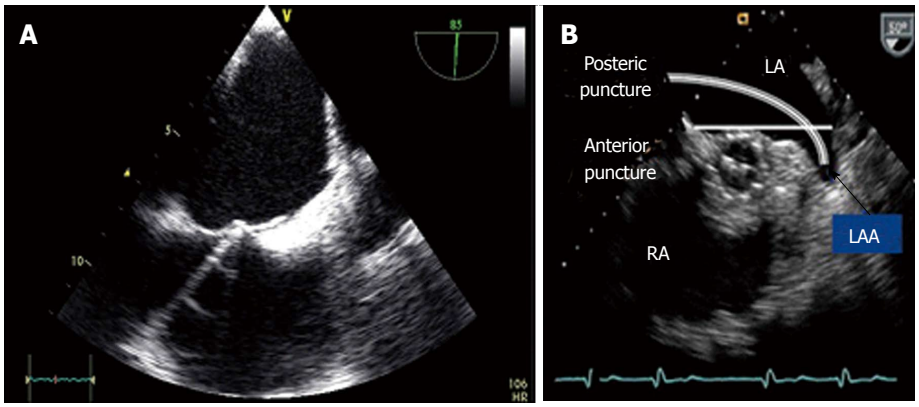

Figure 3 Echocardiography in transseptal puncture. A: Tenting of transseptal needle at the middle part of the atrial septum; B: Access sheath passing through the atrial septum within left atrium. LAA: Left atrial appendage.

Transseptal puncture

Transseptal puncture is described elsewhere[17]. Transseptal puncture should be ideally performed under pressure control and with TEE and fluoroscopic guidance. To enhance successful implantation of the LAA closure device the site of transseptal puncture should be at the posterior atrial septum. The more anterior or inferior the LAA is located, the higher transseptal puncture should be performed. The more cranial the axis of the LAA, the more inferior puncture site should be. This can be easily controlled by TEE in the bicaval view (90°) for cranio-caudal orientation and in the 45° view for anterior/posterior direction (Figure 3). Anterior puncture of the septum likewise going through an open PFO should be avoided due to the impossibility to turn the guiding catheter adequately to an anterior located axis of the LAA. An atrial septal defect may be used having enough space for turning the guide. After successful transseptal puncture heparin is given using a dosage of 100 U/kg body weight to achieve an ACT between 200 and 300 s. Heparin could be applied already before transseptal puncture, which, however might lead to an increased risk of bleeding during the

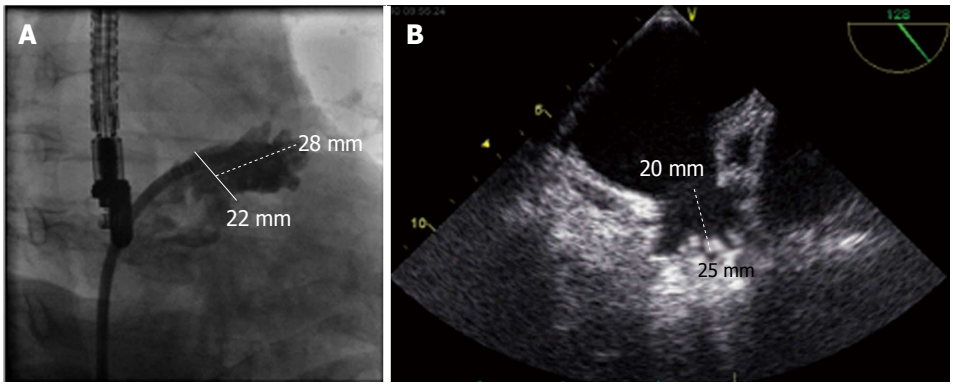

Figure 4 Measurement of the left atrial appendage during implantation procedure. A: After angiography (RAO 25°, caudal 20°)-measurement of ostium size (22 mm) and depth (28 mm); B: Echocardiographic measurement at around 135° of ostium size (20 mm) and depth (25 mm).

transseptal procedure.

Device implantation

Device implantation has been described previously[18] After exchange of the transseptal sheath over a stiff wire located best in the left upper pulmonary vein, the guiding catheter can be introduced. Wire positioning in the LAA with a loop may be also possible, however there is some risk of perforation. Two different curved sheaths (single and double curve) are available for implantation of the Watchman® device. For the Watchman device in more than 90% of patients the double curved sheath is used. To avoid undersizing of the LAA, the mean filling pressure of the left atrium should be in the high normal range (> 10 mmHg). For Watchman implantation a 4 or 5 French standard Pigtail catheter should be placed through the sheath. By turning the guiding catheter counter clockwise the pigtail can be advanced into the LAA under TEE and fluoroscopic guidance. The access sheath is then advanced slowly and carefully over the pigtail catheter into the LAA, thus at least reducing the risk of perforation. The marker bands on the access sheath of the Watchman® Device will help to determine the landing zone of the cover of the device at the site of the left atrium. The most suitable projections for angiographic visualization of the LAA seem to be RAO 30° with caudal 25° and cranial 20° for measurement of the orifice width and length of the LAA (Figure 4). Ideally the angiographic measurements will match the echocardiographic measurements in different angles from 0° to 135°, although they may vary by several mm depending on calibration methods.

Devices should be prepared according to the instructions for use. Careful flushing of the device and retrograde bleeding out of the access sheath is essential to avoid air embolism. Slight pressure on the patient's abdomen will increase venous pressure thus increasing backflow of blood through the sheath. A saline pressure infusion over the side branch of the guiding cath may be helpful.

Implantation of the watchman device

The Watchman device should be advanced in the sheath until the marker of the device catheter matches the most distal marker on the access sheath. The next step is to pull back the access sheath over the device until device catheter and access sheath are connected. At this point the device should remain in position and forward pushing of the device must be strictly avoided in terms of the risk of LAA injury or perforation with subsequent cardiac tamponade. The device is deployed by retracting the sheath and device catheter simultaneously while the device is held in place. Small amounts of contrast injections may help to visualize the relation between the tip of the device and the LAA wall during deployment (Figure 5).

Once the device is deployed within the LAA, correct positioning of the Watchman device at the LAA ostium must be demonstrated by echocardiography and angiography (Figure 6). To avoid embolism of the Watchman Device, there are four release criteria that should be evaluated before release: Position, Anchor, Size and Seal (PASS).

Position: To confirm that the device is properly positioned, ensure that the plane of maximum diameter of the device is at or just distal to the orifice of the LAA.

Anchor: To confirm the device is anchored in place, withdraw the access sheath/delivery catheter assembly 1-2 cm from the face of the device. After injecting a small puff of contrast gently retract and push the deployment knob to see the combined movement of the device and the LAA tissue.

Size: To confirm the correct device size, measure the plane of the maximum diameter of the device using TEE in the 4 standard views 0, 45, 90, and 135 degrees, ensuring the threaded insert is visible. The device size should be 80%-92% of the nominal diameter.

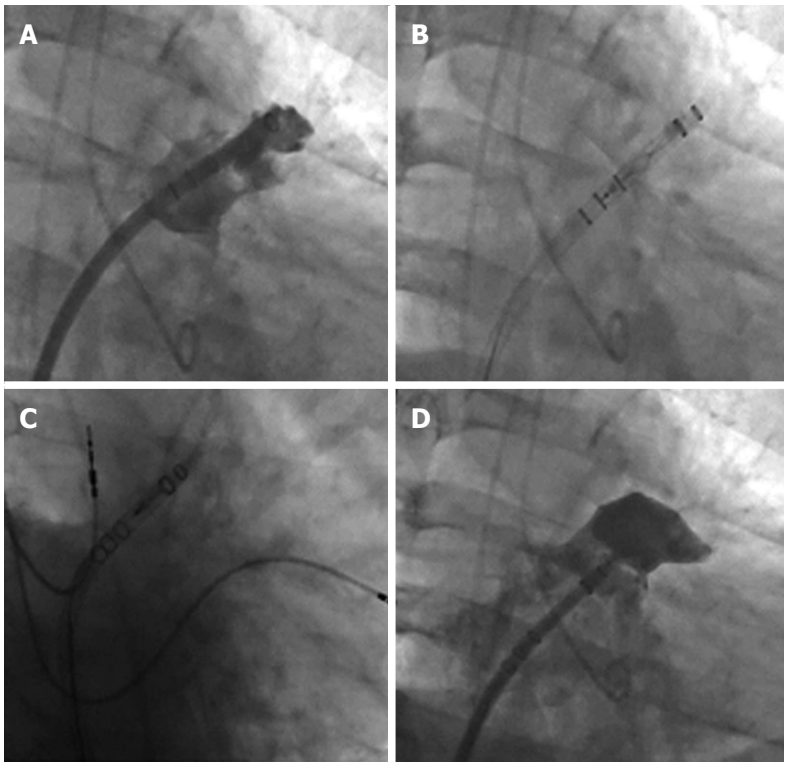

Figure 5 Deployment of a Watchman® device (fluoroscopic views). A: Deployment sheath in correct position; B: Watchman device loaded within the sheath before deployment; C: Watchman device deployment; D: Watchman device completely deployed within the LAA. LAA: Left atrial appendage.

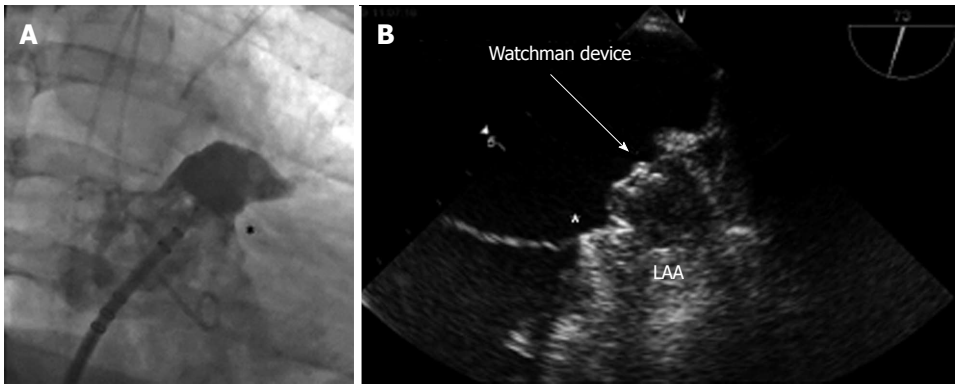

Figure 6 Optimal position of the Watchman device within the left atrial appendage. A: Angiographic view (RAO 25° caudal 20°); B: Echocardiographic view. Indicates inferior transition from left atrial appendage to LA (star).

Seal: Using colour Doppler, ensure that all of the lobes are distal of the device and are sealed. If there is a gap visible between the wall of LAA and the device with more than 3 mm, the device should be repositioned.

PREVENTION AND MANAGEMENT OF COMPLICATIONS

Pericardial effusion

Pericardial effusion as acute/subacute cardiac tamponade or as an asymptomatic effusion is one of the most serious complications in LAA-occlusion procedures[12,19]. The transseptal puncture itself[19], manipulation of stiff wires, guiding catheters and the device itself within the left atrium and the thin-walled LAA, as well as too aggressive movement of the device during stability testing may result in LAA wall injury leading to pericardial effusions.

In the Protect AF trial[12], the rate of pericardial effusion occurring within 7 d of Watchman implantation was 4.5%, 3.3% of patients required pericardiocentesis. These complications are mainly observed at the beginning of the learning curve and became less frequent with more experience[12]. In the CAP registry, where experienced operators implanted Watchman® devices after the randomized trial was completed, the rate of pericardial effusions decreased to 2.2%[20] and could be held in the same

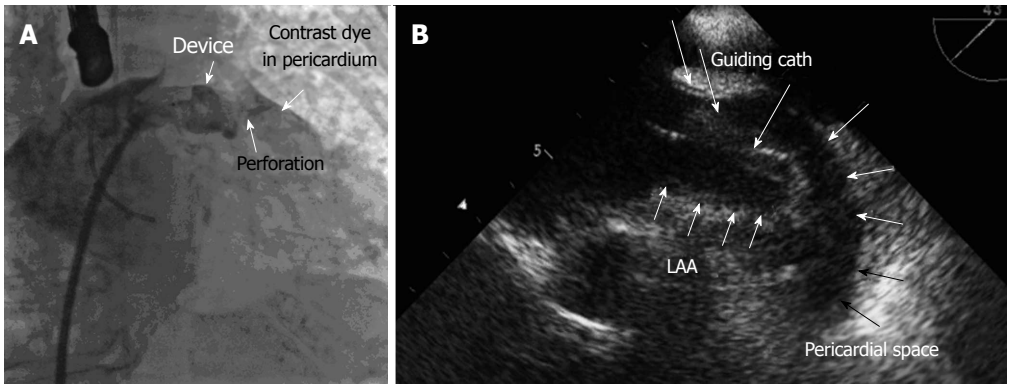

Figure 7 Pericardial effusion. A: Angiographic view; B: Echo view. LAA: Left atrial appendage.

range in the PREVAIL-trial with adequate training of new operators[21-23].

Several techniques to avoid pericardial effusions are: (1) TEE guidance and pressure monitoring to ensure a safe transseptal puncture at the correct site before advancing the sheath; (2) use of a 4 or 5 F. pigtail catheter inside the access sheath or a looped wire in the LAA to facilitate a safe movement of the guiding into the LAA; (3) slow and careful movements of the catheter and device manipulation within the left atrium; and (4) stability (tug-) testing after device implantation should be performed under TEE-control and fluoroscopy with injection of small amounts of contrast dye.

Cardiac tamponade with hypotension requires an aggressive approach with pericardiocentesis and reversal of anticoagulation (Figure 7). In case of recurrent tamponade, surgery is needed. Therefore early detection of an effusion by TEE is very important before hemodynamic deterioration arises from cardiac tamponade. Though most pericardial effusions occur early, subacute and late effusions are also possible. Therefore monitoring over a period of 48 h including 6 h close heart rate and pressure control and performance of trans-thoracic echocardiography at least before discharge to rule out pericardial effusion and to proof stable position of the device is recommended. Subacute effusions may arise from the anchors of the devices due to the thickness of only 0.5-0.8 mm of myocardial tissue of the LAA. If the effusion results in tamponade, pericardiocentesis and sometimes surgery is required. In case of late pericardial effusions also inflammatory processes may play a role, probably due to chronic injury of the hooks to the pericardium. In these cases anti-inflammatory therapy with non-steroidal antirheumatics like ASA, ibuprofen, diclofenac or even steroid therapy may be required at least for a certain period of time.

Air embolism

Air embolism is frequently a clinically silent event. However, acute coronary ischemia, stroke, hypotension, cardiac arrest and/or death are all possible outcomes. Holmes *et al*[12] report, that 5 of 449 patients with implantation of a Watchman® device suffered from a periprocedural stroke. The most common cause was air embolism, which is usually short-lived. Air emboli may enter the left atrium due to accidental injection of air, trapped air despite of flushing of the catheter or by air intrusion driven by a gradient between atmospheric and intracardiac pressure with a deep inspiration of the patient[24]. Therefore the left atrial pressure should be increased to normal or slightly high mean pressure using saline infusions. High pressure infusion through the side arm of the guiding catheter conversely can even lead to air embolism due to the Venturi-effect when opening the stop cock.

The management of air embolism is largely supportive. Hyperbaric oxygen has been shown to be of benefit in up to 80% of cases of cerebral air embolism, but controlled trials have not been performed yet[25]. However, as cerebral air embolism is mostly short-lived, there are usually no sequelae to be expected in longterm follow up.

Air embolism to the coronary circulation is most common in the right coronary artery because of the anterior position of the ostium (Figure 8). It often resolves within several minutes. However, marked ST-segment elevation, hypotension and ventricular arrhythmias may result, leading to cardiogenic shock. Aspiration of the air with an aspiration device (*e.g.*, EXPORT Catheter, Medtronic Inc. Minneapolis, MN, United States) or rigorous contrast dye injection into the coronary artery may be helpful in selected cases (Figure 8). In this case the arterial access may be helpful to advance a right coronary catheter quickly to the aortic rout or even having a right coronary diagnostic catheter already in place during transseptal puncture to mark the aortic rout Also Trendelenburg position is recommended; as air trapped anywhere within the heart (*e.g.*, the LAA) might be dislodged leading to another air embolism. If there is a large amount of air within the left or right atrium, the LAA or in the ascending aorta, this may also be aspirated through the sheath or *via* a coronary multipurpose or right coronary catheter.

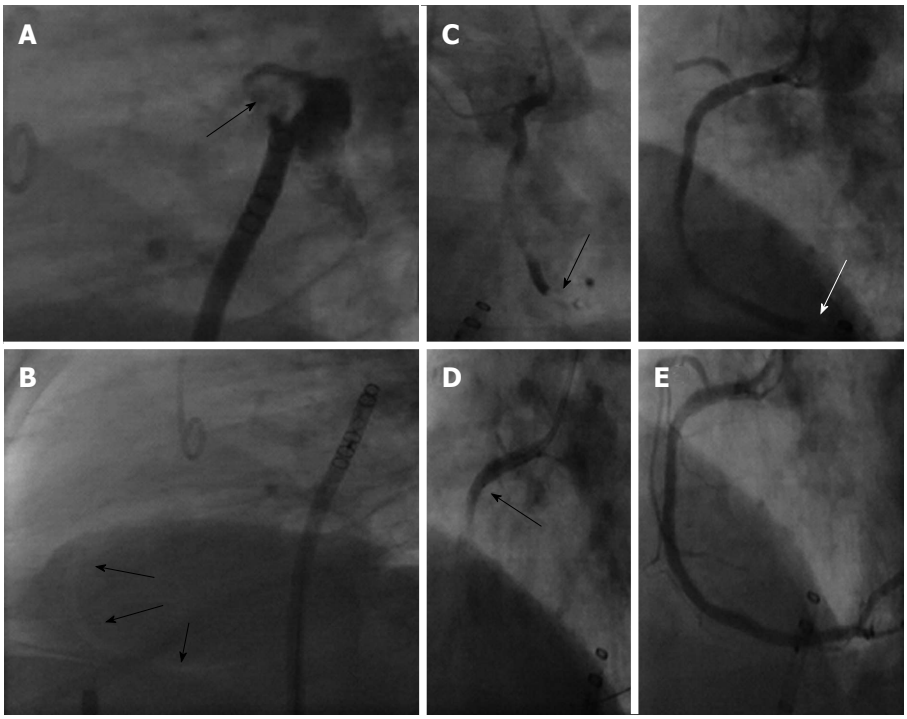

Figure 8 Air embolism. A: Air bubble within the left atrial appendage; B: Right coronary artery (RCA) filled with air (bright shadows); C: RCA with large air bubble; D: Placement of a aspiration catheter (EXPORT, Medtronic) within the RCA; E: RCA after successful aspiration of air bubbles without filling defect. LAA: Left atrial appendage

Aspiration of air should be performed before catecholamines are given for pressure management. This can protect from air movement into the brain circulation.

Thrombus formation during device implantation

During the procedure an activated clotting time of about 250 s should be aimed at using heparin and continious flushing of the guiding catheter is recommended to avoid thrombus formation within the catheter. In case of new thrombus formation in the LAA, the operator must decide if it is prudent to continue the procedure. If a good position of the delivery sheath has been achieved, implantation might be possible, especially if it is deemed to be more dangerous to retract the device and sheath. The membrane of the device, once deployed, is able to catch a thrombus in the LAA.

If the sheath has not yet been maneuvered into the LAA, aspiration of blood and possible thrombus through the side port should be attempted followed by removal of the sheath for an outside flushing.

If thrombus formation is observed outside the access sheath in the left atrium, the only option is to withdraw the sheath back into the right atrium applying pressure on both proximal carotid arteries to minimize the risk of cerebral thromboembolism followed by close neurological monitoring.

Early device embolization

Percutaneous closure of the LAA may be complicated by immediate or late device embolization. Device embolization occurs in about 0.2% of cases with the Watchman® device (Figure 9)[12] Selection of patients with favorable LAA morphology and appropriate device sizing are crucial to prevent embolization. Negative predictors are: large LAA ostial size, use of undersized devices, short LAA length for the Watchman and unusual LAA morphologies.

The Watchman-Device must be fully expanded and compressed by at least 10%-30% of its original size. If the device is too deep in the LAA and therefore not fully expanded, the device must be partially recaptured and repositioned. If the device is too proximal, a complete recapture and exchange of the device is necessary.

The above mentioned Device release criteria should be fulfilled before release.

Late device embolization

Routine post procedural TTE to exclude a new or expanding pericardial effusion and as a screen for device embolization is mandatory one to two days after implantation, even if the patient is asymptomatic[12,14]. The best way to visualize a LAA-occluder is from subxiphoidal. If the device cannot be seen, we recommend fluoroscopy to confirm correct position of the device.

Embolized devices that are found in the left atrium or left ventricle may be safely moved antegradely across the mitral and aortic valve by using coronary catheters. Snaring of devices within the heart itself is challenging and dangerous. However, retrieval from the descending aorta using a snare or bioptome

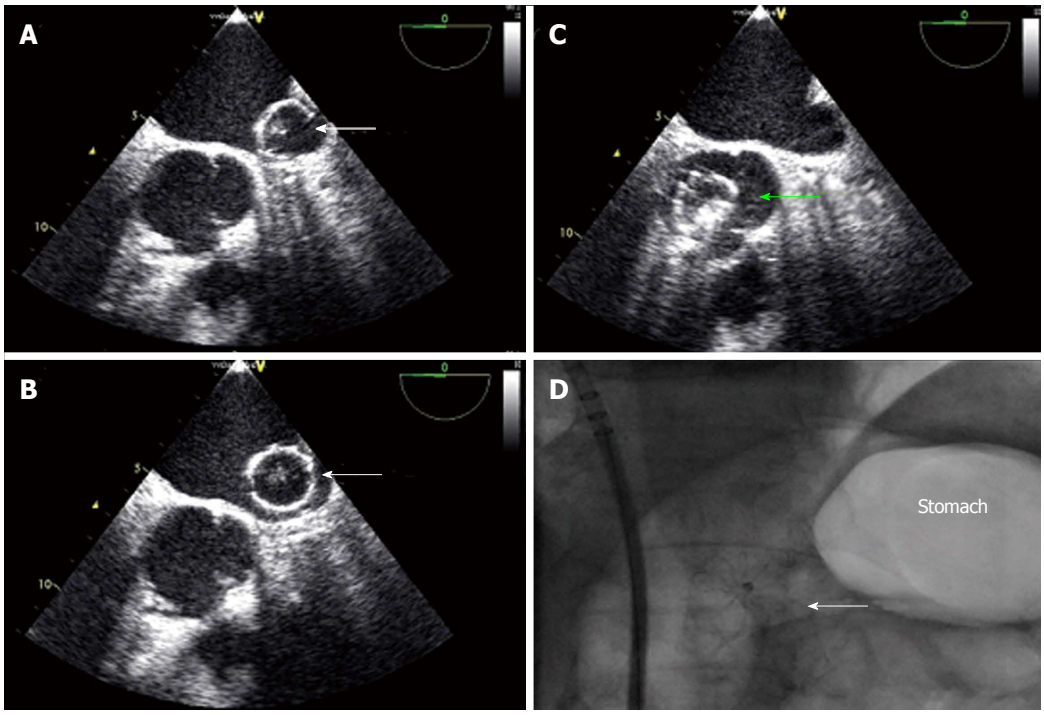

Figure 9 Device embolisation of watchman-device. A: Within the left atrial appendage immediately after release (arrow indicates device); B: Embolisation from the left atrial appendage; C: Passage of the aortic valve; D: Device within the lower thoracic aorta after embolization.

through an appropriately sized retrieval sheath (min. 14 Fr.) (Figure 10) is both safer and more feasible. In rare cases of embolisation of larger devices, surgical retrieval might be necessary even through the groin. Therefore, close collaboration with cardiac/vascular surgery ensures open access retrieval, if the percutaneous maneuver fails.

PROCEDURAL FOLLOW UP AND MEDICAL TREATMENT TO AVOID COMPLICATIONS

To avoid thrombus formation on the device for the Watchman® device, aspirin 100 mg/d and warfarin (INR goal 2-3x normal) should be administered until 45 d TEE control according to the PROTECT AF-trial[12]. If the device is still in position, the LAA occluded and no or minimal flow (residual jet < 5 mm) around the device, oral anticoagulation can be stopped and clopidogrel 75 mg/d should be added up to 6 mo after implantation. After another TEE-control aspirin alone should be administered lifelong at least according to the actual study results, though there are some centers that even stop aspirin therapy after three to six months. However, there are no data about long term results without any antiplatelet therapy. Within the Protect AF trial, patients having a residual gap < 5 mm were not likely to develop more stroke/TIA than patients without a gap, as a recent publication by Viles-Gonzalez was able to demonstrate[26]. If the 45 d TEE demonstrates a jet > 5 mm, warfarin must be continued with another TEE after 3 mo. If there is no change, the implant is deemed to have failed and the patient should remain on chronic oral anticoagulation therapy. If the gap has decreased to < 5 mm, therapy can be changed to ASA and clopidogrel.

In case of absolute or relative contraindications for warfarin therapy, another regimen recommends to give ASA and Clopidogrel immediately after implantation for 6 mo followed by ASA alone, which was similar effective in a small registry trial called ASAP[27]. If ASA could be even stopped at 6 mo or some time later is not clear yet. There are no data really supporting continuation or discontinuation of ASA lifelong except the experience of PROTECT AF.

In some cases, thrombus formation on the device may be detected by TEE (Figure 11). In these cases, low molecular weight heparin or oral anticoagulation should be restarted for another 4-8 wk. A repeat TEE will direct further treatment as described above.

CONCLUSION

Percutaneous closure of the left atrial appendage has been shown to be feasible with promising results in terms of reducing the rate of stroke and hemorrhagic complications, and has become an alternative therapy to standard anticoagulation therapy in patients with atrial fibrillation in Europe and other countries. The actual accepted indications for the use of LAA-occlusion therapy to be considered is published in an EHRA/EAPCI expert consensus statement[28].

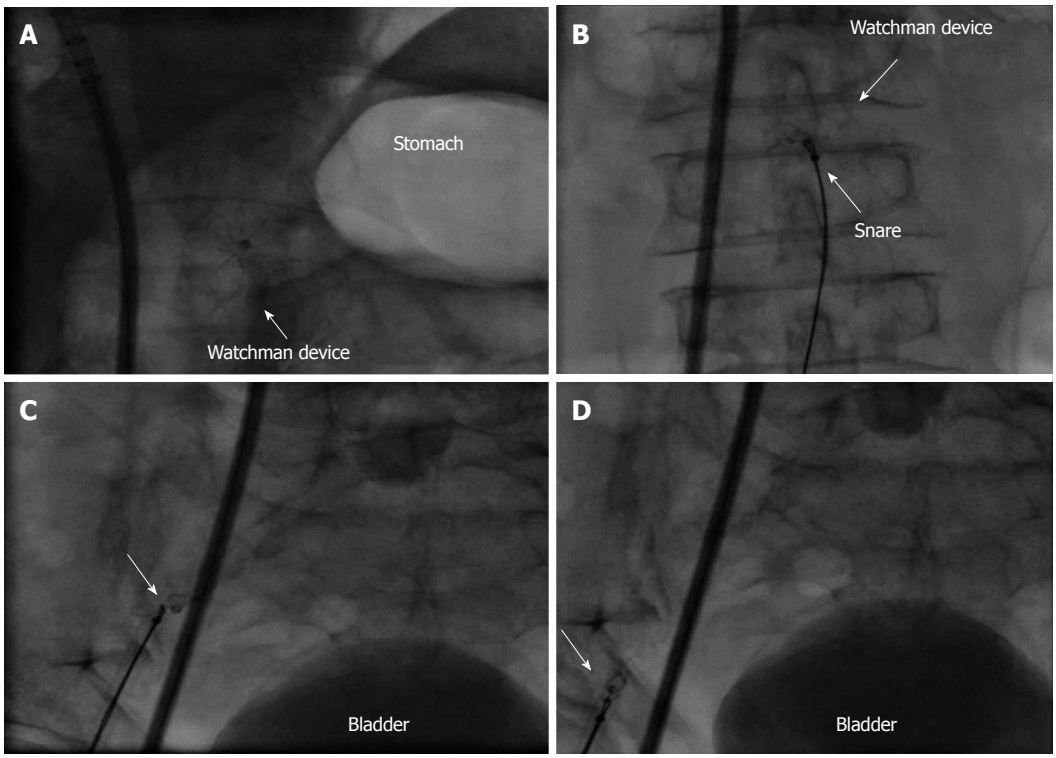

Figure 10 Device retrieval after embolization. A: Watchman device within the lower thoracic aorta after embolization; B: Snaring of the Watchman device with a goose neck snare 20 mm; C: Retraction of the device into the right arteria iliaca; D: Device retracted into a large (14 Fr.) sheath.

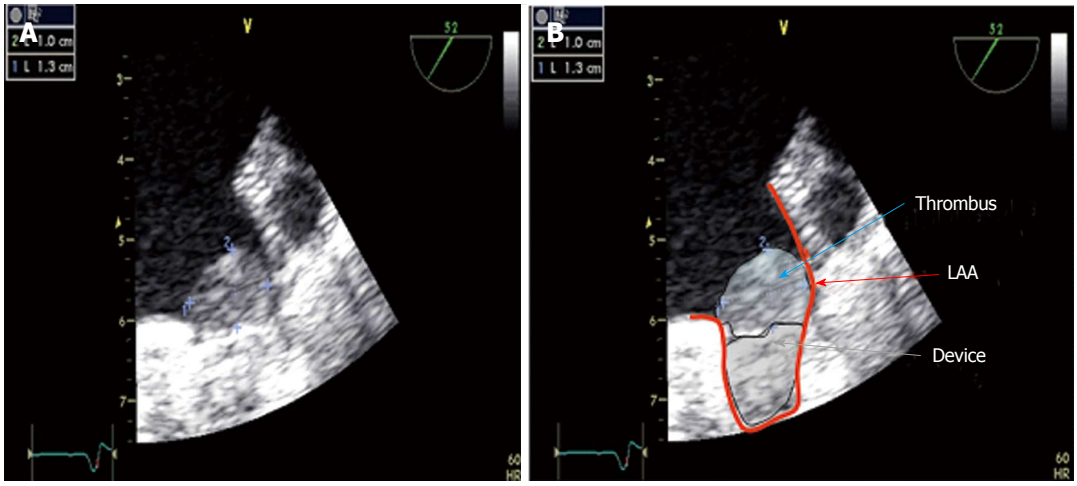

Figure 11 Thrombus formation (1.0 cm x 1.3 cm) 45 d after implantation on a Watchman device (A) and schematic view: Thrombus, device and left atrial appendage are highlighted (B).

Main indications are real contraindications for oral anticoagulation even for NOACs, patient refusal despite adequate information about different anticoagulation modalities, increased risk for bleeding due to a high HASBLED-score, need for prolonged triple therapy for example after coronary stenting, increased bleeding risk not reflected by the HASBLED-score and severe renal failure as a contraindication to NOACs. An individual risk benefit evaluation for each patient should be performed. FDA-approval may be expected in the beginning of the year 2015.

As a new invasive procedure, transcatheter LAA closure has several device- and procedure-specific complications, mainly pericardial effusions with or without tamponade, air embolism with subsequent stroke or device embolization. To minimize these complications, the procedure should be performed only by operators experienced in transseptal puncture and structural heart interventions. Additionally, TEE guidance by an experienced echocardiographer is important to ensure a complication-free and successful procedure. Profound knowledge of the

nature, management and prevention of complications is essential to optimize the outcome of transcatheter LAA closure.

Abstract

Flecainide acetate is a class IC antiarrhythmic agent and its clinical efficacy has been confirmed by the results of several clinical trials. Nowadays, flecainide is recommended as one of the first line therapies for pharmacological conversion as well as maintenance of sinus rhythm in patients with atrial fibrillation and/or supraventricular tachycardias. Based on the Cardiac Arrhythmia Suppression Trial study results, flecainide is not recommended in patients with structural heart disease due to high proarrhythmic risk. Recent data support the role of flecainide in preventing ventricular tachyarrhythmias in patients with catecholaminergic polymorphic ventricular tachycardia associated both with ryanodine receptor and calsequestrin mutations. We herein review the current clinical data related to flecainide use in clinical practice and some concerns about its role in the management of patients with coronary artery disease.

Key words: Flecainide; Class IC antiarrhythmic drugs; Atrial fibrillation; Ventricular tachycardia; Proarrhythmia

Core tip: Flecainide acetate is recommended as one of the first line antiarrhythmic drugs in patients with atrial fibrillation and/or supraventricular tachycardias for the restoration and maintance of sinus rhythm. Based on the Cardiac Arrhythmia Suppression Trial study results, flecainide is contraindicated for patients with structural heart disease due to high proarrhythmic risk. Recent data support the role of flecainide in preventing ventricular tachyarrhythmias in patients with catecholaminergic polymorphic ventricular tachycardia associated both with ryanodine receptor and calsequestrin mutations.

INTRODUCTION

Flecainide acetate is a class IC antiarrhythmic agent that was first synthesized in 1972. Its development began in 1966 in an attempt to generate new fluorinated anesthetic organic agents with the substitution of a trifluoroethoxy group on the aro-

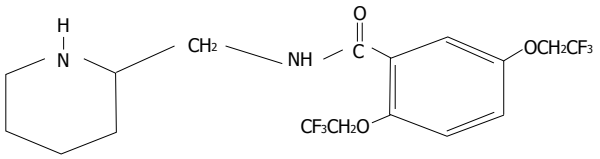

Figure 1 Chemical structure of flecainide acetate.

matic ring in the place of the amine group (Figure 1)[1]. The clinical efficacy of flecainide was confirmed by the results of several clinical trials, both in animals and humans[2-6]. Oral use of flecainide was approved in 1984 from the Food and Drug Administration for the suppression of sustained ventricular tachycardia since study results showed about 90% efficacy without significant adverse events[7]. However, safety data from 1330 patients between 1980 and 1985 demonstrated that flecainide use was associated with increased proarrhythmic events in patients with severe cardiac disease primarily in those who were starting therapy with high-dose[8].

The publication of the Cardiac Arrhythmia Suppression Trial (CAST) study in 1989, which was designed to investigate the efficacy of class Ⅰ antiarrhythmic agents moricizine, encainide or flecainide in patients after myocardial infarction with reduced ejection fraction and frequent ventricular ectopic beats, resulted in a major revision of the role of these antiarrhythmic drugs[9]. Thus, while flecainide suppressed ventricular ectopy in those patients, a threefold increase of arrhythmic death was recorded compared to placebo[9]. Based on CAST results, flecainide nowadays is not recommended for patients with structural heart disease and coronary artery disease. However, it is recommended as one of the first line therapies for pharmacological conversion as well as maintenance of sinus rhythm in patients with atrial fibrillation and/or supraventricular tachycardias without structural heart disease[10]. This review aims to present the existing data regarding the use, effectiveness and safety of flecainide in current clinical practice of arrhythmia management.

CLINICAL PHARMACOLOGY OF FLECAINIDE

Pharmacodynamics

Orally administrated flecainide is administrated twice daily and is absorbed rapidly without any significant interactions with food or antacid. Its bioavailability is around 90%, indicating no significant first pass effect through the liver. In normal subjects, plasma peak levels are reached after 2-3 h and steady state levels within 3-5 d. The half-life of flecainide ranges from 7 to 23 h and seems to be unaffected by dose[11,12]. Patients with ventricular ectopic beats have a longer half-life (mean 20 h) compared with normal subjects, mainly due to reduced renal function[13]. Flecainide levels are higher in cardiac tissues compared to plasma[14]. Two major metabolites, the active meta-O-dealkylated flecainide and its inactive lactam, are produced by hepatic oxidative metabolism *via* cytochrome CYP2D6 and CYP1A2. Both flecainide and metabolites are excreted mostly in urine, so patients with impaired renal function require close monitoring and dose reduction. Approximately 30% of flecainide is excreted unchanged into the urine[13,14]. It should be pointed that the antiarrhythmic efficacy of flecainide is closely correlated to the QRS duration. Therapeutic plasma levels range between 0.2 and 1.0 mg/mL and higher values are associated with toxic cardiac effects, such as bradycardia or conduction abnormalities[15]. The recommended starting dose in patients without renal insufficiency and paroxysmal supraventricular tachycardia or paroxysmal atrial fibrillation is 50 mg *bid* and may be increased in increments of 50 mg *bid* until efficacy is achieved (maximum recommended dose 300 mg/d). In patients with ventricular tachycardia and no contraindications for flecainide administration, the starting dose is 100 mg *bid* and the maximum recommended dose is 400 mg/d. Attention should be paid in patients concomitantly receiving amiodarone, although rare to encounter, who may require a dose reduction about 50%[11]. Additionally, caution is needed prior to but also following drug initiation, to exclude concomitant electrolyte disturbances, especially hypokalemia. In patients with severe hepatic insufficiency, flecainide administration should be carefully considered and monitoring of drug levels in plasma may be required[12].

Electrophysiological properties

As mentioned above flecainide belongs to the class IC antiarrhythmic agents which produce a potent and selective blockade of the cardiac fast inward sodium (Na^+) current resulting in conduction slowing[11]. A high affinity for open-state Na^+ channels and the slow unbinding kinetics from these channels during diastole has been described, explaining the slowing of the recovery time during the cardiac diastole and the prolongation of refractoriness[11,12]. Moreover, flecainide inhibits opening of potassium channels, especially the rapid component of the delayed rectifier K^+ current (I_{Kr}), prolonging the action potential duration (APD) in ventricular and atrial muscle fibers. In opposite, in Purkinje fibers, flecainide causes a shortening in the APD due to the Na^+ channel blockade[16-18]. Recent data suggest that flecainide blockades ryanodine receptor opening, thus reducing spontaneous sarcoplasmic reticulum Ca^{2+} release, which potentially results in afterdepolarization and triggered activity[19,20]. Therefore, flecainide has been used for the therapy of catecholaminergic polymorphic ventricular tachycardia (CPVT), which is an inherited arrhythmogenic disease with mutations of either the

cardiac ryanodine receptor or calsequestrin that can cause sudden cardiac death[21].

Regarding the impact of flecainide in the intra-cardiac intervals, flecainide increases the AH interval (15%-22%) and the HV interval (25%-50%), thus slightly slowing both intra-atrial and atrioventricular nodal conduction[22,23]. In patients with evidence of dual atrioventricular node pathway physiology, flecainide has shown to prolong mainly the retrograde refractoriness of the fast pathway[22]. Also, in patients with accessory atrioventricular pathways, flecainide can cause complete retrograde pathway block especially in patients with refractoriness more than 270 ms at baseline, although potentially decreases both anterograde and retrograde refractory periods[24]. Additionally, flecainide does not seem to affect normal sinus node function but in patients with sinus node dysfunction an increase of the corrected sinus node recovery time and the sinoatrial conduction time have been reported[25,26]. Finally, patients with implanted cardiac rhythm devices (pacemakers or internal cardiac defibrillators) and concomitant flecainide treatment may experience an increase in the pacing thresholds[25].

All the above mentioned electrophysiological properties of flecainide are deflected in the twelve lead surface electrocardiogram with an increase in PR, QRS and QT intervals duration. The QTc interval is not significantly increased since most of QT prolongation is due to the QRS widening[11,22]. During exercise, flecainide usually shortens QTc interval[27].

Proarrhythmic and inotropic effects of flecainide

It is well known that class IC antiarrhythmic drugs may potentially be associated with proarrhythmia, either as atrial flutter with 1:1 antrioventricular conduction or ventricular tachyarrhythmia. Flecainide can convert atrial fibrillation into atrial flutter, potentially resulting in a rapid tachycardia with more than 200 bpm in case of 1:1 atrioventricular conduction[28]. The reported rate of this proarrhythmic effect is 3.5% to 5.0% and has been associated with high adrenergic conditions[29]. Drugs with atrioventricular nodal blockade properties, such as β-blockers, verapamil and diltiazem, should be administered concomitantly in order to lower the risk.

Ventricular tachycardias due to proarrhythmic effect seem to be rare in patients without structural heart disease, electrolyte disturbances and coronary artery disease. Ventricular proarrhythmia manifests either as monomorphic or polymorphic tachycardia not only early but also late after the initiation of therapy according to the results of CAST study[9]. The incidence of ventricular proarrhythmia in patients receiving flecainide for acute cardioversion of atrial fibrillation was reported in a systematic review to be less than 3%[30].

Flecainide exerts a negative inotropic effect and therefore is contraindicated in patients with congestive heart failure, coronary artery disease and reduced ejection fraction. In this population flecainide significantly reduces stroke volume index and left ventricle ejection fraction and increases right atrial and pulmonary capillary wedge pressures[31,32]. Even in patients with normal ejection fraction, oral administration of flecainide can slightly reduce the ejection fraction. Intravenous administration of flecainide (2 mg/kg) in healthy subjects was associated with a reduction in cardiac output and stroke volume during the first 90 min after dosing[33]. These hemodynamic effects are related to the reduced Na^+ and Ca^{2+} entry into the myocardial cells. Moreover, as discussed above, flecainide has proved to blockade the ryanodine receptor opening and its interaction with the Ca^{2+} diastolic waves[34].

Mechanism of action of flecainide in maintenance of sinus rhythm and cardioversion in patients with atrial fibrillation

It is well known that atrial fibrillation causes both electrical and structural remodeling in atrial myocardium. Flecainide has proven its efficacy in the cardioversion of atrial fibrillation in sinus rhythm in both human and animal trials causing a shortening of the APD and prolongation of atrial refractoriness in a rate-dependent manner. Trial data have shown that the slow conduction properties of flecainide could result in a significant reduction of atrial wavelength so that atrial fibrillation cannot be maintained[34,35].

Atrial fibrillation has been associated with significant structural changes in the atria which subsequently cause remodeling of the myocardial fibers and mitochondrial dysfunction due to oxidative stress[34]. Several inflammatory adhesion molecules associated with oxidative stress and subsequent myocardial ischemia, such as nuclear factor kappa β ($NF_{\kappa}B$), reactive oxygen species and glycogen, impair the cellular physiology enhancing apoptotic process and cellular protein decomposition[36]. Rapid atrial activation encountered during atrial fibrillation results in intracellular Ca^{2+} accumulation, thus promoting ischemia and cellular dysfunction. This process is facilitated by the high transient intracellular Na^+ concentration during tachycardia, which accentuates the entry of Ca^{2+} *via* the Na^+/Ca^{2+} exchanger (Figure 2). Flecainide attenuates the intracellular Ca^{2+} accumulation by blocking Na^+ channels, thus reducing oxidative stress process and further atrial remodeling[37].

CLINICAL TRIALS

Acute conversion of atrial fibrillation of recent onset

The efficacy of flecainide, both oral and intravenous formulation, in terminating recent-onset atrial fibrillation has been evaluated in several studies (Table 1) and is affected from the study design

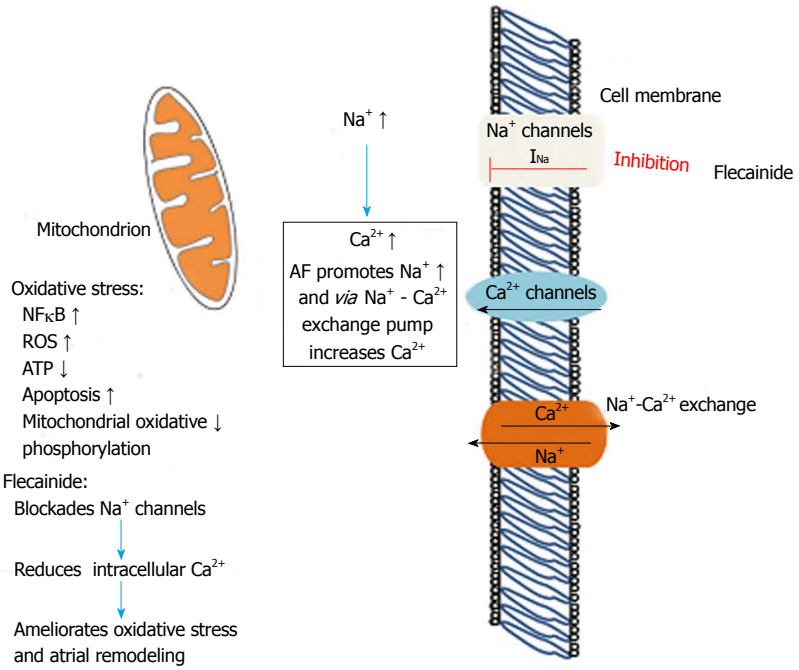

Figure 2 Mechanism of flecainide action during atrial fibrillation by inhibition of Na^+ channels which reduces intracellular Ca^{2+} accumulation and reduces oxidative stress and mitochondrial dysfunction. AF: Atrial fibrillation; INa: Fast inward Na^+ current; ROS: Reactive oxygen species; NFκB: Nuclear factor kappa β; ATP: Adenosine triphosphate.

Table 1 Reversion rate of recent-onset atrial fibrillation to sinus rhythm in clinical trials evaluating the conversion efficacy of oral or intravenous flecainide

Clinical trial	Patients in flecainide arm	AF duration	Formulation	Reversion rate
Capucci *et al*[38]	22 patients	≤ 7 d	Single oral dose (300 mg)	8 h → 91% 24 h → 95%
Donovan *et al*[39]	51 patients	≤ 3 d	*iv* (2 mg/kg-max 150 mg)	1 h → 57% 6 h → 67%
Donovan *et al*[40]	34 patients	≤ 3 d	*iv* (2 mg/kg-max 150 mg)	2 h → 59% 8 h → 68%
Boriani *et al*[41]	69 patients	< 8 d	Single oral dose (300 mg)	1 h → 13% 3 h → 57% 8 h → 75%
Martínez-Marcos *et al*[42]	50 patients	≤ 2 d	*iv* (2 mg/kg followed by 1 mg/kg at 8 h if not SR)	1 h → 58% 8 h → 82% 12 h → 90%
Romano *et al*[43]	138 patients	≤ 3 d	Intravenous	1 h → 73% 3 h → 80% 6 h → 86% 24 h → 90%

AF: Atrial fibrillation; SR: Sinus rhythm.

characteristics and the time intervals from drug initiation to assessment of reversion rate[38-42].

Several randomized controlled clinical trials have also compared the efficacy of flecainide to other antiarrhythmic agents in acute conversion of recent-onset atrial fibrillation. Capucci *et al*[38] found that a single oral loading dose of flecainide was significantly more efficient than intravenous amiodarone within 8 h but not at 24 h. In a randomized, double-blind trial, intravenous flecainide was also shown to result in earlier reversion of recent onset atrial fibrillation to sinus rhythm as compared to intravenous amiodarone[40]. In accordance, Martínez-Marcos *et al*[42] found that a significantly higher proportion of patients reverted to sinus rhythm when treated with intravenous flecainide as compared to intravenous amiodarone and propafenone, although the difference in reversion rate with intravenous propafenone reached statistical significance at 12 h but not at 8 h following treatment onset[42]. On the other hand, Romano *et al*[43] found a significantly higher efficacy of intravenous flecainide compared to intravenous propafenone in acute conversion of recent onset atrial fibrillation at 1, 3 and 6 h, although no difference was evident at 24 h. Finally, in a comparative study, Boriani *et al*[41] evaluated the conversion efficacy of different antiarrhythmic drug protocols and reported that oral flecainide had a similar conversion rate to oral propafenone.

Prevention of atrial fibrillation recurrences

Continuous treatment: The long-term safety and

efficacy of continuous treatment with flecainide for prevention of atrial fibrillation recurrences has been studied extensively in comparison to either placebo or other antiarrhythmic agents (Table 2). However, the majority of the trials published in the literature are hampered by methodological limitations, such as open-label design, small sample size, suboptimal follow-up and underestimation of AF burden mainly due to inability to document asymptomatic or short-lasting arrhythmia bouts. In the context of these limitations, oral flecainide has been demonstrated to be superior to placebo[44-48], and similar to quinidine[49,50], sotalol[48] and propafenone[51,52] in preventing AF recurrences. The clinical efficacy of flecainide in the maintenance of sinus rhythm has been proved in a meta-analysis of 60 trials showing that 65% of patients were responders to short term treatment and 49% in the long term treatment[53]. In terms of safety, flecainide is better tolerated than quinidine[46,50], and is associated with a lower rate of adverse events as compared to propafenone[51,52].

Special emphasis should be placed in two trials, the PITAGORA[54,55] and the FLEC-SL trial[56]. The PITAGORA trial was a multicenter, prospective, single-blind randomized trial which aimed to compare amiodarone with class IC antiarrhythmic agents (propafenone and flecainide) when administered as prophylactic treatment for sinus rhythm maintenance among pacemaker recipients with sinus node disease and history of atrial fibrillation[54]. The maintenance daily doses of tested antiarrhythmic agents were 200 mg amiodarone, 450-750 mg propafenone and 200 mg flecainide. The main strength of the study was the ability to quantify the frequency and burden of both symptomatic and asymptomatic atrial fibrillation episodes *via* pacemaker diagnostics. However, the primary endpoint of the study was not related to AF burden *per se* but was a composite endpoint defined as time to the first occurrence of one of the following adverse events: death, hospitalization for AF or heart failure, atrial cardioversion or AAD change owing to failure of AF prophylaxis or adverse events[54]. In terms of the incidence of this endpoint, flecainide and propafenone proved to be non-inferior to amiodarone[55]. Furthermore, when flecainide and propafenone, as single agents, were compared with amiodarone, only flecainide satisfied the criterion for noninferiority. Post-hoc analysis of arrhythmia burden data demonstrated that amiodarone and class Ic agents demonstrated similar efficacy in preventing arrhythmic episodes > 10 min, or > 1 d, with a trend in favor of amiofarone for prevention of episodes lasting more than a week[55].

The Flec-SL trial is the largest, prospective randomized clinical trial testing the efficacy of oral antiarrhythmic treatment for prevention of atrial fibrillation recurrence, with a meticulous follow-up and endpoint assessment[56]. The aim of the study was to evaluate whether short-term (4 wk) flecainide treatment is non-inferior to long-term (6 mo) treatment following cardioversion of persistent atrial fibrillation. The tested hypothesis was based on the concept that provision of antiarrhythmic protection n until completion of reverse atrial electrical remodeling might provide a long-term effect with an enhanced safety profile due to reduced drug exposure. In total, 635 patients were randomly assigned in three treatment arms (placebo *vs* short-term *vs* long-term oral flecainide treatment). Patients were followed up for 6 mo with daily telemetric electrocardiograph recordings and Holter ECGs when atrial fibrillation was noted in more than two consecutive telemetric recordings. The primary outcome measure of the study was time to first recurrence of persistent atrial fibrillation or death from any cause. Based on the study results, in the per-protocol population 46% of patients receiving short-term treatment presented a recurrence of persistent AF as compared to 39% in the long-term treatment group. Additionally, short-term treatment with flecainide was superior to placebo but failed to demonstrate non-inferiority as compared to long-term treatment. However, short-term treatment demonstrated about 80% of the 6-mo effect of long-term treatment, supporting that the former could be considered a viable treatment option in patients with infrequent AF recurrences or increased risk of proarrhythmia.

Pill-in-the-pocket strategy: The safety and feasibility of treatment with a single oral dose of either flecainide (200-300 mg) or propafenone (450-600 mg) on an outpatient basis, for termination of recent onset atrial fibrillation was validated in a pivotal trial including 268 patients without severe heart disease and a previously successful in-hospital treatment[57]. The tested "pill-in-the-pocket" strategy was successful in 94% of arrhythmic episodes (equally effective for both propafenone and flecainide), while in 84% of patients the treatment was effective during all the arrhythmic episodes. The mean conversion time to sinus rhythm was about 2 h, while only one case (0.6%) of atrial flutter with rapid ventricular rate was reported. Furthermore, the implemented treatment approach resulted in significant reduction of hospitalizations and visits to the emergency rooms.

The pill-in-the-pocket strategy can be used in symptomatic patients with infrequent recurrences of atrial fibrillation. Patients with sinus node dysfunction causing bradycardia and patients with bradycardia or syncope due to atrioventricular conduction defects may not be considered candidates for the pill-in-the-pocket strategy. Prerequisites for the safe implementation of this strategy are the initial in-hospital testing of its efficacy and safety as well as careful screening of candidate patients to rule

Table 2 Flecainide for prevention of atrial fibrillation recurrences - Randomized controlled clinical trials

Clinical trial	Patient population	Compared treatments	Endpoint of AF recurrence	Results	Comments
Steinbeck *et al*[44]	45 patients Paroxysmal AF	Quinidine + digoxin Flecainide + digoxin Digoxin	AF recurrence at 12 mo	Flecainide and digoxin superior to other regimens and safer than quinidine and digoxin	Quinidine is practically not used any more for sinus rhythm maintenance
Anderson *et al*[45]	64 patients Paroxysmal AF	Flecainide (median daily dose: 300 mg) Placebo	Patients without AF recurrences Time to first AF recurrence Time interval between AF recurrences	Flecainide superior to placebo Five-fold increase in time to first recurrence Four-fold increase in time interval between attacks Significantly increased percentage of patients free of AF recurrences Adverse cardiac events in 11% of patients during flecainide therapy	Transtelephonic monitoring Double-blind randomized crossover trial (8-wk observation period) Daily flecainide dose > 300 mg in 29% of patients
van Wijk *et al*[49]	26 patients Paroxysmal AF	Flecainide (200-300 mg daily) Quinidine (1.0-1.5 daily)	AF recurrence during 3-mo follow-up period	Flecainide superior to quinidine in the lower dosing regimen Flecainide similar efficacy to quinidine in higher dosing regimen	20% discontinuation rate with higher quinidine dosing regimen FU with 24-h Holter at the end of each month
van Gelder *et al*[46]	81 patients Persistent AF/ flutter	Flecainide Placebo	AF recurrence at 12 mo	Flecainide superior to placebo in preventing arrhythmia recurrences	Difficult to treat patients (mean AF duration: 12 mo)
Pietersen *et al*[47]	43 patients Paroxysmal AF/flutter	Flecainide (300 mg/d) Placebo	AF recurrence at 3 mo	Flecainide superior to placebo in preventing arrhythmia recurrences Adverse effects in 74% of patients treated with flecainide	Tolerable adverse events in flecainide group (only 2 withdrawals) One episode of sudden death
Carunchio *et al*[48]	66 patients Paroxysmal AF	Flecainide Sotalol Placebo	AF recurrence at 1, 3, 6 and 12 mo	Flecainide similar efficacy to sotalol and superior to placebo	
Aliot *et al*[51]	97 patients Paroxysmal AF/flutter	Flecainide (100-300 mg/d) Propafenone (600-1200 mg/d)	AF recurrence at 12 mo	Flecainide similar efficacy to propafenone Treatment discontinuation rate lower with flecainide (38% *vs* 53%, $P = 0.079$)	Multicenter, randomized, open-label study One episode of sudden death in the propafenone group
Chimienti *et al*[52]	200 patients Paroxysmal AF	Flecainide (200-300 mg/d) Propafenone (450-900 mg/d)	Palpitation recurrence on days 15, 30, 90, 180, 270, and 360	Flecainide similar efficacy to propafenone Similar rate of adverse cardiac and noncardiac events	Multicenter, open label, randomized, parallel study Suboptimal follow-up of AF recurrence
Naccarelli *et al*[50]	239 patients Paroxysmal AF	Flecainide (100-300 mg/d) Quinidine	AF recurrence at 12 mo	Flecainide similar efficacy to quinidine Flecainide better tolerated than quinidine	Multicenter, open label, randomized, parallel study Self-reporting of symptomatic AF recurrences (diary recording)
Gulizia *et al*[54]	176 pacemaker recipients with sinus node disease and paroxysmal AF	Ic AAD (flecainide or propafenone) Amiodarone	Primary endpoint: time to first occurrence of death, atrial cardioversion, cardiovascular hospitalization, or change of AAD	Class Ic AADs non-inferior to amiodarone in terms of the primary endpoint. Similar efficacy in freedom from AT recurrences based on post-hoc analyses	One patient experienced sudden cardiac death in flecainide group Capability of continuous rhythm monitoring by pacemaker AF recurrence and burden not included in primary endpoint
Kirchhof *et al*[56]	635 patients Persistent AF	Short-term flecainide Long-term flecainide Placebo	Time to first recurrence of persistent atrial fibrillation or death from any cause	Flecainide superior to placebo Short-term flecainide not non-inferior to long-term	Largest, prospective randomized clinical trial Meticulous follow-up

AF: Atrial fibrillation; AAD: Antiarrhythmic drug; AT: Atrial tachycardia.

out underlying structural heart disease. However, it should be noted that in-hospital testing should include only oral formulations of antiarrhythmic agents, since tolerance to intravenous administration of flecainide or propafenone has not been shown to predict adverse events during out-of-hospital self administration of these drugs[57].

RECOMMENDATIONS FOR FLECAINIDE USE IN ATRIAL FIBRILLATION - ESC GUIDELINES

Based on the guidelines of the European Society of Cardiology, *iv* flecainide (2 mg/kg over 10 min)

is recommended for cardioversion of recent onset AF (duration less than 48 h) when pharmacological cardioversion is preferred and there is no structural heart disease (Class ⅠA recommendation). In selected patients without significant structural heart disease, the pill-in-the-pocket strategy (single dose of 200-300 mg) should be considered if previously tested in a medically secure environment (Class Ⅱa recommendation). Flecainide is also recommended for long-term rhythm control in patients without significant underlying heart disease (Class ⅠA recommendation)[10].

Ventricular tachycardias

Ventricular tachycardias in patients with underlying heart disease: The role of flecainide in the treatment of ventricular tachycardias among patients with underlying heart disease has been formulated mainly by the results of the CAST trial[1]. This multicenter, randomized, placebo-controlled trial was conducted to evaluate whether suppression of asymptomatic or mildly symptomatic ventricular arrhythmias after myocardial infarction with antiarrhythmic drugs (flecainide, encainide or moricizine) would result in reduction of arrhythmic mortality. Eligible patients had prior myocardial infarction (6 d to 2 years), ventricular arrhythmias (≥ 6 ventricular extrasystoles per hour or ventricular tachycardia runs less than 15 beats) and impaired ventricular function (ejection fraction ≤ 0.55 if recruited within 90 d of the myocardial infarction, or ≤ 0.40 if 90 d or more after the myocardial infarction). Flecainide was not given to patients with an ejection fraction below 0.30. It should be highlighted that 789 of 1498 patients included in the study had ejection fraction ≥ 0.40[23]. The treatment arms of flecainide and encainide were prematurely discontinued after a mean follow-up of 10 mo due to a significantly increased risk of arrhythmia-related (2.64; 95%CI: 1.60-4.36) and all-cause mortality (2.38; 95%CI: 1.59-3.57)[1].

As regards the role of flecainide in patients with ventricular tachycardia without structural heart disease, type IC antiarrhythmic drugs seem to be useful in patients with right ventricular outflow ventricular tachycardia[58].

Catecholaminergic polymorphic ventricular tachycardia: Accumulating data have verified that flecainide inhibits the cardiac ryanodine receptor open state, thus directly targeting the molecular defect responsible for diastolic calcium release, delayed afterdepolarizations, and triggered arrhythmias in CPVT[33,59]. Case reports and series have reported that flecainide may prove useful in preventing ventricular tachyarrhythmias in patients with CPVT associated both with ryanodine receptor and calsequestrin mutations[21,60]. Van der Werf *et al*[61] reported the clinical experience from several international centers on the efficacy and safety of flecainide treatment in CPVT. The role of flecainide (median daily dose 150 mg in responders) was evaluated in 33 genotype-positive CPVT patients on optimal tolerated conventional treatment using as primary outcome measure the reduction of ventricular arrhythmias during exercise testing[61]. In total, 76% of patients had either a partial or complete suppression of exercise-induced ventricular arrhythmias by flecainide while no patient experienced worsening of exercise-induced ventricular arrhythmias[61]. Flecainide has also been shown to be effective in reducing ventricular arrhythmias during exercise testing and preventing arrhythmia events during long-term follow-up in patients with genotype-negative CPVT[62]. Marai *et al*[63] recently reported that the combination of flecainide and β-blockers can completely suppress exercise-induced ventricular arrhythmias and prevent recurrent ICD shocks in patients with calsequestrin-associated CPVT and high-risk features despite treatment with β-blockers.

PRACTICAL ASPECTS OF FLECAINIDE USE

The following practical considerations should be kept in mind in the management of patients under flecainide treatment: (1) performance of exercise stress test before treatment initiation to assess the presence of underlying coronary artery disease; (2) screening of candidates for sinus and atrioventricular node disease; (3) performance of regular ECG monitoring upon treatment initiation and upon dose titration. In case of QRS prolongation more than 25% as compared to baseline value, flecainide dosage should be halved and if QRS is not normalized thereafter it should be discontinued; (4) performance of exercise stress testing under flecainide treatment to assess increased risk of proarrhythmia, especially in the presence of slight QRS prolongation at rest. Flecainide exerts use-dependent properties and a potential minor or modest increase in QRS duration at rest may increase dramatically during exercise-related rapid heart rate; (5) control of pacing threshold in pacemaker recipients, especially if pacemaker-dependent. Flecainide may increase the pacing threshold occasionally to a significant extent; and (6) concomitant use of agents with negative dromotropic effect is recommended to avoid one-to-one atrio-ventricular conduction and very rapid ventricular rates, if atrial fibrillation is converted to atrial flutter.

IS THERE ANY ROOM FOR FLECAINIDE IN CORONARY ARTERY DISEASE PATIENTS?

The main precaution for flecainide administration is to rule out the presence of "structural" heart disease

and/or ischemic cardiomyopathy in order to avoid the associated increased risk of proarrhythmia. This caveat was mainly formulated on the basis of the CAST results which demonstrated that flecainide is associated with increased mortality when administered in patients with prior myocardial infarction. In this trial more than half of the enrolled patients had an ejection fraction > 40% and it is noteworthy that the hazard ratio of AAD therapy versus placebo for arrhythmic death was similar in patients with ejection fraction < 0.40 as compared to those with ejection fraction ⩾ 0.40. Furthermore, the presence of a non-Q wave myocardial infarction was the only variable which significantly interacted with encainide or flecainide for prediction of arrhythmic or all cause mortality (hazard ratio 7.9 in non-Q wave myocardial infarction patients as compared to 1.8 in those with Q-wave myocardial infarction)[57]. Therefore, it seems prudent to contraindicate flecainide treatment among patients with prior myocardial infarction (either Q or non-Q wave) even if left ventricular ejection fraction is preserved. Furthermore, flecainide administration should be precluded in the presence of myocardial ischemia since the latter increases the risk of proarrhythmia.

However, the group of coronary artery disease patients, with preserved ejection fraction, no prior myocardial infarction and no evidence of ischemia represents a grey zone where there is absolute paucity of data regarding safety of flecainide treatment. According to the 2012 update of the ESC guidelines for the management of atrial fibrillation[10], flecainide can be used in patients with "minimal structural heart disease", but it cannot be used in patients with coronary artery disease. Two main issues can be raised from these recommendations. Firstly, there is no commonly accepted and well established definition of "minimal structural heart disease". Secondly, there are no data supporting an increased proarrhythmic risk of flecainide among coronary artery disease patients in the absence of underlying scar and myocardial ischemia. Besides, even the definition of coronary artery disease may be obscured by the widespread use of advanced imaging techniques which may actually identify patients with coronary lesions but in low arrhythmic risk. Meanwhile, decision making in similar cases is not supported by solid evidence and all available treatment options, including catheter ablation in atrial fibrillation patients, should be taken into account.

Taking into consideration the limited therapeutic modalities that are currently available for the patients with coronary artery disease and atrial fibrillation, it is obvious that new studies need to be undertaken aiming to evaluate the safety of old antiarrhythmics, like flecainide, in the wide spectrum of patients with coronary artery disease, that we treat today. Nowadays, it is quite common to treat patients with stable coronary artery disease who have preserved left ventricular ejection fraction, lack of symptoms and absence of detectable myocardial ischemia. Flecainide and other antiarrhythmics may be useful in the management of these patients, who remain vulnerable to atrial fibrillation and have limited access to invasive management of atrial tachyarrhythmias.

Finally, there is one more unsolved issue in the area of antiarrhythmic therapy in patients with ischemic heart disease. There is lack of evidence for the potential benefit from flecainide treatment in patients with implantable cardioverter defibrillators (ICDs) who have "minimal heart disease" and present symptomatic arrhythmias, refractory to sotalol and/or amiodarone. Although there is no available evidence to support this hypothesis, given that ICDs ameliorate the proarrhythmic risk, flecainide may be an alternative treatment. Unfortunately, due to medical and economic restrains, the aforementioned hypotheses have not been properly addressed in the scheme of a specifically designed randomized clinical trial.

Salah AM Said, Rene Bloo, Ramon de Nooijer, Andries Slootweg, Department of Cardiology, Hospital Group Twente, Almelo-Hengelo, 7555 DL Hengelo, The Netherlands

Author contributions: Said SAM, Bloo R, de Nooijer R and Slootweg A treated patients and collected material and clinical data from patients; Bloo R performed the assays; de Nooijer R analysed data; Said SAM wrote the paper; all authors approved the final version of the manuscript.

Ethics approval: The study is reviewed and approved by the Hospital Group Twente, Institutional Review Board. Verbal consent was taken from the patients and ethical clearance and permission to publish the cases is obtained from the Hospital Group Twente, Institutional Review Board.

Informed consent: All study participants provided verbal informed consent.

Conflict-of-interest: The authors declare no conflict of interest.

Data sharing: Technical appendix, statistical code, and dataset available from the corresponding author at salah.said@gmail.com. Informed consent, neither verbal nor written, was obtained for data sharing but the presented data are anonymized and risk of identification is negligible.

Abstract

AIM: To describe the electrocardiographic (ECG) phenomena characterized by T-wave inversion in the precordial leads in adults and to highlight its differential diagnosis.

METHODS: A retrospective chart review of 8 adult patients who were admitted with ECG T-wave inversion in the anterior chest leads with or without prolongation of corrected QT (QTc) interval. They had different clinical conditions. Each patient underwent appropriate clinical assessment including investigation for myocardial involvement. Single and multimodality non-invasive, semi-invasive and invasive diagnostic approach were used to ascertain the diagnosis. The diagnostic assessment included biochemical investigation, cardiac and abdominal ultrasound, cerebral and chest computed tomography, nuclear medicine and coronary angiography.

RESULTS: Eight adult subjects (5 females) with a mean age of 66 years (range 51 to 82) are analyzed. The etiology of T-wave inversion in the precordial leads were diverse. On admission, all patients had normal blood pressure and the ECG showed sinus rhythm. Five patients showed marked prolongation of the QTc interval. The longest QTc interval (639 ms) was found in the patient with pheochromocytoma. Giant T-wave inversion ($\geqslant$ 10 mm) was found in pheochromocytoma followed by electroconvulsive therapy and finally ischemic heart disease. The deepest T-wave was measured in lead V_3 (5 ×). In 3 patients presented with mild T-wave inversion (patients 1, 5 and 4 mm), the QTc interval was not prolonged (432, 409 and 424 msec), respectively.

CONCLUSION: T-wave inversion associated with or without QTc prolongation requires meticulous history taking, physical examination and tailored diagnostic

modalities to reach rapid and correct diagnosis to establish appropriate therapeutic intervention.

Key words: T-wave inversion; Coronary angiography; Pulmonary computed tomography angiography; Magnetic resonance imaging; Differential diagnosis

Core tip: Myriad of clinical conditions have been described in association with T-wave inversion in the anterior precordial leads. T-wave inversion associated with or without corrected QT prolongation may be encountered in a variety of clinical conditions. In the reversible (dynamic) types such as vascular coronary, cerebral and pulmonary disorders; metabolic disturbances and acute adrenergic stress cardiomyopathy; resolution of T-wave inversion may occur after days, weeks, months or years following the index event. Tailored diagnostic approach should be conducted avoiding overuse of diagnostic methods. Specific tailored therapeutic interventions were undertaken when high index of clinical suspicion was raised towards certain disease entity.

Said SAM, Bloo R, de Nooijer R, Slootweg A. Cardiac and non-cardiac causes of T-wave inversion in the precordial leads in adult subjects: A Dutch case series and review of the literature. *World J Cardiol* 2015; 7(2): 86-100 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i2/86.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i2.86

INTRODUCTION

T-wave inversion is found in 1% of patients admitted to the coronary care unit[1] and in 14% of patients presented with unstable angina[2]. It has been stated that T-wave inversion in right precordial leads is relatively rare (0.5%) in the general population and not associated with adverse outcome[3]. The tendency to inversion of T-wave declines with increasing age. Normally in females, the T-wave in V_3 may be shallowly inverted. But in adult males, it is considered pathologic if the T-wave is inverted in V_{3-6}[4]. The T-wave in V_1 may be inverted normally at any age and in V_2 it is sometimes normally negative[5].

Generally, the T-waves are negative in leads aVR, V_1 and Ⅲ. Giant T-wave inversion in the precordial leads are seen in different pathologies, such as anterior myocardial wall ischemia in patients with acute coronary syndrome, apical hypertrophic cardiomyopathy, cerebral and pulmonary disorders and post-pacing or tachyarrhythmia states.

The definite diagnosis in the presence of inverted T-wave can usually be assessed by meticulous history taking including family history of sudden cardiac death or arrhythmias, physical examination as well as appropriate non-invasive, semi-invasive or invasive diagnostic investigations. This current review, will focus on T-wave inversion in the anterior chest wall leads and discuss its differential diagnosis with emphasis on the non-coronary non-cardiac disorders.

Diagnostic approach should be tailored according to the clinical presentation, medical and family history. We present a Dutch case series of eight patients with T-wave inversion in the precordial leads due to different etiologies and the literature is briefly reviewed.

MATERIALS AND METHODS

The study was reviewed and approved by the Hospital Group Twente, Institutional Review Board. All study participants provided verbal informed consent.

Eight representative adult patients were identified and evaluated. In all patients, physical examination, electrocardiography and transthoracic echocardiography (TTE) were routinely performed. When necessary for adequate clarification of the clinical presentation, tailored diagnostic methods were undertaken in the individual patient at the clinician' s discretion [TTE, n = 8; coronary angiography "coronary angiography (CAG)", n = 7; magnetic resonance imaging "magnetic resonance imaging (MRI)", n = 3; perfusion-ventilation scan, n = 2; computed tomography "computed tomography (CT)" abdomen, n = 1; CT brain, n = 1; CT thoracic aorta, n = 1; ^{123}Iodine-metaiodibenzylguanidine (MIBG) scan, n = 1 and DOPA- positron emission tomography (PET), n = 1].

Diagnostic criteria

The diagnostic criteria included presentation with T-wave inversion in the anterior chest leads on the admission ECG.

Definitions

Electrocardiography: The admission ECGs were analyzed using standard criteria for measurements of T-wave axis, T-wave amplitude and QT interval. ECGs were analyzed for the presence of Left ventricular hypertrophy (LVH) using the Sokolow criteria[6].

T-wave negativity: was defined as a voltage of giant negative T-wave ⩾ 10 mm in any of the leads[7-9], deep ⩾ 5 mm[8] and mild 1-3 mm[8].

Corrected QT prolongation: Corrected QT (QTc) interval for heart rate was performed in V_2 and was defined as QTc > 450 msec. according to Bazett[10] and Ahnve[11].

Measured serum biomarkers were creatine kinase and cardiac troponin T.

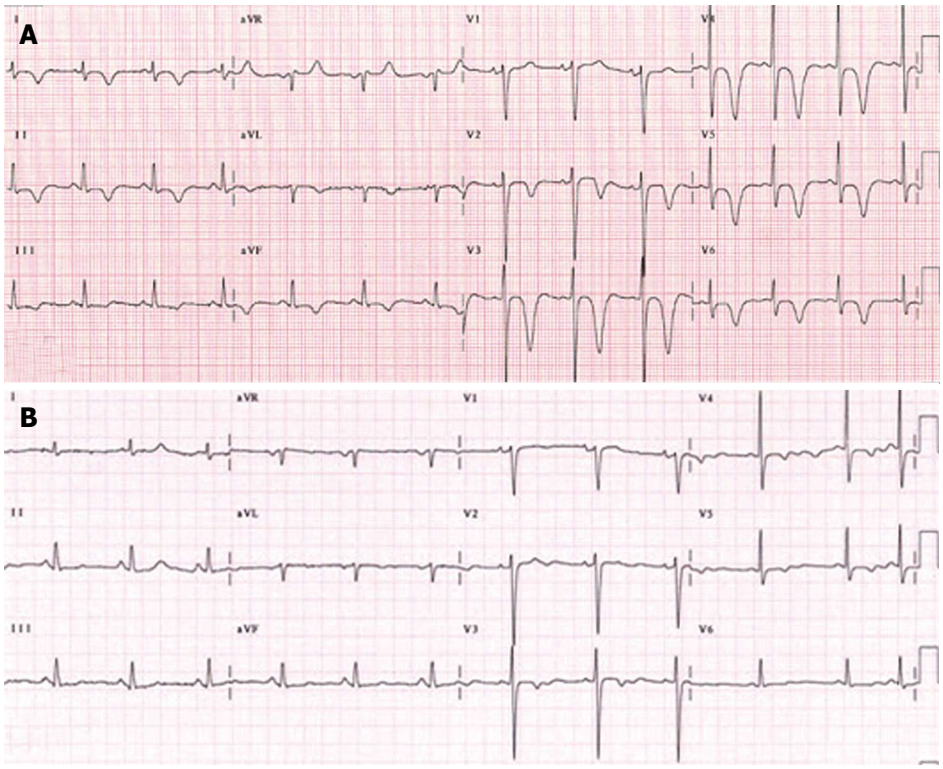

Figure 1 Patient 1. A: An electrocardiographic (ECG) tracing, illustrating the negative T-wave in the precordial leads $V_{2\text{-}6}$, of a 51-year-old-female patient presented with palpitation following electroconvulsive therapy for her depression. In 2001, she underwent catheter ablation for atrioventricular nodal reentry tachycardia. She complained of palpitation after a shock of electroconvulsive therapy for treatment of depression. Post-electroconvulsive therapy, the ECG showed giant T-wave inversion in the precordial leads. The cardiac enzymes were minimally raised. Takotsubo cardiomyopathy is suggested due to emotional stress and electrical shock. Transthoracic echocardiography demonstrated apical hypokinesia and basal normokinesia with trivial valvular regurgitation without massive pericardial effusion. The estimated right ventricular systolic pressure was 35 mmHg. Coronary angiography and cardiac magnetic resonance imaging demonstrated normal findings. Medical treatment with beta blocker was initiated and the symptoms disappeared and (B) the ECG returned to base line in 2 wk time. The antidepressant drug was not discontinued.

Transthoracic echocardiography: Left ventricular (LV) wall thickness as well as septal thickness were measured according to the established standards and guidelines of the American College of Cardiology/American Heart Association/European Society of Cardiology[12,13]. LVH was defined as a LV wall thickness > 13 mm.

Radionuclide studies: Radionuclide imaging and positron emission tomography: One patient (patient 7) underwent ^{123}I-MIBG and dihydroxyphenylalanine-Positron Emission tomography (DOPA-PET) scanning. In 2 patients, pulmonary perfusion/ventilation scintigraphy were performed.

Computed tomography: Abdominal, cerebral and thoracic aorta CT scanning were performed in one patient each.

Pulmonary computed tomography angiography (PCTA) was performed in one patient.

Coronary angiography contrast angiography was performed in standard views *via* the femoral approach.

Follow-up: Follow-up was obtained by direct contact with patients, their physicians or by chart review.

Statistical analysis

No statistical data are available.

RESULTS

A total of 8 adult patients presented with chest pain and negative T-wave in the anterior chest wall leads on the admission ECG were identified (Figures 1-8).

Clinical features

On presentation, the blood pressure was normal in all patients and all were in sinus rhythm (Table 1). Cerebral pathology was excluded by the absence of neurological signs. No neurological deficits were found.

All patients had on physical examination no neurological abnormalities. One patient known with a previous transient ischemic attack showed a complete recovery. Of the 8 patients, one presented with abnormal rest ECG, three with chest pain, one with palpitation, one with fatigue, one with left abdominal pain and psychomotor agitation and one with out-of-hospital cardiac arrest (OHCA).

None of the patients, except one (patient 8)

Figure 2 Patient 2. An electrocardiographic (ECG) tracing, illustrating the negative T-wave with minimal ST segment elevation in the precordial leads $V_{1\text{-}4}$, of a 82-year-old-female patient presented with acute coronary syndrome due to non ST elevation myocardial infarction. Her previous medical history included hormonal substitution for hypothyroidism, ablatio retinae, polymylagia rheumatica, arterial hypertension, mild concentric left ventricular hypertrophy, aortic valvular stenosis with a peak gradient of 18 mmHg and mild aortic regurgitation grade 2/4. In 2011, analysis with ambulatory ECG recording for a syncopal attack revealed no abnormalities. Transthoracic echocardiography demonstrated apicoinferior hypokinesia. The patient was treated medically and remained free of symptoms. Her maintenance drug therapy consisted of BB, aspirin (ASA), clopidogrel, Angiotensin-Ⅱ antagonist, prednisolon, diuretic and statin.

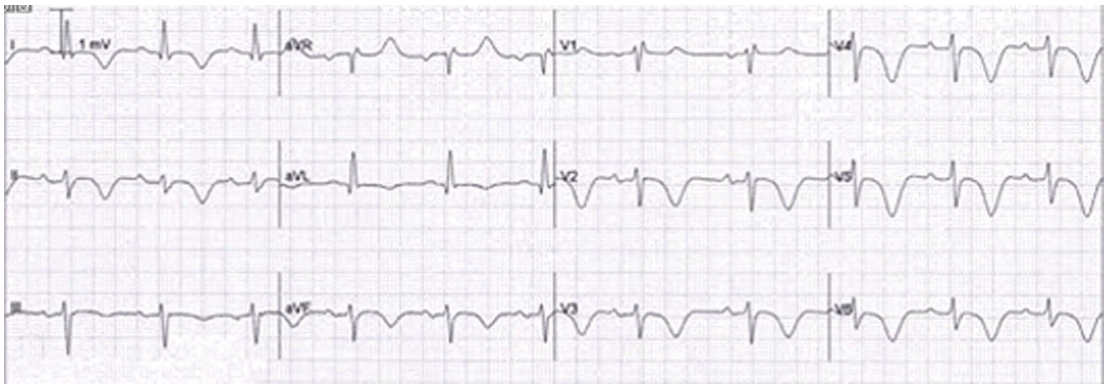

Figure 3 Patient 3. An electrocardiographic (ECG) tracing, illustrating the negative T-wave in the precordial leads $V_{2\text{-}6}$, of a 72-year-old-woman who underwent 6 mo earlier direct current electric cardioversion for persistent atrial fibrillation. Her concomitant medical history includes temporal arteritis, carotid endarterectomy and cluster headache. She presented with abnormal rest ECG during out-patient follow-up. Her spouse died 2 wk prior to presentation. The cardiac markers were minimally elevated. The diagnosis of Takotsubo cardiomyopathy was strongly suggested as the emotional stress may have been the trigger. Transthoracic echocardiography depicted biventricular normokinesia with hypertrophic LV. Pulmonary perfusion-ventilation scintigraphy, Coronary angiography and cardiac MRI were all normal. She did well on pharmacological treatment with oral vit K antagonist, class 3 antiarrhythmic drug, anti-depressive drug and diuretics. The ECG alterations returned to baseline over a 6 mo period.

performed endurance sports activities all had no family history of sudden cardiac death or arrhythmias.

Electrocardiography

The admission ECGs were analyzed using standard criteria for measurements of T-wave amplitude and QTc interval. Giant T-wave inversion (≥ 10 mm) was found in the patients with pheochromocytoma (20 mm) followed by electroconvulsive therapy (15 mm) then ischemic heart disease (10 mm). Deep T-wave inversion (≥ 5 mm) was detected in three and mild (1-3 mm) in two of the patients. The deepest T-wave was measured in lead V3 (5 ×), V4 (2 ×) and V2 (1 ×). Epsilon wave was present in one patient with arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) (patient 8) (Figure 8B). Electrocardiographic criteria for left ventricular hypertrophy was found in 4 patients (patients 2, 3, 6 and 7).

In 3 patients diagnosed with pulmonary embolism (PE) (patient 5), LVH (patient 6) and ARVC/D (patient 8) presented with mild T wave inversion (1, 5 and 4 mm), the QTc interval was not prolonged (432, 409 and 424 msec), respectively.

Corrected QT prolongation

Corrected QT prolongation defined as QTc > 450 msec. measured in lead V_2. The corrected QT interval exceeded 450 ms in 5 (452-639) with a mean of 530 ms and it was not prolonged in 3 (409, 424 and 432 ms) of the patients. The amplitude of the inverted T-wave varied significantly with the maximum negative T-wave amplitude ranging from one to 20 mm. A gradual complete resolution of the T-wave inversion and QT prolongation occurred in 5 of the patients.

Other ECG findings were as follow: two patients (patients 2 and 3) showed first degree AV block, one patient (patient 8) revealed microvoltage in the standard and limb leads, negative T wave in I and

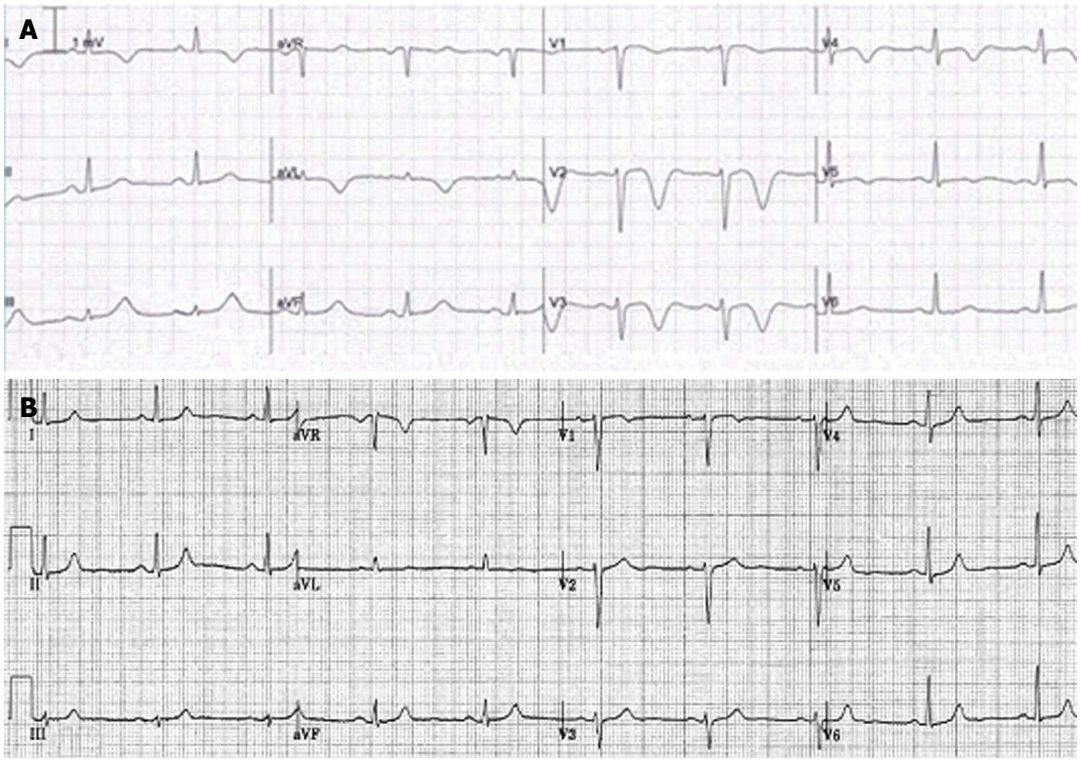

Figure 4 Patient 4. A: An electrocardiographic (ECG) tracing, demonstrating negative T wave in the precordial leads $V_{2\text{-}5}$, of a 69-year female patient with past medical history of transient ischemic attack two years previously, presented with interscapular pain. She had no emotional or physical stress. Normal results were found on transthoracic echocardiography, perfusion-ventilation scintigraphy, Coronary angiography and cardiac MRI. Brain CT scan revealed mild cerebral atrophy and minimal ischemic changes; B: The ECG showed spontaneous regression in 2 mo time. The etiology of the negative T wave inversion remains undetermined. Her medical regimen included aspirin, beta blocker, statin and diuretic.

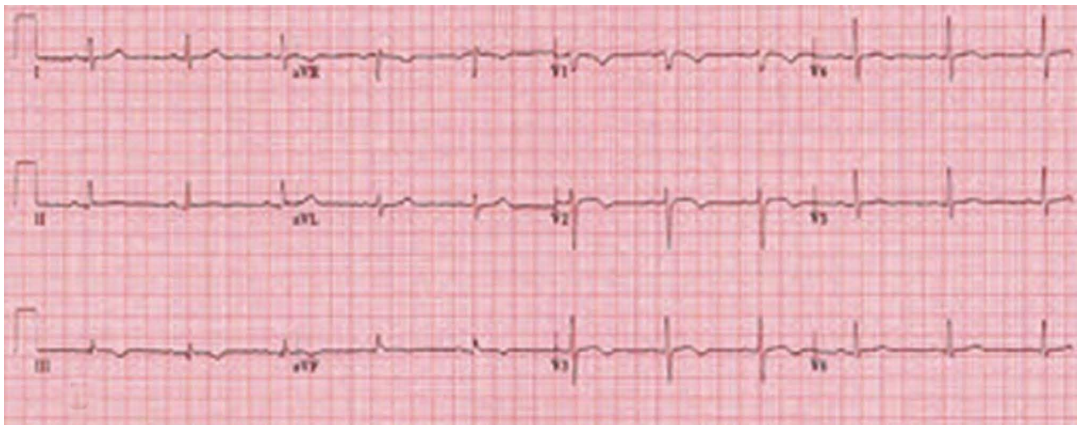

Figure 5 Patient 5. An electrocardiographic (ECG) tracing, showing negative T wave in the precordial leads $V_{1\text{-}3}$ and S_1 Q_3 T_3, of a 55-year obese male patient without antecedent medical history presented with chest pain and minimally elevated serum cardiac biomarkers. Transthoracic echocardiography revealed dilated and hypokinetic RV with pulmonary hypertension and distended inferior caval vein. Coronary angiography was normal and pulmonary CT angiography confirmed the clinical diagnosis showing massive bilateral pulmonary embolism with central and peripheral localization. A continuous positive airway pressure was implemented for newly detected severe obstructive sleep apnea syndrome. He was successfully treated with medical regimen and on follow-up he became asymptomatic and the abnormal ECG findings gradually disappeared.

aVL in 2 patients (patients 4 and 7), negative T wave in leads Ⅰ, Ⅱ, Ⅲ, aVL and aVF in (patients 1 and 3), negative T wave in II, III and aVF without (patient 5) or with (patient 6) ST segment depression.

Serum biomarkers

Cardiac troponin T were assessed. Myocardial infarction was ruled out in 7 patients. One (patient 2) with non ST elevation myocardial infarction (NSTEMI) showed typical biomarker rise and fall course with markedly elevation of troponin level. Mild elevation of troponin value was found in 4 patients (patients 3, 4, 5 and 7). No elevation was detected in 3 patients (patients 1, 6 and 8).

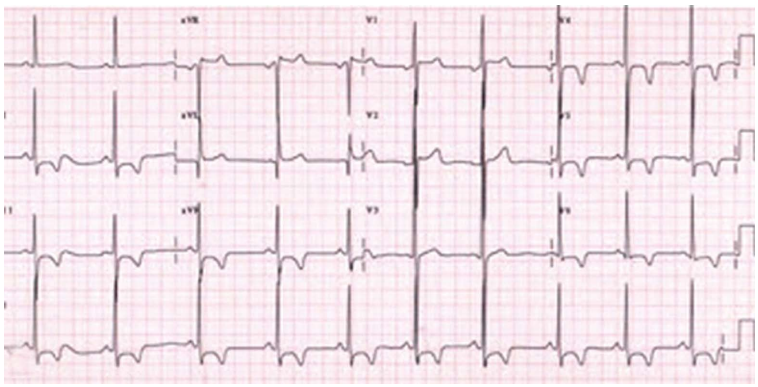

Figure 6 Patient 6. An electrocardiographic (ECG)tracing, showing voltage criteria for left ventricular hypertrophy with ST depression and negative T wave in the precordial and inferior leads $V_{3\text{-}6}$, of a 52-year female patient with non-obstructive hypertrophic cardiomyopathy (thickness of septum 20 mm and posterior wall of 24 mm without septal anterior movement or obstruction of outflow tract). Normal coronary arteries were found on coronary angiography. She refused genetic counseling and invasive intervention. She was treated medically with beta blocker.

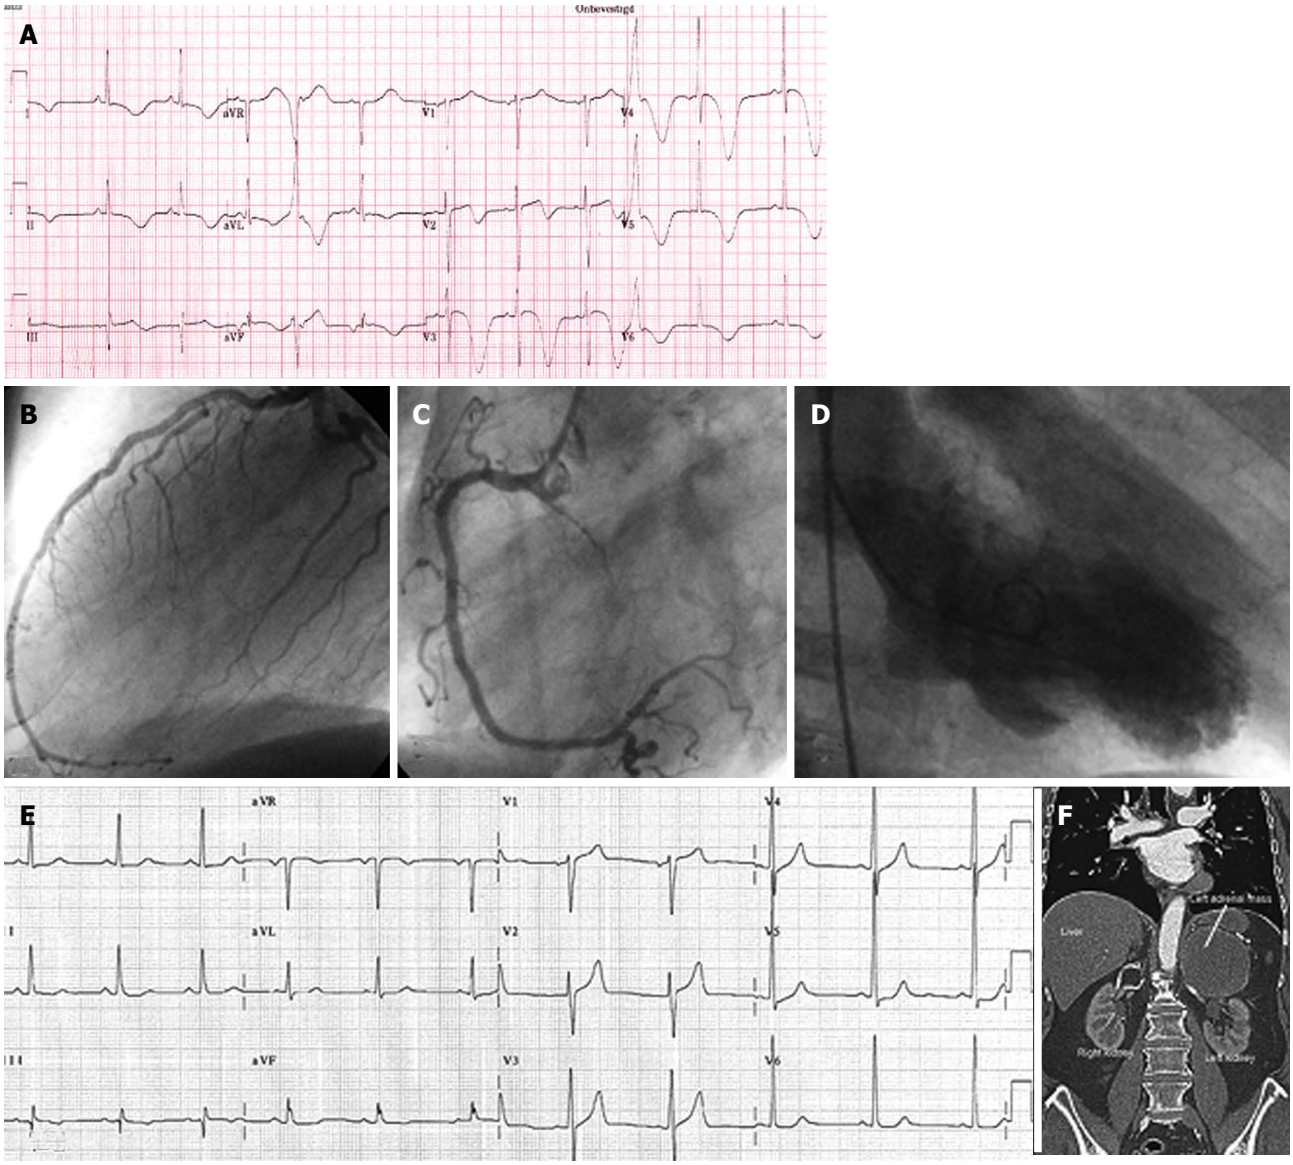

Figure 7 Patient 7. A: An electrocardiographic (ECG) tracing, showing giant T wave inversion in the precordial leads $V_{2\text{-}6}$, of a 76-year Caucasian male with a past medical history of an old inferior myocardial infarction, percutaneous coronary intervention of the right coronary artery (RCA) and left anterior descending coronary artery, acutely presented with left abdominal pain, psychomotor unrest, diaphoresis and blood pressure difference between the right and left arm. Acute aortic dissection was excluded as well as recurrent MI. Coronary angiography frame of (B) the left coronary artery and (C) the RCA depicting no significant stenosis of the arterial tree. Serum cardiac markers were slightly elevated. Echocardiographic (hypokinesia of the mid and apical regions and hyperkinesia of the basal segments) findings and (D) ventriculography (apical ballooning) were all compatible with Takotsubo cardiomyopathy; E: Base line ECG. The abdominal ultrasound and (F) CT demonstrated a pheochromocytoma in the left adrenal region which was confirmed with 123I-MIBG scan and dihydroxyphenylalanine-Positron Emission tomography and proved by pathological results. Plasma and urine metanephrin and normetanephrin were highly elevated. After removal of the hormonally active tumor, the patient became symptom free and the ECG normalized. The medical treatment continued including calcium reentry blocker, beta blocker, aspirin, angiotensin converting enzyme inhibitor, statin and an α-blocker.

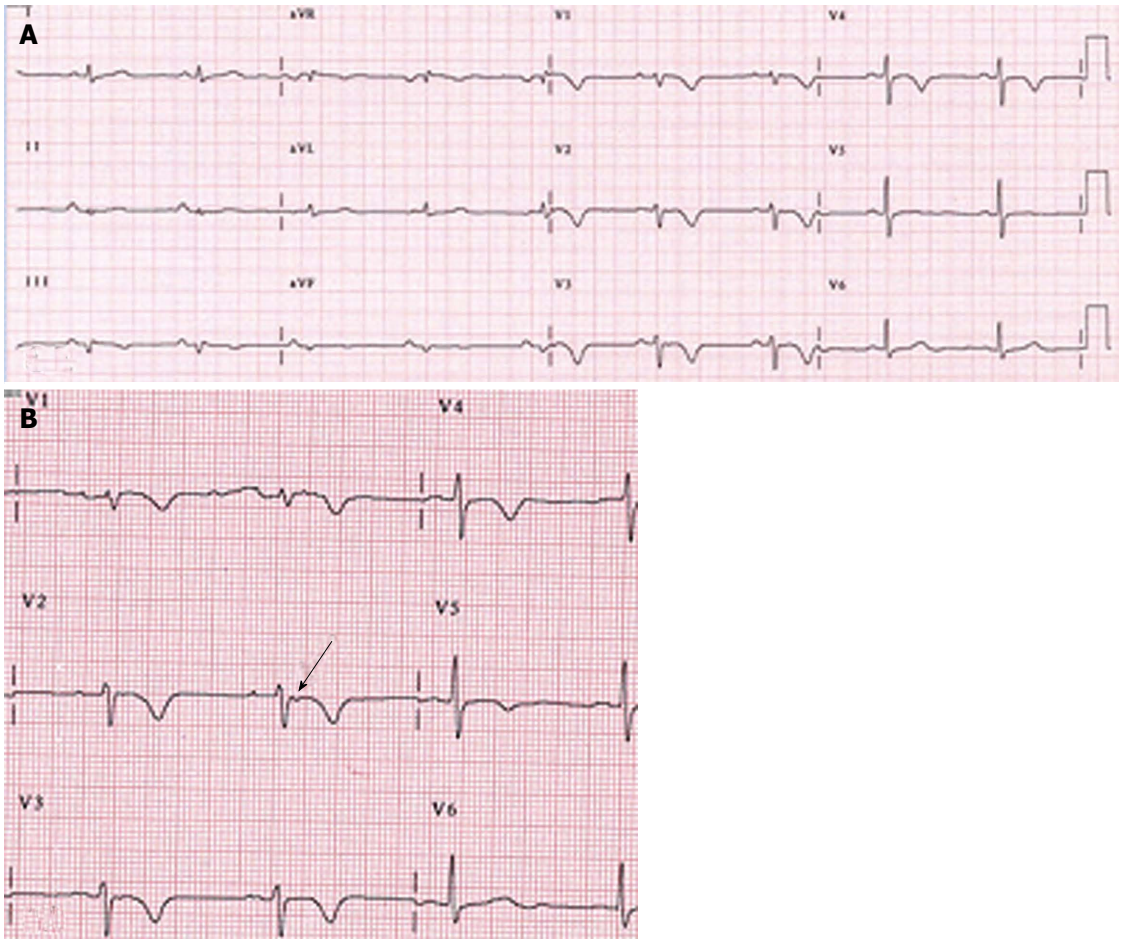

Figure 8 Patient 8. Electrocardiographic (ECG) tracing, demonstrating negative T-wave in the precordial leads V_{1-5}, microvoltage in the standard leads and an Epsilon wave (arrow) which can be appreciated on magnification of ECG lead V_2, of a 73-year-old man, amateur marathon runner after successful resuscitation for OHCA due to ventricular fibrillation. His coronary angiography and transthoracic echocardiography were normal. Genetic counseling revealed mutation 1238C > A (Tyr616X) in the plakophilline2 gen, compatible with AC. He refused implantable cardioverter defibrillator implantation and remained on medical treatment including class III antiarrhythmic drug. He was advised to refrain from marathon running and other strenuous exercise.

Transthoracic echocardiography

Transthoracic echocardiography was performed in all patients. Mild and moderate tricuspid regurgitation was detected in 6 (patients 1, 3, 4, 5, 6 and 7) and one (patient 2) of the patients, respectively. In 3 patients (patients 2, 3 and 7) trivial aortic regurgitation was present. Mild and moderate mitral regurgitation was demonstrated in 4 (patients 3, 4, 5 and 7) and 3 (patients 1, 2 and 6) patients, respectively. Dilatation of the right ventricle (RV) was demonstrated in one patient (patient 8). In five patients (patients 1, 2, 3, 4 and 5) the estimated RV systolic pressure was 35, 28, 35, 32 and 59 mmHg, respectively. Echocardiographic criteria for LVH was found in 4 patients (patients 2, 3, 6 and 7). Apical hypokinesia was detected in two patients (patients 1 and 7).

Cardiac magnetic resonance imaging

Cardiac magnetic resonance imaging was performed in three patients (patients 1, 3 and 4). All had normal findings.

Pulmonary computed tomography angiography

Pulmonary computed tomography angiography was performed in one patient (patient 5). Tailored individual diagnostic investigation was performed. In 2 patients (patients 3 and 4), pulmonary perfusion/ventilation scintigraphy were performed and pulmonary embolism was ruled out.

Computed tomography

Abdominal CT scan was performed in one which revealed an abdominal mass in the left adrenal region, a CT scan of the thoracic aorta excluding acute aortic dissection (patient 7) and brain CT scan in another (patient 4) showing mild atrophy and minimal ischemic changes.

Radionuclide imaging and positron emission tomography

One patient (patient 7) underwent ^{123}I-MIBG scan and DOPA-PET scanning. This revealed MIBG uptake in the left adrenal region and a solitary lesion was detected at the left adrenal area with central necrosis

Table 1 Demographic features, clinical presentations, diagnostic modalities and management

Case/ gender/ age	Clinical presentation	ECG (SR) T-wave inversion	QTc (msec)	Associated disorders	TTE	Diagnostic modalities	Management	Condition

AAD: Antiarrhythmic drug; ARVC/D: Arrhythmogenic right ventricular cardiomyopathy/dysplasia; AS: Aortic valvular stenosis; AVNRT: Atrioventricular nodal reentry tachycardia; BB: Beta blocker; CAD: Coronary artery disease; CAG: Coronary angiography; ECT: Electroconvulsive therapy; MM: Medical management; CRB: Calcium reentry blocker; CT: Computed tomography; ePAP: Estimated pulmonary artery pressure; F: Female; HCM: Hypertrophic cardiomyopathy; IMI: Inferior myocardial infarction; LAD: Left anterior descending coronary artery; LVH: Left ventricular hypertrophy; M: Male; MRI: Magnetic resonance imaging; NSTEMI: Non ST elevation myocardial infarction; OHCA: Out of hospital cardiac arrest; PAF: Persistent atrial fibrillation; PCI: Percutaneous coronary intervention; PCTA: Pulmonary computed tomography angiography; PET-CT: Positron emission tomography-computed tomography; PG: Peak gradient; PV scan: Perfusion-ventilation scan; RCA: Right coronary artery; RV: Right ventricle; SR: Sinus rhythm; TIA: Transient ischemic attack; TTC: Takotsubo cardiomyopathy; TTE: Transthoracic echocardiography; VF: Ventricular fibrillation; ECG: Electrocardiographic.

with DOPA-PET scanning.

Coronary angiography

Seven patients underwent selective contrast angiography which revealed non-obstructive coronary artery disease in one patient and normal coronary arterial tree in 6 patients.

Follow-up: Follow-up was obtained by direct contact with patients, general practitioner, their physicians or by chart review.

DISCUSSION

In middle-aged subjects, T-wave inversion in the precordial leads is relatively rare in the general population occurring in 0.5% (54/10899[3] of the subjects. T-wave inversion in the anterior chest wall leads is relatively common in children and adolescents[9] but infrequently found in healthy adults and is considered as "normal variants"[4]. This pattern is more common in young females and young adults (1%-3%)[14,15]. The prevalence was associated with gender difference, which was higher (0.9%) in women than in men (0.1%)[3].

Primary and secondary T-wave abnormalities

Primary T-wave abnormalities (ischemia or injury) are due to alterations in myocardial cellular electrophysiology and secondary T-wave abnormalities

(bundle branch block or ventricular Hypertrophy) are subsequent to alterations of sequence of ventricular activation.

Differential diagnosis of T-wave inversion

In the 1960s of last century, Jacobson and Schrire described the differential diagnosis of T-wave inversion that included heart block, ischemic heart disease, bradycardia, right ventricular hypertrophy, right bundle branch block, metabolic disturbances, changes during diagnostic coronary angiography and cerebral disturbances[16]. Nowadays, the current differential diagnosis of T-waves inversion has expanded including, besides the abovementioned citations of Jacobson and Schrire, LV anterior wall ischemia, acute central nervous system disorders, acute adrenergic stress (Takotsubo cardiomyopathy "TTC")[17,18], pulmonary edema[19,20], antiarrhythmic drug effects[21], pulmonary embolism[22], cardiac memory secondary to transient tachycardia[8], post-ventricular pacing states[23], idiopathic[24] or in relation to cocaine use[25,26]. In a recent review, reversible or permanent inverted T-waves were found in 38% of patients with congenital coronary artery-ventricular multiple micro-fistulas (MMFs)[27]. Hence, congenital MMFs may be included in the differential diagnosis of anterior chest wall T-wave inversion.

Transient and permanent T-wave inversion

Transient T-wave inversion may occur in the following conditions: Acute coronary syndrome[1], cardiac memory T-wave[8,23], cardiogenic non-ischemic pulmonary edema[19], gastroenteritis[28], post max-illofacial surgery[29], subarachnoid hemorrhage[30], electroconvulsive therapy[31-33], Takotsubo cardio-myopathy[18,34], pheochromocytoma[35] and indeter-minate origin[24]. On the other hand, permanent T-wave inversion may accompany a variety of disorders associated with LV or RV cardiomyopathy such as apical hypertrophic cardiomyopathy (AHCM)[4,7,36,37] and arrhythmogenic right ventricular cardiomyopathy/dysplasia[38-41].

Non-coronary cardiac and non-cardiac disorders

Several non-coronary cardiac and non-cardiac diso-rders have been associated with the development of T-wave inversion. Among the Non-coronary cardiac disorders: are pericarditis, myocarditis, cardiac metastasis, athletic heart syndrome, AHCM[4], hyper-trophic cardiomyopathy[37], post-tachycardia and right ventricular pacing (cardiac memory)[8,23].

Prognosis

In the middle-aged population, inverted T-wave in the right precordial leads V_{1-3} was associated with good prognosis in contrast to inverted T-wave in leads other than V_{1-3} which predicted adverse outcomes such as increased risk of hospitalization due to congestive heart failure and coronary artery disease[3]. Fisch *et al*[42], stated that inverted shallow asymmetric T-wave with the descending limb longer than the abruptly ascending limb seen in middle-aged women are not associated with cardiac disease.

Non-coronary non-cardiac disorders

Non-coronary non-cardiac disorders (T-wave wide asymmetric and associated with prolonged QT interval) include severe brain injury (subarachnoid hemorrhage "SAH", intracranial hemorrhage)[30,43], traumatic head injury, maxillofacial surgery[29], bilateral carotid endarterectomy, after vagotomy, cocaine abuse[44], flecainide use[21], pheochromocytoma[45] and gastrointestinal emergencies (perforated ulcer, acute pancreatitis and acute cholecystitis)[28,46-49].

Transient T-wave inversion

Acute coronary syndrome[1]: T-wave inversion in the precordial leads have been reported since 1982 as narrow, sharp, and symmetrical waves; the so called "coronary type" reflecting high-grade stenosis of the proximal left anterior descending coronary artery due to regional delay in ventricular repolarization as generally found in ischemic heart disease[50,51]. In this condition, T-wave inversion may persist for days or weeks.

Cardiac memory pattern: Memory T wave was first presented by Chatterjee *et al*[52], in 1969 in 94% of patients with intermittent right ventricular pacing. Transient T-wave inversion occurring after conversion to sinus rhythm from tachycardia or artificial pacing which is caused by abnormal ventricular activation. This pattern of transient T-wave inversion in the precordial leads is associated with tall T-wave in leads I and aVL and are common in patients with permanent pacemakers or ensue after recovery from ventricular or supraventricular tachycardia[23]. It is a diagnosis of exclusion. This pattern of T-wave inversion in RV pacing is caused by dyssynchronous LV activation and involvement of potassium ion channels are postulated to be the key issues in its pathogenesis[53].

Electroconvulsive therapy: ECT may induce ECG changes with simultaneous echocardiographic regional wall motion abnormalities especially when arterial blood pressure and heart rate are markedly elevated[54]. It has been reported that transient T wave inversion Occurs in 4% of the patients undergoing ECT[55]. Transient T-wave inversion, not associated with cardiac abnormalities, has been reported due to increased sympathetic stimulation associated with ECT[31,32]. Conversely, Tuininga reported two cases of T-wave inversion following ECT with significant obstructive coronary artery disease requiring anti-anginal therapy and percutaneous coronary intervention[33]. It was recommended that further investigation to rule out significant coronary

artery disease should be performed especially in patients with cardiovascular risk factors. Moreover, transient T-wave inversion has been reported after electroconvulsive therapy but not following transthoracic direct current electrical cardioversion for treatment of atrial fibrillation[56]. In representative case (patient 1), the findings of CAG and cardiac MRI were normal.

Cardiac sarcoidosis: Cardiac sarcoidosis (CS) is a systemic inflammatory disease with unknown etiology characterized with non-caseating granulomas in multiple organ systems and may be associated with negative T-wave in the anterior precordial leads.

Subarachnoid hemorrhage: In the 1960s, electrocardiographic changes mimicking myocardial ischemia and infarction associated with spontaneous intracranial hemorrhage have been reported[57]. Reversible T-wave abnormalities accompanied with prolongation of QT interval were found in 32% of patients with SAH[30]. ECG changes and arrhythmias occurred within the first 48 h after SAH[43,58]. The postulated pathogenesis is cardiomyocytolysis due to excessive sympathetic stimulation. Possible mechanisms[30] are autonomic neural stimulation from the hypothalamus and elevated levels of circulating catecholamine. The care of patients with subarachnoid hemorrhage has improved dramatically over the last few decades. These gains are the result of improved microsurgical, endovascular, and medical management techniques. This intensive management subjects patients to multiple radiographic studies and thus increased radiation exposure. Thus, tailored diagnostic modalities are required for early and correct establishment of the diagnosis. This to avoid over exposure to ionizing radiation and other invasive procedures. T-wave abnormalities in patients suffering SAH are subsequent to TTC secondary to elevated levels of circulating catecholamine and excessive sympathetic stimulation[29].

Pulmonary embolism: Acute pulmonary embolism may occasionally result in reversible deep T-wave inversion with QT interval prolongation[59]. T-wave inversion associated with PE was first described in 1938 by Love *et al*[60]. T-wave inversion in the precordial leads have been noticed in a moderate-size PE[61], partially occlusive[22] and non-occlusive[23] PE. Precordial T-wave inversion was the most common abnormal ECG finding (68%), this anterior wall ischemic pattern was found in 85% of massive PE and in 19% of mild-moderate PE followed by S1 Q3 T3 pattern detected in 54% of the patients[62]. The proposed mechanisms include RV strain and decreased perfusion of LV anterior wall caused by hypotension consequent to pulmonary embolism[63]. The above mentioned findings were present in the patient with PE (patient 5).

Diagnostic workup for T-wave inversion should always focus on the most likely causes and patient individually tailored diagnostic program should be followed. This to avoid and to limit unnecessary radiation exposure including diagnostic invasive cardiac catheterization.

Pulmonary edema: T wave inversion in the precordial leads has rarely been reported: Possible postulated mechanisms are: an acute rise in the cardiac sympathetic tone either *via* an increased sympathetic discharge from the central nervous system or through subendocardial ischemia due to elevated wall stress, high end-diastolic pressure and decreased coronary arterial blood flow and the electrical heterogeneity in the ventricular wall[19].

Pheochromocytomas: Pheochromocytomas are catecholamine secreting tumours that arise from the chromaffin cells of the adrenal gland. Biochemical diagnosis is established by measuring plasma free metanephrins or nor-metanephrin levels. Localization of the tumour is reached by performing computed tomography or magnetic resonance imaging scans and specifically using metaiodibenzylguanidine scan. The latter is considered the gold standard. Finally, it is confirmed by histopathologic examination[64]. Occasionally, pheochromocytoma may resemble acute coronary syndrome[35,65]. Pheochromocytoma-related cardiomyopathy has incidentally been reported with inverted takotsubo contractile pattern[45]. In patient No. 7, diagnosed with pheochromocytoma (Figure 7F) presented with chest pain and psychomotor agitation, showed periodic fluctuations of blood pressure and ECG abnormalities mimicking acute coronary syndrome (Figure 7A) without significant obstructive coronary artery disease (CAD) on his CAG (Figure 7B and C).

Pheochromocytomas are rare neuroendocrine tumours with a highly variable clinical presentation but most commonly presenting with bouts of headaches, sweating, palpitation and hypertension. Imaging techniques such as CT or MRI and functional assessments using ^{123}I-MIBG are applied to localize biochemically active tumors. In our patient (patient 7), full recovery occurred after left adrenalectomy was successfully performed in an academic hospital. The deepest T-wave inversion (Figure 7A) was found in this patient.

Takotsubo cardiomyopathy: TTC in relation to neurohormonal active adrenal tumor pheochromocytoma or after pulmonary resection for bilateral non-small cell lung neoplasms has rarely been reported[45,66]. TTC accounts for 2% of total hospital admissions for suspected acute coronary syndrome[67]. It Accounts for approximately 1% of admissions for suspected acute myocardial infarction in Japan[68]. Satoh *et al*[69] and Dote and

associates first described this syndrome in Japanese patients[70]. In 2001, Tsuchihashi *et al*[17] reported on cardiomyopathy with apical ballooning mimicking acute myocardial infarction (MI) without obstructive epicardial CAD, 97% of patients demonstrated T-wave inversion in the precordial leads with female predominance (86%). They observed that in 70% of the subjects there was a preceding heavy psychological or physical stress[17]. While the pathogenesis of TTC is not fully understood and remains to be elucidated, several hypotheses, including multivessel epicardial coronary artery spasm, storm of catecholamine excess and coronary microvascular disorder have been proposed[17,71,72]. In a comparison between patients with acute MI and heart failure and patients admitted with a LV systolic dysfunction after sudden emotional stress (95% female subject), Wittstein *et al*[18], found CAD in only 5% in the latter group with significantly higher plasma catecholamine levels suggesting a relation between an exaggerated sympathetic stimulation and transient LV dysfunction[18]. The following criteria are required for establishing the diagnosis TTC; transient LV systolic dysfunction frequently emerging following a stressful trigger, not associated with significant obstructive CAD, novel ECG changes with ST-segment elevation or T-wave inversion usually accompanied with slightly elevation of cardiac markers and no signs of myocarditis and pheochromocytoma[73-75]. Occasionally, in the hyperacute phase of TTC, transient J wave may precede T-wave inversion[72]. Diagnostic work-up may include history, ECG, echocardiography, CAG, ventriculography and less frequent Cardiac magnetic resonance imaging[76]. Cardiac MRI has been useful to differentiate stress TTC from anterior ST-Elevation MI with segmental wall necrosis, by absence of late enhancement in the former condition on delayed image sequence. Other pivotal MRI findings for the diagnosis of TTC are diffuse edema of the left ventricular apical or mid wall associated with akinesia or hypokinesia and absence of perfusion defects[34]. Furthermore, T2-weighted MRI delineated the ECG characterizations (dynamic negative T waves and QTc prolongation) in TCC, resembling the ischemic-like Wellens' ECG pattern, correlating with the apicobasal gradient of myocardial edema, reflecting the edema-induced transient apicobasal inhomogeneity[77]. Recently, positron emission tomography computed tomography has been used to differentiate takotsubo cardiomyopathy TTC from acute coronary syndrome[78]. TTC may occur subsequent to aneurysmal subarachnoid hemorrhage[79]. The relation between TTC and SAH is well known. Many reports have shown the reversible pattern of T-wave inversion associated with SAH[29,78].

Athletic heart: In 1899, Henschen[80] described cardiac enlargement in cross-country skiers. Several ECG changes have been observed in athletes engaged in high intensity dynamic endurance sport activities which may mimic pathological and structural heart diseases. Among others, T-wave inversion in the precordial leads and relative bradycardia were reported[81]. Echocardiographic features of athletic left ventricular hypertrophy may include mild concentric LVH, mild LV dilatation, normal diastolic filling and normal systolic function[82]. It is important to distinguish between physiological adaptive ECG changes and pathological ECG abnormalities to prevent unnecessary distress [83,84]. Regression of LVH occurs when athletes decide to decondition. Some authors consider this adaptation of endurance sports athletic heart as pathologic since LVH regresses on cessation of endurance training in a similar response to a successful treatment of aortic stenosis or arterial hypertension[85].

Permanent T-wave inversion

Arrhythmogenic right ventricular hypertrophy was first described by Dalla volta *et al*[86] in 1961 in Italy and it was brought comprehensively under attention by Frank *et al*[87] in 1978. They reported individuals with extending fibro-fatty non-ischemic changes of the right ventricle. Sudden death may be the first sign of disease[88]. Prevalence is 1/5000 individuals[89]. They have an autosomal dominant or recessive mode of inheritance with incomplete penetrance. ARVC/D affects mainly the right ventricular myocardium characterized with progressive fibro-fatty replacement and infiltration of the RV myocardium and is considered a major cause of sudden arrhythmic death. Recently, involvement of the left ventricle at a later stage may be associated with severe manifestation and carry a worse prognosis[90]. It has been suggested by Gallo *et al*[91] and others for the implementation of a broader term as arrhythmogenic cardiomyopathy (AC)[91,92]. In AC, two major criteria or one major and 2 minor criteria are required to establish the diagnosis[38]. T wave inversion may be the first presentation[3]. Recently, in 2010, the revised task force criteria and guidelines for the clinical diagnosis of AC have been updated and T-wave inversion in the right precordial leads V_{1-3} or beyond was upgraded to a major criterion, in subjects > 14 years of age in the absence of complete right bundle branch block[93], as was found in patient No. 8. The 12-lead ECG demonstrated abnormal changes in 90% of the cases with T-wave inversion in V_{1-3} and sometimes across V_6 as the most common finding[38]. Right precordial T-wave inversions were present in 48%-85% of suspected subjects and Epsilon wave (terminal notch in the QRS complex due to slowed intraventricular conduction) was found in 8%-33% of patients with AC[38-40] as was the case in patient No. 8. In subjects with AC, global and or regional dysfunction and structural alterations may be detected by echocardiography,

angiography, radionuclide scintigraphy or MRI. Cardiac MRI has a high negative predictive value with sensitivity of 100% and specificity of 87%[94]. Mutations in the genes responsible for coding of connecting proteins, called desmosomes are the culprit. In the Dutch population, a founder mutation of p.Arg79X in plakophillin-2 (PKP2) gen with the same desmosome gene mutation in AC has been described[95]. Analysis of DNA in patient No. 8, showed a mutation of plakophillin-2 gen (1248C>A Tyr 616X). Rarely, cardiac sarcoidosis may mimic AC[96].

Apical hypertrophic cardiomyopathy[4,7,36,37]**:** It Is also called (Yamaguchi syndrome) and is considered a rare variant of hypertrophic cardiomyopathy. In the majority of cases (93%) of AHCM, negative T-wave in the precordial leads is the most frequent finding[7]. Its prevalence (15%) in Japan is high in comparison to the United States (3%)[97] and in Europe (< 5%)[98]. Giant negative T-wave exceeding 10 mm is found in 47% of patients with AHCM[7]. Typical findings were first described by Sakamoto in 1976[99] and Yamaguchi *et al*[100] in 1979. In the retrospective study of Eriksson *et al*[7], T-wave inversion was found in (98/105) 93% of the patients. Apical wall thickness of 15 mm was based on TTE or MRI measurements. The T-wave inversion is permanent without tendency for recovery. The permanent ECG features of AHCM are among others giant negative T waves in the precordial leads, ST depression and negative U waves in Ⅱ, Ⅲ, aVF, V4-V6, a prolonged QTc and tallest R wave in V4; however, these permanent features may vary over time[101].

Awareness of the differential diagnosis of T-wave inversion in the precordial leads will help trainees and physicians to discern different entities and will prevent some patients from undergoing unnecessary invasive investigations and procedures. Tailored individual diagnostic investigation was performed and specific diagnostic tools were undertaken when high index of clinical suspicion was raised towards a certain disease entity.

COMMENTS

Background

Myriad of clinical conditions have been described in association with T-wave inversion in the precordial leads. T-wave inversion associated with or without corrected QT prolongation may be encountered in a variety of clinical conditions.

Research frontiers

In patients with T-wave inversion in the precordial leads, tailored diagnostic approach should be conducted avoiding overuse of diagnostic methods. Specific tailored diagnostic modalities and directed therapeutic interventions may be undertaken when high index of clinical suspicion is raised towards certain disease entity.

Innovations and breakthroughs

This study is a retrospective analysis of patients presented with T-wave inversion in the anterior chest leads. The T-wave inversion may be accompanied with or without QTc prolongation. Classification has been made into reversible and irreversible types to facilitate its differential diagnostic approach.

Applications

Awareness of the differential diagnosis of T-wave inversion in the precordial leads will help trainees and physicians to discern different entities and will prevent some patients from undergoing unnecessary invasive investigations and procedures.

Peer-review

In this paper, authors report the various clinical conditions of patients with T wave inversion in the anterior chest wall leads. This review article is interesting and very educational.

Abstract

Pulmonary arterial dissection is an uncommon but usually a deadly complication of chronic pulmonary hypertension. A 26-year-old female patient was admitted to our clinics with sudden dyspnea and chest discomfort one hour after giving birth to twins by vaginal delivery. An echocardiography was performed with a pre-diagnosis of pulmonary embolism. However, echocardiographic examination revealed a dilated main pulmonary artery and a dissection flap extending from main pulmonary artery to left pulmonary artery. In summary, in this report, we described a very rare case of pulmonary artery dissection in a pregnant patient with a previously un-diagnosed patent ductus arteriosus without an obvious rise in pulmonary artery pressure and reviewed the relevant literature.

Key words: Pulmonary dissection; Patent ductus arteriosus; Pregnancy; Echocardiography; Computed tomography

Core tip: A 26-year-old female patient was admitted to our clinics with sudden dyspnea and chest discomfort one hour after giving birth to twins by vaginal delivery. Dilated main pulmonary artery and dissection flap extending from main pulmonary artery to left pulmonary artery were found in echocardiographic examination, there after, pulmonary dissection was confirmed by a computed tomography and the patient underwent surgery. In summary, in this report, we described a very rare case of pulmonary artery dissection in a pregnant patient with a previously un-diagnosed Patent ductus arteriosus without an obvious rise in pulmonary artery pressure and reviewed the relevant literature.

INTRODUCTION

Pulmonary arterial dissection is an uncommon but usually a deadly complication of chronic pulmonary hypertension. However, with the development of diagnostic and therapeutic interventions in recent

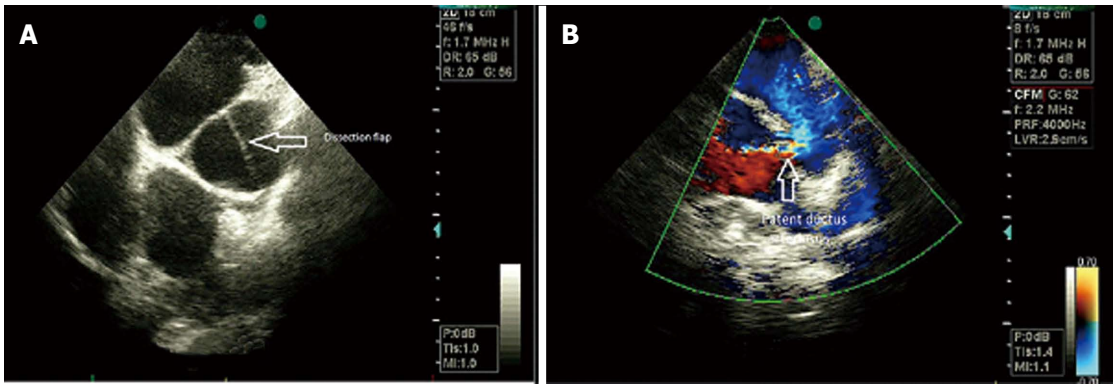

Figure 1 Echocardiographic views of pulmonary dissection (A) and patent ductus arteriosus (B).

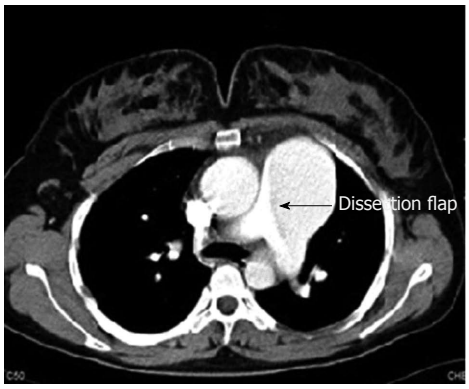

Figure 2 Computed tomography views of pulmonary dissection.

years, a few reports in surviving patients with pulmonary artery dissection have been reported[1].

Patent ductus arteriosus (PDA) is a congenital anomaly caused by a failure to close of a fetal vessel which connects the pulmonary artery directly to the ascending aorta after birth. A rare but lethal complication of PDA is pulmonary artery dissection and dissection usually occurs as a result of chronic pulmonary arterial hypertension associated with PDA and is typically seen in patients with Eisenmenger's syndrome[2-5]. In this report, we described pulmonary artery dissection in a pregnant patient with a previously un-diagnosed PDA without an obvious rise in pulmonary artery pressure.

CASE REPORT

A 26-year-old female patient was admitted to our clinics with sudden dyspnea and chest discomfort one hour after giving birth to twins by vaginal delivery. She had no previous medical history. On physical examination, her blood pressure was 100/60 mmHg and pulse rate was 125/min. The ECG was consistent with sinus tachycardia. An echocardiography was performed with a pre-diagnosis of pulmonary embolism. However, echocardiographic examination revealed a dilated main pulmonary artery and a dissection flap extending from main pulmonary artery to left pulmonary artery (Figure 1A). Besides, in suprasternal and parasternal views, a PDA was observed (Figure 1B). Moderate tricuspid regurgitation was present with a peak continuous wave velocity 2.7 m/s. A thorax computed tomography examination was then performed which showed the dissection flap and the false lumen in the main pulmonary artery (Figure 2). The patient underwent emergent surgery after clarifying the diagnosis. A Dacron graft was positioned in the main pulmonary artery and the PDA was closed. She was discharged from the hospital at the 12th post-operative day. She was in a good clinical condition and asymptomatic at her regular policlinic controls.

DISCUSSION

PDA is a congenital heart disease resulting from the postnatal closure defect of the ductus arteriosus. It represents 5%-10% of all congenital heart diseases, with a female-to-male ratio of 2:1. Delayed treatment may lead to certain complications including pulmonary hypertension, Eisenmenger's syndrome, congestive heart failure, and infective endarteritis. Though rare, pulmonary artery dissection may also be included in the above list of complications.

Posing a high mortality risk, pulmonary artery dissection results from congenital heart diseases, pulmonary hypertension and cardiac interventions[1]. Right heart endocarditis, amyloidosis, trauma and severe atherosclerosis may also result in pulmonary artery dissection[6]. The most common cause is pulmonary hypertension associated with congenital heart disease. Interestingly, in our case, the patient did not have pulmonary hypertension.

The main pulmonary artery is involved in 80% of the pulmonary artery dissection cases. However, isolated cases with right or left pulmonary artery involvement can also be seen. Localized small dissections are rare. Because rupture causes cardiogenic shock and sudden death, diagnosis is rare in the living subject and pulmonary artery dissection is frequently detected in autopsy[5]. Khattar *et al*[1] stated that only

8 (12.6%) out of 63 cases were diagnosed to have pulmonary artery dissection while living, and that 34 (53.9%) of the cases had congenital heart disease[1]. In our case report, pulmonary dissection was reliably diagnosed by transthoracic echocardiography, and thereafter the diagnosis was confirmed by computed tomography examination.

Pulmonary artery dissections usually occur in patients with medial degeneration and pulmonary arterial dilatation due to chronic increases in pulmonary arterial pressures[7-10]. Medial degeneration is a common cause of weakened pulmonary arterial wall and dilatation of the vessel and if intravascular pressure and shear stresses increase due to pulmonary hypertension, intimal tear may develop and cause dissection in the arterial wall. In our case, we thought that pregnancy predisposed the patient to dissection due to weakening of the connective tissue and pulmonary dissection occurred during difficult twin labour which increases venous return and blood pressure in the alreadily dilated pulmonary bed due to PDA.

In aortic dissection, the false lumen usually extends distally and develops a re-entry site. However, in pulmonary dissection, the false lumen usually ruptures causing sudden death of the patient[7-10]. Cardiac tamponade due to rupture seems to be the most common mechanism of death in case of pulmonary dissection[10]. We were lucky because our patient survived this serious clinical situation.

For the first time in literature, we reported a very rare case of pulmonary dissection after giving birth to twins. Presence of PDA without an obvious increase in pulmonary arterial pressures made us think that a transient increase in venous return and pressure during labour caused the dissection to occur. With the development of new imaging techniques providing high quality images in acceptably short time intervals, this mortal disease has become to be diagnosed before death. Moreover, successful repair of pulmonary dissection with surgery has been reported in recent reports including ours. In conclusion, the success of early diagnosis and surgical intervention in pulmonary dissection necessitates an increased awareness of this highly mortal condition.

COMMENTS

Case characteristics

A post-partum patient with sudden dyspnea and chest discomfort after giving birth was admitted.

Clinical diagnosis

Tachycardia and a systolic murmur were found on physical examination.

Differential diagnosis

Pulmonary embolism, aortic dissection.

Imaging diagnosis

Echocardiography and computed tomography were used for the diagnosis of patent ductus arteriosus and pulmonary dissection.

Treatment

Surgical treatment for pulmonary dissection and patent ductus arteriosus closure was performed.

Related reports

Few reports are present about pulmonary dissection in the literature and this is the first report regarding the presence of pulmonary dissection in a post-partum patient without an obvious rise in pulmonary arterial pressures.

Experiences and lessons

An increased awareness of pulmonary dissection with a view to early diagnosis and corrective intervention is necessary in selected cases.

Peer-review

It is an excellent work.

Abstract

A 65-year-old man developed chest pain under cardiogenic shock. Coronary angiography revealed severe stenosis from the ostium of the left main coronary artery (LMCA) to the left anterior descending artery (LAD). Intravascular ultrasound (IVUS) identified a large hematoma that originated from the aorta and extended into the LAD, thereby compressing the true lumen. Type A aortic dissection (TAAD) that involved the LMCA was diagnosed by IVUS. Coronary stenting was performed *via* the LMCA to the proximal LAD, which resulted in coronary blood flow restoration and no further propagation of dissection. Elective surgical aortic repair was performed 2 wk after the stenting. LMCA stenting under IVUS guidance is effective for prompt diagnosis and precise stent deployment in patients with cardiogenic shock due to TAAD with LMCA dissection.

Key words: Aortic dissection; Left main coronary artery; Myocardial infarction; Intravascular ultrasound; Coronary artery stenting

Core tip: Type A aortic dissection (TAAD) involving the left main coronary artery (LMCA) is a rare but potentially lethal condition. However, the precise diagnosis of TAAD prior to the treatment of acute myocardial infarction is difficult, and percutaneous intervention for LMCA obstruction secondary to TAAD is often complicated. This case report represents successful LMCA stenting under intravascular ultrasound (IVUS) guidance in a patient with cardiogenic shock due to TAAD with LMCA dissection. This procedure, particularly in terms of the use of IVUS, may be effective for rapid hemodynamic stabilization in patients in critical condition.

Coronary stenting with cardiogenic shock due to acute ascending aortic dissection. *World J Cardiol* 2015; 7(2): 104-110 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i2/104.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i2.104

INTRODUCTION

Acute myocardial infarction (AMI) concomitant

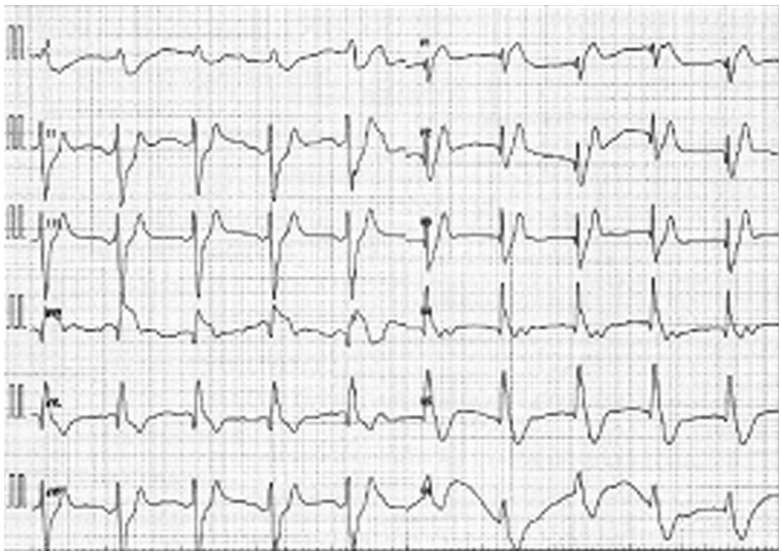

Figure 1 Electrocardiogram on admission. Electrocardiogram shows an idioventricular rhythm with wide QRS complexes. A clear ST elevation is shown in lead aVR.

with acute type A aortic dissection (TAAD) is associated with a high hospital mortality rate despite improvements in TAAD surgical outcomes[1-3]. In particular, TAAD involving the left main coronary artery (LMCA) is a rare but lethal condition associated with low output syndrome, which results from extensive myocardial necrosis regardless of whether an aortic repair surgery is successful. Early coronary revascularization should be performed to minimize cardiac dysfunction[3]. The treatment of dissected coronary arteries with stent implantation achieves prompt and adequate myocardial blood flow and helps prevent extensive myocardial damage. However, an accurate diagnosis of TAAD prior to treatment for AMI is difficult, particularly in patients with hemodynamic instability[4,5]. Furthermore, percutaneous coronary intervention for LMCA obstruction due to TAAD is a complicated procedure unless the mechanism of the LMCA obstruction has been clarified[6]. Here, we describe a case of successful coronary intervention under intravascular ultrasound (IVUS) guidance in a patient with shock due to an unusually localized TAAD with LMCA obstruction.

CASE REPORT

A 65-year-old man was admitted due to sudden-onset chest pain accompanied with cold sweats. The patient had previously undergone a drug-eluting stent implantation in the left anterior descending artery (LAD) 5 years earlier to treat stable angina. His hypertension and hyperlipidemia were well controlled with medication, and he had continued dual antiplatelet therapy (DAPT) since the stent implantation. The patient was transported by ambulance to our hospital within an hour of onset, and his status on arrival included an unmeasurable blood pressure below 60 mmHg and a heart rate of 50 beats/min. The initial electrocardiogram demonstrated bradycardia with an idioventricular rhythm, wide QRS complexes, and ST elevation in the lead aVR (Figure 1). Transthoracic echocardiography (TTE) revealed marked left ventricular dysfunction and a left ventricular ejection fraction of < 30% based on visual estimation. No aortic intimal flap, severe aortic regurgitation, or pericardial effusion was observed. The patient was immediately transferred to the cardiac catheterization laboratory because of ongoing myocardial ischemia and hemodynamic instability. An intra-aortic balloon pump was immediately inserted into the left femoral artery, and coronary angiography was performed from the right femoral artery without difficulty. The right coronary artery did not exhibit stenosis or collateral vessels. The left coronary artery exhibited severe stenosis from the ostium of the LMCA to the proximal LAD, which involved the ostium of the left circumflex artery (LCX) with TIMI grade 1 flow (Figure 2). Coronary intervention was subsequently performed. Run-through NS guidewire (Terumo, Tokyo, Japan) and SION guidewire (Asahi Intecc, Aichi, Japan) were inserted into the LAD and LCX, respectively. To confirm the wire position and evaluate the LMCA obstruction, IVUS (ViewIT, Terumo, Tokyo, Japan) was performed with quick pull-back. The IVUS revealed a large hematoma that originated from the aorta and extended into the LMCA and LAD (Figure 3A-C). The true lumen was compressed by the false lumen throughout the LAD immediately prior to the bifurcation of the diagonal branch (Figure 2D). A large intramural hematoma that involved the ostium of the LCX (Figure 3B) continued into the aortic wall in accordance with the double contour image in the coronary angiogram (Figure 3). We diagnosed an LMCA obstruction due to TAAD; thus, we decided to place a stent for immediate restoration of the coronary blood flow followed by aortic surgery. A 4.0- × 22.0-mm bare metal stent (Integrity; Medtronic, Minnesota, United States) was deployed *via* the

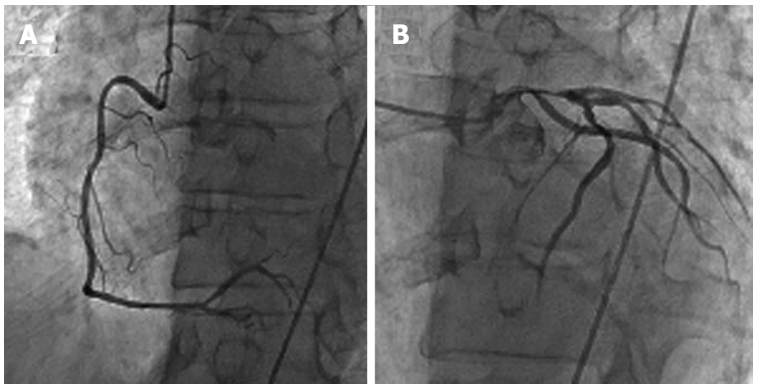

Figure 2 Urgent coronary angiography. A coronary angiography of RCA reveals no stenosis (A), but there is severe stenosis from the ostium of the left main coronary artery to the LAD with TIMI grade 1 flow (B). RCA: Right coronary artery; LMCA: Left main coronary artery; LAD: Left anterior descending artery; TIMI: Thrombolysis in myocardial infarction.

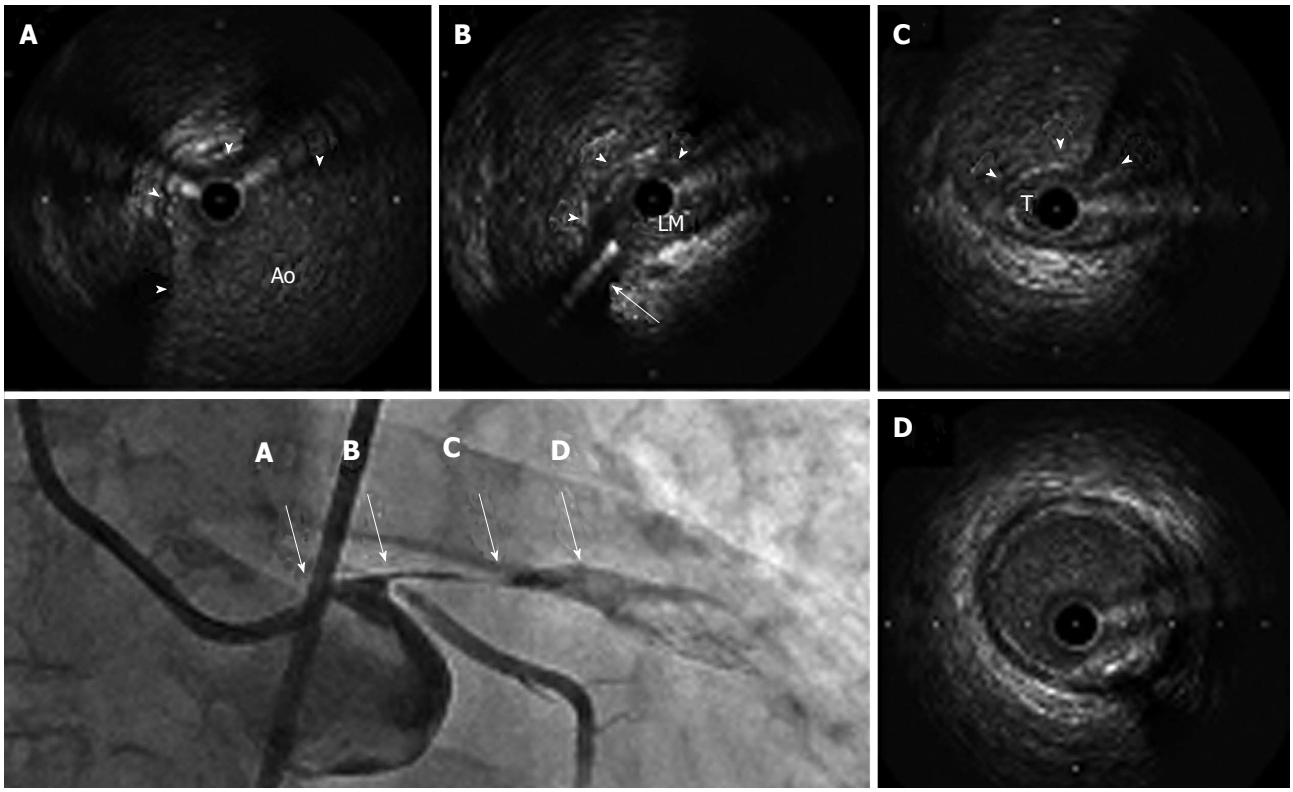

Figure 3 Coronary angiography and intravascular ultrasound findings prior to stent implantation. IVUS shows compression of the true lumen from the LMCA ostium to the LAD by a large false lumen. A: The large hematoma (arrowhead) eviscerates into the aorta (Ao); B: The false lumen (arrowhead) compresses the LMCA (LM), including both the LAD and LCX ostium. The arrow indicates the guidewire in the LCX; C: The large false lumen (arrowhead) compresses the true lumen (T) in the proximal LAD; D: The false lumen disappears before the bifurcation of the diagonal branch. Scale measures in 1 mm. IVUS: Intravascular ultrasound; LCX: Left circumflex artery; LAD: Left anterior descending artery.

LMCA through the LAD across the LCX ostium with satisfactory restoration of coronary blood flow. IVUS confirmed that the implanted stent appeared well-expanded and completely sealed the false lumen. No propagation of the false lumen into the distal LAD or the ostium of the LCX was observed (Figure 4). The patient's hemodynamic failure and symptoms improved immediately after stenting. We removed the intra-aortic balloon pump immediately after hemodynamic stabilization because of the potential exacerbation of TAAD. Contrast-enhanced computed tomography (CT) following the coronary intervention revealed a localized retrograde dissection of the ascending aorta that extended to the ostium of the LMCA (Figure 5). The implanted stent protected the LMCA ostium from TAAD. Marked lung congestion was present. The following day, the patient's maximum creatine kinase and creatine kinase-myocardial band levels were 16190 and 829 IU/L, respectively. The DAPT comprised aspirin (100 mg/d) and clopidogrel (75 mg/d). An elective ascending aortic repair surgery was performed pending improvement of congestive heart failure under continued DAPT 2 wk after coronary stenting. Ascending aortic replacement with an interposition vascular prosthesis graft was performed; coronary artery bypass grafting (CABG), which included the left internal thoracic artery (LITA) to the distal portion of the LAD and a

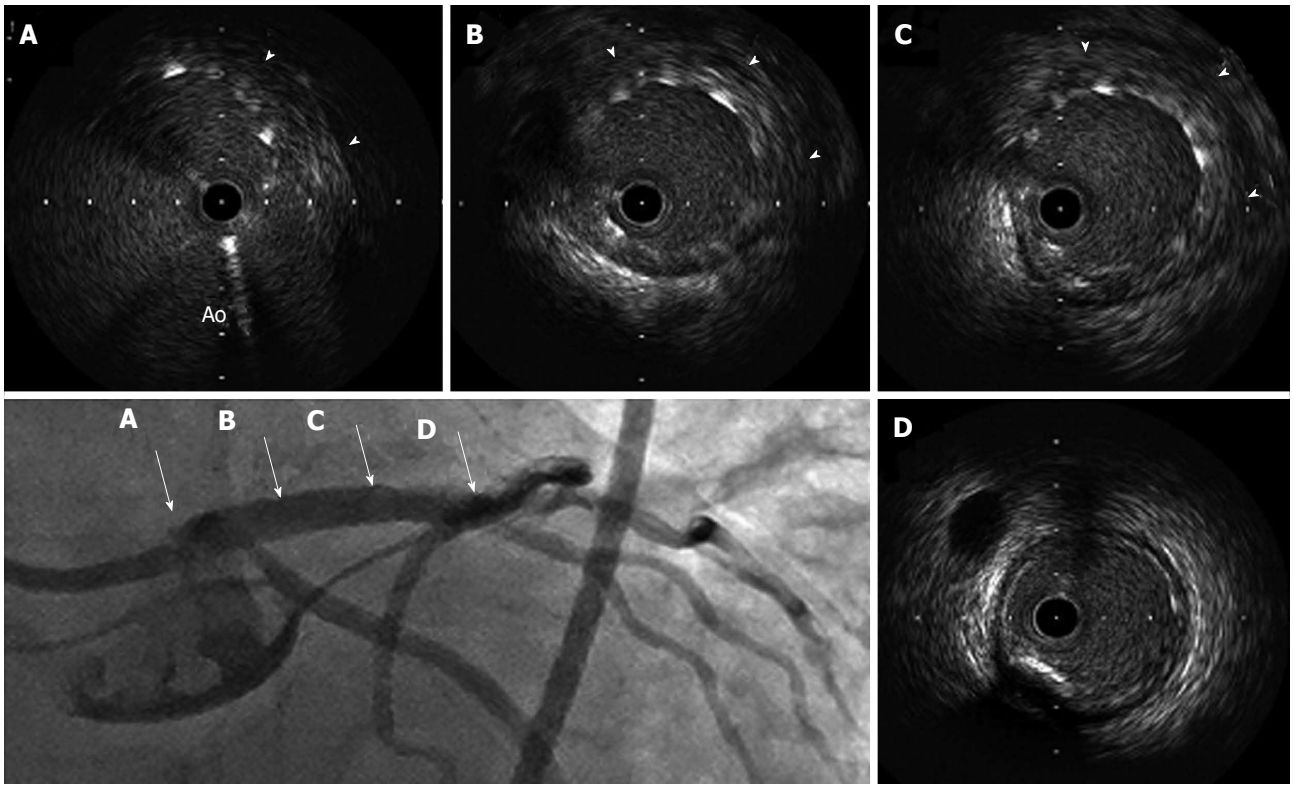

Figure 4 Coronary angiography and intravascular ultrasound findings after stent implantation. The implanted stent appears to be well expanded and completely seals the false lumen. There was no evidence of distal propagation of the false lumen or a flow limitation of the LCX. A: The hematoma (arrowhead) in the aorta is well covered by the stent; B, C: Implanted stent completely sealed the hematoma (arrowhead); D: No extension of the hematoma beyond the stent. Scale bars represent 1 mm.

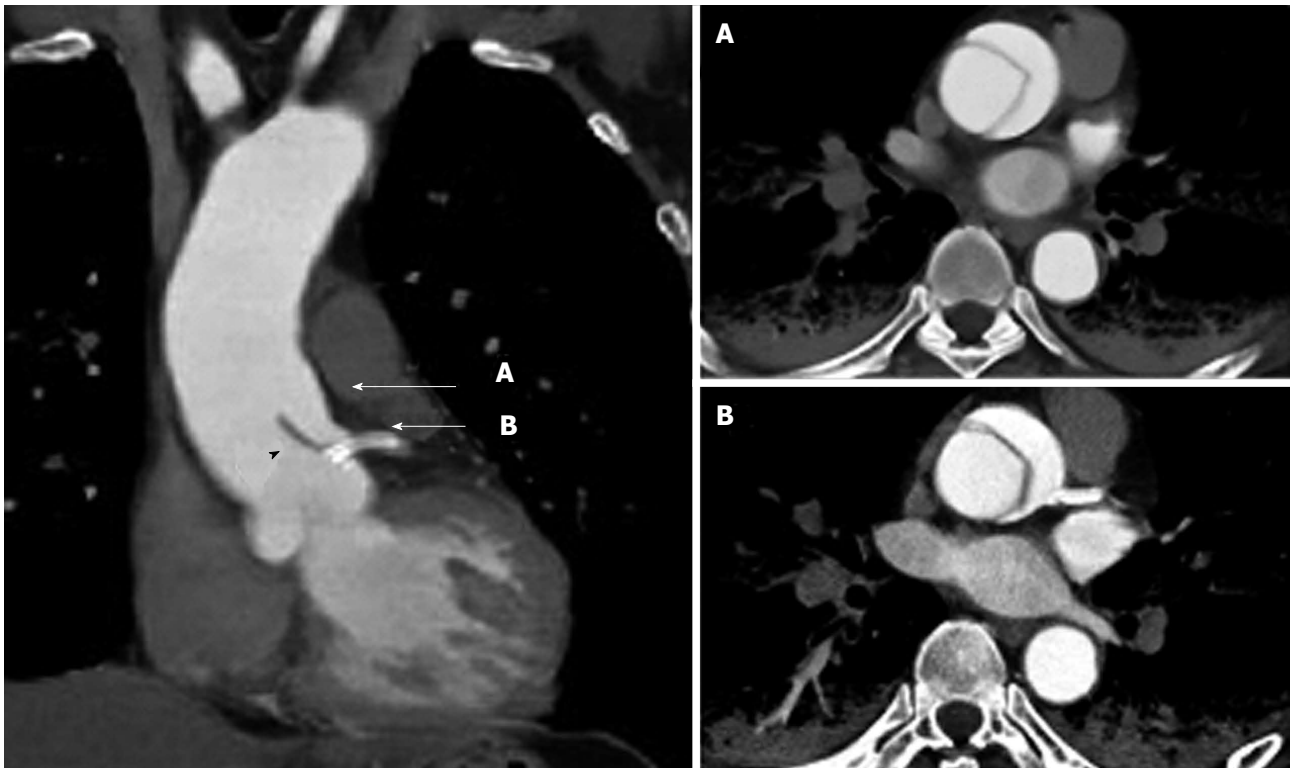

Figure 5 Contrast-enhanced computed tomography after coronary stenting. The sagittal view (left image) reveals the localized dissection of the ascending aorta that extends to the left main coronary artery ostium. The implanted coronary stent (arrow) protects against the intrusion of the dissection flap (black arrowhead) into the left coronary artery. Ascending aortic dissection is clearly visible in the horizontal view (right images) in accordance with A and B in the sagittal view.

Table 1 Previously reported cases of coronary stenting for left main coronary artery due to acute ascending aortic dissection

Ref.	Patient (age/sex)	Hemodynamic status	Timing of diagnosis	Diagnostic modality	Timing of operation	CABG	Outcome

PCI: Percutaneous coronary intervention; CABG: Coronary artery bypass graft; CT: Computed tomography; TEE: Transesophageal echocardiogram.

saphenous vein graft (SVG) to the middle portion of the LCX, was performed at the surgeon's discretion. Intraoperatively, an intimal tear in the ascending aorta with the false lumen that extended to the ostium of the LMCA was identified without an intimal rupture or aortic valvular destruction. Satisfactory restoration of the intracoronary stent for the left coronary artery and wide patency of the ostia of the left and right coronary arteries were visibly confirmed at the time of surgery. The intraoperative bleeding volume was 1230 mL, which necessitated a blood transfusion of 650 mL. The patient was discharged 51 d after admission. The physical status at the one-month follow-up visit was characterized as New York Heart Association class 1 despite a high concentration of brain natriuretic peptide (400 pg/mL: normal range < 20 pg/mL). The TEE demonstrated reduced antero-septal wall motion; however, the overall ejection fraction recovered to 50%. A follow-up coronary angiography 6 mo after discharge revealed that the left coronary artery maintained excellent blood flow without in-stent restenosis. The SVG was patent; however, the LITA revealed shrinkage as a non-functional bypass.

DISCUSSION

AMI with TAAD is associated with a high risk of extensive and irreversible myocardial damage and hemodynamic instability, which leads to high mortality regardless whether the surgical repair is successful[1,2]. TAAD that involves the LMCA is associated with a particularly high incidence of preoperative cardiopulmonary arrest and high operative mortality[3]. Postoperative low output syndrome due to extensive myocardial damage from AMI involving the LMCA is a major concern in surgical management. Although stent implantation in the treatment of dissected coronary arteries achieves immediate restoration of coronary blood flow and prevents extensive myocardial damage, the confirmation of the correct diagnosis and the performance of the optimal treatment procedure remain challenging[7-9] (Table 1).

AMI with shock might be overlooked as an underlying factor of TAAD[4]. The diagnosis of TAAD with concomitant AMI is difficult because TAAD may be hidden in patients in critical condition. The present patient did not have back pain or a widened mediastinum on the chest X-ray obtained for suspected TAAD. Furthermore, the TTE revealed no evidence of localized TAAD. Although early revascularization should be strongly considered for patients with AMI secondary to cardiogenic shock[10], subsequent thrombolytic therapy and/or coronary intervention can be complicated in patients with underlying TAAD[5]. CT is recommended as the first line of investigation for patients with suspected TAAD. However, CT imaging is more time consuming for critical shock patients with an ST segment elevation myocardial infarction[11]. TTE is also useful; however, it is a limited screening technique for the quick diagnosis of TAAD because of the unavoidable operator dependency, reduced image resolution, and limited field of view[12]. The IVUS findings in the present case enabled the determination of the precise diagnosis of TAAD with typical findings of coronary artery compression[13,14].

Although coronary stenting is helpful in patients with TAAD, it remains challenging because of technical difficulties. The technical issues regarding coronary stenting include the navigation of the guidewire through the true lumen. IVUS imaging can be used to detect the orifice of the dissection, confirm the correct wire placement in the true lumen, and assist in the determination of the precise stent position, size, and length in a short time. Inappropriate ballooning or stenting that fails to completely seal the dissection might propagate the false lumen to the distal or proximal region. Repeated contrast injections should also be avoided because the extension of the dissection may result in the deterioration of the patient's condition[15].

Imoto *et al*[3] reported that preoperative cardiopulmonary arrest and myocardial ischemia, particularly of the left coronary artery territory, negatively affected the survival outcomes in patients undergoing surgery for TAAD with coronary artery dissection. Early coronary intervention *via* stent implantation effectively prevents postoperative low cardiac output

syndrome. Several bridge approaches to surgery have consequently been developed to facilitate early coronary intervention and reduce the extent of myocardial cell necrosis.

The timing of surgical repair for TAAD after coronary stenting is important. A delay in surgical repair may lead to the propagation and rupture of the aortic dissection. Prompt intervention can serve as a bridge approach to gain time for critically unstable patients prior to definitive surgery. In contrast, perioperative stent thrombosis is a serious complication that is associated with a significant increase in mortality, particularly in LMCA stenting. This complication is caused by antiplatelet therapy discontinuation and a surgery-induced prothrombotic situation. DAPT is necessary after coronary artery stenting, particularly in the acute phase. Hansson *et al*[16] studied the association of antiplatelet therapy with bleeding complications and mortality in patients undergoing operations for TAAD. The patients with ongoing platelet inhibition had significantly larger intraoperative and postoperative bleeding volumes; furthermore, the patients on DAPT had high 30-d mortality rates. In the present case, surgical aortic repair was performed after 2 wk while DAPT was continued. The duration of DAPT may be shortened, thus reducing bleeding during aortic surgery, by using a large bare metal stent with IVUS guidance to confirm the proper stent apposition. However, premature cessation of DAPT is likely to induce critical stent thrombosis. The addition of CABG is encouraging even after successful recanalization with stenting during the preparation for stent thrombosis after aortic surgery[3]. The optimal timing of surgical repair, the duration of DAPT and the efficacy of CABG addition after coronary artery stenting have not been established (Table 1).

LMCA stenting prior to the surgical repair of TAAD with LMCA dissection could be effective for an immediate improvement in hemodynamic instability. We emphasize the use of IVUS during the treatment of AMI because LMCA obstruction is necessary to exclude the presence of TAAD.

COMMENTS

Case characteristics

A 65-year-old male with a history of sudden-onset chest pain with hemodynamic instability.

Clinical diagnosis

The shock status, peripheral coldness and electrocardiogram indicated a severe myocardial infarction with hemodynamic instability.

Differential diagnosis

Coronary artery disease with or without coronary atherosclerosis, for example coronary spasm, thrombosis, or Takotsubo cardiomyopathy.

Laboratory diagnosis

The cardiac enzyme levels were extremely elevated after the catheter procedure, with the following results: WBC 21.6 k/uL; AST 1706 U/L; LDH 2945 U/L; CK 16190 U/L; CK-MB 829 U/L; and D-dimer 10.18 μg/mL.

Imaging diagnosis

The intravascular ultrasound (IVUS) findings during coronary intervention revealed a large hematoma that originated from the aorta and extended into the left main coronary artery (LMCA) and left anterior descending artery. An enhanced computed tomography scan revealed a localized retrograde dissection of the ascending aorta that extended to the ostium of the LMCA.

Pathological diagnosis

No specimen materials were collected.

Treatment

The patient was treated with a percutaneous coronary intervention and surgical procedure.

Related reports

Type A aortic dissection (TAAD) involving the LMCA is rare; however, there are a few case reports of the efficacy of LMCA stenting prior to surgical repair for immediate improvement in hemodynamic instability.

Experiences and lessons

The use of IVUS during acute myocardial infarction secondary to LMCA obstruction is effective for not only achieving appropriate stenting but also excluding the presence of TAAD.

Peer-review

A well-written and interesting case report nicely outlining management strategy of acute myocardial infarction secondary to involvement of left main coronary artery by type A acute aortic dissection.

Abstract

Accumulating data have shown that elimination of atrial fibrillation (AF) sources should be the goal in persistent AF ablation. Pulmonary vein isolation, linear lesions and complex fractionated atrial electrograms (CFAEs) ablation have shown limited efficacy in patients with persistent AF. A combined approach using voltage, CFAEs and dominant frequency (DF) mapping may be helpful for the identification of AF sources and subsequent focal substrate modification. The fibrillatory activity is maintained by intramural reentry centered on fibrotic patches. Voltage mapping may assist in the identification of fibrotic areas. Stable rotors display the higher DF and possibly drive AF. Furthermore, the single rotor is usually consistent with organized AF electrograms without fractionation. It is therefore quite possible that rotors are located at relatively "healthy islands" within the patchy fibrosis. This is supported by the fact that high DF sites have been negatively correlated to the amount of fibrosis. CFAEs are located in areas adjacent to high DF. In conclusion, patchy fibrotic areas displaying the maximum DF along with high organization index and the lower fractionation index are potential targets of ablation. Prospective studies are required to validate the efficacy of substrate modification in left atrial ablation outcomes.

Key words: Ablation; Atrial fibrillation; Persistent; Substrate; Dominant frequency

Core tip: A combined approach using voltage, complex fractionated atrial electrograms and dominant frequency mapping may be helpful for the identification of atrial fibrillation sources, and therefore for sufficient substrate modification in patients with persistent atrial fibrillation undergoing left atrial ablation.

Catheter ablation of persistent atrial fibrillation: The importance of substrate modification. *World J Cardiol* 2015; 7(3): 111-118 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i3/111.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i3.111

INTRODUCTION

Catheter ablation of atrial fibrillation (AF) is indicated in patients with symptomatic AF, refractory or intolerant to at least one class Ⅰ or Ⅲ antiarrhythmic medication[1-3]. Indications for catheter ablation of AF have expanded to include increasingly complex cases including patients with long-standing persistent AF and structural heart disease. Circumferential pulmonary vein antral isolation (PVAI) has become a standard therapy for paroxysmal AF[4]. On the contrary, PVAI displays a significantly lower success rate in patients with persistent or long-lasting persistent AF[1,2,5,6]. This difference suggests that the mechanisms underlying the maintenance of persistent AF are different in relation to paroxysmal AF. Recently, catheter ablation of stable rotors or focal sources in individuals with paroxysmal and persistent AF has given promising results[7-9]. Additional substrate modification is therefore required in the setting of persistent AF. However, the optimal ablation approach in these complex cases remains uncertain.

PATHOPHYSIOLOGY OF AF

AF represents the final common phenotype for multiple disease pathways and mechanisms that are incompletely understood. The multiple re-entrant wavelet hypothesis as a mechanism of AF was described by Moe and colleagues in 1959[10] with supportive experimental work by Alessie[11]. The "multiple re-entrant wavelet hypothesis" supports that fractionation of wavefronts propagating through the atria results in self-perpetuating "daughter wavelets". Multiple re-entrant wavelets are separated by lines of functional conduction block. The lines of the conduction block can occur around the anatomical structures within the atria with different inherent electrophysiological properties, such as scars, patchy fibrosis and myocardium, at different stages of recovery and excitability. However, this hypothesis can not easily explain why AF exhibits consistent spatial non-uniformities in rate and activation vector[12-14], how ablation may terminate AF relatively early in some cases before compartmentalization of meandering wavelets[1,6], or why extensive ablation often has little acute impact[1,15]. Alternatively, the "localised source hypothesis" is supported by elegant experiments in which localised spiral waves (rotors)[16,17] or focal sources[14] disorganise into AF. Stable microreentrant sources appears to be the most likely underlying mechanism of AF in experimental models[18,19]. Recent developments of patient-tailored and physiology-based computational mapping systems have identified localized electrical spiral waves, or rotors, and focal sources as mechanisms that may represent novel targets for therapy[7-9].

Studies have emphasised the importance of ion channel remodelling, changes in signalling pathways, oxidative stress, altered calcium handling, changes in atrial architecture, and altered connexin expression in the pathogenesis and maintenance of AF[20,21]. AF in turn causes AF-promoting abnormalities in each of these areas and enhances the vulnerability of the heart to AF induction and maintenance (AF begets AF)[21]. In particular, structural remodeling is characterized by atrial enlargement and tissue fibrosis. The presence of interstitial fibrosis leading to changes in cellular coupling results in spatial "non-uniform anisotropic" impulse propagation and is a potential cause of atrial activation abnormalities that may underlie the initiation and perpetuation of re-entrant arrhythmias including AF[22,23]. As AF progresses from paroxysmal to persistent, the atrial substrate becomes increasingly abnormal and displays a more prominent role in maintaining the arrhythmia[1,20,21]. In patients with persistent AF, a better understanding of arrhythmia mechanisms is therefore needed so that ablation approaches can be targeted to a clearly shown mechanism.

LEFT ATRIAL ABLATION

Pulmonary vein antral isolation

Despite the evolution of left atrial ablation strategies, PVAI remains the cornerstone of in both paroxysmal and persistent AF ablation procedures[1,2]. Isolation of wide circumferential areas around both ipsilateral pulmonary veins (PVs) with verification of conduction block is more effective than isolation of each individual PV using a segmental approach[4]. A lower success rate of PVAI as a stand-alone strategy has been reported in patients with persistent or long-lasting[1,2,5,6]. However, relatively new data on this topic have given contradictory results. The RASTA study have demonstrated that additional substrate modification beyond PVAI including ablation of non-PV triggers and ablation of complex fractionated electrogram sites does not improve single-procedure efficacy in patients with persistent AF[24]. The recently published STAR AF Ⅱ trial has clearly showed that additional substrate modification (fractionated atrial electrograms or linear lesions) following PVAI has no benefit in AF reduction[25]. A high incidence of PV reconnection is similarly observed in patients with and without recurrence of AF[26], suggesting that sustained PV isolation is not required for freedom from clinical recurrence of AF. This finding may be explained by the important substrate modification performed after the circumferential lines. In CONFIRM trial, AF sources were ablated coincidentally in 45% of cases after wide area circumferential ablation and left atrial roof line in persistent AF cases[8]. These data provide an alternative potential explanation for why PVAI treats AF in some patients and not others. Elimination of AF sources may explain why wide-area ablation is more

effective than ostial PV isolation, why AF may not recur in patients whose PVs have reconnected, why non-PV encircling lines or fractionated electrogram ablation may be effective and, potentially, why ablation success correlates with the extent of ablated tissue in persistent AF[8].

Linear lesions

Based on surgical MAZE procedures, linear lesions including roof and mitral isthmus lines have been also adapted in percutaneous left atrial ablation procedures providing additional substrate modification[27]. The additional benefit of linear lesions on top of ostial PV isolation has been prospectively demonstrated[28,29]. However, in these studies an ostial and not a wide circumferential PV isolation was performed. The intrapulmonary region has been also implicated as an important source of PV triggers[30]. In a randomized study, we investigated the efficacy of additional radiofrequency energy delivery in the interpulmonary isthmus following PVAI[31]. A continuous line in the interpulmonary isthmus connecting the anterior and the posterior part of the ipsilateral circumferential line creating a "theta" model (the Greek letter θ) was performed. Although patients with additional energy delivery in the interpulmonary isthmus displayed a better long-term outcome (free from arrhythmia recurrence), this was not statistically significant. Nevertheless, left atrial linear lesions remain technically challenging. Incomplete linear lesions may have a proarrhythmic effect[5,6]. Most atrial tachycardias result from gaps in the ablation lines.

DIRECT SUBSTRATE MODIFICATION STRATEGIES

Voltage mapping: Identification and modification of heterogeneous substrate and local barriers

As previously stated, interstitial fibrosis play a key-role in the pathophysiology of AF[22,23]. Delayed enhancement-cardiac magnetic resonance imaging (DE-CMRI) has demonstrated fibrosis and scarring in the left atrium of patients undergoing AF ablation[32,33]. Among patients with AF undergoing catheter ablation, atrial tissue fibrosis estimated by DE-CMRI has been independently associated with likelihood of recurrent arrhythmia[34,35]. Electroanatomic bipolar voltage mapping has been described to define the relationship between anatomic and electrophysiological abnormalities. Although, specific bipolar and unipolar voltage cut-off values have been reproducibly shown to accurately identify scar and/or fibrosis in the ventricles, data regarding voltage cut-off values in the atria are limited. In preliminary studies, the bipolar voltage cut-off value were set at < 0.05 mV for the identification of atrial scar, partly influenced by the background noise from early electroanatomic mapping systems, and < 0.5 mV for low-voltage regions[36,37]. In a recent study, the global mean left atrial bipolar and unipolar voltage amplitude in SR was 2.83 ± 2.25 and 4.12 ± 2.14 mV, respectively; 95% of all bipolar and unipolar electrograms recorded from the LA were > 0.50 and > 1.57 mV, respectively[38]. There was no difference in the segmental distribution of low-voltage areas between patients with AF and healthy controls. Jadidi *et al*[39] have demonstrated bipolar voltages of 0.63 ± 0.8 in dense DE-CMRI areas, compared with 0.86 ± 0.89 in non DE-MRI areas. These measurements were performed during AF. By using both electroanatomic mapping system and DE-MRI, Spragg *et al*[32] have demonstrated that the mean atrial voltage in areas identified as scar by DE-MRI was 0.39 ± 0.61 mV, while in areas identified as normal by DE-CMRI was 1.38 ± 1.23 mV. In a similar study, a bipolar voltage of < 0.38 ± 0.28 mV was associated with fully scarred atrial myocardium[40]. Kapa *et al*[41] using electroanatomic mapping along with DE-CMRI have shown that a bipolar voltage cut-off of 0.27 mV performed best for delineating scar (sensitivity: 90%, specificity: 83%).

Substrate mapping in patients with postinfarction cardiomyopathy and ventricular tachycardia may involve lowering the voltage cut-off that defines the scar in order to identify "channels" of relative higher voltage within the scar[42,43]. Conducting channels within the unexcitable scar areas (particularly those displaying late potentials) are considered as an appropriate ablation target[43]. In a similar way, scar homogenization may be also performed in left atrium. Rolf *et al*[44] have recently shown that catheter ablation at low voltage areas aiming to homogenize the diseased left atrium in addition to PVAI resulted in better long-term outcomes compared to PVAI alone. Catheter ablation of stable rotors in patients with paroxysmal and persistent AF has given promising results[7-9]. It is quite possible that these stable sources correlate with areas of atrial fibrosis where the site-specific micro-architecture of connective tissue fibres and the remaining myocardial fibres allows reentrant/rotor activation to occur and to sustain. The combination of localizing atrial fibrosis plus mapping of specific functional areas allowing re-entrant/rotor activation may hold promise for catheter based AF substrate modification in the future.

Mapping and ablation of complex fractionated atrial electrograms

Complex fractionated atrial electrograms (CFAEs) are seen in all forms of AF (paroxysmal and persistent). The underlying mechanisms of CFAEs remain controversial. Two leading hypothesis have been proposed for CFAEs formation. First, the "rotor hypothesis" where the rotor encounters heterogeneous substrate (*e.g.,* dispersion of refractoriness), and the CFAEs are the by-product of the reentrant rotor that breaks down at its boundary; the posterior left atrium is a histologically and

electrically complex region, in which firing from the PVs meets regions of functional block due to anisotropic conduction. The atrial signals in the area of this line of block are frequently fractionated[45]. As paroxysmal AF progresses to persistent AF, the progressive fibrotic and microarchitectural changes determine the propagation, collision, and fragmentation of the wave front as it emanates from focal triggers[46]. Second, the "autonomic hypothesis" where CFAEs indicate sites of ganglionated plexi[47,48]. Lin *et al*[48] showed in a canine model that CFAEs can be produced locally at the site where acetylcholine was topically applied. Moreover, CFAEs can be eliminated by ablating the GP at a distance, indicating that activating the "network" of the intrinsic cardiac autonomic nervous system may be a critical element in the formation of CFAEs.

The use of CFAEs has become an important tool in the clinical electrophysiology laboratory to guide catheter ablation of AF sources. However, their clinical significance is questionable. In Nademanee's original report, CFAEs were defined as (1) fractionated electrograms composed of >2 deflections and/or perturbation of the baseline with continuous deflection of a prolonged activation complex; and (2) atrial electrograms with very short cycle length (< 120 milliseconds)[49]. Nademanee *et al*[49] have demonstrated 92% freedom from AF one year after CFAEs ablation without PV isolation after two procedures. This level of success has not been reproduced by other groups. Ablation of CFAE as a stand-alone ablation strategy seems insufficient for the treatment of patients with persistent AF[50,51]. In addition, there are clear data that CFAEs ablation as an adjunct therapy to PVAI does not improve the success rate of left atrial ablation[52]. As previously reported, the recently published STAR AF II trial has clearly showed that additional substrate modification (fractionated atrial electrograms or linear lesions) following PVAI has no benefit in AF reduction[25].

Whether certain subtypes of CFAE, such as those exhibiting continuous fractionation or particular types of activation gradients, are more important than others is not known[53]. Using multipolar catheters and monophasic action potentials (MAPs) to define local activation and repolarization, Narayan *et al*[54] identified four types of CFAEs in human AF: (1) CFAEs with discrete rapid MAPs and pansystolic local activation (8%); (2) CFAEs with discrete MAPs after AF acceleration (8%); (3) CFAEs pattern with distinct MAPs and dissociated superimposed signals consistent with far-field electrograms (67%); and (4) CFAEs pattern without discrete MAPs (17%), consistent with spatial disorganization. CFAEs with discrete MAPs and pansystolic activation had shorter cycle length and lower voltage and trended to have higher dominant frequency than other CFAEs sites. The majority of CFAEs were the result of superimposed far-field atrial activations from overlying atrial structures. In contrast, only a small proportion of CFAEs exhibited rapid, discrete, organized MAP recording activity consistent with an AF driver. Jadidi *et al*[39] have elegantly shown that the distribution of fractionated electrograms is highly variable, depending on direction and rate of activation. Fractionation in sinus rhythm and pacing rhythms mostly resulted from wave collision. All sites with continuous fractionation in AF displayed normal voltage in sinus rhythm, suggesting absence of structural scar[39]. Thus, many fractionated electrograms are functional in nature, and their sites dynamic. The same group of investigators has demonstrated an inverse relationship between fractionated electrograms and atrial fibrosis in persistent atrial fibrillation[55]. Ninety percent of continuous CFAE sites occur at non-delayed-enhancement and patchy delayed-enhancement LA sites. Finally, there are many limitations arising from the definition of CFAEs. Lee *et al*[56] aimed to determine the prevalence and spatial correlation of CFAEs using two definitions: (1) multicomponent/continuous electrograms; and (2) AF cycle length < 120 ms. Multicomponent/continuous electrograms and sites of short CL activity (< 120 ms) identified different atrial regions.

Dominant frequency mapping

Dominant frequency (DF) mapping is aimed at identifying localized sites of high DF during AF[57]. Initial reports using optical mapping systems have identified the presence of localized regions of high-frequency activity demonstrating spatiotemporal periodicity which may act as drivers of AF[19]. Most importantly, the highest DF using spectral analysis of the biatrial electrogram correlates well with the rotor frequency observed during optical mapping[58], suggesting that this technique of signal decomposition and DF analysis may allow identification of reentrant circuits sustaining AF. Sites of high DF typically show rapid periodicity but lack significant fractionation[47]. In paroxysmal AF, the high DF sites are more prevalent within the PVs, whereas in persistent AF, the high DF sites commonly exist within the left atrium[57]. Retrospective analyses have shown that ablation at such high DF sites results in slowing and termination in a significant proportion of paroxysmal AF patients, indicating their role in AF maintenance[57,59,60]. The higher AF recurrence rate in patients with non-ablated high DF sites at the end of the procedure supports the important role of extrapulmonary sites in persistent AF maintenance[60].

Sites showing DFs that were at least 20% higher than their surrounding points were identified as primary and secondary high DF sites[57,59,60]. Two indices from fast Fourier transform (FFT) power spectrum analysis describe the degree of organization within AF: (1) the regularity index, defined as the ratio of the area under the dominant peak in the power spectrum to the total area[47]; and (2) the organization index, a ratio consisting of the sum of the areas under the dominant peak and its harmonics divided by the

total area[61].

High DF sites typically show rapid periodicity but lack significant fractionation[47]. Kumagai *et al*[62] have shown that high DF sites and continuous CFAEs sites overlap in only 14% of mapped areas after PVAI. Lee *et al*[56] have demonstrated a poor direct spatial correlation between sites of multicomponent/continuous electrograms and sites of high DF, with only 23.1% of multicomponent/continuous electrograms sites occurring at the same location as a site of high DF. Spatial analysis confirmed that the vast majority (84%) of the multicomponent/continuous electrograms sites occurred directly adjacent (< 2.5 mm) to a site of high DF[57]. If high DF identifies a focal source, then visual fractionation may represent wave front breakup at the periphery. Stiles *et al*[63] reported similar findings. Correlation between CFAEs and DF was poor. Exploration of their spatial relationship demonstrates CFAEs in areas adjacent to high DF (within 10 mm in 80% and 10-20 mm in 10%). Lin *et al*[64] demonstrated that the most consistent CFAEs activity is observed near maximum DF sites and that the core of the widely distributed continuous CFAEs is correlated with the sites of maximum DF. Maximal fractionated sites are observed in the center or the boundary region of maximum DF sites.

High DF sites have been negatively correlated to the amount of fibrosis, whereas fractionation index was positively correlated with fibrosis in the posterior left atrium[65]. Atrial fibrosis as defined by DE-CMRI have been associated with slower and more organized electrical activity but with lower voltage than healthy atrial areas[55]. As suggested by Koduri *et al*[65], the increased regularity of electrograms (indicated by increased organization index) in the presence of slower activation rates (indicated by lower DFs and higher fractionation index sites) in experimental heart failure models may indicate the presence of regions of underlying fibrosis.

Currently, there are several limitations of DF mapping as an ablation strategy. These factors include lack of high-resolution mapping to precisely locate DF sites, real-time analysis of DF, and spatiotemporal stability of DF sites[66].

HOW TO PERFORM SUBSTRATE MODIFICATION IN PERSISTENT AF ON TOP OF PVAI?

Summarizing the above data, it's clear that the additional substrate modification involving linear lesions and CFAEs sites in patients with persistent AF is debatable. Based on the recent findings by Narayan's group[7-9], elimination of AF sources (principally rotors) should be the goal in persistent AF ablation. How can we localize these AF sources with current diagnostic modalities? A combined approach using voltage, CFAEs and DF mapping may be helpful for this purpose. Voltage mapping may assist in the identification of fibrotic areas. Tanaka *et al*[67] have demonstrated that the largest fibrotic patches and the PV ostia are potential anchoring sites for "micro-anatomical" reentry. In their experiments, the fibrillatory activity is maintained by intramural reentry centered on fibrotic patches and that it appeared at the posterior left atrial wall as breakthroughs. The average area of fibrosis in the periphery is significantly larger than in the center. Differences in voltage amplitude may be important to identify relatively healthy areas within the patchy fibrotic tissue. For this purpose, upper and the lower voltage thresholds have to be decreased in decrements.

Stable rotors display the higher DF and possibly drive AF[18,19,57,58]. Furthermore, the single rotor is usually consistent with organized AF electrograms without fractionation[68]. It is therefore quite possible that rotors are located at relatively "healthy islands" within the patchy fibrosis. This is supported by the fact that high DF sites have been negatively correlated to the amount of fibrosis[65]. This assumption also explains why CFAEs are the by-product of the reentrant rotor that breaks down at its fibrotic boundaries[67]. As previously reported, correlation between CFAEs and high DF sites is poor. CFAEs are located in areas adjacent to high DF (within 10 mm)[62]. Regularity index showed that fractionation is low within the area with the maximum DF and high within a band of approximately 3 mm at boundaries with lower-frequency domains[47]. CFAEs mapping has to be therefore performed with great caution. Only CFAEs with a discrete MAP should be targeted for ablation[53]. Of note, these are low voltage and high DF sites[53]. In conclusion, areas with relatively higher voltage compared to the surrounding tissue displaying the maximum DF along with high organization index are potential targets of ablation. Prospective studies are required to validate the efficacy of substrate modification in left atrial ablation outcomes.

Abstract

Patients with type 2 diabetes mellitus (T2DM) are at a higher risk of developing coronary artery disease (CAD) than are non-T2DM patients. Moreover, the clinical outcomes in CAD with T2DM are poor despite improvements in medications and other interventions. Coronary artery bypass grafting is superior to percutaneous coronary intervention in treating multivessel coronary artery disease in diabetic patients. However, selecting a revascularization strategy depends not only on the lesion complexity but also on the patient's medical history and comorbidities. Additionally, comprehensive risk management with medical and non-pharmacological therapies is important, as is confirmation regarding whether the risk-management strategies are being appropriately achieved. Furthermore, non-pharmacological interventions using exercise and diet during the earlier stages of glucose metabolism abnormalities, such as impaired glucose tolerance, might be beneficial in preventing the development or progression of T2DM and in reducing the occurrence of cardiovascular events.

Key words: Diabetes; Comprehensive risk management; Multivessel disease; Drug-eluting stents; Percutaneous coronary intervention

Core tip: Clinical outcomes in coronary artery disease with type 2 diabetes mellitus (T2DM) are poor despite improvements in medications and other interventions. Although coronary artery bypass grafting is superior to percutaneous coronary intervention in multivessel coronary artery disease with T2DM, selecting the revascularization strategy depends not only on the lesion complexity but also on the patient's medical history and comorbidities. In these patients, comprehensive risk management with medical and non-pharmacological therapies is indispensable, and confirming whether such risk management is being appropriately achieved is also important. Furthermore, interventions with exercise and diet therapy during the early stages of glucose abnormalities might be effective in preventing the development or progression of T2DM and in reducing the occurrence of cardiovascular events.

INTRODUCTION

Patients with type 2 diabetes mellitus (T2DM) have a higher risk of developing coronary artery disease (CAD) than do patients without T2DM[1]. Additionally, 75% of T2DM patients die as a consequence of cardiovascular diseases, including CAD[2]. In patients with T2DM, CAD tends to be a more complex disease characterized by small, diffuse, calcified, multivessel involvement [multivessel disease (MVD)][3,4] and often requires coronary revascularization in addition to optimal medical therapy to control angina[5]. Regarding coronary revascularization, recent advances in the techniques and devices used during percutaneous coronary intervention (PCI) have expanded the indication of PCI to more complex lesions[6-8]. In particular, drug-eluting stents (DES) have reduced the restenosis and repeat revascularization rates[9,10]. However, the morbidity and mortality of CAD in patients with T2DM continues to be high, even in the current DES era[11]. Although most clinical trials comparing outcomes among T2DM patients with MVD have shown that coronary artery bypass grafting (CABG) was superior to PCI in terms of repeat revascularization and the incidence of myocardial infarction and mortality[12-17] (Table 1), it is not feasible to perform CABG in all diabetic patients with MVD. Because CABG is highly invasive in contrast to PCI, selecting a revascularization therapy depends not only on the lesion complexity but also on a patient's medical history and comorbidities. SYNTAX score is a reliable score to assess coronary anatomical features and lesion complexity[16]. EuroSCORE is also a useful scoring system that is based on the clinical background information of an individual patient, which might predict the operative mortality for patients undergoing cardiac surgery[18]. Recently, revised versions of these two scoring systems were proposed. Because combining the SYNTAX score and other clinical variables have been demonstrated to be more accurate in identifying the risk of patients with complex CAD compared with the SYNTAX score alone, the SYNTAX score Ⅱ was constructed, which included the original SYNTAX score and the following variables: the presence of unprotected left main CAD, female gender, chronic obstructive pulmonary disease, age and left ventricular ejection fraction[19]. Similarly, EuroSCORE Ⅱ is an updated version of the original EuroSCORE, reconstructed from a large database of 22381 consecutive patients undergoing cardiac surgery in 43 countries in 2010 using a logistic regression model[20]. These scoring systems may provide additional and reliable information to better decide revascularization strategies. In clinical trials, higher-risk surgical patients, such as the elderly and those with more comorbid diseases, have been excluded. Therefore, selecting a revascularization therapy for CAD with T2DM requires a thorough discussion of the patient's coronary anatomical features and lesion characteristics, age, and comorbid conditions.

Considering this issue, several important and as yet unresolved questions are raised including the following: (1) whether the newer DES are superior or similar in terms of repeat revascularization, incidence of myocardial infarction and mortality; (2) what can be done in conjunction with optimal medical and revascularization therapy to improve patient outcomes; and (3) whether early detection and intervention for CAD patients with undiagnosed T2DM or impaired glucose tolerance may improve mortality. In this editorial, we aim to provide novel insights into each of these specific questions and to consider the directions for future research.

REVASCULARIZATION THERAPY-THE POTENTIAL OF NEWER DRUG-ELUTING STENTS AND BIORESORBABLE VASCULAR SCAFFOLDS

First, it is essential to understand what types of outcome measures were used in clinical trials to evaluate the effectiveness of a given revascularization strategy or to determine the superiority of one revascularization therapy over another. Clinical trials for cardiovascular diseases often use a composite assessment of major adverse cardiovascular events as outcome measures including all-cause mortality, myocardial infarction, stroke and repeat revascularization. Because death and myocardial infarction are considered to be hard and preferably primary endpoints, whereas repeat revascularization is a less hard and secondary endpoint according to the severity of each case, the primary and secondary endpoints should be treated as two distinct endpoints.

Advances in PCI have prompted the selection of this procedure in more complex lesions that previously had been indicated for CABG. However, MVD in T2DM patients is associated with a high incidence of repeat revascularization after PCI with DES; therefore, CABG remains superior to PCI in such lesions. A meta-analysis has demonstrated that the superiority of CABG to PCI with balloon angioplasty or bare metal stents in terms of all-cause mortality was greater in patients with than without T2DM[21].

To date, several clinical trials have been conducted at 85 centers in the United States and Europe to compare CABG and PCI with DES. The SYNergy between percutaneous coronary intervention with TAXus and cardiac surgery (SYNTAX) was a prospective randomized trial that compared the efficacy of CABG and PCI with paclitaxel-eluting stents (PES) for patients with de-novo left main

Table 1 Clinical trials of percutaneous coronary intervention with coronary artery bypass grafting in diabetic patients

Trial	Type of trial years of recruitment	Number of study population	Type of PCI	Endpoint	Main results (PCI *vs* CABG)
ARTS I [12]	Randomized 1997-1998	208	BMS	1 yr freedom from death, stroke, MI or revascularization)	63.4% *vs* 84.4% ($P < 0.001$)
MASS II [13]	Randomized 1995-2000	115	N/A	1 yr death	5.3% *vs* 6.8% ($P = 0.5$)
BARI-2D[14]	Randomized	1605	1st DES: 34.7%	5 yr freedom from death, MI, repeat revascularization	PCI *vs* medical (77.0 *vs* 78.9; $P = 0.15$)
	Comparison between revascularization and medical 2001-2005		BMS: 56.0%		CABG *vs* medical (77.6% *vs* 69.5%; $P = 0.01$)
			Others: 9.3%		P for interaction 0.002
CARDIa[15]	Randomized 2002-2007	510	1st DES: 61% BMS: 31%	1 yr death, stroke, or MI	13.0% *vs* 10.5% ($P = 0.39$)
SYNTAX[16]	Randomized 2005-2007	452	1st DES	5 yr death, stroke, MI, or revascularization	46.5% *vs* 29.0% ($P < 0.001$)
FREEDOM[17]	Randomized 2005-2010	1900	1st DES	5 yr death	16.3% *vs* 10.9% ($P = 0.049$)
				5 yr death, nonfatal MI, or nonfatal stroke	26.6% *vs* 18.7% ($P = 0.005$)

PCI: Percutaneous coronary intervention; CABG: Coronary artery bypass grafting; DES: Drug-eluting stent; ARTS: Arterial revasucularization Therapies Study; BMS: Bare metal stent; MACE: Major adverse cardiovascular event; MI: Myocardial infarction; MASS: Medicine, Angioplasty, or Surgery Study; 1st DES: First generation DES.

coronary disease, three-vessel disease or both, which were considered equally suitable for CABG or PCI by both a cardiac surgeon and an interventional cardiologist at each center[22]. In the trial, 452 (25.1%) of the study population patients were diabetic, and these patients were included in a pre-specified sub-analysis. For 3-year major adverse cardiac and cerebrovascular events in the diabetic cohort, the incidence was 37.0% in the PCI group and 22.9% in the CABG group ($P = 0.002$). The rate of revascularization was also higher in the PCI group (PCI, 28.0% and CABG, 12.9%, $P < 0.001$)[23]. In 2012, a large-scale randomized trial known as the future revascularization evaluation in patients with diabetes mellitus (FREEDOM) trial was conducted. A total of 1900 diabetic patients with MVD were randomly assigned to CABG or to PCI with mainly sirolimus-eluting stents (SES) and PES[17]. The incidence of all-cause mortality and myocardial infarction was significantly lower in the CABG group during the mean follow-up period of 5 years compared with the DES group (CABG, 18.7% *vs* DES, 26.6%). Based on these results, the latest guidelines from the European Cardiology Society for the management of T2DM patients stated that PCI for MVD was a Class IIb indication for relieving symptoms as an alternative to CABG in patients with low SYNTAX scores[24]. However, in the FREEDOM trial, almost all patients in the PCI group were treated with first-generation DES that were replaced by newer-generation DES used in current clinical practice. The newer generation DES have overcome the critical issue of stent thrombosis; in particular, the everolimus-eluting stent (EES) reduced myocardial infarction and stent thrombosis compared with other DES in a meta-analysis[25]. Recently, Bangalore and colleagues reported a meta-analysis of 68 randomized clinical trials to compare clinical outcomes in CAD patients with T2DM between those who received CABG and DES, including SES, PES and EES[26]. All-cause mortality was higher in the patients who received SES and PES compared with CABG, whereas the mortality rates in the EES group were similar to those of the CABG group (reference rate ratio to CABG, 1.31, 95%CI: 0.74-2.29). These results should be carefully interpreted because they were generated from an indirect comparison of individual clinical trials. Ongoing randomized trials in evaluation of the Xience Prime or Xience V stents *vs* coronary artery bypass surgery for the effectiveness of left main revascularization (EXCEL) and bypass surgery *vs* everolimus-eluting stent implantation for approaching multivessel disease (BEST) aim to determine the effectiveness of EES. EXCEL is a randomized trial comparing EES and CABG in patients with left main trunk lesions and SYNTAX scores of 32 or less. The BEST trial aims to compare EES and CABG in MVD. In both trials, a sub-analysis for diabetic patients is intended.

Regarding other novel devices, bioresorbable vascular scaffolds (BVS) may be a candidate treatment of CAD in diabetic patients. BVS are novel intra-coronary devices that have potential advantages over metallic DES in terms of adverse coronary events such as stent thrombosis because unlike metallic DES, no uncovered struts or polymers exist after the scaffolds are resorbed[27]. To date, only a single clinical study has reported on the efficacy of BVS in diabetic patients. Muramatsu *et al*[27] compared BVS and EES in diabetic patients using different clinical trials of each device and reported that the incidence of the clinical outcome, which was a composite of cardiac death, target vessel MI, or ischemia-driven target lesion revascularization, was similar between BVS and EES in diabetic patients (3.9% for the BVS *vs* 6.4% for EES, $P = 0.38$)[28].

As described by the authors, the data analysis was performed using different pooled data and the study population number was quite small (n = 102 in the BVS group and 172 in the EES group). Further studies in a larger cohort of diabetic patients are required to demonstrate the safety and efficacy of BVS.

COMPREHENSIVE RISK MANAGEMENT AND INTERVENTIONS

Because clinical outcomes in T2DM patients with CAD are poor, aggressive medical and non-pharmacological therapies are indispensable, regardless of the revascularization strategy pursued. The bypass angioplasty revascularization investigation in type 2 diabetes (BARI-2D) trial examined and compared long-term clinical outcomes between medical therapy alone and revascularization by PCI or CABG in T2DM patients[14]. No significant difference was observed between the PCI and CABG groups in all-cause mortality or in the event-free survival rates for cardiovascular events during the 5-year follow-up period. These data indicated the importance of comprehensive risk management with glycemic control and the administration of statins, angiotensin receptor blockers, angiotensin converting enzyme inhibitors and antiplatelet therapy in T2DM patients with CAD[21]. Guidelines for the management of diabetes mellitus from the American Diabetes Association, the American College of Cardiology and the American Heart Association recommend the following prevention strategies for CAD: blood pressure 130/80 mmHg or less, low-density lipoprotein cholesterol (LDL-C) below 100 mg/dL (below 70 mg/dL for CAD patients) and prompt smoking cessation[29-31]. However, a previous study examining the achievement of risk management in the large-scale clinical trials of clinical outcomes utilizing revascularization and aggressive drug evaluation (COURAGE), BARI-2D and FREEDOM, showed unexpectedly low achievement rates[32]. One-year risk management achievement rates (LDL-C < 100 mg/dL (70 mg/dL in the FREEDOM trial), systolic blood pressure < 130 mmHg, glycated hemoglobin < 7.0% and smoking cessation) were 18%, 23% and 8% in the COURAGE, BARI-2D and FREEDOM trials, respectively. Although the achievement rate was not originally included in the clinical trial endpoints, these results prompted us to review our clinical practices regarding not only adherence to evidence-based medical therapy but also whether risk management is being properly achieved. Furthermore, non-pharmacotherapeutic strategies including exercise, diet and smoking cessation should be pursued.

INTERVENTIONS FOR IMPAIRED GLUCOSE TOLERANCE

Considering that patients with T2DM tend to have macro- and microvascular complications and that the clinical outcomes of CAD patients are poor, interventions are desirable during the earlier stages of T2DM, such as impaired glucose tolerance (IGT). We understand that IGT is not simply an early stage of T2DM but rather an important state predisposing to T2DM. In fact, progression to diabetes was observed in 10% of IGT patients[33]. Additionally, it was suggested that IGT itself might have an impact on CAD morbidity and mortality[34]. However, it is not fully elucidated whether IGT in CAD patients might be a treatment target for secondary prevention the effects of anti-diabetic agents on reducing progression to diabetes or the incidence of cardiovascular events in such patients. Nevertheless, non-pharmacological therapies such as nutrition and exercise are important even in IGT patients. Previous studies reported that about one-third of CAD patients who had not been diagnosed with diabetes were actually diabetic[35,36]. Thus, aggressive evaluation for diabetes and IGT are required in CAD patients. In current clinical practice, although fasting blood glucose and glycated hemoglobin diabetes testing is routinely performed, the glucose tolerance test is not frequently performed in CAD patients unless the fasting blood glucose or glycated hemoglobin levels are above the upper limits of normal. To detect diabetes at an earlier stage, blood glucose, glycated hemoglobin and glucose tolerance tests for diabetes are considerably important.

CONCLUSION

When selecting revascularization strategies in diabetic patients, physicians must thoroughly consider not only a patient's coronary artery lesions but also his/her medical history. Additionally, comprehensive risk management with medical and non-pharmacological therapies should be performed and the proper achievement of risk management should be confirmed. Furthermore, non-pharmacological interventions through exercise and diet therapy during the earlier stages of glucose metabolism abnormalities such as IGT may also be beneficial in preventing the development or progression of T2DM and in reducing the occurrence of cardiovascular events by either primary or secondary prevention of CAD.

Abstract

Cell transplantation is an attractive potential therapy for heart diseases. For example, myocardial infarction (MI) is a leading cause of mortality in many countries. Numerous medical interventions have been developed to stabilize patients with MI and, although this has increased survival rates, there is currently no clinically approved method to reverse the loss of cardiac muscle cells (cardiomyocytes) that accompanies this disease. Cell transplantation has been proposed as a method to replace cardiomyocytes, but a safe and reliable source of cardiogenic cells is required. An ideal source would be the patients' own somatic tissue cells, which could be converted into cardiogenic cells and transplanted into the site of MI. However, these are difficult to produce in large quantities and standardized protocols to produce cardiac cells would be advantageous for the research community. To achieve these research goals, small molecules represent attractive tools to control cell behavior. In this editorial, we introduce the use of small molecules in stem cell research and summarize their application to the induction of cardiogenesis in non-cardiac cells. Exciting new developments in this field are discussed, which we hope will encourage cardiac stem cell biologists to further consider employing small molecules in their culture protocols.

Key words: Cardiogenesis; Cell reprogramming; Somatic cells; Small molecules; Cardiovascular disease

Core tip: There are a plethora of methods to manipulate the phenotype of somatic cells and convert them into different cell types, such as cardiac cells. The use of small molecules provides numerous advantages, such as ease of use, tight temporal control and reversible effects on target proteins. Significantly, the production of small molecules is cheap and synthesis can be readily standardized. This would allow non-specialist stem cell laboratories to readily adopt small molecule-based methods to produce functional cardiac cells from multiple

cell sources, including therapeutic applications requiring the somatic cells of patients with cardiovascular disease.

WHY SHOULD CARDIOMYOCYTES BE PRODUCED USING NON-CARDIAC CELLS?

Heart contraction is produced by cardiomyocytes, which comprise the cardiac muscle cell population. It was thought that the heart is a refractory organ that is incapable of replacing cardiomyocytes that are lost by normal tissue damage or cardiac disease. However, over the past decade this view has been challenged by numerous studies indicating that the heart can regenerate cardiomyocytes; at least with a capacity to replace those cells lost by regular tissue turnover[1]. Unfortunately, this regenerative capacity is significantly lower compared to skeletal muscle. Thus, major disease insults, such as myocardial infarction (MI), result in an irreversible, catastrophic loss of cardiomyocytes. Typically, MI results in the death of around 20% of the total cardiomyocytes population in the heart. The ventricle is a major site of cardiomyocyte death, with billions of dead cells being eventually replaced by fibrous scar tissue[2-4]. Acute MI produces significant mortality (for example, 36% fatality in the United Kingdom, over the years 2002-2010[5]). For those patients that survive, the poor capacity of heart regeneration means that many are predisposed to eventually develop clinical heart failure[2,6,7].

It can be envisaged that one potential therapy for preventing the progression of MI to heart failure would be the transplantation of functional cardiomyocytes to the infarction site. This cell therapy approach has been demonstrated as an achievable cure for degenerative diseases, such as the transplantation of hematopoietic multipotent stem cells to treat certain types of leukemia[8]. Cardiac cell therapy could prevent progression to heart failure by allowing functional recovery of the heart. Most cell therapy approaches involving cardiomyocyte transplantation aim to treat the consequences of MI, because of the significant impact of this disease on human health.

Cell therapy approaches have been developed to treat cardiac dysfunction, such as MI (reviewed in[9]). Multiple strategies exist for cell delivery and cell source. For example, different types of stem cells have been used for transplantation, including mesenchymal stem cells or cardiac stem cells. More differentiated cells have also been utilized, such as skeletal muscle cells and cardiomyocytes. Unfortunately, the results of clinical trials have only shown a modest improvement after MI. One approach to improve the outcome of cell therapy for MI would be the development of an ideal, optimized cell type for transplantation. This would also require the development of a rigorous, defined experimental methodology to ensure quality control for the cells prior to grafting. However, standardized protocols for culturing transplantable cells are lacking and laboratories tend to develop thief own "in house" techniques and culture media recipes.

The research field of chemical biology is ideally suited to provide reagents that can enhance cell culture and scale-up for transplantation. Chemical biology is a multidisciplinary field that uses chemical "tools" or probes provided by synthetic chemistry to understand and manipulate biological systems[10,11]. These chemical tools are usually small molecules, which are defined as organic compounds with a molecular weight below 800 Daltons. This allows diffusion across the cell membrane and is an upper limit for oral bioavailability[12,13]. A significant example of the contribution of chemical biology to cell research is the generation of induced pluripotent stem cells (iPSCs) from differentiated adult cells[14]. This was originally achieved by overexpressing four "Yamanaka" transcription factors: Oct4, Sox2, c-Myc, and Klf4. Within just a few years, the protocol to produce iPSCs was optimized and simplified by chemical biologists. It was shown that iPSCs could be generated by expressing only the Oct4 transcription factor and a two-step combination of small molecule inhibitors of cell signaling pathways and gene regulatory mechanisms[13]. This is an important example of the ability of small molecules to substitute for transcription factors that have a global influence on genes regulating cell differentiation. Small molecules also possess significant advantages compared to other technologies for controlling cell phenotype, such as genetic methods. In the following section, we briefly discuss these advantages and provide examples of the application of small molecules to the derivation of cardiogenic cells for cell therapy.

Why use small molecules to control cardiogenesis?

Small molecules allow flexibility over the manipulation of the target protein[13,15]. This is not always possible with alternative approaches, such as genetic manipulation. In addition, the effects of small molecule treatment are usually reversible. This means that the target protein can be manipulated with relatively precise timing. An additional level of control can be achieved by fine-tuning the treatment concentration. Small molecules do not always modulate a single protein target in cells; they can produce multiple effects by binding to different protein classes. An example is the molecule BIX-01294, which inhibits different histone-modifying enzymes[16]. Thus, different

small molecules can act synergistically to produce multiple effects, with the potential to produce dramatic changes in cell phenotype. The structural diversity of small molecule libraries developed exponentially in the 1990s, due to advances in chemical synthesis, such as combinatorial chemistry and diversity-orientated synthesis[17,18]. This greater diversity increases the potential to control molecular interactions with target proteins. Small molecules also provide logistical advantages for researchers. Compared to protein or nucleic acid reagents, they are cheap to produce, simple to store in the laboratory and more amenable to quality control. Small molecule-based methods do have some disadvantages, such as the potential for off-target effects on other proteins possessing similar structural elements. Notwithstanding, small molecules have become prominently used in stem cell biology and regenerative medicine, including the production of cardiomyocytes or cardiogenic stem cells[3,15,19]. Next, we discuss some prominent examples of small molecule-based strategies for cardiac cell therapy.

Due to the major health impact of cardiac disease, many small molecules have been developed to simplify the generation of cardiomyocytes or enhance the production of cardiogenic stem cells for potential cell therapy. A selection of these small molecules is shown in Figure 1. The use of small molecules to generate cardiomyocytes can be traced back to 1982, with the discovery that the small organic molecule, DMSO, could induce cardiomyocytes differentiation in murine teratocarcinoma-derived embryonic stem cells[20]. However, it was the development of cell therapy applications for cardiac diseases, such as MI in the 1990s[21] that spurred the discovery of bioactive compounds for enhancing cardiogenesis.

A significant advance came with the report that a small molecule inhibitor of DNA methylation, 5-azacytidine, could induce cardiomyocyte differentiation in murine bone marrow stromal cells[22]. DNA methylation is an epigenetic modification that regulates global gene expression patterns. Thus, it was demonstrated that a small molecule could modulate the epigenetic status of the cell genome to make it amenable to differentiation when exposed to a cardiogenic environment, such as transplantation into to heart or exposure to cardiomyocyte differentiation factors. A follow-up study showed that 5-azacytidine could also induce cardiomyocyte differentiation in embryonic stem cells (ESCs)[23]. Consequently, numerous studies focused on the application of small molecules to derive cardiomyocytes from ESCs. Prominent examples included the discovery of cardiogenol, which activates the Wnt cell signaling pathway and chromatin remodeling enzymes[24]; dorsomorphin, which inhibits the bone morphogenetic (BMP) signaling pathway[25]; and a series of isoxazoyl serines, which act as peroxisome activated proliferation receptor (PPAR) agonists[26] (Figure 1).

These small molecules are not only useful as tools to induce cardiomyocyte differentiation. Characterizing their biological activity also gives insights into the cellular mechanisms that regulate the differentiation process. For example, the pivotal role of the Wnt signaling pathway was confirmed in a screening study for small molecule inducers of cardiogenesis[27]. Cardiogenesis is initiated in ESCs by the formation of embryonic bodies that induce formation of the mesodermal lineage, from which cardiomyocytes are eventually derived[28]. Small molecule screening at 6 d after embryoid formation revealed that Wnt signaling inhibitors significantly enhance cardiomyocyte differentiation, confirming the important role of this signaling pathway in cardiogenesis. This finding also contrasts with the known importance of Wnt signaling for mesodermal induction at the earlier stage of cardiogenesis[28]. This was confirmed in a study which used the Wnt activating molecule, BIO (Figure 1), at the embryoid body stage to increase the number of beating cells after differentiation[29]. Another interesting finding was that inactivation of the mitogen-activated protein kinase (MAPK) signaling pathway by small molecule SB203580 (Figure 1) enhanced cardiomyocyte differentiation from ESCs[30]. SB203580 was treated to embryoid bodies at 24 h after formation, indicating the important role of the MAPK pathway in maintaining the undifferentiated cell state and inhibiting cardiogenesis.

The development of iPSCs (described above) also provided extra impetus to develop small molecule-based methods to induce cardiogenesis, because iPSCs circumvent the ethical and technical problems associated with using ESCs[31]. In addition, iPSCs can be derived from somatic cells, which offers an opportunity to derive cardiac cells from differentiated cells residing in non-cardiac tissues. An interesting example of a small molecule based approach to induce cardiac differentiation in iPSCs utilizes JAK inhibitor-1 (Figure 1), which blocks signaling by janus protein tyrosine kinase and repression of the JAK-STAT pathway (the major alternative second messenger system in cells)[32]. The usefulness of this approach is that it bypasses the need to induce fully reprogrammed iPSCs from somatic cells. Application of JAK-1 during the iPSC generation step blocked the acquisition of full "stemness" and produced a cell population that could be efficiently induced to form functional cardiomyocytes by culture in chemically defined cardiogenic media. Impressively, 100% of the treated cells underwent spontaneous contractions and the protocol was significantly faster than alternative methods, such as the forced expression of master cardiogenic transcription factors[33].

Pluripotent stem cells, such as ESCs and iPSCs, are not the only cell source that has been used for small molecule-induced cardiogenesis. Cells from a diverse range of tissues have been demonstrated to be amenable to cardiomyocyte differentiation (Figure 2). These tissue-specific stem and precursor

Name	Structure	Mechanism	Ref.
5-azacytidine		DNA methyltransferase inhibitor	[22,23]
BIO		Wnt signaling pathway activator	[29]

Wnt C-59		Wnt signaling pathway inhibitor	[41]
XAV939		Wnt signaling pathway inhibitor	[48]

Figure 1 Selected small molecules that are used to regulate cardiogenesis (in alphabetical order). BMP: Bone morphogenetic; MAPK: Mitogen-activated protein kinase; TGF-β: Transforming growth factor-β.

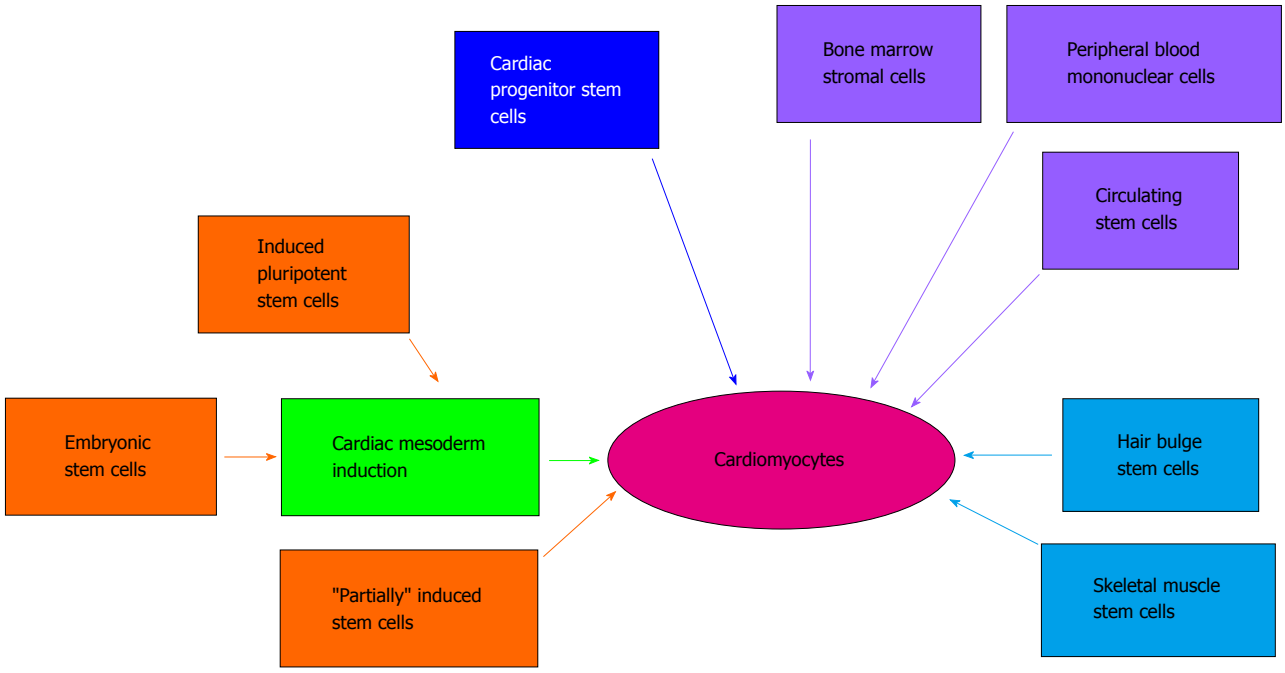

Figure 2 Pathways of small molecule-mediated cardiomyocyte production. It is now established that cardiomyocyte differentiation can be induced in multiple cells types using small molecule-based approaches. Embryonic stem cells and induced pluripotent stem cells are typically induced to undergo cardiac mesoderm differentiation before culture conditions are switched to cardiomyocyte differentiation media. "Partially" induced stem cells are somatic cells that were transfected with induced pluripotent stem cells reprogramming factors and then treated with the small molecule, JAK inhibitor-1 (as described in the text).

cells possess different levels of potency, such as skeletal muscle stems (unipotent) or bone marrow stromal cells (multipotent)[34]. These approaches may be useful for patient-specific cell therapy, because tissues such as skeletal muscle and blood are readily assessable. As an example of this small molecule-based approach, the DNA methyltransferase inhibitor RG108 was successfully used to convert skeletal muscle stem cells into a pluripotent state. These cells could then be induced to form embryoid bodies and undergo cardiogenic differentiation[35]. Significantly, transplantation of these cells could improve cardiac performance and reduce scarring in animal models of MI. Interestingly, a stem cell population has also been found to reside at the base of hair follicles (bulge stem cells)[36] and treatment with the small molecule Wnt pathway activator, cardiogenol C, induced expression of cardiomyocyte markers in these cells[37]. Thus, there are multiple "paths" to generate cardiac cells from diverse tissue types, which are facilitated by small molecule treatments (Figure 2). Moreover, small molecule methods can significantly enhance genetic-based approaches for cardiogenesis in somatic cells. For example, compound SB431542 (Figure

1), which inhibits the transforming growth factor-β (TGF-β) can produce a five-fold increase in the direct reprogramming of fibroblasts into cardiomyocytes using master cardiomyocyte transcription factors[38].

It can also be observed that, over time, these small molecule-based approaches are being optimized and simplified by the research community to allow easier derivation of cardiogenic cells. An important development in this regard is the development of chemically defined culture media for cardiogenic differentiation. This is important because serum should be eliminated from cell therapy applications. Serum supplies can suffer from batch variability and contain unspecified growth factors that may interfere with the differentiation process. Serum may also contain xenoantigens or infectious agents, which may induce an immune response in the host after transplantation[39]. To address this problem, a recently published study describes the development of a small molecule-based protocol to induce cardiomyocytes from bone marrow stem cells[40]. The development of these chemically-defined cardiogenic media cocktails are discussed in more detail below.

Latest progress in small molecule mediated cardiogenesis: Development of chemically defined induction media

A recently published study indicates the rapid progress that has been made for developing small molecule-based methods for cardiomyocyte differentiation. The study by Burridge *et al*[41] represents an impressively detailed investigation to define an optimized, chemically defined protocol for cardiomyocyte differentiation from human iPSCs. Their previous protocol for cardiomyocyte induction required the supplement B27, which is a complex mixture of 21 components. Some of these components are derived from animals, which necessitated the need to develop a chemically defined cardiogenic media. Interestingly, the iPSCs used in this study were also generated using a chemically defined methodology: human primary fibroblasts were transduced/transfected with the Yamanaka factors and cultured sequentially in the defined E8 and E7 culture media containing the small molecule histone deacetylase inhibitor, sodium butyrate. iPSC colonies could be selected after three weeks. The induction of cardiomyocyte differentiation was rigorously investigated using different combinations of small molecules and matrix scaffolds for cell attachment. Before the onset of cardiogenesis, cells were incubated with the small molecule thiazovivin, which is a selective inhibitor of Rho-associated coiled-coil containing protein kinase (ROCK) that has been shown to facilitate iPSC generation[13,42]. As mentioned above, modulation of the Wnt cell signaling pathway is a crucial aspect of the differentiation process, with positive signaling required for mesoderm specification and inhibition required for subsequent cardiomyocyte differentiation. A wide range of small molecule Wnt pathway modulators was tested to find the optimal combination for cardiac induction. Cardiomyocyte differentiation was monitored by measuring expression of the early cardiomyocyte marker gene, troponin T (TNNT)[43]. Interestingly, different small molecule Wnt pathway activators showed markedly diverse effects on cardiogenesis. Of six activators tested, only two [CHIR99021 and BIO (Figure 1)] facilitated the production of TNNT expressing cells without causing cell death. This finding emphasizes the need to compare small molecules that target identical pathways to eliminate the potential for significant off-target effects.

Further optimization of this cardiomyocyte differentiation protocol involved comparison of small molecule inhibitors of various signaling pathways (such as BMP or TGF-β) during the mesoderm induction step and Wnt signaling inhibition during the later cardiomyocyte differentiation step. Remarkably, these optimizations led to the development of a simplified induction protocol that could produce 95% TNNT positive contractile cardiomyocytes, with around 100 cells being derived from a single human iPSC. This protocol is based on the CDM3 media, which contains the chemically defined RPMI-1640 base media and is supplemented with just two reagents: l-ascorbic acid 2-phosphate and human recombinant albumin. iPSCs are cultured with CDM3 plus the Wnt pathway activator, CHIR99021 for two days, followed by two days incubation with CDM3 plus the small molecule Wnt pathway inhibitor, Wnt C-59 (Figure 1). Impressively, cardiomyocyte differentiation was observed just 96 h after this step, using additional incubation with CDM3 media alone. The cardiomyocyte phenotype was assessed by nanopillar-based microscopic observation and it was observed that the majority of cardiomyocytes (> 60%) were ventricular-like compared to atrial-like, with no nodal cardiomyocytes being observed. This observation is important, because new strategies to induce cardiomyocyte differentiation aim to produce specific, adult cardiomyocyte subtypes. The role of small molecules in these differentiation strategies are discussed in the next section.

New small molecule-based methods to induce epicardial cells for facilitating regeneration

As mentioned in the introduction for this editorial, cell therapy approaches for degenerative diseases require a high quality source of purified, functional cells for transplantation. This is also relevant for other applications, such as disease modeling, developmental studies and cell-based drug screening[44]. Early small molecule-based methods for inducing cardiogenesis, such as treatment with 5-azacytidine, were found to produce mixed populations of cells containing approximately 30% cardiomyocytes[22]. As described above, recent developments in producing chemically defined conditions for cardiogenesis from stem cells

allows the derivation of cell populations containing up to 95% cardiomyocytes[41]. However, the heart comprises multiple cell types and cardiomyocytes account for only around 30% of total cells[45]. Therefore, for applications such as modeling cardiac development or cell therapy approaches for MI, it would be useful to generate these non-cardiomyocyte cell types. This is especially relevant for the epicardial cell type, because it is known that epicardial tissue plays a pivotal role in both cardiac development and cardiomyocyte regeneration after disease[46,47]. A recently published study demonstrates that it is indeed possible to derive epicardial cells from iPSCs, with small molecules being used as "control switches" to regulate cell differentiation potential[48].

Epicardial cells can be defined by their cobblestone morphology, specific gene marker expression [Wilms tumor protein (WT1) and T-box 18 (TBX18)] and the ability to synthesize retinoic acid[49-51]. In this study, human ESCs were induced to form embryoid bodies and undergo mesoderm formation by treatment with BMP4 alone for one day, followed by treatment with combined BMP, fibroblast growth factors (FGF) and activin A (a TGF pathway stimulator). Crucially, after 96 h the TGF pathway was inhibited with the small molecule SB431542 (Figure 2). This small molecule was removed after 48 h to facilitate the derivation of cardiomyocytes. In an attempt to block this cardiomyocyte differentiation and allow epicardial cells to be generated, the authors of this study focused on manipulating the Wnt signaling pathway after the addition of BMP. Such precise manipulation of Wnt signaling within this time window of differentiation could be achieved using small molecules. The effects of small molecule Wnt inhibitors (XAV939 and IWP2) were compared with a small molecule activator (CHIR99021). The effect of BMP-mediated signaling on differentiation was assessed using the small molecule inhibitor, dorsomorphin. The use of these small molecule combinations showed that BMP signaling has no effect on the canonical Wnt signaling pathway. Most significantly, it was observed that maintaining Wnt signaling using CHIR99021 allowed the derivation of epicardial lineage cells, as assessed by gene marker expression, morphological characteristics, differentiation into vascular or smooth muscle cells and the ability to synthesize retinoic acid[48]. The population of cells expressing the epicardial marker WT1 could be expanded to account for over 95% of the differentiated cell population, with one mesodermal lineage cell at day 4 of differentiation producing 4-5 epicardial cells. This study provides a high profile example of the advantages that small molecule methodologies offer to cell biologists. In this study, small molecules were used with precise timing to derive a valuable cardiac cell population which has been of great interest to investigators of heart development and regeneration after injury.

CONCLUSION

In this editorial, we have described some prominent examples of small molecule-based methods to facilitate the production of cardiac cells from diverse cell sources. We have shown that small molecules have numerous advantages as tools to control cell differentiation. They can be viewed as cheap, simple and reliable "switches" that provide rapid and reversible control of key cell signaling pathways. Our editorial has focused on the generation of cardiomyocytes from non-cardiac cells, but small molecules are also used in many other areas of cardiac regeneration research. Examples include improving the survival of cardiac tissue grafts, inducing cardiomyocyte dedifferentiation/proliferation and activating endogenous cardiac progenitor cells[3,52]. In addition, the impact of small molecule approaches is shown in the recent demonstration that iPSCs can be derived from somatic cells using just these chemicals alone, *i.e.,* without the need for expressing reprogramming transcription factors[53]. This was achieved using a stepwise protocol requiring only seven small molecules: RepSox (a TGF signaling pathway inhibitor), PD0325901 (a MAPK pathway inhibitor), CHIR99021 (a Wnt pathway activator), TTNPB (a retinoic acid analog), 3 deazaneplanocin-A (which reduces histone methylation), valproic acid (which increases histone acetylation) and forskolin (which increases protein kinase A signaling). Remarkably, the efficiency of iPSC generation using this small molecule method was similar to that achieved using the reprogramming factors. It can be envisaged that this iPSC method could be joined with the chemically defined, small molecule method for cardiomyocyte differentiation, described above. Theoretically, this would allow the derivation of cardiac cells from almost any somatic cell source in the body.

Overall, we hope that this editorial has provided convincing evidence of the many advantages of using small molecules in biological research and cardiac regenerative medicine in particular. Chemical biologists continue to develop new bioactive small molecules or optimize the structures of existing compounds, to improve specificity and/or lower effective concentration. In concert with this research effort, cell biologists are also discovering new applications for known bioactive molecule or developing novel small molecule cocktails to manipulate cell behavior. Therefore, it seems likely that even more diverse and exciting progress is the field of cardiac regeneration can be achieved using small molecules.

Abstract

Though a century old hypothesis, infection as a cause for atherosclerosis is still a debatable issue. Epidemiological and clinical studies had shown a possible association but inhomogeneity in the study population and study methods along with potential confounders have yielded conflicting results. Infection triggers a chronic inflammatory state which along with other mechanisms such as dyslipidemia, hyper-homocysteinemia, hypercoagulability, impaired glucose metabolism and endothelial dysfunction, contribute in pathogenesis of atherosclerosis. Studies have shown a positive relations between Cytotoxic associated gene-A positive strains of *Helicobacter pylori* and vascular diseases such as coronary artery disease and stroke. Infection mediated genetic modulation is a new emerging theory in this regard. Further large scale studies on infection and atherosclerosis focusing on multiple pathogenetic mechanisms may help in refining our knowledge in this aspect.

Key words: Atherosclerosis; Coronary artery disease; *Helicobacter pylori* ; Infection; Stroke

Core tip: Though a century old hypothesis, infection as a cause of atherosclerosis is still a debatable issue. Clinical and epidemiological studies had shown a possible association, however in-homogeneity in the study population and methodology has yielded conflicting results. We performed a literature search on MEDLINE electronic database using keywords such as *Helicobacter pylori* (*H. pylori*), infection, atherosclerosis, coronary artery disease, myocardial infarction, stroke, cerebro-vascular disease and peripheral arterial disease using MeSH terms, to review this subject. The association between *H. pylori* and atherosclerosis is not strong and a causal role is not yet established. Large scale studies on infection and atherosclerosis focusing on multiple pathogenetic mechanisms may help in refining our knowledge in this aspect.

Vijayvergiya R, Vadivelu R. Role of *Helicobacter pylori* infection in pathogenesis of atherosclerosis. *World J Cardiol* 2015; 7(3): 134-143 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i3/134.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i3.134

INTRODUCTION

Though a century old hypothesis, infection is still debated as a cause of atherosclerosis[1]. Infection triggers a chronic inflammatory state which along with other mechanisms such as dyslipidemia, hyperhomocysteinaemia, hypercoagulability, impaired glucose metabolism and endothelial dysfunction contribute in pathogenesis of atherosclerosis. Studies have shown a positive relations between Cytotoxic associated gene-A (Cag-A) positive *Helicobacter pylori* (*H. pylori*) strains with vascular diseases such as coronary artery disease (CAD) and stroke. Infection mediated genetic modulation is a new emerging theory in this regard. Minick and Fabricant's work on infection and atherosclerosis in animal model had made the ground for revolutionary research in this field[2,3]. Chronic infection triggers T1 Helper cell (Th1) mediated inflammatory reaction, which plays a crucial role in atherosclerosis. Markers of infection and inflammation were also studied as the risk factors for atherosclerosis[4-6]. An association between infection and atherosclerosis was established following detection of infectious agents from arterial vessels, positive immunehistochemistry studies, detection of microbial DNA sequences in atherosclerotic plaques by PCR method, positive serological response with higher titres in infected patients, and a positive correlation of infection with atherosclerotic burden and dyslipidaemia[7-23]. The microbial agents that have been implicated in the etiopathogenesis of atherosclerosis are presented in Table 1, Figure 1.

This review has been divided into two parts. Part Ⅰ elucidates different mechanisms of *H. pylori* related atherosclerosis and relevant studies. Part Ⅱ reviews the literature about *H. pylori* association with atherosclerotic diseases such as CAD, stroke and peripheral arterial disease (PAD).

MECHANISMS OF *H. PYLORI* RELATED ATHEROSCLEROSIS

Development of CAD in patients without conventional risk factors suggests a possible role of an additional unexplored mechanism. The evolution of atherosclerosis in the background of chronic inflammatory milieu involves multiple pathways (Table 2, Figure 1). Some of these pathways will be discussed in following section.

H. pylori and endothelial dysfunction

Infection related chronic vascular inflammation can result in endothelial dysfunction. Tousoulis *et al*[24] first proposed an inflammatory mechanism for endothelial dysfunction. C-reactive protein (CRP) and inflammatory adhesion molecule such as intracellular adhesion molecule-1 (ICAM-1) are elevated in patients with *H. pylori* infection, suggesting a possible link between infection and endothelial dysfunction[25].

Table 1 Microbial agents associated with atherosclerosis

Bacteria	Viruses
Chlamydia pneumonia	H simplex virus type 1 and 2
Helicobacter pylori	Cytomegalovirus
Helicobacter cinaedi	Epstein- Barr virus
Hemophilus influenza	
Mycoplasma pneumonia	

Chronic infection triggers release of inflammatory cytokines such as interleukin (IL)-1, IL-6 and tumor necrosis factor-α (TNF-α), which affects microvascular vasomotor functions, resulting into vasoconstriction and endothelial dysfunction. Coskun *et al*[26] studied a possible relation between *H. pylori* infection in children and endothelial dysfunction as a precursor for future atherosclerosis. There was no significant association between *H. pylori* seropositivity and CRP levels with flow mediated vasodilation. Another evidence is about increase prevalence of slow flow in the major epicardial coronary arteries in patients with *H. pylori* infection[27]. The possible mechanism of slow flow was endothelial dysfunction secondary to raised homocysteine levels. *H. pylori* infection causes malabsorption of vitamin B12 and folic acid and thus increases serum homocysteine levels. Evrengul *et al*[27] reported a mean TIMI frame count of coronary flow as 46.3 ± 8.7 and 24.3 ± 2.9 in patients with and without *H. pylori* infection, respectively. An association between *H. pylori* infection and functional vascular disorders such as cardiac syndrome-X, migraine and primary Reynaud phenomenon provides evidence about its role in endothelial dysfunction and atherosclerosis[28-32].

Chronic inflammation

Presence of chronic, persistent inflammation provides a vital clue for infectious theory of CAD. Chronic *H. pylori* infection induces a pro-inflammatory state, resulting into an increase in cytokines levels such as TNF-α, Interleukins (IL-1, IL-6, IL-8), gamma interferon, coagulant factors - fibrinogen, thrombin and soluble adhesion molecules such as intercellular adhesion molecule (ICAM-1), vascular cell adhesion molecule (VCAM-1)[33-35]. Eradication of *H. pylori* infection by use of antibiotics leads to reduction in cytokines levels[34,36]. These evidences suggest that *H. pylori* induced inflammatory cascade plays an active role in atherosclerosis. Activated T lymphocytes and macrophages following cytokines release induce proliferation of smooth muscle cells and extracellular matrix, which plays a crucial role in pathogenesis of atherosclerosis. It also stimulates metalloproteinases production, which causes rupture of atheroma cap and leads to acute coronary syndromes. However, a large population based study failed to support the association between *H. pylori* and increased inflammatory cytokines[37].

Recent research has unveiled novel molecular

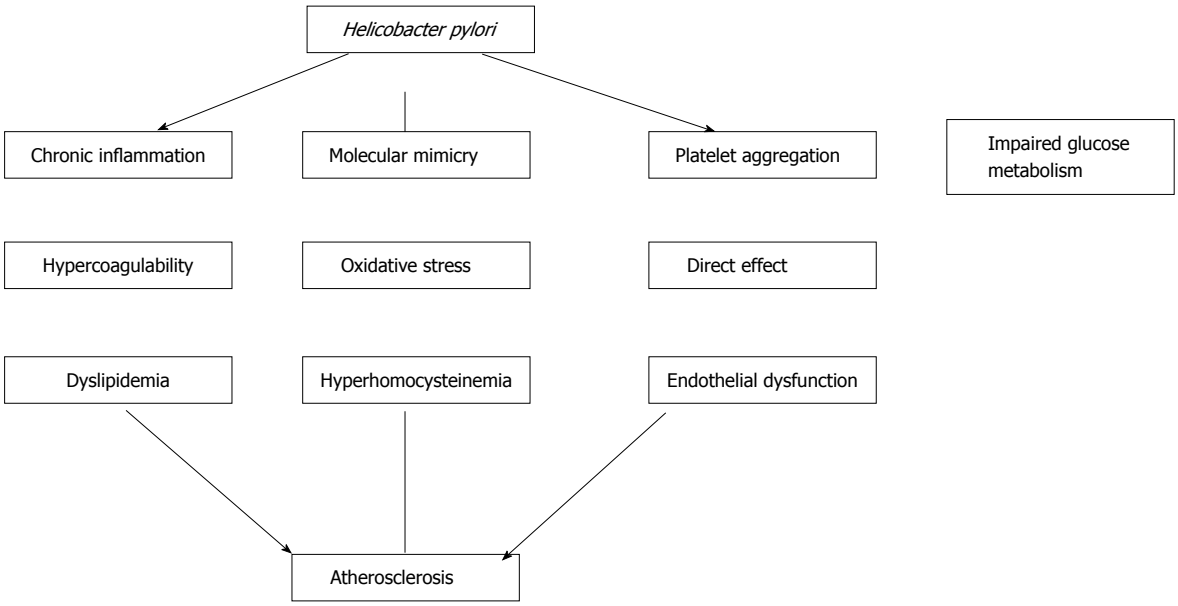

Figure 1 Theories of infection related atherosclerosis.

Table 2 Mechanisms of *Helicobacter pylori* related atherosclerosis

Induction of inflammatory response secondary to chronic infectious state
Endothelial damage
Chronic low grade activation of coagulation cascade
Dysregulation of lipid metabolism resulting in increased total cholesterol and triglyceride levels and reduced high density lipoprotein levels
Hyperhomocysteinaemia

While the proponents support the possible association[52,70,104], the opponents refute this hypothesis[46,71,105].

mechanisms of *H. pylori* mediated inflammation[38-41]. *H. pylori* infection exerts an immune-inflammatory reaction by activating cyclooxygenase enzyme-2 (COX-2), which causes increase production of prostaglandin (PGE_2) and nitric oxide (NO). *H. pylori* cell wall lipopolysaccharide (LPS) triggers toll-like receptor-4, which activates various secondary mediators such as mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase, c-Jun N-terminal kinase (JNK) and p38 kinase resulting in enhanced stimulation of *NOS* and *COX-2* gene expression[38,39]. LPS-induced activation of MAPK cascade is also associated with epidermal growth factor receptor (EGFR) transactivation which is a key protein regulating cellular proliferation, differentiation, migration and modulation of apoptosis[41]. Gherlin, a peptide hormone activates NO synthase, thereby inhibiting *H. pylori* LPS induced activation of COX-2 and other inflammatory pathways[40].

H. pylori and hyper-homocysteinaemia

H. pylori causes atrophic gastritis, which is associated with malabsorption of vitamin B12 and folic acid. Deficiency of these vitamins causes hyper-homocysteinaemia due to interruption of re-methylation pathway[42-45]. Hence, it may have a role in the pathogenesis of premature atherosclerosis[45]. In a study by Kutluana *et al*[45], carotid intima media thickness was found to be higher in patients with *H. pylori* related atrophic gastritis. In this study, *H. pylori* positive patients had significantly higher homocysteine levels compared to controls (14.17 ± 9.24 μmol/L *vs* 9.81 ± 3.42 μmol/L, $P = 0.01$). Senmaru *et al*[46] reported a higher prevalence of CAD in atrophic gastritis (5.8% *vs* 2.8%). Torisu *et al*[47] had shown an association between increased pulse wave velocity, a preclinical marker of atherosclerosis with atrophic gastritis. Apart from hyper-homocysteinaemia, other mechanisms are reduced ghrelin levels and induction of chronic pro-inflammatory cascade resulting into endothelial damage[46,47]. However, Bloemenkamp *et al*[48] did not support the hypothesis about *H. pylori* infection induced hyper-homocysteinemia and atherosclerosis.

H. pylori and dyslipidemia

H. pylori infection is associated with lower HDL cholesterol (HDL-C) and higher total cholesterol (TC), LDL cholesterol (LDL-C) and triglyceride levels. Higher apolipoprotein-B and lower apolipoprotein-A (apo-A) levels were also reported[11]. Murray *et al*[49] demonstrated that women with *H. pylori* infection had lower HDL-C ($P = 0.006$). Another study had also shown significantly lower HDL-C levels in

infected patients[11]. Niemelä *et al*[50] and Laurila *et al*[22] reported an increase triglyceride levels in *H. pylori* positive patients. These alterations in lipid homeostasis proved to be significant even after adjusting co-variables such as socioeconomic class, body weight, age and diabetic status[22,51]. de Luis *et al*[52] showed that eradication of *H. pylori* decreases apo-A and increases HDL-C. Other studies had also shown reduction in TC, LDL-C levels and increase in HDL-C, apo-AI and apo-AII levels following *H. pylori* eradication[53-55]. However, this association was not supported by few other authors[56-59].

H. pylori, impaired glucose metabolism and metabolic syndrome

Gillum *et al*[60] reported a significant association of *H. pylori* seropositivity with CAD in diabetic males. de Luis *et al*[51] showed that CAD and cerebrovascular diseases were significantly more seen in *H. pylori* infected diabetic patients. Yoshikawa *et al*[61] suggested that *H. pylori* seropositivity increases brachial-ankle pulse wave velocity, a marker of atherosclerosis, in patients with impaired glucose metabolism. Aydemir *et al*[62] reported that *H. pylori* positive subjects had higher homeostatic model assessment-insulin resistance (HOMA-IR) levels (2.56 ± 1.54 *vs* 1.73 ± 1.1, $P < 0.05$), a surrogate of insulin resistance, as compared to *H. pylori* negative controls. Aslan *et al*[63] had shown that paraoxanase, a marker of oxidative stress is well correlated with HOMA-IR levels and is significantly elevated in *H. pylori* positive patients. Regarding role of *H. pylori* eradication therapy in improvement of glucose tolerance, Gen *et al*[64] reported that HOMA-IR level significantly reduced after successful therapy, whereas Park *et al*[65] did not show any significant reduction. Polyzos *et al*[66] in his systematic review concluded that available evidences indicate a potential association between *H. pylori* infection and insulin resistance. Gunji *et al*[67] reported that *H. pylori* infection was significantly and independently associated with metabolic syndrome. A recent study by Ando *et al*[68] revealed that eradication of *H. pylori* increases circulating adiponectin levels and might be helpful in prevention of metabolic syndrome. Naja *et al*[69] suggested no association between *H. pylori* infection and metabolic syndrome or impaired glucose tolerance.

H. pylori, hypertension and arterial stiffness

Migneco *et al*[70] demonstrated a significant reduction in blood pressure after eradication of *H. pylori* in hypertensive subjects. The possible association of *H. pylori* with arterial stiffness was initially reported by Adachi and Yoshikawa. Adachi *et al*[71] reported that carotid pulse wave velocity was higher in seropositive subjects. Yoshikawa *et al*[61] similarly reported a higher brachial-ankle pulse wave velocity in seropositive patients with impaired glucose metabolism. The possible association of *H. pylori* and arterial stiffness tends to be more in younger subjects, whereas in the elderly arterial stiffness is more often due to aging[72]. Honda *et al*[73] demonstrated that *H. pylori* infection did not affect the age related progression of arteriosclerosis over a 4 years follow-up period.

EVIDENCE OF ASSOCIATION BETWEEN *H. PYLORI* AND ATHEROSCLEROSIS

H. pylori and CAD

Demonstration of an association between *H. pylori* and CAD is always challenging. Both conditions are more prevalent in the population, increases with age and are related to socioeconomic status. The following section reviews the evidence of *H. pylori* association with CAD.

Numerous studies have shown that CAD patients have a higher prevalence of *H. pylori* infection[74-77]. Vijayvergiya *et al*[77] demonstrated that CAD patients had higher IgG seropositivity as compared to controls (42% *vs* 23%, $P = 0.06$). Franceschi *et al*[78] found that *H. pylori* Cag-A was significantly associated with acute coronary events (OR = 1.34; 95%CI: 1.15-1.58, $P = 0.0003$). Niemelä *et al*[50] showed that the association between CAD and *H. pylori* infection was not strong. A meta-analysis revealed that there is a little association between *H. pylori* infection and stroke, but the strength of association was greater for Cag-A positive strains[79]. *H. pylori* was shown to be associated with premature CAD even in patients without conventional cardiovascular risk factors[80,81]. A number of studies had shown a negative association between *H. pylori* and CAD which include serological[82,83] and histological studies[84-86]. A negative association is even reported in long term follow-up studies[87]. The Australian Busselton health study comprising of 1612 healthy subjects demonstrated negative association between infection and CAD or stroke[88]. Danesh *et al*[89] in his meta-analysis of five prospective studies reported no significant association of *H. pylori* infection with CAD (RR = 1.13). Association of *H. pylori* infection and outcome of CAD treatment had also been studied. Schiele *et al*[90] found that *H. pylori* infection was not a risk factor for restenosis after percutaneous coronary angioplasty. Limnell *et al*[91] had shown an inverse relationship between *H. pylori* infection and coronary bypass graft occlusion. Results from Caerphilly heart disease study suggested that Cag-A seropositivity had no relations with CAD or CAD related mortality[92].

H. pylori has been associated with cardiac syndrome X, *i.e.*, angina pectoris with normal epicardial coronaries[28-30]. The proposed mechanism is chronic endothelial dysfunction. Eskandrian *et al*[28] reported a higher prevalence of *H. pylori* positivity in syndrome X patients compared to controls (95% *vs* 47.5%). Patients with syndrome X were found to be more commonly associated with *H. pylori* Cag-A positivity and elevated IL-1 and TNF-α[93]. Lanza *et al*[94] has

also described association of inflammation, infectious burden and vascular dysfunction. Assadi *et al*[30] reported 15% of patients with syndrome X had urea breath test (UBT) positivity for *H. pylori* while none of the patients with chronic stable angina or controls had UBT positivity.

H. pylori and acute myocardial infarction

H. pylori induced inflammatory reaction is possibly responsible for plaque instability and platelet aggregation in acute coronary syndrome patients. Danesh *et al*[95] demonstrated a higher prevalence of *H. pylori* infection (42% *vs* 24%, OR = 1.75) in young acute myocardial infarction (AMI) survivors. Alkout *et al*[96] showed a higher titre of *H. pylori* IgG titre in patients who died of AMI (151 ng/mL *vs* 88 ng/mL, p= 0.034). Kahan *et al*[97] reported a higher prevalence of *H. pylori* seropositivity in recent myocardial infarction patients as compared to controls (68% *vs* 53%, OR = 1.36). This remained significant even after adjusting for other CAD risk factors like age, sex, smoking and hypertension. Kinjo *et al*[98] suggested that *H. pylori* infection was significantly associated with AMI in younger patients (age < 55 years, OR = 2.7) but not in those with age of > 55 years. Frazer *et al* showed a higher prevalence of *H. pylori* infection in AMI patients compared to control (41.6% *vs* 34.5%; $P = 0.038$)[99].

Similar to CAD, negative associations is also been reported between *H. pylori* and myocardial infarction. Zhu *et al*[100] hypothesised that *H. pylori* infection could not lead to CAD or myocardial infarction. Murray *et al*[101] had shown a negative association between *H. pylori* and risk for myocardial infarction. Pellicano *et al*[102] reported a negative association between cytotoxic *H. pylori* strains and myocardial infarction, with insignificant anti-Cag-A antibody seropositivtiy between cases and controls (33.8% *vs* 26.8%).

H. pylori Cag-A positivity - Is the risk greater?

Cag-A positivity has raised a curiosity in the infectious theory of atherosclerosis. Several studies had shown a significant relationship between Cag-A strain and CAD or stroke. Carriers of Cag-A positive strains had a higher risk for stroke (OR = 2.99) and carotid plaque instability (OR = 8.42)[103]. De Bastiani *et al*[104] showed increased prevalence of Cag-A seropositivity and ischemic stroke. Rasmi *et al*[93] reported a positive relation between Cag-A seropositivity and cardiac syndrome-X. Huang *et al*[105] revealed that Cag-A positive strains enhanced atherosclerosis in CAD patients by modifying oxidised LDL levels and high sensitive C-reactive protein (hsCRP) levels. Kowalski[36] showed that Cag-A positivity was significantly associated with greater coronary artery lumen loss and restenosis after percutaneous coronary artery stenting. He also demonstrated that *H. pylori* eradication significantly attenuate reduction in coronary artery lumen after coronary artery stenting[36]. But various authors had denied the excess risk of Cag-A positive strains with atherosclerosis. Koenig *et al*[106] demonstrated a similar prevalence of Cag-A seropositivity in CAD patients and healthy subjects. Whincup *et al*[107] in his prospective study comprising of 505 patients and 1025 healthy subjects had clearly shown that there was no significant association of seropositivity with CAD. Murray *et al*[101] reported negative association between the virulent *H. pylori* Cag-A strains and acute myocardial infarction.

H. pylori and stroke

By catalysing atherosclerotic pathways, *H. pylori* infection may be a risk factor for ischemic stroke. Single infectious agent is weakly linked to stroke but cumulative chronic infectious exposures, or "infectious burden", have been associated with the risk of stroke. The adjusted hazard ratio demonstrating the risk of association between *H. pylori* and stroke was 1.13, whereas that of infectious burden and stroke was 1.39[108]. The possible mechanisms include macrophage activated plaque destabilization, increased expression of various adhesion molecules and inflammatory cytokines, localized hypercoagulability, altered gene expression, and a molecular mimicry. Markus *et al*[109] found a higher prevalence of *H. pylori* seropositivity in stroke cases compared to controls. There was an association between *H. pylori* infection and large vessel disease and lacunar stroke irrespective of other confounding factors. Another study by Grau *et al*[110] demonstrated an association between *H. pylori* seropositivity and ischemic stroke. Elkind *et al*[111] suggested that that chronic infectious burden results in increase carotid plaque thickness and stroke. A retrospective study reported higher incidence of ischemic stroke in patients with *H. pylori* infection than in non-infected group (14.8 *vs* 8.45 per 1000 person years)[112]. Diomedi *et al*[113] showed that Cag-A positive *H. pylori* infection was associated with poorer short term clinical outcomes and greater carotid intima media thickness in stroke patients. Increased risk of stroke in Cag-A positive *H. pylori* patients may be due to enhanced plaque vulnerability[103,114]. In one of the studies, the positive correlation between *H. pylori* and stroke was confounded by socioeconomic class[115]. A study on chronic bacterial infection and stroke demonstrated that elevated anti- *H. pylori* antibody was not significantly associated with ischemic stroke[116].

H. pylori and peripheral arterial disease

Studies about association of *H. pylori* infection with peripheral arterial disease (PAD) are limited. Bloemenkamp *et al*[117] demonstrated infection as a novel risk factor for PAD in young women. A case control study on infection and PAD in young women suggested that *H. pylori* infection was positively correlated with PAD only in those with high CRP levels[118]. Sawayama *et al*[119] reported a significantly higher prevalence of *H.*

pylori infection in PAD cases than in controls (79.7% *vs* 44.8%; $P < 0.01$).

CONCLUSION

Overall the association between *H. pylori* and CAD is not strong and a causal role is yet to be established. Future studies on larger scale may possibly establish a stronger link between the two. If it gets established, there can be drastic reduction in burden of CAD by managing *H. pylori* infection. Proponents of infectious theory will have a real challenge in the years to come because establishing a definite causal role of *H. pylori* in CAD will be a nightmare due to the existence of numerous confounding factors. Opponents may continue to criticise the infectious theory of CAD because of lack of strong scientific evidence.

Abstract

Palm oil consumption and its effects on serum lipid levels and cardiovascular disease in humans is still a subject of debate. Advocacy groups with varying agenda fuel the controversy. This update intends to identify evidence-based evaluations of the influence of palm oil on serum lipid profile and cardiovascular disease. Furthermore, it suggests a direction for future research. The sources of information were based on a PubMed, Google Scholar, African Journal online and Medline search using key words including: palm oil, palmitic acid, saturated fatty acids and heart disease. Published animal and human experiments on the association of palm oil and its constituents on the serum lipid profile and cardiovascular disease were also explored for relevant information. These papers are reviewed and the available evidence is discussed. Most of the information in mainstream literature is targeted at consumers and food companies with a view to discourage the consumption of palm oil. The main argument against the use of palm oil as an edible oil is the fact that it contains palmitic acid, which is a saturated fatty acid and by extrapolation should give rise to elevated total cholesterol and low-density lipoprotein cholesterol levels. However, there are many scientific studies, both in animals and humans that clearly show that palm oil consumption does not give rise to elevated serum cholesterol levels and that palm oil is not atherogenic. Apart from palmitic acid, palm oil consists of oleic and linoleic acids which are monounsaturated and polyunsaturated respectively. Palm oil also consists of vitamins A and E, which are powerful antioxidants. Palm oil has been scientifically shown to protect the heart and blood vessels from plaques and ischemic injuries. Palm oil consumed as a dietary fat as a part of a healthy balanced diet does not have incremental risk for cardiovascular disease. Little or no additional benefit will be obtained by replacing it with other oils rich in mono or polyunsaturated fatty acids.

Key words: Palm oil; Serum lipid profile; Heart disease; Palmitic acid; Antioxidants

Core tip: With the increase in the prevalence of cardiovascular diseases (CVD) worldwide including developing countries, increasing attention is paid to underlying risk factors. Low-density lipoprotein (LDL) cholesterol is related to CVD in a linear and continous manner and one of the strongest risk factors for CVD. Dietary saturated fat increases LDL. Palm oil contains saturated fat and has thus been touted to be "bad for the heart". However it also contains unsaturated fats and beneficial antioxidants. This review sought to clarify the role of this important source of nutrients (to a

large part of the worlds' population) in CVD.

INTRODUCTION

In recent times, there has been a running debate mainly in mainstream literature regarding the effects of palm oil consumption on the heart especially in the development of coronary artery disease. Advocacy groups and consumer protection groups drive most of the controversy with conflicting interests and agenda[1]. For thousands of years palm oil has been a major source of cooking oil in many communities in Asia and Africa[2-5].

In 2012, the World Heart Organization listed ischaemic cardiovascular disease (CVD) as the leading cause of death worldwide[6]. The relationship between serum cholesterol and CVD risk is linear and dose dependent with a 20%-25% reduction in the risk of death from CVD and non-fatal MI as low-density lipoprotein (LDL) cholesterol decreases by 1.0 mmol/L[7]. Palm oil consists of various fatty acids and this has been of major concern in discussing the value of palm oil vis-a-vis its relationship to cardiovascular disease[4,8]. The concern about palm oil is mainly because it contains palmitic acid, which is a saturated fatty acid and by extrapolation, using the Keys-Anderson equation which proposes that dietary intake of saturated fat increases serum cholesterol, will give rise to hypercholesterolemia when used as dietary oil[8]. However the main dietary saturated fatty acids (palmitic, stearic, lauric, and myristic acids) have varying effects on serum cholesterol. Saturated fatty acids with 12 and 14 carbon atoms (lauric and myristic acids) increase all the cholesterol fractions more than palmitic acid, and palmitic acid increases all the cholesterol fractions more than stearic acid[9]. On the other hand, oleic and linoleic acids which are unsaturated fatty acids do not have an adverse effect on serum cholesterol[9]. Palm oil has almost equal parts saturated and unsaturated fatty acids. Myristic acid (1%), stearic acid (5%) and palmitic acid (44%) make up the saturated fatty acid component in addition to monounsaturated oleic acid (39%), and polyunsaturated linoleic acid (11%)[10]. Furthermore, palm oil also contains vitamin E, carotenoids and antioxidants that do, at least in theory, protect the heart and also prevent cancer[4,5,11]. This review critically evaluates the scientific literature on palm oil in order to clearly show whether or not the consumption of palm oil indeed adversely alters the serum lipid profile and increases the prevalence of heart disease.

CHEMICAL COMPOSITION OF PALM OIL

The oil palm tree belongs to the genus Elaeis. The palm fruit has a fleshy mesocarp from which palm oil is derived and a seed from which palm kernel oil is derived[10]. These are two different types of oil and this paper is concerned with the former only.

The genus Elaeis has two species: E. guineensis and E. oleifera. The former is found mainly in West Africa, particularly in Nigeria and was propagated to Malaysia, Brazil, and Indonesia by the Portuguese in the 19th century for commercial purposes. E. oleifera originated from South America and is a dwarfish plant[5].

The major constituents of palm oil are triacylglycerols (TG). The glycerol molecule is esterified with three fatty acids. During the process of palm oil extraction from the fleshy mesocarp of the fruit, triacylglycerols attract other fat-soluble cellular components. These include phosphatives, sterols, pigments, tocopherols, tocotrienols, monoglycerols, diglycerol and free fatty acids (FFAs). The fatty acids are aliphatic acids like myristic, palmitic, stearic, linoleic acid. Palm oil also contains vitamins, antioxidants and other phytonutrients[10].

EFFECT OF PALM OIL CONSUMPTION ON SERUM LIPID PROFILE AND THE HEART

Animal studies

Onyeali *et al*[3] studied the influence of a palm oil-laced diet on the plasma lipid profile of Wister albino rats. The experimental animals were given a diet supplemented with 20% palm oil for 12 wk and compared to controls that were fed standard rat feed. They estimated the serum level of total cholesterol (TC), LDL, TG and high-density lipoprotein (HDL) at intervals of 0, 4, 8, and 12 wk. They demonstrated that although in the short term (4 wk) LDL and TC levels increased, sustained intake of the palm oil diet resulted in a significant reduction of the serum TG, TC and LDL levels compared to the control diet by 12 wk. The palm oil diet had no significant effect on HDL. The authors attributed most of these beneficial effects to the high content of antioxidants and vitamin A and E in the palm oil used. Tocotrienol and tocopherol make up 70% and 30% of the vitamin E present in red palm oil respectively[10]. The tocotrienols have been suggested to inhibit HMG CoA reductase enzyme activity and thus regulate serum cholesterol levels[12]. The findings from their study were in keeping with an earlier experiment in which Sulli *et al*[13] demonstrated that the supplementation of diet with α Tocopherol and β carotene (components of palm oil) reduced plasma cholesterol in hypercholesterolemic rabbits after 8 wk. Oluba *et al*[4] in Benin City Nigeria supplemented the diets of male albino Wister rats with palm oil and studied the effect of this on peroxidation of lipids and

activity of gluthathione peroxidase in their livers[4]. They showed clearly that as compared to the rats that were fed 5% cholesterol-diets without palm oil, those that had palm oil supplementation had a significantly reduced rate of lipid peroxidation in the liver. In addition, the activity of glutathione peroxidase increased significantly in the livers of the rats who fed on the supplemented diets. They extrapolated that in atheromatous plaques, oxidative damage induced by lipids could therefore be prevented by diets containing palm oil.

In the heart, ischemic episodes induces cell damage that can be made worse by sudden reperfusion due to the release of oxygen free radicals. Palm oil has been demonstrated to attenuate this effect in animal experiments. During reperfusion in rats that were fed diets supplemented by palm oil compared to control rats that had no supplementation, Tosaki *et al*[14] demonstrated a reduction in the level of oxidatively-modified proteins as well as an attenuation of the increase in free oxygen radicals in the heart. In a similar more recent study, Narang *et al*[15] used an isolated heart model of rats to demonstrate the effect of palm olein in the diet on ischemia reperfusion injury (IRI). Three groups of Wister rats were used. Two groups received different doses of palm olein (5% and 10% respectively). The third was the control group fed a normal diet. Thirty days later, each group was divided in two and each half was made to undergo global ischaemia for twenty minutes followed by reperfusion for 40 min. Following this, the investigators demonstrated that in the rats that were given the 5% olein-supplemented diet, there was an increase in the level of antioxidants in the myocardium but the levels of thiobabituric acid and reactive substance (TBARS) did not change. This was significant when compared to the rats fed the control diet that had significant oxidative injury with no concurrent increase in anti-oxidant activity. They however failed to observe a dose-dependent effect. Their study provided further evidence of the benefit of a palm oil supplemented diet in protecting the heart from oxidative stress and tissue injury following ischaemia-reperfusion. Furthermore, Kruger *et al*[16] clearly demonstrated a reduction in ischemia reperfusion injury in rats that were fed cholesterol rich diets when supplemented with palm oil. Many other studies have confirmed this[17-19].

Although they provide some evidence for the benefits of palm oil, they do not provide evidence of the effects of using palm oil that has been heated repeatedly on serum lipid profile and oxidant-antioxidant balance. It is well known that in parts of the world where palm oil is utilized for domestic cooking, it is reheated several times especially when used as frying oil. Adam *et al*[20] studied the influence of palm oil that had been heated repeatedly (five times) on serum lipid and homocysteine levels as well as peroxidation of lipids in rats. They found that the rats that were fed the heated palm oil had significantly increased lipid peroxidation, total cholesterol and TBARS compared to controls ($P < 0.05$).

These studies are inherently limited by the fact that they were conducted in rat models, which are not generalisable to humans as rats predominantly carry their cholesterol in HDL form[10]. Moreover the natural rat-diet is not fatty acid based further limiting the extrapolation of these results to humans.

Human studies

Palm oil especially as part of an overall low-fat diet has been shown to effectively maintain total cholesterol and lipoprotein cholesterol values. Kesteloot *et al*[21] measured serum lipids and apoproteins in 542 adults living in Nigeria. The subjects used palm oil exclusively as their source of cooking oil. The researchers reported that the subjects had lower cholesterol levels compared to values obtained from black and white Americans at the time.

Peanut oil and olive oil have 52%-60% and 65%-80% of their fatty acid composition as oleic acid respectively. Oleic acid has been demonstrated in several studies to have beneficial effects on serum lipids and cardiovascular disease[22]. These oils are thus recommended as healthier options. However, palm oil has 40% oleic acid. In addition the palmitic acid it contains, has been shown to have similar effects on the serum lipid profile as oleic acid.

Zhang *et al*[23] assessed the effect of palm oil used in Chinese diets in comparison to soya bean oil, peanut oil and lard. They showed that diets containing palm oil significantly reduced the levels of cholesterol in the serum of subjects who had normal serum cholesterol levels at baseline compared to lard but comparable to the effect of the mostly polyunsaturated soybean oil. Even among those who were hypercholesterolemic, palm oil significantly reduced the TC/HDL ratio more than peanut oil as the latter reduces HDL. It is important to note however that the Chinese diet contains less animal protein and cholesterol compared to typical "western" diets. This may have influenced their results, limiting their generalisability.

Ng *et al*[24] demonstrated that the main saturated fat in palm oil, palmitic acid was comparable to oleic acid in terms of its effect on cholesterol and lipoprotein levels in serum, as well as eicosanoids. Oleic acid is the major component of olive oil that is recognized as "heart-healthy" oil[24]. They achieved this by challenging 33 subjects (whose ages ranged between 22 and 41 years) that had normal serum levels of cholesterol with a diet rich in coconut oil for four weeks. Following this, they were given diets rich in palm olein or olive oil with a subsequent crossover after 6 wk. During this time, the only oil the subjects were allowed to use was the test oil group to which they were assigned. The coconut oil containing lauric and myristic fatty acids elevated all the lipoprotein and lipid parameters in

serum significantly. During the crossover periods, the olive oil and palm olein diets did not differ significantly in their effects on all measured lipid parameters. They concluded that in healthy humans with normal serum cholesterol levels, olive oil could be substituted with palm oil without significant changes in lipid profile. Similarly Sundram conducted a cross over study that was double blinded and demonstrated that palm olein and oleic acid were similar in their ability to lower cholesterol levels in serum[25]. An Indian study by Chafoorunissa *et al*[26] reported that groundnut oil and palm olein also have similar effects on cholesterol levels. They both maintain comparatively normal serum cholesterol levels.

In a systematic review and meta-analysis of 51 human dietary intervention trials, the authors compared trials in which palm oil was substituted for diets rich in polyunsaturated fatty acids (PUFAs), stearic acid and monounsaturated fatty acids (MUFAs)[27]. Although serum lipid profile (TC, HDL and LDL cholesterol, apolipoprotein A-I and apolipoprotein B) was beneficially altered with diets containing palm oil compared to myristic and lauric acid, the same was not the case when compared to PUFAs and MUFAs. In young people and those subjects that had overall lower energy intake from fat, this latter finding was not significant. The diets rich in palm oil did not significantly change the TC/HDL or LDL/HDL cholesterol ratios. On the other hand, the palm oil rich diets significantly increased the levels of apolipoprotein A-I and HDL cholesterol and reduced the levels of TC/HDL, triacylglycerols and apolipoprotein B when compared to trans fatty acid-rich diets. They concluded that with regards to usual dietary sources of fat, palm oil was not much different except when it was substituted for trans fat where it proved beneficial. Considering that majority of global fat consumption is in the form of solid fats and the process of converting liquid oils to solid fats involves hydrogenation, which produces trans fats, palm oil has a distinct advantage; it does not require hydrogenation to turn it to solid fats. In this way solid fats made from palm oil are free from trans fats[28].

Dietary fats influence on coronary heart disease risk has traditionally been estimated from their effects on total and LDL cholesterol. Following large epidemiologic studies in the 50's and 60's saturated fats gained a bad reputation in terms of being significantly associated with cardiovascular disease especially coronary heart disease (CHD) and cardiovascular mortality[8,9,22]. Furthermore several meta-analysis and systematic reviews of randomised controlled trials and cohort studies recommended that polyunsaturated fatty acids should substitute saturated fatty acids. This was based on the supposition that this reduces the risk of CHD events and fatal CHD despite the fact that they demonstrated no direct link between saturated fatty acids and CHD death[29-31]. This informed various guideline recommendations to reduce total dietary energy intake from saturated fats in a bid to decrease the prevalence of coronary heart disease[32-34]. A recent meta-analysis has countered this theory as the authors found that a significant relationship did not exist between saturated fat intake and cardiovascular disease (coronary heart disease and stroke)[35]. In patients with established CHD, secondary prevention by means of a reduced fat or modified fat diet (in which saturated fat is substituted by mono- or poly unsaturated fat) is also recommended[34]. However, another recent meta-analysis by Schwingshackl and Hoffmann has shown that this had no significant effect on all-cause mortality and cardiovascular mortality, combined cardiovascular events and myocardial infarction[36]. Furthermore multivariate meta-regression in their study did not reveal significant relationships between changes in saturated fatty acids, monounsaturated and polyunsaturated fatty acids and risk of all-cause or cardiovascular mortality, myocardial infarction and cardiovascular events. It remains important to note however that this meta-analysis included studies that differed in various ways including the protocols of the studies resulting in some heterogeneity. In addition there was publication bias and the quality of evidence was graded as moderate.

CONCLUSION

Taking all the above into consideration, it is known that saturated fat adversely affects lipid profile and raised serum total and low-density lipoprotein cholesterol is associated with cardiovascular risk. However not all saturated fats have this adverse effect. Palmitic acid the main saturated fat in palm oil has a similar effect on lipid profile as the monounsaturated fat oleic acid that is currently recommended. In addition palm oil also contains oleic and linoleic acids, and vitamin E tocotrienols that are powerful antioxidants and inhibit cholesterol synthesis as well[37].

Therefore, in conclusion it is the opinion of the authors that palm oil consumed as a dietary fat as part of a healthy balanced diet does not have incremental risk for cardiovascular disease. Little or no additional benefit will be obtained by replacing it with other oils rich in mono or polyunsaturated fatty acids. We recognize that more longitudinal population-based studies are needed to fully characterize the impact of the consumption of diets, which utilize palm oil compared to other accepted "heart healthy" oils like olive oil on the future risk of heart disease using lipid parameters as intermediate markers of risk.

Abstract

AIM: To investigate long-term efficacy of two different devices more than five years after percutaneous atrial septal defect (ASD) closure in adults.

METHODS: All patients who underwent percutaneous closure of an ASD in the St. Antonius Hospital, Nieuwegein, The Netherlands, between February 1998 and December 2006 were included. Percutaneous closure took place under general anaesthesia and transesophageal echocardiographic monitoring. Transthoracic echocardiography (TTE) was performed 24 h post-procedure to visualize the device position and to look for residual shunting using color Doppler. All complications were registered. All patients were invited for an outpatient visit and contrast TTE more than 5-years after closure. Efficacy was based on the presence of a residual right-to-left shunt (RLS), graded as minimal, moderate or severe. The presence of a residual left-to-right shunt (LRS) was diagnosed using color Doppler, and was not graded. Descriptive statistics were used for patients' characteristics. Univariate analysis was used to identify predictors for residual shunting.

RESULTS: In total, 104 patients (mean age 45.5 ± 17.1 years) underwent percutaneous ASD closure using an Amplatzer device (ASO) in 76 patients and a Cardioseal/Starflex device (CS/SF) in 28 patients. The mean follow-up was 6.4 ± 3.4 years. Device migration occurred in 4 patients of whom two cases occurred during the index hospitalization (1 ASO, 1 CS/SF). The other 2 cases of device migration occurred during the first 6 mo of follow-up (2 CS/SF). The recurrent thrombo-embolic event rate was similar in both groups: 0.4% per follow-up year. More than 12 mo post-ASD closure and latest follow-up, new-onset supraventricular tachyarrhythmia's occurred in 3.9% and 0% for the ASO and CS/SF group, respectively. The RLS rate at latest follow-up was 17.4% (minimal 10.9%, moderate 2.2%, severe 4.3%) and 45.5% (minimal 27.3%, moderate 18.2%, severe 0%) for the ASO- and CS/SF groups, respectively. There was no residual LRS in both

groups.

CONCLUSION: Percutaneous ASD closure has good long-term safety and efficacy profiles. The residual RLS rate seems to be high more than 5 years after closure, especially in the CS/SF. Residual LRS was not observed.

Key words: Percutaneous intervention; Atrial septal defect; Closure device; Right-to-left interatrial shunt; Left-to-right interatrial shunt; Echocardiography

Core tip: Several atrial septal defect (ASD) closing devices have been proven safe and effective for percutaneous ASD closure. We evaluated long-term (*i.e.*, more than 5-year of follow-up) efficacy of two different devices used in adults. Percutaneous ASD closure seems to be relatively safe using the Amplatzer device. Though, the right-to-left shunt (RLS) rate is high, a residual left-to-right shunt was absent at latest follow up. The Cardioseal/Starflex device appears to be associated with a higher complication- and residual RLS rate. The importance of a residual RLS is unclear. Therefore, long-term follow up might be necessary.

INTRODUCTION

An atrial septal defect (ASD) is a common cardiac defect and accounts for one third of all congenital heart diseases detected in adults[1,2]. The diagnosis in adults is often made when complications of the shunt occur, such as pulmonary hypertension, heart failure, arrhythmias, or paradoxical embolism. Most of these complications might be prevented by closure.

Since the first description of the transcatheter closure device for an ASD in 1976 by King *et al*[3], percutaneous ASD closure has been practiced and described extensively. Other studies evaluated various ASD closure devices and showed good mid-term (up to 2 years) safety and efficacy profiles[4-7]. However, long-term (*i.e.*, more than 5-year after closure) safety and efficacy data on percutaneous closure devices has not been available yet. We report long-term efficacy and safety of two types of ASD closure devices.

MATERIALS AND METHODS

Population

All patients who underwent a percutaneous closure of an ASD in the St. Antonius Hospital, Nieuwegein, The Netherlands, between February 1998 and December 2006 were included in this study. All patients were invited for an outpatient visit and transthoracic echocardiography (TTE).

Closing procedure

As reported earlier, percutaneous closure took place under general anaesthesia and transesophageal echocardiographic (TEE) monitoring according to standard techniques[4]. TTE was performed 24 h post-procedure to visualize the device position and to look for residual shunting using color Doppler.

Follow-up and complications

Follow-up information was obtained at the outpatient clinic or by a telephone interview. All complications were documented, and divided into major and minor as described by Khairy *et al*[8]. Major complications included procedure related events such as haemorrhage requiring blood transfusion, occurrence of cardiac tamponade, need for procedure-related surgical intervention, massive fatal pulmonary emboli, occurrence of new thrombo-embolic events and death[8].

New-onset supraventricular tachycardia's were diagnosed by routine ECG when patients visited the outpatient clinic or when patients visited the emergency department because of symptoms.

Efficacy

The efficacy of the ASD closure was based on the presence of residual shunting using contrast TTE (cTTE) with Valsalva manoeuvre, and color Doppler. A residual right-to-left shunt (RLS) was present if microbubbles appeared in the left atrium. Opacification of the left ventricle and shunt grade were classified as minimal (maximum of 30 micro-bubbles in left ventricle), moderate (between 30 and 100 bubbles in left ventricle), and large (> 100 micro-bubbles in the left ventricle). This division was based on the maximum number of microbubbles counted in one still frame, as previously reported[9]. The presence of a left-to-right shunt (LRS) was based color Doppler imaging at the atrial septum. The LRS was not graded.

Statistical analysis

Descriptive statistics were used for patients' characteristics. Continuous variables with normal distribution are presented as mean ± SD or median with range if normal distribution was absent. Univariate analysis was used to identify predictors for residual shunting. All statistical analyses were performed using SPSS software (version 22.0 for Windows).

RESULTS

Study population

Percutaneous ASD closure was performed in 104

consecutive patients (75% women; mean age, 45.5 ± 17.1 years). Baseline characteristics, risk factors, co-morbidity and indication for closure are summarized in Table 1.

Less than 12-mo follow-up: Safety and efficacy

Device implantation was initially uneventful in 102 patients (98.1%). In 76 patients (73.1%) an Amplatzer (ASO), and in 28 patients (26.9%) a Cardioseal/Starflex (CS/SF) was used for closure. In total, 4 major complications occurred within the first 6 mo. Two patients (1.9%, 1 ASO, 1 CS/SF) suffered from embolization of the device during the index hospitalization and two (1.9%, 2 CS/SF) within the first 6 mo after closure. All underwent surgical device extraction; the ASD was closed using a patch during the same operation. All patients recovered well. Procedural characteristics are shown in Table 2.

Between 6- and 12 mo, another two patients (1.9%, 2 CS/SF) underwent surgical extraction of the device and the ASD was closed with a patch during the same operation. One patient had a large residual shunt, which could not be closed with a second device. The other patient needed rhythm surgery, therefore, device extraction was performed.

Within the first 12-mo, recurrent thrombo-embolic events occurred in 1 patient (0.9%, 1 CS/SF). This 58-year-old patient suffered a transient ischemic attack (TIA). Because of a history of supraventricular tachyarrhythmia's (SVT) the patient was already using oral anticoagulation. cTTE showed no residual RLS.

[1]Data presented as median (range); [2]Data available in 79 patients. TEE: Transesophageal echocardiography; SVT: Supraventricular tachycardia; TTE: Transthoracic echocardiography.

New-onset SVT's occurred in 6.6% of the ASO group and in 17.9% of the CS/SF group.

More than 12-mo follow-up: Efficacy and complications

Contrast TTE was performed in 57 patients (54.8%, 46 ASO and 11 CF/SF). Median follow-up time for the ASO group was 6.6 years (5.0-11.1 years) and the CS/SF group 9.9 years (6.3-13.4 years). Though, cTTE could only be performed in 57 patients, follow-up information was available in a total of 81 patients.

Long-term follow-up data could not be retrieved (interview or cTTE) in 23 patients of which 6 were surgically closed, 4 died (no device related cause was suspected) and 13 were lost to follow-up.

Contrast TTE showed a RLS shunt in eight patients (17.4%) who received an ASO. Of these, five patients (10.9%) had a minimal, one patient (2.2%) a moderate and two patients (4.3%) a severe residual shunt. Five patients who received a CS/SF device (45.5%) had a residual RLS of which three patients (27.3%) had a minimal and two patients (18.2%) a moderate residual RLS. When minimal shunts were excluded, the closure rate was 93.5% for ASO and 81.8% for the CS/SF device, respectively. There was no recurrent LRS at latest follow up. Our analyses showed no significant differences in the diameters of the ASD or the device used between the patients with or without a residual shunt. Secondly, no predictors for a right-to-left shunt at long-term follow-up could be found using univariate analysis.

Recurrent thrombo-embolic events after more than 12 mo of follow-up occurred in two patients (1.9%, 2 ASO). One 40-year-old patient suffered a cerebrovascular accident 2.5 years after ASD closure, while on aspirin because of coronary artery disease.

Table 3 Five years follow-up

	Amplatzer	Cardioseal/STARflex

Follow up (yr)	6.6 (5.0-11.1)	9.9 (6.3-13.4)

SVT: Supraventricular arrhythmia; TIA: Transient ischaemic attack; TTE: Transthoracic echocardiography; FU: Follow-up; RLS: Right-to-left shunt; LRS: Left-to-right shunt.

Although there was no history of SVT or device thrombus, oral anticoagulation was initiated after this event. At long-term follow up, a minimal residual RLS was found. The other patient (48-year-old) was known with a history of multiple TIA's prior to closure and was therefore treated with Aspirin. Despite closure of the ASD and optimal medical treatment, the patient suffered from another TIA more than 5 years after ASD closure. At the long-term follow-up visit no residual shunt or thrombus formation on the device was found. This patient had no history of SVT. In total, 3 patients suffered a recurrent neurological event during a mean follow up of 6.4 years (0.5% per year follow up).

During long-term follow-up, new-onset SVT occurred in 3 patients (3.9%) who received an ASO and in none of the patients who received a CS/SF device.

Long-term residual shunt rate, recurrent thrombo-embolic event rate and new-onset SVT rate are presented in Table 3. Figure 1 shows the percentage of patients with residual right-to-left shunt at more than 5-year follow-up after percutaneous ASD closure.

A flow-chart showing the results of this study during follow-up is presented in Figure 2.

DISCUSSION

Percutaneous ASD closure has relatively good long-term safety- and efficacy profiles, especially using the ASO device. A high residual RLS was present in CS/SF. Residual LRS was not observed in either the ASO- or the CS/SF group.

Complications

Device embolization and dislocation is a well-known complication after percutaneous ASD closure[10,11]. The CS/SF is related to a relatively high embolization rate compared to the ASO[12]. In literature, embolization of the CS/SF has been described between 1.4% and 2.5% and for the ASO between 0.1% and 2.4%[7,10,13,14]. In all studies, embolization occurred during the procedure or the index hospitalization. Kefer *et al*[15] and Masura *et al*[16], described 112 and 151 patients with a mean follow-up of 5 and 6.5 years, respectively, and showed no device embolization using the ASO device.

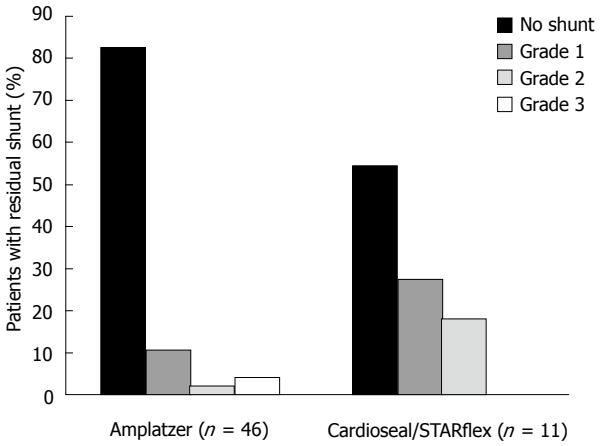

Figure 1 Percentage of patients with residual right-to-left shunt at more than 5-year follow-up after percutaneous atrial septal defect closure.

In our study 4 major complications (3.8%) occurred within the first six months after closure. Device migration occurred in 10.7% of the patients with a CS/SF device and in 1.3% using an ASO device. All devices were surgically extracted and the ASD was closed with a patch. Compared to the literature our CS/SF subgroup had a higher complication rate, while the ASO subgroup was similar. Hence, the CS/SF devices are no longer available for ASD closure. However, long-term follow-up of patients who received a CS/SF device is recommended.

Because device embolization occurred more often in patients with a Cardioseal/Startflex device, we analysed potential reasons/risk factors only for this device. Post *et al*[5] showed that the initial ASD and the device diameter were significantly higher in the patients in whom the device was embolized. However, due to the small sample size of this study it is difficult to make any conclusions.

Recurrent thrombo-embolic events

Kefer *et al*[15] described a recurrent stroke rate of 0% after percutaneous ASD closure with similar devices and follow-up time as in our study. Masura *et al*[16] described no thrombo-embolisms during the entire follow-up period. One patient (0.6% per follow-up year) with an ASO device in the study of Spies *et al*[7] suffered a thrombo-embolic event, which could not be related to a residual shunt or device related thrombus formation.

In our study, the recurrent thrombo-embolic event rate during long-term follow-up was 0.4% per

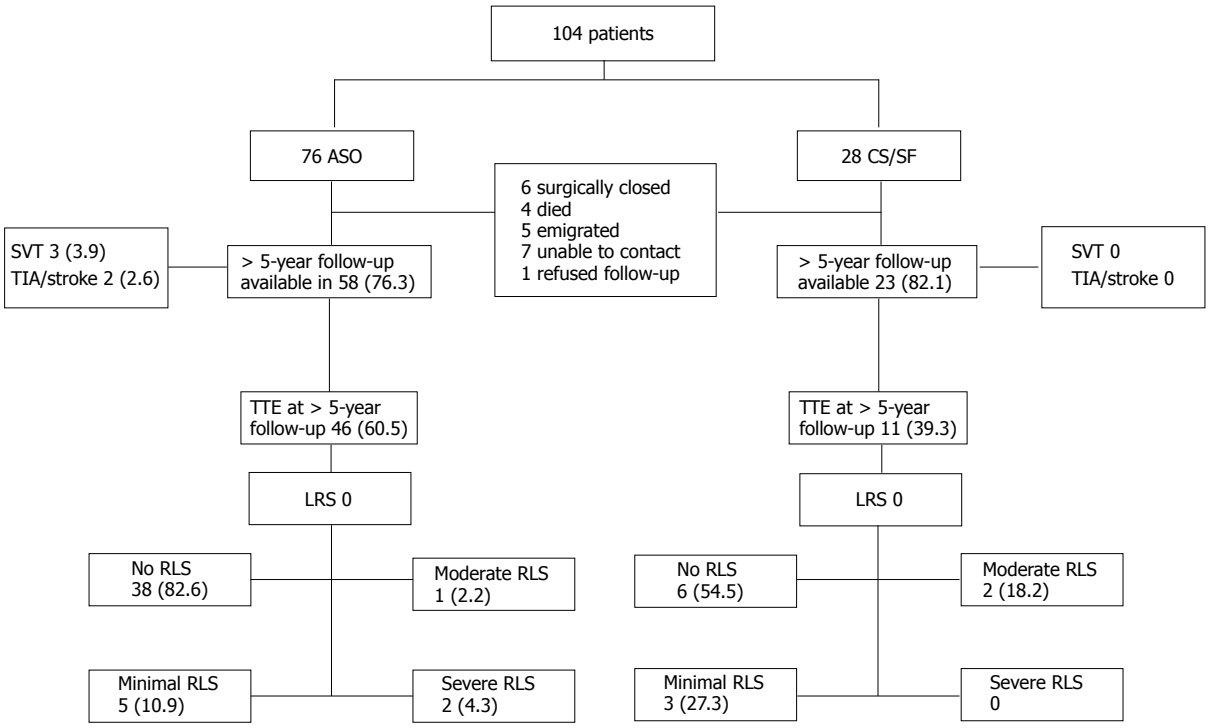

Figure 2 Flow-chart showing the results of this study during follow-up. Data is presented as number of patients (%). ASO: Amplatzer; CS/SF: Cardioseal/Starflex; SVT: Supraventricular arrhythmia; TIA: Transient ischemic attack; TTE: Transthoracic echocardiography; LRS: Left-to-right shunt; RLS: Right-to-left shunt.

follow-up year for both devices, which is similar when compared to the literature. As described above, all patients were treated with anti-platelet therapy or oral anticoagulation and a minimal residual RLS was found in only one patient.

Arrhythmias

arrhythmias early after ASO or other devices implantation are common and extensively described[10,17,18]. Masura *et al*[16] also mentioned SVT's at early follow-up, but none during long-term follow-up. Chessa *et al*[10] noted that arrhythmias are the second most common complication in their study (2.6%) early after the procedure using both the ASO and the CS/SF. Tomar *et al*[19] described peri-procedural arrhythmias but none were seen during long-term follow-up (median 56 mo). At 2-year follow-up, Spies *et al*[18] found an annual incidence of new-onset atrial fibrillation of 4.1%. Butera *et al*[13] described 274 patients (153 ASO, 121 CS/SF) and showed no arrhythmias at follow-up (respectively 16- and 24-mo).

In our study, 3.9% of the patients with an ASO device had new-onset SVT without any abnormalities during cTTE at long-term follow up.

Residual shunting

Residual LRS rates for the ASO has previously been described in several studies and ranged between 0%-12.5% at long-term follow up[13-16,19,20]. Kefer *et al*[15] described a residual LRS rate of 4%. However, only 2 patients (1.8%) with a residual LRS had received an ASO. At 3-year follow-up, Masura *et al*[16] showed no residual shunt using color-Doppler. Butera *et al*[20] described 165 patients with a residual LRS rate of 2% in patients suffering multiple ASD's. At 24-mo follow-up, a non-significant difference between the ASO and CS/SF was found (respectively 0% *vs* 4.4%). In a study by Nugent *et al*[14], 72 patients received a CS/SF device with a total residual LRS of 12.5% between 12- and 24-mo of follow-up.

Our study showed no residual LRS for both devices at more than 5-year of follow-up. However, the prevalence of a RLS is relatively high. Earlier, Luermans *et al*[12] described a residual RLS rate of 14% 3.4 years after closure in 29 patients who received a CS/SF device.

In our study, the RLS rate for the ASO was 17.4% and 45.5% for the CS/SF device more than five years after closure. When excluding the minimal shunts, the ASO had a RLS rate of 6.5% and the CS/SF of 18.2%. The importance of this relatively high rate of RLS is unclear, as the reason for closure was mainly related to the presence of a LRS. Therefore, the fact that we did not notice residual LRS is an important observation. Moreover, to assess the clinical importance of the presence of a RLS, long-term follow-up might be necessary.

The difference in RLS rate after percutaneous ASD closure might be due to the different closing mechanisms; the ASO has a "stent-like" mechanism and consists of Nitinol metal with rounded disks with a polyester fabric sewn inside the meshed disks. The CS/SF device has a "double patch" mechanism and

the fabric is directly exposed to blood[13,21]. The latter might delay the endothelialisation of the devices, which is important for complete closure of the ASD. Why endothelialisation happens in some patients better than others is unclear.

Limitations

Firstly, it is a single-centre design with a small sample-size. Secondly, we used cTTE at follow-up for residual shunt classification while the gold standard is contrast TEE. Though, we did not use contrast TEE, literature describes mostly studies where only color Doppler is used for the assessment of residual shunts. Thirdly, an independent core lab did not review the TTE's. Fourthly, the long-term follow up data was available in about 80% of patients; this might lead to an under- or overestimation.

Percutaneous closure of a secundum-type atrial septal defect seems to be safe using the ASO. Though, the RLS rate is relatively high, a residual LRS is absent more than 5-year after closure. The CS/SF appears to be associated with a relatively high complication- and residual RLS rate. Because of the unclear importance of a RLS after percutaneous ASD closure, long-term follow-up might be necessary.

COMMENTS

Background

An atrial septal defect (ASD) is a common cardiac defect and accounts for one third of all congenital heart diseases detected in adults. The diagnosis in adults is often made when complications of the shunt occur, such as pulmonary hypertension, heart failure, arrhythmias, or paradoxical embolism. Most of these complications might be prevented by closure.

Research frontiers

Since the first description of transcatheter device closure of an ASD in 1976, percutaneous closure of an ASD has been practiced and described extensively. Other studies showed the efficacy and safety of percutaneous closure of ASD's with different devices, mainly during mid-term follow up. Little is known about follow-up more than 5 years after percutaneous ASD closure in adults. We report the efficacy of ASD device closure at more than 5 years follow-up (long-term follow-up).

Innovations and breakthroughs

Previous studies showed that a percutaneous closed ASD using a Cardioseal/Startflex (CS/SF) is associated with a high residual right-to-left shunt (RLS) at mid-term follow-up. This study confirmed that a high residual RLS is still present during long-term follow-up. However, no left-to-right shunt (LRS) was present. Percutaneous closure using a Amplatzer device (ASO) has proven to be efficient at mid-term follow-up. During long-term follow-up no LRS was found. However, a relatively high RLS was present. The importance of RLS at follow-up is unclear. The safety for both devices is similar when compared to literature.

Applications

During long-term follow-up, percutaneous closure of ASD's seems to be safe using different devices, especially using the ASO device. A high residual RLS is present in CS/SF, however there was no residual LRS observed using both the ASO- and the CS/SF device.

Terminology

An ASD is an opening in the septum between the right- and left atrium. It is a congenital heart disease and therefore present at birth. An ASD can cause symptoms due to heart failure, arrhythmia's, paradoxical embolism and pulmonary hypertension. Percutaneous closure of an ASD is a relatively simple procedure where a Nitinol device is placed in the opening between the right- and left atrium. Tansthoracic ultrasound of the heart is used to check whether there is a residual opening in the atrial septum.

Peer-review

The paper by Dr. Snijder *et al* reports the experience in percutaneous closure of atrial septal defects in 104 patients using two devices. Interestingly, in a long-term follow-up a residual left-to-right shunt is absent, although the rate of a residual right-to-left shunt is relatively high.

Abstract

We are presenting a case of one of the largest unruptured abdominal aortic aneurysm ever reported. Presented here is a rare case of a 69-year-old active smoker male with history of hypertension and incidental diagnosis of abdominal aortic aneurysm of 6.2 cm in 2003, who refused surgical intervention at the time of diagnosis with continued smoking habit and was managed medically. Patient was subsequently admitted in 2012 to the hospital due to unresponsiveness secondary to hypoglycemia along with diagnosis of massive symptomatic pulmonary embolism and non-ST elevation myocardial infarction. With the further inpatient workup along with known history of abdominal aortic aneurysm, subsequent computed tomography scan of abdomen pelvis revealed increased in size of infrarenal abdominal aortic aneurysm to 9.1 cm of without any signs of rupture. Patient was unable to undergo any surgical intervention this time because of his medical instability and was eventually passed away under hospice care.

Key words: Abdominal aortic aneurysm; Unruptured; Elderly male; Active smoking

Core tip: Regular screening of patients with abdominal aortic aneurysm with abdominal ultrasound to prevent catastrophic complication of aortic rupture and early aggressive surgical intervention when indicated.

Saade C, Pandya B, Raza M, Meghani M, Asti D, Ghavami F. 9.1 cm abdominal aortic aneurysm in a 69-year-old male patient. *World J Cardiol* 2015; 7(3): 157-160 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i3/157.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i3.157

INTRODUCTION

Abdominal aortic aneurysm is one of the most common conditions seen in elderly hypertensive male with active smoking. Aortic rupture is seen to be the

commonest catastrophic complication associated with the condition[1-3]. Purpose of our case report is to illustrate importance of regular screening and timely intervention of abdominal aortic aneurysm along with one of the largest reported image of un-ruptured aortic aneurysm.

CASE REPORT

A 69-year-old man was brought to the emergency department by emergency medical services (EMS) after being found unresponsive by his partner's mother. Initially he was detected to be hypoglycemic with blood glucose of less then 30 mg/dL, which was managed by Ⅳ dextrose administered by EMS prior to arriving at the hospital.

The patient was diagnosed 6.2 cm infra renal artery aneurysm in 2003. He also had a 3.4 cm saccular aneurysm of the descending thoracic aorta, an aneurysm of 1.9 cm in the common iliac artery, and an aneurysm of the left renal artery. At that time, he decided to receive medical treatment. His past medical history is also significant for systolic congestive heart failure (CHF) mitral regurgitation, myocardial infarction, hypertension, type 2 diabetes mellitus, peripheral vascular disease, smoking (40 packs per year), lower gastrointestinal bleeding and depression. His medications included Aspirin, Carvedilol, Digoxin, Lasix, spironolactone, Lantus insulin, Dexilant, Lorazepam, Gabapentin, and Percocet. Upon arrival to the emergency room in October 2012, the physical exam was characterized by an altered mental status, and he was barely responsive to painful stimuli. He was tachypneic and tachycardic with bilateral rhonchi and rales in respiratory exam, but had stable blood pressure. The rest of his physical exam was unremarkable.

Electrocardiogram showed sinus rhythm with premature ventricular complexes, right bundle branch block, and ST segment depression in inferior leads. Chest X-Ray revealed cardiomegaly and a right lower lobe infiltrate. Computed tomography (CT) scan of the chest with contrast revealed a segmental pulmonary embolism in the right lower lobe consistent with a small infarction, a new 1.0 cm × 0.8 cm × 1 cm marginated left upper lobe pulmonary nodule suspicious for neoplasm, a moderate centrilobular emphysema, small bilateral pleural effusions and a new filling defect within a dilated left ventricle which is suggestive of left ventricular thrombus. CT scan of the abdomen and pelvis with contrast was significant for an increase in size of the descending thoracic aortic aneurysm to 4.2 cm × 3.6 cm, an infrarenal abdominal aorta measuring 9.1 cm × 8.7 cm and right common iliac artery at about 2.4 cm × 2.6 cm. Left renal artery was stable at 3.1 cm × 2.7 cm. There was no evidence of rupture in the abdominal aortic aneurysm.

The patient had elevated troponins level possibly due to a NSTEMI. He received Ⅳ heparin to manage pulmonary embolism and possible NSTEMI. Considering his extensive medical history, poor medical management outcome and deteriorating mental condition, his family decided to place the patient in hospice care on 10/10/12. The patient died on 10/12/12.

DISCUSSION

Aortic aneurismal disease is defined as a focal dilation of the aorta with a diameter greater than 3.5 cm. Thoracic aneurysms are located above the diaphragm. The abdominal aneurysm is more common and is located below the diaphragm with a prevalence of 1.4% in the United States population age 50 to 84[2]. Aortic rupture is the most common complication of these aneurysms with a mortality rate as high as 75% for the abdominal aneurysm[3]. The profile of a patient that might have an aneurysm and eventually may benefit from a screening test would be a man between 65 and 75 with a history of smoking or a younger patient with a family history of a genetic disease associated with aneurysms[1,4]. The 2005 United States Preventive Services Task Force (USPSTF) report recommended ultrasonography as the screening test for the abdominal aneurysm with a sensitivity rate as high as 100%. Multiple risk predictors for the growth and rupture of an AAA were determined and included: continuous smoking which is the major risk factor, female gender, diastolic hypertension, maximum transverse diameter > 5.5 cm, and dyslipidemia[1,4-9]. On the other hand, other factors were found to decrease the growth rate and subsequently the risk of rupture of abdominal aortic aneurysm (AAA). The use of statins in a recent metanalysis[10] has been shown to reduce by 0.63 mm/year the growth rate of the AAA. Both macrolides and tetracyclines[11-13] were associated with a lower expansion rate of the AAA. However, propanolol use hasn't been beneficial in preventing the growth rate of AAA in a double-blind randomized study[14]. When it comes to surgical management, the threshold recognized currently is 5.5 cm or above. This was demonstrated in two trials conducted in the United Kingdom and United States[6,7]. A CT scan is warranted as part of the preoperative planning because it can help characterizing the AAA for a better surgical approach.

Our patient had both thoracic and abdominal aneurysms with the latter measuring 9.1 cm as a maximum diameter at the time of his death. To our knowledge, this is the largest unruptured AAA to be diagnosed. The patient was incidentally diagnosed to have an AAA of 6.6 cm on CT scan (Figure 1). The incidental finding of an AAA is as high as 0.5% on CT scan as reported in Al-Tahani study[15]. Even though the patient was eligible for surgical reparation of the AAA, he refused the operation knowing the risks of his decision. Between 2003 and 2012, the patient

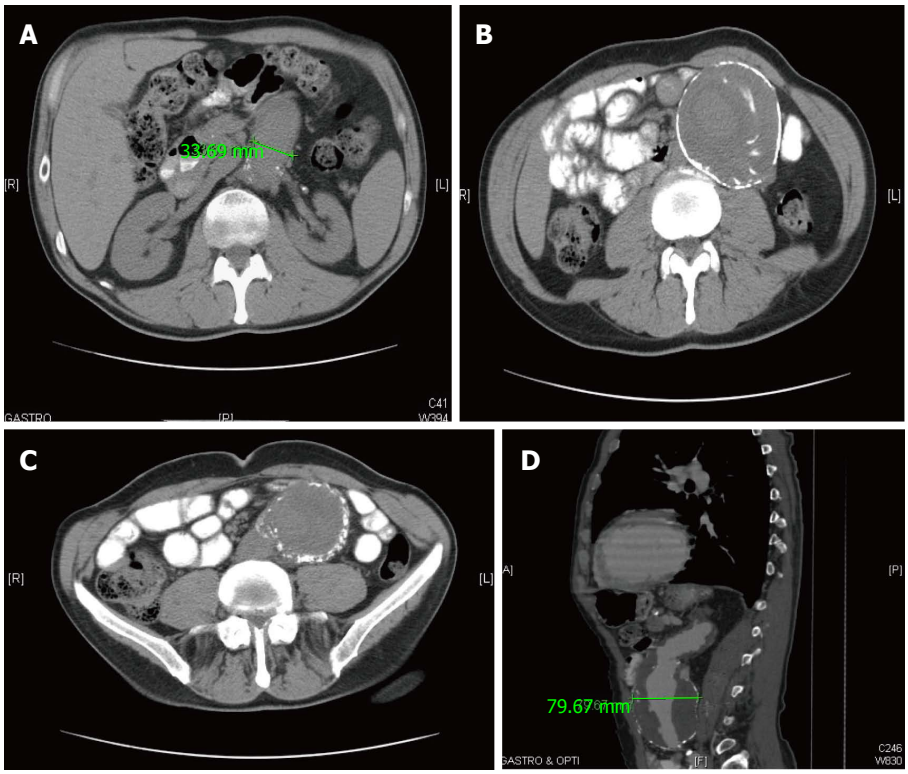

Figure 1 Computed tomography scan. A: Showing aortic abdominal aneurysm at the level of renal arteries; B: Showing massive unruptured abdominal aortic aneurysm along with loops of small intestine; C: Showing continuation of abdominal aortic aneurysm along with plaques of calcification surrounding it; D: Showing longitudinal section of contrast filled abdominal aortic aneurysm with bilateral mural thrombus.

continued to smoke and was taking medications for his hypertension and CHF. He had thus 2 major risk factors for the growth of his AAA considering that his hypertension was medically controlled. In 2012, the size of his AAA increased to 9.1 cm thus at a rate of 0.32 cm/year. At this point, the patient was inoperable because of his worsening CHF and his massive pulmonary embolism. The CT scan also showed the continuous growth of the thoracic aneurysm and the right common iliac artery aneurysm. As per Brown et al study[9], this male patient with an AAA greater than 6 cm had a 14.1% risk per year of having a ruptured AAA. The Helsinki study[16] showed that in 154 cases excluded from the surgical repair of AAA due to severe co morbidities in the patients, 43% eventually died because of a ruptured AAA. Therefore, it can be postulated that the patient had an imminent risk for AAA rupture. No autopsy was done as per the request of the family but it might be speculated that the patient's death was due to ruptured AAA especially that he had to be started on therapeutic heparin for his massive symptomatic PE.

COMMENTS

Case characteristics

A 69-year-old male presented with hypoglycemia found to have 9.1 cm × 8.7 cm unruptured AAA.

Clinical diagnosis

Patient was found to have subsequent pulmonary embolism and Non ST elevation Myocardial infarction.

Imaging diagnosis

CT scan of the abdomen and pelvis with contrast was significant for an increase in size of the descending thoracic aortic aneurysm to 4.2 cm × 3.6 cm, an infrarenal abdominal aorta measuring 9.1 cm × 8.7 cm and right common iliac artery at about 2.4 cm × 2.6 cm.

Treatment

Due to patient's medical instability, he was not a surgical candidate.

Related reports

So far reported cases in literatures are either ruptured abdominal aortic aneurysm or not significantly enlarged. Reported here is case of unruptured largest abdominal aortic aneurysm, which can be managed successfully with timely intervention.

Experiences and lessons

Regular screening of patients with abdominal aortic aneurysm with abdominal ultrasound helps prevent catastrophic complication of aortic rupture and early aggressive surgical intervention when indicated.

Peer-review

This is a well-written clinical case report regarding to the large un-ruptured abdominal aortic aneurysm. The case is interesting and illustrates importance of regular screening and timely intervention of abdominal aortic aneurysm, which will gather the great interests from the readers.

Abstract

We report on an 83-year-old male with traumatic brain injury after syncope with a fall in the morning. He had a history of seizures, coronary artery disease and paroxysmal atrial fibrillation (AF). No medical cause for seizures and syncope was determined. During rehabilitation, the patient still complained of seizures, and also reported sleepiness and snoring. Sleep apnea diagnostics revealed obstructive sleep apnea (SA) with an apnea-hypopnoea index of 35/h, and sudden onset of tachycardia with variations of heart rate based on paroxysmal atrial fibrillation. Additional tests showed nocturnal AF which spontaneously converted to sinus rhythm mid-morning with an arrest of 5 s (sick sinus syndrome) and seizures. A DDD-pacer was implanted and no further seizures occurred. SA therapy with nasal continuous positive airway pressure was refused by the patient. Our findings suggests that screening for SA may offer the possibility to reveal causes of syncope and may introduce additional therapeutic options as arrhythmia and SA often occur together which in turn might be responsible for trauma due to syncope episodes.

Key words: Sleep apnea; Syncope; Atrial fibrillation; Trauma

Core tip: Arrhythmias and sleep apnea should be considered as relevant factors resulting in syncope and trauma in the elderly. This case report applies screening for sleep apnea to detect arrhythmia as a common cause of syncope. Screening for sleep apnea may offer the possibility of additional therapeutic options and diagnostic in trauma and syncope after performing standard diagnostics.

and syncope-evidence for further sleep study? A case report. *World J Cardiol* 2015; 7(3): 161-166 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i3/161.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i3.161

INTRODUCTION

Sleep apnea (SA) has been shown to be an independent risk factor for cardiovascular diseases[1-4]. Obstructive sleep apnea (OSA) is the most prevalent type of SA. It is defined as repetitive episodes of partial or complete cessation of airflow in the upper airways during sleep. The number of people in the United States estimated to be affected by OSA is 3%-7%[5,6] and, according to US National Commission of Sleep Disorders Research, OSA contributes to 38000 cardiovascular deaths annually[7]. In Europe, a Spanish study reported that 7% of women and 15% of men aged 30-70 years had OSA, defined as an apnea-hypopnoea index (AHI) of $\geqslant$ 15/h[8].

Patients with OSA typically present with symptoms such as disruptive snoring, witnessed apneas or gasping, excessive daytime sleepiness, morning headache, sleep disturbance and cognitive dysfunction[9,10]. OSA is associated with higher prevalence of diabetes and hypertension[11,12], coronary artery disease and myocardial infarction[13], heart failure[14] and arrhythmias such as bradycardia or atrial fibrillation or flutter (AF)[15]. Traumatic brain injury (TBI) is often associated with SA and sleep disturbances[16,17]. Although the incidence of arrhythmia in the presence of SA is high[15,18,19], the influence of SA on traumatic loss of consciousness (syncope) and TBI have rarely been evaluated[20-22].

Syncope is the most common cause of TBI in the elderly and it often has an underlying cardiovascular aetiology (*e.g.*, bradycardia, tachycardia, myocardial infarction or valvular disease)[23]. The incidence of syncope is 5-11 events per 1000 person years[23]. Different forms of disease sometimes make the diagnosis difficult and different approaches may be needed. Screening for sleep apnea is not standard practice in the evaluation of syncope[20].

This case report describes a male patient with frequent syncope and seizures with SA related arrhythmia.

CASE REPORT

An 82-year-old male (BMI: 26 kg/m^2) was transferred to our rehabilitation facility after experiencing syncope 3 wk previously. He reported a history of seizures mostly in the morning hours at rest and on the day of the most recent syncope episode he fell down without warning soon after breakfast and was transferred to an emergency unit with a frontal head laceration. The patient also had a history of hypertension, dyslipidaemia, coronary artery disease (CAD) without infarction, bypass surgery (14 years ago) and paroxysmal AF. The patient was taking warfarin, ACE inhibitors, β-blockers, statins and diuretics. In the emergency department, the patient was awake without neurologic impairment. Paroxysmal AF was documented on ECG, without evidence of ischemia or myocardial infarction, and troponin testing was negative. Pulmonary embolism was ruled out. A computed tomographic (CT) scan revealed frontal cerebral haemorrhage, which was treated conservatively and warfarin therapy was stopped. Magnetic resonance (MR) imaging one week later showed that the haemorrhage was resolving.

Some further cardiac evaluation of syncope showed no abnormalities. Twenty four hours blood pressure monitoring was normal. Holter 24-h monitoring revealed sinus rhythm without bradycardia, or tachycardia, or paroxysmal AF. Two-dimensional echocardiography showed normal left ventricular function without valve disease, but no carotid sinus massage, tilting test or electrophysiological studies were performed.

At the rehabilitation facility, the patient was assessed as being well without neurologic disorders. The patient reported snoring and hypersomnia (Epworth Sleepiness Scale score of 9 points, with normal being < 5) and complained of intermediate seizures without falling. Sinus rhythm was present on 12-lead ECG.

The patient was screened for SA using 2-channel polygraphy (Figure 1), which showed intermittent nocturnal oxygen desaturations and recurrent apneas with an AHI of 35/h. Heart rate data from polygraphy revealed an increase in the morning hours (Figure 1) with arrhythmic pulse curve based on onset of paroxysmal AF during sleep apnea. A second period of 24-h Holter monitoring was performed the following day to evaluate the incidence of paroxysmal AF. Nocturnal paroxysmal AF was seen with onset in the early morning hours, which spontaneously converted to sinus rhythm mid-morning with an arrest of 5 s (sick sinus syndrome) and the patient reported a seizure at the time of the arrest (Figures 2 and 3). The patient was transferred to the cardiac department for pacer implantation (DDD) and then transferred back to the rehabilitation facility for further rehabilitation. Seizures fully resolved after pacemaker implantation and an increase in β-blocker therapy eliminated paroxysmal AF. A further performed polysomnography for SA diagnostics conformed severe OSA (Table 1).

Treatment of sleep with nasal continuous positive airway pressure (nCPAP) therapy was discussed with the patient but he refused this treatment.

DISCUSSION

In this case report, sleep apnea screening revealed the nocturnal onset of arrhythmia and facilitated further evaluation of syncope. The temporal relationship between the documented pause in the ECG and seizures in our patient means that this was highly likely to be the underlying cause of the repeated

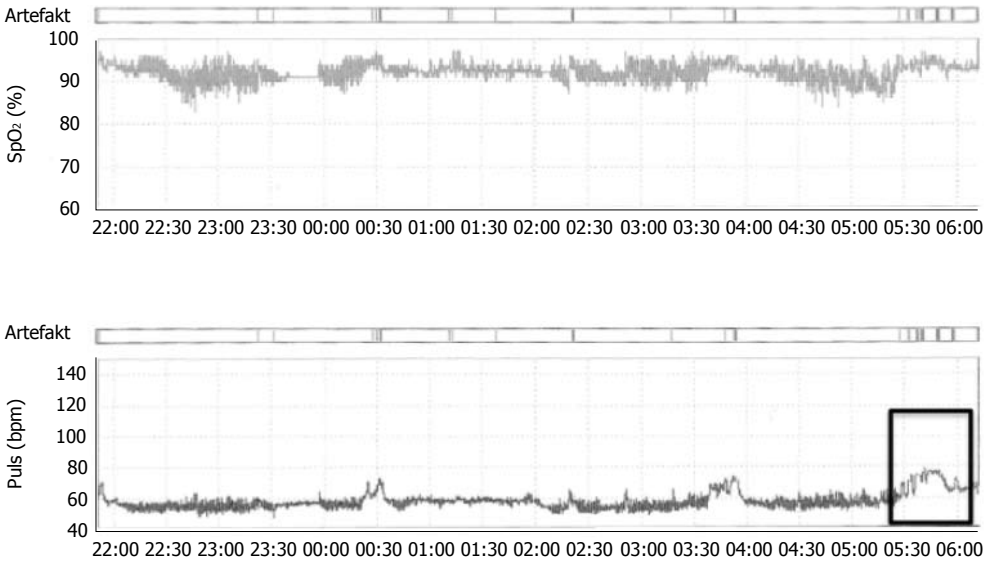

Figure 1 Overnight polygraph recording showing recurrent desaturations at night (above), increased heart rate in the morning hours (down) and arrhythmia onset due to changes in heart rate (see marker box).

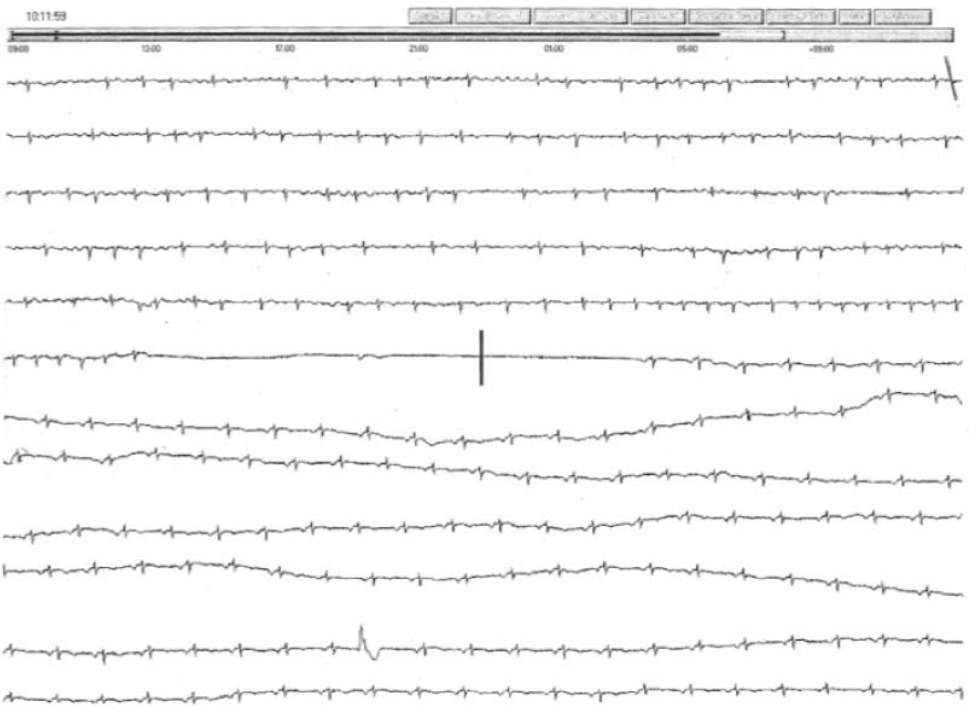

Figure 2 Twenty-hour Holter monitor recording showing atrial fibrillation in the morning with arrest of 5 s (marker) followed by sinus rhythm.

seizures and falls, and ultimately the traumatic injury he sustained. A limitation in this case report is the lack of standard diagnostic for syncope, *e.g*., carotid sinus massage, tilting test or electrophysiological studies before the rehabilitation setting.

The indication for pacing in our patient was based on syncope with trauma and documentation of sick sinus syndrome in the morning hours after onset of paroxysmal AF. After pacemaker implantation the patient had no further seizures, providing further evidence that sick sinus syndrome was the cause of syncope.

AF and nocturnal bradycardia are often triggered by sleep apnea[24]. This is based on nocturnal hypoxemia and its effects on the cardiac autonomic nerve system[25,26]. Accordingly, our patient was offered, but refused, nCPAP therapy. However, there is evidence to show that CPAP not only effectively treats SA but also reduces nocturnal arrhythmias[27,28]. Although nCPAP therapy can reduce arrhythmia burden and possibly reduce the incidence of paroxysmal AF[24], it is not clear whether nCPAP therapy can prevent

Figure 3 Twenty-hour Holter monitor recording showing atrial fibrillation in the morning with arrest of 5 s (marker) followed by sinus rhythm (enlargement of Figure 2).

Table 1 Polysomnographic data revealing obstructive sleep apnea

Polysomnographic parameter	Value
AHI (h)	33
Obstructive apnoea index (h)	31.4
Central apnoea index (h)	0
Mixed apnoea index (h)	0
Hypopnoea index (h)	1.6
Snoring, min	9
Mean oxygen saturation (%)	91
Minimum oxygen saturation (%)	85
Oxygen desaturation index (h)	18

all arrhythmias and arrests, justifying the use of a pacemaker in this case. In addition, compliance with nCPAP is necessary for the benefits of therapy to be realised, which is another justification for pacemaker implantation. However, it has been shown that patients with a pacemaker and ongoing syncope have a high incidence of SA[19], indicating that screening for SA in patients with pacemaker implement and syncope would be appropriate.

Sleep disorders are common in TBI and develop in 12%-36 % of patients[16,17,29]. For example, Verma *et al*[29] found that 50% of patients with TBI reported daytime hypersomnia and 30% were diagnosed with OSA. TBI can result in sleep/wake disturbances, sleep fragmentation, and insomnia or hypersomnia. However, the mechanism of sleep disorders in the setting of TBI is not clear. On one hand the mechanism of injury could trigger sleep disorders such as posttraumatic insomnia or hypersomnia with sleep fragmentation[30,31]. On the other hand, the underlying cause of the accident resulting in TBI may be hypersomnia as a result of nocturnal OSA or, as in this case, nocturnal arrhythmia with syncope and following TBI. Further studies are needed to evaluate the incidence of sleep-related arrhythmias and traumatic injury with the goal of determining whether screening for SA is appropriate in this setting.

Arrhythmias and SA should be considered relevant factors resulting in syncope and trauma. Screening for SA may offer the possibility of additional therapeutic options and diagnostic in trauma and syncope.

COMMENTS

Case characteristics

An 83-year-old male with traumatic brain injury after syncope of unknown origin in the morning and seizures.

Clinical diagnosis

2-channel polygraphy showed intermittent nocturnal oxygen desaturations and recurrent apneas with an apnoea-hypopnoea index (AHI) of 35/h. Heart rate data from polygraphy revealed an increase in the morning hours with arrhythmic pulse curve based on onset of atrial fibrillation (AF) during sleep apnea.

Imaging diagnosis

Nocturnal paroxysmal AF was seen with onset in the early morning hours, which spontaneously converted to sinus rhythm mid-morning with an arrest of 5 s (sick sinus syndrome) and the patient reported a seizure at the time of the arrest.

Pathological diagnosis

Diagnostic of severe obstructive sleep apnea, AHI 33/h.

Treatment

Pacer implantation (DDD). Treatment of sleep with nasal continuous positive airway pressure therapy was discussed but refused.

Related reports

Syncope is the most common cause of traumatic brain injury in the elderly and it often has an underlying cardiovascular aetiology. Arrhythmias and sleep apnea (SA) should be considered relevant factors resulting in syncope and

trauma as SA is one trigger of sudden onset of arrhythmia.

Experience and lessons

Further studies are needed to evaluate the incidence of sleep-related arrhythmias and traumatic injury with the goal of determining whether screening for SA is appropriate in this setting.

Peer-review

This manuscript reports a typical case of sick sinus syndrome in an 83-year-old male, with paroxysmal atrial fibrillation and sinus arrest, presenting clinically with syncope.

Abstract

The field of percutaneous valvular interventions is one of the most exciting and rapidly developing within interventional cardiology. Percutaneous procedures focusing on aortic and mitral valve replacement or interventional treatment as well as techniques of percutaneous pulmonary valve implantation have already reached worldwide clinical acceptance and routine interventional procedure status. Although techniques of percutaneous pulmonary valve implantation have been described just a decade ago, two stent-mounted complementary devices were successfully introduced and more than 3000 of these procedures have been performed worldwide. In contrast, percutaneous treatment of tricuspid valve dysfunction is still evolving on a much earlier level and has so far not reached routine interventional procedure status. Taking into account that an "interdisciplinary challenging", heterogeneous population of patients previously treated by corrective, semi-corrective or palliative surgical procedures is growing inexorably, there is a rapidly increasing need of treatment options besides redo-surgery. Therefore, the review intends to reflect on clinical expansion of percutaneous pulmonary and tricuspid valve procedures, to update on current devices, to discuss indications and patient selection criteria, to report on clinical results and finally to consider future directions.

Key words: Congenital heart disease; Right ventricular outflow tract dysfunction; Pulmonary regurgitation; Percutaneous pulmonary valve implantation; Percutaneous tricuspid valve implantation

Core tip: The field of percutaneous valve implantation/repair is rapidly developing within interventional cardiology. Percutaneous procedures focusing on aortic, mitral or pulmonary valve dysfunction have almost reached daily routine. In contrast, percutaneous treatment of tricuspid valve dysfunction is still evolving on a much earlier level. Taking into account that an "interdisciplinary challenging" population of patients previously treated by corrective, semi-corrective or palliative surgery is growing inexorably, there is an increasing need of options besides redo-surgery. This review intends to report on clinical application of pulmonary and tricuspid valve procedures. It updates on current devices, patient selection criteria, results and future directions.

Wagner R, Daehnert I, Lurz P. Percutaneous pulmonary and tricuspid valve implantations: An update. *World J Cardiol* 2015; 7(4): 167-177 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i4/167.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i4.167

INTRODUCTION

Isolated pulmonary and tricuspid valve dysfunction, whether acquired or in the context of congenital heart disease, can be clinically asymptomatic and be tolerated for a long time[1]. In the western world, acquired primary tricuspid or pulmonary valve diseases are rare conditions and mostly related to rheumatic fever, infective endocarditis or rarities (*e.g.*, carcinoid syndrome).

For those cases with underlying congenital heart disease, dysfunction of these valves is both a primary component of many anatomical conditions and a secondary, but common consequence of several early repair strategies[2].

Increasing knowledge about potential harmful effects of chronic pulmonary artery (PA) regurgitation has made the surgical revision of the right ventricular (RV) outflow tract (RVOT) a frequently performed operation in this population[3]. Typically, most of these patients require several redo-operations during their lifetime to halt the detrimental effects of valvular dysfunction. Since techniques of percutaneous pulmonary valve implantation (PPVI) were first described by Bonhoeffer *et al*[4] more than a decade ago, the procedure has reached worldwide clinical acceptance and routine interventional procedure status. Several devices have been investigated for purposes of PPVI, but so far only the MELODY™ device (Medtronic, MN, United States) has obtained regulatory approval. Interventional procedures focusing on percutaneous tricuspid valve replacement or interventional treatment of severe tricuspid regurgitation are evolving, but yet remain at a much earlier stage and have so far not reached levels of standard procedures[5]. The authors review on clinical expansion of this revolutionary technology, discuss current indications and patient selection criteria, report on clinical results and finally consider future directions.

PPVI

Background and clinical indications

Over the last decades, advances in cardiac surgery, interventional procedures, intensive care and non-invasive imaging have led to a substantial increase in life expectancy for many patients with congenital heart disease. Therefore, an "interdisciplinary challenging", heterogeneous population of patients treated by corrective, semi-corrective or palliative surgical procedures, sometimes decades ago, is growing inexorably. For approximately 20% of these patients RVOT dysfunction caused by predominant obstruction, by predominant pulmonary regurgitation or both in combined conditions, becomes clinically evident.

Undeniably, surgical pulmonary valve replacement is the most frequent mode of redo-operation in patients with congenital heart disease[3]. Surgery for RVOT dysfunction can be performed with low morbidity and mortality[3]. However, an important drawback of this treatment is the limited lifespan of used conduits that has been reported to be around ten years[6-9]. As a consequence, the majority of patients have to undergo several open-heart procedures during their life that raise potential individual risks for a diversity of complications. To limit the need for redo-operations delaying surgery for as long as possible is the strategy of choice in any individual patient. If the necessary treatment is delayed beyond a certain point of no return, adverse RV loading conditions might lead to irreversible ventricular dysfunction, reduced exercise capacity and ultimately to an increased risk for sudden cardiac death[10-13]. Decision making on ideal timing of pulmonary valve replacement is still challenging in most cases and represents one of the most controversial issues of cardiologists who take care of children and adults with congenital heart disease[3,14,15]. RV volume thresholds on magnetic resonance imaging (MRI) have been proposed as predictors for outcome after conduit placement[14]. An RV end-systolic volume of 150-170 mL/m^2 has been reported to deserve as cut-off point above which normalisation of RV dimensions is unlikely following pulmonary valve replacement[13-17]. Nevertheless, the impact of the timing of pulmonary valve replacement on RV function, exercise performance and patient long-term survival remains undefined[13].

With the evolution of PPVI, an effective and feasible non-surgical technique was introduced. It offers a minimally invasive method which can potentially avoid open-heart surgery for RVOT dysfunction in children and adults by restoring acceptable RV loading conditions.

Since the first description of PPVI in 2000[4], more than 3000 percutaneous pulmonary valves have been implanted worldwide[18]. PPVI is performed to prolong the lifespan of RV-to-PA conduits and thereby delaying redo-operations in children and adults with congenital heart disease. Over the last decade, a marked learning curve in outcome post-PPVI could be demonstrated, with improved safety, efficacy and freedom from redo-surgery or re-intervention for pediatric or adult patients who underwent this procedure[13,19-25].

Current devices

The MELODY™ transcatheter pulmonary valve is designed of a segment of bovine jugular vein with a central valve (Figures 1 and 2) that is sewn inside an expanded platinum-iridium stent. The current carrying

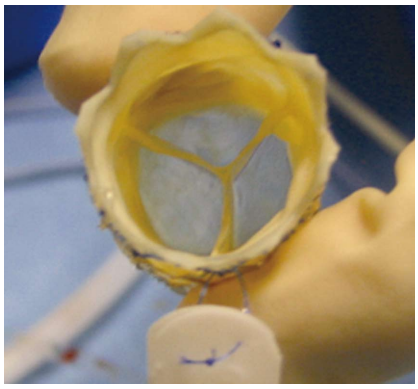

Figure 1 The MELODY™ percutaneous pulmonary valve (Medtronic, MN). The Melody device in "en face" view. Note the blue outflow line to identify the outflow end of the device (courtesy of P.Lurz).

Cheatham platinum stent (NuMED CP Stent CP8Z34) is of a length 34 mm, "crimpable" to minimum of 6 mm and re-expandable up to 22 mm. The balloon in balloon (BiB) delivery system (Ensemble™, Medtronic, MN) is commercially available with different outer balloon diameters of 18, 20 and 22 mm.

The Edwards SAPIEN™ valve (Edwards Lifesciences LLC, Irvine, CA) is radiopaque and made of a trileaflet bovine pericardial valve hand-sewn into a stainless-steel stent (length of 14 or 16 mm) (Figure 3). A sealing cuff covers the proximal part of the stent designed to prevent paravalvular leakage. Currently, the valve is commercially available in 23 and 26 mm diameter sizes and is crimped onto a designated balloon delivery system Retroflex™ Ⅲ. A 29 mm diameter valve is also available (Edwards SAPIEN™ XT). The delivery system requires either 22 Fr (SAPIEN™ 23 mm valve) or 24 Fr hydrophilic sheaths (SAPIEN™ 26 mm and SAPIEN™ XT 29 mm valve) (Figure 3). Promising improvements of design (Edwards eSheath™) offer even smaller sheath sizes.

Technical details regarding both devices for PPVI are summarized in Table 1.

Patient selection criteria

Although sophisticated MR data have been reported, the clinicians' dilemma of the right timing for treatment of RVOT dysfunction, whether predominantly caused by obstruction or regurgitation has not been solved yet[13]. According to current guidelines for the management of grown-up congenital heart disease[26], patients with RVOT obstruction should be treated if the RV to PA gradient exceeds 60 mmHg or in presence of symptoms due to RVOT obstruction regardless of RVOT gradients. Pulmonary regurgitation can be clinically asymptomatic and be tolerated for a long time[1]. When to intervene is subject to ongoing discussions. It is common sense to base the indication criteria for transcatheter or surgical treatment on a combined assessment of MR-imaging derived RV EDV and systolic function, cardiopulmonary exercise testing and the presence of atrial or ventricular dysrhythmia[13]. According to the 2010 recommendations of the ESC task force PPVI can therefore be indicated, if severe pulmonary regurgitation (as assessed on echocardiography or MR imaging) is accompanied by severe RV dilatation, severe RV dysfunction, clinical symptoms and/or impaired exercise capacity[13,26].

In 2011, the American Heart Association (AHA) stated: "It is reasonable to consider the percutaneous pulmonary valve replacement in patient with RV-to-PA conduits with moderate to severe pulmonary regurgitation or stenosis provided the patient meets inclusion/exclusion criteria for the available valve". The AHA writing committee recommended this procedure with a Class IIa evidence (Level of evidence: B)[27]. Clinical indications applicable regardless of the device used for valve implantation (MELODY™ and SAPIEN™) are summarized in Table 2.

Although there is no absolute lower age limit, an adequate body size (*e.g.*, weight > 20 kg) is required to accommodate femoral placement of the introducer[21].

Size and shape of the implantation site ("landing zone") and its anatomical relation to coronary arteries are decisive morphological criteria which have to be appropriate when considering patients as potential candidates for PPVI: In regulatory approved routine use, current MELODY™ devices are not intended for dilatations to diameters of more than 22 mm. Patients with (non-dilated) conduits between the RV and PA of 22 mm and less offer an ideal environment to perform PPVI. In contrast, native or patched RV outflow tracts after surgical repair for Tetralogy of Fallot are often enlarged (> 22 mm) and therefore do not provide a secure landing zone for MELODY™ valves[14]. In these cases (but not larger than 29 mm) the SAPIEN™ valve might be a possible alternative[28-30]. Furthermore, in our experience the RVOT shape (after prior pre-stenting) is of importance: due to its "engineered" nature of sutured pericardial tissue, optimal valved stent function in SAPIEN™ procedures is guaranteed by a circular RVOT shape. In PPVI procedures with the MELODY™ valve the RVOT shape itself appears to have less impact on valvular competence.

Coronary artery anatomy varies due to a broad spectrum of complex congenital heart defects or after surgical re-insertion into the aorta. In some cases there is relevant proximity of one or more of the relevant coronary artery branches to the main PA. This exposes patients who undergo interventions of the RVOT to the risk for fatal coronary artery obstruction due to expansion of the RVOT[31,32]. Therefore, it is essential to assess the course of proximal coronary arteries in relation to the RVOT prior to PPVI deployment. Some centers prefer MR 3-D whole heart images (Figure 4), but we recommend performing selective coronary angiography and particularly aortic root angiography and simultaneous high-pressure balloon inflation within the landing zone at the time of catheterization in all patients to rule out the risk of coronary compression

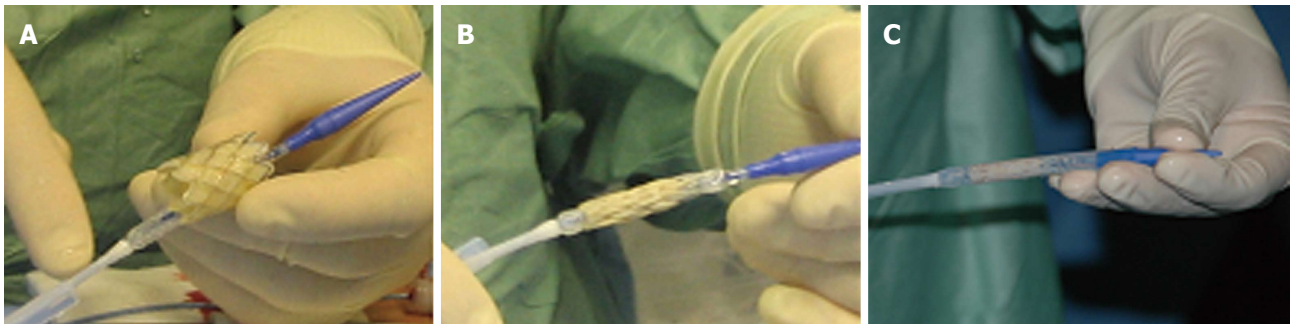

Figure 2 MELODY™ device and its delivery system. A: Uncrimped device on the delivery system with a retractable sheath; B: Crimped device before covering the device to protect it during the delivery; C: Crimped and covered device prepared for delivery (courtesy of Lurz P).

Table 1 Devices and delivery systems for percutaneous pulmonary valve implantation

	The MELODY™ transcatheter pulmonary valve	The SAPIEN™ pulmonic transcatheter heart valve
Manufactor	Medtronic Inc., MN, United States	Edwards Lifesciences LLC, Irvine, CA, United States
Regulatory approval	CE 9/2006 FDA 01/2010	CE 5/2010 FDA 10/2012
(Tissue) characteristics	Segment of bovine jugular vein with a central valve hand-sewn inside a stent	Trileaflet bovine pericardial valve hand-sewn inside a stent
Stent type	Cheatham platinum stent (NuMED CP Stent CP8Z34) Length 34 mm Expandable up to 22 mm	Stainless-steel stent Length of 14 or 16 mm
Available sizes	18, 20, 22 mm (depending on the favoured Ensemble™ delivery (system)	23, 26, (XT 29[a]) mm
Delivery system	Ensemble™ (Medtronic, MN) with balloon in balloon (BiB) deployment design	Edwards Retroflex™ Ⅲ containing a balloon catheter and a deflectable guiding catheter
Sheats for implantation	One-piece 22 Fr Teflon sheath	(18 Fr[b]) 22 Fr for 23 mm valves (19 Fr[b]) 24 Fr for 26 mm valves (16 Fr[b]) 24 Fr for 29 mm XT valves

Technical comparision of the commercially available devices for percutaneous pulmonary valve implantation: the MELODY™ device and the SAPIEN™ pulmonic transcatheter heart valve as non-surgical treatment options for RV outflow tract dysfunction ([a]"Off label-use" in pulmonary position; [b]Manufacturer's data given for the Edwards eSheath™). RV: Right ventricle.

Table 2 Clinical and morphological requirements for percutaneous pulmonary valve implantation

Clinical indications in the context of RV pressure overload/pulmonary stenosis
RV systolic pressure > 65% of systemic pressure in symptomatic patients
RV systolic pressure > 75% of systemic pressure in asymptomatic patients
Clinical indications in the context of RV volume overload/pulmonary regurgitation
Severe pulmonary regurgitation on echocardiography or MR imaging and
Severe RV dilatation > 150 mL/m^2 or the RV to LV end-diastolic ratio of > 1.7 and/or
Rapid progressiv RV dilatation and/or
Severe RV dysfunction and/or
Symptoms and/or
Sustained atrial or venticular arrhythmia and/or
Impaired exercise capacity [< 65% compared to norm peak oxygen consumption related to bodyweight (VO_2/kg)]
Morphological indications
Circumferential RV to PA conduit with dimensions ranging from 16 to 22 mm (Melody™)
Circumferential RV to PA conduit with dimension at surgical implantation of at least 18 mm but no larger than 29 mm (with some degree of conduit narrowing) (SAPIEN™)
Exclusion of risk for coronary compression

RV: Right ventricle; PA: Pulmonary artery.

(Figure 5).

To facilitate superior immediate haemodynamic results several peri-procedural interventions should be considered: (1) pre-dilatation of the landing zone to resolve relevant stenosis and facilitate positioning of the system; (2) pre-stenting of the RVOT to mark, cover and enhance the "landing zone" and avoid stent fractures; and (3) post-dilatation in any case of residual stenosis more than > 20 mmHg of invasively measured gradient[13].

The optimal timing of pre-dilatation/stenting in relation to definitive PPVI is unknown. Some centers

allow stent ingrowth for two to three months. Combined procedures as well as a two-staged procedure are valid options.

Results

Data regarding the haemodynamic outcome post PPVI reported by major reports using MELODY™ [18,19,21,24,33] and using the SAPIEN™ device[28,30] are summarized in Table 3.

Several mono- and multicenter trials consistently reported a low periprocedural complication rate of six percent using the MELODY™ pulmonic valve[19,33]. Data analysis of the "MELODY™ Registry" data distinguishes between major procedural complications [*e.g.*, homograft rupture, perforation of branch pulmonary arteries, guidewire injury, damage to tricuspid valve, device dislodgement, compression of coronary arterie(s) or obstruction of PA] in 2.7% and 11.9% of minor complications in total of 1003 MELODY™ procedures[34].

The "Early Phase 1 International Multicenter Clinical Trial" reporting on SAPIEN™ PPVI in 36 patients reported on a successful valve deployment of 97 percent, but seven patients (20.5%) experienced adverse events[30]. The major complication was device dislodgement. In none of the patients, homograft rupture occurred. All of the SAPIEN™ patients received pre-stenting (33.3%) or peri-procedural stenting procedures (66.6%).

Coronary compression due to RVOT interventions with bare metal stenting of the RVOT is a well-known and previously described complication[31]. Approximately five to six percent of all patients who are potential candidates for PPVI will have a coronary artery anatomy which bears the risk for coronary obstruction[24]. There are several reports of this potential catastrophic complication[35,36] which is strongly related to early procedural mortality[21]. Ruling out the risk for this complication represents one of the most difficult steps in pre-procedural planning for PPVI. In any case of doubt about the risk of coronary compression, we recommend to abandon the implant in either MELODY™ or SAPIEN™ valve procedures (Figure 5).

Follow-up

Short- and medium-term results of PPVI with the MELODY™ and SAPIEN™ are thought to be similar, although more data are available for the former. Long-term outcome data for both valved stent types are not yet available.

Overall mortality of PPVI during follow-up procedures was zero to five percent and seems not related to the device itself.

Failure of the device either for the MELODY™ or the SAPIEN™ could be related to malfunction of its stent or its sewn valve. Relevant dysfunction of the engrafted valve leads to pulmonary regurgitation which is rare condition that almost only occurs in the context of graft endocarditis[37-40], However, the most common reason for re-operation and re-intervention is re-stenosis of the stent portion of the device. Re-stenosis of the stent can be caused by late recoil or lost of radial strength of the device due to stent fractures. Novel data by Nordmeyer reported of a rate of 11 percent cases of stent fractures[34] representing the most common reason for re-intervention.

Overall, data are available from the major four short- and medium-term observational studies with a total of over 450 patients with one- to five-year follow-up[19,21,25,33]: freedom from valve dysfunction or re-intervention was approximately 94% at one year follow-up. Patients who did not require re-intervention had consistently mild or none pulmonic valve regurgitation at one-year follow-up. Pulmonary regurgitation decreased from median values of 16% to 27% to one to two percent. Median peak velocity over the RVOT was 1.9 to 2.7 m/s at one-year

Table 3 Haemodynamic outcome immediately post-percutaneous pulmonary valve implantation

Invasively measured pressures and gradients pre and post percutaneous pulmonary valve implantation within the largest trials (n > 100) of the MELODY™[18,19,21,33] and of SAPIEN™ implants[28,30] in pulmonary position. In all studies, a profound improvement in RV to systemic pressure ratio in response to PPVI was seen ([b]$P \leq 0.001$) (all parameters expressed by medians). RV: Right ventricular; PA: Pulmonary artery. NA: Not available.

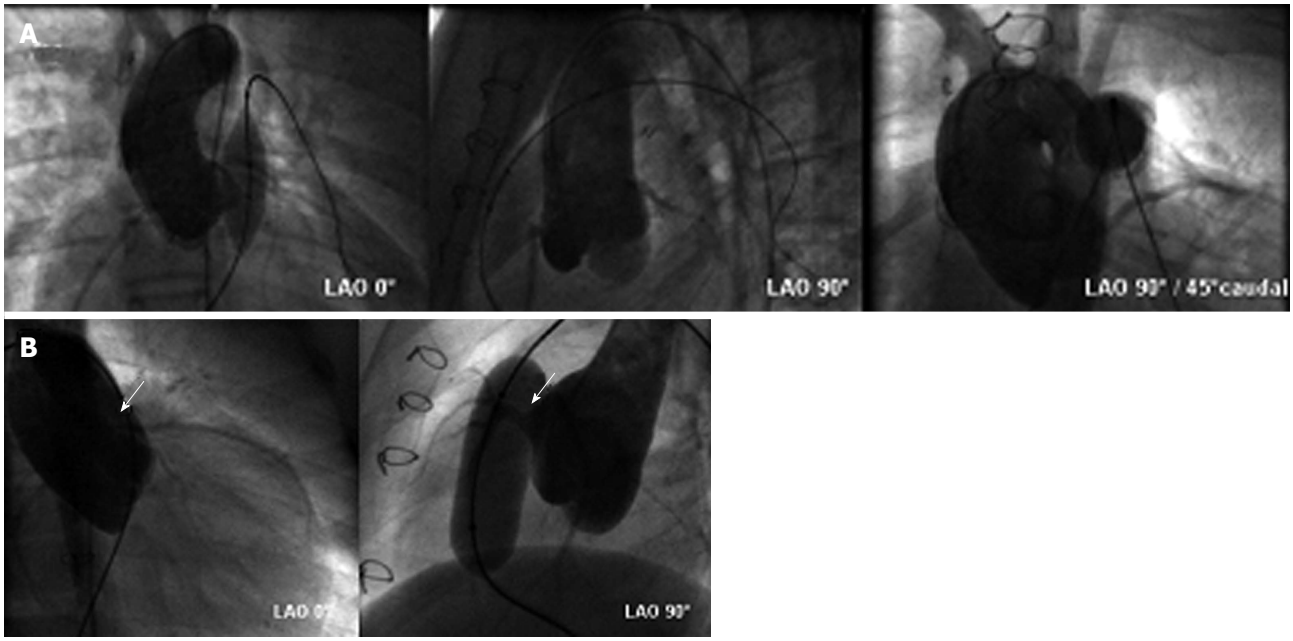

Figure 5 Assessment of risk for coronary compression. A: Aortic root angiogram and simultaneous (high-pressure) balloon inflation within the eligible landing zone is performed to rule out potential for coronary compression (courtesy of Wagner R); B: Aortic root angiogram showing compression of the left anterior descending coronary artery (arrows) during balloon inflation in the conduit. The procedure was therefore abandoned in this patient and no percutaneus pulmonary valve implantation was performed (courtesy of Wagner R).

echocardiographic follow-up. Nordmeyer recently reported preliminary but promising MELODY™ Registry data with a one-year freedom for all case events with 92.5% and 94.2% for PPVI-related events[34].

Data on device function of the SAPIEN™ valve are limited and available from smaller short- and medium-term observational studies with a total of less than 100 patients[28,30,41,42]. In the largest series (COMPASSION trial), successful valve deployment was achieved in 33 of 34 attempts[30]. Freedom from re-intervention at six-month follow-up was 97%. Haas *et al*[41] demonstrated a significant reduction of the RVOT to PA gradient, reduction in RV systolic pressure, increasing of diastolic pulmonary pressure from 6.3 to 14.5 mmHg as a sign of tremendously decreased pulmonary regurgitation with freedom from re-intervention after six months[41].

As for the MELODY™ valve, there are no comparison studies with conventional surgery regarding pulmonary valve replacement by SAPIEN™ valves.

Regarding the functional outcome, several studies have shown a marked improvement in NYHA functional class post-PPVI[18,19,33]. The improvement has been maintained consistently for the duration of follow-up, irrespective of the treated lesion (predominant stenosis *vs* predominant regurgitation)[24].

Parameters of exercise cardiopulmonary function such as peak oxygen consumption related to body weight (VO_2/kg), ventilatory efficiency and anaerobic oxygen consumption have been assessed in several studies addressing PPVI[20,43-45]. Only patients with a predominant stenotic lesion showed an improvement in peak VO_2/kg. Assuming that significant RVOT

obstruction may limit the increase of cardiac output in exercise testing resolving of the obstructive lesion at least partially reverses limited exercise capacity in these patients[45,46]. Recently, we reported on the ability to recovery from exercise as described by VO_2 and VCO_2 decay after maximal exercise. Recovery form exercise after PPVI improves in both groups (predominant stenosis *vs* predominant regurgitation). These findings could explain the symptomatic improvement observed in patients with predominant regurgitation despite the lack of increased maximal exercise capacity and might have implications for how we judge procedural success[47].

Right and left ventricular function and calculation of great vessel blood flow analyzed by functional and morphologic MR imaging performed prior to and within one month after PPVI has shown mixed data regarding changes in RV ejection fraction following PPVI, with some studies finding no change[21,33] and others reporting on improvements in the acute or short term[23,43,44,46]. Importantly, PPVI also results in improved left ventricular filling[13,44,48].

Extended indications and future directions

Many patients are not ideal candidates for PPVI procedures due to their small physical size, limited vascular access or, most important, due to the size and shape of the RVOT[49]. The majority of patients suffering from dysfunction of the RVOT have enlargement of the patched RVOT as part of the initial surgical repair strategy[24]. This unmet clinical challenge led to the development of novel approaches to treat RVOT dysfunction using existing interventional pulmonic valve technology. A small case series reveals an approach to implant or post-dilate the MELODY™ valve using 24 mm balloons. This practice does not compromise function of the engrafted valve and may effectively broaden the pool of eligible patients[24,50].

However, RVOT dysfunction with predominant regurgitation and marked dilatation are not be eligible to this approach. Treatment strategies, *e.g.*, MELODY™ valve implantation into the branch pulmonary arteries[51,52] or a "jailing" procedure of the pulmonary bifurcation by implanting a bare metal stent across the main pulmonary into a pulmonary branch have been described as potential options[53].

A hybrid approach combining intra-operative PPVI with simultaneous conduit down-sizing[54] or direct exposure of the RV or RVOT (*e.g.*, after failed percutaneous attempt, "bailout" procedure) have also proven to be feasible[55].

Innovative (experimental) technologies, *e.g.*, the self-expanding Medtronic Native Outflow Tract device[56], infundibular reducer devices[57] or newer low-profile pulmonary valves such as the Colibri Heart Valve (Colibri Heart Valve, LLC, CO, United States) indicate future treatment alternatives and hopefully will offer a non-surgical treatment to a much broader patient population[58].

PERCUTANEOUS TRICUSPID VALVE IMPLANTATION

Background and clinical indications

Primary tricuspid valve disease is rare: the underlying etiology can be of either congenital (Ebstein, tricuspid valve dysplasia) or of acquired nature (*e.g.*, rheumatic, endocarditis or carcinoid disease). RV volume and/or pressure overload, left heart failure or mitral valve dysfunction can result in secondary RV enlargement, geometric distortion and tricuspid annular dilation. These circumstances can promote concomitant tricuspid regurgitation, thus called functional tricuspid regurgitation (80 percent of all cases)[59,60]. Patients with tricuspid regurgitation may be asymptomatic for prolonged periods. Surgical treatment is often reserved for advanced stages of tricuspid disease when dysfunction, particularly in patients with congestive heart failure, has led to symptomatic right heart failure[61]. For that reason, patients undergoing tricuspid repair or replacement procedures tend to be at higher risk with poorer outcome[61]. European and American guidelines on surgical management of valvular heart disease were updated in 2012[62] and confirmed in 2014[60]. The level of indication was raised to Class I and IIa for most situations of functional tricuspid regurgitation[62]. A transcatheter approach for tricuspid valve repair or replacement seems to be desirable and beneficial to his high-risk population but is still a long way ahead[2].

Patient selection criteria (in selected series)

Van Garsse *et al*[63] reported on the first "Percutaneous Transcatheter Valve-in-Valve Implantation in stenosed Tricuspid Valve Bioprosthesis" in 2011 amongst other case reports with small patient numbers[64-66].

A multicenter series by Roberts *et al*[67] enrolled 15 patients with failing tricuspid prostheses of whom ten underwent implantation into various failing bioprosthetic valves after careful (echocardiographic) confirmation of a suitable anchor point that allows safe positioning of the stented-valve. Median NYHA class was III and all patients were considered to be "high risk" for conventional surgery for tricuspid prothesis failure. The primary lesion was predominant stenosis (mean gradient > 5 mmHg, mean inflow gradient 12.9 mmHg), although a few had significant regurgitation.

Recently, Cullen *et al*[5] has reported a single-center series on transvenous Melody "Valve-in-Valve" implantation for bioprosthetic valve dysfunction that enrolled ten "high risk" patients with failing tricuspid prosthesis among others. Patients were considered candidates for the interventional procedure if they had significant bioprosthetic tricuspid valve dysfunction (either stenosis, regurgitation, or both) with co-morbid

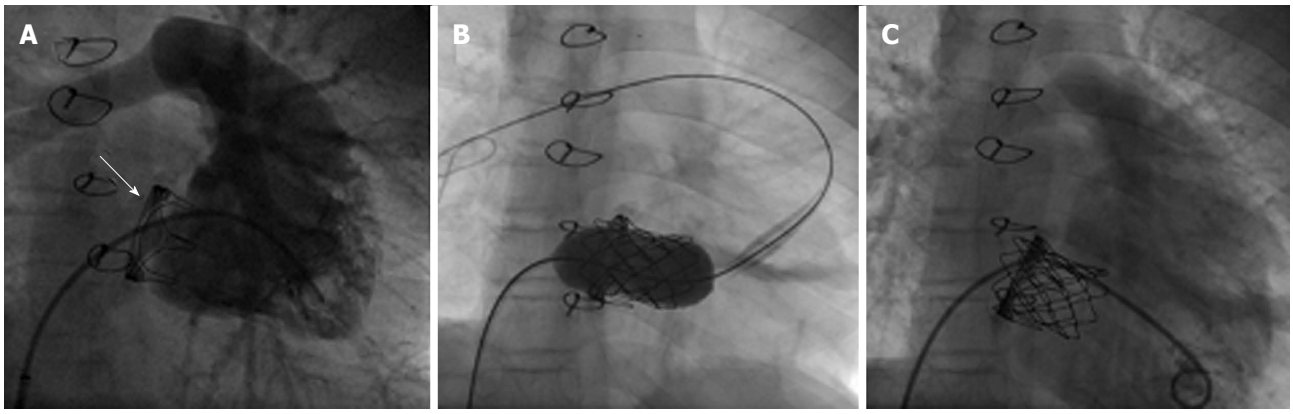

Figure 6 MELODY™ device for "Valve-in-Valve" implantation in tricuspid position. MELODY™ valve implantation procedure in a patient with severe stenosis of a prosthetic biological tricuspid valve (arrow): fluroscopy reveals (A) a RV angiogram in systoly prior to implantation (B) guidewire in the right PA and stable device position after inflating of both balloons of the BiB-delivery system and (C) RV angiogram showing stent position within the biological prosthesis and relative to the ventricle. There is no tricuspid regurgitation. (Courtesy of Wagner R). RV: Right ventricular; PA: Pulmonary artery.

conditions which would preclude surgery. Median NYHA class was Ⅲ with seven of the ten tricuspid patients suffering from moderate or worse tricuspid valve regurgitation with a mean inflow gradient 10 ± 4.3 mmHg.

After all, patient selection criteria for percutaneous tricuspid valve replacement are yet based on (very) limited data. Principally, if a percutaneous approach seems to be an option of treatment in clinical practice, the clinical indication for "Valve-in-Valve" implantation should be based on the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS) or the American College of Cardiology/American Heart Association guidelines for tricuspid valve surgery. The percutaneous approach should be reserved particularly for those cases considered to be high-risk cases for conventional surgery[68].

Devices for tricuspid valve implantation

Two percutaneous devices have been described for transcatheter valve implantation in failing bioprosthetic valves so far. These are the Edwards SAPIEN™ and its iterations and the Medtronic MELODY™ valve as described previously (Figure 6).

So far, none of them have been approved or certified to be delivered in tricuspid position. Therefore, implantation of these devices in tricuspid position is off-label-use.

Results

In both series procedural success with device deployment was achieved in all of the tricuspid patients[5,67]. There were no early periprocedural complications in the Cullen series. Procedural complications occurred in one of Roberts' patients (atrioventricular block requiring a pacemaker). Another patient suffered endocarditis eight weeks post-procedural. In both series mean tricuspid gradient decreased significantly (drop to 5.6 ± 2.5 mmHg in Cullen's patients, drop to 3.9 mmHg in Roberts' series). The level of regurgitation revealed to be mild or none in all but one case of the Cullen's series.

Follow-up and outcome

Mean follow-up was nine months in the series by Roberts but with 41 d (range 11 to 209) shorter and more heterogeneous in Cullen's patients. As reported by Roberts *et al*[67] functional class improved in 12 of the treated patients. Nine of the patients sustained the good interventional result nine months after implantation with one percutaneous valve-in-valve which had to be replaced. Cullen's group observed a 30-d readmission rate with three out of ten in the tricuspid patients. And NYHA functional class improvement in nine of the ten treated patients.

Extended indications and future directions

Several groups selected similar patients to demonstrate the feasibility of percutaneous deployment of stent-mounted valves (SAPIEN, SAPIEN™ XT or MELODY™) into the venous system (inferior and/or superior vena cava). The focus is not on the tricuspid regurgitation itself, but rather on its hemodynamic disturbance. These procedures are therefore called "Caval-valve Implantation"[69-72].

Although, a number of animal studies examined the experimental feasibility of percutaneous valve implantation into a native tricuspid valve[2,73,74], Kefer *et al*[75] recently demonstrated feasibility of SAPIEN™ valve implantation into a "native" tricuspid annulus after failed repair without bioprothesis but mixed tricuspid disease.

SUMMARY AND PERSPECTIVE

The aim of PPVI is to prolong the lifespan of surgically placed conduits. The prolonged conduit lifespan, and hence delayed surgery, should limit the number of needed open chest redo-operations over the

patients' total lifespan in cases of congenital and acquired heart disease that indicated the implantation of pulmonic conduits. This sophisticated strategy potentially improves these patients' life expectancy. Pulmonary valve replacement with stent-mounted with stent-mounted valves containing xenograft materials represents the derived valves represents the non-surgical treatment of choice in patients with dysfunction of the RVOT. Although indications continue to extend even to patients with "native", but dysfunctional RV outflow tracts, the diameter of the proposed implantation site limits the feasibility in a relevant number of patients. Even though significant improvement has been achieved in early and late outcomes after PPVI, the risk of stent fractures and graft rupture have not yet been sufficiently explored. Further research is necessary to avoid these complications.

Besides, the extending use of PPVI, the percutaneous approach to tricuspid valve replacement has briefly moved beyond its experimental character. It has been shown to be feasible, but should mainly be reserved for high-risk patients with conditions that preclude surgery.

In conclusion, evolution of the interventional treatment of dysfunctional valves/RVOTs can only be achieved by continuous creative thinking and encouraged teamworking of cardiologists, surgeons, specialists in imaging and bio-medical engineers.

Abstract

After very rapid advances in the development of the technique and devices, transcatheter aortic valve implantation (named TAVI or TAVR), is today a reality that is here to stay. It has become the minimally-invasive treatment option for high-risk and non-surgical patients with severe symptomatic aortic stenosis. Requiring the participation of a multidisciplinary team for its implementation, cardiac imaging plays an important role. From pre-assessment to determine the suitability of the patient, the access site, the type of device, to the guidance during the procedure, and ultimately the long term monitoring of the patient. Correct selection of the patient and device, correct placement of the stent-valve and early detection of complications are of paramount importance for procedural success and for patient outcome. Each technique has advantages and disadvantages, being the cardiologist who will determine the best approach according to the type of patient and the expertise of the center in each one of them. This article summarizes the last contributions of the most common used imaging techniques, in each step of the procedure.

Key words: TAVI; TAVR; Echocardiography; Multislice tomography; Cardiac magnetic resonance; Aortic stenosis

Core tip: Cardiac imaging is of crucial importance in the whole process of transcatheter aortic valve implantation, from initial evaluation, intraprocedural guidance and post implantation evaluation and early detection of complications. Multiple techniques are available for this, and as the rapid development of new devices and equipments, the greater the necessity of being aware of these advances. We provide current data and tips for this purpose. This is the reason of this work.

INTRODUCTION

Since its beginnings 20 years ago, with first implantations in animals, transcatheter aortic valve implantation (TAVI or TAVR) has evolved substantially[1].

With the advancement of cardiovascular imaging, the application of the most innovative techniques acts jointly to obtain the best clinical results. At present, TAVI is a serious alternative treatment for inoperable or high risk patients with aortic stenosis (AS). In addition, is expected to expand quickly to other subgroups (intermediate risk and aortic regurgitation), since trial results are encouraging compared with medical treatment and cardiac surgery.

Several bioprosthesis types are available, being by far the most commonly used the self-expandable porcine Medtronic CoreValve (Medtronic Inc, Minneapolis, MN, United States), available in the sizes 23 mm, 26 mm, 29 mm, and 31 mm, and the balloon-expandable Edwards Sapien XT bovine valve (Edwards Lifesciences Inc, Irvine, CA, United States), available in multiple sizes: 20 mm, 23 mm, 26 mm, and 29 mm. Both models recently introduced their latest valve generations: Corevalve Evolut R and the Sapien 3, with several advantages and thinner sheaths-introducers (up to 14F). There are now being marketed other valves with different delivery systems, like for instance the Direct Flow valve, the Jena Valve or the Lotus valve, between others.

The preferred implantation route is usually transfemoral. If this is not possible because of patient characteristics, both valve types can be implanted via the subclavian artery, and the Edwards Sapien valve can be implanted *via* a transapical access.

Here we review the contribution of imaging techniques to the whole process of selection of patients and prosthesis, intraprocedural guidance and evaluation of deployment and complications.

PRE-IMPLANTATION EVALUATION

Aortic stenosis severity

Invasive cardiac catheterization used to be the standard for quantification of AS, but nowadays echocardiography is used for diagnostic purposes and in its replacement. Transthoracic echocardiography (TTE) allows evaluation of a calcified valve with restricted leaflet opening and quantification of peak and mean aortic valve (AV) gradient by applying the simplified Bernoulli equation ($\Delta p = 4v2$) to the maximal velocity recorded through the AV by continuous wave Doppler. Severe aortic stenosis is defined as a peak velocity > 4.0 m/s (peak gradient of 64 mmHg), a mean gradient > 40 mmHg, or valve area (AVA) < 1.0 cm^2 (0.6 cm^2/m^2) whith normal left ventricular (LV) systolic function[2]. In cases of low gradient with small area, a dobutamine stress study (maximum dose 20 mcg/kg per minute), may be helpful to determine if the valve is truly severely stenotic, when the maximum jet velocity rises over 4 m/s with the dobutamine-induced increase in stroke volume, whereas the AVA remains less than 1.0 cm[2]. The AS is only mild to moderate in severity if stroke volume increases but there is a small rise in gradient (and therefore the valve area increases greatly), and thus other causes are the origin of LV dysfunction[3].

Annular size

Particularly in the candidates selected for TAVI, other parameters than the severity of the stenosis and the ejection fraction must be evaluated previously to the intervention.

The most important aspect of anatomical screening includes assessment of the arterial vasculature and aortic valvar complex [left ventricular outflow tract (LVOT), aortic annulus, sinus of Valsalva, sinutubular junction and ascending aorta]. All this data will guide physicians to choose the most appropriate access route (subclavian, transfemoral, transaortic or apical) and transcatheter valve size, and it will help to be alert in the detection of potential complications during the procedure[4].

An annular size accurate evaluation is of utmost importance. Underestimation of its dimension could lead to selection and deployment of a smaller valve, with possible complications like paravalvular regurgitation, poor hemodynamics, valve migration and embolism. Overestimation of annular size and deployment of a larger valve can lead to incomplete unfolding (with the consequence of valvular and paravalvular regurgitation) or annular rupture. TAVIs are designed to be utilized in slightly smaller annuli than the prosthesis size[5]. The annular size and the correspondent prosthesis are listed in Table 1.

Aortic annulus can be evaluated using various techniques. Echocardiography is extensively available, repeatable, and easy to perform even taking into account that transesophageal echocardiography (TEE) is semi-invasive and usually requires sedation[6] (Figure 1). We use the sagital plane obtained from a 2-dimensional (2D) parasternal long axis image (TTE) or a mid-esophageal long axis (TEE) image among 120° and 140°, during early systole, measuring from the right coronary cusp to the left noncoronary commissure. To obtain measurements in the coronal and sagittal planes three-dimensional (3D) reconstructions and biplane imaging can be performed.

Multislice computed tomography (MSCT) can give appropriate measurements and may provide important additional information like the anatomy of the coronary arteries, the aortic valve anatomy and area, the plane of the valve and the amount and distribution of calcifications, but iodine injection and radiation are relative limitations. It is important to remember that the aortic annulus is not only a complex 3-dimensional structure, but also that its shape is oval and not circular in the vast majority of patients, as it was demonstrated in previous MSCT studies[7]. The aortic annulus plane is acquired by a reconstruction using two orthogonal planes, the short and long axis of the virtual basal ring, and measurements are taken from systolic phase reconstructions from 20% to 45% of the R-R interval. MSCT multiplanar reconstructions

Table 1 The annular size and the correspondent prosthesis

Prosthesis type	Prosthesis size (mm)	Annular size (mm)	Introducer profile (F)	Minimun vessel diameter (mm)
Edwards Sapien	23	18-22	22	⩾ 7
	26	21-25	24	⩾ 8
Edwards Sapien XT	20	16-19		
	23	18-22	16	⩾ 6
	26	21-25	18	⩾ 6.5
	29	24-27	20	⩾ 7
Edwards Sapien 3	23	18-22	14	⩾ 5.5
	26	21-25	14	⩾ 5.5
	29	24-28	16	⩾ 6
CoreValve	23	18-20	18	⩾ 6
	26	20-23	18	⩾ 6
	29	23-26	18	⩾ 6
	31	26-29	18	⩾ 6
CoreValve evolut R	23	18-20	12	⩾ 6

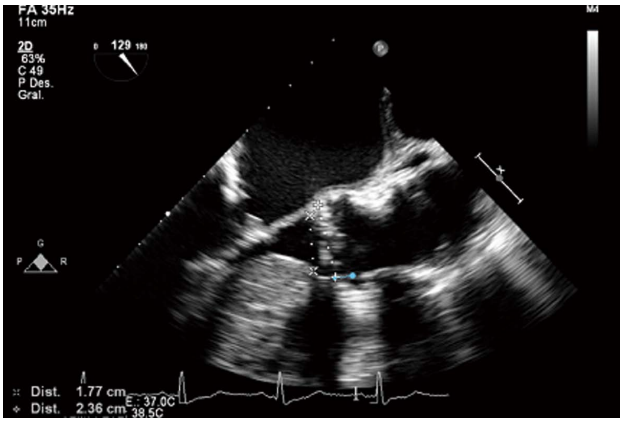

Figure 1 Transesophageal echocardiography 2D at 129° in long axis view in systole with measurements of the left ventricular outflow tract and aortic annulus. The measurement in blue is the distance to the rigth coronary artery.

(MPRs) can provide coronal, sagittal and axial images of the aortic root, with accurate measuraments, almost always underestimated by 2D echocardiography.

On the other hand, cardiac magnetic resonance (CMR) permits an anatomic and functional evaluation of the aortic valve and aortic root, with most sequences in 2D and the selection of the imaging plane during the examination. However, whole heart, echogated 3D CMR with contrast allows obtaining images for multiplanar reconstruction and demonstrates the oval shape of the annulus with minimal and maximal diameters.

Every technique has its advantages and disadvantages. The annulus size is in general 1 mm smaller by TTE than by TEE, and the TEE measurement is 1 to 1.5 mm smaller than MSCT measurements[8,9]. Echocardiography (TTE or TEE) still is the most used technique to assess the aortic annulus, nevertheless, with the acquisition of more data in the near future, MSCT will probably become the first imaging modality to do this.

Aortic anatomy

The characteristics of the aortic valve, like the number of cusps, grade of calcification, thickness and mobility are important to predict the procedure success. Congenital or acquired bicuspid aortic valve stenosis were initially considered a contraindication for TAVI, nevertheless, several successful case reports have been documented and today is considered a relative issue[10-12]. It is frequently not easy to examine cusp anatomy in the severely calcified valves, but in these cases, MSCT or review of old echocardiograms may permit better evaluation of the underlying anatomy. With echocardiography important calcification might cause acoustic shadowing, so MSCT is nowadays the technique of choice in evaluating severity and showing the location of aortic cusp calcification. CMR is not a good choice because of the signal void caused by calcium. Large aortic valve calcifications raise the risk of gaps between the external face of the prosthesis and the patient's native valve, allowing paravalvular regurgitation leaks. Also, the asymmetry, severity and the prosthesis "landing zone" calcification, may produce differences in the tension-force across the valve, with the consequent asymmetric deployment of the device and increased risk of obstruction of the coronary arteries ostium; and important sinotubular junction calcifications may cause limitation during balloon dilatation at the aortic end and may produce ventricular displacement of the prosthesis at the moment of unfolding[13].

Another important issue to consider is the distance from the annulus to the coronary ostia, in order to avoid its compromise during the valve deployment. The distance to the right coronary ostia is easily determined with TEE (Figure 1), but not to the left coronary ostia, which requires 3D TEE (Figure 2). MSCT provides a more comprehensive assessment, showing an average annular-right coronary artery distance of 13.6 ± 2.8 mm and annular-left coronary artery distance of 13.4 ± 3.2 mm[5]. The distance between the aortic valve annular plane and the coronary ostia should be at least of ⩾ 10-11 mm for both type of prosthesis.

Aorta evaluation

Evaluation of the aortic root and tubular portion of the aorta is as well essential, specially when using Core Valve, because its length is greater compared with regular valves, ranging from 52 mm (31-mm valve) to 55 mm (26-mm valve, *i.e.*,). It is advised that the dimensions of the tubular aorta measured at 45 mm above the annulus be 40 mm for the 26-mm valve and 43 mm for the 29-mm and 31-mm CoreValve prosthesis. MSCT can provide an excellent reconstruction and evaluation of the aortic sinus diameter, sinotubular junction, ascending and descending aorta and its iliofemoral branches (Figure 3). This is very important for the selection of the vascular

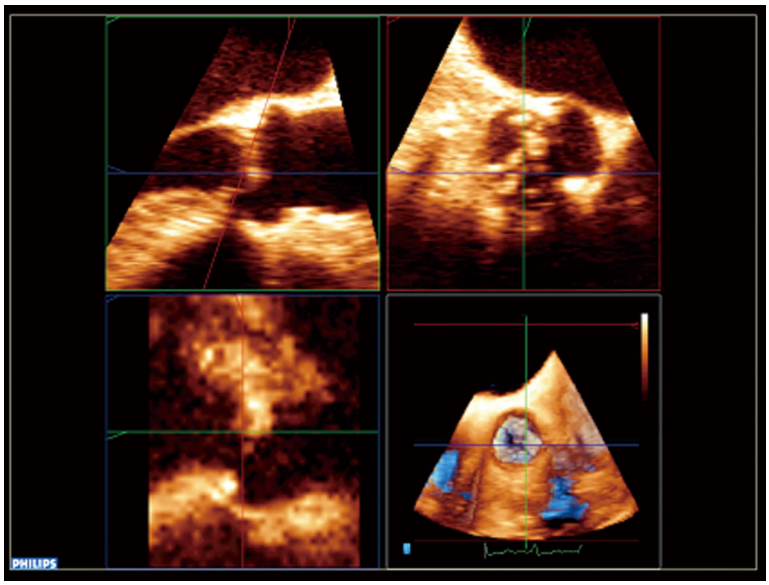

Figure 2 Transesophageal echocardiography 3D with multiplanar projection showing the measurements at annulus level.

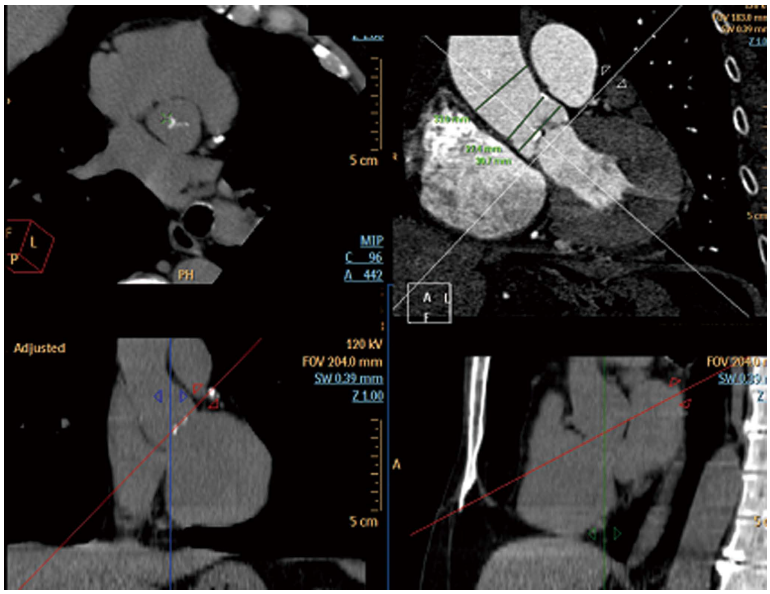

Figure 3 Computed tomography with multiplanar reconstruction showing measurements at different levels of the aorta.

access, because its complications rates range from 5% to 25%[14], and are associated with a striking increase in early mortality risk. Its evaluation often begins with conventional angiography, but it proportionates a very limited data. MSCT provides many reconstructions, as 3D volume rendered imaging, curved multiplanar reformats, and maximum intensity projection images allowing evaluation of vessel size, minimal luminal diameter, calcification severity, plaque burden, vessel tortuosity and identification of high risk characteristics like dissections and complex atheroma[15] (Figure 4). Calcification of less than 180º or eccentric calcification usually do not cause procedural trouble like would nearly circumferential and luminal calcification do. Vascular complications and 30 d mortality can be predicted with the use of a sheath/femoral artery ratio of 1.05 or higher[16]. It is remarkable that the existence of significant aneurysmal dilatation in ascending aorta is a contraindication for the use of CoreValve.

Like MSCT, CMR can give exhaustive evaluation of the aortic valve, annulus, aortic root, coronary ostia, course of the thoracoabdominal aorta and luminal caliber of the iliofemoral branches, and LV function, with the advantage of not using ionizing radiation (Figure 5). Also, free-breathing noncontrast navigator-gated 3D whole-heart acquisition can be acquired, similar to the volumetric acquisition of CT[17].

Other issues

Calcification in other areas, as dense calcification in the intertrigonal area rises the risk of paravalvular aortic regurgitation (AR) due to asymmetric unfolding of the valve[18]. The angle between the aorta and the LV and proximal septal hypertrophy are essential issues to consider when planning the procedure. A very prominent proximal septum is an important consideration to have in mind during the placement of the valve because can cause valve repositioning when stopping the pacing run[15]. LV function must be evaluated in order to minimize the number of pacing

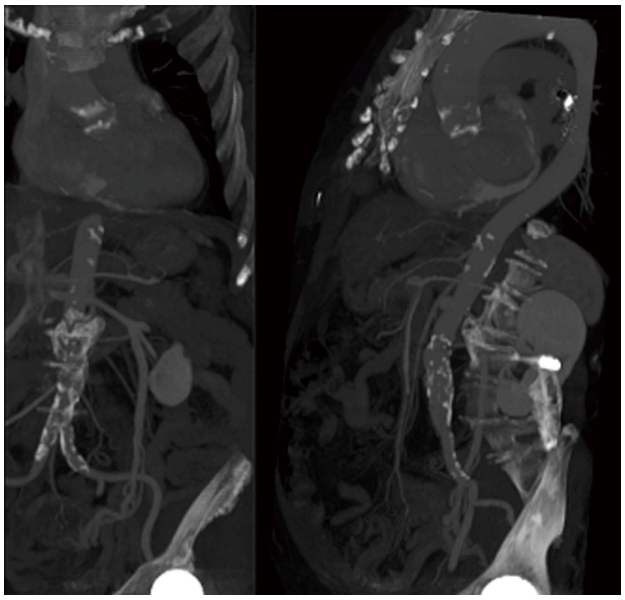

Figure 4 Computed tomography images showing aortic anatomy and calcifications, previous to transcatheter aortic valve implantation procedure.

runs to prevent hemodynamic compromise in those with severe dysfunction. The degree of baseline aortic regurgitation is also very important, since balloon inflation might aggravate regurgitation and cause hemodynamic deterioration.

In conclusion, echocardiography (in all modalities, TTE, TEE, 2D and 3D), MSCT and CMR can be used to make a pre-implantation evaluation, but it is very important to remind that the imaging technique used might influence TAVI size selection and strategy.

INTRAPROCEDURE GUIDANCE

During the procedure, fluoroscopy and angiography are the principal techniques used to guide device placement (Figure 6). However, they involve several shortcomings, for example: (1) radiation use; (2) restricted 2D visualizations with scarce soft-tissue contrast, sometimes preventing early identification of complications (cardiac tamponade, *etc.*); and (3) the reiterated use of nephrotoxic contrast media to observe the aortic annulus and coronary ostia during the procedure.

Nevertheless, other imaging modalities, like TEE, may overcome the lower soft tissue contrast resolution of fluoroscopy and do not use radiation or contrast. Specially 3D-TEE permits a good visualization of the guide wire path and allows a good assessment of the prosthesis position on the balloon, with respect to the native valve annulus and other structures. Using mid-esophagus long axis view is possible to observe the guide wire across the aortic valve in its delivery, retrograde (transaortic, transubclavian, transfemoral) or anterograde (transapical)[13]. For the adequate position of the prosthesis, TEE can be very useful. In

Figure 5 T1 weighted cardiac magnetic resonance image depicting aorta measurements.

the case of Sapien valve, about half of the prosthesis should be below and above the aortic annulus, and when using CoreValve, the nitinol stent must be well within the borders of the calcified native annulus. With 3D TEE it is feasible to observe ortogonal planes simultaneously, aortic valve's views in long and short-axis in realtime, very helpfull for every step of the procedure (aortic valve pass, balloon inflation and prosthesis unfolding).

Intracardiac echocardiography has also been used for TAVI guidance, but imaging abilities are worse than with TEE[19].

In patients with preserved LV systolic function, it was described an improvement in diastolic function, evaluated minutes after deployment with TEE, evaluated through E wave deceleration time, E wave velocity and isovolumetric relaxation time[20].

Immediately after deployment, it is very important to discard complications, for example AR, the most common one. This must be performed rapidly and in multiple echocardiographic views to permit possible reballooning or up delivery of a second prosthesis if the AR is severe and cannot be controlled in another way. It is of utmost importance to differentiate between paravalvular and valvular regurgitation (Figures 7 and 8). Because of irregular calcification in the native valve, small paravalvular leaks are usually observed due to gaps between the annulus and the device, particularly at the commissural areas.

In the case of paravalvular jets, the recommendations indicate that the rate of the circumference of the annulus occupied by the jet offers a guide to severity: < 10% mild, 10%-29% moderate, and ⩾ 30% severe[21]. In a work of our group, we found that the vena contracta planimetry on 3D TTE was better correlated with AR volume than vena contracta width on 2D TTE [Kendall's τ = 0.82 (P < 0.001) *vs* 0.66 (P < 0.001)]. The areas under the receiver operating characteristic curves were 0.96 for vena contracta

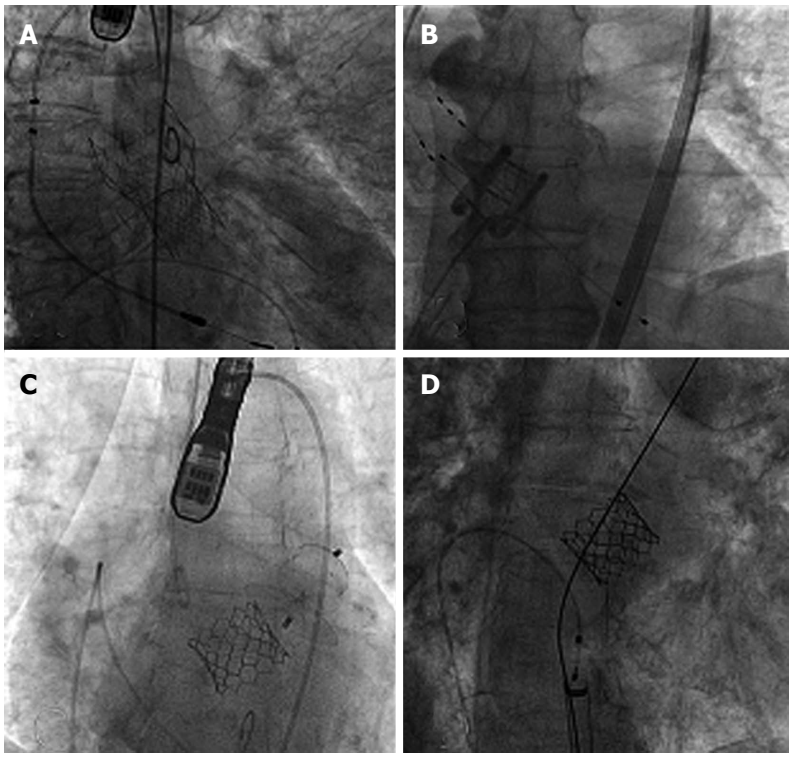

Figure 6 Fluoroscopy images showing different prosthesis models. A: CoreValve evolut R; B: Direct Flow valve; C: Edward Sapien 3; D: Edward Sapien XT.

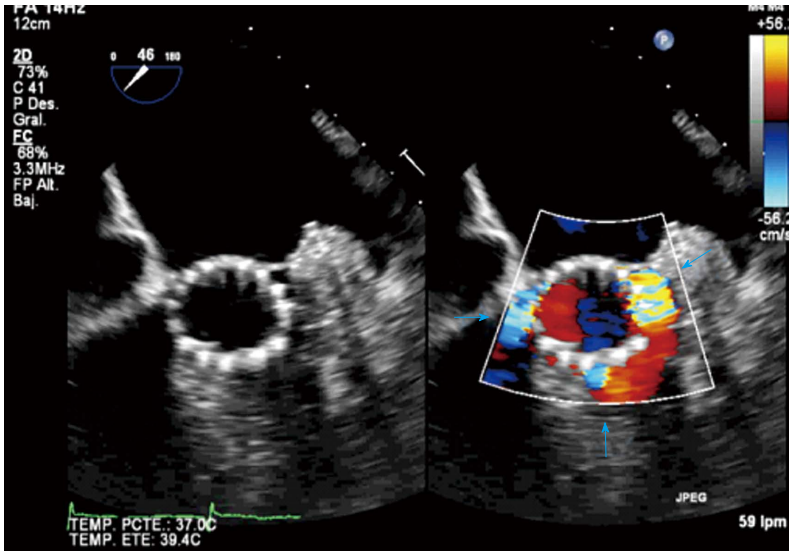

Figure 7 Transesophageal echocardiography at 46° without and with color Doppler showing 3 paravalvular leaks (arrows) after valve implantation.

planimetry and 0.35 for vena contracta width[22]. To avoid paravalvular leak, is required that the covered portion of the prosthesis must be well-apposed to the host valve and interleaflet triangles and the ventricular border of the device just under the hinge points of the AV. It is also common the presence of mild central valvular regurgitation that frequently resolves with removal of the guidewire; otherwise, it must be assessed looking for underexpansion of the prosthesis (Figure 9). Significant valvular AR is generally due to AV harm in the course of the procedure, too large a device for a little annulus with consequent valve distortion, or severe calcification of the patient's AV producing deformation of the frame of the valve[23].

Obstruction of a coronary artery by the prosthesis or displaced calcium is another possible complication. This situation can be seen as regional hypokinesis, best evaluated from the transgastric view and, if it is possible, assessing the coronary arteries flow. If there is LVOT obstruction, this may cause hypotension because of rapid drop in afterload. Other causes must also be considered, like severe mitral regurgitation, pericardial tamponade, displacement of the device, air embolism, right ventricule perforation by a pacemaker lead, aortic dissection and vascular access bleeding.

Other imaging techniques in vogue at the moment are fusion imaging modalities, like C-arm computed tomography with valve landmark detection and automatic aorta segmentation, that tries to make simpler the procedure using 3D over fluoroscopic

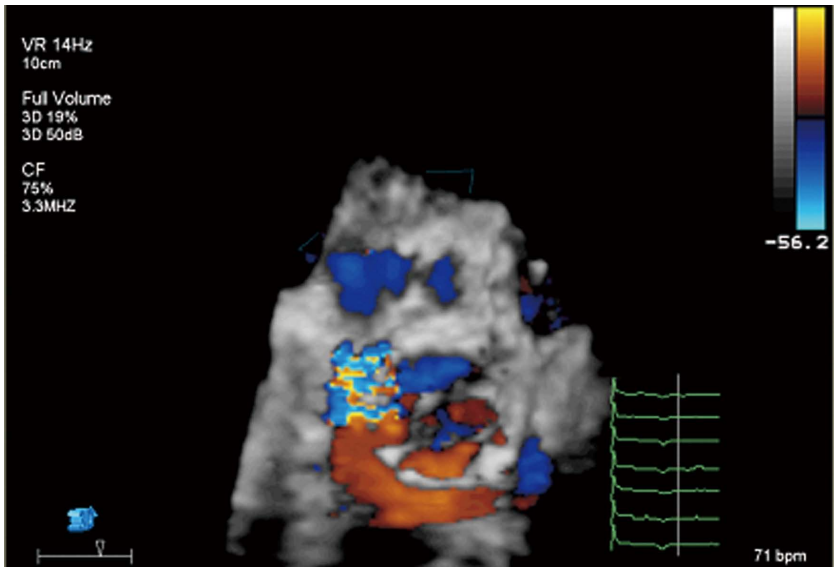

Figure 8 Transesophageal echocardiography 3D full volume showing the exact position of an important paravalvular leak.

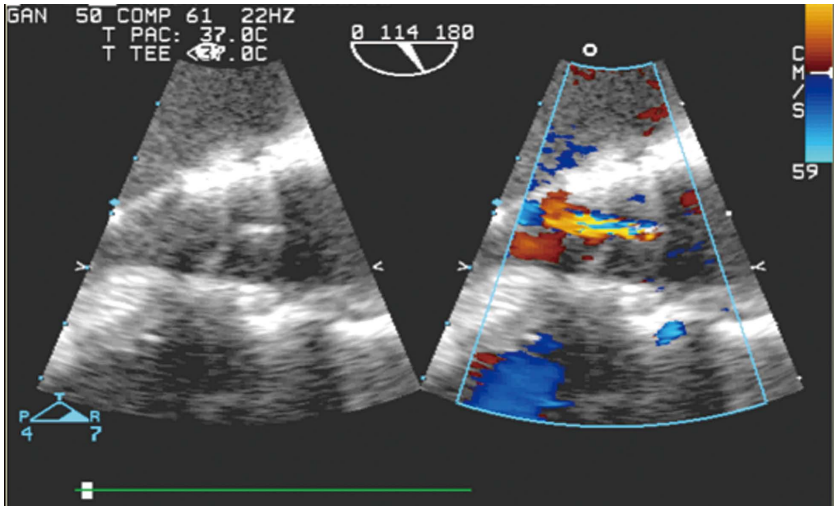

Figure 9 Transesophageal echocardiography at 114° without and with color Doppler depicting the presence of central aortic regurgitation due to underexpansion of the prosthesis.

imaging[24]. CMR capacities are real-time image without restricted scan plane orientation and incomparable soft-tissue contrast, with concomitant display of the prosthesis; and it seems convenient over X-ray angiography and fluoroscopy during all of complete procedure. It allows on-line monitoring cardiac performance, instant recognition of vascular and cardiac harm, and real-time orientation for axial placement and unfolding of the device[25].

POST-IMPLANTATION ASSESSMENT

After TAVI implantation, the imaging evaluation will contribute to determine the valve hemodynamic condition, like effective valve area and gradients; the presence and quantity of valvular and paravalvular regurgitation; the effect of the procedure in ventricular function, hypertrophy, *etc*. and the recognition of long term problems like device migration, endocarditis, ventricular perforation, mitral valve impingement and thrombus formation.

Echocardiography remains the technique of choice for this, because of its wide availability, avoidance of ionizing radiation, together with real time hemodynamic and structural assessment. MSCT and CMR can also provide and excellent anatomic detail and detection of complications like pseudoaneurysm of the root or the apex. Postprocedural evaluation of remaining AR by CMR might have a possible part in TAVI patients[26]. Nevertheless, CMR is a time-intensive method, and this could be an important factor, especially in older patients. In cases of renal disfunction the advantages for the use of gadolinium must be greater than the risks of nephrogenic systemic fibrosis[27]. Also CMR is not warranted in patients with defibrillators, pacemakers or intracranial aneurysm clips, even though the prosthesis used now are CMR compatible.

LV function and hemodynamics

Echocardiography is most common used tool to evaluate the changes described after TAVI, like reductions in LV mass[28], recovery in EF[29], amelioration in diastolic function, and reduction of mitral regurgitation[30].

Although, CMR evaluation of LV mass provides a greatly precise calculation[31].

Valve area and gradients

Determination of mean and peak transvalvular pressure gradients and the calculation of effective orifice area are easily obtained with continuous wave Doppler with TTE, not forgetting suprasternal notch and right parasternal windows to confirm that maximum gradients are catched. CoreValve and Edward Sapien valves have very good flow features with mean gradients of 10-15 mmHg, with relatively stable gradients[32] or little rise in mean transvalvular gradient (3.8%/year) and a low decrease in valve area (0.06 cm^2/year)[33].

Aortic regurgitation

Follow-up echocardiograms should recognize the existence, position, and severity of valvular and paravalvular AR, using all the possible views in case of eccentrical jets. Paravalvular regurgitation is generally produced by imperfect device apposition to the host annulus because of to remaining calcium, undersized prosthesis, or too low position of the valve[34], so imaging in multiple planes is necessary. Valvular and paravalvular AR affect LV hemodynamic condition, determined by raised volume burden, consequently affecting chamber dilatation, LV performance, and progress to pulmonary hypertension, so total AR should routinely be calculated combining information from color and spectral Doppler. Three-dimensional TTE allows quantification of AR with greater accuracy than 2D TTE. CMR might be the technique of election in cases of severe AR, or disagreement in gradients with echocardiography[35].

Although it is always difficult to predict the future, TAVI seems a truly promising therapeutic alternative with settled indications nowadays and expanding indications (intermediate risk, aortic regurgitation, valve in valve[36], *etc.*). What seems clear is that cardiovascular imaging will be needed in this field in order to achieve all its potential objetives.

To sum up, although at the begining multiple test and measurements were required, as experience grows, patients and devices selection are improving, with a more rational imaging algorithm, based in local expertise and availability.

Abstract

In this review, we discussed the findings and concepts underlying the potential role of *Helicobacter pylori* (*H. pylori*) infections in the initiation, development or persistence of atherosclerosis and coronary heart disease (CHD). This Gram-negative bacterium was described by Marshall and Warren in 1984. The majority of infected subjects carries and transmits *H. pylori* with no symptoms; however, in some individuals these bacteria may cause peptic ulcers, and even gastric cancers. The widespread prevalence of *H. pylori* infections and the fact that frequently they remain asymptomatic may suggest that, similarly to intestinal microflora, *H. pylori* may deliver antigens that stimulate not only local, but also systemic inflammatory response. Recently, possible association between *H. pylori* infection and extragastric disorders has been suggested. Knowledge on the etiology of atherosclerosis together with current findings in the area of *H. pylori* infections constitute the background for the newly proposed hypothesis that those two processes may be related. Many research studies confirm the indirect association between the prevalence of *H. pylori* and the occurrence of CHD. According to majority of findings the involvement of *H. pylori* in this process is based on the chronic inflammation which might facilitate the CHD-related pathologies. It needs to be elucidated, if the infection initiates or just accelerates the formation of atheromatous plaque.

Key words: *Helicobacter pylori*; Coronary heart disease; Inflammation; Microbiota; Lipopolysaccharide

Core tip: *Helicobacter pylori* (*H. pylori*) is a Gram-negative spiral bacterium which colonizes gastric mucosa of nearly half of human population. A characteristic feature of *H. pylori* infection is an excessive inflammatory response. The majority of *H. pylori* infections remain asymptomatic. However, still it leads to the development of histological gastritis with the recruitment of immune cells. About 10% of infected subjects develop symptomatic gastritis, erosions or peptic ulcer. Gastric cancer is the most severe consequence of *H. pylori* infection. Recently, a possible association between chronic infections with *H. pylori* and extragastric disorders - including coronary heart disease, has been intensively investigated. Here we have revised recent studies confirming or excluding possible

connections between chronic bacterial infections and the occurrence of coronary heart disease (CHD) within different populations, especially in the context of *H. pylori* infections. We have also presented various study approaches investigating direct and indirect interplay between *H. pylori*-driven consequences and CHD development to clarify already gained knowledge and suggest future directions. Considering the significance of already conducted research studies, the involvement of *H. pylori* infection in the process of CHD development is highly probably, however, still a lot need to be done to clarify whether this association is direct (with the involvement of *H. pylori* antigens and products) or indirect (with the involvement of inflammatory-related molecules accelerating/initiating CHD development).

INTRODUCTION

Since classic risk factors do not explain all cases of coronary heart disease (CHD) the concept that atherogenesis may have infectious background should be considered. The role of virus and bacterial pathogens including *Helicobacter pylori* (*H. pylori*) are now considered as factors implicated in the development of CHD. Chronic infections may influence the course of CHD *via* different mechanisms such as chronic inflammatory reactions, an autoimmune processes and modification of classic CHD risk factors. The pioneer finding of Mendall and co-workers, published in 1994, showed that CHD patients have elevated levels of serum anti-*H. pylori* antibodies. Following this finding, some authors confirm and some exclude the existence of this connection. Still there is no consensus on the role of *H. pylori* in either causation or progression of CHD. In order to describe the involvement of *H. pylori* in the development of CHD, it is necessary to find the largest number of reliable research studies confirming this relationship.

PATHOGENESIS OF CHD

CHD is one of the most severe chronic diseases of the coronary vessels - an important health and social problem - often life-threatening. It occurs due to endothelial dysfunction within the vessels, accompanied by an increased blood pressure, remodeling of vascular wall, local inflammation, platelet aggregation and blood clotting. These disorders promote the formation of atheromatous plaque, which is often unstable and subsequently ruptures. This might impair the blood flow leading to vascular blockage or myocardial infarction. Classic risk factors of CHD include cigarette smoking, hypertension, elevated levels of total cholesterol, triglycerides and low density lipoproteins (LDL) *vs* decreased high density lipoproteins (HDL) fraction, diabetes mellitus, as well as raised homocysteine and coagulation factors. Predisposing factors that increase the probability of CHD development are obesity, lack of physical activity, previous incidents of CHD in relatives, male gender, low socioeconomic status, as well as ethnic and behavioral factors that[1,2].

CHD is a group of symptoms resulting from chronic malnutrition and hypoxia of myocardial cells which is accompanied by oppression, burning, feeling the burden, discomfort and chest choking. These disorders are a consequence of atherosclerosis, which histologically is characterized by the accumulation of macrophages (MØ), LDL fractions, foam cells derived from macrophages filled with oxidized (ox) LDL and extracellular cholesterol complexes deposited within the vessels. On the inner surface of the vessel, lipid deposits are formed, which are gradually surrounded by a connective tissue and undergo fibrosis[3,4]. According to the statistics of World Health Organization (WHO), ischemia associated with atheromatous plaque is the main reason for CHD development, 70% of heart failure cases and 80% of sudden cardiac deaths. The natural history of atherosclerosis suggests that lesions in the arteries may occur already in the uterus or in early childhood. However, clinical manifestations of atherosclerosis are associated with the presence of atherosclerotic plaques, which in men usually develops after the age of 50 and in women postmenopausally[1].

DYSFUNCTION OF VASCULAR ENDOTHELIUM AS AN INITIATOR OF ATHEROMATOUS PLAQUE FORMATION

The interior of blood vessels is covered with a single layer of adjacent endothelial cells (size 0.2-0.3 mm) attached to the basal membrane and extracellular matrix molecules through integrin adhesion molecules[3]. Endothelium contacts with smooth muscle cells through gap junctions, which are permeable to the electric current, ions and low molecular weight compounds. Human vascular endothelium is a barrier that separates blood containing clotting proteins, platelets and inflammatory cells, from connective tissue and muscle layers of the blood vessel wall. The balance between the internal and external environment of the vessel depends on mechanical, chemical and immune reactions occurring within endothelial cells[1]. The endothelium is affected by physical pressure of blood flow (hemodynamic forces), various soluble substances and immune cells. Endothelium delivers many effector substances such as vasolidation and vasoconstrictioning factors (determining the proper tension of the vessel wall), cytokines and adhesion molecules (responsible for interactions with blood

cells and the development of the inflammatory response), factors involved in blood coagulation and fibrinolysis. All together the endothelium plays a role in the maintenance of the vascular homeostasis which is determined by its large mass, distribution and the ability to receive and respond to signals from external environment (hemodynamic and chemical stimuli, pO_2), by changing the expression of various active substances and proteins[1,5]. The endothelium expresses structures that are necessary for adhesion, migration, activation and diapedesis of immune cells and platelets, which allows for the development of inflammatory response[6,7]. These are mostly adhesion molecules (selectins) such as: P-selectin (platelet), E-selectin (endothelial) and L-selectin (leukocyte) and immunoglobulin-derived adressins, including: intracellular adhesion molecules (ICAM)-1 and -2, vascular cell adhesion molecule 1 (VCAM-1), platelet endothelial cell adhesion molecule 1, and macrophage chemotactic protein-1 (MCP-1). If endothelium is damaged it loses its functional integrity and homeostasis which initiates the occurrence of multiple lesions[5,8]. This dysfunction is usually leads to increased tension, vascular wall remodeling, vascular inflammation, increased platelet adhesion and aggregation. These processes contribute to the development of atherosclerosis or destabilization of existing atherosclerotic plaques[2].

CHD AS AN INFLAMMATORY PROCESS

In the late 90s we believed that the atherosclerotic process is a response to a mechanical trauma, resulting in the loss of endothelial cell lining in the vessels. Since the majority of CHD symptoms are induced by both local and systemic inflammatory responses, recently the attention is focused on the role of inflammation in the development of atherosclerosis[9-12]. Inflammatory markers, such as C-reactive protein (CRP) have been found to be higher in CHD patients than in controls, similarly to the concentration of interleukin (IL)-6 and tumor necrosis factor alpha (TNF-α) in plasma and supernatants of immune cells stimulated *in vitro* with bacterial lipopolysaccharide (LPS). Increased expression of E-selectin, L-selectin and P-selectin as well as higher expression of VCAM-1 and ICAM-1 was also noted in CHD cases[9,13]. It is difficult to identify factors that initiate cascade of inflammation and plaque formation. However, it is clear that endothelial dysfunction and raised cholesterol play a major role in the inflammation. Cholesterol contributes to the localization of atherosclerotic lesions, preferentially in the sites where it leads to the activation of endothelial NF-κB signal transduction pathway[14]. The inflammatory response is characterized by the influx of MØ and monocytes to the endothelium, with the latter being transformed first into MØ and subsequently to foam cells prior ingestion of oxLDL. Protein components of the LDL particles are processed by macrophages and dendritic cells and presented to T cells in the context of class Ⅱ major histocompatibility complex[15]. Activated MØ and other inflammatory cells release chemokines that stimulate the migration of smooth muscle cells which together with foam cells, form a fibrous cap. This process is facilitated by interferon gamma (IFN-γ) and TNF-α secreted by T helper (Th)-1 lymphocytes, as well IL-12 produced by macrophages and foam cells[16]. The latter undergo apoptosis, and together with cholesterol crystals form lipid plaque cover[13,17]. It has been revealed that atherosclerotic lesions are associated with the increased reactivity of immune cells. The injured tissue releases IL-33 which alarms the immune system, induces expression of adhesion molecules and attracts Th2 lymphocytes delivering IL-4-considered anti-inflammatory cytokine[18-20]. However, a growing body of evidence indicates that IL-4 may play a role in atherosclerosis through induction of inflammatory responses, such as upregulation of VCAM-1 and MCP-1[21]. The main population of cells in newly formed atherosclerotic lesions are T lymphocytes, while in chronic lesions this proportion is reversed towards MØ that initiate immune processes by presenting antigens to T cells and the production of cytokines and chemokines[1,15,16,22].

MØ and neutrophils contains granules where myeloperoxidase and metalloproteinase are stored - the inflammatory markers correlated with a risk of atherosclerosis[23,24]. Myeloperoxidase contributes to leukocyte migration and the accumulation of foam cells. Indirectly it is involved in endothelial dysfunction and the induction of apoptosis with a consequence of plaque rupture and its destabilization. Due to the this, occurrence of vascular tissue factor is released and the activation of the blood coagulation cascade take place. Myeloperoxidase reduces the availability of endothelial nitric oxide and inhibits its diastolic and anti-inflammatory function. Moreover, it is involved in the oxidative modification of LDL to its atherogenous form, recognized by MØ receptors[3,10]. Prominent inflammation markers, activated by myeloperoxidase are delivered by macrophage-derived metalloproteinases (MMPs), hydrolyzing the components of extracellular matrix such as elastin and collagen, leading to the destabilization of atherosclerotic plaque. Metalloproteinases are also involved in the lipid peroxidation process and accelerated consumption of nitric oxide[22]. CRP belonging to the group of acute phase proteins which raises during infection or tissue damage, is an important marker of inflammation and is considered as an indicator of coronary events associated with endothelial damage. The upregulation of CRP is correlated with the elevation of IL-6, TNF-α, obesity and insulin resistance, which may indicate a link between chronic inflammation and endothelial dysfunction[12]. It has also been shown that CRP is more accurate marker of coronary events than the LDL cholesterol. This was based on the observation that women with the highest levels of CRP and low LDL

were more susceptible to acute coronary insufficiency compared with those with high LDL and low CRP levels[25].

INFECTIOUS RISK FACTORS OF CHD

Classic risk factors do not explain all cases of CHD. Many data indicate that atherogenesis may be associated with chronic infections, accompanied by a long-term persistent inflammation[26-30]. Compelling evidence supports also the concept that gut microbiota actively promotes weight gain as well as fat accumulation, and indirectly sustains a condition of low-grade inflammation, thus escalating the risk of CHD[31-33]. The occurrence of microbiota favors not only intestinal but also the systemic exposure to the LPSs of Gram-negative bacteria. This microbiome-derived compound can cause a condition called "metabolic endotoxemia" characterized by low-grade inflammation, insulin resistance, and augmented cardiovascular risk. LPS is a powerful trigger for the cells of the innate immunity[34]. Variety of immune cells (monocytes, macrophages, Kupfer cells, and preadipocytes) and non-immune cells (adipocytes, hepatocytes, and endothelial cells) express Toll like receptor (TLR) 4 complex recognizing bacterial LPS[35]. Upon binding to TLR, it induces the release of proinflammatory molecules that interferes with metabolic paths of glucose and insulin, promotes development of the atherosclerotic plaque, and favors progression of fatty liver diseases[36,37].

Chronic infections may influence the development of CHD *via* various mechanisms such as chronic inflammatory reactions, an autoimmune responses and the modifications of classic risk factors for CHD[26,38]. They may pose direct effect on the vessel wall by inducing foam cell formation[39]. Therefore, *Herpes simplex* and Hepatitis C viruses as well as bacteria such as *Chlamydophila pneumoniae, Mycoplasma pneumoniae, Porphyromonas gingivalis, Streptococcus mutans* and *H. pylori* have been considered as factors involved in the development of CHD[40-45]. It has also been suggested, that *Ch. pneumoniae* promotes atherogenesis by inducing the synthesis of MCP-1, IL-8 and ICAM-1 in endothelial cells[44]. Among various pathogens possibly involved in atherogenesis *H. pylori* is particularly interesting, since it induces chronic long-term infection within gastric epithelium which leads not only to local but also systemic inflammation[45-48].

H. PYLORI A VERSATILE PATHOGEN

H. pylori is a Gram-negative bacterium demonstrating the affinity to gastric epithelial cells and perfect adaptation to the acidic environment of the stomach. In the majority of infected patients the interplay between *H. pylori* and the host cells are transformed into some sort of long lasting homeostasis. The majority of infected individuals (80%-90%) carry and transmit *H. pylori* with no symptoms, however, in some patients these bacteria induce pathological changes like gastroduodenal ulcers, as well as gastric cancers[49]. *H. pylori* are acquired early in life, and if not successfully treated persist for lifetime[50]. It is believed that the history and adaptation of *H. pylori* is associated with the evolution and migration of *Homo sapiens*. This bacterium has evolved to successfully colonize the hostile environment of the human stomach in the face of innate and adaptive immune responses[51]. In some ways, *H. pylori* resemble commensal bacteria. Contrary to this assumption, stays the fact that *H. pylori* expresses virulence factors with unquestionable pathogenic properties. For these reasons *H. pylori* infections should be monitored since, even if asymptomatic, they may cause systemic complications[52,53].

The interactions between *H. pylori* and gastric tissue cells determines the establishment and development of the disease[54]. Colonization of gastric epithelial cells by *H. pylori via* bacterial adhesins is followed by the occurrence of the acute phase of inflammation accompanied by the infiltration of gastric mucosa with granulocytes and MØ. *H. pylori* survives inside epithelial cells, also temporarily in MØ or in other niches within gastric tissues[55]. When infection becomes persistent, acute phase becomes chronic and is accompanied by an infiltration of lymphocytes. Inflammation is necessary for the proper recognition and elimination of infectious agents and tissue healing. But in case of *H. pylori* the inflammatory reaction is excessive and results in the development of pathological processes in gastric epithelium such as erosions, ulcers, modifications in the cells phenotype, their excessive proliferation as well as secretion of proinflammatory cytokines[56-58]. *H. pylori* possess an abundant composition of antigens[59]. Urease and vacuolating cytotoxin (VacA) stimulate inflammatory responses by damaging gastric epithelial cells, whereas cytotoxin-associated gene A (CagA) antigen, when introduced into the host cells through secretion system Ⅳ, evokes structural and functional changes. Also soluble forms of CagA may influence the activity of host gastric epithelial cells stimulating them to secrete IL-8 with chemotactic properties[60-62]. It inhibits proliferation of lymphocytes[63] and enhances expansion of gastric epithelial cells[64]. *H. pylori* modulates the activity of immune cells *via* different mechanisms such as molecular mimicry, antigen variation and immunomodulation of nonspecific and specific adaptive responses[65,66]. Some antigens of *H. pylori* enhance, while others inhibit the activity of immune cells. The first group includes surface lectins whereas CagA, VacA and LPS represents the second group[63,67-70]. *H. pylori* LPS shares some features common with human tissues. These are Lewis (Le) determinants: Le^X, Le^Y, Le^{XY} present in the O-specific chain of *H. pylori* LPS and on the surface of host cells: erythrocytes, granulocytes, monocytes, epithelial and vascular endothelial cells. In consequence, *H. pylori*

can impair its recognition by host immune cells and pose a risk of autoreactive antibody production[71]. *H. pylori* LPS of Le^{XY} type impairs phagocytic activity of granulocytes, cytotoxic activity of NK cells and lymphocyte proliferation[68,70]. It binds with dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin (DC-SIGN) and may interfere with the development of specific immune response[72].

Recently, possible association between *H. pylori* infection and extragastric disorders, including iron deficiency anemia, chronic idiopathic thrombocytopenic purpura, growth retardation, diabetes mellitus and CHD is being considered[73]. Also, an inverse correlation between *H. pylori* prevalence and an increase in allergies, has been suggested. However, since the understanding of *H. pylori*-related pathologies continues to evolve, the idea that *H. pylori* might confer benefit to humans generates serious controversy. Postulated role of *H. pylori* in the pathogenesis of extragastric disorders is based on the following facts: (1) local inflammation induced by these pathogens has also systemic effects; (2) *H. pylori* infection induces chronic low grade process lasting for decades; and (3) persistent infection induces immune responses, which may have local and remote consequences.

The widespread prevalence of *H. pylori* infection and the fact that they are frequently asymptomatic may suggest that, similarly to intestinal microflora, *H. pylori* can be a source of antigenic components that stimulate not only local, but also systemic inflammatory response. Possibly *H. pylori* together with intestinal microbiota may enhance a risk of cardiovascular disorders, probably through a mechanism that involves an increased exposure to bacterial products translocated from the gut to the circulation[74,75]. Both *H. pylori* proteins and LPS demonstrate pro-inflammatory properties. Considering the role of *H. pylori* LPS as a proinflammatory compound, the different structure of its lipid A is taken into account[76,77]. This component of *H. pylori* LPS determines its diminished proinflammatory properties in comparison to other bacterial LPSs discussed in previous review[75]. Moreover the impact of Le determinants on the severity of *H. pylori* induced-inflammation has also been investigated. For instance, it has been shown that *H. pylori* LPS with or without Le^{XY} determinants exhibits different effectiveness in stimulating the secretion of proinflammatory cytokines: IL-8 and TNF-α[78].

Recent knowledge on the pathoetiology of atherosclerosis together with current findings in the area of *H. pylori* infections constitute the background for the newly proposed hypothesis that those two processes may be related. To describe the involvement of *H. pylori* infection in the development of atherosclerosis, multiple study approaches have been undertaken. To discover a significance of *H. pylori* compounds, in the modulation of cell barrier function and its contribution to CHD development complex studies have to be undertaken. The understanding of subsequent stages of *H. pylori* infections and the processes induced on the level of cellular barriers: gastrointestinal epithelium, vascular endothelium and the cells of innate immunity seem to be crucial.

Local chronic inflammation induced by *H. pylori* in the gastric epithelium, may be reflected on the periphery by the appearance of acute phase proteins and cytokines produced by immune cells and particular tissues[58,59,79]. These soluble systemic inflammatory markers may enhance the development of lesions within vascular endothelium. Also, it cannot be excluded that certain *H. pylori* components crossing the epithelial barrier in the stomach or intestines can have a direct influence on the vascular endothelial cells as well as circulating immune cells maintaining their constant activation (Figure 1). So far, it has been shown that *H. pylori* vacuolating toxin and urease contribute to the intercellular tight junction degradation[80]. If so, bacterial agents penetrating lamina propria may interact with immune cells or even enter the circulation. Although *H. pylori* colonize particularly the gastric epithelium its antigens are translocated to a deeper parts of gastrointestinal tract where they may be easily detected in feces[81]. In the jejunum components of *H. pylori* affect the expression of surface molecules, secretion of cytokines, epithelial permeability and its barrier function. Probably in Peyer's patches *H. pylori* antigens initiate specific adaptive immunity and from this site could be spread into the circulation[79,82]. It has been hypothesized that *H. pylori* antigens may affect vascular endothelium by direct interactions with endothelium, indirectly in a form bound with leukocytes or as complexes with LDL/oxLDL fractions - classic risk factors of CHD[75]. The vascular endothelium can also be affected by *H. pylori* - driven cytokines and chemokines[57,78,83].

In order to evaluate the involvement of *H. pylori* infection in the development of CHD, it is necessary to find the largest number of research studies and possible connections confirming this relationship. The search for such connections should combine serological, biochemical, immunological as well as molecular markers. Serological and molecular studies on the material derived from patients with clinically confirmed CHD can provide markers helpful in defining individual susceptibility to chronic infections and extensive inflammation, predisposing to CHD. These cellular and molecular study approaches would describe the background of *H. pylori*-driven proinflammatory mechanisms directed towards epithelial and endothelial barrier functions, and innate immune cells, which would help to define their role in the atherogenesis.

H. PYLORI VS CHD - CURRENT STATE

Serological studies

The role of *H. pylori* infection in the development of CHD was suggested by Mendall *et al*[84] in 1994, where he observed for the first time the elevation of anti-*H.*

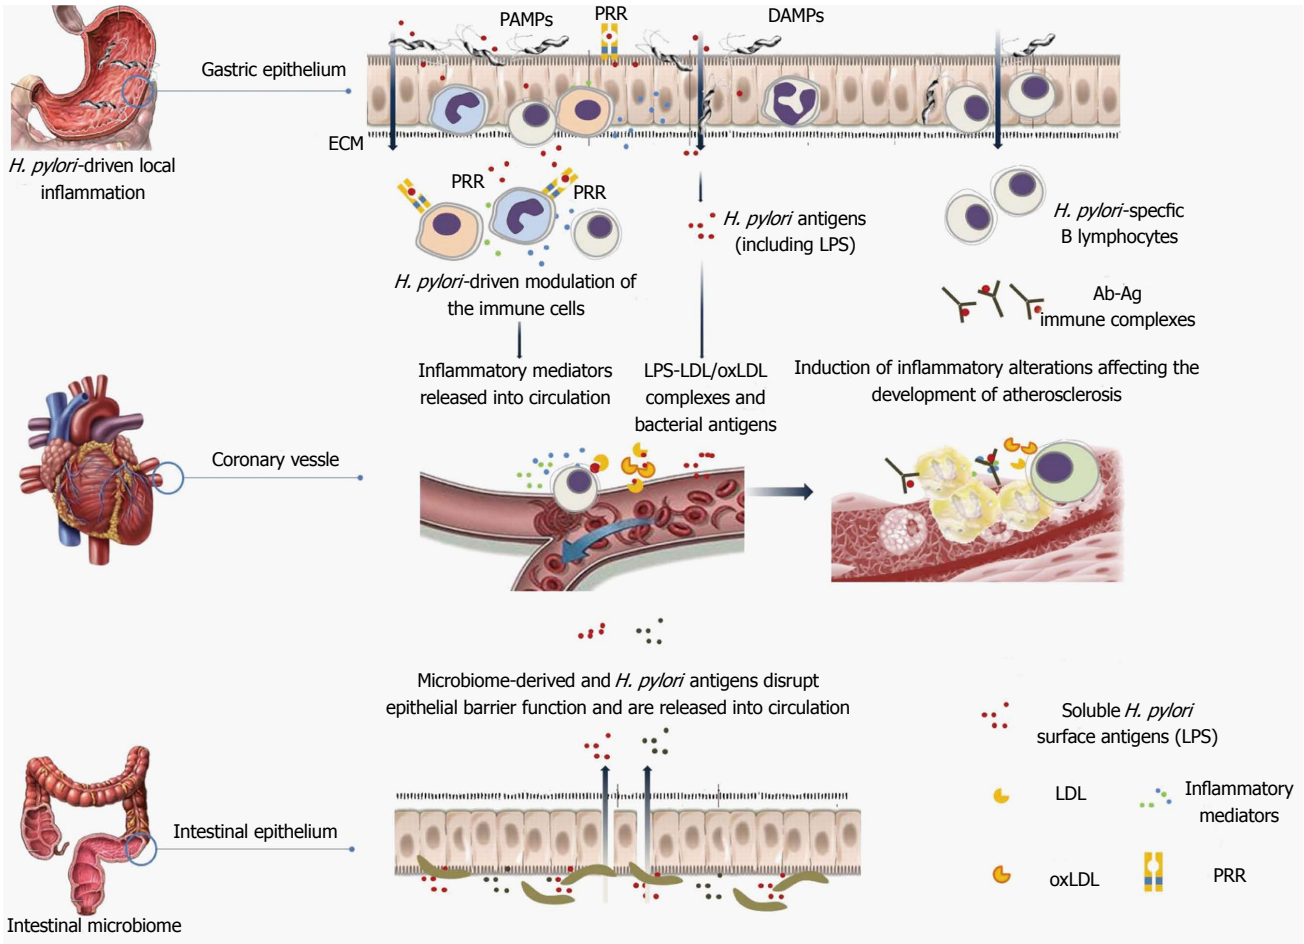

Figure 1 A possible link between local inflammation induced by *Helicobacter pylori* on surface of the gastric epithelium and the inflammatory response within vascular endothelium. *H. pylori*: *Helicobacter pylori*; LDL: Low density lipoproteins; LPS: Lipopolysaccharide; PRR: Pattern recognition receptor; PAMPs: Pathogen associated molecular patterns; DAMPs: Damage associated molecular patterns.

pylori antibodies in the sera of CHD cases[84]. Following this pioneer finding, some authors made confirmed this association in several serological studies[85-88]. Searching for that connection other groups concentrated on the evaluation of bacteriological, biochemical, inflammatory and epidemiological parameters related with CHD and *H. pylori* infection (Table 1). The *H. pylori* seropositivity in CHD group varied from 40% up to 90%. Several studies also supported the association between CagA$^+$ *H. pylori* infection and CHD prevalence. This relation is probably based on the increased levels of trombin - Factor Ⅶ and the prothrombin subunits: F1 + 2 or through the stimulation of low-grade persistent inflammatory response in CHD cases infected with *H. pylori* CagA$^+$ strains[88-92]. However several authors obtained contrary data[93,94]. The findings coming from other studies showed no increase in the production of anti-*H. pylori* antibodies in CHD patients.

Thus, still there is no consensus on the role of *H. pylori* infections in either causation or progression of CHD[95-98]. Possible reasons of these controversies may result from differences in: (1) magnitude of the study groups; (2) exclusion/inclusion criteria used in study groups selection; (3) the usage of serological tests for the *H. pylori* diagnostics; and (4) approaches for data analysis and statistical tests or insufficient knowledge on possible mechanisms involved. However, a new approach suggesting a role of gut microbiota in the development of chronic diseases prompts to continue the research[32]. Particularly stimulating are the results of research conducted in ethnic groups with low incidence of classic risk factors for CHD, and high prevalence of *H. pylori* infection. Recently published data[99] showed that high levels of anti-*H. pylori* IgG were significantly associated with the increased risk for CHD in a group of Central Africans. After adjusting with classic risk factors of CHD, *H. pylori* infection was found to be the only independent predictor of carotid plaque and stroke incidence in this group. Also Sealy-Jefferson *et al*[100] (2013) showed that the exposure to *H. pylori* in Mexican Americans may constitute a risk factor for stroke. Taking into consideration the increased prevalence of *H. pylori* in this population, the infection itself may contribute to the ethnic differences in stroke risk. It has also been suggested that *H. pylori* seroprevalence may influence long term prognosis for patients with unstable angina[101,102]. This finding is supported by several studies where genomic material (16S rRNA) of *H. pylori* was identified in the coronary

Table 1 Major results of the clinical and basic research studies on the relationship between coronary heart disease and *Helicobacter pylori* infection

Study characteristic	Ref.
Serological parameters	
Higher prevalence and concentrations of anti-*H. pylori* antibodies in CHD *vs* non-CHD individuals	[84-88]
Association between *H. pylori* CagA positive infections and CHD; exposure of endothelial and smooth muscle components within atherosclerotic plaques to the anti-CagA antibodies	[88-92]
Autoimmunity hypothesis: the presence of the immune complexes $Le^{X/Y}$-anti-$Le^{X/Y}$ IgG in CHD patients infected with *H. pylori*	[47,127,134]
Bacteriological parameters	
Detection of *H. pylori* genomic material (16S rRNA) in the coronary arteries and atheromatous plaques from patients with cardiologic disorders	[43,91,103-105]
Presence of viable *H. pylori* bacteria in atherogenic plaques	[106]
Biochemical parameters	
Association of *H. pylori* infection with the increased biochemical and inflammatory parameters of CHD as well as coronary lumen reduction	[85,92,107-109]
Higher prevalence of LDL-hiperchlesterolemia, HDL-hypocholesterolemia and elevated levels of CRP in *H. pylori* infected than uninfected individuals	[110,127-129]
Lower activity of serum paraxonase-1 (a major anti-atherogenous component of HDL) and higher carotid-intima media thickness (one of the surrogate marker of atherosclerosis) in *H. pylori* positive in comparison to negative subjects	[108]
Positive correlation between raised LBP levels and the severity of CHD with co-existing *H. pylori* infection. The escalation of inflammatory process occurring *via* Toll-like receptors and LPS-LDL complexes	[127]
Increased levels of homocysteine in *H. pylori* infected individuals caused by malabsorption of vitamine B12 and foliate from diet, leading to obesity-related resistance to insulin	[48,130,131]
Inflammation and inflammation-related parameters	
Increased concentrations of IL-6, IL-8, TNF-α, plasminogen, activator inhibitor type-1, and von Willebrand factor in CHD patients infected with *H. pylori*	[3,38,69,83]
High levels of fibrinogen, a marker of systemic inflammation – putative link between *H. pylori* infections and pathophysiology of CHD	[133]
Recruitment of immune cells to the infectious foci and survival of *H. pylori* within the endothelium due to interaction of *H. pylori* LPS Le determinants with E- and L-selectins	[38,136]
Stimulation of Th1 lymphocytes to produce cytokines by *H. pylori* HspB	[47, 127,134]
Epidemiological studies	
Higher risk of CHD in ethnic groups of Central Africans and Mexican Americans with increased prevalence of *H. pylori* infections	[100-102]
Genetic susceptibility to infections and predisposition to strong inflammatory response	[140,145-146]

CagA: Cytotoxin-associated gene A; CHD: Coronary heart disease; CRP: C-reactive protein; Ig: Immunoglobulines; HDL: High density lipoprotein; Hsp: Heat shock protein; LBP: Lipopolysaccharide binding protein; IL: Interleukin; LDL: Low density lipoprotein; Le: Lewis; TNF: Tumor necrosis factor.

arteries and atheromatous plaques from patients with cardiologic disorders including myocardial infarction and coronary artery disease - suggesting the direct involvement of *H. pylori* in CHD pathogenesis[43,91,103-105]. Some authors postulate the presence of viable *H. pylori* in atherogenic plaques supporting their results by the culture of bacteria on solid media[106].

Inflammatory markers

It has been epidemiologically reported that *H. pylori* infections are associated with the changes in biochemical and inflammatory parameters as well as coronary lumen reduction[85,92,107-109]. In both *H. pylori* infected and CHD patients local inflammation occurring in gastric mucosa or in blood vessels, respectively turns into a chronic phase, which leads to a constitute presence of an inflammation-inducing agents. Increased concentrations of systemic inflammatory markers, both in patients with atherosclerosis and *H. pylori* infected individuals are usually considered a symptom or a result of a local inflammation. However, it has been claimed that systemic inflammation might be a cause and not a result of a local inflammatory reaction within atherosclerotic lesions[110]. Inflammation occurring in both, CHD and *H. pylori* infected individuals is determined by innate immune mechanisms with a participation of cell receptors called "alarmins". They recognize conservative structures of infectious agents - pathogen associated molecular patterns (PAMPs) as well as host endogenous ligands - damage associated molecular patterns (DAMPs) appearing on MØ, dendritic cells (DC) and natural killer (NK) cells, as well as on epithelial and endothelial cells. It is supposed that the activation of immune or epithelial cells *via* pattern recognition receptors (PRRs) may be a reason for subacute inflammation in chronic diseases including CHD[11,69,111,112]. Local inflammation results with increased cytokine levels including IL–6 and TNF-α. Both stimulate the liver to produce acute phase proteins such as CRP, lipopolysaccharide binding protein (LBP) and MMP including MMP-9. Since, acute phase proteins are ligands for PRRs, they enhance the primary inflammation. However, chronic *H. pylori* infection leads to an excessive activation of inflammatory cells and a release of active radicals into the environment. This, due to oxidative stress, leads to tissue damage and apoptosis, therefore providing endogenous DAPMs such as heat shock protein (Hsp) 70, galectin-1, IL-1α, IL-33, mitochondrial damage motifs (mtDNA) and high mobility group box1 protein. Their probable role is a maintenance of inflammation, stimulation of tissue healing within the gastric ulcer

niche, or removing damaged cells from the ischaemic niche, in the vascular endothelium. Mitochondrial DAMPs may increase endothelial permeability through neutrophil dependent and independent pathways[113]. Also specific microRNA expression is associated with the inflammatory response to damaged cells with possible deleterious implications[114]. Prolonged exposure to PAMPs and DAMPs is an apparent reason for a transformation of a local inflammation into a chronic form. The damage of vascular endothelium results in an increased production of reactive oxygen species and inactivation of nitric oxide, which has an anti-atherosclerotic properties. These changes lead to the activation of nuclear transcription factor NF-κB and result with a transformation of endothelium to a proinflammatory phenotype characterized by an increased expression of adhesins and chemokines, including MCP-1 and IL-8, with chemotactic activity towards inflammatory cells[1,14,22]. Proinflammatory phenotype of vascular endothelium exhibits an increased expression of PRR receptors including Toll-like receptors *e.g.*, TLR4, CD14 and TLR2 recognizing bacterial LPS. The enhanced expression of these receptors also occurs on MØ accumulated in the atherosclerotic plaques[6,115,116].

Signaling pathways involving PRR receptors

In recent considerations recognizing CHD as an inflammatory disease, much attention has been paid to the role of signaling pathways involving PRR receptors present on MØ, DC and NK cells as well as endothelial and smooth muscle cells. There are different classes of PRR, including scavenger receptors, and the TLRs. Their role in the pathogenesis of CHD is still unclear and the results obtained in this issue vary greatly[112,117]. Toll-like receptors have been identified as molecules belonging to primary innate immunity. The studies on TLR4 and TLR2 knockout mice confirmed pro-atherogenous effect of TLR4/TLR2 signaling induction[118,119]. Although the expression of TLR2 and TLR4 on endothelial cells in normal arteries is rather low, it was found to be increased in the endothelium from atherosclerosis lesions[112]. Certain studies made an attempt to find a link between the susceptibility to CHD and TLR polymorphisms. Two single nucleotide polymorphisms of TLR4 - Asp299Gly and Thr399Ile were suspected to impair TLR signaling in response to LPS, in carriers of these alleles. It was suggested that both alleles were associated with the protection from carotid artery atherogenesis and the reduction of myocardial infarction risk up to 30%, in carriers of the Asp299Gly polymorphism[112,116,120]. Several TLR types: 1, 2, 4 and 5 are expressed in atherosclerotic plaques by resident cells and leukocytes that migrate into the arterial wall. The upregulation of TLR4 on MØ induced by proatherogenic oxidized LDL suggests that TLRs may provide a potential pathophysiological link between lipids, infection, inflammation and atherosclerosis[115]. The oxidized lipids may also serve as endogenous ligands of TLR2 and TLR4[121]. The study by Talreja *et al*[122] (2004) showed that mast cell-derived histamine up-regulates TLR4 and TLR2 expression on the host cells and by this enhances their sensitivity to cell wall components of Gram-positive and Gram-negative bacteria[122] - with Hsp and LPS considered as potential mediators linking bacterial infections with atherosclerosis. Moreover, it was shown that standard *E. coli* LPS induces the overexpression of TLR4, NF-κB, ICAM-1, VCAM-1 and the endothelial growth factor (VEGF), as well as the production of nitric oxide and IL-8[14,123].

The escalation of inflammatory process occurring in atherosclerosis does not exclude the participation of *H. pylori* LPS, which has low endotoxic activity, however, its proinflammatory potential is preserved. It stimulates MØ to secrete TNF-α, that inhibits lipoprotein lipase activity. This implies an increase in triglycerides and lower HDL cholesterol levels[124]. The recognition of *H. pylori* LPS by the immune cells and its interaction with vascular endothelium are not well understood. In the context of the correlation between the CHD incidence and *H. pylori* infection the interactions of LPS with TLR4 and TLR2 are taken into consideration, especially in regard to the variability of Le determinants in *H. pylori* LPS. It has been shown that *H. pylori* LPS without Le determinants (Le^{X-Y-}) stimulates monocytes to produce lower concentrations of IL-8 and TNF-α than the LPS of Le^{X+Y+} type. Cytokine production induced by the latter type was inhibited by anti–CD14 and anti–LBP antibodies which confirms the involvement of both Le determinants and lipid A in those interactions[78].

H. pylori LPS exhibits weaker activity than the LPS of *E. coli* and express antagonistic properties towards TLR4. Current data do not rule out a role of TLR2 in the signaling induced by LPS of non-enterobacterial origin and its cooperation with TLR4[36]. It was shown that low stimulation of the TLR4 signaling by bacterial LPS may induce the expression of TLR2 in endothelial cells, probably *via* NADPH oxidase released by neutrophils[125]. Chronic *H. pylori* infection favors the formation of LPS-LDL complexes, directly or with the involvement of LBP. Such complexes, when deposited in the vascular endothelium, may enhance proinflammatory atherosclerotic processes[126]. It was shown that the presence of LBP is required for the LPS-dependent activation of intracellular TLR4 in endothelial cells. LBP acts as a catalyst of this process by the translocation of serum sCD14-LPS complexes into the cells[111]. In this context, the positive correlation between raised LBP and the severity of CHD with co-existing *H. pylori* infection seems to be of great importance[127]. It is also possible that *H. pylori* LPS contributes to CHD due to its anti-phagocytic, anti-cytotoxic and anti-proliferative properties, towards phagocytes, NK cells and lymphocytes respectively[68-70].

The expression of TLR4 and TLR2 is intensified in the inflamed endothelium. Recent data indicate that

the binding of *E. coli* LPS with TLR4 may increase the permeability of the vascular epithelium[36]. Any kind of endothelial dysfunction, including a reduction of cell integrity may result in inflammatory cascade. The involvement of TLRs in the development of atherosclerosis is associated with the ability of those receptors to bind ox-LDL, which initiate atherogenesis. Binding of such complexes induces a cascade of signals that activate the transcription factor NF-κB and results in the upregulation of inflammasome components such as cytokines and acute phase proteins[14]. In the context of atherosclerosis the key NF-κB-dependent proteins include inflammatory cytokines: IL-1β and TNF-α, chemokines: IL-8, MCP-1 and MMPs hydrolyzing the extracellular matrix[1]. The role of IL–1β in the development of CHD is associated with the stimulation of endothelial cells to produce IL–6, fibrinogen, CRP and adhesins resulting in a activation of signal cascade leading to the destabilization of atherosclerotic plaques[8].

Acute phase response, lipid metabolism, homocysteine and fibrinogen related mechanisms

Significant association of *H. pylori* infection with LDL-hipercholesterolemia, HDL-hypocholesterolemia and elevated levels of CRP was found. This indicates a possible impact of chronic infection on a lipid metabolism, which is associated with the increased CHD risk[110,128,129]. It was also noted that seropositive patients with unstable angina develop diabetes more frequently than seronegative individuals. *H. pylori* infection increases obesity-related resistance to insulin causing malabsorption of vitamin B12 and foliate from diet, ultimately leading to an increase in circulating homocysteine levels[48,130,131]. Since raised homocysteine may disturb the function of vascular endothelium it might be implicated in the coronary slow flow phenomenon. However, there are also suggestions that homocysteine is a marker rather than a cause of CHD[132]. In *H. pylori* positive subjects the activity of serum paraoxonase-1 (a major anti-atherogenous component of HDL) was lower while carotid-intima media thickness (one of the surrogate marker of atherosclerosis) was higher[108]. The sera of *H. pylori* infected subjects contain increased concentrations of inflammatory cytokines, particularly IL-6, IL-8 and TNF-α, plasminogen, activator inhibitor type-1, and von Willebrand factor - a sensitive indicator of atherosclerosis and a predictive factor of acute coronary syndrome[133]. Certain studies also showed that high levels of fibrinogen, a marker of systemic inflammation can constitute a probable link between *H. pylori* infections and CHD pathophysiology[47]. The putative mechanism of this association might involve *H. pylori*-driven stimulation of mononuclear cells to produce a tissue-factor-like pro-coagulant that, converts fibrinogen to fibrin though the extrinsic blood coagulation pathway. Fibrinogen also stimulates macrophage chemokine secretion through TLR4, promoting immune surveillance at sites of inflammation[134]. However, there are also contradictory results and hypotheses that the occurrence of CHD is positively associated with age and lower social class[135]. It would be of great importance to check, whether *H. pylori* eradication is associated with the decrease in the level of the above markers and lower CHD incidence. To date, anti-*H. pylori* eradication therapy confirmed only some suggestions. Mean coronary artery lumen loss in patients undergoing percutaneous transluminal coronary angioplasty (PTCA) with stent and anti-*H. pylori* eradication therapy was significantly smaller compared to PTCA and placebo treated group. Similarly, cytokines such as TNF-α, IL-1β and IL-8 were significantly lower in plasma of PTCA patients after *H. pylori* eradication, while there were no changes in plasma lipids, homocysteine and clotting factors[85].

Autoimmunity hypothesis

Bacterial pathogens, including *H. pylori* might contribute to CHD pathogenesis. This approach is supported by the fact that CHD is starting to be considered as an autoimmune inflammatory process. The antigenic structures of infectious agents can induce the expansion of potentially autoreactive T and B cells, or B cells producing antibodies cross-reacting with host tissues. This phenomenon is defined as antigenic mimicry. For instance *H. pylori* HspB (60 kDa) might be implicated in CHD pathogenesis *via* stimulation of Th1 lymphocytes to secrete IFN-γ and IL-12 or activation of MØ to express metalloproteinases and adhesins[38]. Antigenic mimicry as a cause of inflammation in CHD is also related to Le determinants. In human tissues Le antigens serve as ligands for endothelial (E and P–selectin) and leukocytes (L–selectin) adhesins. This interaction drives cell migration into the inflammatory milieu and plays an important role in the accumulation of immune cells in peripheral lymph nodes. It was shown that *H. pylori* bearing Le antigens in their LPSs are able to bind E- and L-selectins. This linkage enables the recruitment of immune cells to the infectious foci and may promote survival of *H. pylori* within the endothelium[136]. The activity of *H. pylori* LPS is also manifested by the activation of monocytes, MØ and secretion of proinflammatory cytokines: IL-1, IL-6 and IL-8[69]. *H. pylori* strains bearing Le^X or Le^A attract circulating lymphocytes that express L–selectin. It was shown that *H. pylori* expressing Le determinants induce higher colonization rates and more excessive infiltration of gastric mucosa with neutrophils and lymphocytes - a phenomenon also observed in individuals infected with *H. pylori* expressing Le^X determinants[137]. Due to the ongoing inflammation the endothelial and smooth muscle components within atherosclerotic plaque might be revealed and exposed to the anti-CagA antibodies. The formation of such immune complexes facilitates the risk for further damage of the endothelium caused by lytic complex of complement proteins[46].

INDIVIDUAL SUSCEPTIBILITY TO INFECTION AND INFLAMMATION IN RESPECT TO THE DEVELOPMENT OF CHD

The risk for cardiovascular diseases might also be considered on the genetic level-determining the susceptibility to CHD development related to inflammatory process[138]. For example, one of the explanations for elevated levels of CRP in CHD patients might lay in chronic, bacterial or viral infection. However, since viral as well *H. pylori* and *Ch. pneumoniae* infections, are very common, it is believed that an individual susceptibility to infections and accompanying inflammation could explain the role of infectious agents in the course of CHD. This individual predisposition to persistent infections and chronic inflammatory response can be determined, to some extent, by the Le antigens, receptors for PAMPs and proinflammatory cytokines. It is believed that Lewis antigens can play a key role in shaping the individual susceptibility to CHD development: by directing the adverse effects of infection and excessive inflammatory response[41]. There are also clear examples of protection against infectious diseases (particularly to *H. pylori*, norovirus, and *Vibrio cholerae*) based on polymorphisms in genes encoding and regulating the expression of ABH blood group and Lewis antigens[139]. There are two types of Lewis antigens in humans: Le a and Le b. Their expression depend on genes located on chromosome 1 encoding fucosyltransferases: *FUT2* and *FUT3*. Depending on the genotype, and thus the expression of one or both Le antigens, in the Caucasian population, there are three dominating phenotypes: Le^{a+b-}, Le^{a-b+}, Le^{a-b-}, and Le^{a+b+} which occurs very rarely. Le antigens expressed on cell surface and released in body fluids are associated with the susceptibility to infections especially related to the mucus layer, such as those caused by *H. pylori*[140]. It is assumed that Le antigens promote adhesion-dependent infections[141]. There are speculations on the link between the Le^{a-b-} phenotype and several disorders constituting a risk factors for CHD development, with examples such as insulin resistant diabetes, elevated levels of clotting factor VIII and von Willebrand factor. This phenotype is considered a genetic marker for the risk for CHD development[142,143]. It is also believed that the polymorphism in *FUT3* associated with the presence of point mutations 59T > G, 202T > C, 314 C > T, 1067 T > A, may determine the individual susceptibility to infections and the development of atherosclerotic lesions and strong inflammatory response[144].

The polymorphism of inflammation-related genes, may indirectly contribute to the development of CHD, and the dynamics of the disease. Such a possibility appears especially when the mutations accumulate in several genes related with inflammatory response. Thus, while searching for the relationship between *H. pylori* infections and their role in the development of CHD, mutations in the genes encoding TLR4/CD14 receptors (binding LPS), and IL–1β should be taken into consideration[145]. IL-1β acts as a stimulating mediator of IL-6, fibrinogen, CRP or adhesive molecules expression by endothelial cells within a cascade leading to the development and destabilization of the atherosclerotic plaques. In regard to IL-1β the most frequently considered gene mutations are: -511C > T and -31C > T[145,146]. It was showed that carriers of the two relatively frequent variants of *IL-1β* gene at -31 and -511 positions, *i.e.*, -31 TT and -511 CC, are at a higher risk of developing CHD requiring surgical treatment or two-stage percutaneous angioplasty. In patients prone to the development of atherosclerosis, polymorphism of *IL-1β* gene cluster may be associated with the extent and dynamics of lesions in the coronary arteries[146]. For gene encoding TLR4: Asp299Gly and Thr399Ile and for *CD14* gene: 159C > T mutations are considered to play a role in CHD and chronic infections[112,116]. Patients carrying Asp299Gly, a common variant of the *TLR4* gene presented reduced prevalence of angiographic artery disease and low levels of CRP. This common variant of the TLR4 gene, probably attenuates receptor signalling and diminishes inflammatory response to Gram-negative pathogens[147].

Since neither infection nor the activation of TLR4/TLR2 is sufficient to induce atherosclerosis in animal models[148], it is rather unlikely that microbes and/or TLRs signaling play a causative role in this disease. Instead, it is thought that they may be important as associates of silent disease. For instance, microbial components such as LPS or lipoteichoic acid released during acute infection or exacerbation of chronic infection might activate plaque cells. It has been suggested that such local "echos" of infections could lead to increased local production of cytokines and initiate plaque activation and rupture. The expression of TLRs in plaques suggests a pathway through which such an echo effect could occur[6]. Because *H. pylori* infection is located in the stomach, the question arises why the possible inflammation should only be transferred to the heart blood vessels and not to other vessels of the body? Various activities of the immune cells are mediated by endothelial cells, which form specialized microcirculatory networks used by the immune cells under both physiological and pathological circumstances. Endothelial cells represent a highly heterogenous population of cells with the ability to interact with and modulate the function of immune cells[149]. Atherosclerotic lesions occur at distinct sites within the arterial tree, such as branches, bifurcations, and curvatures, where they cause characteristic alterations in the blood flow, including decreased shear stress and increased turbulence. The nature of the flow appears to determine whether lesions occur at these vascular sites. The low-shear hypothesis of

atherosclerosis has been validated[150]. Decreasing shear stress at branches, bifurcations, and curvatures results in endothelial activation, adhesion molecule expression, and greater monocyte transmigration. It has been shown that atherosclerotic lesions appear first at lesion-prone sites, where activated endothelium expresses specific molecules, which favors the recruitment of monocytes and T cells. For instance, it has been hypothesized that the regiospecitifity of atherosclerotic lesions might be determined by the lower expression of TLR2 molecules[111]. The localization of atherosclerotic lesions could be also related to the local overexpression of NF-κB/IκB pathways[14].

FUTURE RESEARCH PERSPECTIVES

To describe the role of *H. pylori* in the initiation, acceleration or the development of CHD a few fundamental questions need to be addressed. It needs to be elucidated, whether viable *H. pylori* or bacterial compounds are able to break the single layer of epithelial cells and have unimpeded access to the systemic circulation. Also, it is not clear, whether classic risk factors such as hypercholesterolemia may act synergistically with *H. pylori* or their compounds to destabilize or disrupt gastric epithelial barrier function. It is also interesting whether CHD as systemic disease can lead independently to the disruption of gastric epithelial barrier function. The use of well-defined cell lines which mimic the *in vivo* conditions and exclude the naturally occurring phenotypic variations or the influence of external agents will enable to clarify the relationship between *H. pylori* as effective colonizer of gastric mucosa and inflammatory response. Methodology of culturing the cells using trans-well systems can help to examine whether *H. pylori* antigens alone or in combination with classic CHD risk factors interfere with the integrity of gastric epithelial and endothelial cells, cytotoxicity, the cell cycle, chemokines as well as cytokines and cell signaling. Microfluidic culture systems enable to explain if *H. pylori* compounds might be delivered to the inflammatory sites within vascular endothelium and interact with both endothelial and the immune cells[151].

Since, *H. pylori* infection has been defined as class I gastric carcinogen and many epidemiological studies demonstrated positive correlation between serum lipids and the risk of gastrointestinal malignancies, it is tempting to evaluate the prevalence of malignancies in CHD patients infected with *H. pylori*. Although it has been shown that *H. pylori* infection is related with increased LDL level, the association between abnormal concentrations of serum lipid components, the infection with *H. pylori* and the risk of gastrointestinal cancer is unknown[152].

CHD patients are recommended for antitrombocythic therapy with aspirin, which can be beneficial to individuals who already have experienced a heart attack, stroke, angina or peripheral vascular disease, or have had certain procedures such as angiography or bypass. However, aspirin can be prescribed to prevent heart disease and stroke in same individuals who have not previously experienced these events. The United States Preventive Services Task Force recommends that men with no history of heart disease or stroke aged 45-79 years should use aspirin to prevent myocardial infractions and that woman with no history of heart disease or stroke aged 55-79 should use aspirin to prevent stroke[153]. On the other hand, NSAIDs such as aspirin is positively correlated with the incidence of gastrointestinal tract disorders. Such damage can take a form of mucosal erosions or ulcers. NSAIDs can stimulate leukocytes, particularly neutrophils, such that they adhere to the vascular endothelium within the gastrointestinal microcirculation. Moreover NSAIDs impair the rapid restitution that occurs through cell migration following damage to the superficial epithelium of the stomach, reduce rates of epithelial turnover and thus impair the healing process. It is necessary to elucidate, whether ulcers are more likely to develop in long-term NSAIDs users who have mucosal erosions or in individuals infected with *H. pylori*, or both – and what is the role of NSAIDs on the course of CHD and *H. pylori*-related pathologies[153,154].

Proinflammatory agents released directly due to damage induced by *H. pylori* or indirectly by neutrophils recruited to the site of infection break the epithelial barrier. An initial effect of *H. pylori* infection is amplified significantly and impairs the proper action of cellular barrier. The question is whether inflammatory mediators generated in the stomach can reach and harm distant tissues, leading to systemic disorders related with CHD.

Tissue inflammation, cell injury or death result in the release of molecules that are endogenous PRR ligands. DAMPs stimulates cells to produce acute phase cytokines and activates other inflammatory compounds. Depending on the affected tissue, various stromal cells, including epithelial and endothelial cells, may function as sentinels for detection of DAMPs, which felicitate neutrophil recruitment. It was hypothesized that IL-33 may have protective effects during atherosclerosis by inducing a Th1-to-Th2 switch of immune responses[19]. However, many questions regarding the role of specific DAMPs during *H. pylori* infections and cardiovascular diseases remain to be solved.

Since initial moment of *H. pylori* infection is almost impossible to identify, little is known about the natural history and kinetics of infection and immune responses. There is an urgent need to establish and optimize the animal model mimicking human immune system, sensitive for *H. pylori* infection and CHD development. Immunologic similarities between guinea pigs and humans in regard to: leukocyte antigens, complement system, antigen presenting molecules, patterns of IFN-γ, IL-8, IL-12 release, as well as their receptors

suggest that this animal model may be suitable for studies on the relation between *H. pylori* infection and the development of its extragastric consequences. Antigen-specific lymphocyte proliferation has been found a suitable marker of immune response in guinea pigs with sustained *H. pylori* infection. Recently guinea pigs were successfully used to show the role of endotoxemia in the myocardial injury and sepsis-associated dysfunction[42,72,155].

It is believed that an individual susceptibility to infections and accompanying inflammation could help to explain the role of infectious agents in the course of CHD. Using the samples from patients with clinically confirmed CHD infected or not with *H. pylori* in comparison with control group it is necessary to look for cellular and molecular markers which may determine an individual susceptibility to chronic infections and extensive inflammation, predisposing to CHD.

These cellular and molecular studies would help to understand the role of *H. pylori* infections in the pathogenesis of CHD. Describing the background of *H. pylori* - driven proinflammatory mechanisms directed towards epithelial and possibly endothelial barrier, would help to allocate their role in the process of atherogenesis. In case of proven causative role of this bacterium in the pathogenesis of CHD, its eradication will be important for diminishing one of CHD infectious risk factors.

CONCLUSION

CHD, one of the most severe chronic diseases of the coronary vessels is a multifactorial disorder. Since classic risk factors do not explain all cases of CHD it has been suggested that chronic infections and even commensal microorganisms may affect the development or maintenance of CHD. Among various pathogens possibly involved in atherogenesis *H. pylori* is particularly interesting, since it induces chronic long-term infection within gastric epithelium which leads to not only local but systemic inflammation. Recent knowledge on the pathogenesis of atherosclerosis together with current findings in the field of *H. pylori* related diseases constitute the background for the newly proposed hypothesis that those two processes may be related.

Abstract

The function of the heart is to contract and pump oxygenated blood to the body and deoxygenated blood to the lungs. To achieve this goal, a normal human heart must beat regularly and continuously for one's entire life. Heartbeats originate from the rhythmic pacing discharge from the sinoatrial (SA) node within the heart itself. In the absence of extrinsic neural or hormonal influences, the SA node pacing rate would be about 100 beats per minute. Heart rate and cardiac output, however, must vary in response to the needs of the body's cells for oxygen and nutrients under varying conditions. In order to respond rapidly to the changing requirements of the body's tissues, the heart rate and contractility are regulated by the nervous system, hormones, and other factors. Here we review how the cardiovascular system is controlled and influenced by not only a unique intrinsic system, but is also heavily influenced by the autonomic nervous system as well as the endocrine system.

INTRODUCTION

The cardiovascular system is a closed system connecting a pump to blood vessels (*i.e.*, arteries, capillaries, veins). The heart serves as the pump that moves blood through blood vessels thereby providing the needed oxygen and nutrients to the body. The

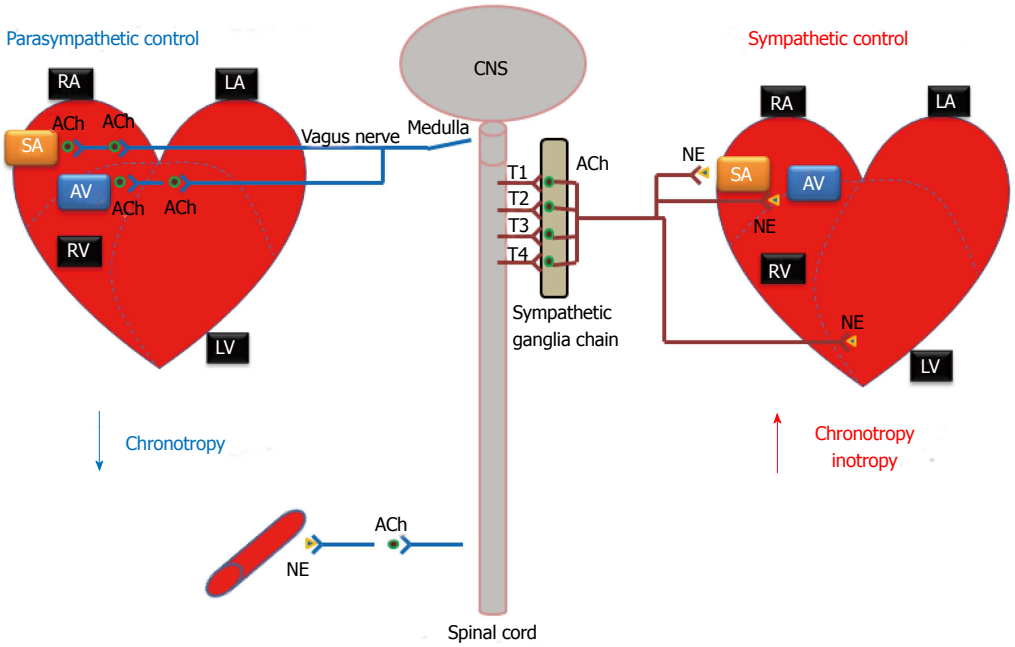

Figure 1 Autonomic nervous system regulation of the heart function. The autonomic nervous system affects the rate and force of heart contractions. CNS: Central nervous system; RA: Right atria; LA: Left atria; RV: Right ventricle; LV: Left ventricle; SA: Sino-atrial node; AV: Atrioventricular node; NE: Norepinephrine; ACh: Acetylcholine.

heart consists of four chambers: right atrium, right ventricle, left atrium and left ventricle. The right atrium receives oxygen-poor blood from the systemic veins; this blood then moves across the tricuspid valve to the right ventricle. From the right ventricle the de-oxygenated blood is pumped pass semilunar valves out through the pulmonary arteries to the lungs. In the lungs, the blood becomes oxygenated and returns to the left atrium *via* the pulmonary veins. This oxygen-rich blood next moves across the mitral valve to the left ventricle and is pumped out across semilunar valves to the systemic arteries and to body tissues. To achieve this goal, a normal human heart must beat regularly and continuously for one's entire life. Autorhythmic cardiac cells initiate and distribute impulses (action potentials) throughout the heart. The intrinsic conduction system coordinates heart electrical activity. This electrical activity in the heart corresponds to electrocardiogram (ECG) wave tracings. On a normal ECG recording, the P wave reflects atrial depolarization followed by atrial contraction. The QRS wave reflects ventricular depolarization followed by ventricular contraction and the T wave reflects ventricular repolarization and ventricular relaxation.

In the intrinsic conduction system, heartbeats originate from the rhythmic pacing discharge from the sinoatrial node (SA node) within the heart itself. The SA node, located in the right atrium, is a part of the intrinsic conduction (or nervous) system found in the heart. This conduction system in order of rate of depolarization starts with the SA node or pacemaker and results in atrial depolarization and atrial contraction, the internodal pathway, the AV node (where the impulse is delayed), AV bundle, the left and right branches of the bundle of His and lastly the Purkinje fibers, both of which result in ventricular depolarization and contraction. All of the components of the intrinsic conduction system contain autorhythmic cells that spontaneously depolarize. In the absence of extrinsic neural or hormonal influences, the SA node pacing rate would be about 100 beats per minute (bpm). The heart rate and cardiac output, however, must vary in response to the needs of the body's cells for oxygen and nutrients under varying conditions. In order to respond rapidly to changing requirements of the body's tissues, the heart rate and contractility are regulated by the autonomic nervous system, hormones, and other factors.

AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system (ANS) is the component of the peripheral nervous system that controls cardiac muscle contraction, visceral activities, and glandular functions of the body. Specifically the ANS can regulate heart rate, blood pressure, rate of respiration, body temperature, sweating, gastrointestinal motility and secretion, as well as other visceral activities that maintain homeostasis[1-4]. The ANS functions continuously without conscious effort. The ANS, however, is controlled by centers located in the spinal cord, brain stem, and hypothalamus.

The ANS has two interacting systems: the sympathetic and parasympathetic systems. As illustrated in Figure 1, sympathetic and parasympathetic neurons exert antagonistic effects on the heart. The sympathetic

system prepares the body for energy expenditure, emergency or stressful situations, *i.e.,* fight or flight. Conversely, the parasympathetic system is most active under restful conditions. The parasympathetic counteracts the sympathetic system after a stressful event and restores the body to a restful state. The sympathetic nervous system releases norepinephrine (NE) while the parasympathetic nervous system releases acetylcholine (ACh). Sympathetic stimulation increases heart rate and myocardial contractility. During exercise, emotional excitement, or under various pathological conditions (*e.g.,* heart failure)[5], the sympathetic nervous system is activated. The stimulation of the sympathetic nervous system causes pupil dilatation, bronchiole dilatation, blood vessel constriction, sweat secretion, inhibits peristalsis, increases renin secretion by the kidneys, as well as can induce reproductive organ contraction and secretion. In contrast, parasympathetic stimulation decreases heart rate and constricts the pupils. It also increases secretion of the eye glands, increases peristalsis, increases secretion of salivary and pancreatic glands, and constricts bronchioles. Most organs receive innervations from both systems, which usually exert opposing actions. However, this is not always the case. Some systems do not have a response to parasympathetic stimulation. For example, most blood vessels lack parasympathetic innervations and their diameter is regulated by sympathetic nervous system input, so that they have a constant state of sympathetic tone. It is a decrease in sympathetic stimulation or tone that allows vasodilatation. During rest, sleep, or emotional tranquility, the parasympathetic nervous system predominates and controls the heart rate at a resting rate of 60-75 bpm. At any given time, the effect of the ANS on the heart is the net balance between the opposing actions of the sympathetic and parasympathetic systems.

Unlike the somatic nervous system, where a single neuron originating in the spinal cord typically connects the central nervous system and a skeletal muscle *via* a neuromuscular junction, both sympathetic and parasympathetic pathways are composed of a two-neuron chain: a preganglionic neuron and a postganglionic neuron. The neurotransmitter between the preganglionic and postganglionic neurons is acetylcholine, the same as that in neuromuscular junctions. Messages from these systems are conveyed as electrical impulses that travel along axons and cross synaptic clefts (using chemical neurotransmitter).

In the sympathetic system (thoracolumbar division), these nerves originate from the thoracolumbar region of the spinal cord (T1-L2) and radiate out towards the target organs. In contrast, the nerves of the parasympathetic system originate within the midbrain, pons and medulla oblongata of the brain stem and part of these fibers originate in the sacral region (S2-S4 sacral spinal nerves) of the spinal cord. While sympathetic nerves utilize a short preganglionic neuron followed by a relatively long postganglionic neuron, parasympathetic nerves (*e.g.,* the vagus nerve, which carries about 75 percent of all parasympathetic fibers) have a much longer preganglionic neuron, followed by a short postganglionic neuron.

Cardiac sympathetic nervous system

The sympathetic nervous system is the component of the ANS that is responsible for controlling the human body's reaction to situations of stress or emergency (otherwise known as the "fight-or-flight" response), while the parasympathetic nervous system is generally responsible for basal organ system function.

Cardiac sympathetic preganglionic nerves (typically all myelinated) emerge from the upper thoracic segments of the spinal cord (T1-T4). After traveling a short distance, preganglionic fibers leave the spinal nerves through branches called white rami and enter sympathetic ganglia. The cardiac sympathetic neurons form the sympathetic chain ganglia located along the side of the viscera column (*i.e.,* paravertebral ganglia). These ganglia comprise the sympatheric trunks with their connecting fibers. The postganglionic fibers, extend to the viscera, such as the heart. In general, sympathetic preganglionic neurons are shorter than sympathetic postganglionic neurons (Figure 1).

Sympathetic neurotransmitters: Neurotransmitters are chemical substances released into the synaptic cleft from nerve terminals in response to action potentials. They transmit signals from a neuron to a target cell across a synapse, *e.g.,* acetylcholine for neuromuscular junctions. While the preganglionic neurons of both the sympathetic and parasympathetic system secret acetylcholine (ACh) which is why they are referred to as cholinergic, the majority of the postganglionic endings of the sympathetic nervous system release NE, which resembles epinephrine (*i.e.,* adrenalin). Thus, these sympathetic postganglionic fibers are commonly called adrenergic fibers.

Sympathetic receptors: There are two types of adrenergic receptors: β and α. In the cardiovascular system there are β_1, β_2, α_1, and α_2 adrenergic receptors (Table 1).

β_1 adrenergic receptors are expressed in the heart (in the SA node, AV node, and on atrial and ventricular cardiomyocytes). The activation of β_1 receptors increases heart rate (*via* the SA node), increases contractility as result of increased intracellular calcium concentrations and increased calcium release by the sarcoplasmic reticulum (SR), and increased AV node conduction velocity. Additionally, activation of this receptor also induces renin release by the kidneys to help maintain blood pressure, plasma sodium levels and blood volume.

β_2 adrenergic receptors are mainly expressed in vascular smooth muscle, skeletal muscle, and in

Table 1 Sympathetic and parasympathetic receptors and their functions in the heart and vessels

	Heart				Vessels	
	Receptor	Function			Receptor	Function
		Inotropy	Chronotropy	Dromotropy		
Norepinephrine	α_1	+	+	+	α_1	Vasoconstriction
	β_1	+	+	+	β_1	Vasoconstriction
	β_2	+	+	+	β_2	Vasodilation
Acetylcholine	M_2	-	-	-	M_2	Vasodilation

the coronary circulation. Their activation elicits vasodilatation, which, in turn increases blood perfusion to target organs (especially the liver, heart, and skeletal muscle). These receptors are not innervated and thus are primarily stimulated by circulating epinephrine. There are also some low expressions of β_2 receptors in cardiomyocytes.

α_1 adrenergic receptors are expressed in vascular smooth muscle proximal to sympathetic nerve terminals. Their activation elicits vasoconstriction. There are also some low expressions of α_1 receptors in cardiomyocytes.

α_2 adrenergic receptors are expressed in vascular smooth muscle distal from sympathetic nerve terminals. Their activation also elicits vasoconstriction.

Sympathetic nervous system control and heart function: Stimulation by the sympathetic nervous system results in the following effects on the heart (Table 1): Positive chronotropic effect (increase in heart rate): The sinoatrial (SA) node is the predominate pacemaker of the heart. It is located within the upper posterior wall of the right atrium, and is responsible for maintaining a sinus rhythm of between 60 and 100 beats per minute. This rate is constantly being affected by innervations from both the sympathetic and parasympathetic nervous systems. Stimulation by the sympathetic system nerves results in an increase of heart rate, as occurs during the "fight-or-flight" response.

Positive inotropic effect (increase of contractility): Myocardial contractility represents the ability of the heart to produce force during contraction. It is determined by the incremental degrees of binding between myosin (thick) and actin (thin) filaments, which in turn depends on the concentration of calcium ions (Ca^{2+}) in the cytosol of the cardiomyocyte. Stimulation by the sympathetic nervous system causes an elevation in intracellular (Ca^{2+}) and thus an increase in contraction of both the atria and ventricles.

Positive dromotropic effect (enhancement of conduction): Stimulation by the sympathetic nervous system also enhances the conductivity of the electrical signal. For example, it increases AV conduction velocity.

Parasympathetic nervous system

As previously mentioned, the parasympathetic nervous system is responsible for the unconscious regulation of the body's systems, most notably, salivation, lacrimation, urination, digestion, and defecation (acronym SLUDD). Importantly, the parasympathetic nervous system plays an antagonistic role in regulating heart function.

The parasympathetic system has preganglionic neurons (craniosacral division) that arise from neurons in the mid-brain, pons and medulla oblongata. The cell bodies of parasympathetic preganglionic neurons are located in the homologous motor nuclei of the cranial nerves. Parasympathetic preganglionic fibers associated with parts of the head are carried by the oculomotor, facial, and glossopharygeal nerves. The fibers that innervate organs of the thorax and upper abdomen are parts of the vagus nerve which as previously mentioned carries approximately 75% of all parasympathetic nerve fibers passing to the heart, the lungs, the stomach, and many other visceral organs. Preganglionic fibers arising from the sacral region of the spinal cord make up parts of S2-S4 sacral spinal nerves and carry impulses to viscera in the pelvic cavity. The short postganglionic neurons reside near effector organs, *e.g.,* lacrimal gland, salivary glands, heart, trachea, lung, liver, gallbladder, spleen, pancreas, intestines, kidney, and urinary bladder, *etc*. Unlike the sympathetic system, most parasympathetic preganglionic fibers reach the target organs and form the peripheral ganglia in the wall of the organ. The preganglionic fibers synapse within the ganglion, and then short postganglionic fibers leave the ganglia to the target organ. Thus, in the parasympathetic system, preganglionic neurons are generally longer than postganglionic neurons (Figure 1).

Parasympathetic neurotransmitters: Acetylcholine is the predominant neurotransmitter from the parasympathetic nervous system, in both the preganglionic and postganglionic neurons. Although excitatory in skeletal muscle by binding to nicotinic receptors and inducing the opening of ligand gated sodium channels, acetylcholine inhibits the contraction of cardiomyocytes by activating muscarinic receptors (M_2). These parasympathetic postganglionic fibers are commonly called cholinergic fibers because they secrete acetylcholine at their nerve endings.

Acetylcholine is synthesized by choline acetlytransferase in cholinergic neurons by combining choline and acetyl-COA molecules. Once assembled in synaptic vesicles near the end of the axon, the entry of calcium causes the vesicles to fuse with the membrane of the

neuron and to release acetylcholine into the synaptic cleft (the space between the neuron and post-synaptic membrane or effector cell). Acetylcholine diffuses across the synaptic cleft and binds to receptors on the post-synaptic membrane increasing the permeability to sodium causing depolarization of the membrane and propagation of the impulse. This chemical transmission is much slower than the electrical "all or none" transmission of the action potential seen in the intrinsic nervous system of the heart. To regulate the function of these neurons (and thus, the muscles they control), acetylcholinesterase is present in the synaptic cleft. It serves to hydrolyze the acetylcholine molecule by breaking it down into choline and acetate, which are then both taken back up by the neuron, to be again synthesized into acetylcholine.

Parasympathetic receptors: The parasympathetic postganglionic fibers are cholinergic. Acetylcholine can bind to two types of cholinergic receptors called nicotinic receptors and muscarinic receptors. Muscarinic receptors are located in the membranes of effector cells at the end of postganglionic parasympathetic nerves and at the ends of cholinergic sympathetic fibers. Responses from these receptors are excitatory and relatively slow. The nicotinic receptors are located at synapses between pre- and post-ganglionic neurons of the sympathetic and parasympathetic pathways. Nicotinic receptors in contrast to muscarinic receptors produce rapid, excitatory responses. Neuromuscular junctions found in skeletal muscle fibers are nicotinic.

In relation to the cardiovascular system the parasympathetic nervous system has two different kinds of muscarinic receptors: the M_2 and M_3 receptors (Table 1).

The M_2 receptors are expressed in the heart; abundant in nodal and atrial tissue, but sparse in the ventricles. The binding of acetylcholine to M_2 receptors serves to slow heart rate till it reaches normal sinus rhythm. This is achieved by slowing the rate of depolarization, as well as by reducing the conduction velocity through the atrioventricular node. Additionally, the activation of M_2 receptors reduces the contractility of atrial cardiomyocytes, thus reducing, in part, the overall cardiac output of the heart as a result of reduced atrial kick, smaller stroke volume, and slower heart rate. Cardiac output is determined by heart rate and stroke volume (CO = HR x SV).

The M_3 receptors are mainly expressed in vascular endothelium. The predominate effect of M_3 receptor activation is dilatation of the vessels, by stimulating nitric oxide production by vascular endothelial cells[6]. M_3 receptors impact afterload and vascular resistance which can again alter cardiac output and blood pressure.

Parasympathetic nervous system control and heart function: As mentioned earlier, parasympathetic activity produces effects that are, in general, opposite to those of sympathetic activation. However, in contrast to sympathetic activity, the parasympathetic nervous system has little effect on myocardial contractility.

Negative chronotropic effect (decrease in heart rate): The vagus nerve directly innervates the sinoatrial node; when activated, it serves to lower the heart rate, thus exhibiting a negative chronotropic effect.

Negative inotropic effect (decrease in myocardial contractility): Currently, it is a matter of debate whether parasympathetic stimulation can exhibit negative inotropic effects, as the vagus nerve does not directly innervate cardiomyocytes other than that of the sinoatrial and atrioventricular nodes, however, recent *in vivo* studies may suggest otherwise, at least in the atrium.

Negative dromotropic effect (decrease conduction velocity): Stimulation of the parasympathetic system serves to inhibit AV node conduction velocity.

Cellular signal transduction

Most sympathetic and parasympathetic receptors are known to be G protein-coupled receptors (GPCRs). In the heart, the G-protein-cAMP-PKA signaling pathway mediates the catecholaminergic control on heart rate and contractility.

Signaling pathway of sympathetic stimulation: The sympathetic stimulation-induced effects in the heart result from activation of β_1-adrenoceptors, which are GPCRs (Figure 2). The sympathetic neurotransmitter NE (as well as other catecholamines) bind to β_1 receptors and activate stimulatory G proteins (G_s) by causing a conformational change within the G_s, so that the disassociated α_s subunit can then bind to and activate adenylyl cyclase (AC). The activation of this enzyme then catalyzes the conversion of ATP into cyclic adenosine monophosphate (cAMP). This second messenger may then activate a myriad of other pathways, ion channels, transcription factors, or enzymes. With regards to the cardiovascular system, the most important enzyme that cAMP activates is protein kinase A (PKA). PKA, which in turn, phosphorylates multiple target proteins, such as L-type Ca channels (LTCC), the SR Ca handling protein phospholamban, and contractile machinery such as troponin C, I and T. Additionally, cAMP binds directly to ion channels responsible for the funny current (I_f), thus increasing the heart rate[7].

Signaling pathway of parasympathetic stimulation: The parasympathetic stimulation-induced effects in the heart result from activation of muscarinic (M_2) receptors, which are also GPCRs by acetylcholine (Figure 2). The parasympathetic neurotransmitter ACh binds to M_2 receptors thereby activating inhibitory G proteins (G_i) by causing a conformational change within the G_i subunit, so that the disassociated α_i

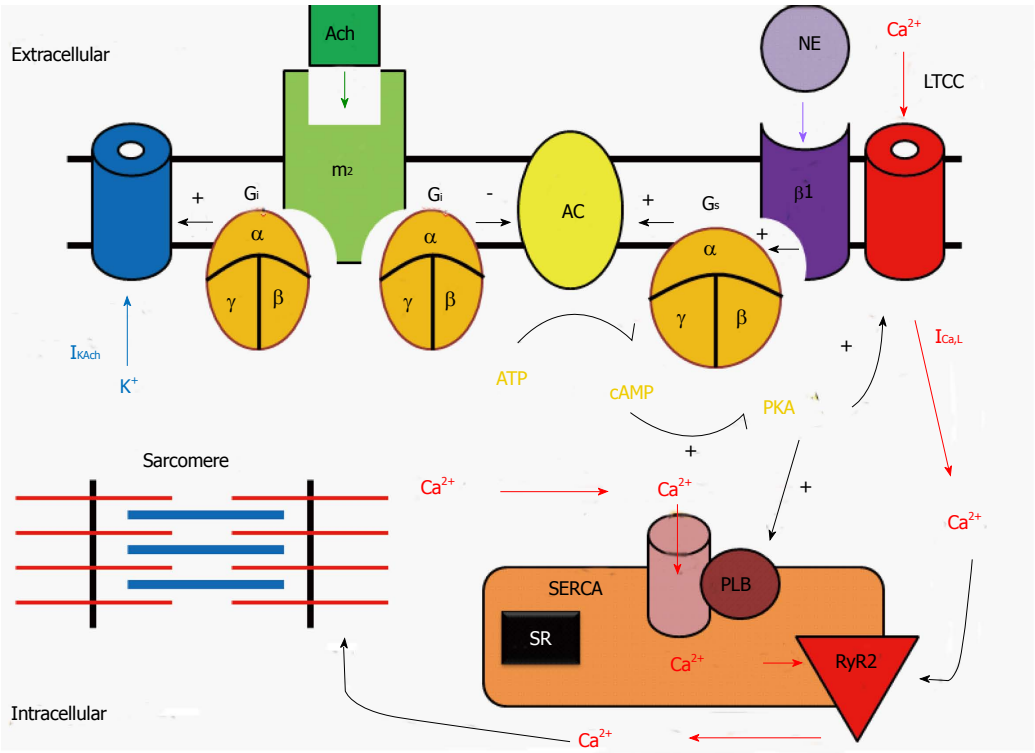

Figure 2 Signal transduction systems for β-adrenergic receptor and muscarinic-receptor stimulations in a cardiac myocyte. NE: Norepinephrine; β1: Beta1-adrenergic receptor; G_s: Stimulatory G-protein: Ach: Acetylcholine; m_2: Type-2 muscarinic receptors; G_i: Inhibitory G-protein; AC: Adenylate cyclase; PKA: Protein kinase A; $I_{Ca,L}$: L-type Ca channel; RyR2: Ryanodine receptor 2; SERCA: Sarcoplasmic reticulum Ca^{2+}-ATPase2a; PLB: Phospholamban.

subunit can then bind to and inhibits AC. Since M_2 receptors are negatively coupled to AC and thus reduce cAMP formation, M_2 receptors act to inhibit PKA activity and exert an opposite effect on ion channels, Ca^{2+} handling proteins, and contractile machinery, compared to sympathetic stimulation.

Autorhythmic cells: Regulation of pacemaking current and heart rate: The funny current (I_f) is thought to be the pace making current in the SA node. It is a non-selective cation channel that can inwardly conduct both sodium and potassium ions. As the membrane potential becomes increasingly hyperpolarized during phase 3 and 4 of the action potential, I_f increases inward potassium and sodium currents, which causes the phase 4 diastolic depolarization. I_f channels are activated by direct binding of cAMP[7].

In addition to the funny current, one of the other driving mechanisms behind the automaticity of the pacemaking cells within the SA node is the calcium clock[8]. As the SR fills with calcium, the probability of spontaneous calcium release increases; in contrast, when the SR calcium stores are depleted, the probability of spontaneous calcium release is reduced. Increased Ca^{2+} entry also increases automaticity because of the effect of $[Ca^{2+}]_i$ on the transient inward current carried by the sodium-calcium exchange current (I_{NCX}). When these pacemaking mechanisms depolarize the resting membrane potential and reach the threshold voltage, which induces the opening of L-type Ca channel (LTCC), an action potential is fired.

On the other hand, M_2 receptor stimulation opens muscarinic potassium channels (K_{ACh})[9]. These channels are opened by M_2 receptors binding to ACh and produce a hyperpolarizing current that opposes the inward pacemaker current. Therefore, the parasympathetic stimulation increases outward K^+ permeability, slowing the heart rate and reducing automaticity.

Cardiomyocytes: Regulation of cellular Ca^{2+} handling and cardiac contraction: Excitation-contraction coupling in cardiomyocytes is dependent on calcium-induced calcium release, whereby an action potential initiates an increase in cellular calcium through opening of the LTCC on the cellular membrane. This creates a positive feedback loop by activating the ryanodine receptors of the SR causing the release of an even greater amount of calcium. This calcium then binds to troponin C, moving the tropomyosin complex off the actin active site, so that the myosin head can bind to the actin filament. Hydrolysis of ATP then causes the myosin head to pull the actin filament toward the center of the sarcomere. Free intracellular calcium is then resequestered into the SR *via* the SR ATPase pump (SERCA), or is pumped from the cell *via* the sodium-calcium exchanger on the cellular membrane. Finally, the troponin complex returns the actin filament to its binding sites to tropomyosin.

Sympathetic stimulation leads to the elevation

of cAMP levels and the activation of PKA, which phosphorylates the α_1 subunits of the LTCCs. This increases the opening probability of LTCCs and the inward Ca^{2+} current, and thus enhances the force of cardiac contraction. In addition, PKA phosphorylates phospholamban, thus relieving its inhibition of SERCA, which in turn facilitates Ca^{2+} uptake by the SR and increases the amount of Ca^{2+} (*i.e.,* SR Ca^{2+} content) available for release by the action potential. Furthermore, activation of β_1-adrenoceptors also increases the Ca^{2+} sensitivity of the contractile machinery, mediated by phosphorylation of troponin C. Taken together, the net result of sympathetic stimulation is to elevate cardiac function and steepen both contraction and relaxation.

Since M_2 receptors are negatively coupled to AC and thus reduce cAMP formation, they act to decrease the open probability of LTCCs and reduce Ca^{2+} current. In opposition to sympathetic stimulation, parasympathetic stimulation reduces the activity of Ca^{2+} handling proteins in cardiomyocytes.

Autonomic regulation of vascular function: In contrast to the heart, most vessels (arteries and veins) only receive sympathetic innervation, while capillaries receive no innervation. These sympathetic nerve fibers tonically release norepinephrine, which activates α_1-adrenergic and β_2-adrenergic receptors on blood vessels thereby providing basal vascular tone. Since there is greater α_1-adrenergic than β_2-adrenergic receptor distribution in the arteries, activation of sympathetic nerves causes vasoconstriction and increases the systemic vascular resistance primarily *via* α_1 receptor activation. On the other hand, modified sympathetic nerve endings in the adrenal medulla release circulating epinephrine, which also binds to α_1 and β_2-adrenergic receptors in vessels. However, β-adrenergic receptors show greater affinity for epinephrine than for norepinephrine. Therefore, circulating epinephrine at low concentrations activates only β_1-adrenergic (mainly in the heart) and β_2-adrenergic (mainly in vessels) receptors, which increase cardiac output and cause vasodilation, respectively. It should be noted that vessels at different locations may react differently to sympathetic stimulation. For example, during the "fight or flight" response the sympathetic nervous system causes vasodilation in skeletal muscle, but vasoconstriction in the skin.

Cardiovascular reflexes and the regulation of blood pressure

In the human body, the ANS is organized as functional reflex arcs (Figure 3). Sensory signals from receptors distributed in certain parts of the body are relayed *via* afferent autonomic pathways to the central nervous system (*i.e.,* spinal cord, brain stem, or hypothalamus), the impulses are then integrated and transmitted *via* efferent pathways to the visceral organs to control their activities. The following reflexes play major roles in regulating cardiovascular functions.

Baroreceptor reflex: Baroreceptors located within the aortic arch and the carotid sinuses detect increases in blood pressure. These mechanoreceptors are activated when distended, and subsequently send action potentials to the rostral ventrolateral medulla (RVLM; located in the medulla oblongata of the brainstem) which further propagates signals, through the autonomic nervous system, adjusting total peripheral resistance through vasodilatation (sympathetic inhibition), and reducing cardiac output through negative inotropic and chronotropic regulation of the heart (parasympathetic activation). Conversely, baroreceptors within the venae cavae and pulmonary veins are activated when blood pressure drops. This feedback results in the release of antidiuretic hormone from cell bodies in the hypothalamus into the bloodstream from the nerve endings in the posterior lobe of the pituitary gland. The renin-angiotensin-aldosterone system is also activated. The subsequent increase in blood plasma volume then results in increased blood pressure. The final baroreceptor reflex involves the stretch receptors located within the atria; like the mechanoreceptors in the aortic arch and carotid sinuses, the receptors are activated when distended (as the atria become filled with blood), however, unlike the other mechanoreceptors, upon activation, the receptors in the atria increase the heart rate through increased sympathetic activation (first to the medulla, then subsequently to the SA node), thus increasing cardiac output and alleviating the increased blood volume-caused pressure in the atria[10].

Chemoreceptor reflex: Peripheral chemoreceptors located in the carotid and aortic bodies monitor oxygen and carbon dioxide content as well as the pH of the blood. Central chemoreceptors are located on the ventrolateral medullary surface in the central nervous system and are sensitive to the surrounding pH and CO_2 levels. During hypovolemia or severe blood loss, blood oxygen content drops and/or pH is decreased (more acidic), and levels of carbon dioxide are likely increased, action potentials are sent along the glossopharyngeal or vagus nerves (the former for the carotid receptors, the latter for the aortic) to the medullary center, where parasympathetic stimulation is decreased, resulting in an increase in heart rate (and thus an increase in gas exchange as well as respiration). Additionally, sympathetic stimulation is increased, resulting in further increases to heart rate, as well as stroke volume, which in turn results in an even greater restoration of cardiac output.

Cardiovascular autonomic dysfunction and heart rate variability: It has been known that sympathetic stress/dominance occurs during heart failure or after myocardial infarction, and may trigger

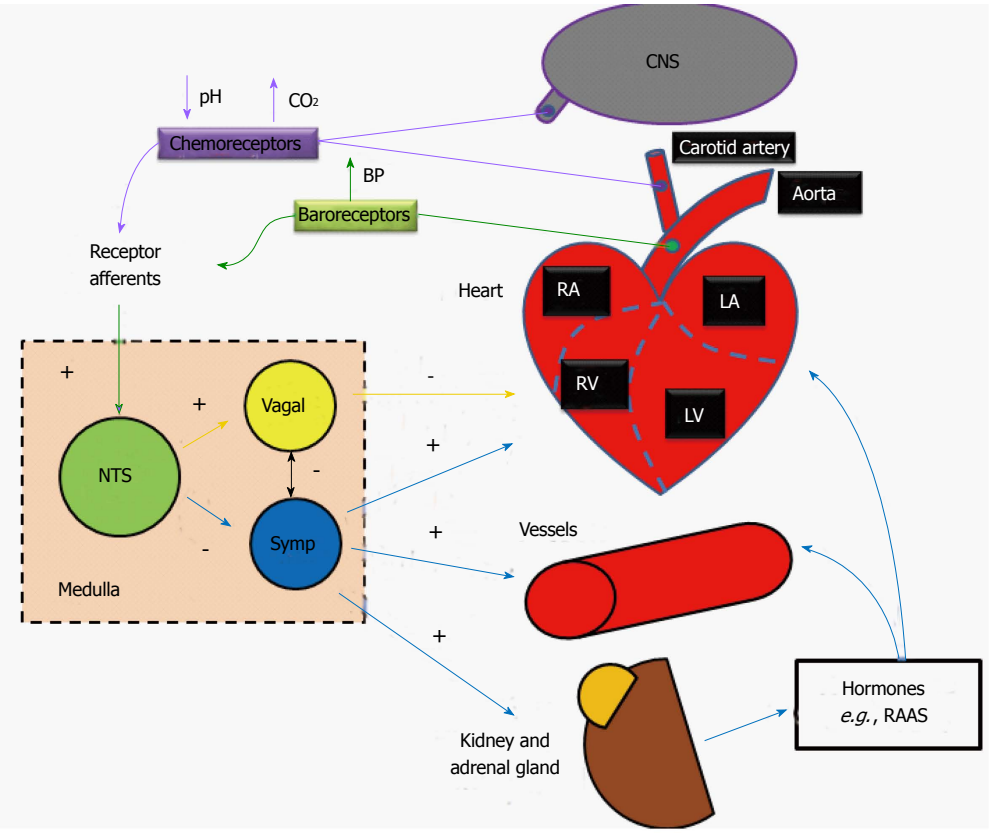

Figure 3 Schematic of cardiovascular reflexes and their influences on heart and vessels functions. NTS: *Nucleus tractussolitarii*; Symp: Sympathetic; CNS: Central nervous system; RAAS: Renin-angiotensin-aldosterone system.

lethal arrhythmias. This sympathovagal imbalance is reflected by reduced heart rate variability (HRV). HRV is determined from ECG and has currently been used clinically as both a diagnostic as well as a prognostic factor for assessing cardiovascular autonomic dysfunction including cardiac autonomic neuropathy. Please refer a recent review article for specific HRV indicators and their interpretations[11].

ENDOCRINE/PARACRINE REFLEXES AND THE REGULATION OF BLOOD PRESSURE REGULATION

In addition to the ANS, cardiovascular function is also influenced by numerous endocrine hormones. Released from the adrenal gland, epinephrine and dopamine (and ultimately, norepinephrine) are all involved in the initiation of the "fight-or-flight" response, while vasopressin, renin, angiotensin, aldosterone, and atrial-natriuretic peptide are all involved in water reabsorption for the purpose of blood pressure regulation.

Adrenal medulla (epinephrine)

An important exception to the usual arrangement in sympathetic fibers is the set of preganglionic fibers that pass through the sympathetic ganglia and extend to the medulla of the adrenal glands. These fibers terminate on special hormone secreting cells, *i.e.*, chromaffin cells, that release norepinephrine (20%) and epinephrine (80%) when stimulated. Epinephrine and norepinephrine are the two main catecholamines that can activate or deactivate sympathetic receptors within the cardiovascular system. Another neurotransmitter dopamine that has limited actions in the autonomic nervous system may excite or inhibit depending on the receptors. Dopamine can be converted into norepinephrine and thus can increase heart rate and blood pressure. Epinephrine is produced (from phenylalanine and tyrosine) and released from chromaffin cells in the adrenal medulla of the adrenal glands. It can stimulate all major adrenergic receptors, including α_1, α_2, β_1, and β_2 receptors. Epinephrine at low concentrations is β_2-selective, producing vasodilatation, while at high concentrations it also stimulates α_1, α_2, and β_1 receptors, producing vasoconstriction (mediated by α_1 and α_2 receptors), and increases heart rate and contractility (mediated by β_1 receptor). Blood pressure is regulated through a system of vasoconstriction and vasodilatation (*i.e.*, vascular resistance). The change in vessel resistance is proportional to the length (L) of the vessel and the viscosity (η) of the blood and inversely proportional to the radius of the vessel to the fourth power (r^4). It is clear from this relationship that vessel diameter controlled by the sympathetic nervous system can have a tremendous impact on

blood pressure regulation *via* small changes in vessel diameter.

$$R \propto \frac{\eta.L}{r^4}$$

Importantly, epinephrine serves to initiate the fight or flight response system by boosting the oxygen and glucose supplies to the brain and skeletal muscle through increased cardiac output and vasodilatation.

Posterior pituitary gland

Vasopressin (antidiuretic hormone) is released during hypovolemic shock as a homeostatic attempt to increase blood pressure and maintain organ perfusion. Vasopressin serves to regulate water retention and vasoconstriction. Vasopressin is produced and released from the parvocellular neurosecretory neurons. It is synthesized in the hypothalamus, and then stored in the posterior pituitary gland, until it is secreted in response to a reduction in plasma volume, an increase in plasma osmolarity, or an increase in cholecystokinin[12]. Within the kidney, vasopressin causes water retention by increasing water permeability of the distal tubule and collecting duct cells, by inserting Aquaporin-2 channels, thus resulting in the inner medullary collecting duct becoming more permeable to urea. Within the cardiovascular system, vasopressin is a vasoconstrictor which increases arterial blood pressure. An increase in blood volume results in increased cardiac output and improved cardiovascular function.

Kidney

There are three hormones produced in the kidneys: calcitriol, thrombopoietin and renin. Of these three, only renin is involved in cardiovascular reflexes and the regulation of blood pressure. Calcitrol works in conjunction with parathyroid hormone to increase the absorption of calcium and phosphate from the gastrointestinal tract[13]. Abnormal calcium metabolism in the cardiovascular system can result in medial arterial calcification and increased vascular stiffness, plaque formation and rupture. Thrombopoietin is made by the proximal convoluted tubule cells, and is responsible for stimulating the production of megakaryocytes of the bone marrow to eventually produce platelets[14]. Low numbers of platelets can lead to hemorrhage and anemic states. Anemia is known to result in high output heart failure.

In the kidney renin is released from the juxtaglomeruler cells, and activates the renin-angiotensin system. The renin-angiotensin-aldosterone system can play both physiological and pathological roles in the cardiovascular system. Angiotensin is known to be involved in heart failure. A main stay in the treatment of heart failure is the use of angiotensin converting enzyme inhibitors.

Renin-angiotensin-aldosterone system: The renin-angiotensin-aldosterone system serves to regulate blood pressure and fluid balance during for example instances of hypovolemia or blood loss. There are three mechanisms by which this system can be activated: baroreceptors with the carotid sinus can detect decreases in blood pressure, a decrease in sodium chloride concentration and/or a decreased rate of blood flow through the macula densa. Once a decrease in blood volume is detected, renin is released by the kidney and cleaves angiotensinogen (produced in the liver) into angiotensin Ⅰ. Angiotensin Ⅰ is further converted to angiotensin Ⅱ by the angiotensin converting enzyme (which is produced in the capillary beds of the lungs). Angiotensin Ⅱ then acts upon the proximal tubules to increase sodium reabsorption, thus helping to retain water while maintaining the glomerular filtration rate and blood pressure. It also serves to constrict the renal arteries, as well as the afferent and efferent arterioles. Through contraction of the mesangial cells, it can also decrease the filtration rate of the kidneys. Angiotensin Ⅱ also increases the sensitivity to tubuloglomerular feedback by increasing the afferent arterioles responsiveness in the macula densa. It can also reduce medullary blood flow. Finally, it causes the adrenal cortex to release aldosterone, which causes sodium retention and potassium excretion.

Angiotensin Ⅱ has three major effects on the cardiovascular system: it is a potent vasoconstrictor, causing a direct increase in systemic blood pressure; it also exhibits prothrombotic effects, stimulating platelet aggregation and causing the production of PAI-1 and PAI-2[15]; finally, it acts as a Gq stimulator when released in an autocrine-paracrine fashion from cardiomyocytes, causing cell growth through protein kinase C during myocardial hypertrophy.

Hormones released by the heart

There are two major hormones produced by the heart. The first, atrial-natriuretic peptide (ANP), is produced by atrial cardiomyocytes, and serves to reduce blood pressure through several mechanisms.

ANP is produced, stored, and released by atrial myocytes (while also being produced in the ventricles, brain, suprarenal glands, and renal glands). There are five major causes for ANP release: distention of the atria, β-adrenergic stimulation, hypernatremia, increases in angiotensin Ⅱ, and increases in endothelin[16]. Upon the vasculature, atrial-natriuretic peptide blocks catecholamines, while in the heart, it inhibits hypertrophy by blocking norepinephrine-stimulated protein synthesis. It is also believed to exhibit cardioprotective properties related to its ability to block cardiac fibrosis following ischemia-reperfusion injuries[17].

The other major hormone, brain-natriuretic peptide

(BNP), is produced by ventricular cardiomyocytes, and works in a similar fashion to ANP. BNP is secreted by the ventricles of the heart in response to excessive stretching of ventricular myocytes and its level is typically increased in patients with left ventricular dysfunction. Therefore, clinically BNP levels are used to monitor heart function. Elevated levels of BNP are thought to be indicative of poor left ventricular function and heart failure.

Additional hormones that may impact cardiovascular function

Endothelin-1: Endothelin-1 is a potent vasoconstrictor that is produced by endothelial cells. There are four endothelin receptors, which are mainly expressed in vascular smooth muscles, each with varying actions upon activation. Activation of ET_A results in smooth muscle vasoconstriction; ET_B causes the release of nitric oxide from endothelial cells, thus resulting in vasodilatation; while activation of ET_{B2} causes vasoconstriction. ET_A receptors also function like G-protein coupled receptors in ventricular cardiomyocytes[18,19]. The effects of ET_C activation are currently unknown[20]. Endothelin-1 may play a role in cardiac hypertrophy *via* intracellular alkalinization.

Thyroxin: Thyroxin (T_4) is a hormone produced by the follicular cells of the thyroid gland. While it acts on nearly every cell type within the human body, one of its most important functions is to increase the effect of epinephrine. Through this permissive relationship, thyroxin increases the number of β_1 receptors and is thus indirectly responsible for increasing cardiac output (in both an inotropic and chronotropic manner) and increasing respiration rates. It is directly responsible for increasing basal metabolic rates by increasing protein and carbohydrate metabolism[21]. Clinical increases in thyroxin are associated with the occurrence of atrial fibrillation, a common cardiac arrhythmia. Elevated heart rates from thyroxin induced atrial fibrillation or other arrhythmias can result in myocardial decompensation and heart failure if not returned to normal sinus rhythm.

CONCLUSION

In conclusion, the heart is not simply an isolated actor. The cardiovascular system responds to not only acute but also chronic changes in blood pressure and homeostasis. Body homeostasis and survival are therefore the main functions of the cardiovascular system. Factors actively influencing the cardiovascular system range from the central nervous system including the brain and spinal cord to the peripheral nervous system with fibers being transported through spinal nerves to the glands, *e.g.*, adrenals, vasculature and even to the urinary system (kidneys). The cardiovascular system is controlled and influenced by not only a unique intrinsic conduction system, but is also heavily influenced by the autonomic nervous system as well as the endocrine system.

Abstract

AIM: To examine the contribution of treatment resistant depression (TRD) to mortality in depressed post-myocardial infarction (MI) patients independent of biological and social predictors.

METHODS: This secondary analysis study utilizes the Enhancing Recovery in Coronary Heart Disease (ENRICHD) clinical trial data. From 1834 depressed patients in the ENRICHD study, there were 770 depressed post-MI patients who were treated for depression. In this study, TRD is defined as having a less than 50% reduction in Hamilton Depression (HAM-D) score from baseline and a HAM-D score of greater than 10 in 6 mo after depression treatment began. Cox regression analysis was used to examine the independent contributions of TRD to mortality after controlling for the biological and social predictors.

RESULTS: TRD occurred in 13.4% (n = 103) of the 770 patients treated for depression. Patients with TRD were significantly younger in age (P = 0.04) (mean = 57.0 years, SD = 11.7) than those without TRD (mean = 59.2 years, SD = 12.0). There was a significantly higher percentage of females with TRD (57.3%) compared to females without TRD (47.4%) [χ^2 (1) = 4.65, P = 0.031]. There were significantly more current smokers with TRD (44.7%) than without TRD (33.0%) [χ^2 (1) = 7.34, P = 0.007]. There were no significant differences in diabetes (P = 0.120), history of heart failure (P = 0.258), prior MI (P = 0.524), and prior stroke (P = 0.180) between patients with TRD and those without TRD. Mortality was 13% (n = 13) in patients with TRD and 7% (n = 49) in patients without TRD, with a mean follow-up of 29 mo (18 mo minimum and maximum of 4.5 years). TRD was a significant independent predictor of mortality (HR =

1.995; 95%CI: 1.011-3.938, *P* = 0.046) after controlling for age (HR = 1.036; 95%CI: 1.011-1.061, *P* = 0.004), diabetes (HR = 2.912; 95%CI: 1.638-5.180, *P* < 0.001), heart failure (HR = 2.736; 95%CI: 1.551-4.827, *P* = 0.001), and smoking (HR = 0.502; 95%CI: 0.228-1.105, *P* = 0.087).

CONCLUSION: The analysis of TRD in the ENRICHD study shows that the effective treatment of depression reduced mortality in depressed post-MI patients. It is important to monitor the effectiveness of depression treatment and change treatments if necessary to reduce depression and improve cardiac outcomes in depressed post-MI patients.

Key words: Depression treatment; Post-myocardial infarction; Mortality; Anti-depressant; Cognitive behavioral therapy

Core tip: Treatment resistant depression (TRD) was associated with increased mortality in post-myocardial infarction (MI) patients with depression. Conversely, effective treatment of depression with cognitive behavioral therapy with or without medication decreased mortality in post-MI patients who were depressed. Since TRD post-MI patients are at higher risk for mortality, closer follow-up and more aggressive treatment for depression and risk factor modification is needed to improve patient outcome. It is important to monitor the effectiveness of depression treatment and change treatments if necessary to reduce depression and improve cardiac outcomes in post-MI patients with depression.

INTRODUCTION

Depression predicts morbidity and mortality in patients after myocardial infarction (MI)[1-5]. Depression in post-MI patients is associated with increased mortality. A meta-analysis of 29 studies with an average of 16 mo follow-up and a total of 16889 patients revealed that post-MI depression is associated with more than doubling in odds of all cause mortality (OR = 2.25, 95%CI: 1.73-2.93; *P* < 0.001)[6]. Prevalence of depression is about 20% in patients with MI, compared to 5% in the general population[7,8]. Depression predicts a poorer prognosis and lower functional status in post-MI patients[4].

Treating depression in depressed post-MI patients should improve their long-term prognosis; however, in randomized clinical trials treating depression in depressed post-MI patients, did not improve their survival[9-12].

Cognitive behavioral therapy, plus adjunctive sertraline treatment in the case of insufficient response, did not improve mortality or nonfatal re-infarction with a mean 29 mo follow-up in post-MI patients with depression and/or low perceived social support (LPSS) enrolled in the Enhancing Recovery in Coronary Heart Disease (ENRICHD) clinical trial[9]. There was no difference in event-free survival between the intervention and usual care groups (75.5% *vs* 74.7%). The intervention resulted in a temporary reduction in depression, which was present at 6 mo but disappeared by 30 mo after randomization[9]. Similarly, depression treatment did not improve cardiac event-free survival (treatment group 86.2% *vs* usual care group 87.3%) during the 18 mo of follow-up in the Myocardial Infarction and Depression-Intervention Trial (MIND-IT)[11]. Antidepressant medication (sertraline) for depressed patients with heart disease (*n* = 369) resulted in a slight, but non-significant reduction in recurrent MI and death after an average of 30 mo of follow-up (RR = 0.77; 95%CI: 0.51-1.16) in the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART)[10]. The recent 8-year follow-up of the MIND-IT trial that evaluated the effects of antidepressant treatment in depressed post-MI patients revealed that the treatment group's mortality was not reduced when compared usual care group[12]. However, patients who actually received treatment for depression, regardless of group assignment, had an improved mortality (HR = 0.52, 95%CI: 0.28-0.97).

Secondary analyses of data from subgroups within clinical trials hint that the effectiveness of the treatment of depression might be a factor in whether treatment improves health outcomes. In an on-treatment secondary analysis of the 1834 depressed patients from the ENRICHD intervention and control groups showed significantly lower risk of recurrent MI and death in patients taking selective serotonin reuptake inhibitors (SSRIs) from both the usual care and treatment group. During an average of 29 mo of follow-up, 26% of patients who did not receive antidepressants died or had a recurrent MI *vs* 21.5% of patients on antidepressant therapy. Use of SSRIs was associated with significant reduction in risk of death or nonfatal MI (HR = 0.72; 95%CI: 0.44-1.22) and of all-cause mortality (HR = 0.73; 95%CI: 0.34-1.38)[13].

In patients with at least 1 prior episode of major depression in the ENRICD intervention group whose depression did not improve over the first 6 mo had higher late mortality (unimproved 21.2% *vs* improved 10.4%) and were more likely to be taking antidepressant medication and have a higher body mass index at enrollment than patients whose

depression symptoms improved. In the usual care arm of ENRICHD, improvement in depression was not related to mortality[2].

In a 7-year follow-up analysis of SADHART, patients whose major depression did not respond to medication experienced 2.39 times as much mortality (28.4%) as those whose depression was treated effectively (15.6%)[14].

The ENRICHD study did not find that randomized treatment of depression in depressed post-MI patients decreased mortality or morbidity. Even with extensive effort to treat their depression, many patients in the intervention arm did not improve their depression symptoms after 6 mo of treatment. Instead, they seem to have a treatment refractory depression that was resistance to current available therapy. This finding and other subsequent analysis of ENRICHD studies left health professionals without clear direction for the treatment of depression in post-MI patients.

Clinical studies show that not all depressed patients respond adequately to treatment. Fava *et al*[15] meta-analysis of 36 clinical trials demonstrated that about 50% of depressed patients have an adequate response to antidepressant therapy, 15% had partial response, and 20%-35% did not respond to depression treatment. Patients who do not respond adequately labeled as treatment resistant. Depression was considered treatment resistant when at least 2 trials of different antidepressant therapy with adequate dose/duration/compliance failed to produce a significant clinical improvement in depression symptoms[16].

Patients with treatment resistant depression (TRD) in previous studies may have masked the effect of reducing depression on improvement of survival of depressed post-MI patients. In a cohort study of 4037 depression post-MI patients, 12.1% of the patients had treatment-resistant depression and they were 1.71 times as likely to die than treated patients[17].

The current study focuses on TRD and compares survival of patients with TRD to survival of patients who responded to treatment of depression.

MATERIALS AND METHODS

Research design

This secondary data analysis uses longitudinal data from the ENRICHD randomized clinical trial. The limited use de-identified data set was obtained from the National Heart, Lung, and Blood Institute (NHLBI) after University of Maryland full IRB review.

Data source

ENRICHD was the first randomized multi-center study to examine the effect of psychosocial intervention on survival in patients who were depressed and/or had LSSP after an MI. This study was sponsored by the NHLBI, and recruitment started in October 1996 and ended in October 1999. Patients were enrolled in the ENRICHD study within 28 d of an acute MI.

All patients with an acute MI admitted to 1 of the 73 participating hospitals were screened for acute MI eligibility including MI documented by cardiac enzymes and by chest pain with typical ST-T changes or new Q waves. Complete ENRICHD inclusion and exclusion criteria are published elsewhere[9]. After informed consent was obtained, patients were screened for depression and/or LPSS. If either depression or LPSS was present, patients were randomly assigned to the intervention or usual care arm. Participants had follow-up examinations at 6 and 18 mo and annually thereafter. The primary end-point of the study was the occurrence of re-infarction or all cause mortality[9].

ENRICHD intervention

Cognitive behavioral therapy (CBT) was utilized as the standard of the ENRICHD intervention[18]. Intervention group patients with scores higher than 24 on the Hamilton rating scale for depression (HAM-D) or who had < 50% reduction in BDI score after 5 wk were referred to study psychiatrists for pharmacotherapy consideration. If there were no contraindications, sertraline hydrochloride was used as the drug of choice. The maximum CBT duration was 6 mo[9].

Patients in the usual care arm of the study received only the care provided by their primary care providers, which was standard medical care for post-MI patients. Patients in both groups received health education regarding cardiovascular disease and its management and both groups received standard medical treatment as practiced in that institution.

ENRICHD measures

Baseline assessment in ENRICHD included demographics, cardiovascular health history, risk factors, current medications, detailed medical record documentation of the course of treatment for the acute MI, an electrocardiogram, the Depression Interview and Structured Hamilton (DISH), beck depression inventory (BDI), and ENRICHD social support inventory (ESSI).

The DISH is a semi-structured interview developed for ENRICHD trial and was used for screening and diagnosing depression[19] using principles and criteria from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-Ⅳ)[20]. The DISH incorporated material from the 17-item version of the Hamilton Rating Scale for Depression (HAM-D)[21], the Structured Interview Guide for the Hamilton Depression Scale (SIGH-D)[22], the Diagnostic Interview Schedule (DIS)[23], and the modified versions of the DIS[24]. The DISH depression severity score was based on the 17-item HAM-D. The first 9 items on HAMD-D are 5 point Likert format ranging from 0 (absent) to 4 (severe). The last 8 items are 3 point Likert format ranging from 0 (absent) to 2 (clearly present). The possible score ranges from 0 to 50. Scores of > 10 indicates the presence of depression symptoms. Hig-

her total scores indicate more depression symptom severity. The concurrent validity of DISH was evaluated using the Pearson correlation coefficient between 17-item HAM-D embedded in the DISH and BDI scores that resulted in a correlation of 0.76 ($P < 0.001$)[19]. The DISH was administered at the screening phase of the ENRICHD study and at 6 mo follow-up.

The BDI[25] was used in the ENRICHD study to evaluate baseline depression status and assess progress during treatment and follow-up. The BDI is the most widely use depression instrument in clinical and research settings. The BDI is considered 1 of the best methods to assess presence and severity of depression. It is easy to use and only takes 5 min to complete by the patient or provider. The BDI is a 21-item inventory, and each item is rated on a 0 to 3 scale with a total score ranging from 0 to 64. BDI scores > 10 indicate depression, scores of 10-15 mild depression, 16-23 moderate depression, and 24-64 severe depression. Concurrent validity of BDI was established by comparing BID to HAM-D that positively correlated (r = 0.71, $n = 87$). This indicates an acceptable concurrent validity of BDI. The BDI was administered to all participants at baseline, 6, 12, 18 mo and annually thereafter.

The ESSI was used in the ENRICHD study to assess perceived social support at baseline and durng treatment and follow-up. It was developed for ENRICHD study to measure functional social support. The ESSI was used as a screening tool to determine patients' eligibility for ENRICHD based on low social support, and to assess changes in patients' social support following treatment. The ESSI is a 7-item inventory, and item 1 to 6 is rated on a 1 to 5 scale, which indicates none to all respectively. Item 7 is not rated on numeric scale. The total score ranges from 6 to 30 with lower scores indicating LPSS. A score < 3 on 2 or more items and a total score < 18, or a score of 2 on 2 items without regard to total score indicated LPSS which was the criteria for inclusion in ENRICHD trial[26]. In this study, 3 variables derived from ESSI instrument that were: live alone, perceived social support, and social isolation. Live alone was the seventh question on the ESSI questionnaire ("do you live alone?") that was separated and transferred into the study dataset. Perceived social support was the total score on the ESSI and social isolation was dichotomous value based on scoring the ESSI. Social isolation was defined as meeting the ENRICHD criteria for LPSS. The reliability of ESSI was estimated by using test-retest reliability that showed no significant differences in mean scores administered 1 mo apart ($P = 0.98$). The internal reliability was measured with the use of Cronbach's alpha that revealed an alpha of 0.88, which indicates a high internal consistency. The intra-class correlation coefficient was 0.94, reflecting excellent reproducibility[26]. The ESSI was administered to all participants at baseline, 6, 12, 18 mo and annually thereafter.

Sample

The study sample consists of the depressed patients in either arm of ENRICHD who received treatment for depression and completed the DISH at 6 mo. Treatment was defined as any combination of CBT and/or antidepressant medication. TRD was defined as < 50% improvement of 6-mo HAM-D score from baseline in patients with 6-mo HAM-D > 10. The outcome variable in this study was all cause mortality. All deaths were documented and verified by the ENRICHD investigators.

Statistical analysis

Data analysis: Normality of distributions of continuous variables was examined; no variables had extreme values that needed transformation[27]. Missing data was < 5% thus there was not a need to examine patterns of missing data[27]. All inferential tests were conducted at the 0.05 level of significance. Statistical procedures were performed using SPSS version 20.0 software.

Cox regression analyses was used to examine the hypothesis. The proportional hazards assumption of Cox regression was confirmed. The contribution of each biological (age, female gender, minority status, and presence of diabetes, history of heart failure, hypertension, prior MI, prior stroke, and current smoker), social (lives alone, perceived social support, social isolation), and psychological (baseline depression symptoms and TRD) predictor to mortality was initially examined in individual Cox regression analyses. Age was centered on 34 years, the lowest age in the study for ease of interpretation. The reference group (0) for dichotomous predictors was the un-named category. A combined model was constructed with biological, psychological, and social factors that predicted mortality at $P < 0.20$ in the individual analyses. Based on prior research showing differences between men and women in reporting depression[28,29], the interaction of TRD and female gender was added to the model. Similarly, based on prior research showing differences between minorities and non-minorities in reporting depression[30], the interaction of TRD and minorities status was added to the model. Neither of the interaction were significant predictors of mortality so they were not included in the final parsimonious Cox regression combined model. Biostatistician reviewed the statistical methods of this study.

Sample description: A total of 770 ENRICHD participants were depressed at the study entry and received depression treatment (Table 1). These participants received cognitive behavior treatment (CBT) ($n = 469$, 60.9%), or antidepressant medication ($n = 85$, 11%), or both ($n = 216$, 28.1%). The sample included 365 (47%) women and 239 (31%) minority participants.

Ages ranged from 34 to 85 with a mean of 59 (SD = 12) years. Treatment resistant depression was present in 103 (13.4%) of the patients who were treated for depression.

Biostatistics

The statistical methods of this study were reviewed by Erika Friedmann from University of Maryland.

RESULTS

Baseline characteristics of patients with and without TRD were compared (Table 1). Patients with TRD were significantly younger (P = 0.04), more likely to be female (P = 0.031), be hypertensive (P = 0.033), and have lower perceived social support (P = 0.006) than those without TRD. Major depression was significantly more common (P < 0.001) and baseline depression symptom severity assessed with the BDI was significantly worse (P < 0.001) among patients who experienced TRD.

Of the 770 participants, there were 62 (8%) deaths with an average follow-up of 29 mo. All cause mortality tended to be higher in the patients with TRD (13/103: 13%) than those whose depression responded to treatment (49/667: 7%) (χ^2 = 3.35, P = 0.05).

In univariate Cox regression analysis (Table 2), age (P < 0.001), female gender (P = 0.005), diabetes (P < 0.001), history of heart failure (P < 0.001), hypertension (P = 0.002), prior MI (P < 0.001), prior stroke (P < 0.001), current smoker (P = 0.002) and live alone (P = 0.032) were significant predictors of mortality. Minority status (P = 0.943), perceived social support (P = 0.279), social isolation (P = 0.446), and baseline depression symptoms (P = 0.978) did not predict mortality.

In the combined simultaneous Cox regression model, TRD (P = 0.046), age (P = 0.004), diabetes (P < 0.001), and history of heart failure (P = 0.001) were significant independent predictors of mortality; current smoker tended to predict mortality (P = 0.087) (Table 3).

When the interaction between female gender and TRD and minority status and TRD were each added to the model, the interactions were not significant (P = 0.467, P =0.87, respectively). Neither interaction was added to the final model. In the final model TRD contributed significantly to mortality (P = 0.046) after controlling for age, diabetes, heart failure, and currently smoking. Patients with TRD had approximately double the risk of all cause mortality compared with patients without TRD (95%CI: 1.011-3.938). Other significant independent predictors of mortality were age, diabetes and heart failure.

This study showed a significant improvement in survival in depressed post-MI patients whose depre-

ssion was effectively treated (Figure 1). Among treated depressed post-MI patients, TRD was a significant independent predictor of mortality after controlling for biological and social factors.

DISCUSSION

Not all depressed patients respond adequately to treatment, and their depression does not improve significantly with current depression treatments. These depressed patients are treatment resistant[13]. Recent studies do not show improved mortality of acute myocardial infarction patients after treatment for depression[8-12]. One explanation of this may be that previous studies of post-MI patients included a subgroup of patients with TRD who may have impacted the results. The presence of the TRD subgroup may cause a failure in the study's ability to show improved survival in the intervention group.

The purpose of this study was to examine the differences in mortality between patients with TRD and those without TRD. The significant predictors for mortality among depressed post-MI patients whose depression was treated were; age, diabetes, and history of heart failure. The presence of TRD significantly predicted mortality after controlling for these other factors (HR = 1.995). TRD was associated with an increased risk of mortality when compared to non-TRD patients. This finding is consistence with the 7-year follow-up analysis of the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) [10]. Initial findings of SADHEART revealed a non-significant reduction in re-current MI and death (RR = 0.77; 95%CI: 0.51-1.16) in treated depressed individuals. At that time, they did not examine the difference between survival in those individuals who responded and not respondent to depression treatment. Subsequently, the 7-year follow-up analysis of the SADHART trial found that patients with major depression who responded to treatment with sertraline had a reduction in mortality *vs* non-responders (15.6% *vs* 28.4%; HR = 2.39)[14]. The current study extends this finding from post MI patients with major depression to less psychologically distressed patients, namely post MI patients with dysthymia through major depression. Further the current study began treatment with cognitive behavioral therapy and added medication if depression was not responsive. This study is also consistent with Scherrer *et al*'s[17] cohort study's finding that post-MI patients with TRD had increased mortality. The criteria for TRD in that study were that: the patient received (1) electroconvulsive therapy, (2) a monoamine oxidase inhibitor, or (3) two or more antidepressant at the same time. In contrast, the current study uses depression measurement tools to identify post-MI patients with TRD.

This re-analysis of the ENRICHD study data clearly shows that successful treatment of depression decreases mortality in post-MI patients. It also demonstrates that current depression treatments are not effective in treating all depressed post-MI patients. According to this study, over 13% of treated patients still suffered from depression at the end the treatment. This is consistent with the Scherre study, which showed 12.1% of post-MI patients experienced TRD. Perhaps a treatment that is more effective in alleviating depression would improve survival in post-MI patients. Until more effective treatments are developed, closer follow-up of depression symptoms, aggressive treatment of depression, actively treating other modifiable risk factors, and modifying risky health behaviors may lead to a better survival in post-MI patients with TRD.

Strengths and limitations

This study was a secondary data analysis of an existing trial. This places limitation to this study regarding

control over the variable definition, measurement, data collection and other crucial aspects of the study design. With this study, we were not able to establish causality of the contributions of TRD for mortality. The study findings were only able to provide evidence of the associations between the variables. Despite the limitations of this study, the strengths outweigh the limitations of the study. Using a large existing database, this study has the advantage of providing a representative sample. Women and minorities were well represented in the ENRICHD data. ENRICHD included detailed questionnaire development, data collection procedures, data management, and quality control measures. The use of ENRICHD dataset provided an opportunity to use high quality dataset without the high cost and effort of obtaining this type and amount of data.

Implications for practice and future research

The analysis of TRD in ENRICHD shows that treatment of depression in the ENRICHD sample was effective in reducing mortality in those whose depression was effectively reduced by cognitive behavioral therapy and/or anti-depressant medication. By separating out those who were depressed and whose treatment was effective it was possible to evaluate the contribution of effective treatment of depression to mortality in post-MI patients. The findings of this study provided evidence that depressed patients with TRD have more than double the risk of mortality when compared with patients whose depression is effectively treated. This sub-group of depressed patients with TRD did not improve their depression symptoms with their current depression treatment. Closer follow-ups of depression symptoms, aggressive treatment of depression, aggressively treating other modifiable risk factors, and modifying risky health behaviors may lead to a better chance of survival in TRD post-MI patients.

As shown in this current study, depression is a risk factor for mortality among TRD post-MI patients. Yet the question remains how to best treat it. Future research is needed to address the development of effective treatment for depression. Both ENRICHD and SADHART trials reported small effect size using current depression interventions, this suggest a need to increase efficacy of current interventions for depressed post-MI patients. The results of the present study accentuate the need for future research for drug development and effective interventions to alleviate depression symptoms in order to improve cardiac outcomes.

The potential mechanisms linking depression and impaired cardiovascular prognosis are still poorly understood and remain an area that is in need of more research. Future studies are needed to give insight and provide evidence that will direct us toward a future in which we, health providers, are able to help and improve survival in post-MI patients who have TRD.

This study provided evidence that TRD is associated with increased mortality in post-MI patients who are depressed. Conversely, effective treatment of depression with cognitive behavioral therapy without or with medication decreased mortality in post-MI patients who were depressed. Since, TRD post-MI patients are at higher risk for mortality, closer follow-up and more aggressive treatment for depression and risk factor modification is needed to improve patients' outcomes. This may lead to an integrated treatment strategy that may decrease risk of mortality in post-MI patients. It is important to monitor the effectiveness of depression treatment and change treatments if necessary to reduce depression and improve cardiac outcomes in post-MI patients who are depressed.

ACKNOWLEDGMENTS

This manuscript was prepared using the Enhancing Recovery in Coronary Heart Disease (ENRICHD)

limited access dataset obtained from the NHLBI Biologic Specimen and Data Repository Information Coordinating Center and does not necessarily reflect the opinions or views of the ENRICHD Study or the NHLBI. COMMENTS

Background

Depression increases mortality after myocardial infarction (MI). Clinical trials have not demonstrated a reduction in mortality with depression treatment. Depression treatment is not effective in a substantial proportion of the depressed patients. The presence of treatment resistant depression (TRD) may explain why previous clinical trials did not demonstrate decreased mortality when depression was treated.

Research frontiers

Recent clinical studies show that not all depressed patients respond adequately to treatment, and their depression does not improve significantly with current depression treatments. These patients have TRD. Presently, there is no study that shows improved outcome of depressed patients with acute MI by treating depression. This can be explained by the presence of TRD in some post-MI patients, which would impact the results of the study. The presence of TRD may cause a failure in the study's ability to show improved survival in the intervention group.

Innovations and breakthroughs

This study considers the presence of TRD in depressed post-MI patients and its influence on prior analysis. Treatment resistant depression is a possible explanation for why previous clinical trials did not demonstrate decreased mortality when depression was treated. The result of this study reveals that TRD significantly predicts mortality after controlling for biological and social factors. Among depression treated post MI patients, TRD was associated with an increased risk of mortality when compared to non-TRD patients. Depressed patients with TRD have double the risk of mortality when compared with patients whose depression is effectively treated.

Applications

This study provides new evidence that depressed patients with TRD did not improve their mortality with current depression treatment, and they are in desperate need for more efficacious depression treatment. Closer follow-ups of depression symptoms, aggressive treatment of other modifiable risk factors, and modifying risky health behaviors may lead to a better chance of survival in depressed post-MI patients. This knowledge may assist primary care providers regarding clinical decision making that provides a better treatment options for patients.

Terminology

TRD is a term describing patients with depression symptoms that do not improve after treatment is completed. In other words, the total hamilton depression (HAM-D) score does not decrease more than 50% from baseline with a total HAM-D score above 10 after completing depression treatment.

Peer-review

Authors showed that effective treatment of depression improved survival of patients after AMI. This paper is well described, and includes important clinical findings.

Abstract

Pannus formation is a rare complication and occurs almost exclusively in mechanical prosthetic valves. It consists of fibrous tissue that covers the surface of the prosthesis either concentrically or eccentrically, resulting in valve dysfunction. The pathophysiology seems to be associated to a chronic inflammatory process that explains the late and insidious clinical presentation. This diagnosis should be considered in patients with high transvalvular gradients on transthoracic echo, and workup should be completed with fluoroscopy and transesophageal echocardiography. Treatment is always surgical and recurrence is rare. We present a case of pannus formation in a prosthetic aortic valve and a review of the literature regarding this disorder.

Key words: Pannus formation; Prosthetic aortic valve; Fluoroscopy; Transthoracic echocardiography; Transesophageal echocardiography

Core tip: Pannus is an infrequent complication that mainly affects mechanical prosthetic valves. Its diagnosis requires clinical suspicion and the association of fluoroscopy, transthoracic and transesophageal echocardiography. The case presented is a characteristic example of pannus, given its clinical presentation

(progressive dyspnea), the steps followed to reach diagnosis and the surgical resolution. Suspecting this disorder and making an accurate diagnosis is of paramount importance, to implement adequate treatment and to avoid prolonging the natural course of the disease and its repercussion on the left ventricle and the quality of life of affected patients.

INTRODUCTION

Mechanical prosthetic valve dysfunction caused by pannus or thrombosis is an unusual but serious complication of heart valve replacement. Thrombotic complications are most common early postoperatively, whereas pannus occurs later, especially in bileaflet valves in the aortic position. Pannus formation consists of fibrous tissue usually covering the circumference of a prosthetic valve, and causing valve dysfunction[1]. The incidence of this rare complication is 1.6%-2% in the different series published[2,3] and occurs almost exclusively in mechanical prostheses. Its most frequent location varies according to the authors, but in most series prostheses in the aortic position were affected more often[4] than those in mitral position[3,5].

CASE REPORT

The patient is a 55-year-old man with multiple cardiovascular risk factors (type 2 diabetes, hypertension, past history of smoking, obesity, dyslipidemia, and family history of cardiovascular disease) and intermittent claudication at 200 meters. Also, in 1998 he underwent aortic valve replacement with a mechanical #23 St. Jude valve, and coronary artery bypass grafting (CABG) with three grafts (left internal mammary artery to the left anterior descending artery and saphenous vein graft to the right coronary artery and circumflex coronary artery). In 2009 he began experiencing dyspnea in FC Ⅱ [New York Heart Association (NYHA) classification], that progressed to FC IV. Upon clinical consultation, a meso-telesystolic murmur radiating to the neck was detected, as well as a pulsus tardus et parvus and an apical beat in the anterior axillary line. No other relevant findings were reported.

His chest X-ray showed a cardiothoracic index slightly above 0.5, an old posterior infarction (R/S > 1 in lead V2) was seen on ECG, and routine laboratory results were within normal values. Transthoracic echocardiography (TTE) and two-dimensional transesophageal echocardiography (TEE) showed a bileaflet mechanical prosthesis in aortic position with normal opening of both discs (Figure 1A), with severely increased mechanical aortic valve gradients (peak instantaneous gradient: 97 mmHg, mean gradient: 58 mmHg) and decreased effective prosthetic area (0.67 cm^2). No detectable image suggestive of pannus or thrombus was seen in the left ventricular (LV) outflow tract. There was infero-posterior akinesis and mild LV dysfunction (EF: 40%). Fluoroscopy revealed normal opening of both tilting discs (Figure 1B). Cardiac multiple detector computed tomography (MDCT) did not showed any soft tissue mass on the ventricular side of the prosthetic aortic. Coronary angiography showed a severe lesion in the venous graft to the right coronary artery, without significant lesions in the other grafts or native arteries.

In spite of absence of any tissue mass on the ventricular side of the prosthetic aortic and absence of limitation of motion of the tilting disc to allow suggest pannus, given the clinical suspicion of prosthetic valve obstruction due to pannus formation, the decision was made to replace the aortic prosthesis with a new mechanical valve (ATS # 23) and perform CABG (venous graft to the right coronary artery); there were no postoperative complications. On pathological examination (Figure 2), the explanted specimen exhibited fibrous tissue with a smooth, annular surface, in contact with the ventricular surface of the mechanical prosthesis, consistent with pannus. Histological examination confirmed the diagnosis (Figure 3).

DISCUSSION

Pannus formation consists of fibrous tissue usually covering the circumference of a prosthetic valve, and causing valve dysfunction[1]. The incidence of this rare complication is 1.6%-2% in the different series published[2,3] and occurs almost exclusively in mechanical prostheses. Its most frequent location varies according to the authors, but in most series (Table 1) prostheses in the aortic position were affected more often[4] than those in mitral position[3,5].

Pathology studies of valves explanted due to pannus formation have shown that it consists of fibrous tissue ingrowth, with a generally smooth surface and a ring-like shape covering the valve surface. Pannus formation may be an isolated finding or associated to various degrees of thrombosis[2,5,6]. According to the type of growth, pannus may be classified as concentric or eccentric[7,8], the latter being more frequent[5]. However, the morphology of pannus could be associated to the type of prosthetic valve affected, which would explain the higher frequency of the eccentric type on single-disc valves[5], while the concentric type is more common in bi-leaflet valves[2].

On histological examination, pannus consists of a structure of collagen fibers interspersed with small

vessels and capillaries surrounded by giant cells, especially around and over suture stitches[5]. Pannus can be systematically divided into three layers and one core[2]. From the surface in contact with blood flow, the three layers towards the prosthetic material are: the lumen (which consists of endothelial cells, is found in the surface of the pannus), the internal lamina media (is composed of myofibroblasts) and the external lamina media (is composed of collagen and elastic fibers).

The core is located between the prosthetic tissue and the pannus, and consists mainly of a chronic inflammatory infiltrate comprising macrophages, lymphocytes, giant cells, plasmocytes and mastocytes[2].

The pathophysiology of this disorder is not yet completely understood. After implantation of a prosthetic valve, two inflammatory events occur. The first involves replacement of the damaged myocardium around the valve ring by a scar formed by nonspecialized connective tissue. The second event involves a foreign body-like inflammatory response to the presence of the prosthetic material. Prolonged exposure to the non-degradable prosthetic material is a persistent stimulus for inflammatory cells such as macrophages (which cluster as giant cells) and for proliferation of fibroblasts; both phenomena are characteristically seen in chronic inflammation. The presence of giant cells should be construed as a severe reaction, in which the foreign material is not well

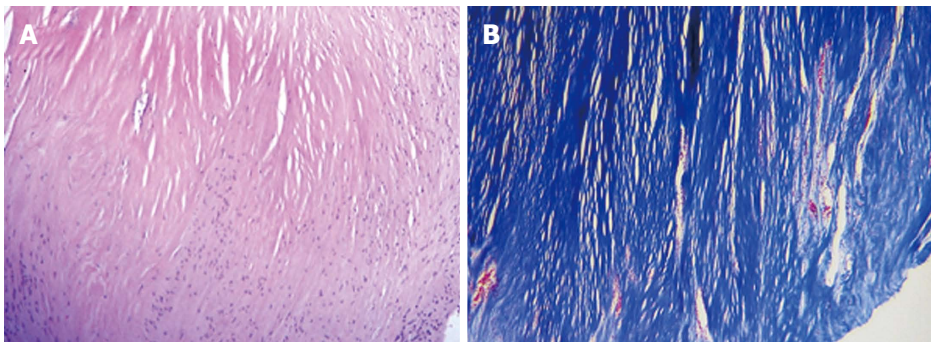

Figure 3 Histology of the pannus. Structure of collagen fibers, interspersed with small vessels and capillaries, surrounded by giant cells. A: Hematoxylin and Eosin staining; B: Masson's Trichrome staining.

tolerated and hence is a target for phagocytosis. This explanation allows to infer that the presence of pannus in only one valve surface represents an early stage of a chronic progressive inflammatory disorder[5].

The clinical presentation of pannus is variable; in most cases signs and symptoms of the disease occur as a consequence of prosthetic valve obstruction. The most common symptom is dyspnea, which may occur as a manifestation of obstruction in valves implanted both in aortic and in mitral valve position. Other less common clinical presentations are: low cardiac output syndrome, shock, embolization, chest pain, absence of a valve click on auscultation, exercise intolerance, cardiorespiratory arrest, and in many cases, patients may be asymptomatic[4,9,10]. In a study[4] that assessed the clinical characteristics of patients with pannus formation *vs* patients with thrombosis, the first group had a longer delay in appearance of symptoms, a longer duration of symptoms at the time of re-intervention, a greater time interval between the first and second surgical intervention and a higher rate of adherence to anticoagulation treatment.

The imaging techniques that are used most often for the diagnosis of this disorder are fluoroscopy, TTE and/or TEE HYPERLINK\l "Cia05"[11], although currently other techniques offer promising results, such as three-dimensional echocardiography and multislice Angio-CT[12-14].

For mechanical prostheses, the use of fluoroscopy is simple and allows to clearly identify the valve ring, cage, ball, the tilting disc/discs and the opening and closure angles; however, in biologic valves its use remains limited[1,11,15-17]. Specifically, in the case of pannus formation, fluoroscopy allows to detect absent motion of the disc/s; a frequent finding in pannus as well as in prosthetic valve thrombosis, albeit more frequent in the latter. In patients with normal leaflet motion, in whom high gradients are found and possible causes are prosthesis-patient mismatch, pannus or thrombosis, the echocardiographic findings shall define the final diagnosis[11]. In a study by Girard *et al*[18] that assessed 16 patients before their second aortic valve replacement, 63% of patients with a post-operative diagnosis of pannus had an abnormal fluoroscopy.

Pannus is suspected in patients who exhibit high gradients on echocardiography. Once structural failure and patient-prosthesis mismatch are ruled out, the only two differential diagnoses that remain to be defined are: pannus or thrombus. Since the advent of thrombolytics as an option for the treatment of valve thrombosis, making an accurate diagnosis has become of utmost importance, since such patients could benefit from the use of thrombolytics, and thus avoid the need for surgical reintervention. Although TTE is most useful in the initial approach to the diagnosis of pannus and thrombus, its usefulness to assess disc/s motion or the etiology of valve obstruction remains limited. However, where TTE fails, TEE appears as a more sensitive and specific method at the time of assessing the etiology of prosthetic valve obstruction. Thus, TEE has allowed to determine certain characteristics associated with pannus, such as: preserved prosthetic disc motion and evidence of a hyper-reflective mass of decreased length and motion, associated to the prosthetic valve[4]. Currently available diagnostic tools including TTE and 2D-TEE are insufficient to detect pannus formation, and detection rate is so poor that a preoperative diagnosis is almost impossible. Real-time three-dimensional transesophageal echocardiography may provide data to the diagnosis of pannus formation.

The treatment of pannus formation is surgical re-intervention to perform a new valve replacement. Occasionally, when pannus does not make contact with the prosthetic ring, the fibrotic tissue could be resected without replacing the prosthetic valve, but certain authors suggest that this surgical option is associated to a greater recurrence of pannus formation. All series agree in that the time to re-intervention is prolonged (Table 1). During follow-up of 63 patients with an obstructed mitral or aortic prosthetic valve, or both (pannus in 71.4% of cases), of whom 100% underwent valve replacement, in-hospital mortality was 20.6%. The main cause of death was low cardiac output syndrome and the only predictor of high mortality on multivariate analysis was LV systolic impairment[19]. In the series by Vitale *et al*[5] which

included 87 patients with obstructive mitral disease, of whom 75.8% had pannus either alone or associated to thrombus, 100% of patients underwent valve replacement (mechanical valve in 88.8%, biologic valve in 11.8%) with a 30-d mortality of 12.5%.

Recurrence is a finding of low prevalence and high mortality, and occurred predominantly in patients who underwent pannus resection without valve replacement[5,10].

Pannus is an infrequent complication that mainly affects mechanical prosthetic valves. Its diagnosis requires clinical suspicion and the association of fluoroscopy + TTE/TEE. Currently, the treatment of choice is a new valve replacement and prognosis depends mainly on LV function. The case presented is a characteristic example of pannus, given its clinical presentation (progressive dyspnea), the steps followed to reach diagnosis and the surgical resolution. Suspecting this disorder and making an accurate diagnosis is of paramount importance, to implement adequate treatment and to avoid prolonging the natural course of the disease and its repercussion on the LV and the quality of life of affected patients.

COMMENTS

Case characteristics

A 55-year-old man with a mechanical aortic prosthetic valve presented with clinical suspicion of prosthetic valve obstruction due to pannus formation.

Clinical diagnosis

The patient began experiencing dyspnea in FC II (NYHA) that progressed to FC IV. A meso-telesystolic murmur radiating to the neck was detected, as well as a pulsus tardus et parvus, with severely increased mechanical aortic valve gradients and decreased effective prosthetic area. No detectable image suggestive of pannus or thrombus was seen in the left ventricular outflow tract in multimodality imaging.

Differential diagnosis

Mechanical prosthetic valve dysfunction caused by pannus or thrombosis.

Imaging diagnosis

Fluoroscopy, transthoracic echocardiography, two-dimensional transesophageal echordiography and cardiac multiple detector computed tomography, failed to diagnose pannus formation.

Treatment

Given the clinical suspicion of prosthetic valve obstruction due to pannus formation, the decision was made to replace the aortic prosthesis with a new mechanical valve (ATS # 23). On pathological examination, the explanted specimen exhibited fibrous tissue with a smooth, annular surface, in contact with the ventricular surface of the mechanical prosthesis, consistent with pannus. Histological examination confirmed the diagnosis.

Related reports

The case presented is a characteristic example of pannus, given its clinical presentation (progressive dyspnea), the steps followed to reach diagnosis and the surgical resolution.

Experiences and lessons

Multimodality imaging in the diagnosis of pannus formation may have limitations. Suspecting this disorder and making an accurate diagnosis is of paramount importance, to implement adequate treatment and to avoid prolonging the natural course of the disease and its repercussion on the left ventricle and the quality of life of affected patients.

Peer-review

Authors have made good and fluent review of pannus formation and presented a clinical case ignored by transesophageal echocardiography and fluoroscopy.

AIM AND SCOPE

World Journal of Cardiology (*World J Cardiol*, *WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJC covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Cardiology is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant inherited disorder characterised by vascular malformations in predominantly the brain, liver and lungs. Pulmonary hypertension (PH) is increasingly recognised as a severe complication of HHT. PH may be categorised into two distinct types in patients with HHT. Post-capillary PH most often results from a high pulmonary blood flow that accompanies the high cardiac output state associated with liver arteriovenous malformations. Less frequently, the HHT-related gene mutations in ENG or ACVRL1 appear to predispose patients with HHT to develop pre-capillary pulmonary arterial hypertension. Differentiation between both forms of PH by right heart catheterisation is essential, since both entities are associated with severe morbidity and mortality with different treatment options. Therefore all HHT patients should be referred to an HHT centre.

Key words: Hereditary haemorrhagic telangiectasia; High cardiac output; Pulmonary arterial hypertension; ENG; ACRVL1; Pulmonary hypertension

Core tip: Pulmonary hypertension (PH) is increasingly recognised as a severe complication of hereditary haemorrhagic telangiectasia (HHT), but the true prevalence of PH in HHT is not known. Post-capillary PH most often results from the high cardiac output associated with hepatic arteriovenous malformations. More rarely the HHT gene mutations (ACRVL1 or ENG) result in pre-capillary pulmonary arterial hypertension (PAH). Differentiation between post-capillary PH en pre-capillary PAH can be done by right heart catheterisation, and is of importance since both entities are associated with severe morbidity and mortality and have different options for treatments.

Vorselaars VMM, Velthuis S, Snijder RJ, Vos JA, Mager JJ, Post MC. Pulmonary hypertension in hereditary haemorrhagic telangiectasia. *World J Cardiol* 2015; 7(5): 230-237 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i5/230.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i5.230

HEREDITARY HAEMORRHAGIC TELANGIECTASIA

Hereditary haemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome, is an autosomal dominant inherited disorder with late onset penetrance (nearly 97% at the age of 60 years) characterised by vascular malformations with an estimated prevalence of 1:5000 individuals[1,2]. The abnormal vascular structures in HHT range from small telangiectasia of the skin and mucosal membranes to arteriovenous malformations (AVMs) in predominantly the brain, liver and lungs[3,4].

Genetics and pathogenesis

HHT consist of two main subtypes, HHT type 1 and HHT type 2, which results from mutations in the ENG gene on chromosome 9, encoding the protein endoglin and from mutations in the activin receptor-like kinase (ACVRL1) gene on chromosome 12, encoding the protein ALK-1 respectively[5,6]. A third disease-causing mutation has been found in the *SMAD4* gene, causing a combination of the juvenile polyposis syndrome and HHT[7] . Most HHT families have a unique mutation and many types of mutations have been described.

The exact pathogenesis of HHT is still unclear. However, hypoxia or local hemodynamic changes could act as a possible trigger promoting tissue inflammation or endothelial cell injury[8,9]. Both endoglin, ALK-1 and SMAD4 proteins are endothelial receptors of the transforming growth factor β (TGF-β) superfamily. All three proteins cooperate in the TGF-β/ALK-1 signalling pathway, which is involved in angiogenesis. In HHT, most vessels are normal, but the mutations in ACVRL1 and ENG result in abnormal angiogenetic responses and lead to the formation of abnormal arteriovenous connections, ranging from small telangiectases that bleed easily, to large arteriovenous malformations, that can occur in every organ, but especially in the lungs, liver and brain[10,11].

Diagnosis

The clinical diagnosis can be based on the four Curaçao criteria[1], which consist of: (1) Spontaneous, recurrent epistaxis; (2) Multiple telangiectasia at characteristic sites (lips, oral cavity, fingers, nose); (3) Visceral lesions (gastrointestinal telangiectasia, pulmonary, hepatic, cerebral or spinal AVMs); and (4) A first degree relative with HHT.

Three criteria suffice for a definitive diagnosis of HHT, two criteria are considered as "possible" HHT, and one or no criterion makes the diagnosis "unlikely". The positive predictive value for a definite clinical diagnosis and the negative predictive value for an unlikely diagnosis are excellent (100% and 97.7% respectively), when compared with DNA testing[12]. However, HHT has an age dependent penetrance and the clinical presentation varies among patients[1]. Therefore genetic testing has emerged as an important tool to help make the diagnosis in paediatric patients and younger adults with a "possible" clinical diagnosis[12].

PULMONARY HYPERTENSION

Pulmonary hypertension (PH) is a haemodynamic and pathophysiological condition defined as an increase in mean pulmonary arterial pressure (mPAP) of equal to or more than 25 mmHg as assessed by right heart catheterisation (RHC)[13]. PH is a progressive disease of many origins, affecting more than 100 million people world wide[14]. The elevated pressure in the pulmonary circulation can lead to various symptoms including limited exercise capacity and dyspnoea on exertion. The chronic elevated pressure may ultimately result in right-sided heart failure and premature death[13].

Depending on the origin, PH can be divided into two main groups; pre- and post capillary PH. Patients with pre-capillary PH are characterised by a mPAP $\geqslant$ 25 mmHg, pulmonary artery wedge pressure (PAWP) $\leqslant$ 15 mmHg, and elevated pulmonary vascular resistance (PVR) (> 3 Wood units)[15]. Pre-capillary PH can be further divided in different clinical groups, based on pathophysiological mechanisms, clinical presentation and therapeutic options (Table 1)[13].

Transthoracic echocardiography is the cornerstone for screening in all patients suspected of PH. Typically, a dilatation of the right ventricle with septal flattening (also called D-sign) and an increase in right ventricular systolic pressure (RVSP) (sum of right ventricle-right atrium pressure gradient and estimated pressure in the right atrium based on the dimension and collapse of the inferior caval vein) (Figure 1)[13,16].

PH and hereditary haemorrhagic telangiectasia

PH is increasingly recognised as an important complication of HHT. HHT associated PH can occur by several mechanisms. Most often, post-capillary PH may develop as a consequence of a hyperkinetic state resulting in heart failure associated with high cardiac output (CO) due to hepatic arteriovenous malformations (HAVMs) (Figure 2)[17], while less frequently, precapillary PH can be related to pulmonary arterial hypertension (PAH) characterised by remodeling of small pulmonary arteries with broadly similar histologic lesions than observed in idiopathic PAH[17]. The HHT-related gene mutations (ENG or ACVRL1) appear to predispose for the development of PAH[18-22]. Various studies found a high estimated prevalence of PH in HHT when screening with echocardiography[23,24]. An elevated RVSP on echocardiography was found in 9 (20.5%) out of 44 HHT patients (22 ACVRL1, 3 ENG, 19 unknown mutation), in 7 out of these 9 subjects an *ACVRL1* gene was found[23]. Sopeña *et al*[24] found a high estimated prevalence of PH (31%) in 29 hospitalised patients with HHT with a mean estimated RVSP of 73 ± 17.0 mmHg measured with echocardiography. HAVMs were

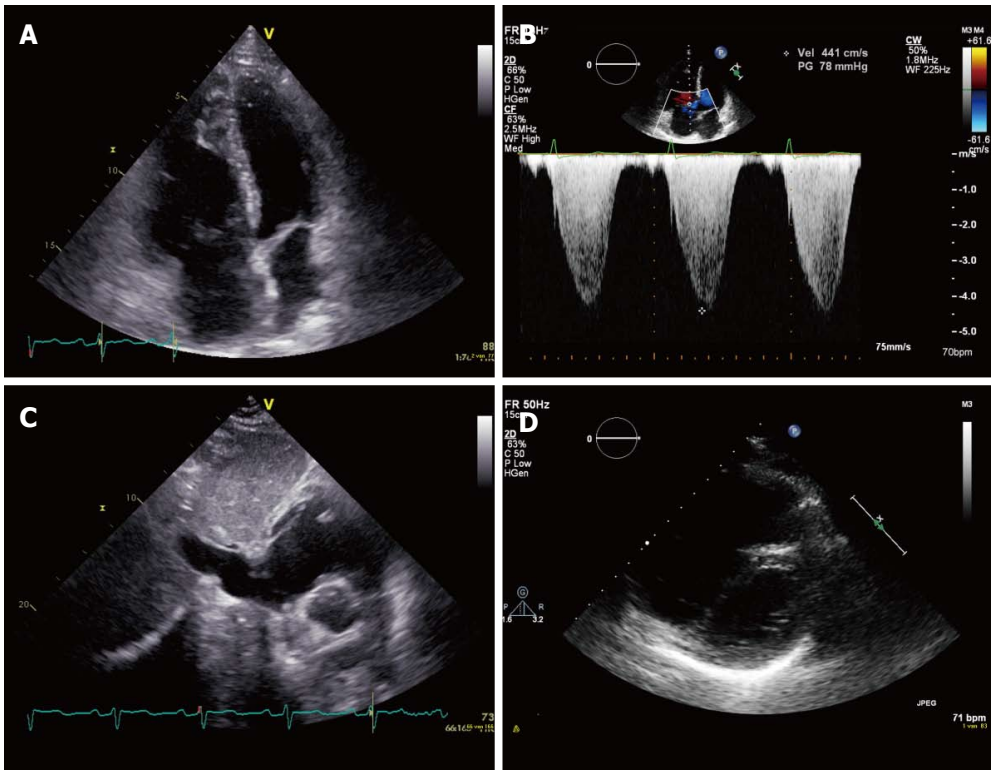

Figure 1 Characteristic echocardiogram of a patient with pulmonary hypertension. A: Apical 4-chamber view showing dilatation of the right ventricle; B: Apical 4-chamber view with Doppler signal (continuous wave) showing an increased right ventricular- right atrial pressure gradient (4.4 m/s); C: Subcostal view showing dilatation of the inferior caval vein corresponding with an increased pressure in the right atrium; D: Parasternal short axis view showing flattening of the interventricular septum (D-sign) and dilatation of the right ventricle.

Figure 2 Hepatic arteriovenous malformations. Computed tomography with contrast in arterial fase showing extensive filling of the hepatic veins (arrows), and diffuse hepatic arteriovenous malformations (asterix).

documented in 67% of these patients. However, large observational studies including consecutive HHT patients are lacking.

Since the treatment strategies differ between post-capillary high-output PH and pre-capillary PAH, it is important to differentiate between these two different entities. RHC is the gold standard for making the diagnosis of both high-output PH and PAH[13,17,25].

In PAH, the mPAP is usually higher with an increase in PVR and transpulmonary gradient due to arteriopathy. Most often a normal or decreased CO and PAWP is seen. In high-output PH on the other hand, there is only a moderate increase in mPAP, with a normal PVR, elevated PAWP and most importantly, an increased CO (Table 2)[13,17].

High output PH

High-output heart failure is the most common initial presentation of HAVMs in HHT. Liver involvement is present in 32%-78% of the HHT patients and is predominantly seen in HHT type 2[1,26-28]. The presence of symptoms is directly associated with significant morbidity and mortality and therefore, screening for liver AVMs with Doppler ultrasound is warranted in all patients who are symptomatic or have abnormal liver enzymes[1,25]. In the majority of cases, only small telangiectasia are seen, which do not lead to symptoms. However, large HAVMs exist in typically three different and often concurrent types of intrahepatic shunting; from the hepatic arteries to hepatic veins, from the hepatic arteries to portal veins, and from the portal veins to hepatic veins[17,25]. These hepatic shunts can lead to high-output cardiac failure, portal hypertension, biliary ischaemia or encephalopathy with a wide range of symptoms[25]. Overall, symptoms due to HAVMs occur in 8% of HHT patients and predominantly in females[29]. Symptoms of high-output cardiac failure usually develop in females between 50 and 70 years of age and are characterised by dyspnoea on exertion,

Table 1 Updated classification of pulmonary hypertension

Pulmonary arterial hypertension
Idiopathic PAH
Hereditable PAH
BMPR2
ALK1, endoglin (with or without hereditary haemorrhagic telangiectasia), SMAD9, CAV1, KCNK3
Unknown
Drug and toxin induced
Associated with:
Connective tissue diseases
HIV infection
Portal hypertension
Congenital heart diseases
Schistosomiasis
Pulmonary veno-occlusive disease and/or pulmonary capillary haemangiomatosis
Persistent pulmonary hypertension of the newborn
Pulmonary hypertension due to left heart disease
Left ventricular systolic dysfunction
Left ventricular diastolic dysfunction
Valvular disease
Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
Pulmonary hypertension due to lung diseases and/or hypoxia
Chronic obstructive pulmonary disease
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities
Chronic thromboembolic pulmonary hypertension
PH with unclear and/or multifactorial mechanisms
Haematological disorders: chronic haemolytic anaemia, myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
Others: tumoural obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

PH: Pulmonary hypertension; BMPR2: Bone morphogenetic protein receptor, type 2; CAV1: Caveolin-1; HIV: Human immunodeficiency virus. Adapted from Simonneau *et al*[46], with permission of the publisher.

fatigue, orthopnoea, ascites and/or oedema[17,29].

Pathophysiology of high output PH: Exercise testing in healthy persons revealed that an increase in CO leads to an elevation in pulmonary artery pressure (increase in mPAP up to 0.5 to 3.0 mmHg/L per minute)[30].

In patients with HAVMs, shunting of blood from the hepatic arteries and/or portal veins to the hepatic veins results in a hyperdynamic state, in which the CO can be elevated two-to-three fold[31]. Besides this cause of high cardiac output, severe epistaxis or gastro-intestinal bleeding in patients with HHT may lead to anaemia with a compensatory increase in CO as well.

In HHT, a multifactorial cascade will eventually lead to high-output cardiac failure. At first, the increase in CO will be compensated by dilatation of the pulmonary arteries and thereby pulmonary pressure will still be maintained. An increase in left atrial (LA) pressure will predispose patients for atrial fibrillation (due to enlargement of the LA) and diastolic dysfunction of the left ventricle. Increased LA pressure and impaired pulmonary vasodilatation will eventually result in PH. The combination of volume and pressure overload leads to right ventricular (RV) dilatation, decreased systolic function of the RV and subsequent right heart failure. Severe bleeding (*e.g.*, epistaxis or gastro-intestinal bleeding) may trigger the cascade because of the subsequent increase in CO[17,29,31].

Table 2 Haemodynamics in pulmonary hypertension associated with hereditary haemorrhagic telangiectasia

	High output PH	PAH
mPAP (mmHg)	+	++
PAWP (mmHg)	=/+	=
PVR (Wood units)	=	++
CO (L/min)	++	-

PH: Pulmonary hypertension; PAH: Pulmonary arterial hypertension; mPAP: Mean pulmonary artery pressure; PAWP: Pulmonary artery wedge pressure; PVR: Pulmonary vascular resistance; CO: Cardiac output. +: Increase; =: Normal; -: Decrease. Adapted from Faughnan *et al*[17], with permission of the publisher.

Treatment of high output PH: The first-line treatment of PH associated with a high-output state consists of intensive medical treatment including salt restriction and diuretics, correction of anaemia, antihypertensive and antiarrhythmic agents and digoxin if necessary[9]. In patients refractory to medical-therapy, liver transplantation is the best option, with a 5-year survival of 83% in a series of 40 patients[29]. However, a high post-operative morbidity is seen[25,32].

Recently, Dupuis-Girod *et al*[33] treated 25 patients with severe HAVMs and a high CO [median cardiac index (CI) 5.1 L/min per square meters (range 4.1-6.2 L/min per square meters)] with bevacizumab, a vascular endothelial growth factor inhibitor. This treatment resulted in a significant decrease in CO [median CI at 6 mo 4.1 L/min per square meters (range 3.0-5.1 L/min per square meters)], normalisation of the pulmonary pressure in 5 out of 8 patients with PH at baseline and clinical improvement of dyspnoea[33]. Other invasive treatments such as surgical hepatic artery ligation or transcatheter therapeutic embolisation of the hepatic artery are associated with a high morbidity and mortality and therefore not recommended[1,17].

PAH

PAH is a clinical condition characterised by the presence of pre-capillary PH due to arteriopathy with media hypertrophy and intima proliferation. It is increasingly recognised as a severe complication of HHT.

There have been a few case series that describe the association between PAH and HHT, however these series all included patients with PH in which HHT

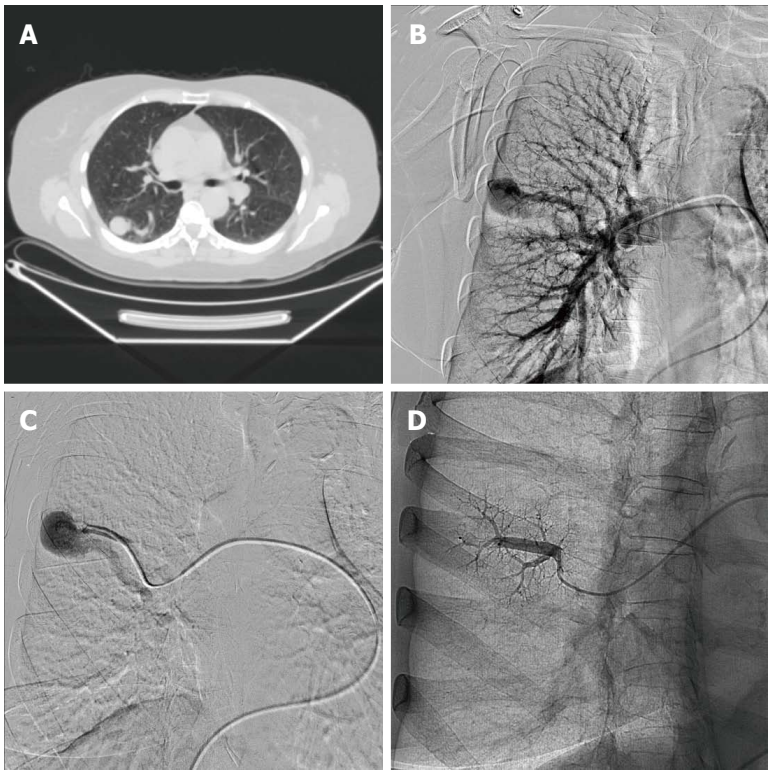

Figure 3 Pulmonary arteriovenous malformations. A: Computed tomography of the chest with large pulmonary arteriovenous malformation (PAVM) in the lower lobe of the right lung; B: Pulmonary angiogram of the PAVM in the same patient; C: Selective pulmonary angiogram of the PAVM in the apex of the lower lobe of the right lung; D: Repeat angiogram after transcatheter embolisation of the PAVM with a vascular plug.

symptoms were also present[18-22].

Pathophysiology and genetics of PAH: In 2001, it was demonstrated for the first time that different mutations in ACVRL1 predispose patients for the development of PAH[18]. This was confirmed in a few case series describing the presence of PAH in patients with an *ACVRL1* mutation and clinical features of HHT[19,21,22]. Trembath *et al*[18] described that mutations in *ACVRL1* may lead to both occlusion of the pulmonary arteries together with vascular dilatation, manifested as AVMs in HHT. Although less frequently, ENG mutations have also been identified in patients with both HHT and PAH, suggesting a less potent association between endoglin and PAH[18,19]. Mutations in the bone morphogenic protein receptor type 2 gene, which is another gene encoding the endothelial surface protein components of the TGF-β receptor that is detected in approximately 70% of the patients with hereditable PAH, were not found in HHT associated PAH[34].

Prognosis: The clinical outcomes of patients with PAH caused by an ACVRL1 mutation have been analysed in 32 patients and compared to other PAH patients without this mutation. PAH caused by an *ACVRL1* mutation was found in significantly younger patients (mean age 21.8 ± 16.7 years) and had a significantly shorter survival, despite similar therapy[34]. No data exist about the prognosis of patients with *PAH* and *ENG* mutations. The overall prognosis of PAH in general ranges from 6 mo to several years based on the underlying disease[13].

It is noteworthy that *ACVRL1* mutation carriers may develop severe PAH without any clinical evidence of HHT because of the early development of PAH in these patients and the late-onset penetrance of ACVRL1 mutation for HHT manifestations[34].

Treatment of PAH in HHT: No systematic evidence exists for treatment of HHT patients with PAH. It seems rational to treat patients according to the guidelines for PAH, with PAH-specific medication and supporting therapy (diuretics, oxygen, and digoxin)[13].

Today there are three different groups of PAH specific medication; endothelin receptor antagonists (ERA), phosphodiesterase inhibitors (PD5I) and prostacyclins. There are two case-reports that describe successful treatment of PAH in HHT patients with the ERA bosentan. After treatment, improvement of symptoms, exercise capacity and laboratory findings and a decrease in mPAP were found[35,36].

There are no reports describing the treatment with other PAH specific medication in patients with PAH and HHT. Since there was no response to acute vasodilator challenge in 32 patients with HHT and PAH, there is probably no role for the use of calcium channel blockers in this population[17,34]. And due to an increase in bleeding complications regular treatment with oral anticoagulation is not advised[1]. However, based on recent literature, treatment with anticoagulation could be considered on a case by case basis[37].

Pulmonary arteriovenous malformations in PH: The coexistence of PH and pulmonary arteriovenous malformations (PAVMs) has specific clinical and therapeutic implications. PAVMs are low-resistance, high-flow abnormal vascular structures that bypass the

normal capillary filter and thereby result in permanent pulmonary right-to-left shunting (Figure 3A-C)[38-40]. Paradoxical embolisation through these PAVMs can lead to severe neurological complications, such as a stroke or brain abscess[1,40]. Contrast echocardiography is the screening test of choice (sensitivity up to 98.6%), with a direct relationship between shunt grade and prevalence of cerebral manifestations in patients screened for HHT[40-42]. To avoid neurologic and bleeding complications, PAVMs can be treated with transcatheter embolisation with coils or plugs (Figure 3D)[1,43]. It may be expected that closing this low resistance system will result in a rise in mPAP. Measuring the pulmonary pressure before and after embolisation of PAVMs in 43 patients, Shovlin *et al*[44] found no significant found no significant increase in mPAP after embolisation, even in patients with pre-existing mild to moderate PH.

A possible explanation is a decrease in CO after embolisation which has a greater effect on the PVR than occlusion of the PAVMs. This fall in CO immediately after PAVM closure was recently described in 29 HHT patients by Vorselaars *et al*[45]. Furthermore, PAVM-related hypoxemia can induce vasoconstriction with a concomitant increase in PVR. Both studies described an increase in saturation after embolisation which may result in a decrease in pulmonary vasoconstriction and thereby PVR[44,45]. One case report described a fatal rupture of a PAVM in a patients with severe PAH. Although patients with severe PH were excluded from the above studies, it would be prudent to consider that the higher the mPAP and PVR at baseline and the larger the PAVM, the greater likelihood of worsening PH after embolisation[44].

Further research and recommendations

Although a number of studies described patients with PH and HHT, no data are available about the exact prevalence of PH in the overall HHT population. Most studies used a small sample size of highly selected patients and data from RHC are lacking. Therefore we recommend to perform a systematic screening to reveal the true prevalence of both forms of PH with their different aetiologies in a HHT population.

Because of the non-specific symptoms and potentially fatal prognosis, all HHT patients should be referred to an HHT centre of excellence.

CONCLUSION

PH is increasingly recognised as a severe complication of HHT, but the true prevalence of PH in HHT is still unknown. PH in HHT is mostly post-capillary in origin and results from high cardiac output due to HAVMs and anaemia. Rarely ACRVL-1 or ENG mutations results in pre-capillary PAH. Differentiation between both forms of PH in HHT by RHC is essential, since both entities are associated with severe morbidity and mortality with different specific treatment options. Therefore all HHT patients should be referred to an HHT centre.

Abstract

New uses of cardiovascular drugs with proven experience are emerging, including for treating cancer. Quinazoline is a compound made up of two fused six member simple aromatic rings, benzene and pyrimidine rings, with several biological effects. Cardiologists first used quinazoline-based α1-adrenoceptor antagonists prazosin, doxazosin, and terazosin; currently available data support their use as safe, well tolerated, and effective add-on therapy in uncontrolled hypertension with additional favourable metabolic effects. Recent findings highlight the anticancer effects of quinazoline-based α1-adrenoceptor antagonists, indicating that they may have a significant role in uncontrolled hypertensive cancer patients without signs of ischemia.

Key words: Cardio-oncology; Multidrug resistance; Prazosin; Terazosin; Doxazosin

Core tip: New uses of cardiovascular drugs with proven experience and without high cost have been emerging, including to have anticancer abilities by targeting human ether-a-go-go-related gene K(+) channels, epidermal growth factor receptors, vascular endothelial growth factor receptors, as well as to overcome cancer multidrug resistance. Quinazoline-based α1-adrenoceptor antagonists (doxazosin, prazosin, and terazosin) exhibit anticancer abilities and emerging findings indicate that these drugs may have a significant role in uncontrolled hypertensive cancer patients without signs of ischemia.

INTRODUCTION

Despite the tremendous efforts, the medicine field has not yet come to absolute conclusions in oncology and the emerging scenario of the onco-cardiovascular patients is emerging[1]. New targeted anticancer therapies have not proven to be free from cardiovascular side effects while old anticancer therapies have shown delayed serious consequences in long-term cancer survivors[1,2]. Moreover, the heavy burden of concomitant problems and diseases requires changes in setting to prevent serious diseases such as infective endocarditis or in

Apoptosis induction	Apoptosis induction	Apoptosis induction
Anoikis induction		Anoikis induction
	Cell autophagy induction	Cell autophagy induction
Role in MDR	Role in MDR	Weaker or no effect in MDR
Akt inhibition	Cdk 1 inactivation	G_1 phase cell cycle arrest
Androgen receptor downregulation	DNA damage stress induction	p27KIP1 up-regulation
Bax expression upregulation	G_2 checkpoint arrest	Proteasome activity downregulation
Caspase-3 activity increase	Mitochondria-mediated apoptosis induction	Ubiquitinated protein accumulation
EphA2 agonism	p53-mediated mechanism	
FGFR-2 antagonism		
Focal adhesion kinase reduction		
HIF-1α inhibition		
MAPK activation decrease		
mTOR inhibition		
p27 downregulation prevention		
PDK1 inhibition		
PKB/Akt activation inhibition		
PI3K inhibition		
Rho kinase-Ⅱ activation decrease		
Soluble guanylate cyclaseα decrease		
TGF-β and IκB activation		
Tubulin-polymerization-enhancing activity		

Figure 1 Structure and polypharmacology of quinazoline-based α1-adrenoceptor antagonists doxazosin, prazosin and terazosin in cardio-oncology. MDR: Multidrug resistance; EGFR: Epidermal growth factor receptor; FGFR-2: Fibroblast growth factor receptor-2; HIF-1α: Hypoxia-inducible factor 1α; mTOR: Mammalian target of rapamycin; PDK1: 3-phosphoinositide-dependent protein kinase 1; TGF: Transforming growth factor.

perioperative oncosurgery[3-12]. The progress in cancer biology and treatment has led to a new frontier: the cardio-oncology[1-27]. New uses of cardiovascular drugs with proven experience have been emerging[1,4,5-9,27-32], including to have anticancer abilities by targeting human ether-a-go-go-related gene K(+) (HERG) channels[5], epidermal growth factor (EGF) receptors[9], vascular endothelial growth factor (VEGF) receptors, as well as to overcome cancer multidrug resistance (MDR)[4,26,29,33,34]. These old cardiovascular drugs do not have high cost, however, there was a lack of noninferiority randomized, controlled trials[33], comparing them with new anticancer therapies.

Quinazoline is a compound made up of two fused six member simple aromatic rings, benzene and pyrimidine rings[35]. The search for quinazoline-based substances as cardiovascular agents begun after pharmacological identification of quinazoline compounds having a glycine amide or β-alanine amide residue in the 3rd position that display a hypotensive activity. Other quinazoline derivatives have also demonstrated significant anticancer activities[26,35-39] and new molecules have been synthesized as gefitinib, erlotinib, afatinib, and lapatinib[26,36]. Cardiologists first used quinazoline-based α_1-adrenoceptor antagonists, including prazosin, doxazosin, and terazosin[26] (Figure 1). Currently available data have supported the use of these antagonists as safe, well tolerated, and effective add-on therapy in uncontrolled hypertension with additional favorable metabolic effects[37] and without association with an increased risk of heart failure[26,37-39]. New data suggest that adverse cardiac outcome of doxazosin is only among patients with moderate-to-severe ischemia on myocardial perfusion imaging[26,40]. Furthermore, it has been reported that the β-plus α_1-blocker pretreatment (propranolol + prazosin) has led to better severity reduction of postresuscitation myocardial tissue injury and myocardial dysfunction with better neurologic function and prolonged duration of survival than propranolol treatment alone[41]. This latter finding will require certainly further evaluation.

Research has suggested several anticancer mechanisms of doxazosin, including upregulation of Bax expression, transforming growth factor (TGF)-β and IκB activation[42], focal adhesion kinase reduction[43],

inhibition of protein kinase B/Akt activation[44], and death receptor mediated apoptosis induction[45,46]. Doxazosin is known to be a HERG ligand, EGFR inhibitor[47], VEGF-mediated angiogenic response antagonist[48], and fibroblast growth factor receptor-2 antagonist[48,49]. Several signalling pathways are also inhibited from doxazosin VEGF antagonism including PI3K, Akt, 3-phosphoinositide-dependent protein kinase 1, mammalian target of rapamycin, and hypoxia-inducible factor 1α[49]. In addition, doxazosin is also an agonist of receptor tyrosine kinase triggering ephrin type-A receptor 2 internalization which, in turn, suppresses haptotactic and chemotactic migration of prostate cancer, breast cancer, and glioma cells[26,50]. Notably, a tubulin polymerization-enhancing activity of doxazosin has been found[51]. A doxazosin derivative, DZ-50, impairs tumour growth and metastasis *via* anoikis[52]; similarly, doxazosin induces changes in morphology consistent with anoikis in both benign and cancerous prostatic cells and increased caspase-3 activity[43]. Moreover, doxazosin significantly decreases benign prostatic hyperplasia-induced mitogen-activated protein kinase kinase and Rho kinase-Ⅱ activation and decreases expression of soluble guanylate cyclasea[53] also leading to prostate cancer cell growth inhibition[54] Doxazosin also downregulates expression of androgen receptor[54], prevents p27 downregulation[55] and may partly reverse P-glycoprotein/MDR1-mediated cancer multidrug resistance (CMDR) and the transport of anticancer drugs[56].

Terazosin, another quinazoline-based antihypertensive α_1-adrenoceptor antagonist[57], is also an HERG ligand[58], a cancer cell growth inhibitor[59], and an apoptosis and anoikis inductor[58,60]. Terazosin induces cell death which is associated with G_1 phase cell cycle arrest, upregulation of cyclin-dependent kinase inhibitor 1B (p27KIP1)[60], accumulation of ubiquitinated proteins and downregulation of proteasome activity[46]. Terazosin seems to have weaker or no effects regarding CMDR[55].

Prazosin, another quinazoline-based and anti-hypertensive α_1-adrenoceptor antagonist[60], is also an HERG ligand[58] and EGFR inhibitor[61]. Prazosin induces autophagic cell death *via* a p53-mediated mechanism[62] and cell apoptosis through the induction of DNA damage stress, leading to cyclin-dependent kinase 1 inactivation and G_2 checkpoint arrest triggering mitochondria-mediated apoptosis induction[62]. In addition, prazosin exhibits an anti-angiogenic activity[63] and its role in MDR modulation has also been suggested[55,64]. These emerging findings indicate that the quinazoline-based antihypertensive α_1-adrenoceptor antagonists may have a significant role in uncontrolled hypertensive cancer patients without signs of ischemia[26,29,38,40].

Abstract

The Third Universal Definition of Myocardial Infarction (MI) requires cardiac myocyte necrosis with an increase and/or a decrease in a patient's plasma of cardiac troponin (cTn) with at least one cTn measurement greater than the 99th percentile of the upper normal reference limit during: (1) symptoms of myocardial ischemia; (2) new significant electrocardiogram (ECG) ST-segment/T-wave changes or left bundle branch block; (3) the development of pathological ECG Q waves; (4) new loss of viable myocardium or regional wall motion abnormality identified by an imaging procedure; or (5) identification of intracoronary thrombus by angiography or autopsy. Myocardial infarction, when diagnosed, is now classified into five types. Detection of a rise and a fall of troponin are essential to the diagnosis of acute MI. However, high sensitivity troponin assays can increase the sensitivity but decrease the specificity of MI diagnosis. The ECG remains a cornerstone in the diagnosis of MI and should be frequently repeated, especially if the initial ECG is not diagnostic of MI.

There have been significant advances in adjunctive pharmacotherapy, procedural techniques and stent technology in the treatment of patients with MIs. The routine use of antiplatelet agents such as clopidogrel, prasugrel or ticagrelor, in addition to aspirin, reduces patient morbidity and mortality. Percutaneous coronary intervention (PCI) in a timely manner is the primary treatment of patients with acute ST segment elevation MI. Drug eluting coronary stents are safe and beneficial with primary coronary intervention. Treatment with direct thrombin inhibitors during PCI is non-inferior to unfractionated heparin and glycoprotein Ⅱb/Ⅲa receptor antagonists and is associated with a significant reduction in bleeding. The intra-coronary use of a glycoprotein Ⅱb/Ⅲa antagonist can reduce infarct size. Pre- and post-conditioning techniques can provide additional cardioprotection. However, the incidence and mortality due to MI continues to be high despite all these recent advances. The initial ten year experience with autologous human bone marrow mononuclear cells (BMCs) in patients with MI showed modest but significant increases in left ventricular (LV) ejection fraction, decreases in LV end-systolic volume and reductions in MI size. These studies established that the intramyocardial or intracoronary administration of stem cells is safe. However, many of these studies consisted of small numbers of patients who were not randomized to BMCs or placebo. The recent LateTime, Time, and Swiss Multicenter Trials in patients

with MI did not demonstrate significant improvement in patient LV ejection fraction with BMCs in comparison with placebo. Possible explanations include the early use of PCI in these patients, heterogeneous BMC populations which died prematurely from patients with chronic ischemic disease, red blood cell contamination which decreases BMC renewal, and heparin which decreases BMC migration. In contrast, cardiac stem cells from the right atrial appendage and ventricular septum and apex in the SCIPIO and CADUCEUS Trials appear to reduce patient MI size and increase viable myocardium. Additional clinical studies with cardiac stem cells are in progress.

Key words: Myocardial necrosis; Type 1-5 myocardial infarctions; Troponin assays; Percutaneous coronary intervention; Fibrinolytic therapy; Thienopyridines; Cardioprotection; Bone marrow stem cells; Cardiac stem cells

Core tip: The Third Universal Definition of myocardial infarction (MI) combines clinical symptoms, cardiac biomarkers and electrocardiogram (ECG) changes. Small amounts of myocardial necrosis may occur with heart failure, renal failure, myocarditis, arrhythmias, pulmonary embolism or uneventful percutaneous or surgical coronary revascularization and should be termed myocardial injury. High sensitivity troponin assays increase the sensitivity but decrease the specificity of MI diagnosis. The ECG remains a cornerstone of MI diagnosis. Primary percutaneous coronary intervention in a timely manner is the primary treatment of patients with acute ST segment elevation MI. Antiplatelet agents (clopidogrel, prasugrel or ticagrelor), in addition to aspirin, reduce patient MI morbidity and mortality. The recent LateTime, Time, and Swiss Multicenter Trials of bone marrow stem cells in MI treatment did not demonstrate significant improvement in patient LV ejection fraction in comparison with placebo. In contrast, cardiac stem cells from the right atrial appendage or ventricular septum/apex in the SCIPIO and CADUCEUS Trials reduced patient MI size and increased viable myocardium. Studies with cardiac stem cells are continuing.

DEFINITION OF MYOCARDIAL INFARCTION

The Third Universal Definition of myocardial infarction (MI) expert consensus document was published in October 2012 by the global Myocardial Infarction Task Force[1]. The definition of MI requires cardiac myocyte necrosis with an increase and/or a decrease in plasma of cardiac troponin (cTn). At least one cTn measurement should be greater than the 99th percentile normal reference limit during: (1) symptoms of myocardial ischemia; (2) new (or presumably new) significant ECG ST-segment/T-wave changes or left bundle branch block; (3) the development of pathological electrocardiographic (ECG) Q waves; (4) new loss of viable myocardium or regional wall motion abnormality identified by an imaging procedure; or (5) identification of intracoronary thrombus by angiography or autopsy.

Cardiac troponin (I or T) has high myocardial tissue specificity as well as high clinical sensitivity because cTn T and I are essential contractile components of myocardial cells and are expressed almost exclusively in the myocardium. Release of cardiac troponin from the myocardium can result from normal turnover of myocardial cells, myocyte apoptosis, myocyte release of troponin degradation products, increased myocyte wall permeability and bleb formation, or myocyte necrosis[1].

Myocardial necrosis due to myocardial ischemia is defined as myocardial infarction[2]. Detection of a rise and a fall of troponin, expressed in ng/L or pg/mL, is essential to the diagnosis of acute MI[3,4]. Blood samples for the measurement of cTn should be drawn during the initial patient assessment and repeated 3-6 h later. Subsequent additional blood samples are required if further ischemic episodes occur, or when the timing of the initial symptoms onset is unclear[5]. The demonstration of a rise and fall in troponin measurements is extremely important in the differentiation of acute from chronic elevations in cTn concentrations that can be associated with structural heart disease such as patients with left ventricular hypertrophy (LVH), renal failure and heart failure (Table 1)[6].

The ECG remains a cornerstone in the diagnosis of MI and should be acquired and interpreted within 10 min after patient presentation[7]. Since ECG changes of MI can be transient, ECGs should be acquired at 15-30 min intervals, especially if the initial ECG is equivocal. Wide spread and profound ST-T changes are associated with greater degrees of myocardial ischemia. The extent and severity of coronary stenosis, collateral coronary circulation and prior myocardial necrosis impact on the ECG manifestations of myocardial ischemia[8]. Prior ECGs, when available, should be compared with current tracings. Mimickers of ECG changes of MI such as acute pericarditis, LVH, left bundle branch block (LBBB), Brugada syndrome, stress cardiomyopathy, and early repolarization patterns should be considered in the differential diagnosis[9].

Electrocardiographic ST-T wave criteria for the diagnosis of acute myocardial ischemia is listed in Table 2. The J point is used to determine the magnitude of the ST-segment shift. "Contiguous leads" refers to lead groups such as anterior leads (V1-V6), inferior leads

Table 1 Causes of troponin elevation

System	Causes of troponin elevation
Cardiovascular	Acute aortic dissection
	Arrhythmia
	Medical ICU patients
	Hypotension
	Heart failure
	Apical ballooning syndrome
	Cardiac inflammation
	Endocarditis, myocarditis, pericarditis
	Hypertension

	Carbon monoxide, hydrogen sulfide

GI: Gastrointestinal; ICU: Intensive care unit; PE: Pulmonary embolus; ARDS: Acute respiratory distress syndrome; SIRS: Systemic inflammatory response syndrome.

(Ⅱ, Ⅲ, aVF) or lateral/apical leads (Ⅰ, aVL).

Supplemental leads such as V3R and V4R, in the third and fourth right intercostal spaces, indicate the electrical activity in the free wall of the right ventricle and V7-V9 indicate the electrical activity in the inferobasal left ventricular wall. In patients with inferior and right ventricular infarction, ST segments are often elevated ⩾ 0.05 mV in V3R and V4R. In addition, ST elevation of ⩾ 0.05 mV ST in leads V7-V9 (V7 at the left posterior axillary line, V8 at the left mid-scapular line, and V9 at the left paraspinal border), supports the diagnosis of inferobasal MI due to left circumflex coronary artery occlusion. ST depression in leads V1-V3 also may be suggestive of inferobasal myocardial ischemia (posterior infarction), especially when the terminal T wave is positive[10-12].

Table 2 Electrocardiogram manifestations of acute myocardial ischemia (in absence of left ventricular hypertrophy and left bundle branch block)

ST elevation
New ST elevation at the J point in two contiguous leads with the cut-points:
⩾ 0.1 mV in all leads other than leads V2–V3 where the following cut points apply: ⩾ 0.2 mV in men ⩾ 40 yr; ⩾ 0.25 mV in men < 40 yr, or ⩾ 0.15 mV in women
ST depression and T wave changes
New horizontal or down-sloping ST depression ⩾ 0.05 mV in two contiguous
leads and/or T inversion ⩾ 0.1 mV in two contiguous leads with prominent R wave or R/S ratio > 1

ST segment elevation of > 0.5 mV is observed in lead aVR in acute left main coronary artery (LMCA) obstruction and proximal left anterior descending coronary artery (LAD) obstruction proximal to the first major septal branch. The ST elevation in aVR is more pronounced than in V1 in patients with acute LMCA occlusion. This pattern occurred in 88% of the patients with acute occlusion of LMCA group in one study[10,13]. Types of MI, five types of MI are based on pathological, clinical and prognostic differences (Table 3).

DIFFERENTIATING BETWEEN SPONTANEOUS TYPE 1 AND ISCHEMIC IMBALANCE TYPE 2 MYOCARDIAL INFARCTION

Differentiation between type 2 and type 1 MI is challenging and needs careful clinical assessment. It is very important that the differentiation be made whether the myocardial injury is likely to be due to plaque rupture (type 1 MI), or whether it is due to an imbalance in myocardial oxygen supply or demand (type 2 MI), because the management of these two conditions is very different. While, the treatment of type 1 MI primarily includes antithrombotic therapy and/or revascularization, as clinically appropriate, the management of type 2 MI is more varied because several different mechanisms may be responsible for pathogenesis ischemic imbalance. In critically ill patients or in patients with major (non-cardiac) surgery, biomarker elevation may be caused by the direct toxic effects of endogenous or exogenous high circulating catecholamines, coronary vasospasm and/or endothelial dysfunction or fixed coronary atherosclerosis and demand-supply mismatch (Figure 1). For example, a post-operative patient with hypotension and troponin elevation due to hypovolemia or acute blood loss, requires treatment with intravascular volume replacement, including blood transfusion. In certain instances, troponin elevation due to ischemic demand may unmask severe coronary artery disease (CAD) by increasing myocardial oxygen demand in the presence of fixed coronary stenosis. Consequently once the

Table 3 Third universal classification of myocardial infarction

Type 1: Spontaneous MI Spontaneous MI due to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries leading to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis. The patient may have underlying severe CAD, non-obstructive coronary disease or no CAD
Type 2: MI secondary to an ischemic imbalance Myocardial injury with necrosis occurs due to conditions other than CAD that contribute to an imbalance between myocardial oxygen supply and/or demand such as coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachycardia-bradycardia arrhythmias, anemia, respiratory failure, hypotension, and hypertension
Type 3: MI resulting in death when biomarker values are unavailable Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes or new LBBB, but death occurs before blood samples can be obtained, before cardiac troponins biomarkers rise, or when cardiac biomarkers were not collected
Type 4A: MI related to percutaneous coronary intervention MI associated with PCI is defined by elevation of cTn values greater than five times the 99th percentile upper normal reference limit (URL) in patients with normal baseline values (< 99th percentile URL) or a rise of cTn values by > 20% if the baseline troponins are elevated and are stable or falling. In addition one of the following criterion are required: (1) symptoms suggestive of myocardial ischemia; (2) new ischemic ECG changes or new LBBB; (3) angiographic loss of patency of a major coronary artery or a side branch or persistent slow- or no coronary flow or coronary embolization; or (4) demonstration with imaging of a new loss of viable myocardium or new regional wall motion abnormality
Type 4B: MI related to stent thrombosis MI associated with stent thrombosis detected by coronary angiography or autopsy in the presence of myocardial ischemia with a rise and/or fall of troponin biomarkers. One troponin measurement should be above the 99th percentile UR
Type 4C: MI related to restenosis MI associated with restenosis defined as ⩾ 50% stenosis or a complex lesion demonstrated at coronary angiography after (1) initial successful stent deployment; or (2) dilatation of a coronary artery stenosis with balloon angioplasty. These coronary angiographic changes should be associated with an increase and/or decrease of cTn values > 99th percentile URL and no other significant obstructive CAD
Type 5: MI related to coronary artery bypass grafting MI associated with CABG is defined by elevation of cardiac troponins greater than ten times the 99th percentile URL in patients with normal baseline cTn values (< 99th percentile URL). In addition, one of the following should be present: (1) new pathological Q waves or new LBBB; or (2) angiographic documented new graft or new native coronary artery occlusion; or (3) new loss of viable myocardium or new regional wall motion abnormality as shown by an imaging modality

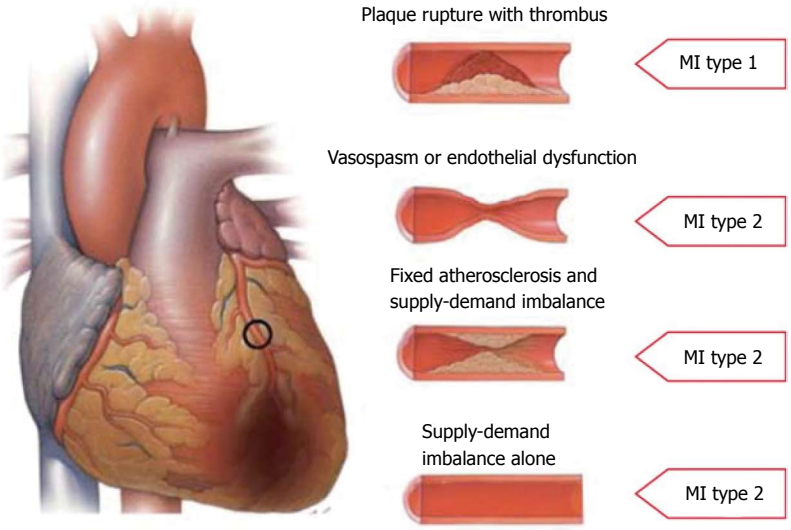

Figure 1 Type 1 and type 2 myocardial infarctions.

patient recovers from the acute illness, a stress test for inducible ischemia or coronary angiography can be helpful.

MYOCARDIAL INFARCTION DUE TO RE-VASCULARIZATION PROCEDURES

The 2007 universal MI definition required the presence of cardiac biomarkers greater than three times the 99th percentile of the upper normal range limit (URL) without requirements for associated ischemic changes or complications from angiographic procedures. This resulted in approximately 15% of patients undergoing PCI being diagnosed with an AMI[15,16]. In the 2012 definition of MI, there is a more strict definition of type 4a MI[1]. Percutaneous coronary intervention related MI is defined by cTn elevation greater than *five times* 99th percentile within 48 h after the procedure with: (1) symptoms suggestive of myocardial ischemia; or

(2) new ischemic ECG changes; or (3) angiographic findings consistent with a procedural complication with loss of a major artery or side coronary artery branch, decreased coronary flow, or coronary embolization; or (4) demonstration of new loss of viable myocardium or new regional wall motion abnormality. The occurrence of procedure-related myocardial cell injury with necrosis can be detected by measurements of cardiac troponin before the procedure, 3-6 h after the procedure and, optionally, re-measurement 12 h thereafter. An increasing cTn can only be interpreted as a procedure-related myocardial injury if the pre-procedural cTn value is $\leqslant 99^{th}$ percentile URL or if the troponin measurements are stable or falling. If the pre-procedural troponin is increased but is either stable or falling, an increase in cTn levels of > 20% is used to characterize a PCI-related MI.

The relationship between troponin increases after revascularization and mortality is controversial. The evidence for the association between biomarkers and mortality has evolved over the last 15 years. Studies have suggested a stronger association with the post-PCI MB fraction of creatine kinase (CK-MB) and subsequent cardiovascular events than with cTn elevation[15,17]. The level of CK-MB measurements varied from three to ten times the URL in these studies. When analyzed in categories of incrementally increasing biomarker elevations, most contemporary PCI studies have reported associations between periprocedural myonecrosis and mortality only for very large patient infarctions[17]. Only pre-procedure cTn elevations are correlated with subsequent mortality[18,19]. Consequently, in patients with baseline troponin elevation prior to PCI, the diagnostic accuracy of using the definition of post-PCI MI is limited.

With the application of the 2007 universal definition of post CABG MI (type 5), 42% to 82% of cardiac surgical patients had cardiac biomarker elevation greater than five times the URL[20], but only 4% to 7% had electrocardiographic evidence required for post-CABG MI[21]. Elevation of cardiac biomarker values after CABG can occur due to myocardial trauma, with dissection of the coronary arteries, manipulation of the heart, inadequate cardiac protection, reperfusion injury, or graft failure. Any increase in cardiac biomarker values > 99^{th} percentile URL is defined as myocardial injury. The new criteria for type 5 MI in patients with CABG requires an increase in biomarkers > 10 × 99^{th} percentile URL from a normal baseline during the first 48 h after surgery, plus new electrocardiographic Q waves or new LBBB, angiographic documentation of new graft or new native coronary artery occlusion, or imaging evidence of new regional wall motion abnormality or new loss of viable myocardium. The 2012 global MI task force emphasized that the threshold for diagnosing MI is more robust for on-pump CABG. The existing criteria for the universal definition of myocardial infarction should be used for diagnosing MI in patients who are more than 48 h after cardiac surgery[1].

The Society for Cardiovascular Angiography and Interventions has published an expert consensus document that defines clinically relevant myocardial infarction after revascularization (Table 4)[14].

REINFARCTION/RECURRENT MI

The term "reinfarction" is used for an acute MI that occurs within 28 d of a MI. If the cTn concentration is elevated, but stable or decreasing at the time of suspected reinfarction, the diagnosis of reinfarction requires a 20% or greater increase in the cTn measurement. If the initial cTn concentration is normal at the time of suspected reinfarction, the criteria for new acute MI apply[1,22].

TROPONIN ELEVATION IN HEART FAILURE

Based on the type of assay used, a range of elevated cTn values, indicative of myocardial injury with necrosis, may be seen in patients with a heart failure (HF) syndrome[23]. In stable heart failure patients, the median concentration of hs-cTnT is 12 ng/L, which is very close to the 99^{th} percentile URL of 14 ng/L for this assay[24]. Hence, using hs-cTn assays, cTn concentrations may be measured in nearly all patients with HF. Many HF patients exceed the 99^{th} percentile URL, especially those patients with severe decompensated HF syndrome[25]. While type 1 MI is an important cause of acutely decompensated heart failure, other mechanism(s) leading to troponin elevation in HF syndromes such as supply-demand inequity (type 2 MI) should be considered. Non-coronary triggers, such as anemia, cellular necrosis, apoptosis, or autophagy in the context of wall stress may cause troponin release in HF, as can the toxic effects of circulating neurohormones, toxins, inflammation, and infiltrative processes. Nonetheless, in patients with HF, troponin elevation independent of its mechanism, is strongly predictive of an adverse outcome and should not be ignored[25].

HIGH SENSITIVITY TROPONIN ASSAYS

Highly sensitive assays for cTnT and cTnI are available and are widely used in many parts of the world, although they are not generally used at the present time in the United States[26]. Two criteria should be met for high sensitivity troponin assays (hs-Tn). First, the coefficient of variation at the 99^{th} percentile value should be $\leqslant$ 10%. Second, the assay should be able to measure cTn concentrations below the 99^{th} percentile in $\geqslant$ 95% of normal individuals[27]. Compared with standard cTn assays, the hs-cTn assays have improved sensitivity and discrimination for MI, particularly in the first 3 to 6 h after symptom onset[28]. These advantages are somewhat offset by a decrease in specificity for MI[28-30] and concerns regarding the broad application of these tests, especially in populations with

Table 4 Proposed definition of clinically relevant myocardial infarction after both percutaneous coronary intervention and coronary artery bypass grafting procedures

In patients with normal baseline CK-MB	The peak CK-MB measured within 48 h of the procedure rises to ≥ 10 × the local laboratory ULN, or to ≥ 5 × ULN with new pathologic Q-waves in ≥ 2 contiguous leads or new persistent LBBB, OR in the absence of CK-MB measurements and a normal baseline cTn, a cTn (I or T) level measured within 48 h of the PCI rises to ≥ 70 × the local laboratory ULN, or ≥ 35 × ULN with new pathologic Q-waves in ≥ 2 contiguous leads or new persistent LBBB
In patients with elevated baseline CK-MB (or cTn) in whom the biomarker levels are stable or falling	The CK-MB (or cTn) rises by an absolute increment equal to those levels recommended above from the most recent pre-procedure level
In patients with elevated CK-MB (or cTn) in whom the biomarker levels have not been shown to be stable or falling	The CK-MB (or cTn) rises by an absolute increment equal to those levels recommended above plus new ST-segment elevation or depression plus signs consistent with a clinically relevant MI, such as new onset or worsening heart failure or sustained hypotension

ULN: Upper limit of normal; MI: Myocardial infarction; cTn: Cardiac troponin.

a low MI prevalence.

There is controversy regarding the metrics that should be used with hs-cTn assays for the diagnosis of AMI. In this regard, attempts have been made to define in these assays the optimal value for relative change or deltas in hs-cTn concentrations. Higher deltas increase specificity while lower ones improve sensitivity. The potential for analytical interferences with hs-cTn assays is greater than with conventional assays. Examples include reductions in hs-cTnT concentrations due to hemolysis and autoantibodies or increases due to heterophilic antibodies[31]. Studies suggest that an absolute increase of hs-cTnT values, *i.e.*, > 7 ng/L over 2 h, is superior to relative percentage changes from the baseline in the diagnosis of MI[32-34].

According to the recent guideline for the management of patients with acute coronary syndromes, blood samples for high-sensitivity cardiac troponin measurements should be obtained at presentation and 3 h after admission[35]. Measurements of hs-cTn should be repeated 6 h after admission in patients in whom the 3 h values are unchanged but in whom the clinical suspicion of MI is still high[36].

Distinguishing between type 1 and type 2 MI is challenging with high sensitivity troponin measurements. As troponin assay sensitivity increases, the frequency of possible type 2 MI increases and the distinction from type 1 MI becomes more complicated. Moreover, the diagnostic accuracy of a baseline measurement of hs-cTn for presence of AMI in patients with renal insufficiency is poor[37]. Nevertheless, elevated hs-cTns have important prognostic implications and patients require additional evaluations because a high cTnT level is associated with all-cause and cardiovascular mortality and with incident heart failure in 3 population based studies[30].

TREATMENT OF ACUTE MYOCARDIAL INFARCTION

The incidence of ST segment myocardial infarction (STEMI) has gradually declined over the past decade. However it still accounts for 25%-40% of all acute coronary syndrome related hospitalizations in the United States[37]. Moreover, the incidence of acute myocardial infarction is increasing in the developing countries[38]. Heart disease is expected to be the leading cause of death in the developing world by the year 2020. With changing dietary and personal habits, the prevalence of smoking, hypertension, diabetes, obesity and metabolic syndrome are increasing in areas of the world with large populations such as India[39], China[40] and South America[41]. Advances made in the area of medical therapy and coronary interventions have resulted in a significant decrease in the mortality rates. Current in-hospital and one year mortality are in the order of 5%-6% and 7%-18% respectively[42,43]. During the course of last three decades, there have been significant advances in our understanding of the pathophysiology and treatment of STEMI. In addition to these scientific advances, substantial progress has been made in the areas of public awareness and guideline driven clinical practice[44]. This has led to a gradual decline in STEMI related mortality and improved patient related outcomes. However, there continues to be significant difference in the 30-d mortality rates based on the geographic region[45], age[46,47], gender[48] and race[49]. In addition, individuals with diabetes and chronic renal insufficiency continue to have high rates of mortality[50-52]. In the recent INFUSE-AMI (Intracoronary Abciximab and Aspiration Thrombectomy During Primary PCI for Anterior STEMI) trial[53], diabetics compared to non-diabetics, had higher incidence of stent thrombosis at 30 d (4.3% *vs* 0.8%, P = 0.03) and higher rates of major cardiovascular and cerebrovascular events at 1 year (16.5% *vs* 8.0%, P = 0.04). It has been shown that patients with end-stage renal disease frequently do not receive guideline based therapies. In one registry, it has been shown that only 45% of eligible patients on dialysis received coronary reperfusion therapy, and only 70% of patients received aspirin on admission for coronary syndromes. In-hospital mortality rate from myocardial infarction is 21.3% in those on dialysis and 11.7% in those with renal disease but not on dialysis[54].

Approximately 7% of the eligible patients with myocardial infarctions do not receive reperfusion therapy[55]. There is evidence suggesting that reperfusion therapy offers benefit in the elderly. However, age is

the strongest predictor associated with an individual not receiving reperfusion therapy[56]. Programs that focus on patient education, systematic organization of STEMI programs and standardization of clinical practice result in improved care of all groups of patients and minimize disparities[57,58].

One of the most important components of STEMI management is getting the patients in a time efficient manner to a hospital that is capable of administering reperfusion therapies such as fibrinolytic therapy and primary percutaneous coronary intervention. Although approximately 98% of the United States population is within the reach of 911 based emergency medical service systems, patients with STEMI do not routinely utilize the system[59]. System based delays have been shown to increase STEMI related morbidity and mortality[60-63]. Hence increased community awareness and preparedness is important. In addition, regional STEMI centers with organized protocols, system based time-to-treatment goals and quality improvement programs must be established. Such efforts minimize delays and lower morbidity and mortality in STEMI patients[64,65]. In a study by Sørensen *et al*[66], where 759 consecutive STEMI patients were divided into a group with pre-hospital diagnosis and direct referral to a primary PCI center *vs* a group without pre-hospital diagnosis. Pre-hospital diagnosis and direct referral resulted in shorter system delay (92 min *vs* 153 min, $P < 0.001$).

CORONARY REPERFUSION STRATEGIES

Fibrinolytic therapy (FT) and Primary Percutaneous Coronary Intervention (P-PCI) are the two currently available modalities of reperfusion therapies. Both of these options are extensively studied. P-PCI, when performed in a timely manner at a high patient volume center is superior to FT. However, P-PCI is not universally available[67]. Delays in door-to-balloon times (D2B) are associated with increased mortality[68]. Adherence to D2B goal of < 90 min lowers mortality[69,70]. Although P-PCI is superior to FT, emphasis should be placed on timely administration of some form of reperfusion therapy rather than the mode of treatment[71].

For patients who present to a P-PCI capable hospital, the door to balloon time should not exceed 90 min. When patients present to a hospital that is not capable of P-PCI, factors such as time of onset of symptoms, risk of bleeding, presence of acute heart failure or shock, risk of mechanical complications, time-to-transfer to a P-PCI capable hospital should be taken into consideration. In patients who present within less than 1-2 h of onset of symptoms, immediate FT may be advantageous even if the transfer times are short[72].

ROLE OF PRE-HOSPITAL FIBRINOLYTIC THERAPY

Multiple trials have shown the safety and efficacy of pre-hospital FT[73-76]. This approach reduces the time to treatment by approximately 60 min and decreases mortality by 17%[77]. Similar findings were also seen in the pooled analysis of two other trials[78]. The Swedish and the French (USIC) registries showed that pre-hospital FT can be administered safely and results in reduces mortality[79,80]. At this time, pre-hospital use of FT is not commonly used in the United States but is used frequently in Western Europe and England.

STEMI PATIENTS WITH OUT-OF-HOSPITAL CARDIAC ARREST

Approximately 70% of CAD related deaths present as cardiac arrest prior to presenting to a hospital[81]. Less than a quarter of patients presenting with sudden cardiac arrest have ventricular tachycardia or ventricular fibrillation that can be electrically converted to normal sinus rhythm[82]. Of the 60% patients who are resuscitated by emergency response teams, the median survival rate to hospital discharge is 7.9%[83]. In patients with STEMI who present with sudden cardiac arrest, timely defibrillation and hypothermia have been shown to increase survival. For every minute delay in defibrillation, there is 7% to 10% drop in survival[83,84]. Increasing access to and use of defibrillators in public places has resulted in an increase in the number of patients that are neurologically intact after sudden cardiac arrest[84-86]. In patients with out-of hospital cardiac arrest, hypothermia with temperatures between 32 ℃ to 34 ℃ increases survival. In a study of 77 patients[87], hypothermia (with the core body temperature reduced to 33 degrees C within 2 h after the return of spontaneous circulation and maintained at that temperature for 12 h) compared to normal temperature increased the survival rates 26% to 49% $P = 0.0046$. In another study, survival was shown to be improved with hypothermia[88]. In patients with out-of hospital cardiac arrest in the setting of STEMI, hypothermia should be initiated as soon as possible.

FIBRINOLYTIC THERAPY

When P-PCI is not available, FT is an alternative. It reduced mortality and morbidity when carefully administered within 12 h of symptom onset[89-94]. The usefulness of FT in patients presenting greater than 12 h from the onset of symptoms is not well established[95-98]. Fibrin specific agents such as tenecteplase, retaplase and alteplase are preferred. Tenecteplase is the most fibrin specific. None of the fibrin specific agents are antigenic. Patency rates of the infarct related artery with fibrin specific agents are approximately 85%[99-103]. Streptokinase is a non-fibrin-specific agent and can cause antigenic reactions. Infarct related artery patency rate with streptokinase is 60%-70%[104]. When the delay from first medical contact to primary PCI is > 120 min, FT is indicated if the time of onset of symptoms is < 12 h.

ADJUNCTIVE PHARMACOTHERAPY WITH FIBRINOLYTIC THERAPY

The role of Aspirin and Clopidogrel with fibrinolytic therapy is well established[105-107]. Aspirin and Clopidogrel should be given prior to the administration of fibrinolytic agent. Dual antiplatelelt therapy should be continued for at least one year[107]. The data on using newer antiplatelet agents like Prasugrel and Ticagrelor as an adjunct to thrombolytic therapy for fibrinolysis is not yet well established.

In addition to antiplatelet therapy, the use of adjunctive anticoagulants is supported when fibrinolytic agents are used for STEMI[108]. Unfractionated heparin, Enoxaparin and Fondaparinux can be used. However, low molecular weight heparins (LMWH) should be avoided in patients with impaired renal function (Creatinine Clearance < 30 mL/min)[109].

FAILED FIBRINOLYTIC THERAPY

Ongoing chest pain, lack of > 50% ST segment resolution and the absence of reperfusion arrhythmias at 60-90 min after the administration of fibrinolytics is considered failure of treatment. These parameters predict TIMI flow < 3 in the infarct artery[110]. In patients who don't respond to (FT), "rescue" PCI has been shown to be beneficial. In the Rapid Early Action for Coronary Treatment Trail[111]. The primary components endpoint of death, reinfarction, stroke, or severe HF at 6 mo, was lower among patients randomized to rescue PCI compared to conservative care or repeat fibrinolysis (event-free survival rate: 84.6% *vs* 70.1% *vs* 68.7%, $P = 0.004$). This was due to reduction in reinfarction. There was no significant survival benefit. Minor bleeding was significantly higher among patients randomized to rescue PCI. However, there were no differences in major bleeding among the conservative therapy, repeat fibrinolysis or, rescue PCI groups. Similar findings of improved event free survival were reported in the Middlesbrough Early Revascularization to Limit Infarction trail. However, higher rates of stroke and periprocedural bleeding were associated with rescue PCI[112,113]. In patients with ongoing symptoms, lack of signs reperfusion, significant hypotension, severe CHF, cardiogenic shock, ECG evidence of large area of myocardium at risk, the benefit of early PCI justifies the risk of bleeding. Conservative treatment might be reasonable in a patient with improving symptoms and a limited inferior infarction despite the persistence of ST elevation.

PATIENTS PRESENTING WITH CARDIOGENIC SHOCK

In the SHOCK trial[114], 302 patient with STEMI with shock were randomized to medical stabilization ($n = 150$) group, which included thrombolysis (63% of patients), intra-aortic balloon counterpulsation (86%), and subsequent revascularization (25%), or to an early revascularization group ($n = 152$). The primary endpoint of survival at 1 year was 46.7% for patients in the early revascularization group compared with 33.6% in the initial medical stabilization group (absolute difference in survival, 13.2%; $P < 0.03$). In a prespecified subgroup analyses, only age (< 75 years *vs* ⩾ 75 years) interacted significantly ($P < 0.03$) with treatment. The benefit was seen only in patients younger than 75 years (51.6% survival in early revascularization group *vs* 33.3% in initial medical stabilization group). The benefit of early revascularization was apparent across a wide time window, extending up to 54 h after MI and 18 h after shock onset. Based on this data, STEMI patients who present with acute cardiogenic shock should undergo emergency cardiac catheterization and revascularization. This is especially true for patients younger than 75 years.

ROUTINE EARLY ANGIOGRAPHY AFTER SUCCESSFUL FIBRINOLYTIC THERAPY

In the Grup de Analisis de la Cardiopatia Isquemica Aguda trial[115], 500 patients with STEMI that were treated with recombinant tissue plasminogen activator were randomly assigned to angiography and coronary intervention if indicated within 24 h of thrombolysis, or to an ischemia-guided conservative approach. The primary endpoint of combined rate of death, reinfarction, or revascularization at 12 mo occurred in 9% of the angiography and intervention group compared to 21% in the conservative group ($P = 0.0008$). There was a trend towards reduced rates of death or reinfarction (7% *vs* 12%, $P = 0.07$). There were no differences in major bleeding or vascular complications.

In the Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction[116], 1059 high-risk patients who had a STEMI received FT at centers not capable of performing P-PCI were randomized to either standard treatment (including rescue PCI, if required, or delayed angiography) or immediate transfer to another hospital and PCI within 6 h after fibrinolysis. At 30 d, the primary composite endpoint of death, reinfarction, recurrent ischemia, new or worsening congestive heart failure, or cardiogenic shock occurred in 11.0% of PCI and in 17.2% of the patients assigned to standard treatment ($P = 0.004$). There was no evidence of increased major bleeding with the early invasive strategy.

In the Norwegian Study on District Treatment of ST-Elevation Myocardial Infarction trial[117] 266 patients with acute STEMI living in rural areas, where the transfer time to P-PCI are greater than 90 min, were initially treated with the combination of tenecteplase, aspirin, enoxaparin, and clopidogrel and were randomized to immediate transfer for P-PCI or to standard man-

agement in the local hospitals with early transfer, only if indicated for rescue or clinical deterioration. The primary outcome of composite of death, reinfarction, stroke, or new ischemia at 12 mo occurred in 21% *vs* 27% in the early invasive group and the conservative treatment group respectively (P = 0.19). Although this study failed to demonstrate a statistically significant difference between the 2 treatment groups in the incidence of the primary composite endpoint, the incidence of death, recurrent MI, or stroke was significantly lower in the immediate-transfer group. The risk reduction was similar to that reported for high-risk patients in the Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction.

In a meta-analysis by Borgia *et al*[118] that included 2961 patients from 7 trials, early PCI after successful fibrinolysis reduced the rate of re-infarction (P = 0.003), the combined endpoint death/re-infarction (P = 0.004) and recurrent ischemia (P < 0.001) at 30-d. There was no evidence of an increase in patient major bleeding or stroke.

In the recent Strategic Reperfusion Early After Myocardial Infarction trial[119], 1892 patients with STEMI who presented within 3 h of symptom onset who were unable to undergo primary PCI within 1 h, were randomly assigned to undergo either primary PCI or fibrinolytic therapy with bolus tenecteplase (half dose in patients ⩾ 75 years of age), clopidogrel, and enoxaparin before transport to a P-PCI capable hospital. Emergency coronary angiography was performed only if fibrinolysis failed, which occurred in 36.3% of the patients; otherwise, angiography was performed 6 to 24 h after randomization. The primary composite end point of death, shock, congestive heart failure, or reinfarction within 30 d occurred in 12.4% of the patients in the fibrinolysis group and in 14.3% in the primary PCI group (P = 0.21). In patients who did not undergo primary PCI within one hour of medical contact, pre-hospital fibrinolysis with coronary angiography with a median time = 17 h resulted in effective reperfusion. The incidence of intracranial bleeding was higher with FT when compared to PCI (1.0% *vs* 0.2% P = 0.04).

Based on these studies, in STEMI patient who are treated successfully with FT, cardiac catheterization can be considered as part of a routine pharmacoinvasive or ischemia-guided approach > 24 h after administration of FT. Very early cardiac catheterization and PCI within 2-3 h after the administration of (FT) increases the risk of bleeding. Very early (< 2-3 h) invasive approach should be utilized for patients who require rescue PCI.

FACILITATED PCI

Fibrinolytic agents use as adjunct to primary PCI has been studied. This approach is called facilitated PCI. Full dose or half dose of a fibrinolytic agent is administered with or without glycoprotein Ⅱb/Ⅲa (GP Ⅱb/Ⅲa) inhibitor prior to planned PCI. This approach is based on the assumption that pre PCI pharmacotherapy will facilitate higher and faster rates of reperfusion.

The Assessment of the Safety and Efficacy of a New Treatment Strategy for Acute Myocardial Infarction trail[120] was stopped prematurely because of an increased mortality associated with facilitated PCI. In the Facilitated Intervention with Enhanced Reperfusion Speed to Stop Events trial[121], patients were randomized to primary PCI or facilitated PCI with abciximab or facilitated PCI with half-dose reteplase and full-dose abciximab. Although the rates of death, heart failure, and ischemic outcome at 90 d for all three groups were similar, there was increased rate of major bleeding with the facilitated strategies. Because of these findings, facilitated PCI is currently not advised.

PRIMARY PCI

Timely reperfusion with primary PCI (P-PCI) by experienced operators at an experienced center is superior to FT. Compared to FT, P-PCI results in higher rates of infarct related artery patency, higher rates of TIMI 3 flow and lower rates of complications such as recurrent ischemia, reinfarction, emergency repeat revascularization procedures, intracranial hemorrhage (ICH), and death. However, P-PCI is associated with increased rates of access site bleeding complications[122]. In addition, PCI can result in the "no reflow" phenomenon where the myocardial perfusion is inadequate despite restoration of TIMI 3 epicardial flow in the infarct related artery. No reflow phenomenon is due to a combination of endothelial injury, edema, atheroembolization, vasospasm, and myocyte reperfusion injury and inflammation[123]. Occurance of no reflow is associated with with increased mortality[123]. Multiple treatment strategies that included the use of GP Ⅱb/Ⅲa antagonists, nitroprusside, verapamil, adenosine, nicorandil, pexelizumab have not shown promising results[123].

The benefits of P-PCI over FT are time sensitive. Door to balloon (D2B) times greater than 90-120 min can eliminate the benefits of P-PCI over FT[124]. Over the past ten years, there has been a significant reduction in the median D2B times. Although approximately 80% of the United States population lives within one hour from a P-PCI capable hospital, the majority of patients in the rural areas do not have access to such facilities. A significant increase in the number of PCI capable hospitals from 2001 to 2006 result in minimal increase in the overall patient access to such facilities[125,126]. One of the strategies to make P-PCI more accessible is to allow hospitals without onsite cardiac surgery facilities to perform PCI procedures. The Cardiovascular Patient Outcomes Research Team trail[127] showed that primary PCI can be performed safely and rapidly at hospitals without cardiac surgery back-up. Other strategies include bypassing the non PCI hospital and transferring the patients to a primary PCI capable hospital where the care and transfer protocols are standardized. These strategies have been shown to extend P-PCI to more

patients and result in better patient outcomes[127-129].

DELAYED PRESENTATION

In patients presenting more than 12 h after the onset of symptoms, cardiac catheterization and PCI should be considered in the setting of ongoing chest pain, cardiogenic shock, acute severe heart failure, or spontaneous or provoked myocardial ischemia.

In the Occluded Artery Trial[130], 2166 patients with occluded infarct related arteries who presented 3-28 d after myocardial infarction and had ejection fractions less than 50% were randomized to PCI *vs* conservative medical therapy. The 4-year cumulative primary event rate was 17.2% in the PCI group and 15.6% in the medical therapy group (P = 0.20). However, patients with high risk features such as New York Heart Association class Ⅲ-Ⅳ, rest angina, high risk stress test, left main or three vessel diseases were excluded from the trial. The trail showed that routine PCI did not reduce the occurrence of death, reinfarction, or heart failure, and there was a trend toward excess reinfarction during 4 years of follow-up in stable patients with occlusion of the infarct-related artery 3 to 28 d after myocardial infarction. Based on this data, in patients who present more than 12 h after their symptom onset and are clinically stable, routine cardiac catheterization and PCI are not advised.

PCI OF THE NON-INFARCT RELATED ARTERY

In patients presenting with STEMI, multivessel coronary artery disease is frequently seen and is associated with poor outcomes[131]. PCI of a non-infarct related artery prior to discharge from the hospital, at a time that is separate from the index STEMI related PCI, is indicated if there is evidence of spontaneous myocardial ischemia. However, this practice is largely based on non-randomized cohort studies[132-134]. The role of fractional flow reserve (FFR) at the time of STEMI, to evaluate the functional significance of a non-infarct related artery is not well established. In a small study by Ntalianis *et al*[135], FFR was useful in evaluating the functional significance of a non-culprit coronary lesion.

In the recent Preventive Angioplasty in Acute Myocardial Infarction trail[136], 465 patients with acute STEMI who were undergoing primary PCI were randomly assigned to either preventive PCI defined as immediate PCI of any lesion with > 50% stenosis or no preventive PCI. The trial was stopped early by the data safety monitoring board. In an intention to treat analysis, the primary composite endpoint of death from cardiac causes, nonfatal myocardial infarction, or refractory angina occurred in 9% of the preventive PCI arm and 23% of the non-preventive PCI arm, respectively (P = 0.001). It should be noted that the trail excluded patients with concomitant disease in the left anterior descending and left circumflex arteries, patients with > 50% stenosis of the left main artery, patients with prior CABG and patient with a non-culprit artery with a chronic total occlusion.

At this time, PCI of a non-infarct related artery should be performed prior to hospital discharge if the patient has evidence of spontaneous or provocable myocardial ischemia.

PCI TECHNIQUE BASED STRATEGIES

During the past decade, we have seen significant advances in the field of interventional cardiology as it relates to the management of acute myocardial infarction. Some of the frequently debated issues include access site (radial *vs* femoral), routine use of aspiration thrombectomy, and bare-metal *vs* drug eluting stents.

Access site

Transradial PCI had gained widespread acceptance and is now used routinely for elective angioplasty. Major advantages with transradial approach include reductions in bleeding complications and length of hospitalizations and improved quality of life. Given these advantages, transradial PCI during STEMI has been extensively studied. Multiple randomized trials and a large meta-analysis showed that transradial primary PCI is associated with significant reduction in access site complications. In the Radial *vs* femoral access for coronary angiography and intervention in patients with acute coronary syndromes trial[137] 7021 patients with STEMI were randomly assigned to radial *vs* femoral access sites. The primary endpoint of death, myocardial infarction, stroke, or non-CABG-related major bleeding at 30 d occurred in 3.7% and 4.0% of the radial access and femoral access patients respectively (P = 0.5). In a pre-specified subgroup analysis, non-CABG-related major bleeding at 30 d occurred in 24 patients in the radial group compared with 33 patients in the femoral group (P = 0.23). At 30 d, 42 of 3507 patients in the radial group had large hematomas compared with 106 of 3514 in the femoral group (P < 0.0001). In the Radial *vs* Femoral Randomized Investigation in ST Elevation Acute Coronary Syndrome[138,139] trial, 1001 STEMI patients undergoing primary/rescue percutaneous coronary intervention were randomized to the radial or femoral approach. The primary endpoint of cardiac death, stroke, myocardial infarction, target lesion revascularization, and bleeding at 30 d occurred in 13.6% in the radial artery group and 21.0% in the femoral artery group (P = 0.003). Radial access was associated with significantly lower rates of cardiac mortality (5.2% *vs* 9.2%, P = 0.020), bleeding (7.8% *vs* 12.2%, P = 0.026), and shorter hospital stay. In the STEMI-RADIAL trail[103] 2959 patients undergoing primary PCI within 12 h of onset of symptoms were randomized to radial *vs* femoral approach. The primary

endpoint of access site complications and bleeding occurred in 7.2% of the femoral *vs* 1.4% of the radial group (80% relative risk reduction, $P = 0.001$). Radial and femoral approaches are both safe and effective for PCI. Lower rates of local vascular complications may be a reason to use the radial access approach. There is some concern about longer D2B times and increased radiaton exposure with radial artery access. This is mostly limited to low volumes centers and operators[140,141]. Data from the randomized control trials suggests that D2B times and the cumulative radiation dose are minimally increased with radial artery catheterization. The impact of the radial artery approach on patient mortality remains unclear at this time as the reported studies are underpowered to evaluate this end-point.

Adjunctive thrombectomy

A vast majority of patients with STEMI have large thrombus burden. It seems intuitive that thrombectomy may improve epicardial coronary flow, prevent distal embolization, reduce microvascular obstruction and the no-reflow phenomenon. However, trials that have used mechanical thrombectomy have been largely negative without any improvement in myocardial blush grade, final infarct size and overall left ventricular ejection fraction[142-144]. Recently there has been renewed interest in aspiration thrombectomy. In the Thrombus Aspiration during Percutaneous coronary intervention in Acute myocardial infarction Study[145], 1071 patients were randomly assigned to the thrombus-aspiration group or the conventional-PCI group before undergoing coronary angiography. The primary end point of myocardial blush grade of 0 or 1 occurred in 17.1% of the patients in the thrombus-aspiration group and in 26.3% in the conventional-PCI group ($P < 0.001$). At one year follow up, cardiac death occurred in 3.6% of the patients in the thrombus aspiration group and 6.7% in the conventional PCI group ($P = 0.020$). In the Impact of Thrombectomy With Export Catheter in Infarct-Related Artery During Primary Percutaneous Coronary Intervention trail[146], 155 STEMI patients were randomly assigned to standard percutaneous coronary intervention PCI ($n = 87$) or aspiration thrombectomy guided PCI ($n = 88$). The primary end points of myocardial blush grade $\geqslant 2$ and the rate of 90-min ST-segment resolution > 70% occurred more frequently in the thrombectomy guided PCI group (88% *vs* 60%, $P = 0.001$; and 64% *vs* 39%, $P = 0.001$). In a meta-analysis conducted by Bavry *et al*[147], total of 30 studies with 6415 patients were included, a weighted mean follow-up of 5.0 mo showed that the morality was 3.2% for the adjunctive thrombectomy group *vs* 3.7% for conventional PCI. In an by Kumbhani *et al*[148] data from clinical trials that randomized AMI patients to aspiration (18 trials, $n = 3936$) or mechanical thrombectomy (7 trials, $n = 1598$) before PCI compared with conventional PCI alone was analyzed. It showed that at a weighted mean clinical follow-up period of 6 mo major adverse cardiac events (RR = 0.76; 95%CI: 0.63-0.92; $P = 0.006$) and all-cause mortality (RR = 0.71; 95%CI: 0.51-0.99; $P = 0.049$) were significantly reduced with aspiration thrombectomy. ST-segment resolution at 60 min (RR = 1.31; 95%CI: 1.16-1.48; $P < 0.0001$) and Thrombolysis In Myocardial Infarction blush grade 3 post-procedure (RR = 1.37; 95%CI: 1.19-1.59; $P < 0.0001$) were both improved with aspiration thrombectomy.

In the recently published TASTE[149] (The Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia) trial, aspiration thrombectomy did not show reduction in 30 d mortality. The event rate was 2.8% in the aspiration arm *vs* 3.0% in the routine PCI arm ($P = 0.63$). This study has some significant limitations. The treating physician was aware of the group assignment. Event adjudication and review of coronary angiograms was not done in a blinded manner. Despite these limitations, the TASTE trial does suggest that routine use of aspiration thrombectomy, may not be beneficial in reducing mortality. Larger studies are needed to see if aspiration thrombectomy offers mortality benefit. The ongoing TOTAL A Trial of Routine Aspiration Thrombectomy With Percutaneous Coronary Intervention (PCI) *vs* PCI Alone in Patients With ST-Segment Elevation Myocardial Infarction (STEMI) Undergoing Primary PCI trial may answer some of the questions.

TYPE OF STENTS IN THE SETTING OF PRIMARY PCI

It is now a routine practice to use coronary stents during primary PCI. Compared to balloon angioplasty, primary PCI with bare metal stents (BMS) has been shown to reduce the rates of reinfarction and target vessel revascularization. However, this does not translate into a reduction in mortality[150]. Drug eluting stents (DES) are currently being used for both elective and primary PCI. DES when compared with BMS significantly reduces restenosis rates and the need for reintervention but does not definitively reduce rates of death[151]. First generation DES such as Taxus and Cypher, when compared to BMS, can increase the risk of very late stent thrombosis[152]. Newer generation DES such as Xience, Promus and Endeavour, when compared to BMS do not increase the risk of acute or late stent thrombosis. Cobalt-chromium based everolimus eluting stents have the lowest reported rates of stent thrombosis[153]. In the Xience or Vision Stents for Management of Angina in the Elderly trail[154], second generation, everolimus eluting DES were safely used in the elderly without increasing the risk of bleeding. Patients who are taking oral anticoagulation and present with a STEMI pose a significant challenge. Triple therapy significantly increases the risk of bleeding. In the What is the

Optimal antiplatelet and anticoagulant therapy in patients with oral anticoagulation and coronary stenting trial[155], the group receiving warfarin plus clopidogrel had lower bleeding complications compared with the group receiving warfarin, clopidogrel and aspirin. Although the rate of stent thrombosis was not increased, this trial was not powered to evaluate the risk of stent thrombosis.

Given the advantages of marked reduction in the rates of restenosis, target vessel and target lesion revascularization and very low rates of late stent thrombosis, second generation DES should be the preferred choice during primary PCI. However, that decision should be made on a case to case basis. Factors such as bleeding risk, other indications for systemic oral anticoagulants, socioeconomic status, compliance, need for surgical procedures during the following one year should be considered. If these factors are a concern, DES implantation should be avoided. There still remain gaps in our understanding of routine use of DES in the elderly and patients who are on oral anticoagulants. Further research is need in these areas.

ADJUNCTIVE PHARMACOTHERAPY BASED STRATEGIES

In recent years, there has been extensive research done in the area of adjunctive pharmaco-therapy. As a result, we now have multiple antithrombotic and anti-platelet agents that have been shown to reduce major adverse cardiac events in the setting of STEMI.

Unfractionated heparin (UFH) is time tested and the most familiar of all the agents. It is used frequently. When titrated to appropriate activated clotting times of 250-300 s, it is an acceptable strategy. Low molecular weight heparins (LMWN) such as Enoxaparin and Fondaparinux are not well studied in the setting of STEMI. In the STEMI Treated With Primary Angioplasty and Intravenous Lovenox or Unfractionated Heparin trial[156] 901 patients were randomized to treatment with enoxaparin (n = 450) or unfractionated heparin (n = 460). The composite primary endpoint of 30-d incidence of death, complication of myocardial infarction, procedure failure, or major bleeding occurred in 126 (28%) patients after anticoagulation with enoxaparin *vs* 155 (34%) patients on unfractionated heparin (P = 0.06). Data from this trail suggests that enoxaparin can be safely and effectively used in patients with STEMI. In the OASIS-6 trial[157] death or reinfarction at 30 d was significantly reduced from 11.2% in the control group to 9.7% patients in the fondaparinux group (P = 0.008). However, fondaparinux was associated with higher rates of catheter thrombosis. At this time, fondaparinux in not used as an anticoagulant in the setting of primary PCI.

The role of Bivalirduin in the setting of STEMI treated with primary PCI was tested in the Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction trial[158]. Three thousand six hundred and two patients with ST-segment elevation myocardial infarction presenting within 12 h after the onset of symptoms and were undergoing primary PCI, were randomly assigned to treatment with heparin plus a glycoprotein Ⅱb/Ⅲa inhibitor or to treatment with bivalirudin alone. Primary end points of major bleeding and combined adverse clinical events, including death, reinfarction, target-vessel revascularization for ischemia, and stroke within 30 d occurred in 22% of the heparin plus glycoprotein Ⅱb/Ⅲa inhibitor group *vs* 9.2% in the bivalirudin group (P = 0.005). The risk of acute stent thrombosis within 24 h in the bivalirudin group increased, but no significant increase was present by 30 d. This was most likely secondary to a combination of adenosine diphosphate–induced platelet activation before maximal thienopyridine blockade of the platelet P_2Y_{12} receptor or by residual thrombin activity after the discontinuation of bivalirudin. Based on the results from the HORIZONS-AMI trail, it is a reasonable approach to use bivalurudin in patients with STEMI who are undergoing primary PCI. This approach may provide long term survival benefit by lowering the rate of bleeding complications.

ADJUNCTIVE ANTIPLATELET THERAPY

Aspirin

An initial single dose of 325 mg of Aspirin should be administered as early as possible. This should be followed by a maintenance dose of 81 mg once daily. Higher doses of Aspirin for maintenance therapy have shown to increase the risk of bleeding. In the Committee members of the Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events-Seventh Organization to Assess Strategies in Ischemic Syndromes trial[159] 25086 patients with an acute coronary syndrome who underwent cardiac catheterizatoin were randomized to either double-dose clopidogrel (a 600-mg loading dose on day 1, followed by 150 mg daily for 6 d and 75 mg daily thereafter) or standard-dose clopidogrel (a 300-mg loading dose and 75 mg daily thereafter) and either higher-dose aspirin (300 to 325 mg daily) or lower-dose aspirin (75 to 100 mg daily). The primary outcome of cardiovascular death, myocardial infarction, or stroke at 30 d was not different between higher-dose and lower-dose aspirin (4.2% *vs* 4.4%, P = 0.61) or major bleeding (2.3% *vs* 2.3%, P = 0.90).

Clopidogrel

The importance of at least 12 mo of dual antiplatelet therapy with aspirin and clopidogrel in the setting of ACS with and without PCI has been well established based on the data from the Clopidogrel in Unstable Angina to Prevent Recurrent Event (CURE)[160] and PCI-CURE[161] trials. A 600 mg loading dose of clopidogrel offers rapid platelet inhibition compared to 300 mg dose[162]. In the CURRENT-OASIS 7 trail[159] the

primary outcome of cardiovascular death, myocardial infarction, or stroke at 30 d occurred in 4.2% of the double-dose clopidogrel group *vs* 4.4% in the standard-dose clopidogrel (P = 0.30). Major bleeding occurred in 2.5% of the double-dose group and in 2.0% in the standard-dose group patients (P = 0.01). Rates of stent thrombosis was lower in the double dose group (1.6% *vs* 2.3% P = 0.001). Incidence of major bleeding was 2.5% in the double dose group *vs* 2.1% in the standard dose group (P = 0.001). Clopidogrel 600 mg loading dose followed by 75 mg once daily for at least one year should be considered for all patients with acute coronary syndromes.

One common clinical concern with the use of clopidogrel is the variable therapeutic response. This is secondary to multiple factors such as diabetes, obesity, polymorphisms in enteric ABCB 1 and hepatic cytochrome P450 (CYP450) enzymes (CYP2C19*2) and drug interaction that interferes with the metabolism of clopidogrel. Nearly 30% of patients have a reduced functional allele of CYP2C19*2. This has been shown to be associated with decreased levels of the active metabolite of clopidogrel, suboptimal platelet inhibition and increased rates of major adverse cardiac events and stent thrombosis[162-165]. Based on this data, the United States Food and Drug Administration made changes to clopidogrel's prescribing information noting the potential impact of CYP2C19 genotype on clopidogrel's bioavailability and clinical response. However, in a study by Mega *et al*[166] homozygotes and heterozygotes for loss of functional allele had similar rates of primary efficacy outcomes. At this time routine testing for CYP2C19*2 polymorphisms is not indicated. Further studies are needed to fully understand the clinical risk associated with these polymorphisms and to develop effective treatment strategies.

Proton-pump inhibitors, such as omeprazole, have been shown to interfere with clopidogrel metabolism resulting in decreased antiplatelet effect[167]. However, this does not lead to worse clinical outcomes[168]. At this time there is no strong evidence to avoid concomitant use of PPIs, when clinically indicated, in patients receiving clopidogrel.

Prasugrel

Prasugrel is a thienopyridine class of drug that competively antagonizes the P2Y12 receptor. Similar to Clopidogrel, it is also a pro drug that requires biologic conversion to an active metabolites. In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel trial[169] 13608 patients with moderate-to-high-risk acute coronary syndromes treated with early invasive approach were randomly assigned to prasugrel, with a 60-mg loading dose and a 10-mg daily maintenance dose, or clopidogrel, with a 300-mg loading dose and a 75-mg daily maintenance dose, for 6 to 15 mo. The primary efficacy end-point of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke occurred in 12.1% of patients receiving clopidogrel and 9.9% of patients receiving prasugrel (P < 0.001). There was significant reductions in the rates of myocardial infarction (9.7% for clopidogrel *vs* 7.4% for prasugrel; P < 0.001), urgent target-vessel revascularization (3.7% *vs* 2.5%; P < 0.001), and stent thrombosis (2.4% *vs* 1.1%; P < 0.001). Major bleeding was increased with prasugrel 2.4% in comparison with 1.8% of patients with clopidogrel (P = 0.03). The prasugrel group had higher rates of life-threatening bleeding (1.4% *vs* 0.9%; P = 0.01), including nonfatal bleeding (P = 0.23) and fatal bleeding (0.4% *vs* 0.1%; P = 0.002). While prasugrel significantly reduced the rates of ischemic events and stent thrombosis, it increased the risk of major bleeding and did not reduce mortality. The benefits of prasugrel must be carefully weighed against the increased risk of bleeding. Prasugrel may be a preferred agent in younger, high risk acute coronary syndrome patients with large area of myocardium at risk and low bleeding risk. Prasugrel should not be used in patients with history of prior stroke, transient ischemic attacks, age greater than or equal 75, or body weight less than 60 kg. A lower dose of prasugrel 5 mg once daily has been suggested in patients who are at higher risk for bleeding. However, prasugrel 5 mg/d has not been prospectively studied.

Ticagrelor

Ticagrelor is a cyclopentyl triazolo pyrimidine that acts on the platelet P_2Y_{12} receptor as an antagonist. It does not require conversion to active metabolite and is a reversible agent. In The Study of Platelet Inhibition and Patient Outcomes trail[170] 18624 patients with acute coronary syndromes, were randomized to ticagrelor (180-mg loading dose, followed by 90 mg twice daily) or clopidogrel (300-to-600-mg loading dose, followed by 75 mg daily). Thirty-five percent of the patients had STEMI. Overall, at 12 mo, the composite end-point of death from vascular causes, myocardial infarction, or stroke occurred in 9.8% of patients receiving ticagrelor *vs* 11.7% of patients receiving clopidogrel (P < 0.001). The rate of death from any cause was also reduced with ticagrelor (4.5% *vs* 5.9%, P < 0.001). In addition, there were reductions in the rates of myocardial infarction (5.8% in the ticagrelor group *vs* 6.9% in the clopidogrel group, P = 0.005) and death from vascular causes (4.0% *vs* 5.1%, P = 0.001). There was no difference in the frequency of stroke alone (1.5% *vs* 1.3%, P = 0.22) or the rates of major bleeding (11.6% and 11.2%, P = 0.43). However, ticagrelor was associated with a higher rate of major non CABG related bleeding (4.5% *vs* 3.8%, P = 0.03), including more instances of fatal intracranial bleeding.

In a pre-specified subgroup analysis of the Study of Platelet Inhibition and Patient Outcomes trail, the net benefit of ticagrelor was smaller in the North American cohort. This was attributed to chance alone or alternatively to the frequent use of higher dose of aspirin

for maintenance therapy. Based on this observation, the dose of aspirin when used in combination with ticagrelor for maintenance therapy should not exceed 100 mg a day.

When considering adding a second drug to aspirin for dual antiplatelet therapy (DAPT), the decision should be individualized. The anti-ischemic benefits should be carefully weighed against patient comorbidities, risk of bleeding, need for long term treatment with an oral anticoagulant, cost, compliance, and the possibility of surgical procedures during the following year.

DURATION OF ANTIPLATELET THERAPY

Current guidelines[171] support uninterrupted use of dual antiplatelet therapy for at least one year in post ACS patients regardless of invasive or conservative treatment or the type of stent (BMS *vs* DES). Recently, there has been significant data supporting the discontinuation of dual antiplatelet therapy 3 to 6 mo after a PCI in the setting of acute coronary syndrome.

In the Efficacy of Xience/Promus *vs* Cypher in Reducing Late Loss after Stenting trail[172] 1443 patients undergoing implantation of drug-eluting stents were randomized to receive 6- or 12-mo DAPT. The primary end point of target vessel failure at 12 mo was 4.8% in the 6-mo DAPT group and 4.3% in the 12-mo DAPT group (P = 0.001 for non-inferiority). This study was underpowered for evaluation of death and MI.

In the Prolonging dual antiplatelet treatment after grading stent-induced intimal hyperplasia trial[173] 2013 patients were randomly assigned to receive bare-metal, zotarolimus-eluting, paclitaxel-eluting, or everolimus-eluting stent implantation. At 30 d, patients in each stent group were randomly allocated to receive up to 6 or 24 mo of clopidogrel therapy in addition to aspirin. The primary composite endpoint of death from any cause, myocardial infarction, or cerebrovascular accident at 24 mo was similar.

In the Real Safety and Efficacy of a 3-mo dual antiplatelet Therapy following E-ZES Implantation trail[174], 2117 patients with coronary artery stenosis were randomized to 2 groups according to DAPT duration and stent type: 3-mo DAPT following zotarolimus-eluting stent (E-ZES) implantation *vs* 12-mo DAPT following the other (sirolimus, everolimus DES implantation). The primary composite endpoint of cardiovascular death, myocardial infarction, stent thrombosis, target vessel revascularization, or bleeding at 1 year occurred in 4.7% patients assigned to E-ZES + 3-mo DAPT compared with 4.7% patients assigned to the standard therapy (P = 0.001 for noninferiority).

In the recently published Optimized Duration of Clopidogrel Therapy Following Treatment With the Endeavor Zotarolimus - Eluting Stent in the Real World Clinical Practice trail[175], 3119 patients undergoing PCI using zotarolimus DES were randomly assigned to 3 mo *vs* 12 mo of dual antiplatelet therapy. The primary composite end point of all-cause death, myocardial infarction, stroke, or major bleeding occurred in 6.0% *vs* 5.8%, respectively P = 0.002 for noninferiority.

Although the data from these trials is reassuring and supports the discontinuation of dual anti-platelet therapy at the end of 6 mo, it is important to note that these trial included patients with stable coronary disease and low risk acute coronary syndrome. Caution should be used in extrapolating this data to patients with STEMI. At this time, dual anti-platelet therapy should be continued for at least one year without interruption when tolerated in patients with ACS.

Role of glycoprotein IIb/IIIa receptor antagonists

Role of glycoprotein Ⅱb/Ⅲa (GP Ⅱb/Ⅲa) receptor antagonists in the setting of STEMI was extensively studied prior to routine use of dual antiplatelet therapy. Addition of a GP Ⅱb/Ⅲa receptor antagonist to combination of DAPT plus unfractionated heparin or bivalirudin failed to show benefit[176-178]. However, in a meta-analysis by De Luca[179] where 722 patients with STEMI from seven randomized trials were included, early administration of abciximab compared to late/peri-procedural administration was associated with reduction in mortality (20% *vs* 24.6% P = 0.02), improvement in pre-procedural (TIMI) 3 flow (21.6% *vs* 10.1%, P < 0.0001), post-procedural TIMI 3 flow (90% *vs* 84.8%, P = 0.04), post-procedural myocardial blush grade (52.0% *vs* 43.2%, P = 0.03), ST-segment resolution (58.4% *vs* 43.5%, P < 0.0001) and distal embolization (10.1% *vs* 16.2%, P = 0.02). There was no difference in the rates of major bleeding complications between early and late abciximab administration (3.3% *vs* 2.3%, P = 0.4). Adjunctive use of GP Ⅱb/Ⅲa inhibitors can be considered at the time P-PCI if there is evidence of large thrombus or inadequate response to a P_2Y_{12} antagonist[179,180]. Based on the data from the HORIZONS-AMI[158] and CICERO[181] trials, a GP Ⅱb/Ⅲa receptor antagonist can be used as adjunct to bivalirudin in the presence of large thrombus or for "bail-out use" for procedure related dissection. Similar findings were also confirmed in a recent meta-analysis by Shimada *et al*[182]. In a recent MI trail[183], intra-coronary infusion of abciximab reduced infarct size at 30 d. This approach should be considered on an individual patient basis[182,183].

ROLE OF CARDIOPROTECTION IN STEMI

Despite significant improvements in every area of STEMI management, adverse event rates continue to be high. Although, reperfusion therapy and the adjunctive pharmacotherapy help reestablish coronary flow, restoration of coronary blood flow can cause further injury to cardiac myocytes. This type of injury is called lethal reperfusion injury. In animal models, close to 50% of the final infarct size is due to lethal reperfusion injury[184]. This injury results from oxidative stress[185,186], calcium overload[187,188], inflammation[189] and rapid restoration of pH[189]. Understanding these

mechanisms at a cellular level has led to renewed interest in designing treatment strategies that target pathways that mediate lethal reperfusion injury. These strategies mediate their cardioprotective effect by multiple signaling pathways such as reperfusion injury salvage kinase (RISK) group of protective kinases. The cardioprotective signaling pathways inhibit the mitochondrial permeability transition pore and multiple other molecules[190].

PRECONDITIONING

Repeated, brief episodes of coronary occlusion with myocardial ischemia alternating with coronary reperfusion before a prolonged episode of ischemia, is a powerful way to limit infarct size. This is known as ischemic pre-conditioning[191]. However due to the fact that the brief episodes of ischemia need to be applied prior to an ischemic event, this approach has limited value in the setting of STEMI.

POST CONDITIONING

Applying the principles of preconditioning after the ischemic event has been shown to be beneficial in animal models[192,193]. In a small randomized control trial, Staat *et al*[194] showed that post-conditioning by 4 cycles of 1-min coronary angioplasty balloon inflations followed by 1 min of balloon deflation within 1 min of coronary reflow after deployment of a coronary stent reduced infarct size and improved myocardial blush grades. Similar findings have also been noted in other small studies that used different balloon inflation and deflation protocols[195]. A significant limitation of catheter/balloon based post-conditioning is that it is limited to cardiac catheterization laboratories at the time of P-PCI.

Post conditioning by cyclosporine

Cyclosporine has been shown to be cardioprotective by inhibiting the mitochondrial permeability transition pore[196]. In a small randomized study of 58 patients, single bolus of 2.5 milligrams of intravenous cyclosporine, compared to placebo reduced infarct size by 40% as quantified by the degree of plasma creatine-kinase elevation[197]. The cardioprotective effect of cyclosporine appears to be promising.

REMOTE ISCHEMIC CONDITIONING

Transient, repeated episodes of ischemia when applied to an organ distant from the heart have been shown to reduce infarct size[198]. This is called remote ischemic conditioning. One proposed mechanism is the release of a chemical by the distant organ that promotes cardiac conditioning. Another possibility is afferent neural pathway stimulation. In a study by Bøtker *et al*[199], 333 patients with a suspected first STEMI were randomly assigned in a 1:1 ratio to receive P-PCI with or without remote conditioning that consisted of intermittent arm ischemia through four cycles of 5-min inflation and 5-min deflation of a blood-pressure cuff. The patients received remote conditioning during transport to hospital, and P-PCI in hospital. The primary endpoint of myocardial salvage index at 30 d, measured by myocardial perfusion imaging, was significantly improved in the preconditioning group (0.75 in the remote conditioning group *vs* 0.55 in the control group, $P = 0.0333$). Given the ease of use and potential universal applicability of this approach, large-scale trials are underway to study this treatment.

ROLE OF ADENOSINE

Adenosine, by mediating its effects *via* A_1 and A_3 receptors appears to play a key role in promoting a cardioprotective a state. Although the mechanisms are complex, inhibition of the formation of mitochondrial permeability transition pores appears to be a primary mechanism[200]. Intravenous infusion of adenosine in patients with STEMI was tested in the Acute Myocardial Infarction Study of Adenosine Ⅰ trail[201]. Although there was 33% relative reduction in the infarct size, this was mostly limited to individuals with large anterior wall MI. Based on this study, the Acute Myocardial Infarction Study of Adenosine Ⅱ trail[202] randomized 2118 patients to 3-h intravenous infusion of low-dose adenosine (50 μg/kg per minute), high-dose adenosine (70 μg/kg per minute), or placebo before PCI or within 15 min of the initiation of fibrinolysis. There was no difference in the composite endpoint of death, new-onset congestive heart failure, or rehospitalization for congestive heart failure within 6 mo. However, subsequent post-hoc and subgroup analyses showed that there was significant reduction in the infarct size in those who received the high dose and those who received adenosine within 3 h of onset of symptoms[203]. Although the routine use of adenosine is currently not supported, early administration of high dose adenosine may reduce infarct size in patients with anterior wall STEMI with large areas of myocardium at risk.

ROLE OF BETA BLOCKERS

Most of the data on the role of routine use of beta blockers in STEMI either predates or involves thrombolytic therapy. There is very limited data on the cardioprotective benefits of beta blockers in the setting of PPCI. In the recently published Effect of Metoprolol in Cardioprotection during an Acute Myocardial Infarction trail[204], 270 patients with STEMI (Killip Class 2 or less) presenting within 6 h of onset of symptoms were randomized to receive intravenous metoprolol or no metoprolol. The primary endpoint of infarct size by magnetic resonance imaging was smaller after intravenous metoprolol compared with control (25.6

± 15.3 gm *vs* 32.0 ± 22.2 gm, *P* = 0.012). This trail illustrates that a commonly used inexpensive medication may play a significant role in cardioprotection in the setting of reperfusion by P-PCI for STEMI. Larger clinical trials that are powered to analyze hard clinical endpoints are needed to definitively understand the role of intravenous beta blockers in the setting of P-PCI.

The ideal duration of treatment with beta blockers after a STEMI is not well established. At the present time most patients are treated indefinitely with beta blockers after a STEMI. This is mostly based on evidence from a large meta-analysis that included 50000 patients and showed a 23% reduction in mortality at a mean follow up of 1.4 years[205]. Lower rates of reperfusion, suboptimal utilization of medical therapy, and short duration of follow up limit this data.

In a recent meta-analysis by Bangalore *et al*[206], that included 21000 patients with mean follow up of 44 mo, the primary composite outcome of cardiovascular death, nonfatal MI, or nonfatal stroke in post myocardial infarction patients were not significantly different the group that was treated with β-blockers compared with those who were not. (16.93% *vs* 18.60% respectively, *P* = 0.14). At the present time, the data on duration of therapy with beta blockers after an MI in inconclusive. In patients with preserved left ventricular ejection fraction and without any evidence of arrhythmias and ischemia, beta blockers can most likely be stopped after one year.

ROLE OF ATRIAL NATRIURETIC PEPTIDES

The cardioptotective effects of atrial natriuretic peptides (ANP) was tested in the Human Atrial Natriuretic Peptide and Nicorandil as Adjunts to Reperfusion Treatment trail[207]. Following reperfusion by either PCI or fibrinolytic therapy, 569 patients with STEMI were randomized to receive a continuous infusion of ANP or placebo for 3 d. Compared to placebo, there was 14.7% reduction in infarct size by area under the curve for total creatine kinase. ANP infusion was also associated improved ejection fraction at 6 to 12 mo compared with controls (44.7% *vs* 42.5%). Over a median follow-up time of 2.7 years, cardiac death and rates of hospitalization were also reduced in the ANP group. Further large-scale studies are needed to fully understand the cardioprotective role of ANP.

ROLE OF HYPOTHERMIA

In animal models, moderate hypothermia (28 ℃-32 ℃) offers cardioprotection by altering signaling pathways[208]. The Cooling as an Adjunctive Therapy to Percutaneous Intervention in Patients With Acute Myocardial Infarction trail[209] failed to show overall statistically significant reduction in infarct size. However, in patients with large anterior STEMI who were cooled to temperatures of less than 35 ℃ prior to reperfusion there was a reduction in the infarct size (9.3% in treated patients *vs* 18.2% in controls; *P* = 0.05).

The Rapid Cooling by Cold Saline and Endovascular Cooling before Reperfusion in patients with ST-elevation Myocardial Infarction trail[210] randomized 20 patients with STEMI undergoing P-PCI to rapid hypothermia by an endovascular catheter or standard therapy. Temperatures < 35 ℃ were obtained in all hypothermia patients prior to reperfusion. The primary end point of infarct size by cardiac MRI was reduced by 38% in the hypothermia group.

However, in the CHILL-MI[211] trail, hypothermia resulted in only a trend towards reduction in infarct size in patients who presented within 4 h of symptoms onset and were cooled to 33 ℃ large scale randomized trials are needed to determine if hypothermia during or immediately prior to P-PCI will result in significant reductions in infarct size and clinical endpoints.

STEM CELLS IN THE TREATMENT OF ACUTE MYOCARDIAL INFARCTION

Because atherosclerotic coronary vascular disease is the major cause of death in the United States and has recently become a major cause of death throughout the world, stem cell therapy is being investigated in patients with acute myocardial infarction (AMI) to limit myocardial damage and possibly regenerate myocardium[212-214]. Two populations of stem cells have been examined in patients with myocardial infarctions and/or ischemic cardiomyopathies: adult bone marrow mononuclear cells and cardiac stem cells. Adult bone marrow mononuclear cells from bone marrow aspirates contain approximately 0.5%-3% hematopoietic and mesenchymal "progenitor" cells that secrete growth factors and cytokines that can limit myocardial inflammation and infarct size. These cells have limited ability to replicate, do not trans-differentiate into myocytes, but can chemoattract endogenous patient stem cells for repair of cardiac injury. Cardiac stem cells are specific undifferentiated progenitor cells found in the right atrial appendage and the ventricular apices of the heart that have paracrine effects, can chemoattract patient stem cells, and may transdifferentiate into myocytes for cardiac repair.

The initial ten year experience with autologous human bone marrow mononuclear cells (BMCs) in the treatment of patients with AMIs showed significant approximately 2%-3% (range 1.9%-5.4%) increases in left ventricular ejection fraction (LVEF), decreases in left ventricular end-systolic volume of -4.8 mL (range -1.4 to -8.2 mL) and reductions in myocardial infarction size of approximately 5.5% (-1.9% to -9.1%)[213,214]. These studies established that the direct intramyocardial or intracoronary administration of bone marrow mononuclear cells was safe and that significant side effects did not occur with administration of these

cells[213-214], see Tables 5 and 6[215-237]. However many of the initial clinical bone marrow cell studies consisted of small numbers of patients and not all the studies randomized patients to treatment with either bone marrow mononuclear cells or placebo (Tables 5 and 6)[215-237].

Since the initial treatment of patients with AMIs with BMCs, major questions have persisted about the use of these cells: what is the optimal cell for AMI treatment; when is the optimal time to inject cells for treatment; what is the viability of the stem cells prior to injection into patients; what is the best parameter to monitor cardiac patients after stem cell treatment. The LateTIME, the TIME, and the Swiss Myocardial Infarction Trials were multi-center trials that addressed the questions whether adult BMCs limit myocardial damage in comparison with patients treated with placebo and what is the optimal time of cell administration after AMIs.

LATETIME TRIAL

The LateTIME trial was a randomized double blind, placebo-controlled trial designed to determine if delivery of adult BMCs two to 3 wk after primarily anterior wall myocardial infarction would be safe and effective in limiting infarct size and improving left ventricular (LV) function[238]. All patients in this study were successfully treated initially with primary percutaneous coronary intervention (PCI) within a median time of 4 h after the onset of chest pain. Bone marrow mononuclear cells were isolated from bone marrow aspirates in each center with a closed, automated system (Sepax, Biosafe). The Infarct volume and LV global and regional LV function were measured by magnetic resonance imaging (MRI) with gadolinium prior to intracoronary injection and 6 mo after injection. The LVEF prior to intracoronary infusion of cells or placebo in 87 AMI patients averaged 48.7% in the bone marrow cell (BMC) group and 45.3% in the placebo group. 150 × 10^6 autologous BMCs or placebo were infused in 87 patients. The changes between baseline and 6 mo in the BMC group for infarct volume, LVEF, wall motion in the infarct zone, and wall motion in the border zone of the infarction were not statistically different from the placebo group[238].

TIME TRIAL

The TIME Trial was a double-blind, placebo controlled trial that investigated the intracoronary administration of autologous BMCs or placebo in 120 patients three or seven days after primarily anterior AMI[239]. The TIME Trial was based on the REPAIR AMI trial that reported that delivery of BMCs to patients 5 to 7 d after AMI resulted in a 5.1% absolute increase in LVEF[239,240].

All patients had successful coronary reperfusion with coronary angioplasty within a median time of 3-4 h of the onset of ischemic symptoms. The mean LVEF in these patients was $\leqslant$ 45% by echocardiography. The mean time from PCI to bone marrow aspiration and cell processing was 3.3 d in the day 3 group and 7.4 d in the day 7 group. Bone marrow mononuclear cells were isolated in each center with a closed, automated system (Sepax, Biosafe) and the cells or placebo were infused into the coronary arteries within 12 h of aspiration and cell processing. The BMC contained 2.3% CD34 and 1.1% CD34 plus CD131 hematopoietic cells. All patients had baseline cardiac MRIs with gadolinium at day 3 or at day 7 after AMI and the MRIs were repeated at 6 mo after the AMI.

Forty-three patients received BMCs on day 3 and 36 patients received bone marrow cells on day 7 after AMI. Each patient received approximately 147 × 10^6 BMCs within 12 h of aspiration and cell processing. Forty-one patients received a placebo. The median time from bone marrow aspiration to infusion directly into the infarct related coronary artery was 8.3 h. In addition, all patients received heparin during the procedure as well as aspirin and clopidogrel.

The differences between the BMC treatment and the placebo treatment in the 3 d group and in the 7 d group were not significant. When both BMC groups were combined (n = 75) to include patients with MRI measurements at baseline and 6 mo and compared with the combined placebo group (n = 37), LVEF in the BMC group increased from 45.2% at baseline to 48.3% at 6 mo while in the combined placebo group the LVEF increased from 44.5% to 47.8% (P = NS). Moreover, there was no significant difference between the changes in regional wall motion in the infarct zone and the border zone between BMC and placebo groups. Infarct volumes uniformly decreased in both groups but the differences between groups were not statistically significant. No difference was observed in global or regional function in patients stratified by myocardial ischemic time.

SWISS MULTICENTER INTRACORONARY STEM CELL STUDY IN ACUTE MYOCARDIAL INFARCTION TRIAL

The Swiss Study[241] randomized patients with AMIs with LVEF < 45% as measured by ventriculography or echocardiography, who had been successfully treated with PCI of the infarct related artery within a median of 5 h of onset of chest pain, to either the intracoronary administration of 140-160 million autologous BMCs at a median of 6 d after AMI (early group, n = 58) or at a median of 24 d after AMI (late group, n = 49) or to a placebo group (n = 60). Ninety-two percent of the patients had anterior wall infarctions. Bone marrow aspirates were performed only in patients assigned to the BMC treatment. Each 10 mL aspirate was treated with 1000 IU Heparin to prevent clot formation. The

NR: Not recorded or equals no change; CPC: Circulating progenitor cells; BMC: Bone marrow cells; ICM: Ischemic cardiomyopathy; IC: Intracoronary injection; IM: Intramyocardial injection; AMI: Acute myocardial infarction; OMI: Old myocardial infarction; G-CSF: Granulocyte colony stimulating factor; ESV: LV end-systolic volume; SPECT: Single photon emission computer tomography. Adapted from Henning[213].

BMCs were isolated by density gradient centrifugation at a centralized processing facility and contained 1% to 1.3% $CD34^+$ hematopoietic cells. However, the median percentage of mononuclear cells that exhibit migration capacity was only 29%[241].

Cardiac magnetic resonance imaging with gadolinium was performed on patients at baseline prior to cell infusion and at 4 mo after the injection of BMCs into the infarct-related coronary artery and were compared with MRIs of control patients treated with best medical care. At 4 mo after coronary infusion, there were no significant differences in infarct scar size or LV myocardial wall thickening in patients treated with BMCs at either 5-7 d or 3-4 wk after AMI in comparison with control patients. Moreover, LV function did not significantly improve at 4 mo after the intracoronary infusion of autologous BMCs in either the early or late treated groups in comparison with the placebo group.

Adapted from Henning[213]. MI: Myocardial infarctions; LVEF: Left ventricular ejection fraction.

However, patients with NT-proBNP levels at baseline above 1437 ng/L experienced a greater increase in LVEF of 7.1% in the early group and 9% for the late BMC group. In all cell and placebo treatment groups, LV scar as determined by late gadolinium enhancement on MRI decreased by more than 10 g with a 4%-5% decrease in the ratio of myocardial scar to myocardial mass.

ASSESSMENT OF LATETIME, TIME, AND SWISS TRIALS

Several variables in these studies contributed to the lack of significant improvement of AMI patients treated with BMCs in comparison with placebo treated patients.

Early percutaneous coronary intervention

Patients with AMIs in the LateTIME, TIME, and Swiss Multicenter Trials were treated with PCI within a median of 4 to 5 h of the onset of chest pain. Thereafter, the patients were treated with American and European Heart Association guided best medical therapy. Consequently, AMI sizes and the extent of LV remodeling in the different trial patients were significantly limited and the differences between BMC treated patients and placebo treated patients were small. Although the initial qualifying LV ejection fractions by echocardiography after PCI in the LateTIME and TIME trial patients were ⩽ 45%, the LVEFs by MRI at the time of BMC injection were greater than 45%. Bone marrow mononuclear cells are much less effective in patients with small myocardial infarctions with near normal LVEFs. In addition, placebo treated patients continue to improve with best medical therapy after AMIs as demonstrated by the control patients in the Bone Marrow Transfer to Enhance ST-elevation Infarct Regeneration (BOOST) trial in which the LVEFs equaled or exceeded the increases in the LVEFs in the BMC treated patients at 18 mo after AMI[242]. In addition, the Valsartan in Acute Myocardial infarction Trial and trials of neuro-hormonal blockade of patients with AMIs have demonstrated that optimal medical therapy can increase LVEF by a mean of 2.7% at 20 mo[243]. Consequently much larger numbers of patients will be required in clinical trials to demonstrate statistically significant differences between BMC treated patients and placebo treated patients who receive PCI early after the onset of AMI and guideline directed optimal medical therapy.

Heterogeneous bone marrow cell populations

Unfractionated adult BMCs contain less than 3% $CD34^+$ and 1% $CD34^+/CD133^+$ hematopoietic progenitor cells and ⩽ 1% $CD105^+$ mesenchymal stem cells in healthy subjects when marrow cells are separated by Ficoll density gradient-based separation. However, both $CD34^+$ endothelial colony number and the mesenchymal cell colony number were significantly decreased amongst subjects that participated in the LateTime and Time Trials[244]. In addition, the marrow aspirates in the LateTIME and TIME Trials were separated by an automated cell process system (Sepax, Biosafe), which recovered only 23.6% of the total nucleated cells[245]. Consequently, the BMCs delivered in the LateTIME and TIME trials contained smaller numbers of $CD34^+$ and $CD105^+$ cells than earlier BMC studies. Moreover, stem cell motility can decline by as much as 68% 72 h after harvest from the bone marrow[246]. In addition, 140-150 × 10^6 unfractionated BMCs may not be the most optimal dose of BMCs for stem cell treatment of patients with AMI. In this regard, BMCs from patients with advanced age and patients with chronic diseases, such as ischemic heart disease or diabetes mellitus, are often functionally impaired, propagate poorly,

and have a shortened life span[246-248]. Consequently, BMC colony forming units and cell migration capability must be determined in addition to bone marrow cell number and viability prior to use in the treatment of AMI. Furthermore, BMCs produced only a modest increase in the LVEF of approximately 2%-3% in earlier analyses of stem cell trials of patients with AMIs or ischemic cardiomyopathies[213,214]. Despite well conducted clinical trials, unfractionated BMCs selectively infused into an infarct related coronary artery have a small therapeutic effect and may not be the most optimal cells for the treatment of patients with AMIs.

Red blood cell contamination of stem cells

Red blood cell contamination of bone marrow mononuclear cells can significantly decrease the migration ability and the efficacy of BMCs. Large numbers of red blood cells in the cell preparations cause reduced BMC viability, decreased colony forming capacity, and are associated with reduced recovery of LVEF in patients with AMIs[249]. In patients in the REPAIR-AMI Trial, contamination of the bone marrow cells with red blood cells prior to infusion into patients with AMI independently predicted reduced recovery of LVEF[249]. Moreover, the addition of red blood cells to BMCs dose-dependently decreased neovascularization in ischemic hind-limbs compared to treatment with BMCs without red blood cells[249]. The mechanism by which red blood cells interfere with bone marrow cell propagation, migration and neovascularization involves a dose-dependent reduction of BMC mitochondrial membrane potential and a decrease in BMC mitochondrial adenosine triphosphate (ATP) production[249]. As a consequence of decreased mitochondrial metabolism and function, stem cell self-renewal and differentiation are decreased.

Heparin decreases stem cell migration

Heparin can bind to the chemoattractant stromal derived factor-1 (SDF-1), which is released from ischemic myocardium, and also bind to its receptor CXCR4 on stem cells and thereby block CXCR4 signaling and stem cell migration to injured myocardium[250]. Heparin, in a dose-dependent manner, can inhibit SDF-1 induced BMC migration and homing of BMCs to areas of myocardial ischemia[250-253]. Incubation of BMCs with 20 U/mL of heparin for 30 min abrogates SDF-1 BMC migration by 84% *in-vitro* and significantly reduces the homing of injected BMCs to injured and infarcted myocardium by 50% in research animals[250]. Decreased migratory capacity of BMCs also correlates with reduced neovascularization and decreased functional capacity in subjects with limb ischemia[251]. In addition, heparin decreases the concentration of vascular endothelial growth factor (VEGF) in ischemic tissue and thereby decreases neovascularization[252]. Heparin also interferes with activation of the cell survival factor Akt (Protein Kinase B) by SDF-1-CXCR4 signaling and in this manner interferes with cell survival and growth. In contrast, the thrombin inhibitor bivalirudin does not interfere with BMC homing or SDF-1/CXCR4 signaling and does not decrease VEGF[252].

Stem cell expulsion from myocardium

Ninety to 97% of unfractionated BMCs leave the myocardium in less than 2 h after injection directly into the myocardium or into the coronary arteries[254,255]. Most of the cells are ejected out of the myocardium through the myocardial injection sites or through the coronary veins and lymphatics into the right heart due to the massaging action of the contracting myocardium. The cells are ultimately lodged in the lungs, liver, spleen and kidneys. In addition, approximately 12% of BMCs are retained in the catheter delivery system after injection[255]. With the intravenous injection of BMCs or other cells for cardiac repair the majority of the cells become entrapped in the lungs. Consequently, fourfold greater numbers of cells are required above that required for intramyocardial or intracoronary injection for repair of myocardial infarctions[256].

Future bone marrow cell studies

The BAMI Trial (The effect of intracoronary reinfusion of bone marrow derived mononuclear cells on all-cause mortality in acute myocardial infarction) is recruiting 3000 patients with LVEFs $\leqslant$ 45% within 7 d of AMIs, who have undergone successful coronary reperfusion therapy, for randomization into treatment with either intracoronary autologous unfractionated bone marrow mononuclear cells or placebo[257]. Hopefully the BAMI Trial will avoid the important variables that have been described in this paper and will provide definitive answers to the questions whether BMCs can significantly decrease patient mortality due to myocardial infarction, substantially reduce infarct size and increase LVEF over three years in comparison with patients treated with best medical therapy.

CARDIAC STEM CELLS

Cardiovascular investigators have sought alternatives to BMCs for cardiac repair in patients with ischemic heart disease. Cardiac stem cells, which are multi-potent progenitor cells, are present in niches in the heart and contribute to the physiological turnover of myocytes and vascular endothelial cells in the heart. The number of cardiac stem cells in the heart is estimated at one cardiac stem cell per 10000 cardiac myocytes[258]. Consequently, endogenous cardiac stem cells are not normally able to reverse heart damage due to myocardial infarctions. The turnover of cardiac myocytes occurs at rates estimated to be 1% to as much as 22% per year and is dependent on the age, sex, and the health of the individual[259,260]. Two major types of autologous cardiac stem cells have been investigated in patients with injured and infarcted myocardium in the SCIPIO and CADUCEUS clinical trials: C-kit + lineage negative cardiac stem cells

isolated from right atrial appendages and cardiosphere derived cells (CDCs) grown from right ventricular cardiac muscle biopsies.

C-KIT + STEM CELLS

C-kit is a receptor for stem cell factor, which is released from the ischemic myocardium, and is important in the chemoattraction of stem cells to apoptotic, injured and necrotic myocardium. C-kit + stem cells have the capacity for self-renewal, clonogenicity and multi-potency[261,262]. These stem cells can express the cardiac transcription factors GATA-4, Nkx2.5 and MEF2 and can differentiate into myogenic, vascular endothelial and smooth muscles cells *in-vitro*[261,262]. In research animals with AMIs, cardiac stem cells can form new myocardium[262].

Autologous C-kit cardiac stem cells from right atrial appendages have recently been used for the treatment of patients with myocardial infarctions and ischemic cardiomyopathies in the open labeled Cardiac Stem Cell Infusion in Patients with Ischemic Cardiomyopathy (SCIPIO) Trial[263-265]. In this trial C-kit positive stem cells were isolated during coronary artery bypass surgery from the right atrial appendages of patients with LVEFs < 40%. The cells were then propagated in the laboratory. Four mo later, a maximum of one million cardiac stem cells were injected directly into the patient's saphenous vein grafts and coronary arteries supplying infarcted myocardium. The two year results of this trial have been presented at the American Heart Association Scientific Sessions in November of 2012 and 2013. In the SCIPIO trial the LVEF, measured by three-dimensional echocardiography and by MRI with gadolinium in patients who received cardiac stem cells, increased in 12 patients in absolute units by 11.9% at 2 years[265]. Left ventricular scar, determined by MRI, decreased by as much as 20.4 g at 2 years (n = 6) and was associated with an increase in viable myocardium of 17.9 g (n = 6) at 2 years[265]. New York Heart Association Functional Class score decreased in these patients by 0.77 at 2 years (n = 13). A left internal mammary graft dissection occurred in one treated patient, which was treated with a graft stent, and a peri-procedural myocardial infarction occurred in a second treated patient[264]. In this study, C-kit cardiac stem cells were proposed to chemoattract patients' native stem cells to areas of myocardial injury and also to transdifferentiate to myocytes for cardiac repair. A Phase 2 trial of safety and efficacy of C-kit cardiac stem cells in a larger group of patients is currently being planned.

CARDIOSPHERE DERIVED CELLS

Percutaneous endomyocardial biopsy specimens of the right ventricular septal wall and apex in patients, when grown in culture, can yield spherical multicellular clusters termed "cardiospheres". Cardiospheres are a mixture of stromal, mesenchymal and hematopoietic progenitor cells that contain cells that express CD 105 (commonly associated with mesenchymal stem cells) and partially express C-kit[266,267]. Cardiosphere derived cells (CDCs), when injected into the border of myocardial infarctions in mice, engraft and increase viable myocardium[268]. The functional benefit of CDCs is predominantly due to the secretion of growth factors and the recruitment of endogenous stem cells to injured and infarcted myocardium for myocyte generation. In this regard, cardiospheres and CDCs secrete the growth factors angiopoietin-2, basic fibroblastic growth factor, hepatocyte growth factor, insulin-like growth factor 1, stromal derived factor-1 and vascular endothelial growth factor which are beneficial in repair of injured myocardium[267,268].

Autologous CDCs have been investigated in the open labeled Cardiosphere-derived Autologous Stem Cells to Reverse Ventricular Dysfunction (CADUCEUS) Trial[269,270]. In this trial, 17 patients, post myocardial infarction with LVEFs of 25%-45%, underwent endo-myocardial biopsies of the right ventricular septum. Cardiosphere derived cells were obtain from cultures of the endomyocardial biopsies and the cells were propagated. In this trial, between 12.5 and 25 million CDCs were then given directly into the infarct related coronary artery of each of the 17 patients 1.5 to 3 mo after their myocardial infarctions. The one year followup of 12 of the 17 patients treated with autologous CDCs and 8 control patients have been reported[270]. Left ventricular scar by MRI significantly decreased by a mean of 11.9 g in CDC-treated patients and by 1.7 g in control patients. Left ventricular viable mass increased by a mean of 22.6 g in treated patients in comparison with 1.8 g in control patients. Left ventricular ejection fractions did not significantly increase but the regional wall function of infarcted segments did increase and correlated with the decrease in LV myocardial scar size[269,270]. Covariate statistical analysis demonstrated that the lower percentage of infused $CD90^+$ cells caused the greatest reductions in scar size in patients with large infarctions. A Phase 2 study of CDCs (ALLSTAR Trial) is currently in progress that involves allogeneic CDCs for the treatment of patients after myocardial infarction.

ASSESSMENT OF THE SCIPIO AND CADUCEUS TRIALS

In the SCIPIO trial 1545 patients were evaluated. Two hundred thirteen patients had LVEFs < 40% and 20 patients were treated with C-kit + stem cells. Twelve of 20 patients had MRI determinations of left ventricular function whereas the control patients did not have MRI determinations of left ventricular function. In the CADUCEUS Trial 436 patients were evaluated and 17 patients received CDCs. Consequently, these

trials report a highly selected patient population and the results of these trials cannot be applied to all patients with myocardial infarctions and ischemic cardiomyopathies. Much larger trials are necessary of each of these cell types in patients with myocardial infarctions.

In each of these studies, LV infarction was defined by MRI of delayed enhancement of myocardium in the region of coronary artery occlusion/reperfusion due to gadolinium that leaked from myocardial capillaries and pooled in the myocardial interstitial spaces and intracellular spaces. In these patients the gadolinium volume of distribution was increased and washout from the myocardium was reduced. However, cardiac stem cells can incorporate into damaged blood vessels, chemoattract endogenous stem cells that can form entirely new blood vessels, and can also secrete angiogenic growth factors that stimulate new blood vessels from preexisting vessels. Consequently, the blood vessels in the damaged myocardium of patients treated with these stem cells were less permeable to gadolinium[271]. Infarct scars can potentially appear smaller on MRI due to less gadolinium leak as well as contracture of the myocardial infarction. Moreover inter-scan variability and intra- and inter-observer variability in infarct measurements and interpreting MRI scans can account for some myocardial changes between pre- and post-stem cell infusion[272]. Rebuttals to these arguments against the use of contrast enhanced MRI in estimating infarct size and myocardial regeneration after stem cell treatment have been published[273]. The rebuttal is based on a porcine myocardial infarction study in which allogeneic CDCs decreased infarct scar size and led to cardiomyocyte hyperplasia on MRI and also on histological examination[273]. Nevertheless, anatomical and histological examinations of myocardial biopsies of infarcted hearts of patients or myocardial autopsy examinations of patients treated with these stem cells are necessary to determine if infarct fibrosis is significantly decreased and if substantial generation of new myocytes occurs. Trials of larger numbers of patients treated with C-kit + cardiac stem cells and cardiosphere derived cells for longer times are warranted to determine the precise mechanisms of action of these stem cells and their clinical benefit.

FUTURE DIRECTIONS

The LateTIME, TIME, Swiss, SCIPO and CAUDUCEUS Trials demonstrate that stem cells can be safely administered to patients with acute myocardial infarctions and ischemic cardiomyopathies and do not have significant adverse effects. Specific bone marrow cell subsets, such as unconditioned or conditioned mesenchymal cells or $CD34^+$ hematopoietic cells, may prove to be more efficacious in myocardial infarction repair than unfractionated BMCs[274,275]. In this regard, bone marrow mesenchymal stem cells or mesenchymal stem cells conditioned with cardiogenic growth factors have been reported to be beneficial in increasing LV function and functional capacity in patients with ischemic cardiomyopathies[275]. In addition, mesenchymal stem cells may enhance the beneficial effects of C-kit cardiac stem cells when these cells are administered together[276]. The large size of mesenchymal stem cells, however, requires that these cells be most safely delivered into the heart by direct myocardial injection rather than intracoronary injection in order to avoid problems of cell clumping and coronary occlusion. Mesenchymal stem cells and also umbilical cord stem cells are reported to be "immunoprivileged" and lack Class II human leukocyte antigens[277,278]. If allogeneic stem cells prove to be safe and effective in limiting myocardial damage and LV remodeling after myocardial infarction in patients, then these cells might become an "off the shelf" product that surpasses the significant limitations of inter-patient variability of unfractionated bone marrow mononuclear cells. Since the functional benefit of stem cells appears to be predominantly due to the secretion of biologically active factors, the ultimate rejection of allogeneic stem cells may not be of major concern if the rejection is delayed long enough to allow these cells to exert their paracrine effects. Nevertheless, stem cell trials must be performed in patients with large myocardial infarctions and LVEFs by MRI less than 40% at the time of stem cell administration because stem cells may not be efficacious in patients with small infarctions and near normal or normal LVEFs. In these studies, substantial stem cell viability, colony forming and migration capabilities must be established prior to infusion in patients.

A major problem with all stem cell trials is the short term engraftment and survival of stem cells in injured and infarcted myocardium. The cells that remain in the myocardium do not survive due to ischemia, inflammation, or anoikis or migrate from the myocardium in one to two weeks[254,255]. Consequently, stem engraftment in the heart must be increased in order to significantly enhance their beneficial effects. Possible treatment options include "conditioning" of the myocardium prior to stem cell delivery or co-delivery of stem cells directly into the myocardium with extracellular matrix molecules, nanofibers, hydrogels, or fibrin glues[213,214,279]. Co-delivery of stem cells with other molecules will require direct intramyocardial cell injection at the time of cardiac surgery or cardiac catheterization which appears to produce the greatest functional benefit[280]. Alternatively, stem cells can be administered in patches that are applied directly to the epicardial surface of the damaged myocardium at the time of cardiac surgery[213,214]. Direct stem cell to myocyte contact and interactions may be crucial in eliciting beneficial myocyte functional effects. In addition, genetic engineering of stem cells must be developed that facilitate the homing of stem cells to ischemic myocardium and the retention of the stem cells within the myocardium after intracoronary or intravenous injection.

A major mechanism of action of stem cells studied

to date in myocardial repair is the secretion of growth factors, chemokines, anti-inflammatory cytokines and exosomes or microparticles, which contain proteins, messenger ribonucleic acids and micro-ribonucleic acids. Hypoxic stress appears to increase the paracrine effects of stem cells[281,282]. Biologically active factors from stem cells can suppress inflammatory cytokines and inflammatory cells in the injured myocardium, improve myocardial metabolism, promote angiogenesis, inhibit myocyte and endothelial cell apoptosis, recruit endogenous progenitor cells to injured myocardium, and possibly stimulate surviving myocytes to re-enter the cell cycle and proliferate. The most efficacious stem cell biologically active factors must be identified, purified, and the pharmacologic effects established in research animals and ultimately in patients with injured myocardium.

Abstract

The aim of this review is to explore the role of mitochondria in regulating macrophage sterol homeostasis and inflammatory responses within the aetiology of atherosclerosis. Macrophage generation of oxysterol activators of liver X receptors (LXRs), *via* sterol 27-hydroxylase, is regulated by the rate of flux of cholesterol to the inner mitochondrial membrane, *via* a complex of cholesterol trafficking proteins. Oxysterols are key signalling molecules, regulating the transcriptional activity of LXRs which coordinate macrophage sterol metabolism and cytokine production, key features influencing the impact of these cells within atherosclerotic lesions. The precise identity of the complex of proteins mediating mitochondrial cholesterol trafficking in macrophages remains a matter of debate, but may include steroidogenic acute regulatory protein and translocator protein. There is clear evidence that targeting either of these proteins enhances removal of cholesterol *via* LXRα-dependent induction of ATP binding cassette transporters (ABCA1, ABCG1) and limits the production of inflammatory cytokines; interventions which influence mitochondrial structure and bioenergetics also impact on removal of cholesterol from macrophages. Thus, molecules which can sustain or improve mitochondrial structure, the function of the electron transport chain, or increase the activity of components of the protein complex involved in cholesterol transfer, may therefore have utility in limiting or regressing atheroma development, reducing the incidence of coronary heart disease and myocardial infarction.

Key words: Atherosclerosis; Macrophage; Cholesterol; High density lipoproteins; Apolipoproteins; ATP binding cassette transporters; Scavenger receptor B1; Mitochondria (dys)function; Sterol 27-hydroxylase; Liver X receptors

Core tip: Mitochondrial cholesterol trafficking to CYP27A1 located on the inner mitochondrial membrane regulates the formation of oxysterol ligands for liver X receptors (LXRs) in sterol-laden macrophage "foam" cells. In turn, ligation of LXRα has profound implications for sterol removal and inflammatory responses in macrophage "foam" cells, both factors which may contribute to the effective resolution of atherosclerotic lesions and reductions in the incidence of coronary heart disease and its sequelae.

INTRODUCTION

Coronary heart disease (CHD) is the major cause of morbidity and mortality worldwide, and the single largest cause of disease burden, determined according to disability-adjusted life years, the sum of life lost and years lived with disability[1,2]. Genetic factors contribute to coronary heart disease, fuelled by behavioural (smoking, physical inactivity, unhealthy diet, excess alcohol intake), metabolic (hypertension, diabetes, elevated serum cholesterol, overweight and obesity) and environmental (poverty, stress, educational status) factors[1-3].

Atherosclerosis is the primary cause of coronary heart disease characterised by chronic and unresolved inflammatory responses at sites of perturbed laminar blood flow in large and medium-sized arteries[4-6]. Activation of the arterial endothelial layer allows the accumulation of low density lipoprotein (LDL) within the intima of the vessel, where it can become modified *via* oxidation or crosslinking, triggering the recruitment of monocytes, neutrophils, lymphocytes and circulating stem cells to sites of inflammation[4-6]. Within this complex microenvironment, monocytes differentiate into macrophages which lie within a broad phenotypic spectrum, ranging from pro- (M1) to anti-inflammatory (M2)[6].

Arterial macrophages become laden with excess cholesterol and cholesteryl esters, part *via* the unregulated uptake of modified LDL by scavenger receptors (*e.g.*, CD36, CD68, LOX-1 and SR-AI/AII), and by phagocytosis of apoptotic cells, resulting in formation of "foam cells", a hallmark of early "fatty streak", developing, and unstable atherosclerotic lesions[7-10]. During the early phase of lesion development, this process may represent a protective mechanism; however, in more advanced lesions, cholesterol-laden macrophages, by releasing inflammatory cytokines and matrix metalloproteinases, contribute to chronic unresolved inflammation[10], accelerating the disease process and acute thrombotic events such as cerebrovascular stroke or myocardial infarction.

Thus, removal of cholesterol from macrophage "foam cells" may achieve successful regression and stabilisation of atheroma, and the importance of this pathway in protecting against CHD is supported by epidemiological studies in humans, and in genetically modified mice in which components of this pathway have been overexpressed or deleted. For example, HDL-cholesterol (HDL-C) emerged as an independent risk factor for cardiovascular disease in the Framingham Heart Study, offering a risk reduction of 2%-3% for each 1 mg/dL increase in HDL-C concentration[11,12]. HDL particles also possess antioxidant, anti-thrombotic and pro-fibrinolytic properties, and can counteract the chronic inflammation[13-16], proliferation of haemopoietic stem cells[17] and leucocytosis[10,18] which promote atherosclerosis. However, increasing the level of HDL-C, with niacin[19,20], fibrates[20] or dolcetrapib (dal-OUTCOMES Ⅲ trial)[20,21], does not necessarily confer protection against CHD[19-21] and in patients with systemic inflammation, coronary heart disease, chronic renal disease or diabetes, the protective properties of HDL are lost, and the particles transformed into those with pro-atherogenic potential[22-24]. Thus, it is not just the level, but the quality, composition (including levels of cargo molecules such as sphingosine-1-phosphate)[25] and function of HDL particles that are important.

Some, but not all, of the beneficial effects associated with HDL are mediated *via* the interaction of ATP binding cassette (ABC) transporters, such as ABCA1, ABCG1 and ABCG4, with apolipoproteins and HDL (Figure 1). While ABCA1 promotes efflux of cholesterol and phospholipids to lipid-poor apolipoproteins, such as apoA-I and apoE[13], ABCG1 and ABCG4 promote efflux of cholesterol, oxysterols and desmosterol to HDL[26]. Thus, these transporters together in a sequential manner to generate nascent HDL, which can then mature to HDL_3 and HDL_2 within the reverse cholesterol transport pathway in the bloodstream[25].

Both rare and common genetic variations in ABCA1 influence the levels of HDL-C[26] and risk of ischaemic heart disease (IHD). However, the association between ABCA1 variants and coronary disease seem to be independent of the plasma level of HDL-C[27]. Instead, cholesterol efflux from macrophages is strongly linked to atherosclerosis and provides a novel way of assessing cardiovascular risk that provides a greater level of prediction than HDL-C[28]. Thus the expression and activity of the ABCA1 protein, and the quality and functionality of the nascent HDL generated, may prove valuable discriminants of the risk of cardiovascular disease[29].

Importantly, macrophage ABCA1 expression and cholesterol accumulation are intrinsically linked to the inflammatory status of these cells. Excess cholesterol proves cytotoxic and pro-inflammatory if recycling *via* ABCA1 is disrupted in macrophages[30-33]. Enhanced Toll-like receptor signalling is noted in ABCA1/ABCG1 null macrophages, resulting in increased expression of pro-inflammatory genes, and free cholesterol accumulation[34], while activation of Toll-like receptors 3 and 4 represses induction of ABCA1 and reduces macrophage cholesterol efflux[35]. Conversely, interleukin-6 (IL-6) attenuates pro-inflammatory responses and stimulates efflux of cholesterol *via* ABCA1 in human macrophages[36]. In good agreement with this integrated paradigm, macrophage ABCA1 limits inflammatory responses *via* ApoA-I dependent activation of the Jak2/Stat3 pathway[37,38], while macrophage sterol

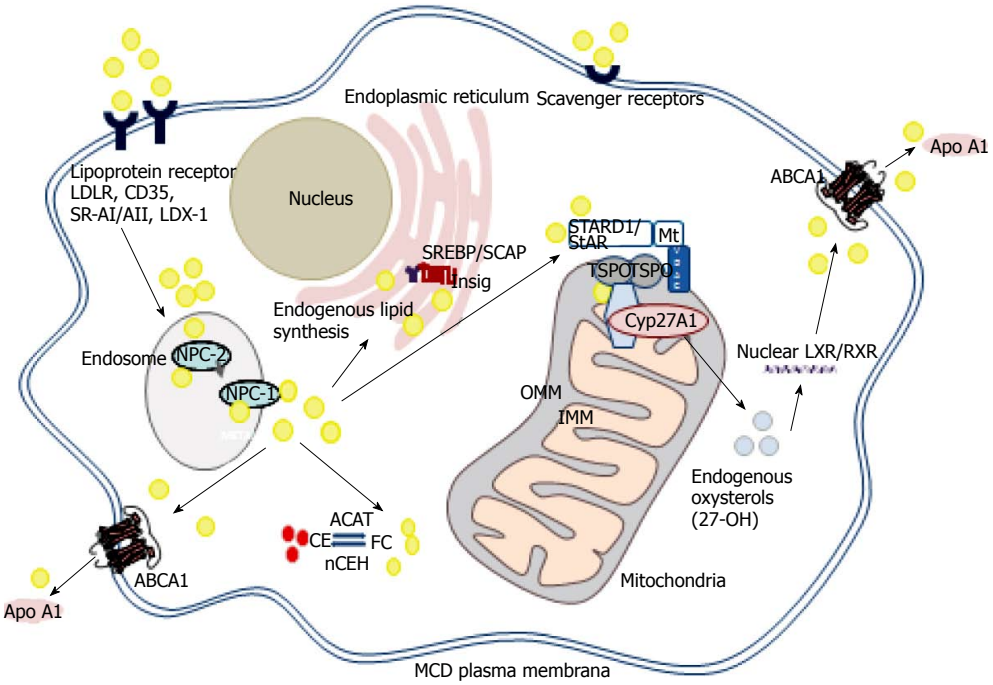

Figure 1 The role of mitochondrial cholesterol trafficking in regulation of macrophage sterol metabolism. Increased expression of steroidogenic acute regulatory protein (StAR, STARD1) or 18 kDa translocator protein (TSPO) drive cholesterol trafficking to mitochondrial sterol 27-hydroxylase (CYP27A1), enhancing endogenous production of oxysterols (24-, 25- and 27-hydroxycholesterol), in turn activating liver X receptors (LXR) and enhancing cholesterol efflux to apolipoprotein A-I (Apo AI) *via* ATP binding cassette transporter A1 (ABCA1). One current model for cholesterol transfer from the outer (OMM) to inner (IMM) mitochondrial membrane, derived from studies in steroidogenic cells, involves a complex of proteins, including StAR, TSPO, voltage-dependent anion channel (VDAC), regulatory subunits of protein kinase A (PKA-R1α), acyl CoA binding domains-1 and -3, ATPase family AAA domain-containing protein 3A (ASTAD3A) and optic atrophy type 1 proteins. Exogenous cholesterol delivered to the endocytic pathway *via* lipoprotein or scavenger receptors is transported either to the plasma membrane, enhancing cholesterol efflux *via* ABCA1, to lipid poor acceptors such as Apo AI or Apo E, or delivered to the endoplasmic reticulum (ER), retaining the Sterol Regulatory Element Binding Protein (SREBP)/SREBP-cleavage activating protein (SCAP) complex, in turn reducing cholesterol biosynthesis. Oxysterols enhance this process by binding to Insig-1/2 (insulin-induced gene-1 or -2). Excess cholesterol is esterified *via* Acyl CoA: Cholesterol Acyltransferase-1 (ACAT-1), and stored in lipid droplets within the cytoplasm as "foamy" droplets. nCEH: Neutral cholesteryl ester hydrolase; FC: Free cholesterol; CE: Cholesteryl ester: NPC-1/NPC-2: Niemann-Pick C1/C2 protein; StAR: Steroidogenic acute regulatory protein: RXR: Retinoic acid receptor.

accumulation activates Liver X Receptor nuclear (LXR) transcription factors, achieving induction of ABCA1 and ABCG1 and repression of inflammation (below)[39,40].

MACROPHAGE LIPID METABOLISM AND INFLAMMATION ARE REGULATED BY LIVER X RECEPTORS

Activation of nuclear LXRs (LXRα/β) is marshals cellular responses to increasing levels of sterol, promoting cholesterol efflux (above)[39-43]. Liver X receptors form heterodimeric complexes with retinoic acid receptors (RXRs), and bind to imperfect direct repeats of the nuclear receptor half-site TGACCT[39-43]. Ligand binding dissociates co-repressor proteins, destined for ubiquitination and proteasomal degradation, and engages co-activator proteins such as histone demethylases and G-protein pathway suppressor-2 (GPS2), stimulating target gene transcription[44].

Activation of LXRα also represses cholesterol biosynthesis *via* novel negative LXR DNA-response elements within the promoter region of squalene synthase and lanosterol 14α-demethylase and suppresses uptake of LDL[45,46]. Oxysterols also bind to Insig-1/2, facilitating sequestration of sterol-regulatory element binding proteins (SREBPs) at the endoplasmic reticulum, ensuring repression of cholesterol biosynthesis and uptake[45]. Deletions of LXRα and LXRβ in murine models of atheroma cause lipid accumulation within the aortic root, even in the absence of an atherogenic diet[47,48].

It is also evident that LXRs modulate innate and adaptive immune responses mediated by macrophages, neutrophils, lymphocytes, neutrophils and dendritic cells[45], decreasing cytokine-mediated expression of a range of pro-inflammatory genes. This is achieved *via* a mechanism involving nuclear receptor co-repressor (NCoR), silencing mediator of retinoid and thyroid receptors (SMRT) and inhibition of nuclear factor kappa B (NFκB) signalling[45,48,49]. Activation of LXRs is also achieved by phagocytosis of apoptotic cells by macrophages increasing expression of receptor tyrosine kinase (*Mertk*), amplifying phagocytosis and cell clearance, and reducing production of inflammatory mediators[50]. Absence of LXR signalling enhances the apoptosis of macrophages challenged with *Listeria monocytogenes*, *Escherichia coli* or *Salmonella typhinurium*, *via* loss of the anti-apoptotic factor AIM/

Spα[51,52].

MACROPHAGE GENERATION OF OXYSTEROL LIGANDS FOR LIVER X RECEPTORS

High levels of mitochondrial sterol 27-hydroxylase (CYP27A1) are found in human macrophages, and this enzyme can produce modified sterols, proven to act as LXR ligands *in vitro* and *in vivo*[53-56]. Loss of CYP27A1 leads to the lipid storage disease, cerebrotendinous xanthomatosis (CTX), which triggers accumulation of cholesterol and cholestanol in brain and tendons, progressive neurological deterioration, xanthomas and, as a secondary complication, accelerated atherosclerosis[57,58].

The rate-limiting step controlling CYP27A1 activity is the flux of cholesterol from the outer to the inner mitochondrial membrane, *via* a mitochondrial cholesterol trafficking complex (discussed below)[59]. Mitochondrial oxysterols therefore act as key cell signalling molecules, the levels of which can be moderated by sulfation (SULT2B1b), esterification (ACAT-1) or metabolism to soluble bile acid derivatives[53]. Conceivably, this process could be "uncoupled" by accumulation of free cholesterol at the interface between endoplasmic reticulum (ER) and mitochondrial membranes, triggering ER stress and proteasomal degradation of ABCA1, and opening of the permeability transition pore in mitochondria[53]. Esterification of excess oxysterols may then result: over 85% of the 27-hydroxycholesterol in human atherosclerotic lesions is esterified and incapable of activating LXRα and its downstream pathways[60,61]. Loss of this protective pathway predicates mitochondrial damage, apoptosis and cytotoxicity, features associated with addition of exogenous atheroma-relevant oxysterols ($\geqslant$ 20 μmol/L) to cultured cells[62].

Thus, it is clear that the biological impact of oxysterols are not solely restricted to LXR activation[63-67]. For example, oxysterols also serve as endogenous ligands for G-protein coupled receptor 183 (Epstein-Barr virus-induced gene 2, *EBI2*)[63], function as selective estrogen receptor modulators[64], bind to the Smoothened molecule to modulate Hedgehog signalling[65], while CYP27A1-derived 7α and 7β, 27-hydroxycholesterol modify innate and adaptive immune responses by acting as agonists of retinoic acid-related (RAR) orphan receptor gamma t (ROPRγτ)[66].

Acute exposure of macrophages to exogenous oxysterols induce rapid (< second) oscillations in cytoplasmic [Ca^{2+}] triggered by influx from the extracellular medium, followed by sustained increases in [Ca^{2+}] mediated by translocation of TRPC1 (transient receptor potential, canonical) channels into lipid rafts in the plasma membrane[68]. Calcium transfer between ER and mitochondria is facilitated by mitochondria-associated membranes, which act as a hub for lipid transfer, regulation of mitochondrial morphology (fission, fusion and trafficking), apoptosis, autophagy and ER stress[69], although the role of endogenously generated oxysterols in these processes remains unknown at present. Certainly, chronic exposure to exogenous oxysterol congeners can activate calcium release from the ER, increasing dephosphorylation of Bcl-2 antagonist of cell death by the calcium-dependent phosphatase calcineurin, and promoting apoptosis[68].

TARGETING PROTEIN CONSTITUENTS OF THE MITOCHONDRIAL CHOLESTEROL TRAFFICKING COMPLEX: IMPACT ON MACROPHAGE STEROL METABOLISM AND INFLAMMATION

Despite intensive investigations in steroidogenic cells and tissues, the nature of the mitochondrial cholesterol trafficking complex remains a matter of debate. One recent model suggests a basal complex, forming contact sites between the outer and inner mitochondrial membranes, composed of the 18 kDa translocator protein (TSPO), adenine nucleotide transporter (ANT) and voltage-dependent anion channel (VDAC)[70-72]. In hormone-stimulated steroidogenic tissues, a "transduceosome" complex is formed, involving recruitment of the regulatory subunits of protein kinase A (PKA-R1α) and acyl CoA binding domain proteins-1 and -3. Elevated levels of cyclic adenosine monophosphate (cAMP) release PKA catalytic subunits to phosphorylate 37 kDa steroidogenic acute regulatory protein at the outer mitochondrial membrane; import of both StAR and cholesterol into the inner mitochondrial membrane and matrix facilitate both proteolytic processing of StAR to its 30 kDa form, and conversion of cholesterol into pregnenolone by CYP11A1[70-72]. However, a dynamic 800 kDa bioactive protein complex in steroidogenic cells has also been described, which does not involve ANT, but is composed of TSPO, VDAC, CYP11A1, ATPase family AAA domain-containing protein 3A (ASTAD3A) and optic atrophy type 1 proteins[73]; in this model, StAR facilitated binding of cholesterol to the 800 kDa complex, enhancing steroidogenesis.

Importantly, there is a growing realisation that key mitochondrial cholesterol trafficking proteins, such as StAR, play an important role in non-steroidogenic tissues[74]. This, combined with conflicting results regarding the impact of genetic deletion of TSPO on steroidogenesis and viability in mice[75-78], may lead to increased consideration of alternate functions for these proteins[74]. For example, StAR is expressed in endothelial cells, monocytes and macrophages[79-82], albeit at levels far lower than those found in adrenal or gonadal tissues[74]. By contrast, other components of the mitochondrial trafficking complex, such as TSPO, are widely expressed in a variety of tissues, including macrophages[78,81].

Importantly, both StAR and TSPO appear to impact on macrophage lipid and inflammatory phenotype, in

part *via* the pathway involving sterol 27-hydroxylase, activation of LXRα and upregulation of ABCA1/ABCG1 mRNA and protein[81-83], arguing a functional role for these proteins in mediating cholesterol supply to CYP27A1. Overexpression of StAR decreased macrophage lipid content[82,83], repressed inflammation[82] and apoptosis[84] and increased macrophage cholesterol efflux[82,83], while a viral vector expressing StAR reduced aortic lipids and atheroma in apoE$^{-/-}$ mice[85]. However, exploiting any putative anti-atherogenic properties of StAR could prove problematic, due to the associated induction of lipogenesis in macrophages[83,86], presumably *via* LXRα dependent induction of *Srebp1c*[87].

This led to focus on other components of the mitochondrial cholesterol trafficking complex and, in particular, TSPO[81]. Transient overexpression of TSPO in human (THP-1) macrophages increased the levels of ABCA1 mRNA and protein, and enhanced efflux of cholesterol to apoA-I, HDL and human serum, a finding reversed by gene knockdown of TSPO. Small molecule TSPO ligands also increased cholesterol efflux, an effect that was amplified in macrophages genetically engineered to overexpress TSPO[81]. Notably, TSPO overexpression caused a decline in macrophage total neutral lipid mass, without induction of lipogenesis, and effectively prevented "foam cell" formation following exposure to modified LDL[81]. These effects were associated with induction of both LXRα and PPARα the latter providing a plausible mechanism for the observed reductions in macrophage lipid mass[81]. Notably, overexpression of some of the other proposed components of the mitochondrial cholesterol trafficking complex, such as VDAC, ANT and ACBD1, discussed above, exerted minimal effects on the macrophage cholesterol efflux pathway[81].

Expression of TSPO is upregulated by exposure to modified LDL in human macrophages[81], and TSPO ligands have been used to image vascular inflammation in CD68 positive macrophages at sites of disturbed flow in murine carotid arteries[88], and macrophage burden[89] and intraplaque inflammation[90] within human carotid atherosclerotic lesions. Despite this evident association with inflammation, it appears that upregulation of TSPO, or signalling *via* this protein, may represent an adaptive mechanism designed to limit tissue damage. Overexpression of TSPO in microglia decreased production of pro-inflammatory cytokines, reflected in increased expression of alternately activated M2 stage-related genes and mediated *via* repression of NF-κB activation[91]. Similarly, TSPO ligands inhibited the proliferation of retinal microglial cells, and repressed the output of reactive oxygen species and TNFα[92]. In good agreement, levels of TSPO are higher in dystrophic murine retina, and in microglia treated with LPS, while TSPO ligand XBD173 repressed the expression of chemokine (C-C motif) ligand 2 (CCL2), IL-6 and iNOS[93]. The TSPO ligand, PK11195 has proved effective in ameliorating the severity of disease in an experimental murine model of multiple sclerosis, by reducing inflammatory responses and promoting oligodendroglial regeneration[94]. TSPO has also been posited as a novel target for Alzheimer's disease[95], anxiety, psychiatric and neurologic disorders[96-99], pain[100], cancer[101] and vascular dysfunction[88-90,102]. At present, it is not known how many of these effects are related to the cholesterol trafficking function of TSPO, although LXRs influence expression of an array of genes involved in cholesterol homeostasis, glucose metabolism, inflammation and Alzheimer's disease[103]. It is also clear that some of the reported effects of TSPO and its ligands may require re-evaluation, given the lack of phenotype recently reported in healthy TSPO$^{-/-}$ mice[75,76].

MITOCHONDRIAL STRUCTURE AND BIOENERGETICS: IMPACT ON CHOLESTEROL HOMEOSTASIS

Mitochondria exhibit constant movement, fusion and fission[104]. The mitochondrial membrane protein mitofusin (Mfn2) is involved in maintaining mitochondrial morphology, energy provision, and cellular growth and apoptosis[105-107]. Recently, Mfn2 has emerged as a regulator of macrophage cholesterol efflux, *via* upregulation of peroxisome proliferator activated receptor-γ (PPARγ) ABCA1, ABCG1 and scavenger receptor-B1 (SR-B1), reflected in marked reductions in cholesterol mass[107]. Overexpression of Mfn2 attenuates the formation of atherosclerotic lesions in rabbit carotid arteries, and levels of Mfn2 are progressively reduced during lesion formation in apoE$^{-/-}$ mice during atherogenesis; levels of Mfn2 are also reduced in atherosclerotic, compared with non-atherosclerotic, human arteries[107].

Remodelling of the inner mitochondrial membrane by optic atrophy 1 (OPA1) also alters the efficiency of mitochondrial cholesterol trafficking, at least in steroidogenic cells[108,109]. Increased steroidogenesis is reported in trophoblasts undergoing syncytilisation, which express increased levels of the pro-fission mitochondrial shaping protein Drp1 increased, and decreased levels of Opa1 and mitofusin. An inverse relationship between levels of Opa1 and steroidogenesis were also evidenced in cells genetically manipulated to express higher levels of Opa1, while accumulation of cholesterol at the inner mitochondrial membrane was observed in mitochondria lacking Opa1[108,109].

Finally, it is self-evident that ATP is needed to mount an effective non-adaptive immune response, and to fuel cholesterol biosynthesis and the activity of ABC transporters that determine the rate of macrophage cholesterol efflux. However, more subtle changes in mitochondrial function or loss of bioenergetic capacity, the emerging concept of the Bioenergetic Health Index (BHI)[110], have been shown to reduce the efficiency of mitochondrial cholesterol trafficking and hormone biosynthesis in steroidogenic tissues[111,112]. Dissipation of the mitochondrial membrane potential ($\Delta\psi_m$ using carbonyl cyanide *m*-chlorophenylhydrazone), inhibition of electron transport at complex Ⅲ (using antimycin), reduction of pH (nigericin) and inhibition

of ATP synthase (oligomycin) blocked the formation of progesterone and synthesis or import of StAR protein in Leydig cells[111,112].

A parallel study in macrophages supports the notion that acute loss of mitochondrial function is also associated with dysregulated cholesterol homeostasis[113]. Cholesterol efflux was inhibited by nigericin and oligomycin in RAW 264.7 macrophages; levels of ABCA1 protein decreased in response to oligomycin treatment, despite paradoxical increases in *Abca1* mRNA[113,114], reflecting findings in carotid atherosclerotic lesions[114] Further, while oligomycin treatment did not alter cholesterol biosynthesis, cholesterol esterification was significantly inhibited, promoting apoptosis. Oligomycin induced expression of genes involved in cholesterol efflux (*Abca1, Abcg4, Stard1*) and cholesterol biosynthesis *(Hmgr, Mvk, Scap, Srepb2*) arguing that loss of coordinated regulation of sterol homeostasis is caused by loss of mitochondrial ATP generation[113]. In turn, accumulation of free cholesterol or fatty acids can trigger mitochondrial dysfunction, which could promote inflammation *via* loss of LXRα-dependent repression of NF-κB (above) and upregulation of cytokine expression, but also by NLRP3 inflammasome-dependent and –independent pathways[115].

QUESTIONS FOR THE FUTURE

This review summarizes the current evidence that, in part, macrophage sterol homeostasis, and inflammatory responses, can be linked to mitochondrial cholesterol trafficking, and mitochondrial structure and bioenergetics. Whether proteins involved in mitochondrial structure, fission, fusion or organelle dynamics can also impact on these processes is currently uninvestigated and an area of keen interest. More particularly, mitochondria-mediated hormetic effects in aging[116,117] suggest a retrograde signalling pathway by which mitochondrial dysfunction in a single distinct tissue elicits the mitochondrial stress response in some (but not all) distal tissues. In turn, this suggests that loss of effective mitochondrial function, such as that caused by hepatic insulin resistance for example, may be transmitted *via* "mitokines" to peripheral tissues, promoting vascular dysfunction and cardiovascular disease. These exciting findings offer some intriguing possibilities for therapeutic strategies aimed at sustaining or improving mitochondrial function.

Abstract

AIM: To compare the predictive value of three methods of epicardial fat (EF) assessment for presence of significant coronary artery disease (CAD) [*i.e.*, epicardial fat volume (EFV), EFV indexed with body surface area (EFV/BSA) and EFV indexed with body mass index (EFV/BMI)].

METHODS: The study was performed on 170 patients (85 women and 85 men) with clinical suspicion of CAD. They aged 26-89 years with a median age of 54 years. The patients were classified into three groups: Group 1: 58 patients with normal coronary arteries; group 2: 48 patients with non-significant CAD and group 3: 64 patients with significant CAD. The three methods for assessment of epicardial fat were retrospectively studied to determine the best method to predict the presence of significant CAD.

RESULTS: The three methods for epicardial fat quantification and measurements, *i.e.*, EFV, EFV/BSA and EFV/BMI with post- hoc analysis showed a significant difference between patients with significant coronary artery disease compared to the normal group. Receiver operating characteristic curve analysis showed no significant difference between the three methods of epicardial fat measurements, the area under curve ranging between 0.6 and 0.62. The optimal cut-off was 80.3 cm^3 for EFV, 2.4 cm^3/m^2 for EFV indexed with BMI and 41.7 $cm^3/(kg/m^2)$ for EFV indexed with BSA. For this cut-off the sensitivity ranged between 0.92 and 0.94, while specificity varied from 0.31 to 0.35.

CONCLUSION: Any one of the three methods for assessment of epicardial fat can be used to predict significant CAD since all have the same equivalent predictive value.

Key words: Quantification of epicardial fat; Coronary heart disease; Epicardial fat volume

Core tip: There is a great correlation between the volume of epicardial fat and presence of significant coronary artery disease. There are different methods for quantification of epicardial fat volume (EFV). The aim of the study is to compare the predictive value of the three methods used for quantification of epicardial fat (EFV, EFV indexed with body surface area and EFV indexed with body mass index) for presence of significant coronary artery disease. The study concluded the three methods for assessment of epicardial fat have the same equivalent predictive value for significant coronary artery disease and any one of them can be used as a sensitive predictor for significant coronary artery disease.

Saad Z, El-Rawy M, Donkol RH, Boghattas S. Quantification of epicardial fat: Which method can predict significant coronary artery disease? *World J Cardiol* 2015; 7(5): 287-292 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i5/287.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i5.287

INTRODUCTION

Epicardial fat (EF) is the visceral fat of the heart deposited under the visceral layer of the pericardium. Under normal physiological conditions, EF tissue displays biochemical, mechanical and thermogenic cardioprotective properties. Under pathological circumstances, EF can be strongly related to the development of coronary artery disease (CAD). The accumulation of EF is known to be a rich source of free fatty acids and a number of proinflammatory cytokines[1-3].

It has been hypothesized that EF may act as a paracrine (immunological) organ that influences the coronary arteries by promoting chronic inflammation and endothelial dysfunction[4-6].

Several imaging modalities can be used to quantify EF volume (EFV) such as echocardiography, computed tomography, and magnetic resonance imaging[7]. Due to distinct low attenuation values of fat on computed tomography (CT). ECG-gated cardiac CT with its high spatial resolution and true volume coverage of the heart, allows accurate measurement of epicardial and thoracic fat distances and volumes[6,7].

Besides EFV, some authors derived a second parameter, the body surface area indexed EFV (EFV/BSA)[8,9]; however, comparison between these two parameters has not been considered. Moreover, despite the predictive value of higher body mass index for cardiovascular event[10,11], the added value of body mass index (BMI)-adjusted EFV (EFV/BMI) also has not been previously assessed as well.

The aim of the current study is to compare the predictive value of the three methods for EF assessment (EFV, EFV/BSA and EFV/BMI) for presence of significant CAD.

MATERIALS AND METHODS

Patients

A total of 170 consecutive patients with clinical suspicion of coronary artery disease (CAD) aged 26-89 years with a median age of 54 years (85 women and 85 men) were included in our study From November 2012 through February 2014. Patients underwent 128-MDCT according to appropriate use criteria for cardiac computed tomography[12]. All participants provided written informed consent and the study was approved by institutional ethics committee.

The patients were divided into 3 groups according to the severity of coronary artery stenosis assessed by quantitative coronary angiography. Patients in group 1 have normal coronary arteries. Patients in group 2 were have non-significant coronary artery stenosis with percent-diameter stenosis less than 50%. Patients in group 3 have significant CAD with percent-diameter stenosis more than 50% or occlusion[13].

Multidetector computed tomography

Our patients were scanned with a 128-multidetector computed tomography (MDCT) dual source scanner (SOMATOM Flash; Siemens Medical Solutions, Erlangen, Germany). Patients with uncontrolled heart rate (> 65 beats per minute) received oral beta blocker (metoprolol 50 mg) before the CT scan. Sublingual nitroglycerin 0.5 mg was administrated before the scan to achieve coronary vasodilation. A non-contrast CT scan was performed to determine the total calcium burden of the coronary tree (sequential scan with 32 Å~ 0.6-mm collimation, tube current 60 mA at 120 kV). Contrast-enhanced CT angiography data were acquired with the use of a spiral scan with 32 Å~ 0.6-mm collimation, 330-ms gantry rotation, pitch of 0.2, and tube voltage at 120 kV.

Sequential ECG-triggering scans were performed in 142 patients with controlled heart rate and retrospective ECG-gating scans with tube current modulation were performed in 28 patients due to heart rate variability. Intravenous contrast agent (60-90 mL; 350 mg iodine/mL) was injected with flow rate of 5.0 mL/s followed by a 30-mL saline chaser[1].

Image interpretation: The total calcium score was calculated and interpretation of CCTA was analysed for all patients using commercially available software packages "Syngo Via", Siemens Healthcare, Forchheim, Germany.

Measurement of EFV

EFV was measured blindly by two observers for all patients using an offline workstation (Aquarius NetStation; TeraRecon Inc., San Mateo, CA). Using the 3.0-mm-thick axial slices used for calcium scoring, the parietal

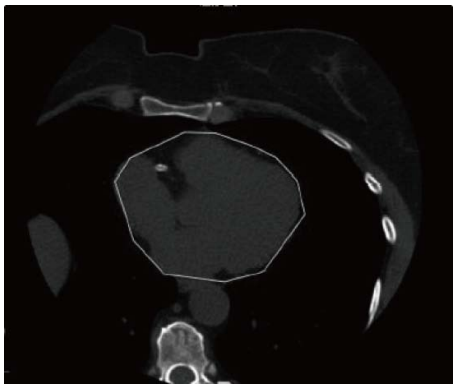

Figure 1 Measurement of epicardial fat volume; the electronic line delineates the contour of epicardiumin in noncontrast computed tomography.

pericardium was traced manually in every 4th slice starting from the aortic root to the cardiac apex[1] (Figure 1). The computer software then automatically interpolated and traced the parietal pericardium in all slices interposed between the manually traced slices. The automatically traced slices were examined and verified for accuracy. Fat voxels were identified using threshold attenuation values of -30 to -190 HU (Figure 2).

Division the estimated EFV of every patient by patient's BSA calculated the indexed EFV to BSA (EFV/BSA). Also, division of EFV by patient's BMI calculated the indexed EFV to BMI (EFVB/MI).

Statistical analysis

The statistical analysis was performed by StatDirect 2.8.0 and Mecalc 9.2.1.0 (for ROC curve analysis and comparison). Because the analyzed quantitative variables (EFV, EFV/BMI, EFV/BSA, BMI, BSA and age) were not normally distributed (Shapiro and Wilk test), the values are expressed as medians with interquartile range. Dichotomous data are presented as frequency (percent).

Differences in characteristics of patients were compared using Pearson's χ^2 test for dichotomous variables (or Fisher's exact test when appropriate) and Kruskall-Wallis test for continuous test.

To compare the predictive performance for risk of significant CAD between the three EF parameters, we plotted receiver operating characteristic (ROC) curve from which the optimal cutoff was derived and we calculated the area under curve (AUC). AUC, optimal cutoff, sensitivity and specificity for each EFP and pairwise comparison of AUC have been determined. A two-tailed *P*-value less than 0.05 were considered as statistically significant; significant differences are presented with asterisk in the tables. The statistical methods of this study were reviewed by a biostatistician.

RESULTS

General characteristics

Table 1 illustrated the important clinical findings and measurements of the patients among the three groups of patients.

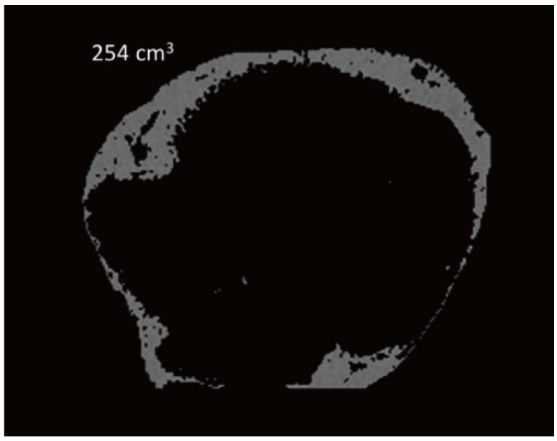

Figure 2 Measurement of epicardial fat volume; the fat voxels were identified using threshold attenuation values (-30 to -190 HU) and the volume of epicardial fat is measures.

Correlation of EFP with CT coronary angiography results

Comparison of EF parameters with CT coronary angiography results is presented in Table 2. Comparison of EFP medians revealed a progressive increase from group 1 to group 3. The medians where 81, 104 and 113 for EFV (cm^3), 2.7, 3.7 and 3.8 for EVV/BMI (cm^3/m^2) and 45.6, 53.9 and 61.8 for EFV/BSA [$cm^3/(kg/m^2)$]. Nevertheless, the post- hoc analysis showed significant difference only between groups 1 and group 3 for all EFP: $P = 0.002$ for EFV, $P = 0.012$ for EFVBMI, and $P = 0.007$ for EFVBSA.

ROC curves analysis

ROC curve for the three the EFP is presented in Figure 3. AUC was 0.62 for EFV, 0.6 for EFVBMI and 0.61 for EFVBSA and pairwise comparison failed to show significant difference. The optimal cut-off was 80.3 cm^3 for EFV, 2.4 cm^3/m^2 for EFVBMI and 41.7 $cm^3/(kg/m^2)$ for EFVBSA. Sensitivity and specificity were respectively 0.92 and 0.35 for EFV, 0.93 and 0.31 for EFVBMI, and 0.94 and 0.32 for EFVBSA.

DISCUSSION

Noninvasive quantitative measurement of epicardial fat volume from CT is feasible, and may play a clinical role in cardiovascular risk assessment[6]. It have shown its reproducibility and correlation to CAD presence, severity, and prognosis[14-16].

Recently, multiple studies have shown a deleterious relationship between epicardial fat burden and coronary atherosclerosis, arrhythmogenesis and major adverse cardiovascular events (MACE)[17,18]. In this study, the epicardial fat volume is correlated with the presence of coronary artery stenosis. In agreement with this findings, Alexopoulos *et al*[19] observed on coronary CT angiography a significant increase in epicardial fat

EFVBSA [$cm^3/(kg/m^2)$]	45.6 (35.3-66.9)	53.9 (44.4-68.6)	61.8 (48.1-75.4)	0.011

EFV: Epicardial fat volume; EFVBMI: EFV indexed with body mass index; EFVBSA: EFV indexed with body surface area.

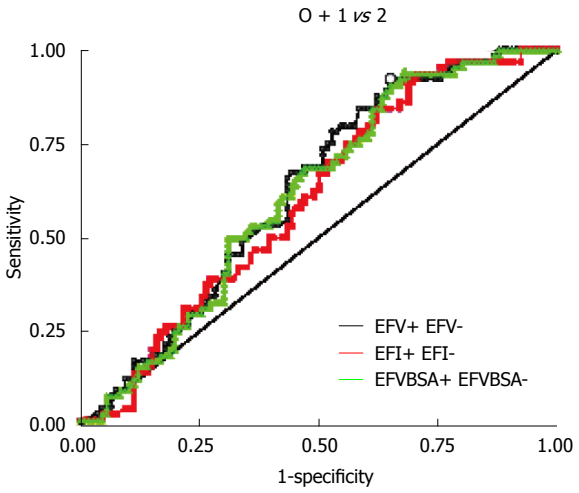

Figure 3 Receiver operating characteristic curves compare the three parameters for measuring the epicardial fat. AUC was 0.62 for EFV, 0.6 for EFVBMI, and 0.61 for EFVBSA (non-significant pairwise comparison). EFV: Epicardial fat volume; EFVBMI: EFV indexed with body mass index; EFVBSA: EFV indexed with body surface area.

volume with increasing coronary luminal stenosis; epicardial fat volume was also larger in patients with mixed or noncalcified plaques.

A recent study by Nakazato *et al*[20] assessed the relationship of epicardial fat volume to weight, BMI and waist circumference, and evaluated whether changes in these parameters over a 4-year period influenced epicardial fat volume measured by noncontrast CT in a relatively healthy asymptomatic population. They found that weight, BMI and waist circumference demonstrated moderate cross-sectional relationships to epicardial fat volume, and that changes in these parameters were related to epicardial fat volume change.

In another study, Shmilovich *et al*[9] assessed the body surface area indexed EVF in a healthy population and validated it as a predictor of major adverse cardiovascular events.

By reviewing the literature, the two parameters EFV and EFV/BSA, have no clear evidence of differences in their accuracies and predictive values[9,18-20]. In the current study we compared the predictive value of three EFP for the presence of significant CAD. To our knowledge, no similar studies have been performed before and EFV/BMI has not previously assessed also, the predictive value of EF/VBSA for CAD has not been compared with EFV.

The major outcome of the present study, derived from the ROC curve analysis, is that the three methods for assessing the EF have an equivalent predictive value for significant CAD and any one of them can be used as a predictor for significant CAD. Therefore, the clinical impact of the indexed EFV seems to be limited. To note that in the series using the indexed EFV to BSA, the benefit of such indexing has not been evaluated and ROC curve analysis has not been applied for assessment of possible increase in the predictive value for total occlusion of coronary arteries[16] or major adverse cardiovascular events[9].

According to the traditional academic point system, the accuracies of the three methods for measuring EF are classified as poor considering that the AUC are in the range 0.6-0.7. This limited accuracy is related mainly to the low specificity, ranging from 0.31 to 0.35, while the sensitivity is high, varying from 0.92 to 0.94, therefore the three methods can be considered as sensitive but poorly specific predictors for significant CAD. Consequently, indexing EFV by BSA or BMI doesn't improve significantly the sensitivity and, more

importantly, the specificity of EF for significant CAD.

In the current study, the optimal cut-off was 80.3 cm^3 for EFV, 2.4 cm^3/m^2 for EFVBMI and 41.7 $cm^3/(kg/m^2)$ for EFVBSA. The optimal cut-off for EFVBSA was lower than the value 50 cm^3/m^2 reported by Ueno *et al*[16] (labeled VEAT in their series), despite a higher median value in our series: 53.7 cm^3/m^2 *vs* 47.1 cm^3/m^2. This difference is likely related to the definition of the end-point itself: significant CAD in the current study *vs* total occlusion of the coronary arteries in the series of Ueno *et al*[16]. More recently, Shmilovich *et al*[9] derived the threshold for the upper normal limit of indexed EF to BSA in a healthy population. The indexed EFV was also non-normally distributed, and the 75th-percentile was 47.1 cm^3/m^2, while in our series the 75th-percentile for the group 1 (composed of patients without CAD) 1 was 66.9 cm^3/m^2. Clearly, these values cannot be compared considering the major differences in the design of the two studies, the series of Shmilovich *et al*[9] including only asymptomatic patients with low risk and without clinical or biological risk factors for CAD.

Analysis of the correlation between the EFP and CT coronary angiography results revealed a trend of increase form group 1 to group 3. This result is similar to the conclusion of Taguchi *et al*[21] that pericardial fat is the strongest independent variable for the severity of CAD. Nevertheless, only groups 1 and 3 differed significantly. The overlap of values, for all EFP, between groups 2 and 3 may explain in great part the low specificity observed for the optimal cut-off. This point merits further analysis to achieve a higher predictive value of EF for significant CAD.

Relatively small number of studied patients with no available follow up data to observe the outcome or prognostic value of EFP considered a study limitation. Additionally our study may be affected by selection bias as we evaluate patients with clinical suspicion of CAD.

In conclusion, the major outcome of the present study that the three methods for assessment of EF have the same equivalent predictive value for significant CAD and any one of them can be used as a sensitive predictor for significant CAD. Additionally, we provided a threshold for each one of the three EFP. For further validation of this threshold additional larger study is recommended.

COMMENTS

Background

Epicardial fat (EF) under normal physiological conditions, EF tissue displays biochemical, mechanical and thermogenic cardio protective properties. Under pathological circumstances, EF can be strongly related to the development of coronary artery disease (CAD). Several imaging modalities can be used to quantify EF volume (EFV) such as echocardiography, computed tomography, and magnetic resonance imaging.

Research frontiers

ECG-gated cardiac computed tomography with its high spatial resolution and true volume coverage of the heart, allows accurate measurement of epicardial fat volumes. Besides EFV, some authors derived a second parameter, the body surface area indexed EFV (EFV/BSA); however, comparison between these two parameters has not been considered. Moreover, despite the predictive value of higher body mass index for cardiovascular event, the added value of body mass index (BMI)-adjusted EFV (EFV/BMI) also has not been previously assessed as well. The current study compares the predictive value of the three methods for EF assessment (EFV, EFV/BSA and EFV/BMI) for presence of significant CAD.

Innovations and breakthroughs

In the current study the authors compared the predictive value of three EFP for the presence of significant CAD. To our knowledge, no similar studies have been performed before and EFV/BMI has not previously assessed also, the predictive value of EF/VBSA for CAD has not been compared with EFV. The major outcome of the present study is that the three methods for assessing the EF have an equivalent predictive value for significant CAD. Furthermore the authors provided a threshold for each one of the three EF parameters.

Applications

The study results suggested that; any one of the three methods for assessment of epicardial fat can be used to predict significant CAD since all have the same equivalent predictive value.

Terminology

EF is the visceral fat of the heart deposited under the visceral layer of the pericardium and has the same origin as abdominal visceral fat.

Peer-review

This is a good study in which the authors compare the predictive value of three methods used for quantification of epicardial fat [*i.e.*, EFV, EFV indexed with body surface area (EFV/BSA) and EFV indexed with body mass index (EFV/BMI)] for presence of significant CAD. The results are interesting and suggest that any one of the three methods for assessment of epicardial fat can be used to predict significant CAD since all have the same equivalent predictive value.

Abstract

Myocarditis is a bacterial or viral inflammatory disease, often unnoticed or misdiagnosed. Athletes with myocarditis must stop practicing their activity since International medical Literature described some cases of sudden death. In the present report, we describe a case of an asymptomatic, apparently healthy, competitive athletes, who was diagnosed a myocarditis and as incidental finding a myocardial bridging. We focused the attention on the importance of anamnesis, electrocardiogram and athletes' entourage for the diagnosis of such insidious pathologies and we evaluated the follow up, focusing the attention on electrocardiogram changes as well as on restitution ad integrum and prognosis, especially for the athletes.

Key words: Myocarditis; Sudden cardiac death; Pre-participation screening

Core tip: Pre participation screening allows sports physicians to diagnose potential causes of sudden death in athletes. We describe a case of an athlete with a previous myocarditis, and an incidental myocardial bridging, suspended from competition and followed in the later time. We also pointed out the question of the possible scarring of myocarditis in relation to the restart of physical activity and training.

Myocarditis in athlete and myocardial bridge: An innocent bystander? *World J Cardiol* 2015; 7(5): 293-298 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i5/293.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i5.293

INTRODUCTION

Myocarditis is an inflammatory disease of the myocardium,

possibly determined by both bacterial and viral infections. Coxsackievirus B, enteroviruses adenovirus and parvovirus B19 are often involved in acute processes[1]. Myocardial involvement caused by granulomatous or (auto) immune processes with unknown pathogenetic mechanisms, but this is less common than virus-induced myocarditis or post-infectious inflammatory cardiomyopathy.

Myocarditis is frequently anticipated by flu-like signs and symptoms like chills, fever, headache, muscle aches, general malaise. Moreover, gastrointestinal symptoms such as decreased appetite, nausea, vomiting, and diarrhoea are commonly reported. Cardiac signs and symptoms may appear a few hours to a few days since the beginning of myocardial inflammation and consist in chest pain, palpitations, dyspnea, hypotension, gallop rhythm, rales, jugular venous dilatation, and cardiac tamponade.

In rare cases, the inflammatory condition causes acute hemodynamic compromise, possibly leading to heart failure, complex arrhythmias and fatal events[2]. In reported cases, Myocarditis scenario can overlap Ischemic disease[3], and acute coronary syndrome, even an ST-segment elevation myocardial infarction.

Nevertheless, myocarditis can be undiagnosed and completely asymptomatic with not perceived short lasting fever (5-7 d).

In the absence of structural heart diseases myocarditis accounts for approximately 10% of recent-onset cardiomyopathy in adults. Early fulminant disease is still associated with a high mortality rate. Patients who survive the critical phase have a fairly good prognosis and survival from myocarditis is approximately 60%-70%. In the remaining patients progressive chronic heart failure and unpredictable sudden cardiac death remain a serious concern, often occurring years after the initial clinical event and sometimes despite complete recovery of the myocardial function.

Diagnosis is commonly carried out by integrating different methods[4].

Electrocardiogram (ECG): a sensitive cheap tool of diagnosis. Abnormal ST-T waves and conduction block are frequently observed in myocarditis as well as isolated or complex/polymorphic ventricular arrhythmias present at rest or during stress test[5]. A gradual increase in the width of the QRS complex can be a sign of exacerbation of myocarditis. Continuous ECG monitoring is crucial to detect arrhythmic burden and presence of threatening rhythm disorder.

Echocardiography: in case of echo alterations, myocarditis can be confirmed by transient wall thickening, reduced wall motion and reduced cardiac chamber size in addition to pericardial effusion on echocardiography and increase of echo reflection[6].

Cardiac magnetic resonance imaging (MRI): in addition to the cinematic mode on MRI, T1-weighted early signal enhancement and gadolinium-delayed imaging of the heart are useful to make a diagnosis of myocarditis[7]. T2-weighted images reveal the regions of the heart affected by inflammation. Cardiac magnetic resonance (CMR) has emerged as a leading modality in the noninvasive diagnosis of myocarditis due to its ability to detect myocardial edema, hyperaemia, necrosis and fibrosis in a safe and reproducible fashion. The presence of late enhancement gadolinium (LGE) has been reported in 24%-95% of patients with myocarditis, typically being multifocal and located in the epicardium of the lateral wall and mid wall of the septum. Moreover, the long term prognosis can be determined by the magnitude of damage at MRI, since the left ventricle end diastolic volume, the presence of LGE in the septum and the total amount of LGE are the strongest independent predictors of impaired ventricular function and ventricular dilatation at follow up[8].

Blood Biochemistry: during the acute phase of myocarditis, it is possible to observe a plasma increased elevation of C-reactive protein, aspartate aminotransferase, lactate dehydrogenase, MB form of creatine kinase, and cardiac troponin T[9].

Other techniques may include computed tomography (CT) of the heart to assess possible artery disease[2,10], chest X-ray (qualitative quick assessment of cardiac enlargement and pulmonary congestion); cardiac catheterization, including endomyocardial biopsy (the gold standard for diagnosis but an invasive method not risk free and usually performed only after the acute phase and in clinical stability of the patient)[11].

Myocarditis is reported as a cause of Sudden death in athletes[2].

Italian guidelines for the pre-participation screening sustain that "subjects with certain diagnosis of myocarditis cannot be involved in any kind of sport activity, until the illness process is completely resolved, and however not before of at least 6 mo since the diagnosis was made. The competitive sport activity can be restarted only if clinical evaluation and instrumental evaluations demonstrate the lack of alterations in myocardial contractile function as well as the absence of relevant arrhythmias"[12].

CASE REPORT

A 41-year-old male, regularly involved in competitive sport (American football and weightlifting) came, on march 2013, to our Sport's Medicine laboratory, for the annual mandatory pre-participation screening. Football screening protocol include Cardiological examination, basal ECG, Stress Test. Family and personal history was negative. Clinical examination was unremarkable.

Rest-ECG showed deep T-wave inversion in $\geqslant$ 2 contiguous anterior, inferior or lateral leads, particularly in leads Ⅰ, Ⅱ, Ⅲ, aVF and in V4-V5-V6. This pattern was absent in all the previous ECGs the patient made for previous screening, and in particular it was absent recently, when he underwent job medical exam (ECG January 2013) (Figure 1).

The patient underwent echocardiography which

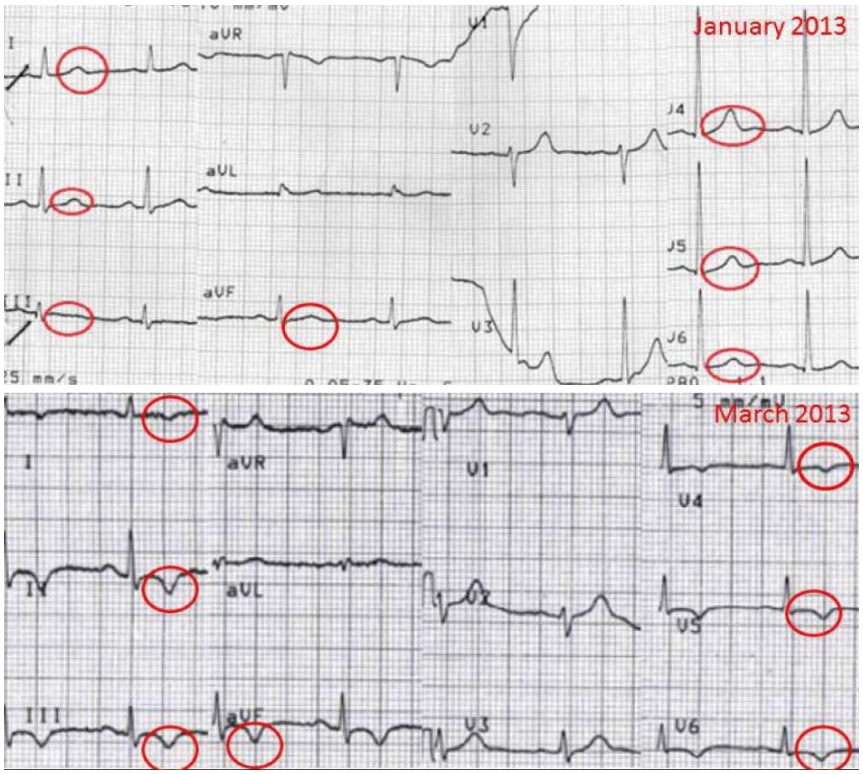

Figure 1 Electrocardiogram changes: Ventricular.

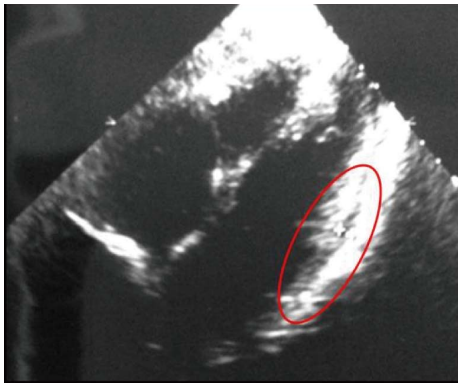

Figure 2 Echocardiogram (March 2013): Echo-free space in the lateral wall and hyper echogenicity of the lateral portion of the left ventricle.

Figure 3 Cardiac magnetic resonance: Areas of intramural and subepicardial delayed enhancement in the lateral wall, suggestive of fibrosis.

showed a mild echo-free space with pericardial effusion in the lateral wall and a slight increase in the hyper echogenicity level of the lateral portion of the left ventricle (Figure 2).

As the patient was completely asymptomatic and actually training and competing a cardiac exercise stress test was performed. T-waves inversion was stable all along the duration of the test. Patient reached 168 beats per minute at peak exercise heart rate and 200 watt of peak mechanical Power. Blood pressure kinetics was normal. No presence of Arrhythmias. No symptoms were reported. Holter ECG monitoring showed absence of ventricular arrhythmias.

The patients underwent through blood examination and biochemistry, which didn't show any alterations.

Through anamnesis the patient remembered having experienced a "persistent flu" on January 2013, characterized by elevated fever (40 ℃) and atypical chest pain which he considered aspecific and not to be referred to his General practitioner, for several days. He was administered a broad-spectrum antibiotic therapy (Cephalexin) and symptoms completely disappeared within 4 d.

As a third level examination we performed a cardiac MRI which showed the presence of some areas of intramural and subepicardial delayed enhancement in the lateral wall, suggestive of fibrosis, in a contest of normal dimensions and function (Figure 3). The characteristic pattern of LGE in myocarditis is patchy or multifocal in a subepicardial or intramyocardial distribution, often involving the lateral wall. This feature is not pathognomonic but is clearly distinct from ischemic heart disease, which typically presents with subendocardial or transmural LGE within a

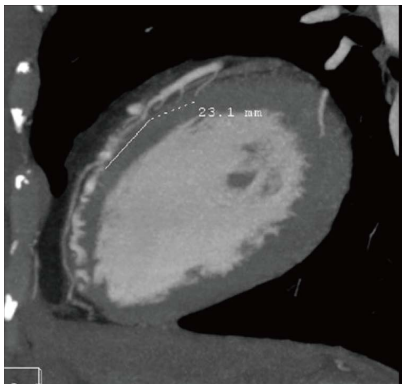

Figure 4 Tomographic computed scan: Myocardial bridge (23 mm).

coronary artery territory.

Despite it, considering the age of the athlete and possible overlapping with ischemic disease even if in absence of wall abnormalities at echo scan of the heart, we excluded coronary involvement through a CT scan of coronary arteries. As a collateral finding a coronary abnormal 23 mm superficial intramiocardial course in the medium tract of Left descending artery was found.

The intramuscular course of coronary arteries can be detected and characterized by Computed Coronary Tomographic Angiography (CCTA). CCTA is an easy and reliable tool for comprehensive *in vivo* diagnosis of the intramuscular course of coronary arteries. It is generally estimated that the myocardial bridging can be detected in about one-third of the adults in autopsy series, whereas the reported incidence in angiographic series is much lower < 5%. The incidence of myocardial bridging in CCTA studies (30.5%) is in concordance with the reported incidence in autopsy series[13].

We concluded for Myocarditis in association with incidental finding of Myocardial bridge (Figure 4).

According to cardiologic Italian guidelines for competitive sports, we recommended to avoid physical overload and sport practice. A therapy with low dose Bisoprolol was started and a follow up was based on monthly ECG and a repetition of echocardiography and stress-test at three months' time.

T wave inversion pattern showed a gradual reduction in amplitude up to complete reversal after 4 mo (Figure 5).

Echocardiogram performed in October 2013 was normal and no sign of effusion was present. Stress test was within normal limits and no repolarization abnormalities could be found.

Clinical evaluation, normalization of basal ECG and echocardiogram demonstrated the complete electrical recovery of the athlete from myocarditis. He continued to be excluded from competitive sports, according to cardiologic Italian guidelines for competitive sports for the presence of intramiocardial Coronary bridge.

After one year of follow up the patient did not experience any cardiological symptoms, clinical examination was unremarkable and electrocardiographic and echocardiographic findings as well as stress test were within normal limits.

DISCUSSION

Myocarditis is a rare recognised cause of sudden death in athletes, its signs and symptoms may overlap ischemic disease as well as cardiomyopathy and it can be minimally symptomatic or able to determine rare fatal events[14]. Even in asymptomatic subjects, recognition of this disease can modify prognosis since inflammatory cardiomyopathy can determine adverse event also many years after apparently total restitution ad integrum, this is the reason why indication for clinical follow up and for adequate exercise prescription can change the patient "scenario".

Intramiocardial bridge is a recognised cause of sudden death in athletes too[15]. The prevalence of this abnormality shows a wide range of frequency, up to 44% with 64-slice coronary CT scan[16]. In the last years Computed Scan has allowed diagnosis even in asymptomatic subjects. This finding requires, accordingly to cardiological Italian guidelines for competitive sports, to avoid competition and high intensity training.

With this report, we firstly intend to remark the relevance of anamnesis and combined techniques such as basal ECG[17], echocardiography, MRI and Computed Scan of the heart, in the diagnosis or exclusion of myocarditis when clearing athletes for competition. ECG is reported to be normal in over 32% of subjects with acute myocarditis. This can also be due to the time at which the ECG is performed, for the transitory nature of abnormalities[18]. MRI has a sensitivity of 81%, specificity of 71% and accuracy of 81% for diagnosing acute myocarditis[5].

Moreover, T wave inversion were in the same location of increased echo reflex and in proximity of mild echo free area interpreted as mild pericardial effusion, in lateral portion of left ventricle. Such data was also confirmed at MRI and at Computed Scan of the heart, with no sign of oedema, but with presence of fibrosis, indicating a past inflammatory based necrosis. This information is crucial to possibly diagnose Myocarditis as well as for the prognosis.

Secondly, we would like to underline the importance of a proper dialogue between sport physicians and the athletes, the medical team and even, in some cases, the family doctor. A focal point is that even if mandatory pre-participation screening in our country is annually based, it seems essential that sports physicians recommend to re-evaluate athletes experiencing persistent flues or not common signs and symptoms such as atypical thoracic pain, asthenia and palpitations. This information is to be extended to athletes and general practitioner.

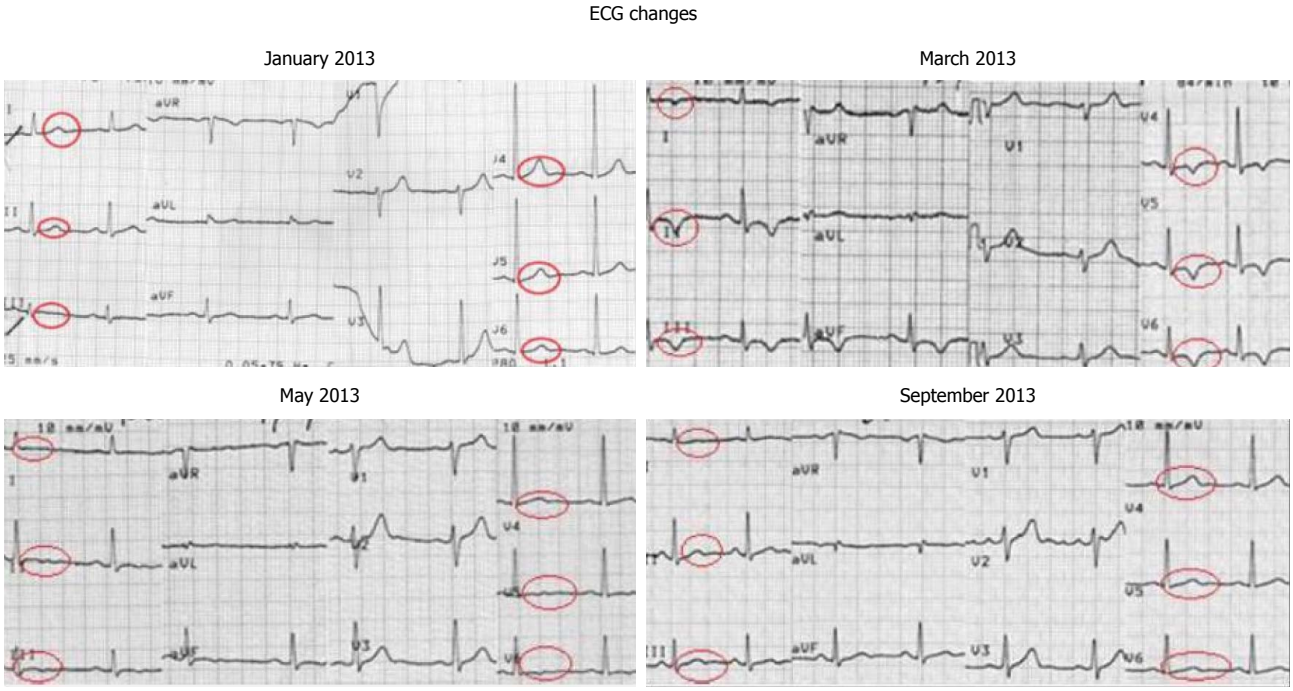

Figure 5 Electrocardiogram follow up.

According to actual Italian guidelines, a period of 6 mo following restitution ad integrum is sufficient to be again eligible for sport competition. With MRI, myocardial damage, previously not detected can be well appreciated as fibrosis or sub epicardial or intramural damage.

It seems important to note that the presence of delayed enhancement and fibrosis is not considered as a risk predictor in previous Italian Cardiological Guidelines for pre participation screening, in fact a complete reversal of T waves abnormalities, with preserved function and absence of symptoms and arrhythmias is considered sufficient for a restitution and integrum. Are now this concept still valid? Which is the role of Myocardial scar in determining a good prognosis? Is an ECG reversal to normality also a sign of better prognosis?

COMMENTS

Case characteristics

The athlete during the pre-participation screening was asymptomatic, he reported elevated fever (40 °C), atypical chest pain with asthenia and persistent flu, 2 mo before.

Clinical diagnosis

The athlete, with a previously normal electrocardiogram (ECG), showed T wave inversion in most leads, after a "persistent flu" with elevated fever 2 mo later.

Differential diagnosis

Differential diagnosis with myocardial infarction was performed through computed tomography (CT) scan which didn't show coronary artery disease as well as through echocardiography which showed normal systolic function.

Laboratory diagnosis

The patient underwent blood examination (C-reactive protein, aspartate aminotransferase, lactate dehydrogenase, MB form of creatine kinase, and cardiac troponin T) which didn't show any alterations.

Imaging diagnosis

The authors performed the following instrumental examinations: (1) ECG: T wave inversion in leads I, II, III, aVF and in V4-V5-V6; (2) Echocardiogram: mild echo-free space with pericardial effusion in the lateral wall and a slight increase in the hyper echogenicity level of the lateral portion of the left ventricle; (3) magnetic resonance imaging (MRI): areas of intramural and subepicardial delayed enhancement in the lateral wall, suggestive of fibrosis; and (4) CT scan: coronary abnormal 23 mm superficial intramiocardial course in the medium tract of left descending artery.

Pathological diagnosis

The authors didn't perform any histological examination.

Treatment

After the detection of the intramyocardial bridge the authors started a therapy with low dose bisoprolol and the authors suspended the athlete from competition and training. A monthly follow up was started.

Term explanation

Pre participation screening is the annual medical evaluation mandatory for competitive athlete in Italy.

Experiences and lessons

It would be desirable that sports physicians recommend to re-evaluate athletes experiencing persistent flues or not common signs and symptoms such as atypical thoracic pain, asthenia and palpitations, during the sports season; this information is to be extended to athletes and general practitioner.

Peer-review

This case report highlights the importance of anamnesis and 12 leads ECG examination for the athletes in diagnosis of subtle transitory myocardial alterations due to infections. Moreover, despite a normalization of ECG during follow up, after a myocarditis, the authors emphasized the eventuality to focus on the possibility of myocardial scars, which can be easily detected with MRI.

AIM AND SCOPE

World Journal of Cardiology (*World J Cardiol*, *WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJC covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Cardiology is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

The left atrium (LA) acts as a modulator of left ventricular (LV) filling. Although there is considerable evidence to support the use of LA maximum and minimum volumes for disease prediction, theoretical considerations and a growing body of literature suggest to focus on the quantification of the three basic LA functions: (1) Reservoir function: collection of pulmonary venous return during LV systole; (2) Conduit function: passage of blood to the left ventricle during early LV diastole; and (3) Contractile booster pump function (augmentation of ventricular filling during late LV diastole. Tremendous advances in our ability to non-invasively characterize all three elements of atrial function include speckle tracking echocardiography (STE), and more recently cardiovascular magnetic resonance myocardial feature tracking (CMR-FT). Corresponding imaging biomarkers are increasingly recognized to have incremental roles in determining prognosis and risk stratification in cardiac dysfunction of different origins. The current editorial introduces the role of STE and CMR-FT for the functional assessment of LA deformation as determined by strain and strain rate imaging and provides an outlook of how this exciting field may develop in the future.

Key words: Left atrium; Strain; Strain rate; Physiology; Pathophysiology; Cardiovascular magnetic resonance; Echocardiography; Feature tracking; Speckle tracking; Diastolic dysfunction

Core tip: Recent advances in speckle tracking echocardiography (STE) and cardiovascular magnetic resonance myocardial feature tracking (CMR-FT) allow a detailed quantification of left atrium (LA) dynamics in terms of strain and strain rate imaging. Corresponding imaging biomarkers are progressively found to have the potential to predict the outcome in a variety of cardiovascular disease states. The current editorial introduces the role of STE and CMR-FT for the functional assessment of LA deformation and provides an outlook of how this exciting field may evolve in the future.

Kowallick JT, Lotz J, Hasenfuß G, Schuster A. Left atrial physiology and pathophysiology: Role of deformation imaging. *World J Cardiol* 2015; 7(6): 299-305 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/299.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.299

INTRODUCTION

Heart failure of different origins including ischemic aetiology remains a major determinant of mortality[1]. Left atrial (LA) enlargement has been shown to be a sensitive parameter for the prediction of adverse cardiac events[2,3]. The interplay between LA enlargement and atrial remodelling in the development of atrial fibrillation (AF) has been demonstrated[4,5]. However, the pure relation of LA pathology to its enlargement within different diseases may oversimplify cardiovascular physiology. It is important to note that the LA does not merely represent a stiff chamber, which passively transports blood from the pulmonary veins to the left ventricle (LV), but a more complex and active chamber. Its role should rather be described as a dynamic modulation of LV filling by functioning as a reservoir, conduit and contractile booster pump[6,7]. There have been tremendous advances in terms of our ability to characterize all three elements of atrial function using non-invasive imaging techniques[8]. Recent advances include LA deformation analysis using speckle tracking echocardiography (STE)[9,10] as well as cardiovascular magnetic resonance myocardial feature tracking (CMR-FT)[7,11]. Corresponding imaging biomarkers are progressively found to have the potential to predict the outcome in a variety of cardiovascular disease states[6]. The current editorial introduces the role of STE and CMR-FT for the quantification of LA dynamics as expressed by strain and strain rate (SR) imaging and provides an outlook of how this exciting field may evolve in the future.

LA DEFORMATION ANALYSIS

Besides conventional techniques to analyse LA functional parameters (*e.g.*, pulmonary venous velocity, LA phasic volumes, mitral valve inflow velocity or mitral annular velocity; recent advances in deformation analysis allow to quantify LA longitudinal strain and SR using STE or - more recently - CMR-FT[7,11] (Figure 1). Strain and SR represent the magnitude and rate of myocardial deformation (please see the review by Gorcsan and Tanaka for in depth explanation[12]). LA strain profiles result in three aspects of LA physiology: passive strain (ε_E, representing LA conduit function), active strain (ε_A, representing LA contractile booster pump function) and total strain (ε_S, representing atrial reservoir function)[7] (Figure 1 and Table 1). Correspondingly, three SR parameters can be quantified: peak positive strain rate (SR_S, representing LA reservoir function), peak early negative strain rate (SR_E, representing LA conduit function) and peak late negative strain rate (SR_A, representing LA contractile booster pump function)[7] (Figure 1 and Table 1). It is interesting to speculate on the physiological relevance of the three LA functional elements: LA reservoir function as a measure of LA compliance and LA active relaxation may represent a compensatory mechanism at early stages of congestive LV failure. Conversely, LA conduit function as a measure of LA compliance is already affected by early diastolic LV relaxation abnormalities with changes in LV stiffness and compliance. Lastly LA booster pump function representing LA contractility has impact on ventricular filling and cardiac output[13].

LA deformation quantification comprises challenges that are not present when dealing with ventricular strain and SR imaging. These include the insertion of pulmonary veins and the presence of the LA appendage, the thin LA wall and the variable LA geometry[7]. Notwithstanding these facts, 2D STE and CMR-FT have both shown good performance and reproducibility of LA deformation analysis[7,14]. However, using two-dimensional representations of 3D structures may oversimplify the complex LA anatomy. Through-plane motion or reduced STE imaging quality with poor imaging windows can affect LA deformation analysis and may be difficult to correct. Recent advances in STE provide three-dimensional imaging that eliminates the effects of through-plane motion in patients with sufficient imaging windows and may allow the comprehensive analysis of global and regional LA strain[15,16]. At the present time, similar developments for CMR-FT based on three-dimensional imaging have not yet been introduced.

STE

Two-dimensional STE makes use of offline software analysis using conventional gray scale B-mode images, which are typically acquired during a breath-hold. The frame rate is set between 50 and 70 frames/sec. Speckles can be described as acoustic markers distributed within the myocardium, which can be

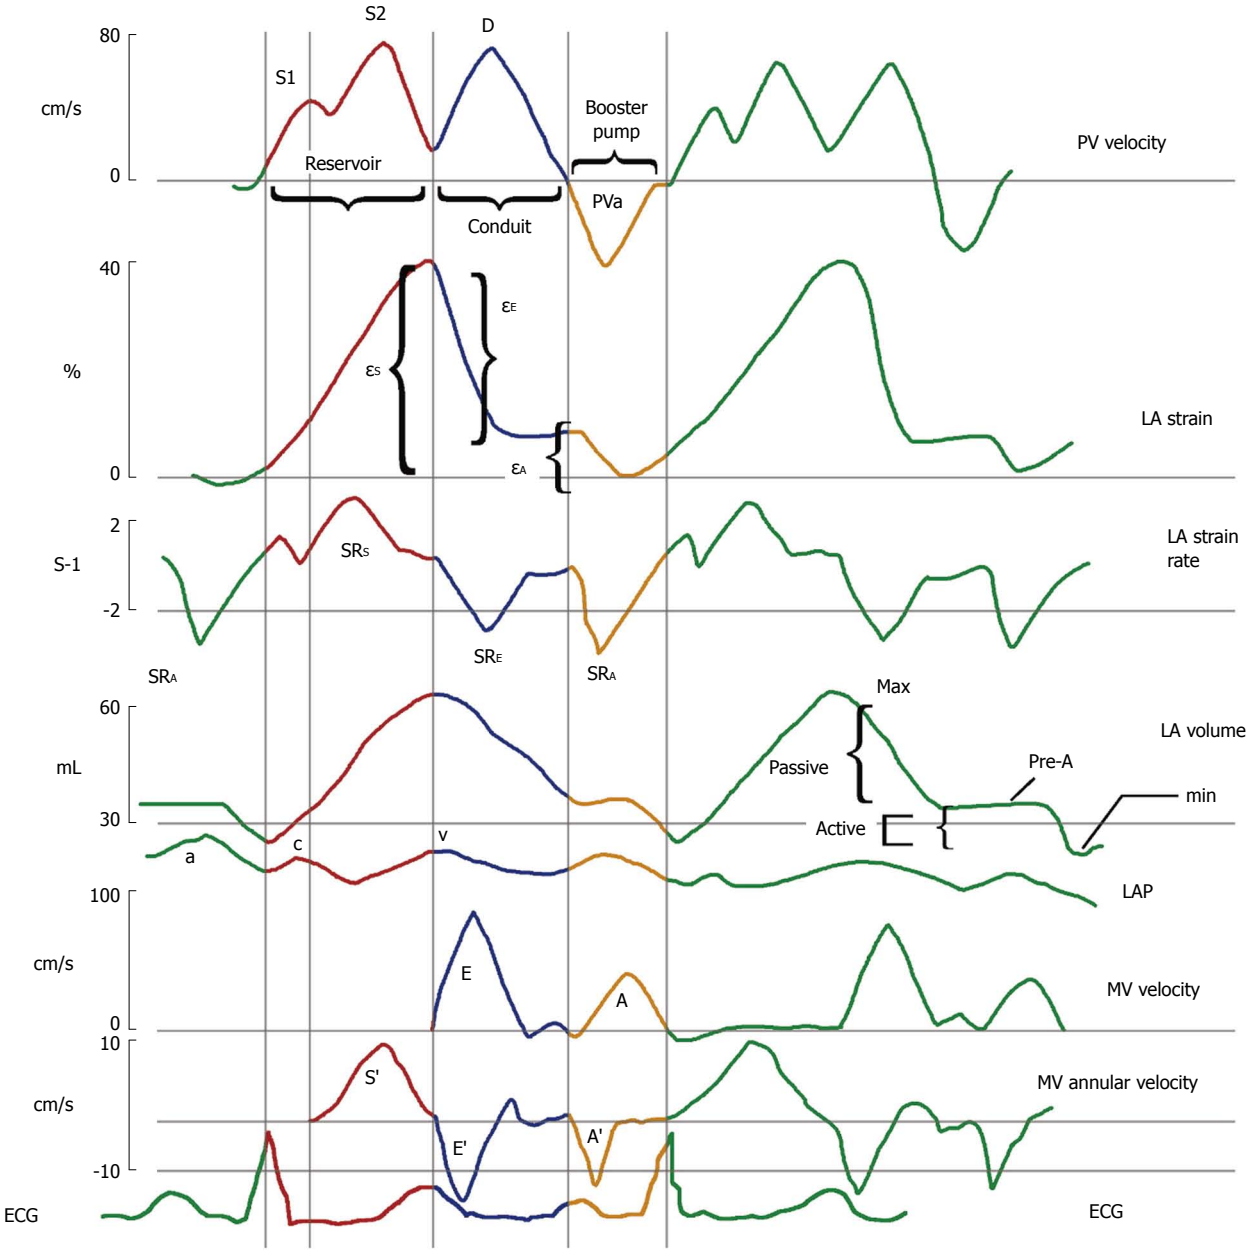

Figure 1 Left atrial physiology imaging using different methods. The figure displays pulmonary venous (PV) velocity, left atrial (LA) strain (ε), LA strain rate (SR), LA volume, left atrial pressure (LAP), and mitral spectral and tissue Doppler. Displayed are two cardiac cycles and the color-coded imaging of reservoir, conduit, and booster pump functions in red, blue, and yellow lines are shown within the first cardiac cycle, respectively. Reprinted from Journal of the American College of Cardiology, Vol 63, Brian D. Hoit, Left atrial size and function: role in prognosis, 493-505, 2014 with permission from Elsevier[6].

tracked from frame to frame[17]. This provides local myocardial displacement information, which can be utilized for the calculation of velocity, strain or SR. It is important to note that there is currently a lack of standardization for LA STE resulting in different approaches to calculate LA deformation indexes: LA strain and SR have been calculated by averaging values from a 15-segment model[18] (six equidistant segments in the apical 4-chamber view, six in the 2-chamber view and three in the 3-chamber view) or from a 12-segment model[14] (six equidistant segments in the 4-chamber view and six segments in the 2-chamber view). Usually, strain and SR indexes are averaged from a total of three consecutive cardiac cycles that provide stable electrocardiographic recording. Furthermore, it is important to understand that there are two different approaches to quantify LA strain with STE. Based on the reference point set at the onset of the P wave (corresponding to the beginning of the atrial cycle)[10,19] or set at the QRS-complex (corresponding to the beginning of the ventricular cycle)[14,20], different LA strain profiles are generated. The description above and the explanation in Figure 1 represent strain profiles acquired with the reference point set at the onset of the QRS-complex resulting in the acquisition of reservoir, conduit and booster pump

Table 1 Left atrial strain and strain rate indexes as determined by speckle tracking echocardiography and cardiovascular magnetic resonance myocardial feature tracking

LA function	Strain	Strain rate
Reservoir	ε_S	SR_S
Conduit	ε_E	SR_E
Booster pump	ε_A	SR_A

Nomenclature refers to the QRS complex set as the reference point and is therefore applicable to both peckle tracking echocardiography and cardiovascular magnetic resonance myocardial feature tracking. LA: Left atrial; ε: Strain; SR: Strain rate.

function[6]. In contrast, if the reference point is set at the onset of the P wave, LA strain profiles display early negative strain (representing LA booster pump function) followed by peak positive strain (representing LA conduit function) while their sum corresponds to LA reservoir function[6].

The wide availability and high temporal resolution of echocardiographic real time images are advantages of STE. However, due to the far-field location of the LA, the main drawback of STE is its dependency on high quality images that frequently cannot be guaranteed in patients with limited acoustic windows[14].

CMR-FT

CMR-FT allows tracking of tissue voxel motion directly from standard steady-state free precession (SSFP) cine CMR images and derivation of myocardial deformation (Figure 2) without the need for additional sequence acquisition as compared to myocardial MR Tagging[7]. Therefore, this technique appears particularly applicable from a clinical perspective and can be easily implemented into a running CMR laboratory. Although CMR-FT was initially validated for ventricular function analysis[21-27], its applicability has recently been extended to quantitative longitudinal LA strain and SR analysis[7]. Typically, LA endocardial borders are initially traced in the 2- and 4-chamber views at the minimum atrial volume after atrial contraction[7]. Subsequently, an automatic tracking algorithm is applied. According to STE, LA contours are divided into six segments[20] and subsequently averaged to global strain and SR indexes using a 12-segment model (six equidistant segments in the 4 and 2-chamber views). CMR-FT benefits from high quality CMR images allowing robust contouring of the thin LA myocardium. Furthermore, CMR includes the acquisition of standardised and highly reproducible imaging planes, which is particularly important in longitudinal studies with repeated measurements[28]. Future studies will need to address whether or not CMR-FT has better inter-study reproducibility than STE. On the other hand, low temporal resolution of CMR images might affect deformation analysis, *e.g.*, the ability to accurately quantify peak strain rates[7]. Future evaluations will have to compare STE and CMR-FT regarding the analysis of LA dynamics to determine whether or not results are interchangeable between modalities or one approach should be preferred over the other.

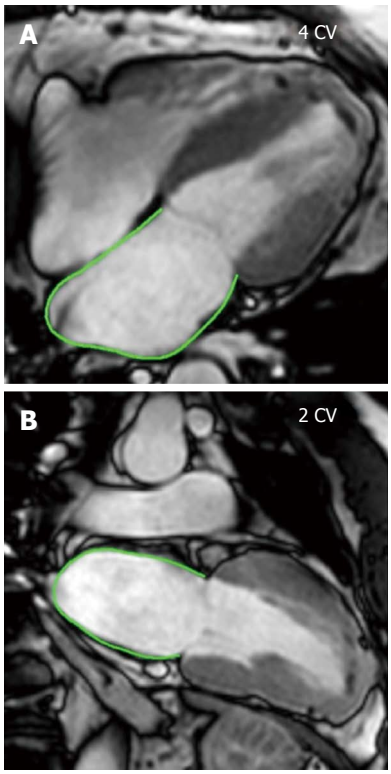

Figure 2 Cardiovascular magnetic resonance myocardial feature tracking of the left atrium in a patient with hypertrophic cardiomyopathy. Cardiovascular magnetic resonance myocardial feature tracking is performed in 4-chamber (A) and 2-chamber (B) views. Contours are based on 48 features, which are tracked throughout the cardiac cycle to generate longitudinal strain and strain rate profiles as displayed in Figure 1.

FUTURE POTENTIAL OF LA DEFORMATION QUANTIFICATION

A growing body of literature suggests to focus on the quantification of the three basic LA functions rather than on the LA volumes only: LA reservoir function has shown to closely correlate with LV filling pressures[29] and has demonstrated to be a sensitive biomarker for the prediction of adverse cardiac events independently of other measures of cardiac dysfunction in patients with heart failure[30]. Strong association between LA conduit function and recurrent atrial fibrillation after pulmonary vein isolation has been described[31]. Accordingly, there has been tremendous effort to study LA dynamics with STE. Mounting evidence suggests that impaired LA strain and SR dynamics have the potential to serve as imaging biomarkers for the prognosis and risk stratification or the decision to intervene in heart failure[32,33], hypertension[34], coronary artery disease[35], atrial fibrillation[36], valvular heart disease[20] and cardiomyopathies[37,38] (please see reviews by Hoit[6] and

Viera *et al*[17] for in depth information).

CMR-FT has been introduced more recently[7]. However, recent studies were able to demonstrate an association of impaired LA reservoir function and the development of heart failure in the general population[39]. Impaired reservoir function as determined by volumetric indexes, strain and SR measurements is also closely related to LV fibrosis[40]. With respect to previous reports on the relevance of LV fibrosis[41], LA reservoir function may also represent a promising target for risk stratification. Furthermore, initial experiences on patients with hypertrophic cardiomyopathy (HCM) and heart failure with preserved ejection fraction (HFpEF) demonstrate impaired LA reservoir and conduit function in HCM and HFpEF[7], when compared to healthy controls. In contrast, patients with HCM exhibit increased LA booster pump function while this is decreased in HFpEF[7]. Future studies will need to investigate whether or not this might refer to a potential compensatory mechanism in HCM, as opposed to a complete impairment of LA dynamics in HFpEF[7]. LA CMR-FT has not been applied to patients with atrial fibrillation yet. Deteriorated image quality, which is frequently present in patients with atrial fibrillation, might negatively impact on CMR-FT quality. It remains to be investigated whether or not CMR-FT is feasible in patients with atrial fibrillation using both, conventional ECG-gated SSFP sequences or real-time CMR techniques[42,43], which have demonstrated improved image quality in arrhythmic patients as compared to conventional ECG-gated techniques[44].

CONCLUSION

LA physiology and pathophysiology as quantified by STE and CMR-FT carry promising clinical and prognostic implications. Future studies will need to apply LA deformation imaging to support our understanding of heart failure development and risk stratification in valvular heart disease, atrial fibrillation, hypertension, coronary artery disease and different types of cardiomyopathy.

Abstract

According to a genome-wide association study, intronic SNPs within the human sterile 20/SPS1-related proline/alanine-rich kinase (*SPAK*) gene was linked to 20% of the general population and may be associated with elevated blood pressure. As cell volume changes, mammalian SPAK kinases respond to phosphorylate and regulate cation-coupled chloride co-transporter activity. To our knowledge, phosphorylation of upstream with-no-lysine (K) (WNK) kinases would activate SPAK kinases. The activation of WNK-OSR1/SPAK cascade on the kidneys and aortic tissue is related to the development of hypertension. Several regulators of the WNK pathway such as the Kelch kinase protein 3 - Cullin 3 E3 ligase, hyperinsulinemia, and low potassium intake to mediate hypertension have been identified. In addition, the SPAK kinases may affect the action of renin-angiotensin-aldosterone system on blood pressure as well. In 2010, two SPAK knock-in and knock-out mouse models have clarified the pathogenesis of lowering blood pressure by influencing the receptors on the kidneys and aortic smooth muscle. More recently, two novel SPAK inhibitors for mice, Stock 1S-14279 and Closantel were discovered in 2014. Targeting of SPAK seems to be promising for future antihypertensive therapy. Therefore we raised some viewpoints for the issue for the antihypertensive therapy on the SPAK (gene or kinase).

Key words: With-no-lysine (K) kinase; Oxidative stress-responsive kinase 1/SPS1-related proline/alanine-rich kinase kinase; Na-Cl co-transporter; Na^+-K^+-$2Cl^-$ cotransporter; Hypertension

Core tip: According to a genome-wide association study, intronic SNPs within the human sterile 20/SPS1-related proline/alanine-rich kinase (*SPAK*) gene was linked to 20% of the general population and may be associated with elevated blood pressure. Based on current studies, targeting of SPAK seems to be promising for future antihypertensive therapy. Therefore, we raised some viewpoints regarding the issue for antihypertensive therapy on the SPAK (gene or kinase).

Perspective of future drugs targeting sterile 20/SPS1-related proline/alanine-rich kinase for blood pressure control. *World J Cardiol* 2015; 7(6): 306-310 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/306.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.306

THE WITH-NO-LYSINE (K) KINASES AND HYPERTENSION AND HYPERKALEMIA

Pseudohypoaldosteronism type Ⅱ, a disease characterizing hypertension with hyperkalemia has been caused by mutations in WNK [with-no-lysine (K)] 1 and WNK4[1]. WNK4 is predominantly produced in the kidneys and epithelial tissues and hence the expression of WNK4 is more restricted than that of WNK1. WNK4 has been shown as a potent inhibitor of diverse epithelial transporters including the renal outer medullary potassium ion channel and the thiazide-sensitive sodium chloride co-transporter (NCC)[2]. In addition, paracellular chloride ion flux is enhanced by WNK4 activity[2]. Importantly, mutations in WNK4 have divergent effects on these transport pathways. WNK4 mutations could increase the inhibition of the renal outer medullary potassium ion channel, relieve the inhibition of NCC, and further promote paracellular chloride ion flux[2,3]. These findings can support a model in which WNK4, as a molecular switch, can alter the balance between potassium ion secretion and chloride ion reabsorption and explain the physiological abnormalities in patients with pseudohypoaldosteronism type Ⅱ. Other WNK kinases also distribute in diverse epithelia throughout the body and are involved in chloride ion flux, suggesting that these kinases may generally participate in the regulation of chloride ion flux.

MOLECULAR PATHWAYS FOR WNK-SPAK/OSR1-NCC/NKCC TO CONTROL BLOOD PRESSURE

As cell volume changes, mammalian SPAK (SPS1-related proline/alanine-rich kinase) and OSR1 (oxidative stress-responsive kinase 1) kinases respond to phosphorylate and regulate cation-coupled chloride cotransporter activity[4]. Phosphorylation of upstream WNK kinases would activate SPAK and OSR1. There are four mammalian WNK kinases: WNK1-WNK4. In humans, WNK1 and WNK4 mutations result in hyperkalemia and hypertension partly by altering renal sodium and potassium transport. WNK1 and WNK4 recruit an endocytic scaffold protein, intersectin, and thereby stimulate endocytosis of ROMK1. This recruitment occurs between the PXXP motif of the WNKs and the SH3 domain of intersectin which is independent of WNK kinase activity. WNKs regulate cation-chloride-coupled cotransporters, Na^+-K^+-2Cl^- cotransporter (NKCC) 1 and NKCC2 (and NCC, under some conditions) dependent on kinase activity[5]. OSR1 and SPAK, two Ste20-related protein kinases, which are bound with and phosphorylated by WNK1 and WNK4, in turn bind with and phosphorylate cation-chloride-coupled cotransporters to increase their activity. Binding of OSR1/SPAK to upstream WNKs and downstream cation-chloride-coupled cotransporters are both mediated by a docking site in the C-terminus of OSR1/SPAK and RFX[V/I] motifs present in WNKs or in NKCCs and NCC[5].

Several regulators of the activation of WNK kinase have been identified in recent animal studies as the Kelch kinase protein 3-Cullin 3 E3 ligase, low potassium intake, hyperinsulinemia, and some hormones (angiotensin Ⅱ, aldosterone and vasopressin), which may act on the kidneys or aortic tissues to affect blood pressure[6-10]. Chávez-Canales *et al*[11] showed that WNK4 could decrease the WNK1 and WNK3-mediated activation of NCC in the kidneys. This finding suggests that WNK kinases form a network in which WNK4 associates with WNK1 and WNK3 to regulate NCC. In addition, the activity of OSR1/SPAK in the kidneys could be enhanced by AMP-activated protein kinase resulting in sodium retention *via* phosphorylation of NKCC2 in obesity[12]. The effect of vasopressin on sodium reabsorption is mediated by SPAK along the distal nephron to control blood pressure as well[13]. Figure 1 shows the potential mechanisms of hypertension related to the WNK-SPAK/OSR1-NCC/NKCC cascade.

SPAK KNOCK-IN AND KNOCK-OUT MOUSE MODELS AND THE EXPRESSION AND FUNCTION OF NCC/NKCC IN THE KIDNEY AND AORTIC TISSUE

Since intronic SNPs within the human *SPAK* gene (also known as *Stk*39) was linked to 20% of the general population and may be associated with hypertension in a genome-wide association study, targeting of SPAK seems to be promising for future

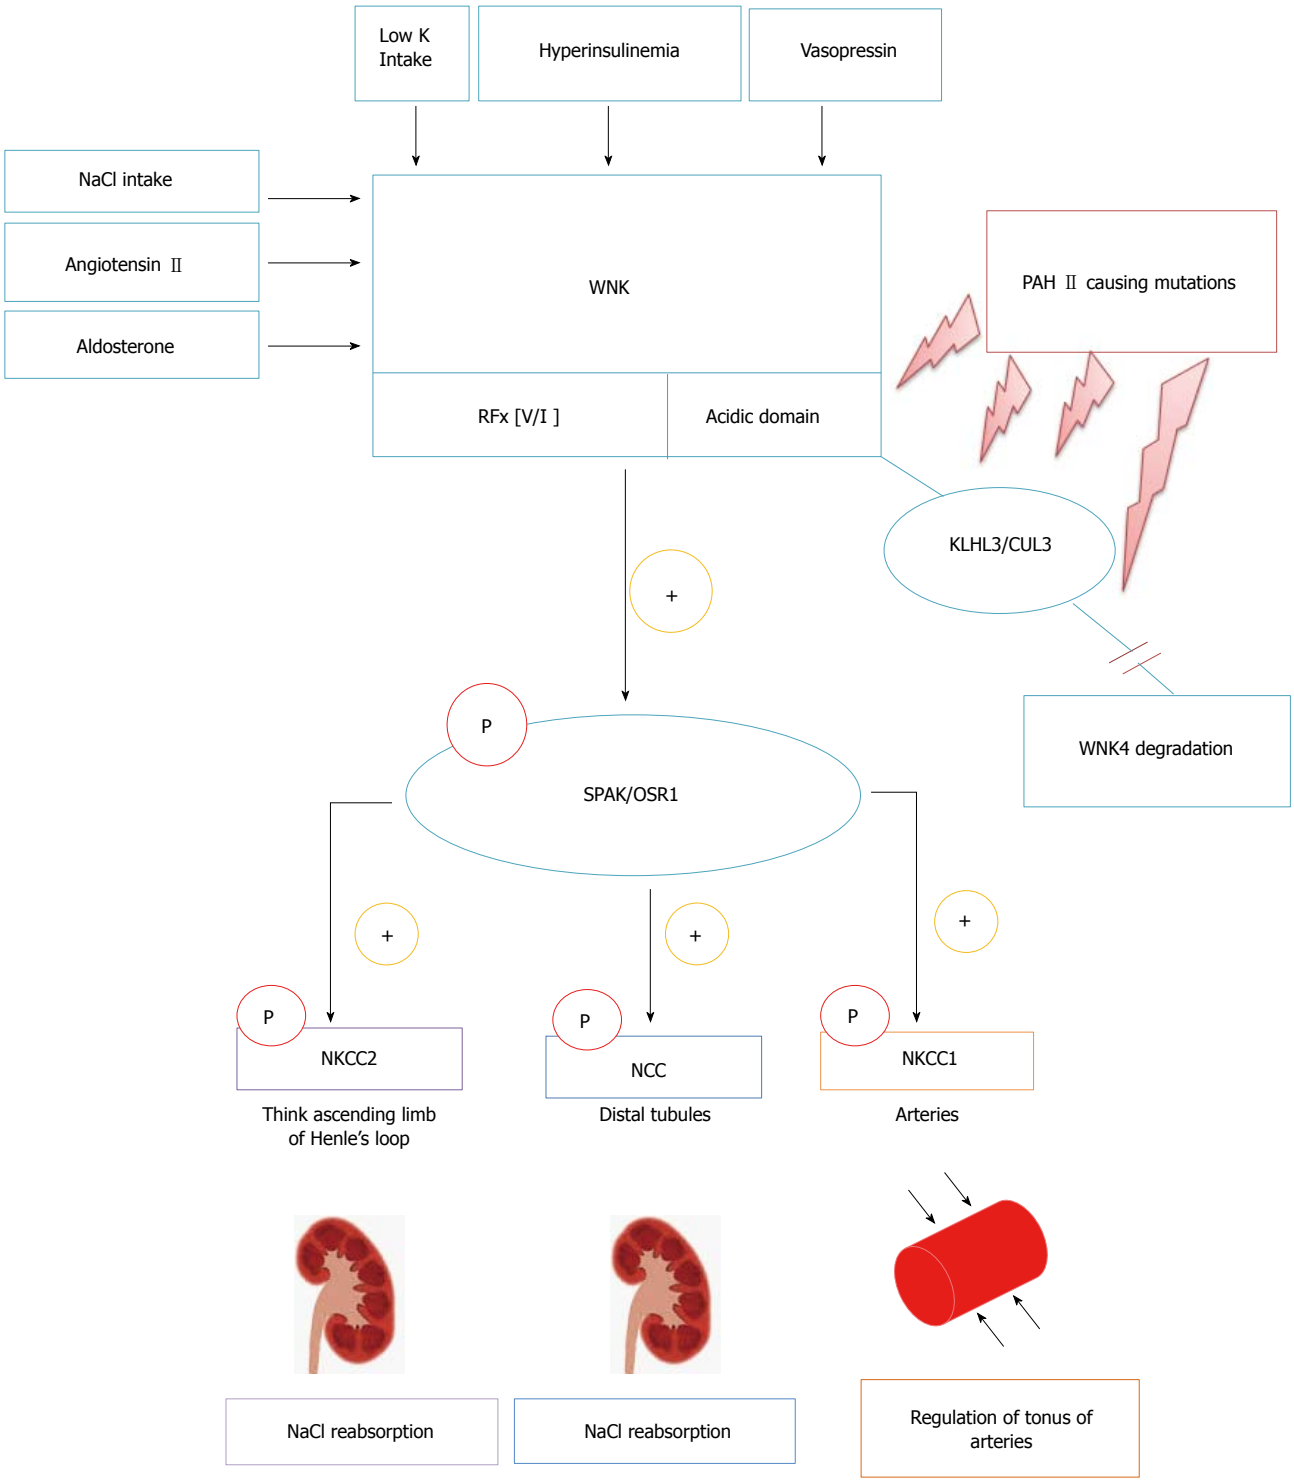

Figure 1 Potential mechanisms of With-no-lysine (K) - SPS1-related proline/alanine-rich kinase/oxidative stress-responsive kinase 1 - Na-Cl co-transporter/ Na^+-K^+-2Cl ($^-$) cotransporter to contribute to hypertension. Several regulators of the activation of WNK cascade, such as KLHL3/CUL3, low potassium intake, hyperinsulinemia and some hormones (angiotensin Ⅱ, aldosterone and vasopressin) may act on the kidneys or aortic tissues. SPAK and OSR1 are activated *via* phosphorylation by upstream WNK kinases using docking site in the RFX (V/I). As a result, SPAK/OSR1 may regulate cation-chloride-coupled cotransporters in kidneys, tonus of aortic tissues, and blood pressure. PAH Ⅱ causing mutations in acidic domain of WNK4, KLHL3 and Cullin 3 activate SPAK/OSR1-NCC signaling by decreasing WNK4 degradation and accumulation of WNK4. KLHL3: Kelch kinase protein-3; CUL3: Cullin3; PAH Ⅱ: Pseudohypoaldosteronism type Ⅱ; WNK: With-no-lysine (K); SPAK: SPS1-related proline/alanine-rich kinase; NCC: Na-Cl co-transporter; NKCC: Na^+-K^+-2Cl ($^-$) cotransporter; OSR1: Oxidative stress-responsive kinase 1.

antihypertensive therapy[14]. In 2010, Yang *et al*[15] generated SPAK null mice in which exons 9 and 10 of the *Stk*39 gene were deleted to investigate its role in the kidneys and aortic blood vessels[15]. Earlier, Rafiqi *et al*[16] had generated knock-in mice in which SPAK could not respond to the WNK kinases. Both

the homozygous SPAK knock-in ($SPAK^{243A/243A}$) and knock-out mice ($SPAK^{-/-}$) demonstrated the same phenotype of hypotension. Rafiqi *et al*[16] accounted for the mechanisms of hypotension in knock-out mice as possibly by lowering expression and phosphorylation of NKCC2 and NCC in the kidneys. Yang *et al*[15] further pointed out that the impaired vasoconstriction may be caused by both reduced function in aortic tissues and NKCC1 phosphorylation in addition to defects of NCC in the kidneys leading to hypotension in their SPAK null mice. However, some different characteristics are present between the SPAK knock-in and knock-out mice that need to be explained. For example, Yang *et al*[15] reasoned the increased NKCC2 phosphorylation in the SPAK null mice due to compensatory up-regulation of OSR1 in the kidneys, which is contrary to the decreased NKCC2 phosphorylation and normal activity of OSR1 in the SPAK inactivated mice.

A PERSPECTIVE FOR DRUG DEVELOPMENT TARGETING OF SPAK TO LOWER BLOOD PRESSURE

To our best knowledge, the SPAK knock-in mice ($SPAK^{+/243A}$/$SPAK^{243A/243A}$) have partial or complete inactivated SPAK function together with WNK1/4 when binding to a cluster of conserved Thr residues which are located at the N-terminal cytosolic domain of the electroneutral cation-coupled chloride cotransporters (SCL2). Because OSR1 binds to a similar cytosolic site on SCL2 with SPAK, to design a drug blocking the binding site between SPAK/OSR1 and SCL2 may affect OSR1 function and result in a hazardous effect. Therefore, the SPAK knock-in mice are more like a model for developing a new drug to target the SPAK protein instead of the binding site of SCL2. As drugs within the cells would inactivate SPAK, they would be competitive antagonist for the site of the N-terminal cytosolic domain of SCL2 with OSR1. As a result, the activity of OSR1 would not be enhanced in SPAK knock-in mice, would subsequently lead to reduced activation of NKCC2 in the kidneys when all the SPAK is inactivated. From this point of view, could we be convinced whether targeting the protein component of SPAK is a promising route? The answer may be derived partly from the blood pressure of $SPAK^{+/243A}$ knock-in mice, which was not reported by Rafiqi *et al*[16]. Although $SPAK^{+/-}$ knock-out mice were observed to have the phenotype of hypotension, this result could not be translated to the knock-in mice directly. Since the SPAK knock-out mice had secondary hyperaldosteronism implying an aldosterone-resistant status which the SPAK knock-in mice did not have, hypotension in SPAK null mice may be associated with this condition rather than the reduction of NKCC1 activity that Yang *et al*[15] proposed. A more definite proof of this would require tissue-specific SPAK knock-out in the vasculature[17], the distribution of SPAK in reference to OSR1 in the arterial vessels in mice should also be estimated. Given that the $SPAK^{+/243A}$ knock-in mice had either a normal range or only a little lower than normal blood pressure, drugs targeting SPAK would work ineffectively. Apparently, the importance of SPAK for the activation of different SCL2 is variable according to their affinity (Kd, dissociation constant) and distributions in tissues. Pharmacokinetically, a drug should be bound to at least half of the SPAK contents to achieve 20% reduction of the epithelial functional NCC and 20% up-regulation of the functional NKCC2 in the kidneys and 40% down regulation of functional NKCC1 in the kidneys and vasculature similar to $SPAK^{+/243A}$ knock-in model[16]. How to determine the optimal drug concentration to obtain the goal of lowering blood pressure would also be a challenge due to different SPAK contents in the tissues and the competition from OSR1.

Alternatively, targeting the gene of *SPAK* in the kidneys and vasculature to produce the heterogeneous knock-out genotype of $SPAK^{+/-}$ with the phenotype of hypotension is a more difficult task. Secondary hyprerreninemia and hyperaldosteronism standing for an aldosterone-resistant status should be highlighted in which they may be harmful to the heart with predominant OSR1 and less SPAK[16,18]. In addition, whether it is useful in people with primary or secondary hyperaldosteronsim should be tested by a hypertensive mouse model with hyperaldosteronism.

Finally, there are some uncertainties regarding the inhibition of SPAK to control blood pressure including the adverse effects of infertility and reduced gastrointestinal glands secretion ability and the protective benefits from sepsis associated with the reduction of NKCC1[19-21]. Recently, Kikuchi *et al*[22] have discovered one small-molecule compound (Stock 1S-14279) and an antiparasitic agent (Closantel) that could inhibit SPAK-regulated phosphorylation and activation of NCC and NKCC1 *in vitro* and in mice[22].

The safety and efficacy of these novel SPAK inhibitors for mice and SPAK knock-in or knock-out mice could provide future models for the control of blood pressure and drug design for human beings. In summary, targeting of the gene or protein of SPAK should be evaluated systematically and the interactions among WNT, OSR1, SCL2 and Renin-Angiotensin-Aldosterone system would need further investigations.

Abstract

We evaluated the clinical feasibility of using drug-coated balloon (DCB) angioplasty in patients undergoing primary percutaneous coronary intervention (PPCI). Between January 2010 to September 2014, 89 ST-elevation myocardial infarction patients (83% male, mean age 59 ± 14 years) with a total of 89 coronary lesions were treated with DCB during PPCI. Clinical outcomes are reported at 30 d follow-up. Left anterior descending artery was the most common target vessel for PCI (37%). Twenty-eight percent of the patients had underlying diabetes mellitus. Mean left ventricular ejection fraction was 44% ± 11%. DCB-only PCI was the predominant approach (96%) with the remaining 4% of patients receiving bail-out stenting. Thrombolysis in Myocardial Infarction (TIMI) 3 flow was successfully restored in 98% of patients. An average of 1.2 ± 0.5 DCB were used per patient, with mean DCB diameter of 2.6 ± 0.5 mm and average length of 23.2 ± 10.2 mm. At 30-d follow-up, there were 4 deaths (4.5%). No patients experienced abrupt closure of the infarct-related artery and there was no reported target-lesion failure. Our preliminary experience showed that DCB angioplasty in PPCI was feasible and associated with a high rate of TIMI 3 flow and low 30-d ischaemic event.

Key words: Acute myocardial infarction; Drug coated balloon; Efficacy; Primary angioplasty; Safety

Core tip: Primary percutaneous coronary intervention (PPCI) is the preferred reperfusion therapy for ST-elevation myocardial infarction (STEMI). Stent implantation is considered as a routine during PPCI as it is associated with reduction of ischaemic end-points. Drug-coated balloon (DCB) has emerged as a new therapeutic option to treat coronary artery disease as stent technology has certain limitations. There is however limited data on the feasibility of using DCB as primary therapy in PPCI. We evaluated the clinical safety and efficacy of using paclitaxel-coated balloon in patients undergoing PPCI

for STEMI and report on our 30 d clinical outcomes.

INTRODUCTION

Primary percutaneous coronary intervention (PPCI) is the preferred reperfusion therapy for ST-elevation myocardial infarction (STEMI) if performed in a timely fashion[1]. Stent implantation[2-5] whether with bare metal stent (BMS) or drug-eluting stent (DES) is considered as a routine during PPCI as it is associated with reduction of early ischaemia, restenosis and re-occlusion of culprit artery in comparison with pure old balloon angioplasty (POBA).

Drug-coated balloon (DCB)[6-8] has emerged as a new therapeutic option to treat coronary artery disease (CAD) as stent technology has certain limitations. There is however limited data on the feasibility of using DCB as primary therapy in PPCI. Previous clinical studies[2-3] had shown no difference in the mortality rates between those who received stents or POBA during PPCI with the main difference driven largely by lower rate of target vessel revascularization (TVR) in the stenting group.

It is possible that DCB could close this gap for the POBA group and we therefore evaluated the clinical feasibility (*i.e.*, safety and efficacy) of using paclitaxel-coated balloon in our cohort of South-East Asian patients undergoing PPCI for STEMI.

RESEARCH

Between January 2010 to September 2014, 89 STEMI patients with a total of 89 coronary lesions were treated with SeQuent Please DCB (B.Braun, Melsungen, Germany) as primary therapy during PPCI. The PPCI strategy was to perform thrombus aspiration followed by predilatation of the lesion site before treatment with DCB. Bail-out stenting was performed only when there was significant vessel recoil/coronary dissection. Clinical outcomes are reported at 30 d follow-up.

RESULTS

Table 1 shows the baseline clinical characteristics, angiographic features, procedural data and clinical outcomes of the study patients. The mean age of the patients at presentation was 59 ± 14 years with male preponderance (83%). Twenty-eight percent of the patients had underlying diabetes mellitus. Mean left ventricular ejection fraction was 44% ± 11%. The majority of patients presented with inferior STEMI (55%) with the left anterior descending artery (LAD) being the most common target vessel for PCI (37%) followed by right coronary artery (33%), left circumflex (13%) and others (17%).

Target lesion thrombosis	0 (0)

LVEF: Left ventricular ejection fraction; MI: Myocardial infarction; LAD: Left anterior descending artery; CIRC: Left circumflex artery; RCA: Right coronary artery; TIMI: Thrombolysis in myocardial infarction.

Thrombus aspiration was performed in 50 patients (56%) with glycoprotein 2b/3a inhibitors administered in 71 patients (80%). Pre-procedural Thrombolysis in Myocardial Infarction (TIMI) flow was 0 in 70% of patients. At the end of PPCI, TIMI 3 flow was successfully restored in 98% of patients with residual stenosis of 29%.

DCB-only PCI was the predominant approach (96% of patients) with the remaining 4% of patients receiving bail-out stenting for significant recoil/dissection after treatment with DCB. An average of 1.2 ± 0.5 DCB were used per patient, with mean DCB diameter of 2.6 ± 0.5 mm and average length of 23.2 ± 10.2 mm. The mean inflation pressure for DCB was 10 ± 3 atm and mean inflation time was 54 ± 22 s.

At 30-d follow-up, there were 4 deaths (4.5%). Three patients succumbed due to cardiogenic shock and 1 died of sepsis. No patient experienced abrupt closure of the infarct-related artery (IRA) and there

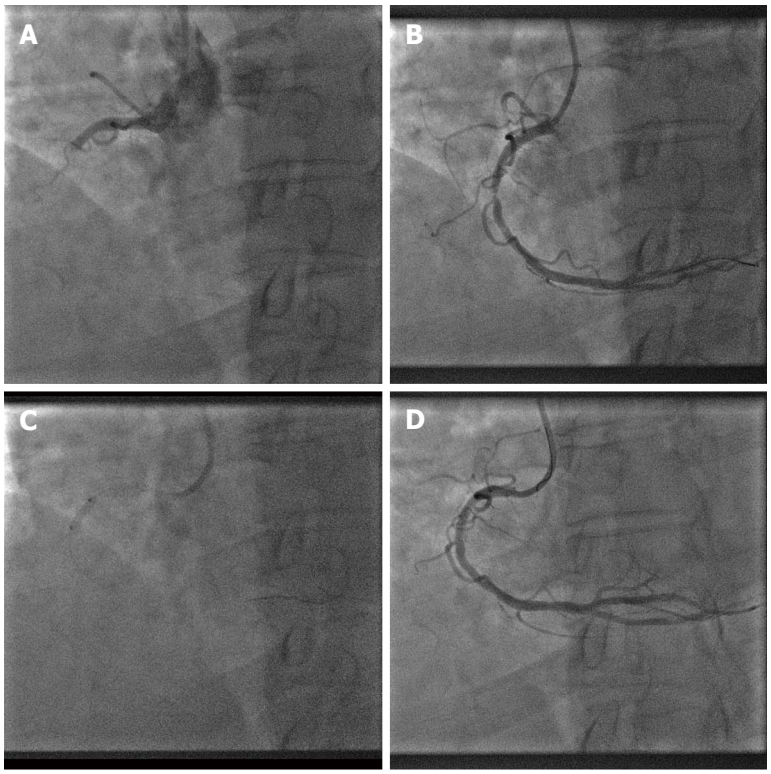

Figure 1 Thrombus aspiration (for visible thrombus) and predilatation with a non-coated balloon prior to drug-coated balloon angioplasty as the final step. A: Baseline coronary angiography showing acute thrombotic occlusion of mid right coronary artery (RCA); B: Mid RCA after thrombus aspiration; C: Predilatation of mid RCA with non-coated balloon; D: Final angiography of mid RCA (after DCB angioplasty).

was no reported TVR, target-vessel-MI or target lesion thrombosis.

DISCUSSION

When compared with fibrinolytic therapy, PPCI in STEMI[1] reduced the rates of death, reinfarction, and stroke. The use of POBA in PPCI has been superseded by routine stenting[2-3] in the contemporary era as the former approach was associated with recurrent ischemia, restenosis, and reocclusion of the IRA. However, prior studies so far had not shown any difference in the mortality rates between those who received stents or POBA during PPCI. The main difference is consistently a lower rate of TVR in the stenting group and it is possible that DCB could close this gap for selected group of patients in the POBA arm. From our preliminary experiences, we demonstrated that the use of DCB as primary therapy for STEMI patients in PPCI was feasible and associated with a high rate of final TIMI 3 flow and low 30-d major adverse cardiac event (MACE).

In recent years, DCB[6-8] has emerged as a viable therapeutic option for treating CAD as the current DES technology has limitations like late stent thrombosis and prolonged dual anti-platelet therapy. Paclitaxel is the drug of choice for all the commercially available DCBs because of its highly lipophilic properties which allows rapid diffusion into the vessel wall and sustained anti-proliferative effect despite its short contact with the vessel wall. The best long term results with DCB is achieved with a DCB-only approach when compared to DCB plus BMS as the former approach is associated with a lower late lumen loss and lower target vessel revascularization.

To gain the utmost benefit from DCB[9], adequate lesion preparation is necessary so that we can maximize balloon contact area to vessel wall for a minimum of 30 s. Similarly in PPCI, we advocate 2 key steps, *i.e.,* thrombus aspiration (for visible thrombus) and predilatation with a non-coated balloon prior to DCB angioplasty as the final step (Figure 1). Removal of thrombus will enable DCB to have better contact with the vessel wall and initial predilatation of the lesion will also allow us to evaluate whether the patient can tolerate prolonged balloon inflation with DCB.

Coronary dissection (iatrogenic) occurs inevitably as result of POBA and abrupt closure of vessel remains one of the most fearful complications. Having good knowledge on the different grades of coronary dissection according to the National Heart, Lung, and Blood Institute (NHLBI) classification[10], one can carefully select patients for DCB angioplasty during PPCI and in our study, no patients experienced abrupt closure of IRA. Only 4% of our patients required bailout stenting for significant recoil/dissection (> Type B dissection). The incidence of abrupt closure of IRA is also significantly reduced in the current era of more

potent anti-platelet agents.

There were several limitations to our study. The number of patients is relatively small and our study was a single-center registry, subject to selection and operator bias. All patients in our study received treatment with SeQuent Please DCB and our results could only be extrapolated to those who had received similar therapy. Whether similar results would be seen with patients receiving other types of DCB is unknown as not all DCBs are equal in terms of clinical efficacy.

In conclusion, the use of DCB as primary therapy in PPCI represents a novel approach in treating STEMI patients. Our preliminary experiences were favourable ie a high rate of final TIMI 3 flow and low 30-d MACE. This approach is possible with appropriate patient selection and by performing 2 key preconditioning steps. Further studies with longer follow-up are necessary to confirm our preliminary findings.

Abstract

Assessment of the QT interval on a standard 12 lead electrocardiogram is of value in the recognition of a number of conditions. A critical part of its use is the adjustment for the effect of heart rate on QT interval. A systematic search was conducted to identify studies that proposed formulae to standardize the QT interval by heart rate. A nomenclature was developed for current and subsequent equations based on whether they are corrective (QTc) or predictive (QTp). QTc formulae attempt to separate the dependence of the length of the QT interval from the length of the RR interval. QTp formulae utilize heart rate and the output QTp is compared to the uncorrected QT interval. The nomenclature consists of the first letter of the first author's name followed by the next two consonance (whenever possible) in capital letters; with subscripts in lower case alphabetical letter if the first author develops more than one equation. The single exception was the Framingham equation, because this cohort has developed its own "name" amongst cardiovascular studies. Equations were further categorized according to whether they were linear, rational, exponential, logarithmic, or power based. Data show that a person's QT interval adjusted for heart rate can vary dramatically with the different QTc and QTp formulae depending on the person's heart rate and QT interval. The differences in the QT interval adjustment equations encompasses values that are considered normal or significant prolonged. To further compare the equations, we considered that the slope of QTc versus heart rate should be zero if there was no correlation between QT and heart rate. Reviewing a sample of 107 patient ECGs from a hospital setting, the rank order of the slope - from best (closest to zero) to worst was QTcDMT, QTcRTHa, QTcHDG, QTcGOT, QTcFRM, QTcFRD, QTcBZT and QTcMYD. For two recent formulae based on large data sets specifically QTcDMT and QTcRTHa, there was no significant deviation of the slope from zero. In summary a nomenclature permits easy reference to QT formulae that adjust for heart rate. Twenty different formulae can produce discordant calculations of an adjusted QT interval. While the formulae developed by Bazett and Fridericia (QTcBZT and QTcFRD respectively) may continue to be used clinically, recent formulae from large population studies specifically QTcDMT and QTcRTHa appear to be better

to adjust QT for heart rate in clinical practice.

Key words: QT interval; Heart rate adjustment

Core tip: We propose a nomenclature for QT-heart rate adjustment formulae consisting of the first letter of the first author's name followed by the next two consonance with subscripts if the author develops more than one equation. Twenty different QT-heart rate formulae produced discordant calculations of adjusted QT interval. Formulae were categorization into predictive or corrective (QTc) and into linear, rational, exponential, logarithmic, or power based. QTc equations are the most suitable for clinical application. Based on the ability to minimize the slope of a best fit linear relationship between QTc and heart rate, the new formulae QTcDMT and QTcRTHa warrant introduction into clinical practice.

INTRODUCTION

Assessment of the QT interval on a standard 12 lead electrocardiogram is of value in the recognition of conditions such as electrolyte disturbances, drug-induced cardiac toxicity, genetic abnormalities of cardiac channels (channelopathies) and autonomic nervous system dysregulation[1-6]. Prolonged QT interval has been considered a useful biomarker for electrolyte abnormalities such as hypokalemia or hypomagnesemia[2]. In addition, the duration of the QT interval has been found in epidemiologic studies to identify individuals at high risk of subsequent sudden death[7].

QT interval is highly dependent on heart rate, so that utilization of the QT interval, requires adjustment for the impact of heart rate on the QT interval. Formulae for the adjustment of the QT interval, for heart rate, have been used clinically for almost one hundred years[8,9]. While the original proposals of Bazett[8] and Fridericia[9] remain the most popular methods, there were many other possible choices for heart rate correction proposed in the early years of electrocardiography, as reviewed by Simonson *et al*[10]. There have been considerable concerns about the precision and the validity of the standard QT interval-heart rate adjustments approaches[11-15] that have led to the recent development of QT adjustment formulae from larger numbers of persons[16,17]. Pharmacovigilance data that identified the association of drug-induced sudden cardiac death with prolonged QT interval, generated recommendations by drug approval and monitoring agencies and has led to recommendations to evaluate the effect of drugs on the QT interval - the "Thorough QT Study" (TQT)[18]. Such studies require the careful assessment of the QT interval. The need for evaluation of the QT interval has generated research into how best to isolate the effect of a drug on the QT interval and minimize other factors such as heart rate which changes over time and might influence the QT interval. That research categorized QT-heart rate correction equations and expanded the development of more rate correction approaches that were based on large population studies[16,17,19-21]. This literature has often not been translated to the clinic. The objective of this study is several fold. The first objective was to assemble and review the different QT-heart rate adjustment formulae so as to construct a reference nomenclature which reflects their nature and aids future discussion. The next objective was to compare the QT-heart rate adjustment formulae. The third objective was to assess how well the clinical impact of current widely used methods, which were based on small samples of apparently healthy individuals, compare with the recently proposed formulae that have been based on large sample sizes, often population based.

Our review began with a specific and comprehensive literature search so that all relevant QT interval formulae would be included for our analysis. Second, we applied eligibility criteria to all formulae to limit formulae to those with broad clinical application. Third, we obtained ECGs from a hospital setting to apply the selected formulae to QT and heart rate values. Finally, we compared the most preferred formulae.

LITERATURE SEARCH

A systematic search was conducted to identify studies that proposed equations to standardize the QT interval by heart rate. We searched the Medline and EMbase databases using the PubMed and OvidSP platforms. The full electronic search strategy used was "QT interva" and "heart rate" and reference value. The reference list of publications was searched for other publications so that additional papers from these reference lists were also used for our review.

ELIGIBILITY CRITERIA

Studies that met the following criteria were included: (1) an original study (2) development of the equation in an apparently normal population (3) an adult population (4) clear presentation of the equation, its parameters and conditions (5) equations should be based on ECG measured QT interval. Papers that dealt with cardiac systole rather than QT interval

Goto *et al* (2008)[25]	1276	Men aged 20 to 35 yr	QTcGOT
Rautaharju *et al* (2014)[17]	57595	Men and women, aged 5 to 90 yr	QTcRTHb

measurements were excluded except for the early clinical papers. Papers were also excluded if the QT interval was measured mainly in cases with electrolyte abnormalities, only children or in persons with electronic pacemakers.

ECG QT MEASUREMENT

Resting ECGs from a hospital ECG service were evaluated. Only ECGs with sinus rhythm and without bundle branch block, ST elevation myocardial infarction or significant ST-T wave changes were considered. There were 107 ECGs that were anonymously obtained from an acute care hospital. No clinical information is available similar to the usual clinical ECG interpretation setting. ECGs were acquired and digitally analyzed. ECG waveform were sampled at least at 500 samples per second using the Marquette 12SL analysis program (GE Healthcare, Milwaukee, WI, United States). The QT interval is measured "from the earliest detection of depolarization in any lead (QRS onset) to the latest detection of repolarization in any lead (T offset) (The Marquette 12SL analysis program was Marquette™ 12SL™ ECG Analysis Program, GE Healthcare Milwaukee, WI, United States). The QT interval and heart rate measured by the analysis program was used in the heart rate adjustment formulae.

VALIDATION OF EXISTING QT CORRECTION FORMULAE

Recognizing that the goal of the of each formula is to produce QTc values that do not correlated with heart rate or RR interval so that the slope of QTc/RR regression should zero, we calculated the linear slope of eight corrective formulae for the 107 persons with various heart rates. The eight corrective formulae were selected based on clinical usage and relevance.

Statistical analysis

A linear regression model was used to calculate the slope of QTc *vs* heart rate relationship. The goodness of fit of the data to the linear regression (line) is indicated by the standard deviation of residuals.

CATEGORIZATION OF QT FORMULAE

Over 25 different equations were identified. After examination of the formulae, a nomenclature was developed. Formulae were categorized into QT correction or prediction formulae. A correction formula is defined as a formula which attempts to separate the dependence of the length of the QT interval from the length of the RR interval (Table 1). The correction formulae are identified by the subscript with a lower case c. The other category includes predictive formulae, which are defined as formulae that predict an "optimal" QT interval length given the heart rate. The prediction equations are identified by the subscript with a lower case p or QTp (Table 2). Our rationale for this division is based on how each type of formulae is used. For a QTc equation, the patient's heart rate and QT interval are used to calculate a QTc value, which is compared to a standard value. For a QTp equation only the person's heart rate is required, then, the output QTp will be compared to the patient's uncorrected QT interval. QTc limits would be anticipated to be different for each equation, and the same applies to the difference between uncorrected QT and QTp.

Formulae were then divided according to the nature of correction - classified as linear, rational, power, logarithmic, or exponential[20,22] (Table 1). For our naming convention, we identify formulae by the first letter of the first author's name followed by the next two consonants (whenever possible) in capital letters. If the first author develops more than one equation, the equations are labelled by the lower case alphabetical letter as subscript. The only exception to this rule was the Framingham study which has had many authors over the years and is a population based study that has developed its own name and reputation amongst cardiovascular studies.

Table 2 QT prediction equations

Arrowood *et al* (1993)[42]	16	16 subjects, aged 21 to 62 yr	QTpARR

The proportion of men and women is provided when available.

Correction formulae

The majority of corrective formulae utilize a power function to adjust the heart rate (Table 1). The first and still widely used correction equations were: Bazett's proposal, based on a very small sample of normal subjects, that the QT interval varied according to the square root of the heart rate or cycle length (RR interval)[8] and Fridericia's proposal[9] that the cube root of the RR interval was the best adjustment formula. The original Bazett formula which included constants was examined and had the constants eliminated producing the widely used Bazett formula[23]. Dmitrienko *et al*[16] reported on the ECGs from 13039 individuals (men and women) who had ECGs as part of their baseline assessment in clinical drug trials, conducted in 2000 and 2001, sponsored by Eli Lilly and Company. This correction formula was obtained by fitting a linear model to log-transformed QT and RR data. Mayeda[24] examined the ECGs of 200 apparently healthy Japanese individuals. Goto *et al*[25] studied the relationship between RR and QT, using the bootstrap method, in resting ECGs of 1276 healthy young Japanese men. The major linear equation was developed by Sagie *et al*[26] from the Framingham population in the United States. The sample size used to develop or test the equations varied dramatically between studies. The most recent equation, developed by Rautaharju *et al*[17], was based on pooled data from three different sources-two population studies and one large study of baseline ECGs prior to drug testing for a potential effect on QT, and consisted of 57595 individuals. These authors suggested two equations a rational and a power function formula.

Predictive equations

The largest number of predictive equations also utilizes a power function to adjust for heart rate. The next most frequent adjustment formulae are linear or rational equations (Table 2). Some of the authors have both corrective and predictive equations which differ by the presence of relevant constants in the predictive equation. Simonson *et al*[10] proposed a logarithmic and a linear equation to predict QT interval based on the RR interval. They concluded that "because the logarithmic …and linear ….regression equations gave identical results within the error of measurement, the simpler linear equation … was used for further analysis."[10]. Some of the predictive equations tried to adjust for the nonlinearity of the QT-RR interval relationship by considering different heart rate ranges. Karjalainen *et al*[27] measured the QT intervals in 324 electrocardiograms of healthy young men and weighted the sample for low and high heart rates equally. They concluded that the QT-RR relation does not permit the use of one simple adjustment equation and proposed formulae that provided different

parameters according to the heart rate[27]. Some predictive equations attempted to evaluate the QT-RR interval relationship using interventions to vary heart rate. Sarma *et al*[28] studied 10 healthy, normal men who exercised on a stationary bicycle, and 6 patients with rate-programmable VVI pacemakers whose rates were changed by an external programme, and developed an equation with an exponential function.

The sample size used to develop QTp equations varied between studies but overall the sample sizes were smaller than those used to develop the QTc equations. A number of equations were derived as QTp equations and were subsequently modified to QTc equations with Bazett and Fridericia being the most well-known[8,9].

Application of formulae

To illustrate the application of the various QT adjustment approaches, each of them was applied to three different ECGs (Figures 1-3). The closest correlation between the equations occurred, as expected, in a 71 years old man with a heart rate of 58 bpm where the difference in QTc was 6 milliseconds (ms) (435 to 441 ms) and for QTp the difference was 91 ms with a range from 376 to 467 ms (Figure 1). This is because QTc formulae are largely based on the assumption that the QT interval is accurate at the heart rate of 60 bpm. However, not all QTp equations are based on "normal heart rate" being at 60 bpm. In contrast, a man aged 53 years with a heart rate of 107 bpm, had a QTc ranging from 409 to 502 ms and QTp from 277 to 389 ms (Figure 2). The discrepancy between QTcBZT and QTcFRD was 44 ms. A 53 years old woman had QTc ranging from 424 to 487 ms and QTp from 305 to 408 ms (Figure 3). The discrepancy between QTcBZT and QTcFRD was 30 ms. The differences in the QT interval adjustment between formulae is readily apparent. Importantly the range encompasses values that are considered significant QT prolongation which raise the possibility of the presence of one of the causes for prolonged QT using one equation but a normal QT when considering another equation. The difference between QTcBZT and QTcFRD

QT	384	QTpADM	364

$QTcRTH_b$	442	QTpMYD	327	QTpARR	357

Figure 3 The QTc and QTp heart rate corrections for the uncorrected QT interval measured by computerized assessment of a digitized ECG.

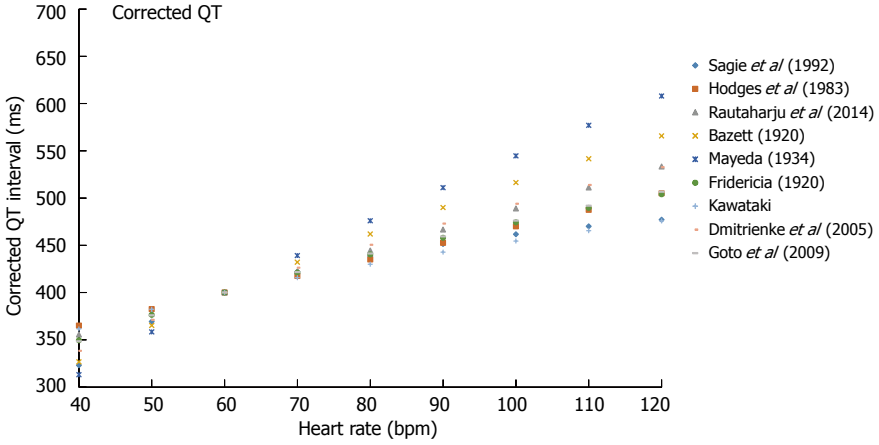

Figure 4 The corrected QT interval for the different correction formulae for a 50 years old man with a QT of 400 ms.

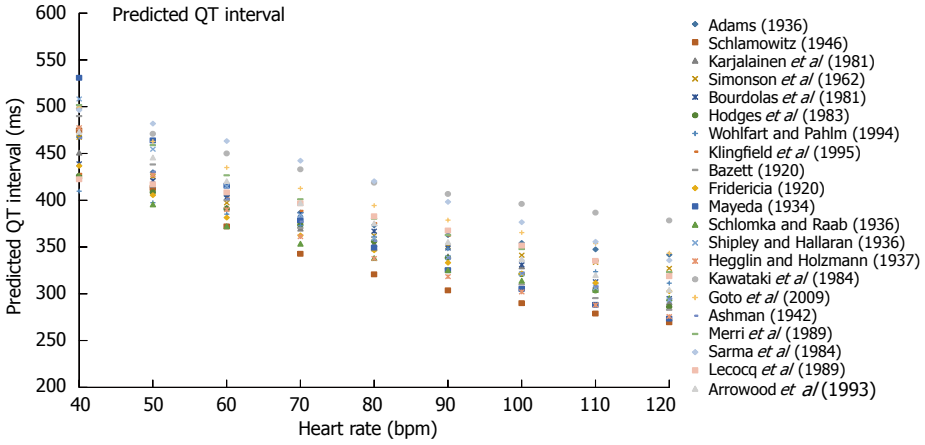

Figure 5 The predicted QT interval for the different correction formulae for a 50 years old man with a QT of 400 ms.

is apparent yet the value used to diagnose prolonged QT syndrome maybe considered to be the same by some clinicians.

To further illustrate the effect of using each of the correction equations an example is used of of an uncorrected QT interval 400 ms in a 50 years old man (Figure 4). By definition, all QTc equations show equipoise at a heart rate of 60 bpm. The discrepancy

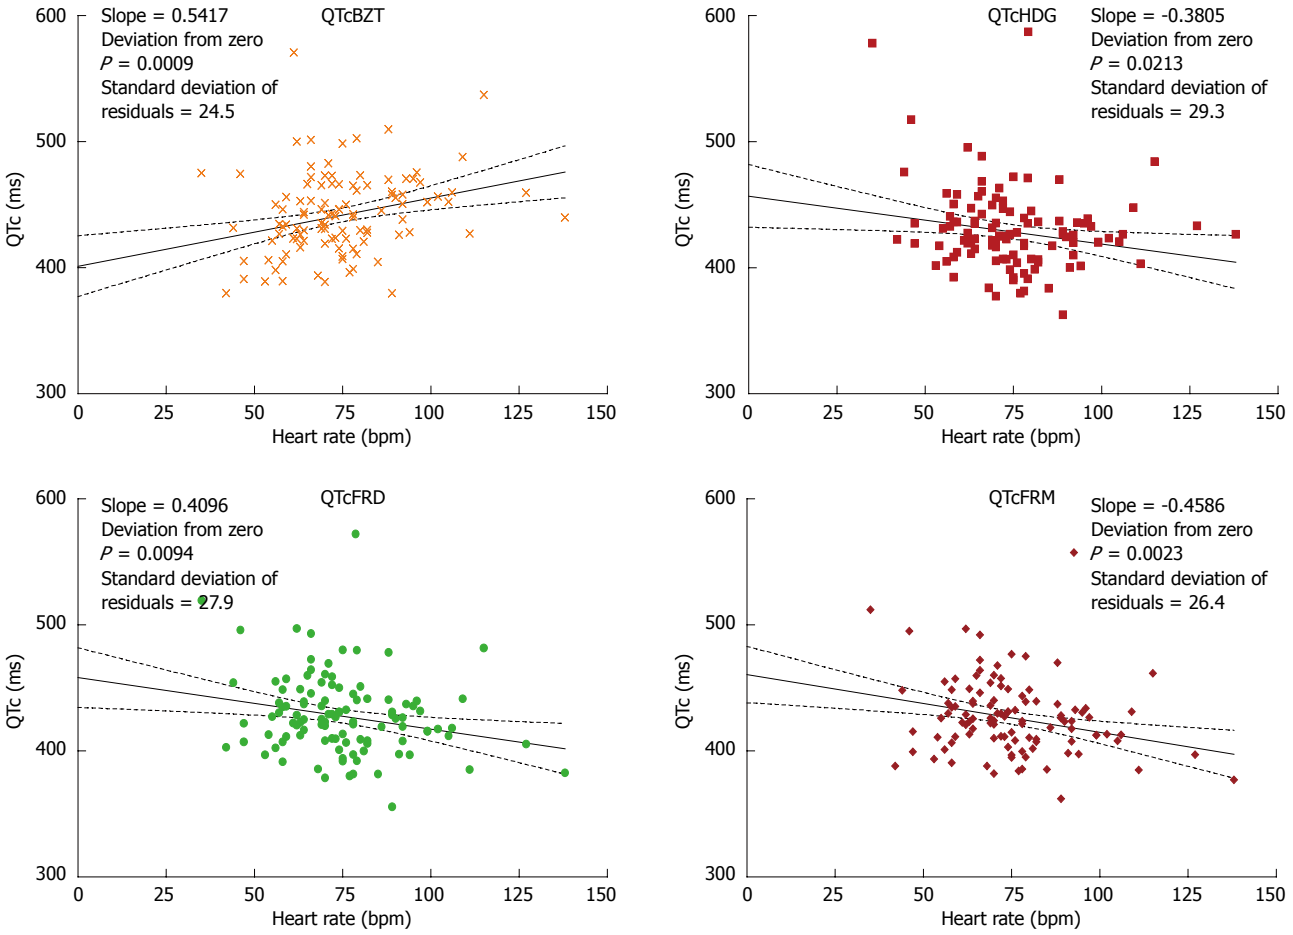

Figure 6 The relationship between QTc and heart rate for QTcBZT, QTcFRD, QTcHDG, and QTcFRM. The slope of the line and how significantly it deviates from zero is shown in the insert. The goodness of fit of the data to the linear regression (line) is shown by the standard deviation of residuals.

in QTc between the different formulae is apparent at slower and faster heart rates with the magnitude of the dispersion increasing at slower and faster heart rates. At a heart rate of 100 bpm, QTc ranges from 462 ms (QTcFRM) to 546 ms (QTcMYD) with QTcBZT at 516 ms and QTcFRD at 474 ms. At a heart rate of 40 bpm, QTc ranges from 313 ms (QTcMYD) to 400 ms (QTcRTHb) with QTcBZT at 327 ms and QTcFRD at 349 ms. The variation among formulae are non-linear, which is again as a result of QTc values being equipoise at 60 bpm.

Prediction equations also show a considerable range of reported QTp values. Considering the same 50 years old man with a QT of 400 ms (Figure 5), at a heart rate of 40 bpm, QTp ranges from 313 (QTpWHL) to 530 ms (QTpMYD) with QTpBZT at 453 and QTpFRD at 436 ms. At a heart rate of 100 bpm, QTp ranges from 290 (QTpSCH) to 396 ms (QTpKWT) with QTpBZT at 287 and QTpFRD at 322 ms. A hypothesis worth considering is that if we combine all QTp equations, which are based on different populations, we may construct an interval where QTp is considered to be normal.

HEART RATE INDEPENDENCE OF QT-HEART RATE FORMULAE

Recognizing that the goal of each formula is to produce QTc values that do not correlated with heart rate, we calculated the linear slope of eight corrective formulae for the 107 persons with various heart rates. The formulae varied in their slope (Figures 6 and 7). Two equations had a slope that was not significantly different from zero namely QTc DMT and QTc RTHa with the former being closest to zero. The other 6 equations had slopes that were significantly different from zero with the largest slope for QTcMYD. Of the equations that showed slopes that deviated from zero QTcBZT was the next largest slope or highest relationship to heart rate. The goodness of fit of the data to the linear regression (line) is shown by the standard deviation of residuals.

QT-heart rate adjustment formulae can generate a range of QT-adjusted values depending on the heart rate. Furthermore a wide range of QT-adjusted values is possible for individuals at any given heart rate. The clinician is confronted with the problem of the correct

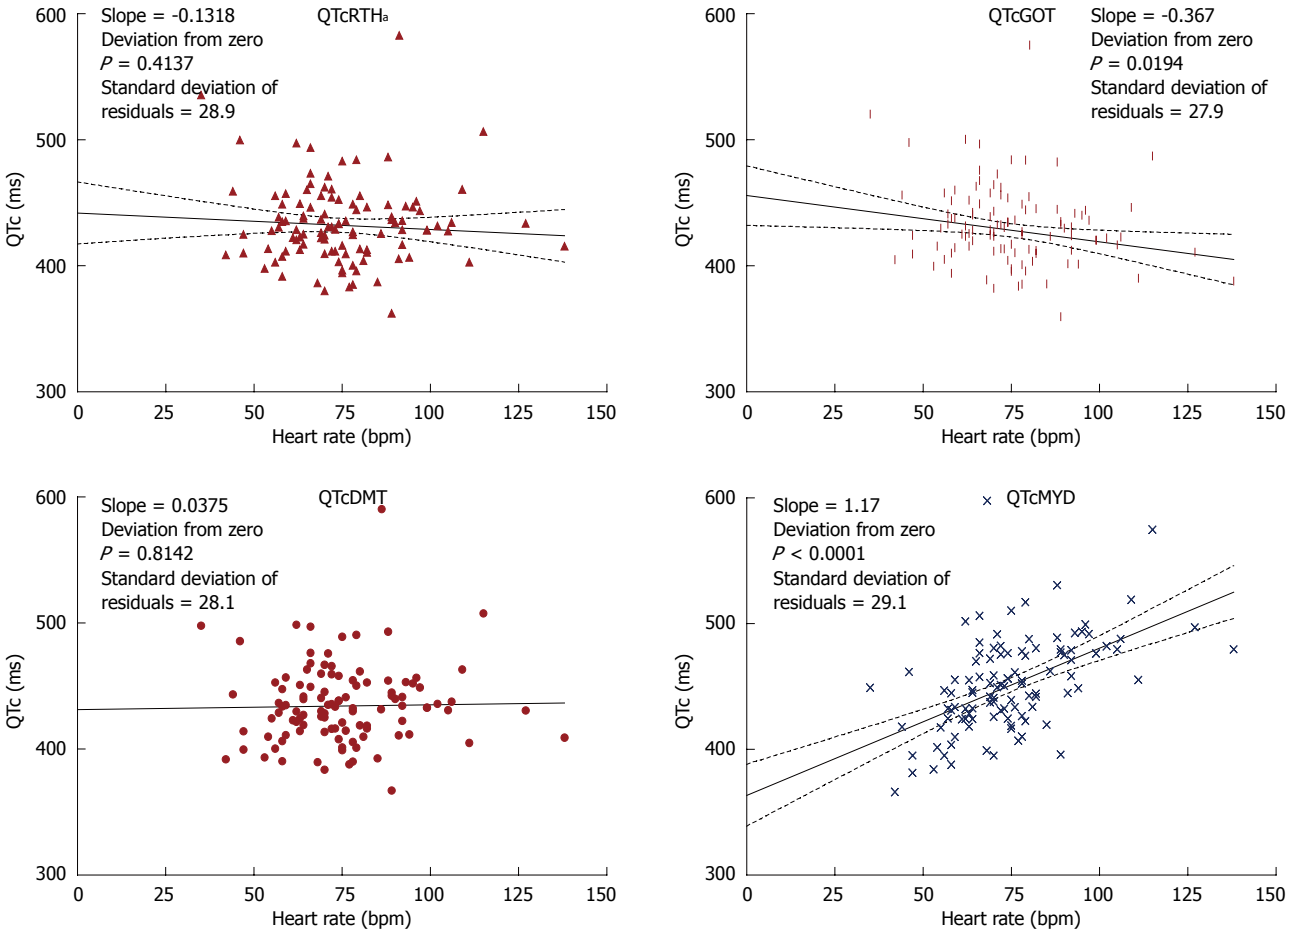

Figure 7 The relationship between QTc and heart rate for QTcRTHa, QTcDMT, QTcGOT, and QTcMYD. The slope of the line and how significantly it deviates from zero is shown in the insert. The goodness of fit of the data to the linear regression (line) is shown by the standard deviation of residuals.

choice for adjusting the QT interval and assessing the implications of the choice.

ABSENCE OF A "GOLD" STANDARD

The central issue is the absence of a true "gold standard" to identify the duration of cardiac repolarization and then to evaluate all the equations against this standard in order to determine the "best" one. The Bazett correction approach (QTcBZT) is a frequently used formula. It has long been known and criticized because it is purportedly "overcorrects" the measured QT interval at fast heart rates and under corrects it at low heart rates"[26]. The absence of a gold standard for heart rate correction makes it difficult to know what the true correction is and what is "over" and "under"-correction. The absence of a "gold" standard has likely played a role in maintaining the use of QTcBZT despite its critics[13,26,29]. While the Fridericia formula (QTcFRD) is believed to be more accurate than QTcBZT, it has already been criticized because it retains the potential for bias at either extreme of heart rate(s)[16] but other formulae also share this feature at clinically relevant faster heart rates.

QTp vs QTc

There are more QTp than QTc equations perhaps because of the manner in which QT adjustment equations are derived. Most QTp equations utilize regressions of population data to a pre-determined form. The procedure is briefly as follows. First, the uncorrected QT interval raw data are presented in a scatter plot. Then, a pre-determined form of equation is selected. The pre-determined form may be linear, rational, exponential, logarithmic, or power based. Next a statistical procedure to minimize the "error" generates parameters for the model. The regressed equation becomes the QTp equation. The error is usually quantified in the form of square of the residuals, but the method to quantify error is ultimately up to the discretion of each author. Predicted QT equations are dependent on the population from which they are derived. Several equations share the same raw form, but only differ in constants. For example, Fridericia[9] and Schlomka and Raab[30] both contain the RR interval raised to the power of one third and Goto *et al*[25] raises RR to the power of 0.3409, which approximates the power of one third. The

reason behind differing constants for the same power may have several explanations. First, there may be variations between studies in selection criteria, genetic factors of the subjects, or environmental factors. Second, there may be systematic differences in data collection such as defining the end of the T wave which is essential for QT measurement. Third, the sample sizes may not be large enough to ensure accuracy for statistical modeling.

The large number of different QTp equations and the multiple different parameters across the different equations is perhaps the reason that clinicians often opt to use QTc formulae rather than QTp formulae. Generally, QTc formulae are stripped of constants and coefficients contained in the initial formula. A presumed advantage of this approach is that some sources of variation due to subject selection, systematic errors, and sample sizes are minimized or eliminated while the important coefficients are determined from the trends of data sets.

A disadvantage of QTc formulae is that while some constants are removed to be less reflective of the sample size, the same constants played a role in the value of regressed parameters. For example, the power parameters without the accompanying constants in QTcBZT and QTcFRD will not minimize the error in the initial sample. This transformation is essentially changing the form of the initial pre-determined equation, without regressing to minimize the error.

A better approach might be fitting the initial data sets without a multiplicative coefficient.

Another problem with QTc formulae is the lack of specific limits for the definition of "prolonged QT" for each QT correction equation. Assuming that each equation is derived from a sample of normal healthy subjects, it is possible to calculate a confidence interval for the predicted duration of the QT interval. There has not, however, been a standard way to determine the confidence interval of a transformed QTc equation from the original data for each formula.

QTc and QTp equations have been categorized according to whether the equations are linear, hyperbolic, parabolic, logarithmic, shifted logarithmic, exponential or general additive models[20,22]. Our classification and nomenclature simplifies the categorization. From usual clinical data, it appears that most recent power correction equations agree with each other, and all equations may use the same limit for prolonged QT. The agreement among power-based QT correction equations is generally good because most resting heart rates are sufficiently close to 60, and that the RR interval is close to 1. For example, at a heart rate of 70 beats per minute, the RR is 1.17 s. The square root of 1.17 is 1.08 and the cube root of 1.17 is 1.05, where the difference is less than 3%. Hence, it is not a coincidence that most power correction equations agree among commonly encountered heart rates. The nature of the equation demands it near the "normal heart rates". The reported phenomenon that some equations fail at higher or lower heart rates is intrinsic to the choice of a power-based model in the regression process. Rautaharju and Zhang[15] concluded that pure power functions generate a rate-dependent bias in the upper and lower ranges of the adjusted QT distribution that can be reduced by incorporating an intercept. We found, however, that approach still led to a rate dependency but agree that the approach minimizes such rate dependency.

From our discussion, it is clear that neither corrective nor predictive formulae have an absolute theoretical benefit over the other. In fact, corrective formulae are often incorrectly derived from predictive equations. However, we advocate for the use of corrective formulae on the basis that they are already readily adopted clinically, and upper limits are already determined by clinicians through decades of experience. Clinically, it is more logical and customary to see if a given measured value (QTc in this case) is within a pre-determined range via a QTc formula rather than a QTp formula. With a QTp formula, an absolute value must be calculated, and such operations can lead to errors in certain instances. To use corrective formulae, more work needs to be done to systemically determine the appropriate upper and lower limits for the duration of QTc for each formula.

QTc HEART RATE INDEPENDENCE

We constructed scatter plots from ECG data obtained from the patient group (Figures 6 and 7). Each QTc formula was applied according to their stated form. This includes any available considerations given to age and gender. Our evaluation begins with Bazett (QTcBZT) and Fridericia (QTcFRD), both commonly used equations in clinical practice. We observe that QTcFRD is associated with a smaller slope with a linear regression line, and this translates into QTcFRD being superior to QTcBZT in attempting to separate the dependence of QT duration on heart rate. However, it is also clear that newer equations with larger sample sizes can achieve much higher accuracy than either QTcFRD or QTcBZT. The rank order of the slope was from best (closest to zero) was QTcDMT, QTcRTHa, QTcHDG, QTcGOT, QTcFRM, QTcFRD, QTcBZT and QTcMYD. As an example, QTcDMT has a slope of 0.04, which is more accurate than other equations studied. Hence, we conclude that QTcDMT should be used in future practice as it best separates the dependence of QTc from heart rate. QTcRTHa was the next best and warrants similar consideration.

There are many steps to take before QTcDMT or QTcRTHa replaces QTcBZT or QTcFRD. First, our results should be corroborated with a larger sized clinical study, with more subjects with well-defined clinical or physiological states. Second, it is essential to determine the upper and lower limits for a normal "QTcDMT" value. We recommend that the upper

and lower bound be set at 95% inclusion of all test subjects, which can be achieved by ranking the results obtained or *via* resampling methods, such as bootstrap or jackknife methods. Lastly, it is important to validate the upper and lower limits in a clinical setting in comparison to a standard by defining the correlation - sensitivity and specificity of newer QTc formulae - QTcDMT or QTcRTH in the detection of electrolyte disturbances, drug-induced cardiac toxicity, genetic abnormalities of cardiac channels (channelopathies) and autonomic nervous system dysregulation.

CONCLUSION

In summary, the clinician has a choice of over 20 different equations to adjust the QT interval to minimize the effect of heart rate on the QT interval. These equations should be referred to by a standard nomenclature such as the one proposed here in. The clinician should recognize that at some heart rates, there will be marked discordances between formulae both for QTc and QTp. We believe that QTc equations are preferred over QTp equations because there are more easily adopted in the clinical setting. Some equations have a slope of their QTc to heart rate close to zero but the fit of the equations may not be ideal. While none of the formulae may completely eliminate the effect of heart rate on the QT interval, some of the recent formulae based on large population samples appear to be better that the older heart rate adjustment formulae. In particular, we have found that QTcDMT and to some extent QTcRTH$_a$ are significantly more accurate than other formulae studied. Larger clinical studies are required to validate their precision. In addition, the lower and upper limits of the newer equations specifically QTcDMT and QTcRTH$_a$ should be tested under a clinical setting to compare them to the current commonly used equations such as QTcBZT and QTcFRD. With these caveats, QTcDMT and QTcRTH$_a$ warrant consideration for implementation in clinical practice.

Abstract

Recent trials and metanalysis even not fully conclusive and still debated, at least suggested that mechanical device-based closure of patent foramen ovale (PFO) is more effective than medical therapy in prevent recurrence of stroke. In a proportion ranging from 20% to nearly 40% of patients in literature, PFO is associated to atrial septal aneurysm (ASA): ASA is a well-known entity often associated with additional fenestration. Additionally small atrial septal defects ("Flat ASD") can present with signs of paradoxical embolism and cannot be easily detected by transthoracic echocardiography or even by transesophageal echocardiography and are usually discovered by intracardiac echocardiography at the moment of transcatheter closure. This evidence might change potentially the anatomical diagnosis from PFO to fenestrated ASA or as we called it to "hybrid defect", being a bidirectional flow through a small ASD or/and an additional fenestration, often present. Despite the differences in anatomy, pathophysiology and haemodynamic paradoxical embolism may occur in both entities and also may be the first appearance of fenestrated ASA. Because some overlapping do really exist between PFO and hybrid defects, which are often not clearly differentiable by standard diagnostic tools, it is likely that a proportion of patients evaluated for potential transcatheter closure of PFO had actually a different anatomical substrate. These different anatomical and pathophysiologic entities have not been address in any of the previous trials, potentially having an impact on overall results despite the similar mechanical treatment. Neurologists and general cardiologists in charge of clinical management of PFO-related cryptogenic stroke should be aware of the role of hybrid defects in the pathophysiology of paradoxical embolism - mediated cerebral ischemic events in order to apply the correct decision - making process and avoid downgrading of patients with paradoxical embolism-related interatrial shunt variants different from PFO.

Key words: Atrial septal defect; Patent foramen ovale; Echocardiography; Anatomy

Core tip: Recent trials and met analysis suggested that mechanical device-based closure of patent foramen ovale (PFO) is more effective than medical therapy in prevent recurrence of stroke. Fenestrated atrial septal aneurysms and small atrial septal defects (hybrid defects) can present with signs of paradoxical embolism and because they are often not clearly differentiable by standard diagnostic tools, it is likely that a proportion of patients evaluated for transcatheter closure of PFO, had actually a different anatomical substrate. These different anatomical entities have not been address in any of the previous trials, potentially having an impact on overall results.

Rigatelli G, Rigatelli A. Closing patent foramen ovale in cryptogenic stroke: The underscored importance of other interatrial shunt variants. *World J Cardiol* 2015; 7(6): 326-330 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/326.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.326

INTRODUCTION

Recent trials and metanalysis and in particular, the RESPECT trial[1], even not fully conclusive and still debated, at least suggested that mechanical device-based closure of patent foramen ovale (PFO) is more effective in prevent recurrence of stroke by near 67%. When looking deeply into the number of different metanalysis of PFO closure for cryptogenic (or better paradoxical embolism mediated) stroke[2-7], it appears clear that in a proportion ranging from 20% to nearly 40% of patients PFO is associated to atrial septal aneurysm (ASA): ASA is a well-known entity often associated with additional fenestration[8]. Additionally small atrial septal defects can present with signs of paradoxical embolism and cannot be easily detected by transthoracic echocardiography or even by transesophageal echocardiography and are usually discovered by intracardiac echocardiography at the moment of transcatheter closure[9], confusing even more the diagnosis of PFO which is at the basis of all the studies about effectiveness of transcatheter closure in cryptogenic stroke. This evidence might change potentially the anatomical diagnosis from PFO to fenestrated ASA (or fenestrated secundum atrial septal defect) or to a so called "hybrid defect", [a small single atrial septal defects (ASD) associated with paradoxical embolism], being a bidirectional flow through a small ASD or and additional fenestration often present. The aim of this review is to analyse conjunction points between PFOs and hybrid defects and outlined the role of these type of interatrial shunt in the pathophysiology of paradoxical embolism.

PRACTICAL EPIDEMIOLOGY

Isolated ASD represent 7% of all cardiac anomalies and can present at any age[10]. Adolescents and adults with isolated atrial septal defects are more likely to reach adult age without being diagnosed. Secundum ASD is by far the most common type, occurring in 1/1500 live births, with 65% to 75% involving females[10]. On the other hand, PFO represents an endemic variant in the normal population with a prevalence of 25%-27%[11]. These two entities appear so different that is difficult to find a conjunction ring: nevertheless we use the same philosophy for the treatment. Indeed, device - based closure has been proved to be effective[12,13] in both settings.

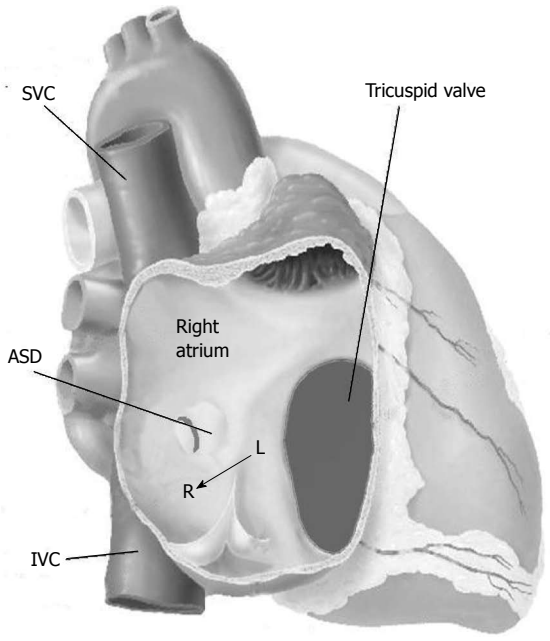

Figure 1 Secundum atrial septal defect is a defect located into the limit of the fossa ovalis. The shunt usually is left-to-right because of the pressure gradient between the left (high pressure) and right (low pressure) atrium. ASD: Atrial septal defect; IVC: Inferior vena cava; L: Left; R: Right; SVC: Superior vena cava.

Anatomy, pathophysiology, and haemodynamic

From an anatomic and pathophysiologic point of view these two entities are absolutely different.

The ostium secundum ASD is a defect of the atrial septum (Figure 1) within the limit of the fossa ovalis and causes usually a left-to-right shunt, being the left atrial pressure higher than the right atrial one. The volume of and direction of flow through an ASD depend on the size of the hole and the relative diastolic filling properties of the left and right chambers. Reduced left ventricle compliance and mitral stenosis increase the left-to-right shunt, whereas reduced right ventricle compliance may decrease the left-to-right shunt or may cause a right-to-left shunt. A Qp/Qs ratio > 1.5:1 or dilation of the right chambers defined a left-to-right shunt as significant[14].

The PFO is defined as the incompetence of the fossa ovale valve determining a right-to-left shunt (Figure 2). The reason because a right-to-left atrial

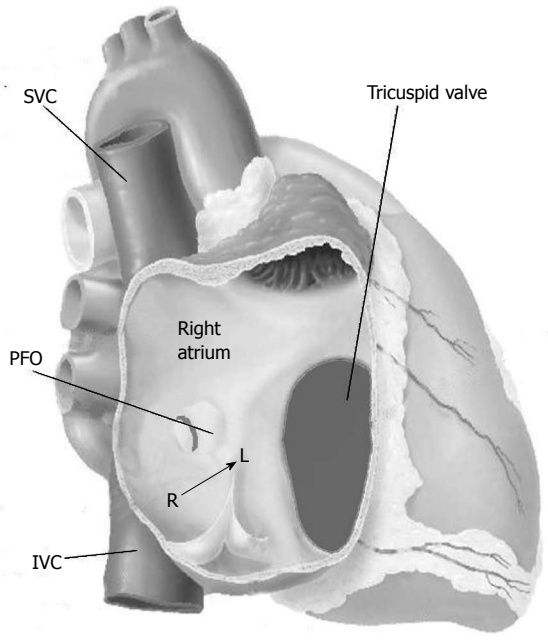

Figure 2 Patent foramen ovale is a communication between the right and left atrium caused by the incompetence of the fossa ovalis valve. The shunt is usually right-to-left despite the gradient pressure between the atria. IVC: Inferior vena cava; L: Left; PFO: Patent foramen ovale; R: Right; SVC: Superior vena cava.

shunting occurs with normal intracardiac pressures and normal or near-normal pulmonary function through a PFO has still not been completely clarified. An explanation may arise from some few considerations. Firstly, a physiologic transient spontaneous reversal of difference between the left and the right pressure is physiologically present during early diastole and during isovolumetric contraction of the right ventricle of each cardiac cycle; this right-to-left gradient may be sustained by physiologic manoeuvres that increase the right atrial pressure such as posture, inspiration, cough or Valsalva manoeuvre, or by situation in which pulmonary vascular resistances results increased, such as acute pulmonary embolism, hypoxemia due to obstructive sleep apnoea, severe chronic obstructive pulmonary disease, right ventricular infarction and positive end-expiratory pressure during neurosurgical procedures in the sitting position. Secondly, another theory explaining the right-to-left shunting through a PFO, is represented by the "so-called" "flow phenomenon". It describes a preferential blood flow from the inferior vena cava towards the atrial septum as a part of the ancient foetal circulation pathway[15].

Thirdly, the increasing stiffness of the right chambers compared to the left chambers caused by aging has been postulated. Finally, conditions such due to mediastinal shift or heart counter-clockwise rotation and/or distortion, following an ascending aorta enlargement, right pneumectomy or pericardial effusion may cause an anatomic disarray of the inferior vena cava relationship with the interatrial septum favouring part of the blood flow to enter the left atrium throughout a PFO[16].

Even from a haemodynamic point of view, ASD obviously differs from PFO. ASD are usually associated with pulmonary hypertension of different degree, an increased Qp/Qs ratio and enlarged right chambers, whereas the usual findings in PFO patients is a normal or slightly elevated pulmonary pressure, normal Qp/Qs ratio, and normal right chambers. Sometimes in presence of a PFO associated with large ASA, a mild impairment of the left atrial function can be observed[17].

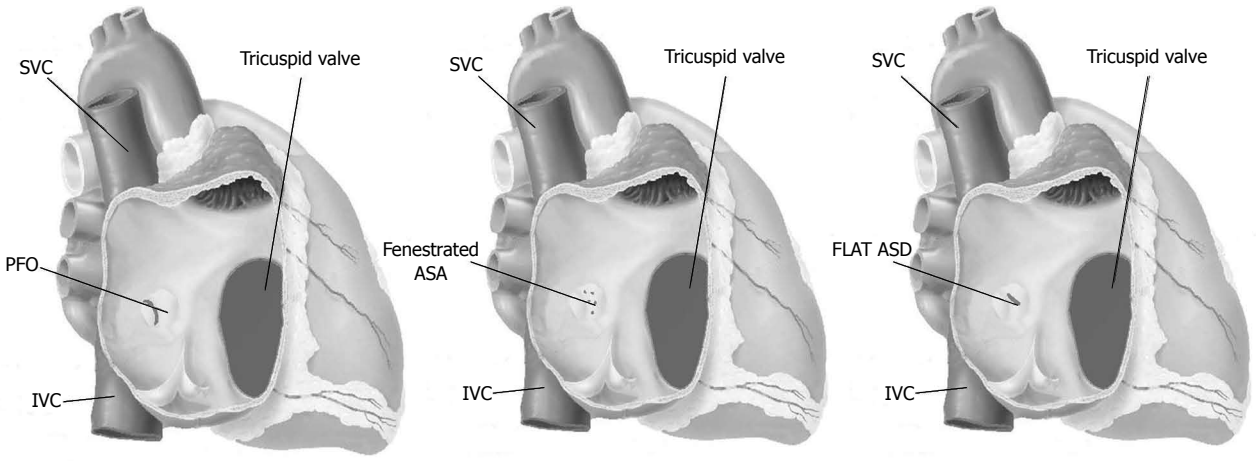
Usually also fenestrated secundum ASD with or without ASA tends to present less right chambers enlargement and only slightly increase in mean pulmonary pressure compared to secundum ASD.

CONJUNCTION POINTS

Despite the gross differences in anatomy and haemodynamic, when we look to the clinical presentation and patho-physiology, we can find some contact points. Excepted for supraventricular arrhythmias and dyspnoea, usually present only in secundum single and fenestrated ASD, paradoxical embolism may occur in both entities and also may be the first appearance of fenestrated ASD with or without ASA.

Usually paradoxical embolism is associated with PFO but occasionally secundum ASD, pulmonary arterio-venous fistula, and other intracardiac septal defects may act as alternative pathophysiological mechanism. Microemboli from a vein thrombotic location, or as recently postulated[17] microthrombotic stratification on the surface of a huge ASA or in the left atrium itself as a result of a left atrial dysfunction induced by the PFO and ASA itself, may navigate to the left side of the circulation through the PFO causing different ischemic syndromes. Differently, the pathophysiology of paradoxical embolism through a secundum ASD is usually caused by a temporaneous right heart pressure increasing which induce a right-to-left shunting which allows a venous thromboembolus to enter the arterial circulation. As an alternative mechanism, Valsalva manoeuvre, coughing, or straining might increase right-to-left component of a bidirectional shunt inducing a paradoxical embolism in ASD patients, in particular in elderly patients, more prone to rapid change of right chambers pressure because of the increasing stiffness of the chambers.

Recently in an analysis of our institutional database we found 24 (6.2%) with a secundum ASD out of 386 patients evaluated for paradoxical embolism. Defects were multifenestrated in 41.6% (10/24). Single ASD (58.3%) had a "flat" elliptical shape with a major axis of 7.6 ± 2.4 and minimal axis of 2.5 ± 1.6 mm when assessed with intracardiac echocardiography. Patients with ASD-related paradoxical embolism had more frequently a deep venous thrombosis, bigger stroke areas compared to PFO patients, and massive curtain shunt on Valsalva maneuver on transcranial



PFO	Hybrid ASD	
	Fenestrated ASA	Flat ASD
R-to-L shunt on TEE	Bidirectional shunt on TEE	
Normal PAP	Normal or slightly increased PAP	
Normal right chambers	Normal or slightly increased right chambers	
Permanent/valsalva shunt on TSD	Valsalva shunt on TSD	

Figure 3 Spectrum of interatrial shunt associated with possible paradoxical embolism and potential related haemodynamic and functional characteristics. ASA: Atrial septal aneurysm; ASD: Atrial septal defect; FO: Fossa ovalis; IVC: Inferior vena cava; PAP: Pulmonary artery pressure; PFO: Patent foramen ovale; R-to-L: Right to left shunt; SVC: Superior vena cava; TCD: Transcranial doppler; TEE: Transesophageal echocardiography.

Doppler. When compared to non-emboligenous ASD, they had lower mean pulmonary pressure, lower mean Qp/Qs, and had bidirectional shunt at rest[18]. As matter of fact, flat elliptical shape ASD and fenestrated ASD with or without ASA appear to represent the conjunction ring between ASD and PFO, being a hybrid hemodynamic and clinical profile compared to each of the others (Figure 3).

FINAL CONSIDERATIONS: ARE THE PAST TRIALS REALLY FOCUSED ON THE PROPER ANATOMICAL ENTITY?

Because some overlapping do really exist between PFO, fenestrated ASD and hybrid defects (Figure 1) which are not always clearly differentiable by standard diagnostic tools, it is likely that a proportion of patients evaluated for potential transcatheter closure of PFO had actually a different anatomical substrate. Past trials and case series used Transeophageal guidance in the majority of patients and the severity of the shunt and presence of permanent shunt has not been evaluated systematically by Transcranial Doppler or transesophageal echocardiography in the enrolment process.

Current modern judgement about medical or mechanical closure is suggested to be based, following the only published multidisciplinary consensus[19], on recurrent stroke or ischemic event with positive neuroimaging studies, severe shunt graded by transcranial Doppler and transesophageal echocardiography, presence of permanent shunt, and of additional anatomical features, such as ASA, tunnel-like opening, and Eustachian valve. The large and permanent shunt in particular, as previously suggested[18,20] is one of the most influent parameters, and it appears clear that in presence of an hybrid defect, it doesn't play the same role as in true PFO, while ASA and Eustachian valve may be more influent facilitating paradoxical shunt through an hybrid defect or a fenestrated ASD when a Valsalva manoeuvre is provoked. These different anatomical and pathophysiologic pictures have not been address in any of the previous trials, potentially having an impact on overall results despite the similar mechanical treatment.

From a practical point of view, patients with deep vein thrombosis and more clinically relevant ischemic syndrome are more likely to have a hybrid defect, whereas patients with no deep vein thrombosis and mild symptomatology are more likely to have a PFO. An ideal screening of a patient with suspected paradoxical embolism should include not only the transthoracic echo, but also the transesophageal echo in order to differentiate between PFO and hybrid defects.

At the light of what we discussed above, neurologists and general cardiologists in charge of clinical management of PFO-related cryptogenic stroke should be aware of the role of hybrid defects and multi-fenestrated ASA in the pathophisiology of paradoxical embolism - mediated cerebral ischemic events in order to apply the correct decision -making process and avoid downgrading of patients with paradoxical embolism-related interatrial shunt variants different from PFO.

Abstract

AIM: To explore *ex vivo* the role of bone morphogenetic protein-4 (BMP-4) and transforming growth factor-beta1 (TGF-β1) in acute valvular response to fluid shear stress (FSS) abnormalities.

METHODS: Porcine valve leaflets were subjected *ex vivo* to physiologic FSS, supra-physiologic FSS magnitude at normal frequency and supra-physiologic FSS frequency at normal magnitude for 48 h in a double-sided cone-and-plate bioreactor filled with standard culture medium. The role of BMP-4 and TGF-β1 in the valvular response was investigated by promoting or inhibiting the downstream action of those cytokines *via* culture medium supplementation with BMP-4 or the BMP antagonist noggin, and TGF-β1 or the TGF-β1 inhibitor SB-431542, respectively. Fresh porcine leaflets were used as controls. Each experimental group consisted of six leaflet samples. Immunostaining and immunoblotting were performed to assess endothelial activation in terms of intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 expressions, paracrine signaling in terms of BMP-4 and TGF-β1 expressions and extracellular matrix (ECM) remodeling in terms of cathepsin L, cathepsin S, metalloproteinases (MMP)-2 and MMP-9 expressions. Immunostained images were quantified by normalizing the intensities of positively stained regions by the number of cells in each image while immunoblots were quantified by densitometry.

RESULTS: Regardless of the culture medium, physiologic FSS maintained valvular homeostasis. Tissue exposure to supra-physiologic FSS magnitude in standard medium stimulated paracrine signaling (TGF-β1: 467% ± 22% *vs* 100% ± 6% in fresh

controls, BMP-4: 258% ± 22% *vs* 100% ± 4% in fresh controls; $P < 0.05$) and ECM degradation (MMP-2: 941% ± 90% *vs* 100% ± 19% in fresh controls, MMP-9: 1219% ± 190% *vs* 100% ± 16% in fresh controls, cathepsin L: 1187% ± 175% *vs* 100% ± 12% in fresh controls, cathepsin S: 603% ± 88% *vs* 100% ± 13% in fresh controls; $P < 0.05$), while BMP-4 supplementation also promoted fibrosa activation and TGF-β1 inhibition reduced MMP-9 expression to the native tissue level (MMP-9: 308% ± 153% with TGF-β1 inhibition *vs* 100% ± 16% in fresh control; $P > 0.05$). Supra-physiologic FSS frequency had no effect on endothelial activation and paracrine signaling regardless of the culture medium but TGF-β1 silencing attenuated FSS-induced ECM degradation *via* MMP-9 downregulation (MMP-9: 302% ± 182% *vs* 100% ± 42% in fresh controls; $P > 0.05$).

CONCLUSION: Valvular tissue is sensitive to FSS abnormalities. The TGF-β1 inhibitor SB-431542 is a potential candidate molecule for attenuating the effects of FSS abnormalities on valvular remodeling.

Key words: Aortic valve; Fluid shear stress; Calcification; Bone morphogenetic protein; Transforming growth factor beta

Core tip: Although flow abnormalities have been shown to promote valvular pathogenesis in a bone morphogenetic protein-4 (BMP-4)- and transforming growth factor-beta1 (TGF-β1)-dependent manner, the mode of action of those molecules in response to fluid shear stress (FSS) abnormalities remains unknown. This *ex vivo* study aimed at isolating the role played by those cytokines in the acute response of porcine leaflets to supra-physiologic FSS magnitude/frequency. The study reveals that: (1) valvular endothelial activation is weakly regulated by BMP-4 in response to FSS abnormalities; (2) TGF-β1 silencing attenuates FSS-induced extracellular matrix degradation *via* MMP-9 downregulation; and (3) BMP-4 and TGF-β1 do not synergistically interact in response to FSS abnormalities.

Bone morphogenetic protein-4 and transforming growth factor-beta1 mechanisms in acute valvular response to supra-physiologic hemodynamic stresses. *World J Cardiol* 2015; 7(6): 331-343 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/331.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.331

INTRODUCTION

Calcific aortic valve disease (CAVD) affects 3% of the general population above 75 years of age and is the first indication for valvular replacement worldwide[1,2]. The formation of calcific lesions on the valve leaflets involves active processes including inflammation[3,4], extracellular matrix (ECM) remodeling[5-7] and osteogenesis[8-10]. Calcified valves typically exhibit increased expression of cytokines such as transforming growth factor-beta1 (TGF-β1)[11] and bone morphogenic protein-4 (BMP-4)[12]. While genetic defects[13] and conventional cardiovascular risk factors[2] have been identified as potential triggers of CAVD, blood flow abnormalities have emerged as a potential concomitant contributor[14-16]. Aging, hypertension and anatomical valve defects such as the bicuspid aortic valve, which are risk factors for CAVD[17-21], generate hemodynamic alterations that result in an abnormal friction force or "fluid shear stress" (FSS) on both sides of the leaflets[22-24].

To date, the evidence of causality between hemodynamic abnormalities and valvular pathogenesis has been provided *ex vivo*, using sophisticated bioreactors aimed at replicating the characteristics of the leaflet FSS environment[25,26]. Due to the challenge to replicate the native side-specific leaflet FSS (*i.e.*, unidirectional on the ventricularis, oscillatory on the fibrosa), early studies investigated the role played by FSS abnormalities in valvular pathogenesis by subjecting only one leaflet surface at a time to flow. Studies conducted using this simplified model demonstrated the capability of combined alterations in FSS magnitude and pulsatility to stimulate inflammation on the leaflet fibrosa in a TGF-β1- and BMP-4-dependent manner[27], and the capability of elevated FSS to activate the fibrosa endothelium *via* synergies between BMP-4 and TGF-β1 pathways[28]. Recent advances in bioreactor design have enabled the replication of the native side-specific leaflet FSS in the laboratory setting. Simultaneous exposure of both leaflet surfaces to abnormalities in FSS magnitude and/or frequency has revealed the high sensitivity of the leaflet tissue to elevated FSS magnitude or frequency, and the ability of FSS abnormalities to promote paracrine signaling and ECM degradation[29].

The clear involvement of BMP-4 and TGF-β1 in hemodynamically induced CAVD provides a rationale for considering those molecules for targeted cell-based therapies aimed at attenuating or blocking the downstream pathological cascade. However, the upstream role of and potential synergies between TGF-β1 and BMP-4 in the transduction of FSS abnormalities have not been evidenced in the native (*i.e.*, side-specific) leaflet FSS environment. Supported by our previous results, the present study addresses the hypothesis that TGF-β1 and BMP-4 synergistically interact to regulate valvular pathogenesis in response to side-specific alterations in FSS magnitude or frequency. This hypothesis was tested *ex vivo* by exploring the effects of each cytokine on the downstream FSS-induced pathological response. This dependence was characterized by measuring endothelial activation, paracrine signaling and ECM

remodeling events secondary to FSS alterations after silencing or promoting pharmacologically the expression of each molecule.

MATERIALS AND METHODS

Experimental conditions

Porcine aortic valve leaflets were subjected to physiologic and supra-physiologic FSS environments *ex vivo* using our double-sided cone-and-plate bioreactor (Figure 1A)[26]. This device has been previously validated mechanically and biologically and implemented in different *ex vivo* studies to subject simultaneously but independently both leaflet surfaces to desired side-specific and time-varying FSS[29,30]. Fresh porcine valves (6-12 mo) were obtained from a local abattoir (Martin's Custom Butchering, Wakarusa, IN), immediately transported to the laboratory in ice-cold phosphate buffered saline. A circular section of 7 mm in diameter was excised from the base of each leaflet. Two samples from each valve were used as experimental samples while the third sample served as fresh control. Six experimental samples were mounted in the bioreactor, exposing both their aortic and ventricular sides to FSS. All experiments were conducted for 48 h, a duration sufficient for valve leaflets to transduce FSS abnormalities into a pathological response[29].

Consistent with our previous studies[27-29], the physiologic FSS environment consisted of a unidirectional FSS varying between 0 and 80 dyn/cm^2 on the ventricularis (leaflet surface facing the ventricle) and a reciprocal FSS varying between -8 and +10 dyn/cm^2 on the fibrosa (leaflet surface facing the aorta; Figure 1B). The two supra-physiologic FSS environments consisted of supra-physiologic FSS magnitude (*i.e.*, twice the physiologic level) at physiologic frequency (Figure 1C) and supra-physiologic FSS frequency (*i.e.*, twice the physiologic frequency) at physiologic magnitude (Figure 1D). Those abnormal FSS environments were selected based on their demonstrated ability to stimulate acute CAVD mechanisms[29].

In order to isolate the possible synergies between BMP-4 and TGF-β1, the experiments were conducted using standard culture medium (Dulbecco's Modified Eagle Medium, Sigma) as well as four additional culture medium variations. The downstream action of BMP-4 was blocked by supplementing the standard culture medium with noggin, a well-known BMP antagonist[31-33], while TGF-β1 signaling was blocked by supplementing the medium with SB-431542, a small molecule inhibitor specifically targeting the TGF-β type-I receptor[34,35]. The inhibitor concentrations used in this study (noggin: 100 ng/mL; SB-431542: 1 μmol/L) have been shown to effectively inhibit BMP- and TGF-β1 signaling in response to stretch and FSS abnormalities *ex vivo*[27,28,36]. Conversely, BMP-4 and TGF-β1 signaling were promoted by supplementing the standard culture medium with recombinant BMP-4 and TGF-β1, respectively, using concentrations (BMP-4: 10 ng/mL; TGF-β1: 10 ng/mL) previously established to effectively enhance paracrine signaling processes in valvular tissue[27,28]. Fresh porcine leaflets were used as controls.

Biological characterization

Endothelial activation was assessed in terms of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). Paracrine signaling events were characterized in terms of the cytokines BMP-4 and TGF-β1. ECM remodeling and degradation were quantified in terms of matrix metalloproteinases (MMP-2 and -9) and cathepsins (cathepsin L and S). Detailed immunostaining and immunoblotting protocols are described in Supplementary Material.

Statistical analysis

Each experimental group consisted of six leaflet samples. Data from each group were quantified as mean ± SD error and then normalized to the values measured in the fresh control. Following this procedure, all biomarker expressions were expressed in terms of a normalized mean value ± normalized standard error. Data from all experiments were tested for normality by the Anderson-Darling method, then analyzed using ANOVA followed by the Bonferroni post-hoc test. A *P*-value of less than 0.05 was used as a measure of statistical significance. The statistical review of the study was performed by a biomedical statistician (Dr. Jun Li, Department of Applied and Computational Mathematics and Statistics, University of Notre Dame, Notre Dame, IN, United States).

RESULTS

BMP-4 supplementation promotes endothelial activation in response to supra-physiologic FSS magnitude

Immunostaining was performed to examine endothelial activation in response to all three FSS environments using standard, pro- and anti-osteogenic culture media. Tissue conditioned under physiologic FSS did not exhibit any positive staining for ICAM-1 or VCAM-1, regardless of the culture medium (Figure 2A). Exposure of leaflet tissue to supra-physiologic FSS magnitude exhibited a similar trend except when BMP-4 was added to the culture medium, which resulted in ICAM-1 expression on the endothelial lining of the fibrosa (Figure 2B). Similarly to the results obtained under physiologic FSS, supra-physiologic FSS frequency did not promote cell adhesion molecule expression with any culture medium (Figure 2C).

Synergistic effects of BMP-4 and TGF-β1

Potential synergies between BMP-4 and TGF-β1 signaling in response to FSS abnormalities were investigated by quantifying the expression of one cytokine following the pharmacological inhibition or supplementation

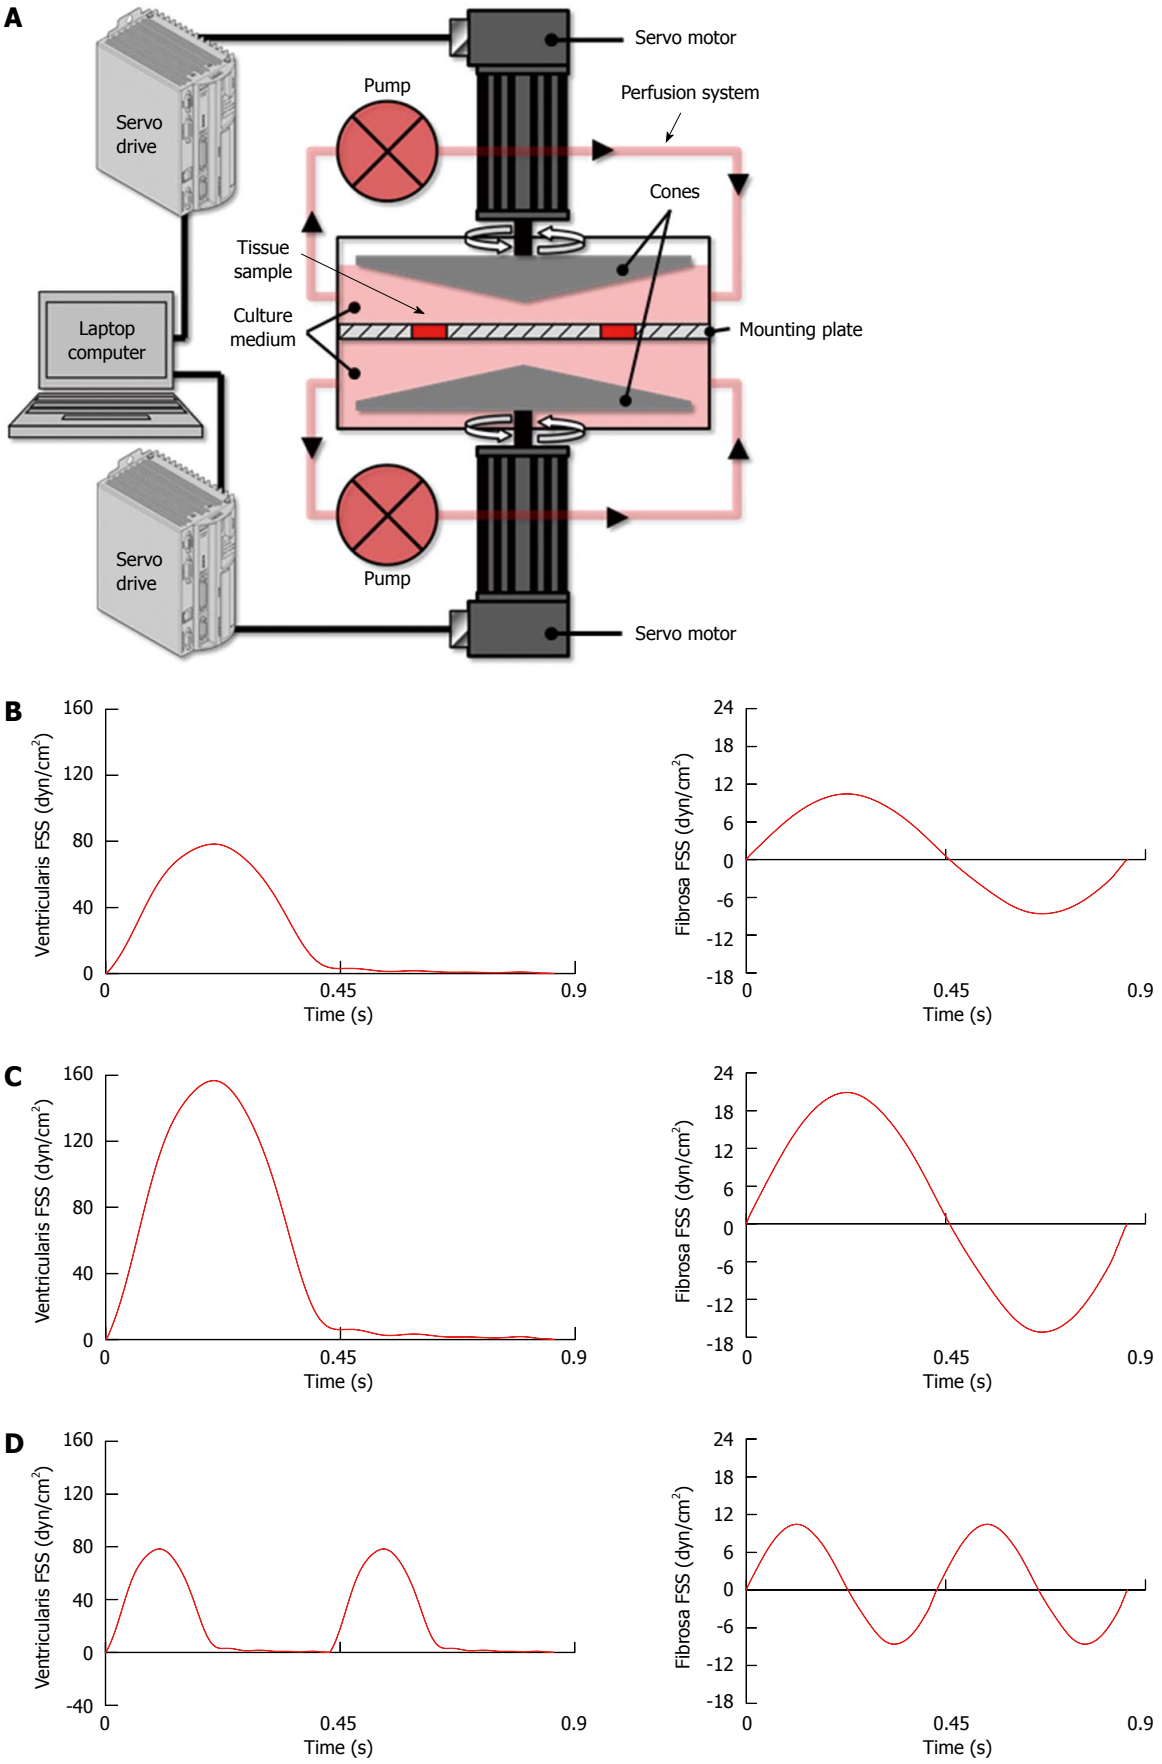

Figure 1 Tissue conditioning methodology and fluid shear stress environments. A: Schematic of the double-sided cone-and-plate bioreactor; B: Physiologic fluid shear stress (FSS); C: Supra-physiologic FSS magnitude at physiologic frequency; D: Supra-physiologic FSS frequency at physiologic magnitude.

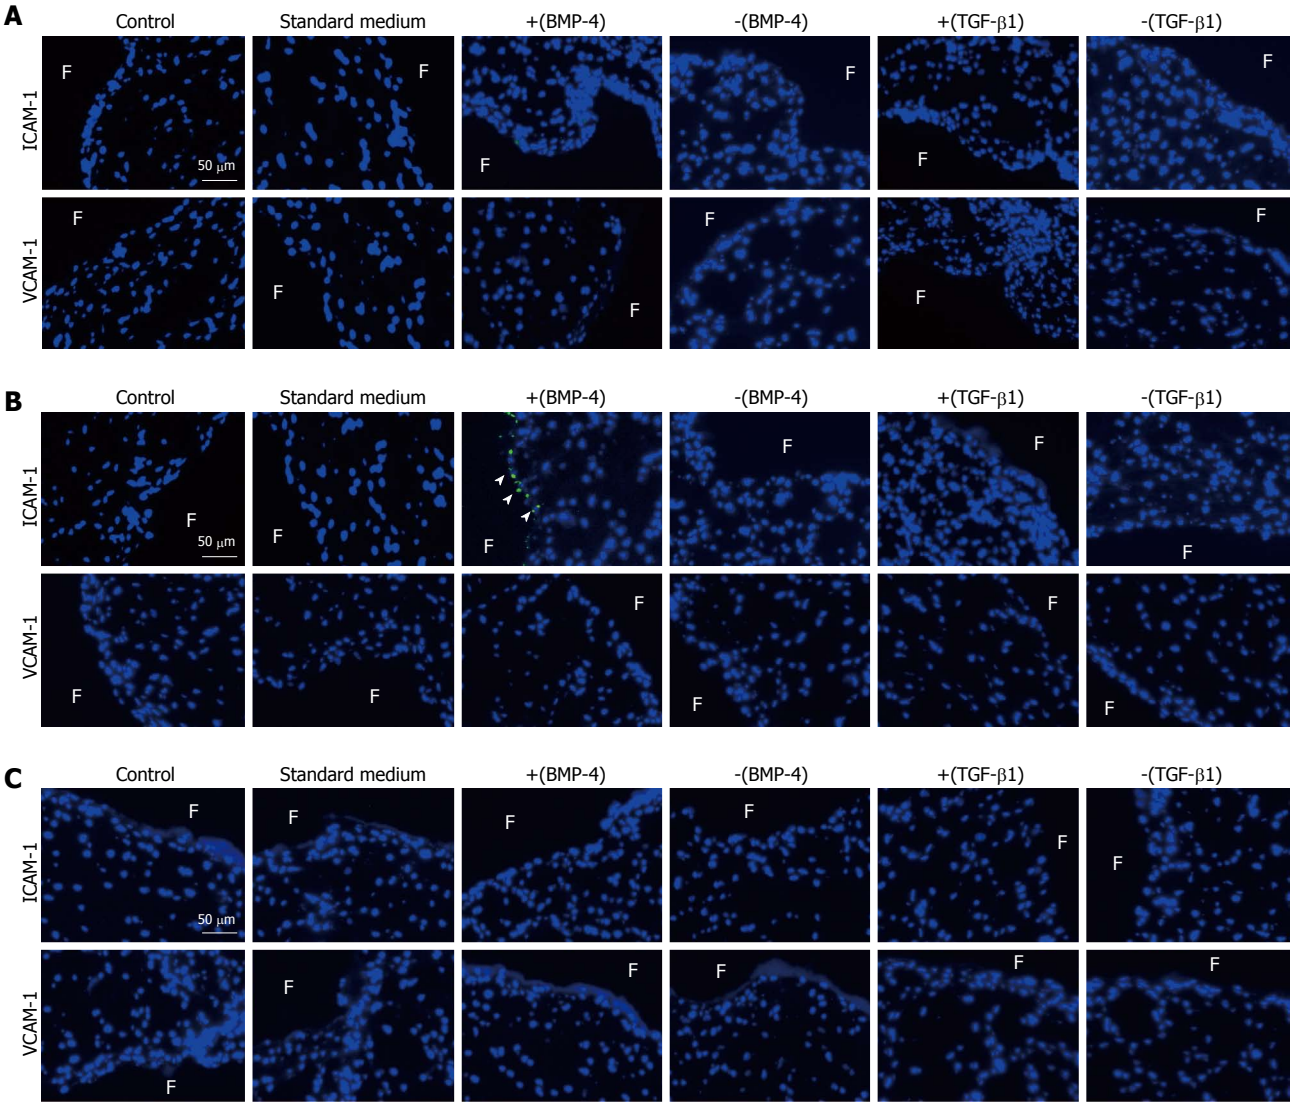

Figure 2 Intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 immunostaining. Tissue exposed for 48 h to: (A) physiologic fluid shear stress (FSS), (B) supra-physiologic FSS magnitude, and (C) supra-physiologic FSS frequency in standard medium and medium supplemented with BMP-4 [+(BMP-4)], noggin [-(BMP-4)], TGF-β1 [+(TGF-β1)] or SB-431542 [-(TGF-β1)] (F: Fibrosa; green: Positively stained cells; blue: Cell nucleus). ICAM-1: Intercellular adhesion molecule-1; VCAM-1: Vascular cell adhesion molecule-1; TGF-β1: Transforming growth factor-beta1; BMP-4: Bone morphogenic protein-4.

of the other. Western blot results indicate that under physiologic FSS, medium supplementation with BMP-4 or noggin had no significant effect on TGF-β1 expression, which remained statistically similar to the levels measured in fresh controls and in tissue conditioned using the standard medium (Figure 3A). Similarly, no significant difference in BMP-4 expression was detected between any culture medium treatment groups. In contrast, analysis of tissue conditioned to supra-physiologic FSS magnitude (Figure 3B) revealed a significant 4.7-fold, 6.2-fold and 4.1-fold increase in TGF-β1 expression using standard medium, medium supplemented with BMP-4 and medium supplemented with noggin, respectively, relative to the fresh controls (467% ± 22%, 624% ± 100%, 405% ± 38%, respectively, *vs* 100% ± 6%; $P < 0.05$). However, no statistical difference in TGF-β1 expression was detected between the standard medium, BMP-4 treatment and noggin treatment groups. While supra-physiologic FSS also resulted in a significant 2.6-fold, 2.2-fold and 2.1-fold increase in BMP-4 expression using standard medium, medium supplemented with TGF-β1 and medium supplemented with SB-431542, respectively, relative to the fresh controls (258% ± 22%, 219% ± 33%, 207% ± 13%, respectively, *vs* 100% ± 4%; $P < 0.05$), no statistical difference in BMP-4 expression was detected between those three culture medium groups. Lastly, exposure of leaflet tissue to supra-physiologic FSS frequency using the five culture media (Figure 3C) produced results similar to those obtained under physiologic FSS, in which no significant difference in TGF-β1 or BMP-4 expression was detected between the fresh controls, the standard medium group, the pro-osteogenic medium groups (BMP-4 or TGF-β1 treatment) and the anti-osteogenic medium groups (noggin or SB-431542 treatment).

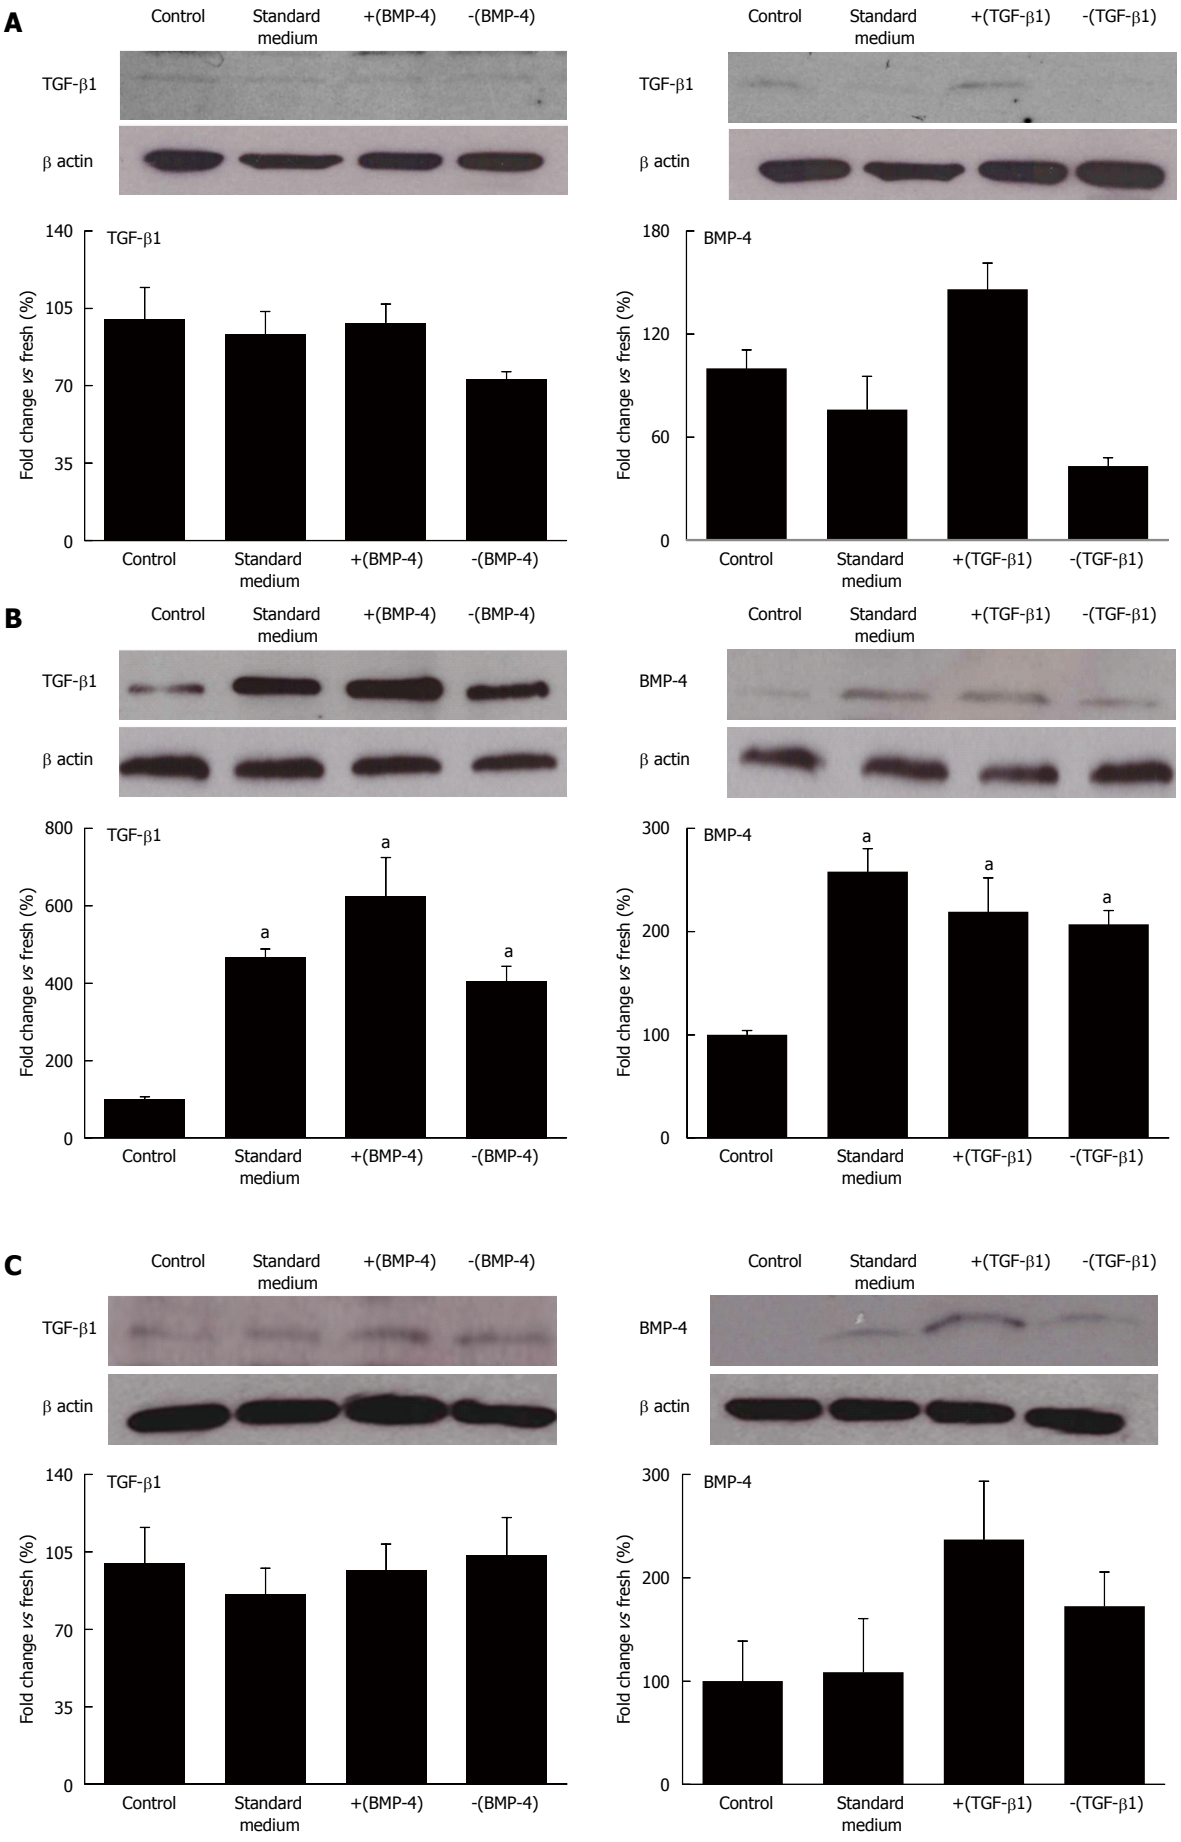

Figure 3 Transforming growth factor-beta1 and bone morphogenic protein-4 immunoblotting. Tissue exposed for 48 h to: (A) physiologic fluid shear stress (FSS), (B) supra-physiologic FSS magnitude, and (C) supra-physiologic FSS frequency standard medium and medium supplemented with BMP-4 [+(BMP-4)], noggin [-(BMP-4)], TGF-β1 [+(TGF-β1)] or SB-431542 [-(TGF-β1)] ($^aP < 0.05$ *vs* fresh control). TGF-β1: Transforming growth factor-beta1; BMP-4: Bone morphogenic protein-4.

TGF-β1 silencing reduces MMP-9 expression in response to FSS abnormalities

MMP-2 and MMP-9 immunostaining was performed in leaflet tissue exposed to physiologic and supra-physiologic FSS using the five culture media to characterize the downstream action of BMP-4 and TGF-β1 on ECM degradation. No significant difference in MMP-2 and MMP-9 expression was detected between any culture medium treatment group and the fresh controls in leaflets subjected to physiologic FSS (Figure 4A). Leaflet exposure to supra-physiologic FSS magnitude resulted in a significant 9.4-fold, 8.4-fold and 11.1-fold increase in MMP-2 expression using standard medium, medium supplemented with BMP-4 and medium supplemented with TGF-β1, respectively, relative to the fresh controls (941% ± 90%, 842% ± 126%, 1108% ± 170%, respectively, *vs* 100% ± 19%; $P < 0.05$; Figure 4B) but no difference in expression was detected between the five culture media. A significant 12.2-fold, 9.3-fold and 16.2-fold increase in MMP-9 expression was also observed with the standard medium, noggin and TGF-β1 treatment groups, respectively, relative to the fresh controls (1219% ± 190%, 931% ± 104%, 1621% ± 261%, respectively, *vs* 100% ± 16%; $P < 0.05$), with no significant difference in MMP-9 expression between the five culture media. In contrast, TGF-β1 silencing resulted in a significant 75% and 81% reduction in MMP-9 expression relative to the standard culture medium and TGF-β1 treatment group, respectively, and resulted in a MMP-9 expression level statistically similar to that measured in fresh controls. Lastly, supra-physiologic FSS frequency resulted in a significant 12.6-fold, 13.2-fold, 14.5-fold and 13.4-fold increase in MMP-2 expression using standard medium, medium supplemented with BMP-4, medium supplemented with TGF-β1 and medium supplemented with SB-431542, respectively, relative to the fresh controls (1264% ± 145%, 1318% ± 239%, 1447% ± 278%, 1339% ± 314%, respectively, *vs* 100% ± 21%; $P < 0.05$) without any significant difference between any culture medium groups (Figure 4C). This FSS environment also resulted in a significant 15.7-fold, 14.9-fold and 17.3-fold increase in MMP-9 expression in the standard culture medium, noggin and TGF-β1 treatment groups, respectively, relative to the fresh controls (1571% ± 191%, 1488% ± 316%, 1728% ± 268%, respectively, *vs* 100% ± 42%; $P < 0.05$). TGF-β1 silencing resulted in a significant 81% and 83% reduction in MMP-9 expression relative to the standard culture medium and TGF-β1 treatment group, respectively (302% ± 182% *vs* 1571% ± 191% and 1728% ± 268%, respectively; $P < 0.05$), and resulted in a MMP-9 expression level statistically similar to that measured in fresh controls.

BMP-4 and TGF-β1 do not synergistically regulate cathepsin expression in response to FSS

The synergistic effects of BMP-4 and TGF-β1 on FSS-mediated protease expression were characterized *via* cathepsin L and cathepsin S immunostaining. Under physiologic FSS, no significant difference in cathepsin L and cathepsin S expression was detected between any culture medium treatment group and the fresh controls (Figure 5A). Tissue exposure to supra-physiologic FSS magnitude resulted in a significant 11.9-fold and 15.5-fold increase in cathepsin L expression using the standard medium and medium supplemented with TGF-β1, respectively, relative to the fresh controls (1187% ± 175%, 1546% ± 171%, respectively, *vs* 100% ± 12%; $P < 0.05$; Figure 5B). The same FSS environment resulted in a significant 6.0-fold, 6.0-fold, 5.5-fold, 5.4-fold and 3.3-fold increase in cathepsin S expression using the standard medium, BMP-4, noggin, TGF-β1 and SB-431542 treatment groups, respectively, relative to the fresh controls (603% ± 88%, 598% ± 96%, 554% ± 94%, 541% ± 92%, 325% ± 57%, respectively, *vs* 100% ± 13%; $P < 0.05$). However, the effects of BMP-4 and TGF-β1 on protease expression remained limited as indicated by the absence of significant difference in cathepsin L and S expression between the different medium treatment groups. Lastly, supra-physiologic FSS frequency did not promote cathepsin L expression, regardless of the culture medium treatment group (Figure 5C). In contrast, the same mechanical treatment resulted in a significant 7.4-fold, 6.4-fold and 7.4-fold increase in cathepsin S expression in the BMP-4, noggin and TGF-β1 treatment groups, respectively, relative to the fresh controls (744% ± 129%, 635% ± 76%, 744% ± 144%, respectively, *vs* 100% ± 7%; $P < 0.05$).

DISCUSSION

In this *ex vivo* study, we investigated the role of the cytokines BMP-4 and TGF-β1 in the acute pathological response of porcine valve leaflets exposed to FSS abnormalities. We demonstrated that: (1) valvular endothelial activation is weakly regulated by BMP-4 in response to FSS abnormalities; (2) TGF-β1 silencing attenuates FSS-induced ECM degradation *via* MMP-9 downregulation; and (3) BMP-4 and TGF-β1 do not synergistically interact in response to FSS abnormalities.

This study first confirms the key role played by FSS in the maintenance of valvular homeostasis. In fact, exposure of leaflet tissue to its native FSS environment did not stimulate any pathological event and resulted in biomarker expressions similar to those measured in fresh tissue, regardless of the culture medium. Valvular tissue has been shown to be sensitive to the forces present in its hemodynamic environment[37,38]. As compared to stretch and pressure which propagate throughout the leaflet and stimulate both valvular endothelial cells (VECs) and interstitial cells (VICs), FSS is an interfacial stress sensed primarily by VECs. Therefore, the ability of FSS alone to maintain leaflet homeostasis in the absence of any other mechanical signal demonstrates the key role played by the

leaflet endothelium in valvular function. In contrast, leaflet exposure to supra-physiologic FSS resulted in increased paracrine signaling and ECM degradation. Those results confirm those of previous *ex vivo* studies on the effects of normal and abnormal FSS on valvular biology[27-29] and on the role played by FSS in bicuspid aortic valve calcification[30].

This study is the first to report the dependence of FSS-mediated valvular ECM degradation on TGF-β1 signaling, as suggested by the dramatic decrease in MMP-9 expression in response to FSS abnormalities following TGF-β1 inhibition. The potential involvement of TGF-β1 in valvular ECM degradation is consistent with previous reports suggesting the modulation of MMP-9 expression by several growth factors and inflammatory cytokines in sheep VICs[39,40]. The ability of the small molecule inhibitor SB-431542 to reduce MMP-9 expression to the level measured in fresh leaflets also suggests the possible use of this molecule in drug-based therapies aimed at attenuating ECM degradation.

Interestingly, this study did not reveal the existence of clear synergies between BMP-4 and TGF-β1 signaling in response to FSS abnormalities, as shown by the inability of the pro- and anti-osteogenic media to alter the expression of those cytokines. This result differs from our previous *ex vivo* results on the effects of single-sided FSS magnitude and/or pulsatility abnormalities on the leaflet fibrosa[27,28], which suggested a downregulation of FSS-induced BMP-4 expression following TGF-β1 inhibition. One possible explanation for this discrepancy is the difference in mechanical environment considered in those studies. While those earlier *ex vivo* studies subjected only one leaflet surface to FSS abnormalities, the present experiments were performed using a more realistic side-specific FSS environment, which potentially attenuated the severity of the pathological response.

Lastly, the interpretation of the results should be put in the perspective of two important considerations. First, noggin is a BMP antagonist that not only binds BMP-4 but also BMP-2, -5, -6 and -7[31,32]. Therefore, the observed biological response following noggin supplementation may be the result of the inhibition of other BMP members. Second, while the study only focuses on the acute biological response, the results may still be relevant to the long-term processes leading to CAVD as valve leaflets respond to FSS alterations in periods as short as 48 h and continued mechanical conditioning for up to 72 h has been shown not to alter that initial response[29].

In summary, this study provides further evidence of the key role played by BMP-4 and TGF-β1 in valvular FSS mechanotransduction and the specific involvement of TGF-β1 in FSS-induced ECM degradation. While inhibition of those cytokines is not sufficient to completely block the FSS-induced pathological response, the TGF-β1 inhibitor SB-431542 emerges as a potential candidate molecule for attenuating the adverse effects of FSS abnormalities on ECM degradation.

COMMENTS

Background

Calcific aortic valve disease (CAVD) is driven by inflammatory, remodeling and osteogenic processes triggered by cardiovascular risk factors and hemodynamic cues. In particular, supra-physiologic fluid shear stress (FSS) environments, which may result from hypertension, aging and valvular defects, have been shown to stimulate early CAVD signaling in a bone morphogenetic protein-4 (BMP-4) and transforming growth factor-beta1 (TGF-β1)-dependent manner. While the demonstrated involvement of BMP-4 and TGF-β1 in early CAVD provides a rationale for considering those molecules in targeted cell-based therapies aimed at attenuating or blocking the downstream pathological cascade, the synergies and modes of action of those molecules in response to FSS abnormalities have not been defined yet.

Research frontiers

The current modality to treat CAVD consists of the complete replacement of the valve by an artificial implant, which only partially restores valvular function and does not address the root cause of the disease. The development of non-invasive pharmacological approaches requires more insights into the basic biology of CAVD. Therefore, the characterization of the signaling pathways involved in the disease and the interacting mechanisms of cardiovascular calcification, micro-scale mechano-transduction and macro-scale hemodynamics are current hotspots in valvular research.

Innovations and breakthroughs

Their previous characterization of the contribution of side-specific FSS magnitude and/or frequency abnormalities to early valvular pathogenesis revealed the sensitivity of the leaflet tissue to elevated FSS magnitude or frequency and the ability of FSS abnormalities to promote paracrine signaling *via* BMP-4- and TGF-β1-dependent pathways. The present study is a logical extension of our previous work as it investigates the upstream roles of BMP-4 and TGF-β1 in the FSS-mediated valvular response. Here, the authors programmed their FSS bioreactor to generate the most unfavorable FSS environment for valvular tissue (*i.e.*, side-specific supra-physiologic FSS magnitude or side-specific supra-physiologic FSS frequency) and the authors aimed at isolating the mechanistic role played by BMP-4 and TGF-β1 in the FSS-mediated pathological response by either promoting or inhibiting pharmacologically the downstream action of those molecules. The results demonstrate for the first time the mechano-sensitivity of BMP-4 and TGF-β1 to alterations in the native valvular FSS environment and their respective role in FSS-mediated pathogenesis. While BMP-4 promotes valvular endothelial activation in response to supra-physiologic FSS, TGF-β1 mediates extracellular matrix (ECM) degradation.

Applications

The ability of the TGF-β1 inhibitor SB-431542 to reduce flow-mediated ECM degradation suggests the possible use of this molecule in non-invasive drug-based therapies aimed at attenuating flow-induced aortic valve pathogenesis.

Terminology

CAVD is the most common valvular disease and is characterized by the formation of calcific lesions on the valve leaflets. FSS is the frictional fluid force resulting from the relative motion between the valve leaflets and the surrounding blood flow.

Peer-review

This is a very well conducted study.

Abstract

AIM: To evaluate the prognostic value of electrophysiological stimulation (EPS) in the risk stratification for tachyarrhythmic events and sudden cardiac death (SCD).

METHODS: We conducted a prospective cohort study and analyzed the long-term follow-up of 265 consecutive patients who underwent programmed ventricular stimulation at the Luzerner Kantonsspital (Lucerne, Switzerland) between October 2003 and April 2012. Patients underwent EPS for SCD risk evaluation because of structural or functional heart disease and/or electrical conduction abnormality and/or after syncope/cardiac arrest. EPS was considered abnormal, if a sustained ventricular tachycardia (VT) was inducible. The primary endpoint of the study was SCD or, in implanted patients, adequate ICD-activation.

RESULTS: During EPS, sustained VT was induced in 125 patients (47.2%) and non-sustained VT in 60 patients (22.6%); in 80 patients (30.2%) no arrhythmia could be induced. In our cohort, 153 patients (57.7%) underwent ICD implantation after the EPS. During follow-up (mean duration 4.8 ± 2.3 years), a primary endpoint event occurred in 49 patients (18.5%). The area under the receiver operating characteristic curve (AUROC) was 0.593 (95%CI: 0.515-0.670) for a left ventricular ejection fraction (LVEF) < 35% and 0.636 (95%CI: 0.563-0.709) for inducible sustained VT during EPS. The AUROC of EPS was higher in the subgroup of patients with LVEF ⩾ 35% (0.681, 95%CI: 0.578-0.785). Cox regression analysis showed that both, sustained VT during EPS (HR: 2.26, 95%CI: 1.22-4.19, P = 0.009) and LVEF < 35% (HR: 2.00, 95%CI: 1.13-3.54, P = 0.018) were independent predictors of primary endpoint events.

CONCLUSION: EPS provides a benefit in risk stratification

for future tachyarrhythmic events and SCD and should especially be considered in patients with LVEF ⩾ 35%.

Key words: Electrophysiologic techniques; Cardiac; Arrhythmia; Cardiac; Sudden cardiac death

Core tip: In our long-term prospective cohort study we could reveal several important findings about the prognostic value of programmed ventricular stimulation for risk stratification of sudden cardiac death (SCD). First, in a mixed population with different cardiac pathologies inducible sustained ventricular tachyarrhythmia during electrophysiological stimulation (EPS) identified those at higher risk for SCD or appropriate implantable cardioverter defibrillators (ICD) activation. Second, left ventricular ejection fraction (LVEF) < 35% was another independent predictor of SCD surrogate. Third, in patients with LVEF > 35% negative EPS had a high negative predictive value for SCD and ICD activation.

INTRODUCTION

Implantable cardioverter defibrillators (ICD) are an established therapy for primary and secondary sudden cardiac death (SCD) prevention. Randomized trials have shown a significant mortality reduction in implanted patients at high risk for SCD[1-4]. For ICD therapy guidance, evaluation of SCD risk is crucial. Guidelines recommend various non-invasive techniques to recognize patients at higher risk for life-threatening arrhythmias[5]. Factors associated with a significantly increased risk of ventricular tachyarrhythmia include increased resting heart rate, wide QRS, presence of late potentials, presence of heart failure, or lower left ventricular ejection fraction[6-10]. However, currently available methods for SCD risk estimation are still imprecise. Therefore, many patients, who received an ICD, are not going to suffer from a future arrhythmic event and do not benefit from ICD. On the other hand, many patients, who are not recognized at high risk, die from SCD and numbers of SCD victims are still highest in these patients with normal left ventricular ejection fraction (LVEF)[11,12]. It remains an ongoing challenge to predict an individual patient's risk.

Currently, the electrophysiological study (EPS) is widely used for risk stratification and several randomized trials suggest a significant predictive value of this examination. However, many previous studies focused on the predictive value in one subgroup of patients with a specific cardiac pathology. Most data are available from post myocardial infarction patients in whom inducible ventricular tachycardias (VT) or ventricular fibrillation (VF) during EPS indicate higher risk for future arrhythmic events[13]. An improved risk stratification with EPS has especially been shown in patients who were preselected as a high risk population based on previous non-invasive tests[14,15]. Other studies provided a prognostic value of EPS in patients with Brugada syndrome, hypertrophic or dilated cardiomyopathy[16-18]. The discussion about the general prognostic value of electrophysiological testing is ongoing. We therefore performed an induction study of VT or VF by programmed electrical stimulation either for primary prevention of SCD, after documented VT or in SCD survivors. The usefulness of EPS for the prediction of future arrhythmic events was evaluated in a prospective long-term follow-up in patients with different cardiac pathologies.

MATERIALS AND METHODS

Study population

This prospective cohort study evaluated all patients who were examined by EPS at the Luzerner Kantonsspital (Lucerne, Switzerland) between October 2003 and April 2012. Patients underwent EPS for SCD risk evaluation because of structural or functional heart disease and/or electrical conduction abnormality and/or after syncope/cardiac arrest. The study population therefore embraced patients with coronary artery disease (CAD), dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy, impaired LVEF, Brugada or Long QT syndrome, and other rare cardiac diseases (*e.g.*, valvular heart disease, tetralogy of Fallot, variant angina). Some patients who underwent EPS did not have cardiac disease but were assessed because of unclear syncope or family history of cardiomyopathy. Patients who did not provide written informed consent were excluded. The study complies with the Declaration of Helsinki and was approved by the local ethics committee.

Baseline evaluation

All participating patients were evaluated at baseline. Patient history was recorded including cardiovascular risk factors, underlying heart disease, and medication. Electrocardiogram (ECG) was recorded in all patients. LVEF was measured with transthoracic echocardiography in all patients and was determined on two- and four-chamber views using the modified biplane Simpson method.

EPS was part of the baseline evaluation and was performed according to the ACC/AHA/ESC guidelines for the management of patients with ventricular arrhythmias and the prevention of sudden cardiac death[19]. The

ventricular arrhythmia induction protocol during EPS included programmed stimulation at three basic cycle lengths (600, 450, and 350 ms) and up to three extrastimuli with a minimum coupling interval of 180 ms. A third extrastimulus was introduced during a basic drive cycle length of minimal 500 ms after completion of programmed ventricular stimulation with 1 and 2 extrastimuli during paced cycle lengths of 600, 450, and 350 ms[20]. EPS was considered abnormal, if a sustained VT was inducible.

Follow-up

Patients with ICD were regularly followed-up at Luzerner Kantonsspital in six-month or yearly intervals. In addition, they were followed-up immediately, if shocks occurred. The clinical course and the numbers of appropriate and inappropriate ICD therapies were protocoled at each follow-up visit. In patients who had no ICD, follow-up was obtained from several sources: first, medical records at Luzerner Kantonsspital were studied, if available (*i.e.*, in patients who were re-admitted after the EPS); second, the patients and/or their general practitioner were contacted by phone and interviewed using a structured protocol. In all patients who died, additional information on the circumstances of death was collected. Death was classified as non-cardiac or cardiac. Among cardiac deaths, SCD was defined according to the Hinkle-Thaler method[21].

Endpoints

The primary endpoint of this study was SCD or, in implanted patients, adequate ICD activation [shock or antitachycardia pacing (ATP)]. The secondary endpoint was SCD or adequate ICD shock. For the secondary endpoint, events with ATP were not counted. If a patient experienced more than one endpoint event (*e.g.*, ICD shock in a patient who later died from SCD), only the first endpoint event was counted.

Statistical analysis

We descriptively analyzed baseline characteristics. We then calculated sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and the area under the receiver operating characteristic curve (AUROC) with its 95%CI of the EPS for the prediction of both endpoints[22]. The diagnostic accuracy of the EPS was compared to that of the LVEF. For this purpose, LVEF was dichotomized at 35% (< 35% indicating higher risk *vs* ⩾ 35% indicating lower risk). We also performed a Cox regression analysis with age, sex, EPS and LVEF as independent variables. Kaplan-Meier survivor functions were generated to illustrate the ability to stratify the risk of both dichotomized predictors separately[23]. Calculations were done for all study participants together and, in a sensitivity analysis, repeated separate for participants with CAD and DCM. Data were analyzed using Stata 11.2 (StataCorp LP, College Station, TX, United States).

RESULTS

Study population

Overall, 289 patients underwent EPS during the study period. Twenty-four patients (8.3%) were lost to follow-up, resulting in 265 patients who were analyzed. Table 1 shows the baseline characteristics of study participants. Mean age was 57.4 ± 10.7 years with a maximum range from 21.8 to 76.7 years. Most participants were male. CAD was present in a majority of patients.

EPS and therapeutic consequences

The EPS was performed for primary prevention in 209 patients (78.9%). In 56 patients (21.1%) the indication was secondary prevention: twenty-nine cardiac arrest survivors (10.9%), and 27 patients (10.2%) who had documented VT/VF on previous ECGs. During EPS, sustained VT was induced in 125 patients (47.2%) and non-sustained VT in 60 patients (22.6%). In 80 patients (30.2%) no arrhythmia could be induced.

In our cohort, 153 patients (57.7%) underwent ICD implantation after the EPS, and 112 patients (42.3%) received no ICD. Patients were selected for device implantation according to the specific ACC/AHA/ESC guidelines for the underlying heart disease. The decision to implant an ICD was influenced by the result of the EPS if recommended in the guidelines. Antiarrhythmic medication consisted of beta blockers in 214 patients (80.8%), amiodarone in 38 patients (14.3%), and digoxin in 37 patients (14.0%).

Follow-up and endpoint events

The mean duration of the follow-up was 4.8 ± 2.3 years (interquartile range 3.1-6.2 years, maximum range 0.2-9.2 years). During follow-up, 28 patients (10.6%) died, 12 of them due to non-cardiac causes. Among the 16 patients with a cardiac cause of death, SCD occurred in 8 patients. A primary endpoint event occurred in 49 patients (18.5%) with a mean time interval since the EPS of 947 ± 778 d (maximum range 16-3050 d). Table 1 shows baseline characteristics separate for patients with and without primary endpoint event. There were no significant differences between the two groups, except for LVEF which was lower in patients with primary endpoint event, and the findings during EPS that found more sustained VTs in patients with primary endpoint event. A secondary endpoint event occurred in 33 patients (12.5%) with a mean time interval since the EPS of 997 ± 761 d (maximum range 63-2709 d).

Diagnostic accuracy

Table 2 shows the diagnostic accuracy of the EPS and the LVEF for primary and secondary endpoint. The AUROCs of EPS and of LVEF did not significantly differ (P = 0.427 for primary endpoint, and P = 0.676 for

LVEF < 35%	54.5%	62.1%	17.0%	90.6%	0.583 (0.491-0.675)

AUROC: Area under the receiver operating characteristic curve; EPS: Electrophysiological study; NPV: Negative predictive value; PPV: Positive predictive value; VT: Ventricular tachycardia; LVEF: Left ventricular ejection fraction.

secondary endpoint). There was a non-significant trend for a higher AUROC of the EPS in the subgroup of patients with an LVEF ⩾ 35% as compared to the subgroup of patients with LVEF < 35% (P = 0.156 for primary endpoint, and P = 0.113 for secondary endpoint). Cox regression analysis showed that both, sustained VT during EPS (HR: 2.26, 95%CI: 1.22-4.19, P = 0.009) and LVEF < 35% (HR: 2.00, 95%CI: 1.13-3.54, P = 0.018) were independent predictors of primary endpoint events. Kaplan-Meier survivor functions of EPS and LVEF for the primary endpoint are shown in Figure 1.

Sensitivity analysis

Main analysis were repeated separate for participants with CAD and DCM. Among the 152 CAD patients, a primary endpoint event occurred in 32 patients (21.1%). The AUROCs of the EPS (0.604, 95%CI: 0.516-0.693) and of LVEF (0.606, 95%CI: 0.509-0.704) were similar to the overall study population and did not significantly differ (P = 0.975). Among the 58 patients with DCM, a primary endpoint event occurred in 13 patients (22.4%). Due to the low numbers of patients, the AUROC of the EPS (0.625, 95%CI: 0.469-0.781) had a broad 95%CI. The AUROC of LVEF (0.425, 95%CI:

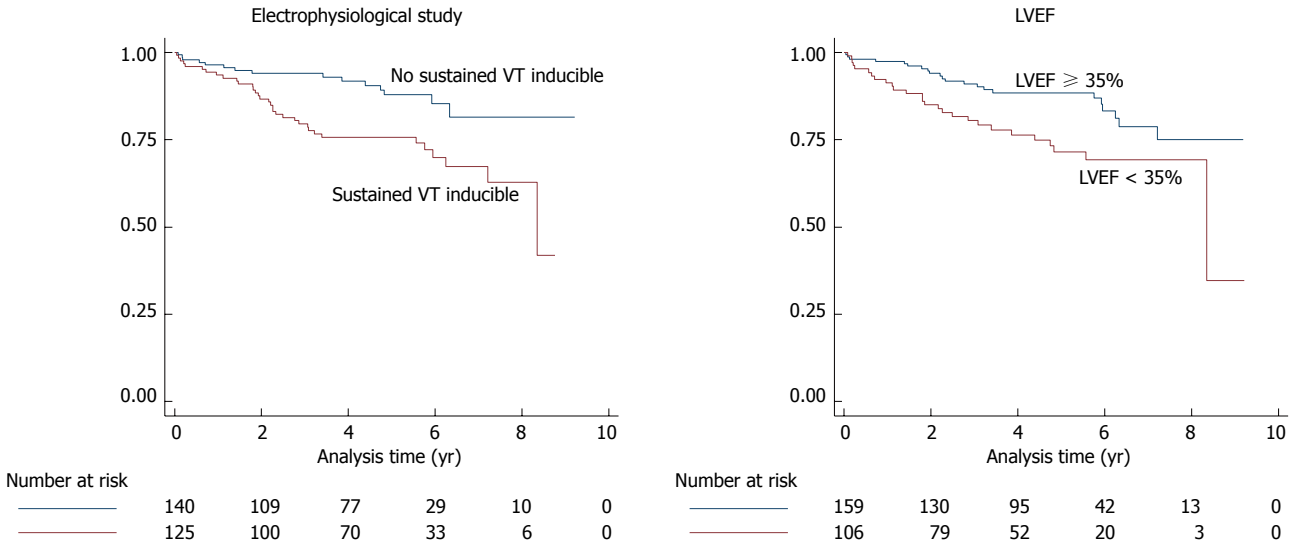

Figure 1 Kaplan-Meier function of primary endpoint event-free survival for patients with or without sustained ventricular tachycardia during the electrophysiological study and for patients with left ventricular ejection fraction < 35% *vs* ⩾ 35%. VT: Ventricular tachycardia; LVEF: Left ventricular ejection fraction.

0.268-0.582) was low (P = 0.105 as compared to the AUROC of the EPS).

DISCUSSION

This long-term prospective cohort study revealed several important findings. First, in a mixed population with different cardiac pathologies inducible sustained ventricular tachyarrhythmia during EPS identified those at higher risk for a SCD surrogate, defined either as appropriate ICD activations and/or as documented SCD. Second, LVEF < 35% was another independent predictor of primary endpoint events. Third, in patients with LVEF > 35% negative EPS had a high negative predictive value for the primary and for the secondary endpoint.

Electrophysiologic testing of ventricular tachycardia was introduced 1972[24]. Amongst others, programmed ventricular stimulation was used to assess the efficacy of antiarrhythmic drugs for suppression of inducible ventricular arrhythmias or the efficacy of antitachycardia surgery[25]. With the availability of ICDs EPS has become an important test for risk stratification to predict SCD[19]. The prognostic value of EPS is based on the assumption that patients with inducible ventricular tachyarrhythmias should have a high likelihood of spontaneous arrhythmic events and that non-inducible patients should be at low risk[26]. In the current guidelines electrophysiologic testing has a class Ⅰ recommendation for diagnostic evaluation of patient with remote myocardial infaction with symptoms suggestive of ventricular arrhythmias, including palpitations, presyncope and syncope. Another class Ⅰ indication is syncope of unkown cause with impaired LV function or structural heart disease[19]. In nonischemic DCM electrophysiologic testing is not recommended for risk stratificiation. However, in a recent study of Gatzoulis *et al*[18] inducibility of VT/VF in patients with idiopathic dilated cardiomyopathy was associated with an increased likelihood of subsequent ICD activation and SCD surrogate. In the present study we have shown, that EPS is useful for the prediction of future arrhythmic events in a collective of patients with different cardiac pathologies. It is well established that the predictive accuracy of LVEF for lifethreatening arrhythmic events is limited[26]. However ICD-Implantation guided by LVEF alone lacks of specificity because in progressive heart failure unexpected SCD accounted for only 30% of deaths while many were due to progressive pump failure not preventable by an ICD.

According to our findings, the additional use of electrophysiologic testing in patients with LVEF < 35% is disputable as the PPV is only improved from 25.5% to 30.5% in cases with a positive EPS. This might not influence the further clinical management of the patient because a 25.5% risk of a future tachyarrhythmic event or SCD already seems to justify ICD implantation. However in patients with LVEF > 35% and a negative EPS the NPV was improved from 86.1% to 93.5%. This means that the risk estimation for future arrhythmic events during the follow-up period of 4.8 ± 2.3 years is reduced from 13.9% to 6.5%. In addition a positive EPS still exhibits a PPV of 24.2% in patients with LVEF > 35%.

Similar results were found in the MUSTT trial[27]. Both, low ejection fraction and inducible sustained ventricular tachycardia during EPS, identified patients at increased mortality risk. Inducible tachyarrhythmias identified patients for whom death was significantly more likely to be arrhythmic and this was observed especially if ejection fraction was higher than or equal to 30%. Due to our findings, invasive testing should especially be considered in this group of higher to

normal LVEF, as it might prevent implantation of ICD in patient who won't benefit.

This study has some limitations. First, the findings of this study are from a single center. Therefore, generalizability is limited and confirmation in an independent sample is of importance. Second, we included patients who underwent EPS for primary prevention as well as for secondary prevention. NPV and PPV of sustained ventricular tachycardia during EPS might differ in these subgroups, however the study population is too small to perform an independent statistical analysis.

EPS provides a benefit in risk stratification for future tachyarrhythmic events and SCD and should especially be considered in patients with LVEF > 35%.

COMMENTS

Background

Patients with preexisting cardiac disease are at higher risk for future cardiac arrhythmias, potentially leading to sudden cardiac death (SCD). In the study the authors evaluated the prognostic value of electrophysiological stimulation (EPS) in the risk stratification for future cardiac arrhythmias.

Research frontiers

Guidelines recommend various non-invasive techniques to recognize patients at higher risk for life-threatening arrhythmias. Currently, the electrophysiological study (EPS) is widely used for risk stratification and several randomized trials suggest a significant predictive value of this examination.

Innovations and breakthroughs

The authors found that in a mixed population with different cardiac pathologies inducible sustained ventricular tachyarrhythmia during EPS identified those at higher risk for SCD or appropriate activation of implantable cardioverter defibrillator (ICD). Furthermore left ventricular ejection fraction (LVEF) < 35% was another independent predictor of SCD surrogate. In patients with LVEF > 35% negative EPS had a high negative predictive value for SCD and ICD activation.

Applications

EPS provides a benefit in risk stratification for future tachyarrhythmic events and SCD and should especially be considered in patients with LVEF > 35%.

Peer-review

The authors have prospectively evaluated the role of programmed ventricular stimulation in the risk stratification of tachyarrhythmic events and sudden cardiac death in a large patient population; the possibility to optimize selection of patients undergoing ICD implantation is very relevant and evidence-based conclusions would be of great clinical importance.

Abstract

Saphenous vein grafts (SVG) pseudoaneurysms, especially giant ones, are rare and occur as a late complication of coronary artery bypass grafting. This condition affects both genders and typically occurs within the sixth decade of life. The clinical presentation ranges from an asymptomatic incidental finding on imaging studies to new onset angina, dyspnea, myocardial infarction or symptoms related to compression of neighboring structures. An 82-year-old woman presented with acute onset back pain, dyspnea and was noted to have significantly engorged neck veins. In the emergency department, a chest computed tomographic angiogram with intravenous contrast revealed a ruptured giant bilobed SVG pseudoaneurysm to the right posterior descending artery (RPDA). This imaging modality also demonstrated compression of the superior vena cava (SVC) by the SVG pseudoaneurysm. Coronary angiogram with bypass study was performed to establish the patency of this graft. Endovascular coiling and embolization of the SVG to RPDA was initially considered but disfavored after the coronary angiogram revealed preserved flow from the graft to this arterial branch. After reviewing the angiogram films, a surgical strategy was favored over a percutaneous intervention with a Nitinol self-expanding stent since the latter would have not addressed the superior vena cava compression caused by the giant pseudoaneurysm. Intraoperative transesophageal echocardiogram demonstrated SVC

compression by the giant pseudoaneurysm cranial lobe. Our patient underwent surgical ligation and excision of the giant pseudoaneurysm and the RPDA was regrafted successfully. In summary, saphenous vein grafts pseudoaneurysms can be life-threatening and its therapy should be guided based on the presence of mechanical complications, the patency of the affected vein graft and the involved myocardial territory viability.

Key words: Giant saphenous graft pseudoaneurysm; Late complication of coronary artery bypass grafting; Superior vena cava syndrome; Endovascular coiling and embolization; Nitinol self-expanding stent

Core tip: Saphenous vein grafts (SVG) pseudoaneurysms, especially giant ones, are rare and occur as a late complication of coronary artery bypass grafting. Although unusual, superior vena cava (SVC) syndrome has been reported as a complication of saphenous vein graft pseudoaneurysms causing compression of the SVC. Here we report a case of such condition illustrated with state-of-the-art multi-modality images which were critical for the planning of the most appropriate treatment strategy. SVG pseudoaneurysms can be life-threatening and their therapy should be guided based on the presence of mechanical complications, the patency of the affected vein graft and the involved myocardial territory viability.

Vargas-Estrada A, Edwards D, Bashir M, Rossen J, Zahr F. Giant saphenous vein graft pseudoaneurysm to right posterior descending artery presenting with superior vena cava syndrome. *World J Cardiol* 2015; 7(6): 351-356 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/351.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.351

INTRODUCTION

Coronary saphenous vein graft pseudoaneurysms are rare complications of coronary artery bypass grafting, occurring several years after the initial procedure. Although very unusual, superior vena cava obstruction has been reported as a complication of a rupture of a coronary artery bypass vein graft[1]. It is uncommon to encounter such patients and the optimal treatment remains uncertain. The improvement of percutaneous interventions and the development of covered and Nitinol self-expanding stents have become an attractive option to spare these subjects from a repeat thoracotomy, however this is not always feasible. To our knowledge, there have been very few similar cases reported, we believe this to be the first reported case of such condition illustrated with state-of-the-art multi-modality imaging.

CASE REPORT

An 82-year-old woman presented to the hospital with complaints of acute onset back pain, dyspnea for twelve hours and significantly engorged neck veins. She had undergone 3-vessel coronary artery bypass graft surgery in 1993. At the time of her coronary artery bypass operation, the left internal mammary artery (LIMA) was used to graft the first diagonal branch. Separate saphenous vein grafts were placed to the left anterior descending artery (LAD) and right posterior descending artery (RPDA). It is unknown to us the reasons for LIMA to diagonal branch anastomosis instead of arterial bypass to LAD which in turn received a venous graft. On her arrival to the emergency department, an electrocardiogram showed sinus rhythm and no ischemic changes. Her cardiac enzymes were negative. Computed tomography with IV contrast of the patient's chest ruled out pulmonary embolism and aortic dissection. Tomographic and 3D reconstruction views identified a ruptured giant bilobed SVG pseudoaneurysm to RPDA causing mass effect on the superior vena cava and right-sided cardiac chambers (Figures 1 and 2). The cranial lobe of the pseudoaneurysm measured 4.7 cm × 5.4 cm and the caudal lobe measured 8.0 cm × 7.0 cm in its larger diameter and demonstrated mural thrombosis. Coronary angiography demonstrated a giant pseudoaneurysm of the SVG with patent flow to the right posterior descending artery (Figure 3). Coiling and embolization of the SVG to RPDA was initially considered but disfavored since the coronary angiogram revealed preserved flow from the graft to RPDA branch. Also a percutaneous intervention with a covered *vs* a Nitinol self-expanding stent to the ruptured SVG was contemplated but ultimately surgical intervention was decided since the former strategy would have not addressed the superior vena cava compression caused by the giant pseudoaneurysm. Intraoperative echocardiography (Figure 4) showed SVC compression by the giant pseudoaneurysm cranial lobe. At surgery, the giant SVG pseudoaneurysm was ligated, excised and the RPDA was regrafted. The patient recovered uneventfully and was discharged on postoperative day 20. After completing her post-surgical rehabilitation, she returned to our clinic six weeks later, asymptomatic and in stable condition.

DISCUSSION

Aneurysmal dilatation of aortocoronary saphenous vein grafts (SVG), first described by Riahi *et al*[2] in 1975 remains a rare yet widely reported phenomenon. This condition is secondary to true aneurysm or pseudoaneurysm, with the former being more common. SVC syndrome is caused by obstruction of blood flow through the superior vena cava due to thrombosis or extrinsic compression. It is a medical emergency

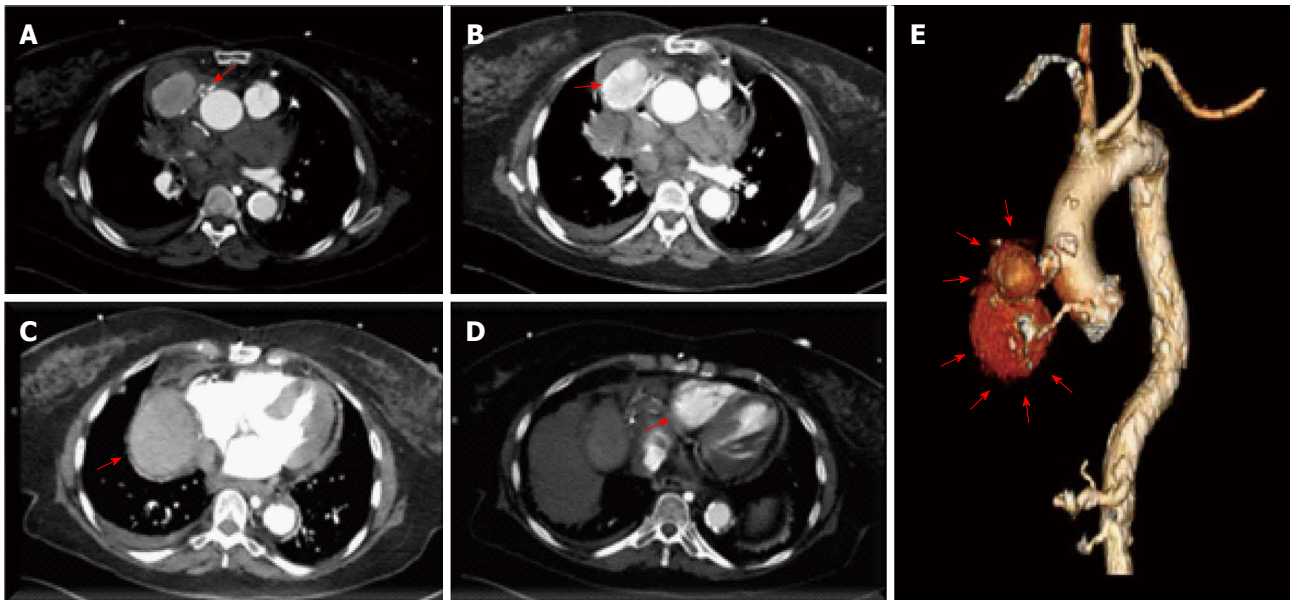

Figure 1 Transaxial tomographic views showing the right coronary artery origin and the saphenous vein grafts pseudoaneurysm lobes. A: The more cranial lobe of the pseudoaneurysm measured 4.7 cm × 5.4 cm in diameter and demonstrated mural thrombosis; B: The caudal lobe of the pseudoaneurysm also demonstrated mural thrombosis and measured 8 cm × 7 cm in its larger diameter; C, D: The caudal lobe of the giant pseudoaneurysm was patent and demonstrated flow into the distal right coronary and right posterior descending artery; E: Computed tomographic 3-D reconstruction of the saphenous vein grafts giant bilobed pseudoaneurysm to the right posterior descending artery.

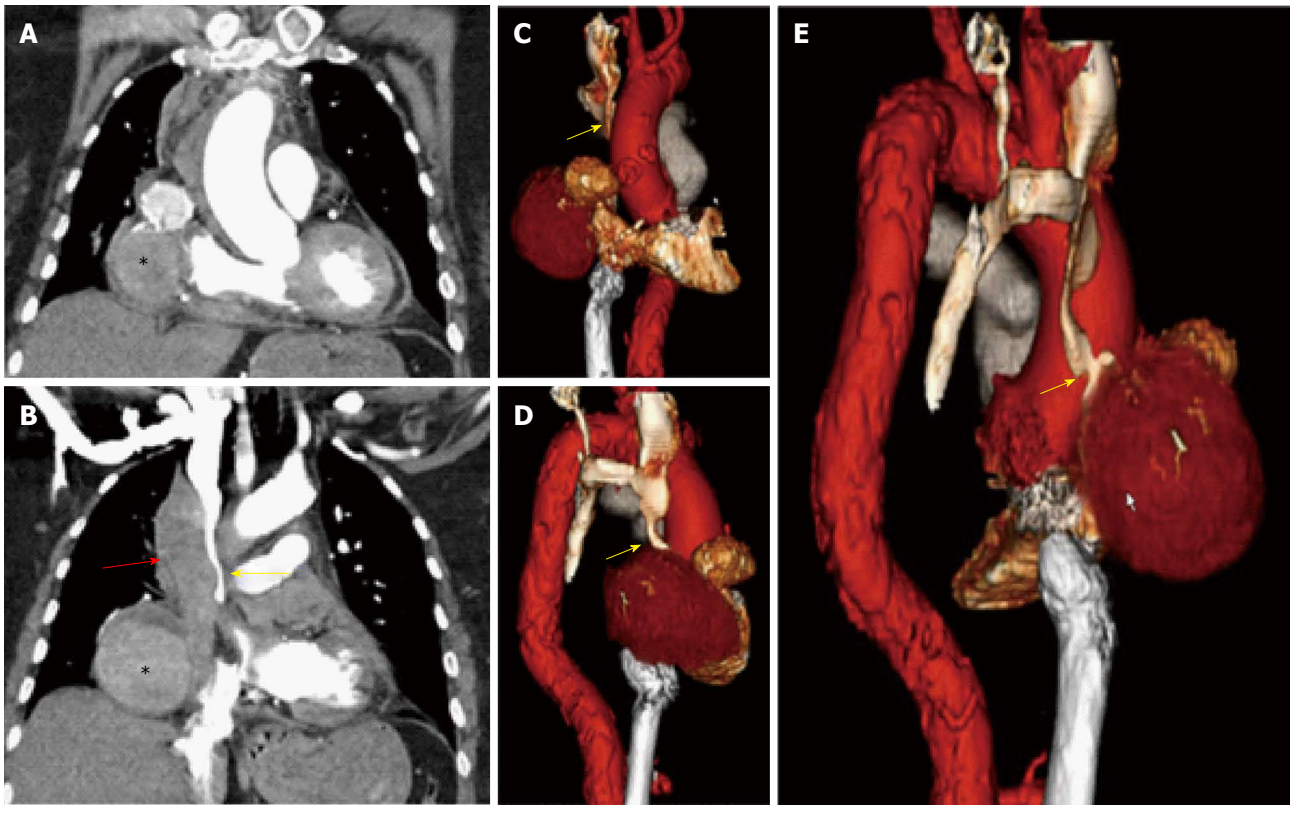

Figure 2 Significantly distended neck veins secondary to compression of the superior vena cava by the giant saphenous vein grafts pseudoaneurysm to right posterior descending artery. A: Coronal tomographic views showing upper and lower lobes of the SVG pseudoaneurysm (asterisks); B: Large hematoma (red arrow) is shown compressing the SVC (yellow arrow); C, D, E: Computed tomographic 3-D reconstruction of the SVG giant bilobed pseudoaneurysm and SVC compression (yellow arrow) in anterior, lateral and posterior views. SVG: Saphenous vein grafts; SVC: Superior vena cava.

and most often manifests in patients with a malignant process within the thorax (particularly lung adenocarcinoma), however as many as 40% of cases are attributable to nonmalignant causes. The first case of

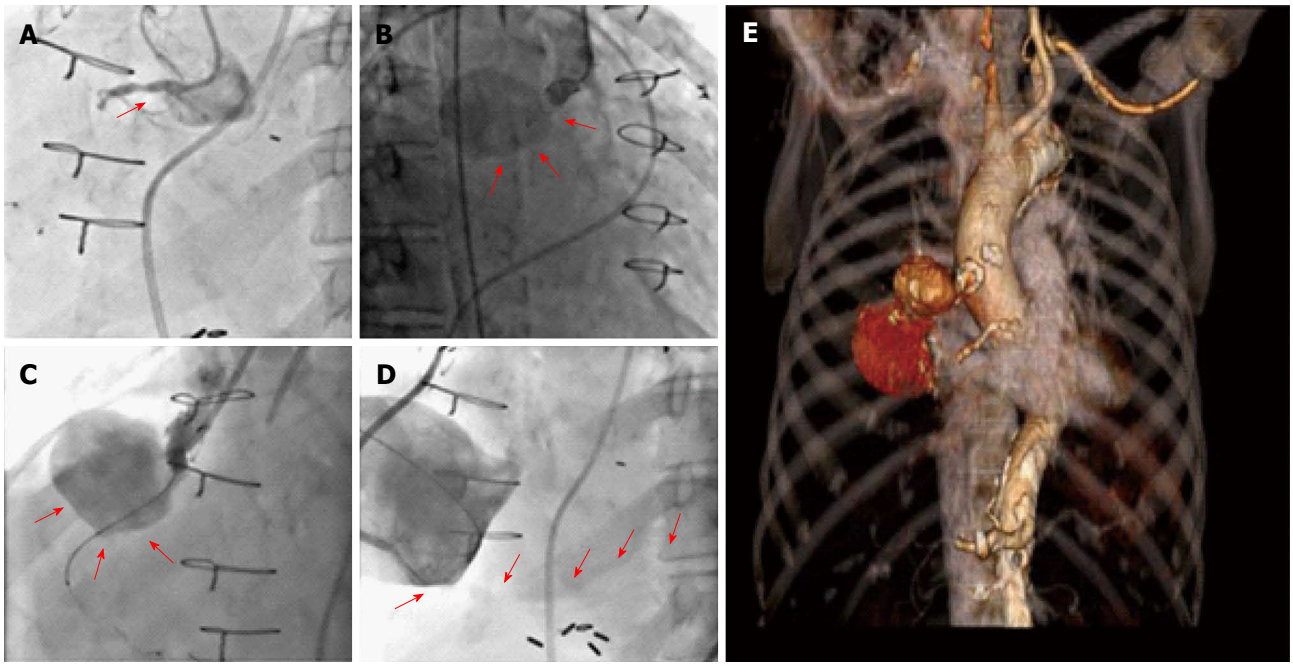

Figure 3 Coronary angiography demonstrated a giant pseudoaneurysm of the saphenous vein grafts with patent flow to the right posterior descending art. A: Coronary angiography showing the ostial and proximal right coronary artery (RCA) occlusion; B: Angiographic image depicting the upper lobe of the SVG to RPDA giant pseudoaneurysm; C: Giant pseudoaneurysm of vein graft with wide neck beginning about 2 cm from the graft origin; D: Injection within the aneurysm sac revealing a patent bypass graft that continues into the distal right coronary artery with a sequential connection to the posterior descending artery; E: Computed tomographic 3-D reconstruction of the SVG giant bilobed pseudoaneurysm to the distal right coronary artery seen in relation to the thoracic structures. SVG: Saphenous vein grafts; RPDA: Right posterior descending artery.

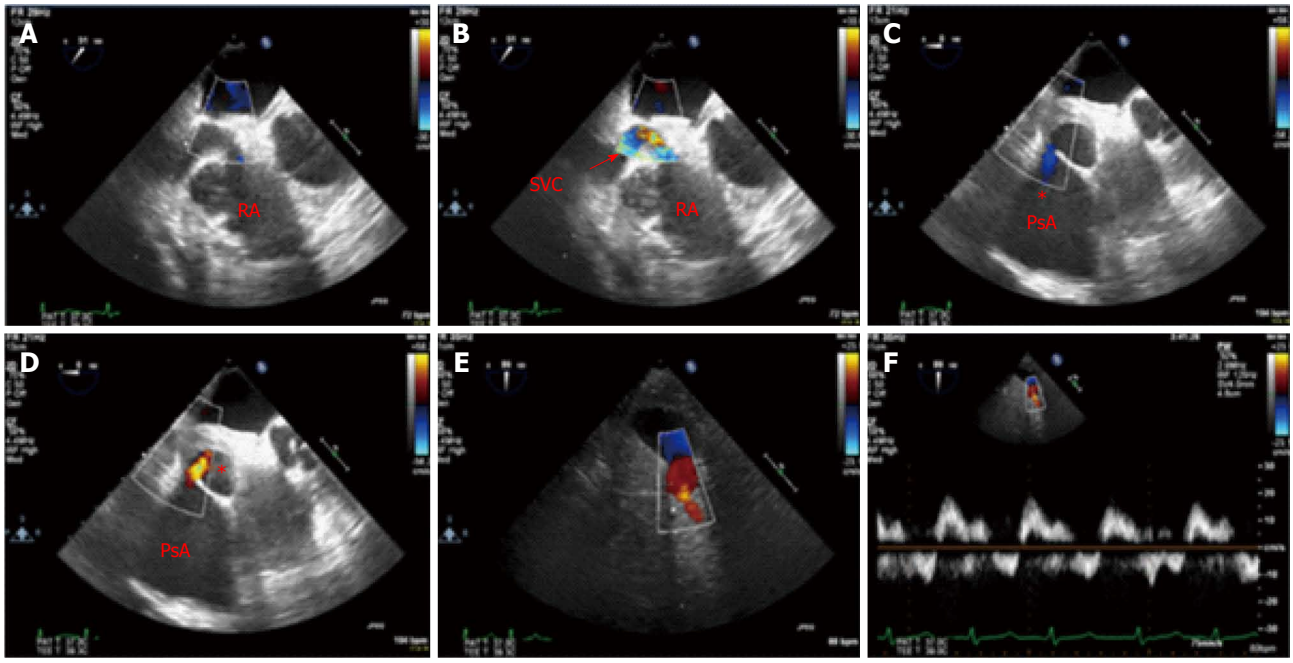

Figure 4 Intraoperative echocardiography showed superior vena cava compression by the giant pseudoaneurysm cranial lobe. A: Intraoperative transesophageal echocardiogram demonstrated normal left ventricular systolic function with left ventricular ejection fraction 60% and the giant pseudoaneurysm of SVG to RPDA in relation to the cardiac structures; B: Echocardiographic view of the pseudoaneurysm upper lobe compressing the superior vena cava (SVC); C, D: Blood flow by color Doppler of the SVC into the right atrium; E, F: Bidirectional flow is seen between the upper and lower pseudoaneurysm (PsA) lobes during diastole and systole respectively. Color Doppler and flow velocities of the giant pseudoaneurysm caudal lobe. RPDA: Right posterior descending artery.

ruptured SVG pseudoaneurysm presenting with SVC syndrome was reported by Rosin and colleagues[3] in 1989. Kavanagh *et al*[4] in 2004 reported the first case in which CT findings of this condition were described. We presented a case of a giant saphenous vein graft pseudoaneurysm to right posterior descending artery in a patient presenting with superior vena cava (SVC) syndrome. The precise incidence of SVG aneurysms

remains difficult to ascertain and more so for SVG pseudoaneurysms. In one case series, an incidence of 0.07% was estimated from a review of 5500 grafts at a single institution[5]. This condition occurs in both genders but predominates in men (87% of reported cases on average within the sixth decade of life). Postulated mechanisms for SVGs aneurysmal dilatation include atherosclerotic degeneration of the graft, vessel wall ischemia secondary to disruption of the vasa vasorum during the harvesting and grafting process, graft endothelial dysfunction and changes in medial smooth muscle cell orientation in the vicinity of valve sites[6]. The clinical presentation is somewhat variable and ranges from an asymptomatic incidental finding on chest X-ray (12%-47%) to new onset angina (46.4%), shortness of breath (12.9%), myocardial infarction (7.7%), hemoptysis (4.8%), hemothorax, or symptoms related to compression of neighboring structures, as well as shock (3.8%) or death[7]. SVGs aneurysms predominate in the right coronary distribution thus compression of right-sided cardiac structures is more common. Our patient presented with significantly distended neck veins secondary to compression of the superior vena cava by the giant SVG pseudoaneurysm to RPDA (Figure 2). The mechanical complications include right atrial compression (11.5% of cases), right ventricular compression (7.2%) and fistula formation (7.7%)[8]. The most feared complication is aneurysm rupture which has been reported as a presenting feature in only a minority of cases. Although frequently identifiable on chest X-ray or echocardiography, coronary angiography is required to evaluate the patency of the coronary arteries and bypass grafts. Confirmation of the size of the aneurysm or pseudoaneurysm and the relationship to the surrounding structures is best achieved with CT angiography or MRA. Different treatments options exist and are applied according to the anatomy of the pseudoaneurysm, mechanical complication and the patency of the affected vein graft. Repeat coronary artery bypass grafting with aneurysmal ligation or excision is the classic approach[9]. In cases in which the affected graft remains patent despite the aneurysmal dilation and in non-surgical candidates for repeat sternotomy, percutaneous management with a covered stent should be considered. In patients in whom preservation of myocardial blood supply is not a concern or non-viable myocardium has been demonstrated, the aneurysmal neck can be occluded by Amplatzer vascular plugs[9] or the aneurysm can be thrombosed by endovascular coiling[10]. Although large-bore Nitinol stents are highly effective for superior vena cava syndrome, in our case it was decided to proceed with re-thoracotomy and excision of the graft pseudoaneurysm after rupture was demonstrated by CT imaging and coronary angiography. The SVC syndrome resolved with the surgical excision of the ruptured SVG pseudoaneurysm. The optimal treatment for this condition remains an area of uncertainty with available data based on case reports and small case series and certainly depends upon the clinical scenario and should be made by a multidisciplinary cardiac team.

COMMENTS

Case characteristics

An 82-year-old woman presented with acute onset back pain, dyspnea and engorged neck veins.

Clinical diagnosis

Dyspnea of twelve hours duration and engorged neck veins, later were found to be caused by superior vena cava syndrome from superior vena cava (SVC) compression by a giant saphenous vein grafts (SVG) pseudoaneurysm.

Differential diagnosis

Any cause for acute onset back pain and dyspnea such as acute coronary syndrome, pulmonary embolism, aortic dissection, *etc.*

Laboratory diagnosis

Lab tests result including cardiac enzymes were unremarkable.

Imaging diagnosis

Multi-imaging modalities including computed tomography chest angiogram, coronary angiogram and TEE revealed a giant bilobed SVG pseudoaneurysm to the right posterior descending artery causing compression of the superior vena cava leading to SVC syndrome.

Treatment

Surgical ligation and excision of the SVG pseudoaneurysm with regrafting of right posterior descending artery.

Experiences and lessons

Saphenous vein graft pseudoaneurysms can present as a late complication following coronary artery bypass grafting. Although most frequently asymptomatic and found incidentally by imaging modalities, the authors should consider this condition in the differential diagnoses for acute coronary syndrome and as a possible explanation of SVC syndrome in patients with prior coronary artery grafting. Different treatments options exist and are applied according to the anatomy of the pseudoaneurysm, mechanical complication and the patency of the affected vein graft.

Peer-review

This is an interesting report for clinical practice.

Abstract

We are reporting a long-time magnetic resonance imaging (MRI) follow-up in a rare case of cardiac left lateral wall hypertrophy. Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiovascular disorder and a significant cause of sudden cardiac death. Cardiac magnetic resonance (CMR) imaging can be a valuable tool for assessment of detailed information on size, localization, and tissue characteristics of hypertrophied myocardium. However, there is still little knowledge of long-term evolution of HCM as visualized by magnetic resonance imaging. Recently, our group reported a case of left lateral wall HCM as a rare variant of the more common forms, such as septal HCM, or apical HCM. As we now retrieved an old cardiac MRI acquired in this patient more than 20 years ago, we are able to provide the thrilling experience of an ultra-long MRI follow-up presentation in this rare case of left lateral wall hypertrophy. Furthermore, this case outlines the tremendous improvements in imaging quality within the last two decades of CMR imaging.

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiovascular disorder and a significant cause of sudden cardiac death. Cardiac magnetic resonance (CMR) imaging can be a valuable tool for assessment of detailed information on size, localization, and tissue characteristics of hypertrophied myocardium. However, there is still little knowledge of long-term evolution of HCM as visualized by magnetic resonance imaging (MRI). Recently, our group reported a case of left lateral wall HCM[1] as a rare variant of the more common forms, such as septal HCM, or apical HCM[2]. As this patient underwent initial cardiac MRI more than 20 years ago, we are able to provide the thrilling experience of an ultra-long MRI follow-up presentation in this rare case of left lateral wall hypertrophy, including the tremendous improvements in imaging quality within the last two decades of CMR imaging.

CASE REPORT

A 52-year-old male presented himself to the emergency department of our institution suffering an episode of nocturnal chest pain. As the electrocardiogram showed ventricular tachycardia, synchronized electrical cardioversion was performed, successfully terminating the arrhythmia. Afterwards, the patient was subjected to sequential clinical investigations, excluding ischemia as cause for the serious symptoms, and CMR imaging, revealing an atypical form of HCM.

CMR was performed five days after the initial arrhythmic event on a MAGNETOM® Trio 3.0 Tesla scanner (Siemens AG Sector Healthcare, Erlangen, Germany). In addition to these current investigations, we were now able to retrieve MR images from the year 1989 (1.5 Tesla Philips Gyroscan, Philips Medical System, Best, the Netherlands) which had been acquired in the pre-PACS era more than 23 years in advance of the current event. This enabled us to present a long term MRI follow-up of this rare manifestation of HCM and to point out the massive improvements in imaging quality of cardiac MRI, due to enormous technical development within the last two decades.

Past images from the year 1989 deliver some limited diagnostic information. Nevertheless, left ventricular wall thickening up to 45 mm was clearly seen in this patient even 23-years ago (Figure 1A). In addition, Gadolinum enhancement (GE) of the noticeable area of interest was depicted after *iv* contrast application (Figure 1B). In the late 1980s, late Gadolinium enhancement (LGE) had not yet been described as a non-invasive method for myocardial tissue characterization, including analysis for myocardial fibrosis.

Current high-quality T1 weighted turbo-spin-echo images with dark blood technique confirmed an extensive, confined thickening of the left ventricular lateral wall up to 45 mm in the 4-chamber view (Figure 1C). Cine-SSFP sequences demonstrated a prolonged longitudinal relaxation of the lateral wall (not shown). After injection of 0.2 mmol/kg intravenous contrast agent (Gadovist®, Bayer HealthCare, Leverkusen, Germany) the myocardial mass showed homogenous contrast enhancement. LGE imaging was acquired 12 min after *iv* contrast administration. PSIR-SSFP images in the 4-chamber (Figure 1D) and short axis views (Figure 2A-C) revealed a homogenous enhancement, corresponding to the left ventricular lateral wall thickening, as it can be typically observed in other, more common forms of HCM.

In addition, a small accompanying circular pericardial effusion (indicated with arrows) was depicted in the present CMR images (Figure 1C and 2B).

Comparison of the studies revealed no significant change over time regarding the extent of wall thickening. It is difficult to judge whether significant change in myocardial fibrosis can be detected by CMR, as LGE techniques had not been described prior to 2001 and the baseline CMR was performed prior to that in 1989[3] (Figure 1, A/B *vs* C/D). In 1989, the contrast enhanced images were acquired about 3 min after Gd administration, a "late-enhancement stop" and the so-called "nulling" technique were not available/invented. However, as far as one can compare the images from 1989 to 2012, no significant change in fibrotic myocardium occurred during this time span. The diagnosis of myocardial fibrosis was already proven in 1989 by myocardial biopsy, showing massive hypertrophy but no signs of malignancy.

Therefore, this intensive myocardial thickening described above has to be considered a highly

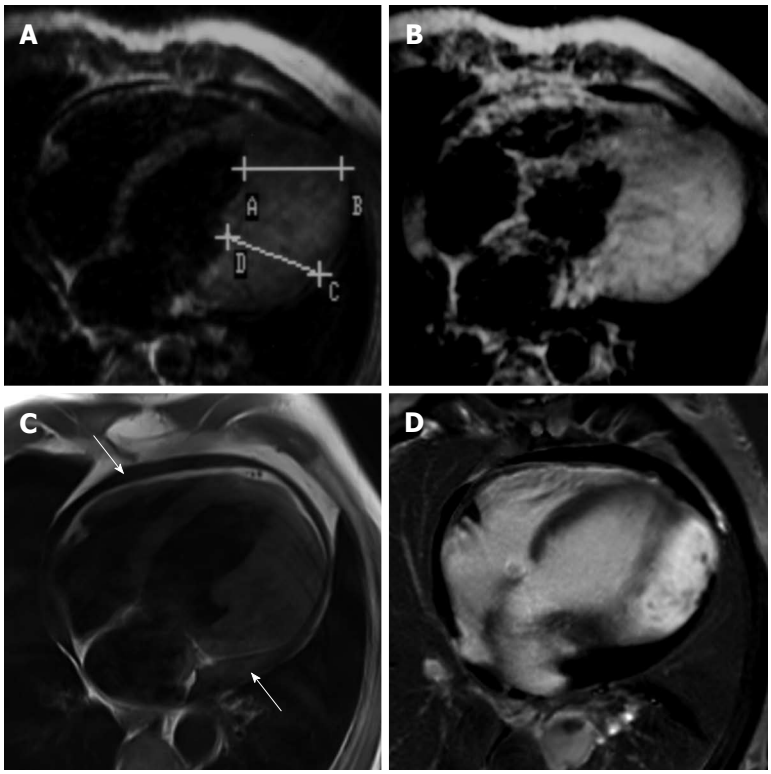

Figure 1 Hypertrophic cardiomyopathy of the left lateral wall in 1989 (A, B) and 2012 (C, D). Note the difference of image quality especially within the GE series from 1989 (B) and the PSIR-SSFP late Gadolinium enhancement (LGE) images in 2012 (D). Within the last 23 years, there was no significant change in respect to morphology (A, C) and LGE (B, D) in this patient. Arrows indicate accompanying circumferential, increasing pericardial effusion.

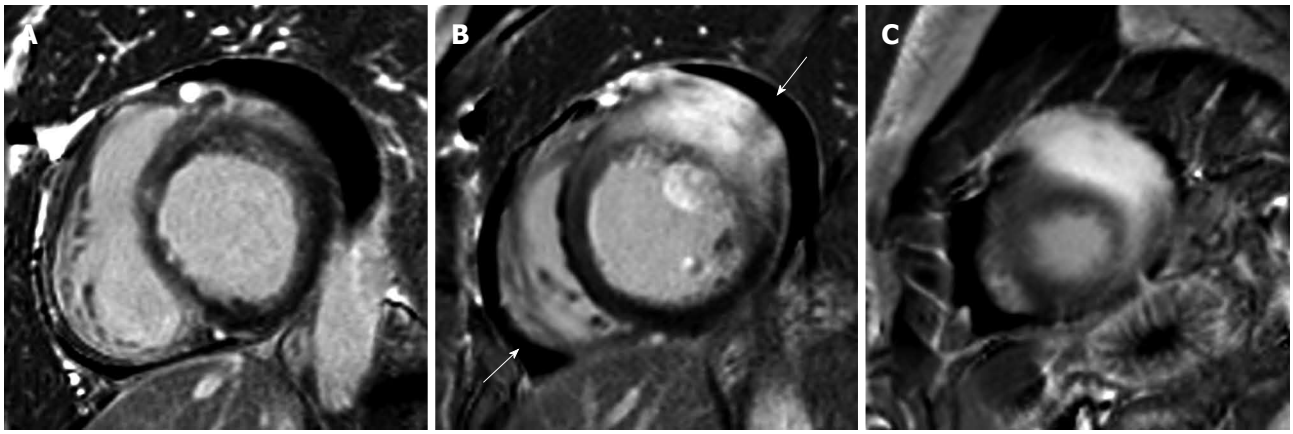

Figure 2 Late Gadolinium enhancement images in basal (A), midventricular (B) and apical (C) slices in the short axis view show significant late Gadolinium enhancement in the area of hypertrophic cardiomyopathy of the left lateral wall. Arrows indicate accompanying pericardial effusion.

uncommon manifestation of HCM limited solely to the left ventricular lateral wall.

Finally, the patient could be discharged in good general condition after the implantation of an ICD for prevention of further episodes of ventricular tachycardia.

DISCUSSION

In a patient with atypical left wall cardiac hypertrophy, CMR was able to provide detailed information on size, localization, and tissue characteristics of the myocardial mass and allowed non-invasive long time assessment of these parameters. Even though limited to the left ventricular lateral wall, our variant of HCM showed some typical characteristics. For instance, LGE is frequently observed in HCM patients and reflects the presence of fibrosis within the myocardium[4,5]. However, the clinical significance of change of LGE over time in HCM is still under debate[6]. Nonetheless, the presence of LGE is an independent risk factor for adverse outcome in HCM and associated with an increased frequency of ventricular tachyarrhythmia, as was the case in our patient[7,8].

However, initial inspection of the LGE images with

the atypical site of LGE and the considerable degree of myocardial hypertrophy raised concerns whether the patient might suffer from a malignant tumor of the myocardium. Pericardial effusion fortified this impression. However, only a short period after the current CMR, reports from the old, previous CMR from 1989 were retrieved. Finally, comparison of the images from 1989 to those of 2012 confirmed that the patient suffered from HCM and excluded a malignant tumor as a potential differential diagnosis.

For future studies, T1 maps might be helpful to differentiate between a cardiac entity (HCM) and non-cardiac entity (tumor). However, this was not performed in the current case, as the utilized MR scanner was not equipped with software applicable for T1 mapping.

COMMENTS

Case characteristics

A 52-year-old male with an episode of nightly chest pain.

Clinical diagnosis

Electrocardiogram showed ventricular tachycardia.

Differential diagnosis

Ischemia, cardiac tumor, atypical hypertrophic cardiomyopathy (HCM).

Laboratory diagnosis

Tests for exclusion of cardiac ischemia were within normal limits.

Imaging diagnosis

Cardiac magnetic resonance imaging showed an extensive, confined thickening of the left ventricular lateral wall up to 45 mm. Comparison with a previous study from 1989 revealed that this left ventricular wall thickening was clearly seen in this patient already 23-years ago.

Pathological diagnosis

Myocardial biopsy had shown massive hypertrophy but no signs of malignancy in 1989.

Treatment

The patient underwent implantation of an ICD for prevention of further episodes of ventricular tachycardia.

Related reports

Isolated left lateral wall hypertrophic cardiomyopathy is a rare variant of the more common forms, such as septal HCM, or apical HCM.

Term explanation

Late gadolinium enhancement is frequently observed in HCM patients and reflects the presence of fibrosis within the myocardium.

Experiences and lessons

This case report outlines the tremendous improvements in imaging quality within the last two decades of cardiac MR imaging.

Peer-review

This article reported a long-time MRI follow-up in a rare case of cardiac left lateral wall hypertrophy. Cardiac magnetic resonance imaging is a valuable tool for assessment characteristics of hypertrophic cardiomyopathy. And this report provided detailed information on location, size and imaging characteristics of hypertrophic cardiomyopathy.

Abstract

Takotsubo cardiomyopathy is characterized by the development of transient left ventricular regional wall motion abnormalities, in the absence of significant coronary artery obstruction. This syndrome usually occurs in women and is frequently associated with an intense emotional or physical stress. It usually involves apical segments, but in the recent years atypical forms have been described. Inverted or reverse Takotsubo is a variant in which the basal and midventricular segments are hypokinetic, sparing contractile function of the apex. In this report we describe the case of a 54-year-old woman, with chronic malnutrition, initially admitted because of hypoglycemia and severe electrolyte disturbance due to a refeeding syndrome. Within the next hours she experienced acute cardiac symptoms and developed heart failure with low cardiac output. Electrocardiogram (ECG), elevation of troponin and echocardiographic findings were consistent with inverted Takotsubo cardiomyopathy. To the best of our knowledge, this is the first incidence reported of inverted Takotsubo triggered by refeeding syndrome.

Key words: Apical ballooning; Refeeding syndrome; Anorexia; Atrial tachycardia; Inverted takotsubo

Core tip: Inverted Takotsubo is a stress-induced cardiomyopathy type that could be encountered in patients suffering from varied physical or emotional triggers. In this report we describe the first case following a refeeding syndrome. There are reported cases of classical apical Takotsubo associated with nutrition disorders, but none of them presenting with the inverted variant.

INTRODUCTION

Takotsubo cardiomyopathy (also called apical ballooning syndrome or stress-induced cardiomyopathy) is an acute cardiac syndrome characterized by transient and reversible wall-motion abnormalities of the left ventricle.

The clinical features include an onset of acute chest symptoms, electrocardiographic changes, and elevated cardiac enzymes, mimicking myocardial infarction, but in the absence of significant obstructive coronary disease.

It is estimated that this condition probably accounts for 1% to 2% of all cases of suspected acute myocardial infarction. Approximately 90% of all reported cases have been in women and the average age of onset range between 58 and 75 years, with < 3% of the patients being < 50 years[1].

In the most commonly described type of stress cardiomyopathy, the contractile function of the mid and apical segments of the left ventricular is depressed and there is hyperkinesis of the basal walls. Less common (atypical) variants include ventricular hypokinesis restricted to the mid-ventricle (mid-ventricular Takotsubo), hypokinesis of the base and mid-ventricle segments with sparing of the apex (reverse or inverted Takotsubo), and localized hypokinesis[2].

The pathophysiology remains unknown, but this syndrome is frequently triggered by intense emotional or physical stress or by an acute medical illness, so catecholamine mediated myocardial stunning is the most accepted explanation[3]. We present a case of inverted Takotsubo in a woman with chronic malnutrition who experienced a rapid oral nutrition repletion. After that she developed refeeding syndrome, a potentially lethal clinical condition characterized by severe metabolic disturbances in undernourished or starved patients undergoing refeeding. Medical complications of this syndrome include cardiovascular system, but it has not usually been described to trigger Takotsubo's cardiomyopathy. The fact that the patient developed an atypical variant (inverted) instead of the classical type of apical stress cardiomyopathy, also makes this case remarkable.

CASE REPORT

A 54-year-old woman was admitted to our hospital on Christmas day with impaired consciousness and severe hypoglycemia (19 mg/dL). She had a past medical history significant for persistent malnutrition, although main organic causes of weight loss had been excluded. The day before admission the relatives of the patient had urged her to ingest a copious dinner on Christmas Eve.

Physical examination on admission revealed marked emaciation with a body weight of 28 kg. She was 162 cm in height and her body mass index (BMI) was 10.66 kg/m^2 (-45% of her ideal BMI). Her body temperature was normal, but she had bradycardia (55 beats/min) and edema in her lower limbs. Her albumin (1.5 g/dL), phosphate (2.2 mg/dL), magnesium (1.6 mg/dL) and potassium (2.7 mmol/L) levels were low. Liver dysfunctions (AST: 122 IU/L, ALT: 72 IU/L) also were noted, as well as coagulation disorders (PT: 55.9%, APTT: 43 s).

First of all, she was treated with 25 g of 50% glucose administrated intravenously, with recovery of consciousness within a few minutes. Then she started receiving specific treatment for electrolyte replacement. The initial ECG showed sinus bradycardia (Figure 1A). Some hours later, the patient referred heart palpitations and a new ECG (Figure 1B and C) was obtained, showing a supraventricular tachycardia. It was remarkable the ST segment elevation in leads Ⅱ, Ⅲ, aVF, V5-V6. The tachycardia was terminated by the administration of adenosine (Figure 1D). Revising the whole electrocardiographic registry the episode was consistent with paroxysmal atrial tachycardia. In the next hours the clinical state of the patient progressively impaired, with development of acute dyspnea, hypotension and obtundation, suggesting heart failure and low cardiac output. Chest X-ray also demonstrated an impairment respect to the previous one on admission (Figure 2). Echocardiography showed dyskinesia of basal and mid-ventricular segments, with hyperkinesia of left ventricular apex (Figure 3). The ejection fraction was estimated at 25%. Serum troponins were mildly elevated with a peak of 4.2 ng/mL, with non-elevated creatine phosphokinase (CPK) levels (80 UI/L). The patient was treated with noninvasive positive pressure ventilation and inotropic drugs at the Intensive Care Unit. Along the next days her clinical situation progressively improved, and a echocardiogram performed one week later showed recovery of the wall motion abnormalities of the left ventricle, with hyperdynamic ejection fraction (Figure 4). Finally, as a complication she developed respiratory distress due to a Serratia marcescens-induced acute pneumonia, and she died. Subsequent necropsy revealed coronary arteries with non obstructive lesions.

DISCUSSION

Once other causes of weight loss had been excluded, all the evidence (clinical signs and findings, along with information provided by the family) pointed towards our patient in the present case suffered from anorexia nervosa (AN).

In patients with AN, cardiac complications can be present in up to 80% of cases and have been reported as cause of at least one-third of all deaths[4].

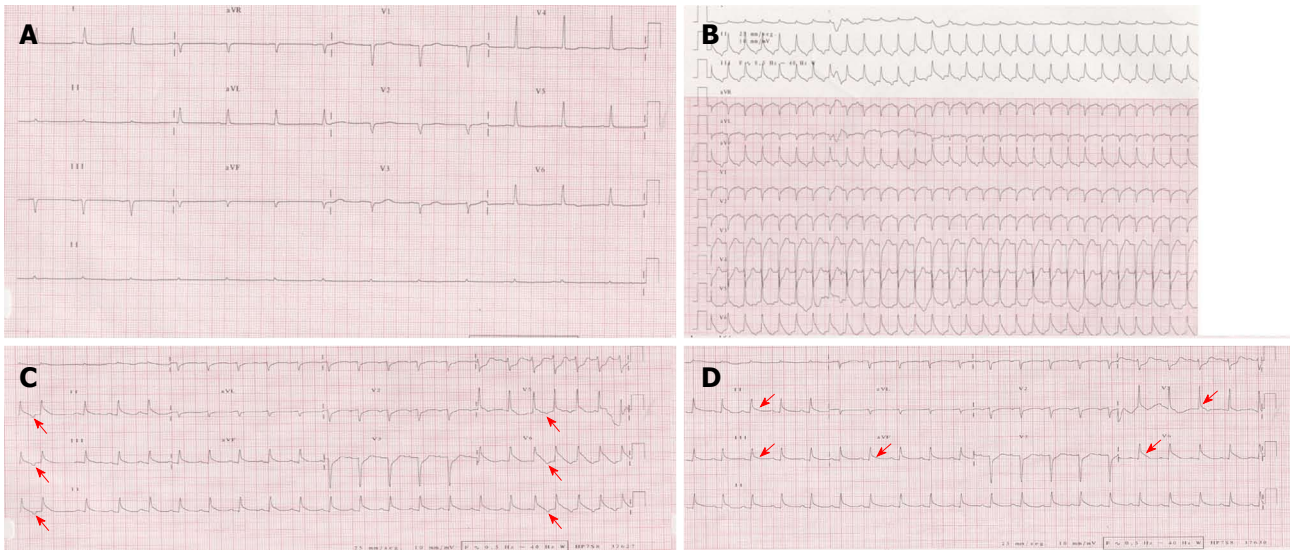

Figure 1 Change process of electrocardiogram. Baseline electrocardiogram (ECG) showed sinus bradycardia and nonspecific repolarization abnormalities (A). Surface ECG of repetitive nonsustained atrial tachycardia (AT). Note that the first P wave of the tachycardia is similar in morphology to the subsequent P waves, consistent with abnormal automaticity as the mechanism of the AT (red arrow). In the setting of posteroseptal AT (originating below and around the coronary sinus ostium), the P wave is positive in lead V1, negative in the inferior leads, and positive in leads aVL and aVR (B and C). ECG after the completion of the tachycardia showed persistent ST elevation in leads Ⅱ, Ⅲ, AVF, V5 and V6 (D) (red arrows).

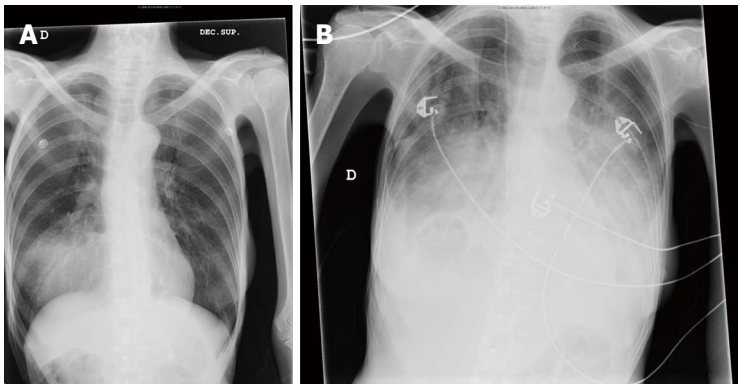

Figure 2 Chest X-ray on admission (A) and after the episode of atrial tachycardia (B) showing signs of severe heart failure.

Main cardiovascular disorders include alterations in hemodynamics (mainly hypotension), in structure (radiographic evidence of decreased cardiac size associated with lower left ventricular mass) and in electrical activity, including sinus bradycardia (present in this patient), reduction in QRS voltage, alterations in ST segment, U waves and prolonged QT interval. QT prolongation may be influenced both by electrolyte abnormalities and psychotropic drugs, with subsequent higher risk of ventricular arrhythmias or torsades de pointes[5,6]. However, left ventricle function generally remains normal, and Takotsubo's cardiomyopathy has only been reported in AN in isolated cases, some of them with hypoglycaemic coma as the precipitating event[7].

Over a chronic severe malnutrition state, the patient had been urged to ingest a copious dinner just before admission. Clinical impairment that she developed within the next hours can be attributed to the appearance of a refeeding syndrome (RF).

RF describes a series of metabolic and biochemical changes that occur as consequence of reintroduction of feeding after a period of starvation or fasting. First reports of the syndrome appeared in the 1950s after observations of malnourished prisoners of war who developed cardiac and neurological symptoms soon after the recommencement of feeding. In 2001 Crook *et al*[8,9] referred to a syndrome of important electrolyte and fluid shifts associated with metabolic abnormalities in malnourished patients undergoing oral, enteral or parenteral refeeding.

This potentially lethal condition encompasses a severe electrolyte disturbance, mainly low serum concentrations of intracellular ions such as phosphate, magnesium, and potassium. Hypophosphataemia is the adopted surrogate marker for diagnosing RF, though low serum phosphate is not pathognomonic. It may produce clinical complications affecting

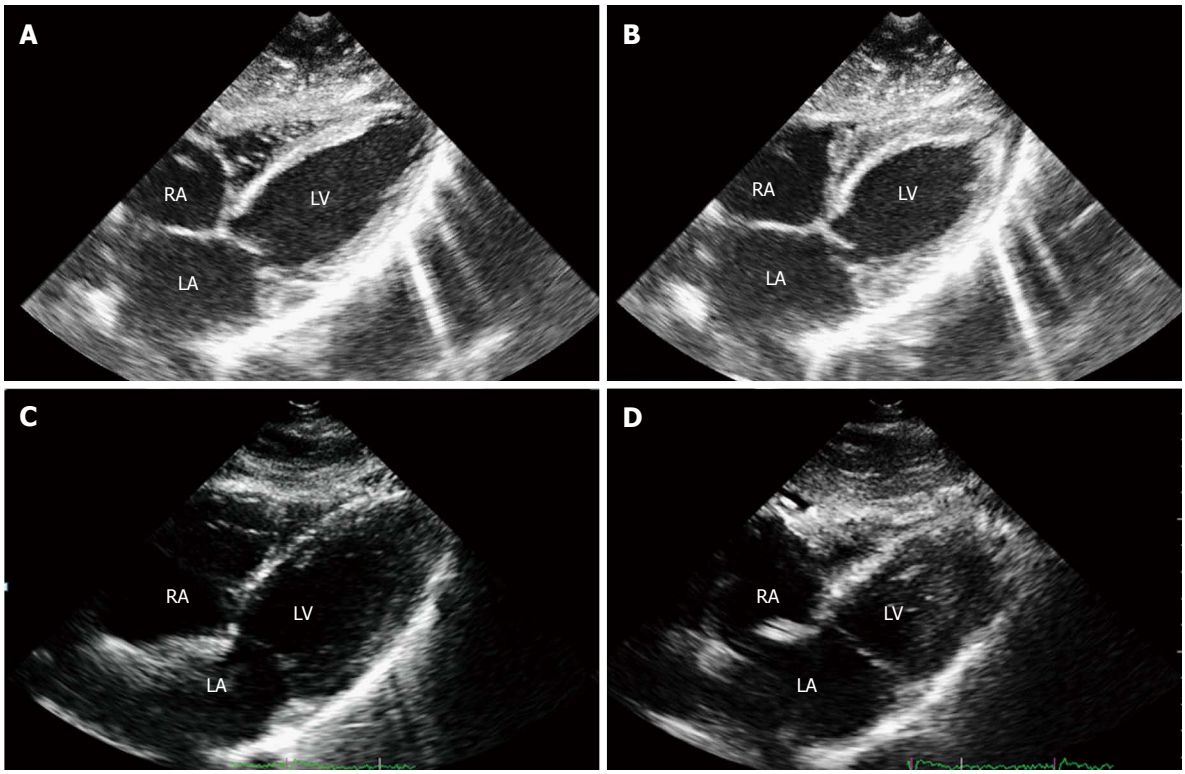

Figure 3 Two-dimensional echocardiogram, subcostal four chambers view, showing the anteroseptal and posterolateral walls of the left ventricle. End-diastolic (A) and mid-systolic (B) frames at the time of acute cardiac symptoms presentation showed dyskinesia of basal and medium segments, with hyperkinesia of the left ventricular apex. One week later, recovery of the wall motion abnormalities was demonstrated, with hyperdynamic ejection fraction (C and D). A previous echocardiogram performed two years before in this patient was similar to this last one. RA: Right atrium; LA: Left atrium; LV: Left ventricle.

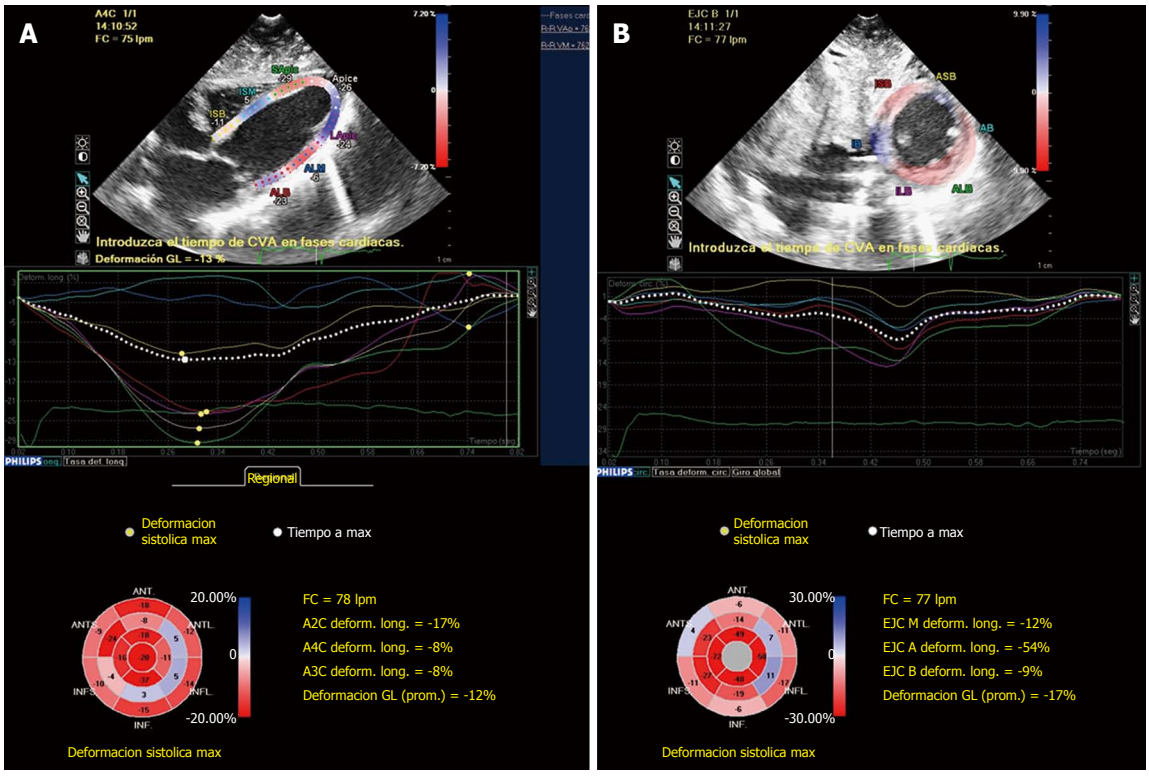

Figure 4 Bull's eye mapping of two-dimensional speckle tracking strain imaging longitudinal (A) and circunferencial (B) showed decreased strain values of the basal and mid-ventricular segments, with normal or increased strain values of the apical segments.

the cardiac, respiratory, haematological, hepatic and neuromuscular systems and leading even to death[10,11].

Atrophy of the heart during starvation renders the patient more vulnerable to fluid overload and heart failure, and electrolyte abnormalities may contribute to ventricular arrhythmias[12]. Nevertheless, our patient developed unusual cardiovascular complications associated with RF, as atrial tachycardia and stress-induced cardiomyopathy.

Automatic atrial tachycardias (caused by abnormal automaticity in cardiac cells) are catecholamine sensitive and the discharge of the abnormal pacemaker involved can be triggered by drugs, various forms of cardiac disease, reduction in extracellular potassium or alterations of autonomic nervous system tone. One or more of them could have influenced in the episode suffered by this patient in the context of RF[13].

Stress-induced (Takotsubo) cardiomyopathy is characterized by the development of transient wall-motion abnormalities in the absence of obstructive coronary artery disease. It was initially described in the Japanese population in 1991 as a syndrome of reversible left ventricular dysfunction with wall-motion abnormalities that involved the apical segments[14]. This condition is typically triggered by severe emotional or physical stress, and it is thought to be caused by a catecholamine-mediated injury. Subarachnoid hemorrhage and pheochromocytoma have been described as common triggers of Takotsubo's cardiomyopathy, which supports this hypothesis, with the exact mechanism of damage caused by catecholamines being less well understood[15].

Various patterns of stress-induced cardiomyopathy have been recently recognized and classified into 4 types based on the involvement of the left ventricle: (1) classic or apical type; (2) reverse or inverted type; (3) mid-ventricular type; and (4) and localized type[16]. We report a case consistent with the inverted type, with dyskinesia of basal and mid-ventricular segments and hyperdynamic contractility of the apex.

Clinical differences affecting inverted type in comparison to common apical and mid-ventricular type have been evaluated by several studies. They conclude that patients with reverse Takotsubo are significantly younger compared with those with other types. It might be due to an asymmetric distribution of adrenergic receptors, which seem to play an important role to determine the area of hypokinesis[17]. The hypothesis is that adrenoceptor density is highest in the apex compared with the base in postmenopausal women, explaining the occurrence of apical variant in older women. The presentation of the inverted type at an early age could be explained by the abundance of adrenoreceptors at the base of the heart, compared with the apex, in younger patients[18].

Release of troponin is higher in inverted Takotsubo compared to other patterns, which might be the consequence of the larger muscle region involved compared to apical type. Nevertheless, in apical and midventricular patterns natriuretic peptides are more elevated and a higher prevalence of significant reversible mitral regurgitation is present, which is clinically translated by more severe heart failure symptoms and higher NYHA functional class[19].

Inverted Takotsubo also seems to be more often associated with either mental or physical stress than other types. Different authors have described cases of inverted type associated with varied physical triggers (pheochromocytoma, pulmonary embolism, cerebellar hemorrhage, pneumomediastinum, *etc.*)[20-22]. Nevertheless to our best knowledge, this is the first report of a case of stress cardiomyopathy presenting with an inverted pattern following a refeeding syndrome.

Regarding to malnourished patients, there are reported cases of classical Takotsubo associated with starvation states of different etiologies, but usually with refractory hypoglycemia as characteristic feature, and none of them presenting with the inverted variant[23]. A particular group would be patients with anorexia nervosa, with some reported cases of development of stress cardiomyopathy maintaining euglycemia; in these cases the syndrome might be triggered by emotional stress or electrolyte disturbances, and neither any of them presenting with the inverted Takotsubo type in the published cases.

In our case, we hypothesize that this particularly unique cardiac manifestations of refeeding syndrome (atrial tachycardia and inverted Takotsubo) might be influenced by hypoglycemia, electrolyte abnormalities, metabolic disturbances, emotional stress....as isolated factors or by a contribution of all of them[24].

COMMENTS

Case characteristics

A 54-year-old woman with chronic malnutrition who experienced a rapid oral nutrition repletion.

Clinical diagnosis

Impaired consciousness, emaciation with a body mass index of 10.66 kg/m^2, bradycardia and edema in her lower limbs.

Differential diagnosis

Hypoglycemia, electrolyte abnormalities, heart failure, renal failure.

Laboratory diagnosis

Severe hypoglycemia (19 mg/dL), low levels of albumin (1.5 g/dL), phosphate (2.2 mg/dL), magnesium (1.6 mg/dL) and potassium (2.7 mmol/L), liver dysfunctions (AST: 122 IU/L, ALT: 72 IU/L) and coagulation disorders (PT: 55.9%; APTT: 43 s).

Imaging diagnosis

Chest X-ray demonstrated marked heart failure signs and echocardiography showed dyskinesia of basal and mid-ventricular segments with hyperkinesia of left ventricular apex, consistent with inverted Takotsubo, with decreased ejection fraction (estimated at 25%).

Pathological diagnosis

Necropsy revealed coronary arteries with non obstructive lesions.

Treatment

The patient was treated with noninvasive positive pressure ventilation and inotropic drugs, but she finally died due to a Serratia marcescens-induced acute pneumonia.

Related reports

Takotsubo cardiomyopathy is a syndrome frequently triggered by intense emotional or physical stress, and although it is thought to be catecholamine mediated, the pathophysiology remains unknown.

Term explanation

Refeeding syndrome describes a series of metabolic and biochemical changes that occur as consequence of reintroduction of feeding after a period of starvation or fasting.

Experiences and lessons

In this report the authors describe the first case of inverted Takotsubo following a refeeding syndrome.

Peer-review

There are reported cases of classical apical Takotsubo associated with nutrition disorders, but none of them presenting with the inverted variant.

Abstract

We present a case of a 71-year-old male who had chest symptoms at rest and during effort. He had felt chest oppression during effort for 1 year, and his chest symptoms had recently worsened. One month before admission he felt chest squeezing at rest in the early morning. He presented at our institution to evaluate his chest symptoms. Electrocardiography and echocardiography failed to show any specific changes. Because of the possibility that his chest symptoms were due to myocardial ischemia, he was admitted to our institution for coronary angiography (CAG). An initial CAG showed mild atherosclerotic changes in the proximal segment of the left anterior descending coronary artery (LAD) and mid-segment of the left circumflex coronary artery. Subsequent spasm provocation testing using acetylcholine revealed a bilateral coronary vasospasm, which was relieved after the intracoronary infusion of nitroglycerin. Finally, a CAG showed myocardial bridging (MB) of the mid-distal segments of the LAD. Fractional flow reserve using the intravenous administration of adenosine triphosphate was positive at 0.77, which jumped up to 0.90 through the myocardial bridging segments when the pressure wire was pulled back. Thus, coronary vasospasm and MB might have contributed to his chest symptoms at rest and during effort. Interventional cardiologists should consider the presence of MB as a potential cause of myocardial ischemia.

Key words: Coronary spasm; Myocardial bridging; Myocardial squeezing; Fractional flow reserve

Core tip: Myocardial bridging (MB), an anomaly in which the myocardium overlies the intramural course of segments of the epicardial coronary arteries, is associated with cardiac events. This may be explained by myocardial ischemia, coronary spasms, and/or mechanical compression of the coronary artery by the MB itself. We encountered a patient with angina pectoris both at rest and during exercise, which was

caused by both coronary spasm and MB-induced direct myocardial ischemia. The latter finding was revealed using a pressure wire. MB sometimes causes two vascular characteristics, coronary spasms and direct myocardial ischemia, whose management is quite different.

Teragawa H, Fujii Y, Ueda T, Murata D, Nomura S. Case of angina pectoris at rest and during effort due to coronary spasm and myocardial bridging. *World J Cardiol* 2015; 7(6): 367-372 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i6/367.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i6.367

INTRODUCTION

Myocardial bridging (MB) is an anomaly in which the myocardium overlies the intramural course of segments of the epicardial coronary arteries[1]. The frequency of MB ranges from 5.4% to 85% in autopsy series[2-4] and from 0.5% to 29.4% on coronary angiography[4-10]. It has been accepted that MB might affect the cardiovascular system[1,8,11-13]. In addition, the presence of MB is associated with myocardial infarction[14-17] and sudden cardiac death[18-20]. Myocardial ischemia due to compression of the coronary artery by MB[21,22] and/or coronary spasm at the MB segments[12,23-25] has been considered a major factor responsible for MB-related cardiac events. In this study, we report a case of angina pectoris at both rest and during exercise due to both coronary spasm and MB-related myocardial ischemia, which was documented using a pressure wire.

CASE REPORT

A 71-year-old male had felt chest oppression on effort, such as when carrying heavy baggage, for 1 year. Recently, his chest symptoms had occurred more frequently. One month before admission he felt chest squeezing at rest in the early morning. He presented at our institution for an evaluation of his chest symptoms in May 2014. Coronary risk factors such as smoking, hypertension, and diabetes mellitus were all absent, although he had a low level of high-density lipoprotein (HDL) cholesterol. His mother had angina pectoris. He had undergone operations for appendicitis and prostate cancer at the ages of 25 and 69 years, respectively. On medical examination, his height was 1.63 m, his weight was 73 kg, and his body mass index was 27.5. His vital signs were stable with a blood pressure of 110/80 mmHg and a pulse of 59 beats/min. No cardiac murmur or abnormal respiratory sounds in the lungs were detected. Blood examinations revealed elevated levels of creatinine (1.06 mg/dL), uric acid (9.4 mg/dL), and triglycerides (227 mg/dL), and a low level of HDL cholesterol (35 mg/dL). Neither a chest X-P, electrocardiogram, nor echocardiography showed any specific changes. He was admitted to our institution for coronary angiography (CAG) because of the possibility that his chest symptoms were due to myocardial ischemia.

An initial CAG showed mild atherosclerotic changes at the proximal segments of the right coronary artery (RCA), the left anterior descending coronary artery (LAD) and the mid-segment of the left circumflex coronary artery (Figure 1). To clarify the cause of his chest symptoms, we performed spasm provocation testing using acetylcholine (ACh). During the spasm provocation test, a pressure wire (PrimeWire Prestige PLUS, Volcano Therapeutics Inc., Rancho Cordova, CA, USA) was inserted into the distal portion of the RCA and distal portion of the LAD. The ratio of the distal pressure, derived from the pressure wire, to the proximal one, derived from the tip of catheter (Pd/Pa), was continuously monitored.

Intracoronary infusion of 50 μg ACh caused a diffuse coronary spasm at the mid-distal portion of the RCA (Figure 2A), which was accompanied by the usual chest symptoms and a reduction in the Pd/Pa from 1.0 to 0.69 at baseline. Because of the prolonged coronary spasm, 600 μg nitroglycerin (NTG) was intracoronarily administered, which relieved the coronary spasm in the RCA (Figure 3A). The subsequent intracoronary infusion of 100 μg ACh in the LCA resulted in no chest symptoms but a diffuse spasm in the mid-distal portion of the LAD (Figure 2B), which was accompanied by a reduction in the Pd/Pa from 0.94 to 0.60 at baseline. The intracoronary infusion of 300 μg NTG relieved the coronary spasm and returned the Pd/Pa to the baseline value of 0.94. A final CAG revealed an MB of the mid-distal segments of the LAD (Figures 3B and C). The length and percent systolic narrowing of the MB segment was 38 mm and 78%, respectively. The fractional flow reserve (FFR) of the LAD, which was assessed using a pressure wire and the intravenous administration of 160 μg/min per kilogram adenosine triphosphate (ATP), was positive at 0.77 from 0.94 at baseline (Figure 4A). It then jumped to 0.90 through the MB segments when the pressure wire was pulled back (Figure 4B). Therefore, multi-vessel coronary spasms and a myocardial bridge may contribute to his chest symptoms at rest and during effort. The following day he was discharged and prescribed diltiazem (300 mg/d). Since then, he has been taking 300 mg/d diltiazem and 15 mg/d nicorandil and his symptoms have been controlled in the outpatient clinic.

DISCUSSION

In this study, we present a case of angina pectoris both during exercise and at rest. These symptoms were due to bilateral coronary spasms and MB-related myocardial ischemia, which was identified using a pressure wire.

Several reports have described MB-related myo-

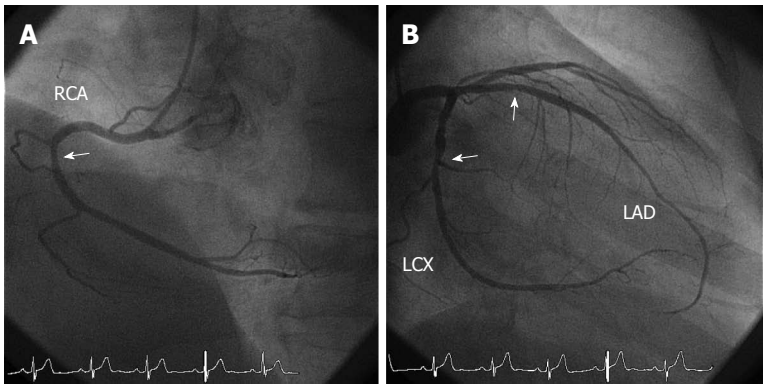

Figure 1 Coronary angiography before spasm provocation tests. A: There were mild atherosclerotic changes at the proximal segment of the right coronary artery (RCA); B: There were mild atherosclerotic changes at the proximal segment of the left anterior descending coronary artery (LAD) and at the mid-segment of the left circumflex coronary artery (LCX). The mild atherosclerotic changes are indicated using arrows.

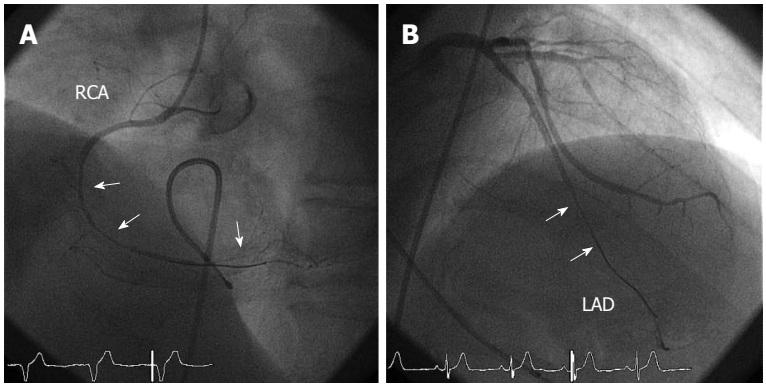

Figure 2 Coronary angiography during the spasm provocation tests. A: In the right coronary artery (RCA), a diffuse coronary spasm occurred at the mid-distal segments after the intracoronary infusion of 50 μg acetylcholine (ACh); B: In the left coronary artery, a diffuse coronary spasm occurred at the mid-distal segments of the left anterior descending coronary artery (LAD) after the intracoronary infusion of 100 μg ACh. The coronary spasm segments are indicated using arrows.

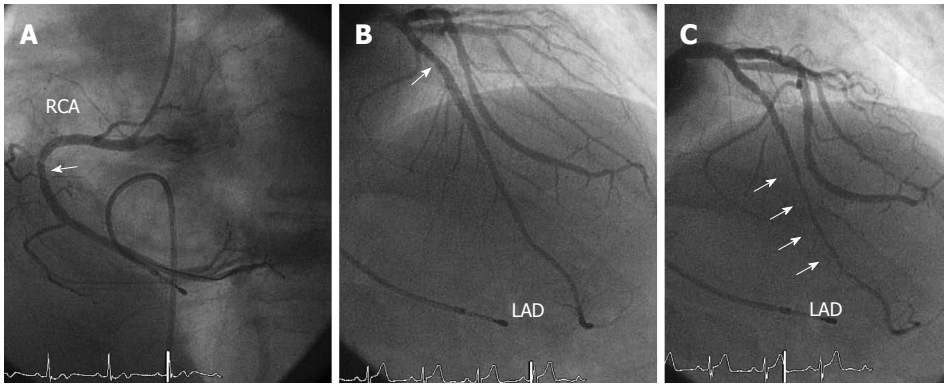

Figure 3 Coronary angiography after the intracoronary infusion of nitroglycerin. A: There was a mild atherosclerotic change at the proximal segment of the right coronary artery (RCA); B: There was a mild atherosclerotic change (indicated with arrows) in the proximal segment of the left anterior descending coronary artery (LAD) at the end-diastolic phase; C: There was myocardial bridging (indicated with arrows) at the mid-distal segments of the LAD at the end-systolic phase.

cardial infarction[14-17] and sudden cardiac death[18-20]. Myocardial ischemia has been suggested to be the main cause of MB-related cardiac events due to mechanical compression of the coronary artery by the MB[21,22] and/or coronary spasm at the MB segments[12,23-25]. It is possible that coronary spasms frequently occur at MB segments because of endothelial dysfunction and/or vascular dysfunction of the coronary artery at MB segments[11,12]. Although the current case had multivessel coronary spasms, the segment of the LAD that underwent coronary spasm was the same as the MB segment, which is consistent with an MB-related coronary spasm. This suggests that cardiologists should consider the possibility of coronary spasm in patients with chest pain and MB on coronary angiograms. Several methods have been used to assess MB-related myocardial ischemia due to mechanical compression of the coronary artery by MB, such as pharmacological stress echocardiography[26], stress myocardial perfusion imaging[27], intracoronary blood flow velocity measurements[21,26], and intracoronary pressure measurements[1,21,26,28]. In the current case, we assessed intracoronary pressure using a pressure wire because this technique has a reliable cutoff value[29] and can be used conveniently in the clinical setting.

Regarding the relationship between intracoronary pressure and MB, reports describing the pressure gradient within the MB segment vary. For example, it has been reported that a pressure gradient within

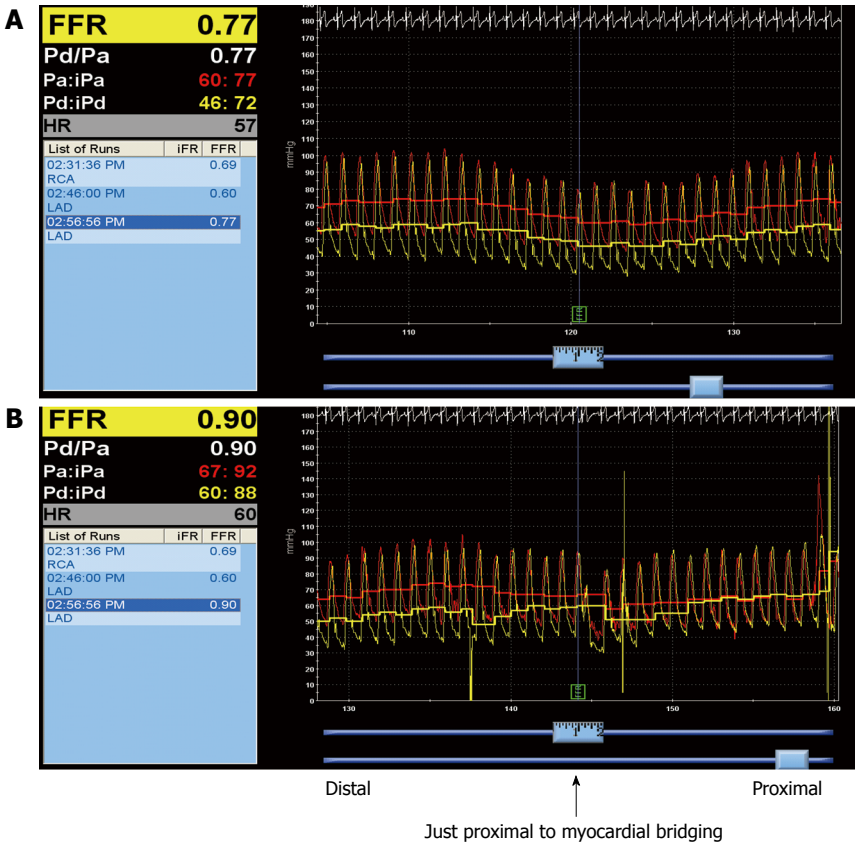

Figure 4 The fractional flow reserve using the intravenous infusion of adenosine triphosphate was 0.77 (A), which jumped up to 0.90 through the myocardial bridging during pullback (B).

the MB segment is present even at baseline[21], only during pharmacological stress[1,26,28], only within the MB segment[26], or both within and beneath MB[1,21,28]. These different results may have been due to differences in the severity and degree of the MB itself as well as differences in the methods used to measure intracoronary pressure. According to the current results, where Pd/Pa was 0.94 and FFR was 0.77 at baseline and the Pd/Pa increased to 0.90 through the MB segments, a pressure gradient was present only during pharmacological stress and within and beneath the MB.

ATP is used frequently to measure FFR in the clinical setting during the assessment of MB. However, it has been reported that dobutamine is more useful as the stress agent during the assessment of MB[1,26,28] because it causes a more severe and longer compression within the MB[28]. Assessing the FFR of the vessel containing the MB can be challenging[30] because atherosclerotic changes often occur proximal to the MB[1], which may reduce FFR. The present case had a minor atherosclerotic lesion proximal to the MB; however, the FFR increased to 0.90 just proximal to the MB when the pressure wire was pulled back. Therefore, in cases with MB and proximal atherosclerotic lesions, assessing FFR using the combination of the pullback method may be more useful.

β-blockers are the mainstay of treatment for symptomatic patients with MB[1]. However, as shown in the present case, coronary spasms sometimes occur in patients with MB, particularly in the MB segments[12]. In general, monotherapy using β-blockers is prohibited in patients with coronary spasms[31]. Furthermore, the use of NTG, which is very effective for relieving coronary spasms, may exacerbate the systolic narrowing of the MB segments[32]. Therefore, it is important to ascertain the presence of coronary spasms in patients with MB. Furthermore, in cases with both MB and coronary spasms, calcium-channel blockers (CCB) or CCB plus β-blockers may be useful. Patients with coronary spasms and MB should be monitored carefully when these drugs are administered. In the present case, CCB with diltiazem plus nicorandil was used to treat the coronary spasm, which was the main pathology in the present case. When chest symptoms are present during exercise the use of β-blockers should be considered. It was reported that percutaneous coronary intervention is useful to relieve chest symptoms in patients with MB[1,22,30,33]; however, it was also reported that the incidence restenosis is relatively high[1,30]. Therefore, pharmacological treatment should be used even in patients with MB and a significantly reduced FFR.

In conclusion, coronary spasms sometimes consolidate in patients with MB, and the presence of coronary spasms should be assessed in such patients.

In addition, intracoronary pressure measurements using a pressure wire may be useful to assess the severity of MB. Interventional cardiologists should keep these concepts in mind.

COMMENTS

Case characteristics

A 71-year-old male presented chest oppression during effort and chest squeezing at rest.

Clinical diagnosis

Angina pectoris due to coronary spasm and myocardial bridging.

Differential diagnosis

Angina pectoris due to significant coronary stenosis, pulmonary thromboembolism.

Laboratory diagnosis

Elevated levels of creatinine (1.06 mg/dL), uric acid (9.4 mg/dL), and triglycerides (227 mg/dL), and a low level of HDL cholesterol (35 mg/dL).

Imaging diagnosis

Coronary angiography showed mild atherosclerotic changes. Spasm provocation testing using acetylcholine showed multi-vessel coronary spasms. Coronary angiography after an intracoronary infusion of nitroglycerin showed myocardial bridging of the left anterior descending coronary artery. The fractional flow reserve using adenosine triphosphate was positive at 0.77.

Treatment

The patient was treated with 300 mg/d diltiazem and 15 mg/d nicorandil.

Related reports

Angina pectoris due to coronary spasms or myocardial bridging is well-known, however, little has been reported regarding angina pectoris at rest and during effort due to both coronary spasms and myocardial bridging.

Term explanation

Myocardial bridging is an anomaly in which the myocardium overlies the intramural course of segments of the epicardial coronary arteries and is associated with cardiac events.

Experiences and lessons

This report presents a case of angina pectoris due to coronary spasm and myocardial bridging. Coronary spasms sometimes consolidate in patients with myocardial bridging, and the presence of coronary spasms should be assessed in such patients. In addition, intracoronary pressure measurements using a pressure wire may be useful to assess the severity of myocardial bridging.

Peer-review

This is an interesting case. The case is well presented and the text well written.

Abstract

The advent of ambulatory blood pressure monitoring permitted examination of blood pressures during sleep and recognition of the associated circadian fall in pressure during this period. The fall in pressure, called the "dip", is defined as the difference between daytime mean systolic pressure and nighttime mean systolic pressure expressed as a percentage of the day value. Ten percent to 20% is considered normal. Dips less than 10%, referred to as blunted or absent, have been considered as predicting an adverse cardiovascular event. This view and the broader concept that white coat hypertension itself is a forerunner of essential hypertension is disputable. This editorial questions whether mean arterial pressures over many hours accurately represent the systolic load, whether nighttime dipping varies from measure to measure or is a fixed phenomenon, whether the abrupt morning pressure rise is a risk factor or whether none of these issues are as important as the actual night time systolic blood pressure itself. The paper discusses the difference between medicated and nonmedicated white coat hypertensives in regard to the cardiovascular risk and suggests that further work is necessary to consider whether the quality and duration of sleep are important factors.

Key words: Nighttime dip; Ambulatory blood pressure monitor; Blunting; Cardiovascular risk

Core tip: While the blunted or absent nighttime pressure dip in nonmedicated white coat hypertensives is generally believed to be a predictor of adverse cardiovascular events, it does not appear to present the same risk in medicated white coat patients. Of the many measurable pressure issues, including pulse pressure and morning surge, during sleep and with awakening, only the mean systolic pressure appears to be the predictor of risk.

Bloomfield D, Park A. Night time blood pressure dip. *World J Cardiol* 2015; 7(7): 373-376 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i7/373.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i7.373

NIGHT TIME BLOOD PRESSURE DIP

The circadian fall in blood pressure during sleep[1] has been fully examined only since the development of

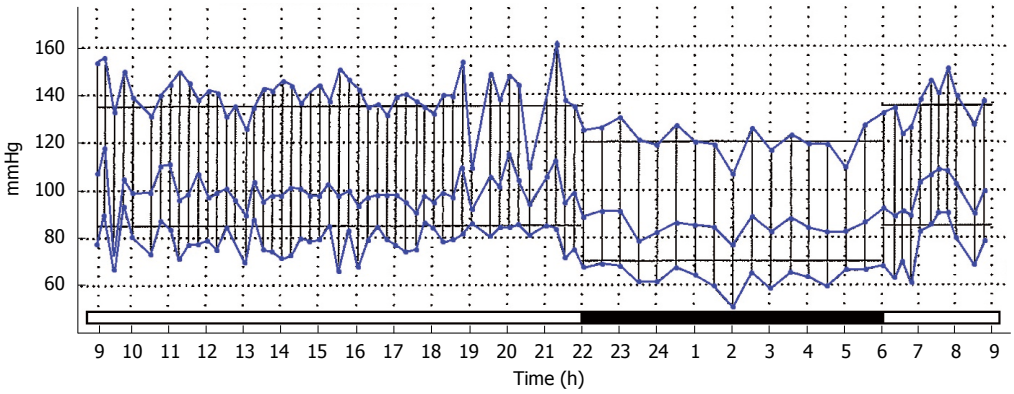

Figure 1 Ambulatory blood pressure recording showing a normal night time dip. In all the ambulatory blood pressure monitoring tracings, the systolic, diastolic, and mean pressures are shown in blue. The pressure scale in mmHg is on the vertical Y-axis on the left and the time scale in hours is on the horizontal X-axis. The duration of sleep corresponding to the night time period is indicated by a heavy black bar.

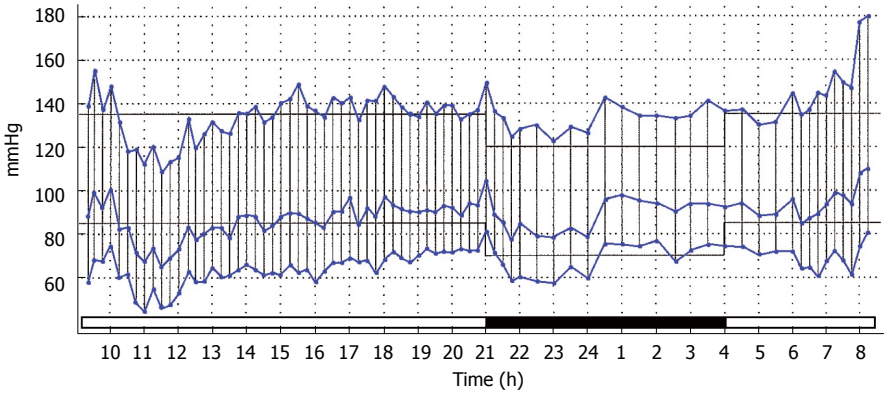

Figure 2 Ambulatory blood pressure recording showing a blunted night time dip.

ambulatory blood pressure monitoring (ABPM) and its occurrence in white coat hypertension (WCH) has not been generally elucidated. First described in 1988, the night time dip has become an accepted measure of cardiovascular risk[1-4]. The dip is defined as the difference between the mean systolic pressure in the day and mean systolic pressure during the night, expressed as a percentage of the day time mean, with the accepted normal between 10% and 20%[5]. A representative ABPM tracing with a normal night time dip is shown in Figure 1.

Dips less than 10% are described as absent or blunted and those in excess of 20% are known as exaggerated or extreme[6]. An example of a blunted dip, such as would be recognized as predicting an adverse cardiovascular event, is shown in Figure 2.

Identification of medical risk factors, particularly cardiovascular ones, carries a couple of requirements. The definition of the conditions must be accepted and unchallengeable and the observations on which this designation is based must be unassailable. These conditions are not met with the night time dip.

The utility of the definition of night time dip is far from practical. It is assumed that the mean systolic pressures are utilized but there is such variation in the actual systolic values during the 24 h that the mean hides much information and bears little relationship to actual daily events. The utilization of average or maximum systolic pressures would be equally inaccurate. In white coat hypertension, mean and average systolic pressures are artificially elevated by the white coat episode.

The ambulatory monitoring data is also soft. It is known that repeated studies do not necessarily provide the same result. Dippers may become non dippers on subsequent testing[7].

Furthermore, the patient-designated "time of sleep" is actually the time of going to bed. The true time of falling asleep clearly cannot be indicated with this methodology. Consequently, the pressures used in the sleep *vs* awake calculations are slightly but inherently inaccurate.

Reported studies in night time dip have almost always been performed in untreated hypertensive patients[8]. In the real world, ABPM is rarely performed in such patients. In our experience, patients are referred for this study to ascertain the effectiveness of the treatment or when progressive medication has failed to control the hypertension. It would be expected that cardiovascular risks would be more evident in the uncontrolled hypertensive patients, however, our studies with medicated patients[8] have

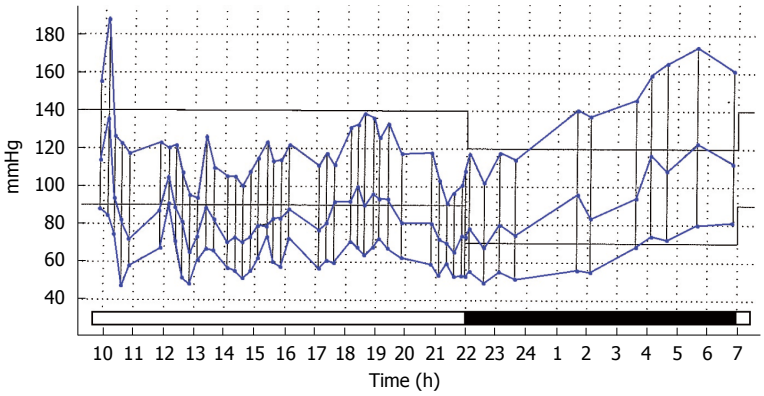

Figure 3 Ambulatory blood pressure recording showing white coat hypertension with a steadily rising pressure of superimposed essential hypertension. The pressure only reaches hypertension levels during sleep when it is likely to be clinically unnoticed.

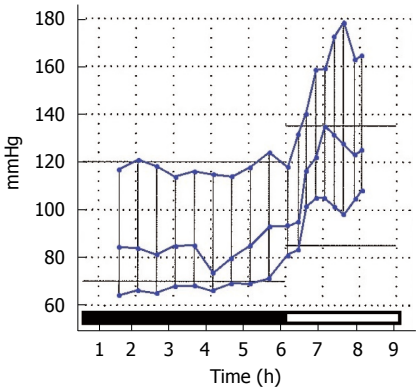

Figure 4 Ambulatory blood pressure recording showing a significantly rapid rise in mean blood pressure upon awakening.

shown no greater incidence of blunted night time dip in uncontrolled hypertensives, controlled hypertensives or white coat hypertensives. Sufficient reduction in the night time pressure may in fact be blunted or negated by protective reflexes if these pressures are already reduced by medication.

Over bridging these considerations is the understanding that the cardiovascular risk associated with the rupture of atheromatous plaques in the coronary and cerebral arteries are essentially systolic issues. They may be related to actual systolic levels or pulse pressure rather than mean pressures or degree of nocturnal dipping.

Masked hypertension, the condition in which the home or the ABPM pressures are significantly higher than the office values must be given considerations here. It is seldom diagnosed in clinical practice as there is little incentive to prescribe ABPM or home pressure devices if the pressure is normal, but occasionally, accidental or incidental incidences of blood pressure measurement may reveal this condition and some explanation is required when masked hypertension is revealed during sleep. This may eliminate the night time dip. Night time narrow peaks of systolic hypertension can occur with dreaming, wider systolic elevations with obstructive sleep apnea and steadily rising pressures are seen with essential hypertension (Figure 3).

A widened pulse pressure has also been recognized as an indicator of cardiovascular risk. White coat hypertensives have a widened pulse pressure during the white-coat episodes but not at night. Analysis of our studies in dippers and non-dippers, hypertensives, white coaters and normal subjects, has found that there is no statistical difference in pulse pressure values between day and night. With the exception of isolated systolic hypertension, a widened pulse pressure occurs in patients who do not have elevated blood pressure as their principle diagnosis and includes those with aortic regurgitation, arteriovenous shunts, thyrotoxicosis and other cardiovascular disorders that, in themselves, increase the risk of death.

Associated with the night time dip, the morning blood pressure surge has been blamed for the increase in cardiovascular events in the morning hours. It is measured as mmHg increase per hour in the mean pressure and it is generally accepted that a rise greater that 10 is significant as a cardiovascular risk factor. Figure 4 shows a typical exaggerated increase in the pressure during the process of awakening.

However, when the rate of rise is continuously calculated during the 24 h ABPM recording, many instances of "significance" are seen to occur at times other than in the morning. Figure 5 adequately depicts this point.

A large study has found that the night time systolic pressure itself, rather than the surge, the dip or the pulse pressure has been shown to correlate more closely with the clinical events[9].

It is clear that the blood pressure at night, in some negative way, impacts the cardiovascular system. What particular element of the pressure, whether it is its depth or its systolic/diastolic width or whether the heart rate or length or quality of sleep is the causative factor remains to be determined.

Unfortunately, the tool to answer these questions, the ambulatory blood pressure monitor, is underutilized in the United States, largely because the study

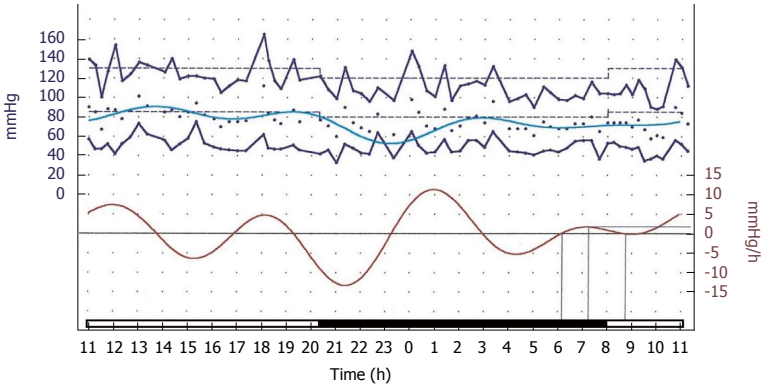

Figure 5 Ambulatory blood pressure recording showing the rate of pressure rise upon awakening at 7 am. At 1 am, the rate of rise reaches cardiac risk significance. The scale in mmHg/h is shown in red on the right.

remains non-reimbursable. As it may hold some basic but unknown secrets of cardiovascular health and disease, the "night time dip" warrants a much more extensive investigation.

Abstract

Although red blood cells (RBCs) transfusion is sometimes associated with adverse reactions, anemia could also lead to increased morbidity and mortality in high-risk patients. For these reasons, the definition of perioperative strategies that aims to detect and treat preoperative anemia, prevent excessive blood loss, and define "optimal" transfusion algorithms is crucial. Although the treatment with preoperative iron and erythropoietin has been recommended in some specific conditions, several controversies exist regarding the benefit-to-risk balance associated with these treatments. Further studies are needed to better define the indications, dosage, and route of administration for preoperative iron with or without erythropoietin supplementation. Although restrictive transfusion strategies in patients undergoing cardiac surgery have been shown to effectively reduce the incidence and the amount of RBCs transfusion without increase in side effects, some high-risk patients (*e.g.*, symptomatic acute coronary syndrome) could benefit from higher hemoglobin concentrations. Despite all efforts made last decade, a significant amount of work remains to be done to improve hemoglobin optimization and transfusion strategies in patients undergoing cardiac surgery.

Key words: Cardiac surgery; Blood transfusion; Anemia; Transfusion threshold; Risk factor

Core tip: Anemia and red blood cells transfusion are common during cardiac surgery, and could be associated with adverse reactions. Preoperative hemoglobin optimization through the identification and treatment of anemia and the definition of standardized transfusion algorithm using restrictive transfusion triggers play a central role in the development of Patient Blood Management programs. However, further researches are needed to better define transfusion triggers, based on pathophysiological indices, rather than single hemoglobin thresholds.

Najafi M, Faraoni D. Hemoglobin optimization and transfusion strategies in patients undergoing cardiac surgery. *World J Cardiol* 2015; 7(7): 377-382 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i7/377.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i7.377

INTRODUCTION

Patients undergoing cardiac surgery are at increased risk of excessive perioperative bleeding, and increased blood product transfusions[1]. Although blood products are safer than ever, transfusion of allogeneic blood products remains associated with a significant incidence of adverse reactions[2]. Last decades the development of Patient Blood Management (PBM) programs improved perioperative management, and decreased the use to blood products through a better identification of both patient-related and procedure-related risk factors[3].

On the one hand, cardiac surgery is among major procedures that significantly influence the distribution of body fluid through the large volumes of fluid administered during cardiopulmonary bypass (CPB), the volume of cardioplegia, and the amount of fluid administered to optimize cardiac output. In addition, the contact between blood and non-endothelial surfaces will lead to the "activation coagulopathy"[4], and all these mechanisms are part of the CPB-induced coagulopathy that significantly influences the requirement for blood products transfusion[5].

On the other hand, with the progress made in medical therapies and interventional cardiology, patients requiring cardiac surgery become older, and arrive to surgery with a huge number of comorbidities, and medications[6]. Patients are usually treated with antiplatelet agents and/or anticoagulants, which will increase the bleeding risk[7]. Although RBCs transfusion could be associated with adverse events; anemia in high-risk patients could also be associated with increased morbidity and mortality[8]. For these reasons, the definition of perioperative strategies that aims to detect and treat preoperative anemia, prevent excessive blood loss, and define "optimal" transfusion algorithms are crucial.

PHYSIOLOGY

Oxygen is major component of cellular homeostasis; the maintenance of an aerobic metabolism through adequate oxygen supply to cells is crucial. Cardiac output and the arterial oxygen concentration (CaO_2) will allow the maintenance of an adequate oxygen delivery (Do_2).

$Do_2 = CO \times CaO_2$, where $CaO_2 = (Hb \times SaO_2 \times 1.39) + (PaO_2 \times 0.0031)$

With SaO_2 corresponding to the arterial oxygen saturation, PaO_2 is the partial arterial pressure in oxygen, 0.0031 is the amount oxygen diluted in plasma, and 1.39 the amount of oxygen linked to 1 g of hemoglobin. Based on this formula, it appears evident that the hemoglobin concentration will play a central role in oxygen transportation throughout the body, and organs.

The adequacy of tissue oxygenation depends on tissue/organ metabolic needs. Tissue oxygenation is adequate when oxygen delivery (Do_2) is at least equal to the rate of oxygen consumed by the tissues (Vo_2: oxygen consumption). The ratio between Do_2 and Vo_2 allow for the determination of the oxygen extraction (O_2 ER), which in physiologic condition correspond to 25%-30% of the oxygen delivery. Interestingly, adaptive mechanisms allow the maintenance of adequate oxygen consumption in the presence of decreased oxygen delivery through an increase in the amount of oxygen extracted by the tissues[9]. Below a certain Do_2 level, the extraction could not be increased and metabolism will be shift to anaerobic metabolism. This change in metabolic characteristics will be associated with increased lactate plasmatic concentration, if prolonged may cause tissue damage[10].

Although a certain degree of anemia could be tolerated, the "critical" hemoglobin level that will not allow the maintenance of an adequate oxygen delivery will depend on different factors that include physiologic status (*e.g.,* sepsis increases oxygen demand) or condition (*e.g.,* anesthesia decreases oxygen demand)[11]. In case of acute and severe anemia, adaptive mechanisms to optimize the balance between oxygen supply and demand are regulated by hypoxia-inducible factors, and included neuronal nitric oxide synthase, erythropoietin, and hypoxia-inducible factors[12]. Although all these mechanisms improve oxygen delivery, organs with higher baseline oxygen extractions, such as the heart, are usually flow-dependent, which is obtained by vasodilatation of the coronary arteries[13]. This will have an important impact in patients suffering from coronary artery disease, and perioperative management of anemia in patients undergoing coronary artery bypass graft (CABG) surgery is crucial[14].

PREOPERATIVE OPTIMIZATION OF HEMOGLOBIN CONCENTRATION

Based on the World Health Organization (WHO), anemia is defined by hemoglobin levels < 12 g/dL in women, and < 13 g/dL in men[3]. If 25% of the general population is anemic, preoperative anemia is reported in 22% to 30% of patients undergoing cardiac surgery[15] Although preoperative anemia was associated with an increased incidence of acute kidney injury and strokes, both short and long-term mortality increased in anemic patients undergoing CABG surgery[16]. In addition, adverse events associated with

hemorrhage, and blood product transfusion was higher in patients with preoperative anemia compared to non-anemic patients[17]. As a consequence, preoperative detection of anemia, and optimization of hemoglobin level is crucial.

Iron deficiency has been shown to be responsible of 29% of the preoperative anemia, followed by the presence of chronic kidney disease in 10.7%[18]. In case of iron deficiency, preoperative iron supplementation should be recommended. In patients undergoing cardiac surgery, Piednoir *et al*[19] reported that on 100 patients undergoing cardiac surgery, 37% had preoperative iron deficiency, from those one third were anemic. The authors also reported that 62% of patients with iron deficiency received RBC transfusion compared to 35% in controls[19]. No study assessed the efficacy of preoperative iron supplementation in patients undergoing cardiac surgery. So far, our experience is based on studies performed in colorectal[20] or orthopedic surgeries[21] that reported a significant reduction in RBCs transfusion in patients that received preoperative oral iron administration. Other authors reported that iv iron administrated within 3-5 wk before orthopedic surgery could significantly increase hemoglobin level[22]. Although a recent meta-analysis reported a significant increase in hemoglobin level, and reduction of RBCs transfusion following the iv administration of iron, this benefit was balanced by an increased incidence of infection. Based on current evidence, oral iron administration (200-300 mg/d) should be recommended in patients with preoperative iron deficiency, while iv supplementation (1000 mg weekly during 3-5 wk) might only be considered in case of contraindication to oral administration or short delay before a surgery that could not be postponed[23].

If the preoperative administration of erythropoietin stimulating agent could be attractive, the benefit-to-risk balance associated with preoperative administration of erythropoietin (EPO) remains weakly studied. Currently, EPO is approved in anemic patients without nutritional deficiency undergoing orthopedic surgery. However, its administration in patients undergoing cardiac surgery is currently prohibited due to an increased incidence of thromboembolic complication reported in pilot studies[24].

RESTRICTIVE *VS* LIBERAL TRANSFUSION TRIGGERS?

Transfusion has been used for years to increase hemoglobin concentration, and oxygen delivery. However, RBCs transfusion is associated with several side effects, and sometimes, increased mortality[25]. On the other hand, anemia has been associated with adverse outcomes ranging from cardiovascular events, heart failure, renal failure, prolonged recovery, and late mortality. Although the safety of blood products transfusion has been extensively enhanced last decades, there are still concerns over the hazards of transfusion, particularly with respect to the high rate of annual consumption of blood products worldwide (around 85 million units)[26]. With regard to complications associated with blood product transfusion, non-infectious risks such as human errors, acute hemolytic and non-hemolytic reactions have overpassed the risk of infection. Based on large studies performed in cardiac patients, blood product transfusion is associated with negative outcomes such as cardiac, pulmonary, renal, and neurologic complications, as well as increased length of hospital stay and death[27]. In addition, these side effects will have a significant impact on health care resource utilization.

As far as the 1990s, Bracey *et al*[28] reported that restrictive transfusion strategies (Hb threshold = 8 g/dL) led to a 20% reduction of RBCs transfusion without increase in the incidence of side effects[28]. However, it took about 10 years before the publication of a second prospective randomized study that compared a restrictive (hematocrit > 24%) *vs* liberal (hematocrit > 30%) transfusion strategy in patients undergoing cardiac surgery[29]. In this study, Hajjar *et al*[29] reported that although the restrictive transfusion strategy was associated with lower intra-operative hemoglobin levels, no difference was observed in term of morbidity and mortality. A Cochrane systematic review of 17 cardiac and non-cardiac trials published in 2010 concluded that restricted transfusion strategy decreases transfusion without increasing adverse outcomes such as cardiac events, thromboembolic complications, and death[30]. However, this review denotes that patients with "serious heart disease" should not be treated in this way. In a recent systematic review with meta-analysis, Curley *et al*[31] reported that only a few studies (n = 7) adequately compared the efficacy and safety of a restrictive transfusion protocol to a liberal approach in patients undergoing cardiac surgery. Although restrictive transfusion strategies significantly reduced the incidence of RBCs transfusion without side effect, the inter-studies variability was important, and further adequately powered studies are needed to assess the appropriate transfusion threshold in the cardiac population.

Based on a pathophysiologic decrease in anemia tolerance in patients with coronary artery disease, perioperative anemia could be associated with poor outcomes, and a specific transfusion strategy could probably be adopted in this high-risk population[14]. In 2013, Carson *et al*[32] published the preliminary results of a prospective randomized multi-center study that aimed to compare a restrictive (Hb > 8 g/dL) *vs* a liberal (Hb > 10 g/dL) transfusion strategy in patients with symptomatic coronary artery disease. The preliminary analysis reported that higher transfusion thresholds were associated with better outcome in this particular population. Recently, Murphy *et al*[33] published the results of a prospective

Table 1 Practice guidelines for red blood cell transfusion

Guidelines	Release date	Hemoglobin threshold definition	Level of evidence
Society of Thoracic Surgeons/Society of Cardiovascular Anesthesiologists[33]	2011	6 g/dL preoperative and on CPB	2C
		7 g/dL postoperative and at risk of ischemia on CPB	2C
British Committee for Standards in Haematology[34]	2012	7 g/dL stable, non-bleeding CAD	C
		8-9 g/dL ACS	
The American Association of Blood Banks[35]	2012	7-8 g/dL in stable patients	1A
		8 g/dL in patients with CVD	2B
		No number for ACS	Uncertain recommendation; very low-quality evidence
European Society of Anesthesiology[36]	2013	7-9 g/dL in bleeding patients	1C
American Society of Anesthesiologists[37]	2015	No number	-

1A: Strong recommendation, high quality evidence; 1B: Strong recommendation, moderate quality evidence; 1C: Strong recommendation, low quality evidence; 2A: Weak recommendation, high quality evidence; 2B: Weak recommendation, moderate quality evidence; 2C: Weak recommendation, low quality evidence; CPB: Cardiopulmonary bypass; CAD: Coronary artery disease; CVD: Cardiovascular disease; ACS: Acute coronary syndrome.

multicenter randomized study (TITRe2 study) that randomized more than 2000 patients undergoing cardiac surgery to a restrictive (Hb threshold < 7.5 g/L) or a liberal transfusion strategy (Hb threshold < 9 d/dL). Interestingly, the authors didn't observe any differences in term of postoperative outcome, mortality, and costs between the two transfusion strategies. The authors concluded that restricted strategy was not superior to a liberal transfusion strategy with respect to morbidity and health care costs. These results confirmed that indication for RBCs transfusion in patients undergoing cardiac surgery might not be guided by a single transfusion threshold and that some patients may benefit from higher hemoglobin level, while other may tolerate lower hemoglobin concentrations.

Recent guidelines emphasized that recommendations on blood transfusion in patients with cardiovascular disease are not supported by strong evidence[26,34-37]. (Table 1) Despite their differences, guidelines generally agreed that RBCs transfusion should not be recommended in case of hemoglobin concentration $\geqslant$ 10 g/L and might be useful in case of hemoglobin concentration < 7 g/L[38]. However, transfusion triggers might be reconsidered in critical scenario, and especially in bleeding situations[26,34-36]. Evidence is particularly limited in clinical contexts such as acute coronary syndrome, where the recommendation for higher hemoglobin threshold is still controversial[26]. Patients with acute coronary syndrome (ACS) or patients who were at risk of end organ ischemia were included in different clinical trials over the past years, but the relationship between ACS, RBCs transfusion, and outcome remains to be determined[26,37]. Further results are waited in this context, but this supports the hypothesis that one single transfusion threshold could not fit to all patients, and that RBCs transfusion should be based on more than a single hemoglobin measurement.

CONCLUSION

Both anemia and transfusion are associated with adverse events and increased morbidity in patients undergoing cardiac surgery. Although the "optimal" RBCs transfusion strategy has not yet been defined, RBCs transfusion should be preferred when its benefits outweigh the risks. Patients with cardiac diseases are more vulnerable to anemia-related hypoxia, and recent data suggested that a restrictive transfusion strategy was not superior to a liberal transfusion, that could be associated with "better" outcome in some high-risk patients with symptomatic coronary artery disease. Each cardiac surgical department might develop standardized transfusion algorithm, based on a multidisciplinary approach. This approach should include preoperative identification of anemic patients, preoperative measures to increase hemoglobin concentration (*e.g.,* iron and/or erythropoietin), intraoperative measure to decrease blood loss, and definition of "optimal" transfusion trigger based on patient's characteristics, rather than a single hemoglobin threshold. Because on current knowledge the "ideal" transfusion thresholds to be recommended in cardiac patients is not yet known, further large prospective studies are urgently needed to determine the efficacy and safety of different transfusion strategies in this high-risk population.

Abstract

Aspirin is the mainstay in prophylaxis of cardiovascular diseases. Impaired aspirin antiplatelet effects are associated with enhanced incidence of cardiovascular events. Comedication with non-opioid analgesic drugs has been described to interfere with aspirin, resulting in impaired aspirin antiplatelet effects. Additionally, non-opioid analgesic medication has been shown to enhance the risk of cardiovascular events and death. Pain is very frequent and many patients rely on analgesic drugs to control pain. Therefore effective analgesic options without increased risk of cardiovascular events are desirable. This review focuses on commonly used non-opioid analgesics, interactions with aspirin medication and impact on cardiovascular risk.

Key words: Non-steroidal anti-inflammatory drug; Drug-drug interaction; Pharmacodynamic; Dipyrone; Aspirin; Paracetamol; Metamizole

Core tip: Aspirin is the mainstay in prophylaxis of cardiovascular diseases. Impaired aspirin antiplatelet effects are associated with enhanced incidence of cardiovascular events. Comedication with non-opioid analgesic drugs has been described to interfere with aspirin, resulting in impaired aspirin antiplatelet effects. Additionally, non-opioid analgesic medication has been shown to enhance the risk of cardiovascular events and death. Pain is very frequent and many patients rely on analgesic drugs to control pain. Therefore effective analgesic options without increased risk of cardiovascular events are desirable. Polzin A, Hohlfeld T, Kelm M, Zeus T. Impairment of aspirin antiplatelet effects by non-opioid analgesic medication. *World J Cardiol* 2015; 7(7): 383-391 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i7/383.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i7.383

INTRODUCTION

Approximately 20% of European adults suffer of acute or chronic pain and rely on analgesic drugs[1,2]. The incidence of pain and usage of non-opioid analgesics is even higher in patients with cardiovascular diseases. Forty percent of patients with coronary artery disease reported intake of non-opioid analgesic drugs[3]. This is not surprising, as the incidence of pain correlates with increasing age[4] and cardiovascular diseases are morbidities of middle to older age patients[5].

Aspirin (acetylsalicylic acid; ASA) is essential secondary prevention of cardio-and cerebrovascular events[6]. It inhibits cyclooxygenase (COX)-1 by irreversible acetylating serine 530 near the active site. This hampers conversion of arachidonic acid to thromboxane (TX) A2 for the life span of the affected platelet[7]. Aspirin has been shown to reduce the incidence of death, myocardial infarction and stroke[8-10]. However, during the last decade substantial inter-individual variation in pharmacodynamic response to aspirin has been described. This is called high on-treatment platelet reactivity (HTPR) (formerly known as "aspirin resistance"). Patients with HTPR have an increased incidence of death, myocardial infarction and stroke[11]. Many potential mechanisms including non-compliance[12,13], impaired absorption[14], genetic polymorphisms[15] increased turnover rate, enteric coating of aspirin[16,17] and COX-1 independent pathways may cause this HTPR[18]. Besides that, non-opioid analgesic medication may impair aspirin antiplatelet effects. In contrast to above mentioned internal factors, this drug-drug interaction is avoidable. Therefore special attention should be paid to this interaction leading to impaired aspirin antiplatelet effects. This review focuses on (1) mechanisms-; (2) laboratory-; and (3) clinical evidence of the aspirin drug-drug interaction with commonly used non-opioid analgesics.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most frequently used drugs in the world[19]. They are available on prescription as well as over the counter. In the United States, 70 million NSAID prescriptions- and 30 billion over the counter sales per year were registered[20]. Approximately 83% of United States - American adults use NSAID to relief pain at least once a year, 29% once a week and 15% daily[21]. In Australia, 55% of people consume NSAIDs at least once per month[22].

The term "NSAID" subsumes a variety of drugs with different chemical structures, pharmacokinetics, pharmacodynamics and mechanism of action but similar effects[23]. The main common feature is prevention of prostaglandin formation by inhibition of COX isoforms. This results in desirable anti-inflammatory and analgesic effects due to COX-2 inhibition in inflamed tissues[24]. On the other hand, inhibition of COX-1 in the gastric mucosa impairs maintenance of the mucosal barrier. This results in an increased risk of gastrointestinal events[25]. Additionally NSAIDs may worsen renal function[26] and affect platelets[27]. Based on the above mentioned differences in pharmacokinetics and pharmacodynamics between different NSAIDs, a considerable variability in analgesic as well as anti-inflammatory and antiplatelet effects is not surprising[23,27]. NSAIDs may also impair cardiovascular prognosis[28,29], possibly by inhibition of prostaglandin synthesis in the vasculature resulting in an increase in blood pressure and disturbed endothelial control of thrombogenesis. This aspect must not be confounded with the pharmacodynamic interaction of non-opioid analgesics with aspirin, which is discussed here. However, it is possible that this interaction contributes to the overall cardiovascular risk of NSAIDs. In the following, we will discuss the most commonly used NSAIDs with respect to their potential to interfere with platelet inhibition by low dose aspirin.

Ibuprofen

Ibuprofen was the first propionic acid derivative NSAID. Worldwide more than 100 million patients consumed ibuprofen and it is available in more than 100 countries[30]. Ibuprofen forms hydrogen bonds to arginine 120 and tyrosine 355 near the active site of the COX[27]. *In-vitro* analysis revealed, that ibuprofen inhibits platelet aggregation of human platelets[27]. In healthy individuals, ibuprofen intake led to inhibition of thromboxane formation[31] and platelet aggregation *ex-vivo*. As ibuprofen inhibited COX transiently, platelet function returned to normal within 4 to 6 h[32]. *In-vitro* coincubation with aspirin completely abrogated platelet inhibition and thromboxane formation by aspirin. This has been shown *ex-vivo* in healthy individuals as well with multiple studies demonstrating hampered aspirin antiplatelet effects in ibuprofen co-treated healthy subjects[33-37]. Catella-Lawson *et al*[33] reported that controlled order of intake with single dose ibuprofen (400 mg) two hours after aspirin intake preserves aspirin antiplatelet effects in healthy individuals. However ibuprofen medication three times per day inhibits aspirin antiplatelet effects independently of the above mentioned order of intake. This finding may be consistent even in lower doses of ibuprofen (150 mg)[36]. None of patients on aspirin for secondary prophylaxis of a cerebrovascular event with ibuprofen co-treatment had adequate aspirin induced inhibition of platelet aggregation. Additionally, 72% of patients experienced recurrent ischemic events. After termination of analgesic medication, aspirin antiplatelet effects restored[32]. In patients with cardiovascular diseases, different studies detected increased incidence of death and recurrent myocardial infarction in aspirin and ibuprofen comedicated patients[38-40]. This finding was confirmed in two meta-analyses, investigating the risk of death

and cardiovascular events in patients at increased risk of vascular disease on ibuprofen medication[29,41].

Naproxen

Naproxen is a propionic acid derivative NSAID like ibuprofen. However, its' pharmacokinetics are different. Plasma half-life of ibuprofen is about two hours, whereas the plasma half-life of naproxen is approximately 12 h[42]. Naproxen forms hydrogen bonds to tyrosine 385 and serine 530 in the active site of COX[27]. This leads to dose-dependent, reversible inhibition of platelet activation *in-vitro*. However, increasing concentrations of arachidonic acid can overcome this COX-inhibition. Additionally, ASA administration after pre-incubation with naproxen prevents ASA antiplatelet effects[43]. In healthy individuals, naproxen co-treatment with aspirin impairs aspirin antiplatelet effects as well[32,35,37]. This effect was consistent in over the counter doses as well as prescription doses[44]. However, data of clinical studies are contradictory. Some studies described an increased incidence of cardiovascular events in naproxen treated patients[32,45]. However others described a beneficial effect on the incidence of adverse events[39,40,46,47]. Two meta-analyses described no significant increase of vascular events and death in naproxen medicated patients[29,41]. The reasons for these inconstant results are unclear. Naproxen inhibits aspirin antiplatelet effects in-vitro similar to ibuprofen[27]. However, Capone *et al*[48] described permanent functionally relevant inhibition of *ex-vivo* platelet function in healthy individuals with 500 mg naproxen twice a day. Therefore, most probably the increased plasma half-life and therefore longer lasting reversible inhibition of platelets by naproxen may be responsible for the protective, respectively less harmful effects of naproxen in patients with cardiovascular diseases. The importance of naproxen's potential to interfere with the antiplatelet action of aspirin is presently not clear. Different authors recommended preferring the use of naproxen in patients with increased cardiovascular risk[49,50].

Diclofenac

Diclofenac is a heteroaryl acetic acid NSAID. It is commonly prescribed to alleviate acute and chronic pain[51]. Like other NSAIDs, diclofenac inhibits COX enzymes (COX-2 > COX-1). There may be additional mechanisms of action inducing its anti-inflammatory, antipyretic and analgesic effects, which are not completely understood. Besides affection of arachidonic acid uptake and release, activation of nitric oxide-cGMP antinociceptive pathway, inhibition of thromboxane prostanoid receptor and lipoxygenase enzymes, it may also inhibit peroxisome proliferator activated receptor gamma, block acid-sensing ion channels, alter interleukin-6 production and inhibit substrate P and N-methyl-D-aspartate receptor hyperalgesia[51].

In-vitro incubation of human platelets with diclofenac inhibited thromboxane formation and platelet aggregation[27]. This was reproducible *ex-vivo* after diclofenac treatment of healthy volunteers[31,52]. Additionally, platelet function was inhibited after diclofenac - treatment in patients[53,54]. However, there seems to be no interaction with aspirin treatment. ASA antiplatelet effects including inhibition of thromboxane formation were preserved *in-vitro* after pre-incubation with diclofenac[27]. Additionally, diclofenac treatment in healthy individuals on aspirin revealed sufficient pharmacodynamic response to aspirin as well[33,34]. This may be explained by molecular docking analyses. Diclofenac did not form any hydrogen bond interactions in the hydrophobic active channel of COX. Therefore it appears not to interfere with the ASA induced acetylation of serine 530, preserving aspirin antiplatelet effects despite of diclofenac co-treatment[27].

In aspirin and analgesic co-treated patients with coronary artery disease, MacDonald *et al*[38] described improved outcome of diclofenac co-treated patients in comparison to ibuprofen comedicated patients. In contrast, in a study including 83667 patients after myocardial infarction, diclofenac co-treatment was associated with the highest risk of recurrent myocardial infarction and death during 90 d[39] as well as in one- and five year follow-up[40]. These findings were confirmed in two meta-analysis investigating death and cardiovascular events in patients with analgesic medication. Both reported an increased risk in diclofenac treated patients as well[29,41].

COX-2 INHIBITORS

Anti-inflammatory and analgesic effects of COX-inhibitors are largely mediated by prevention of COX-2 induced prostaglandin formation in inflamed tissues[24]. Impairment of the gastric mucosal barrier resulting in increased incidence of gastrointestinal events, and affection of platelets are mostly caused by COX-1 inhibition[25,27]. Therefore, during the 90's NSAIDs with COX-2 selectivity were developed[55].

Conflicting data has been reported regarding impairment of aspirin antiplatelet effects by COX-2 inhibitors. Despite COX-2 selectivity, celecoxib was shown to form a hydrogen bond in the hydrophobic channel of COX-1 with tyrosine 355[27]. This goes in line with *in-vitro* experiments, demonstrating inhibition of thromboxane formation and platelet aggregation by celecoxib incubation. In ASA and celecoxib co-incubated platelets, ASA antiplatelet effects were inhibited[27]. Celecoxib administration in dogs interfered with the ability of aspirin to inhibit platelet aggregation[56]. In contrast, no impact on platelet function was observed in healthy individuals on celecoxib treatment[35]. Additionally, different groups reported that COX-2 inhibiting co-treatment in aspirin treated healthy individuals did not impair the pharmacodynamic response to aspirin[33,35,37,57]. Regardless, multiple studies reported increased risk of cardiovascular

events and death in patients receiving COX-2 inhibitors independently of concomitant aspirin intake[28,58-60].

PARACETAMOL (ACETAMINOPHEN)

Paracetamol is an aniline derivative. It is one of the most widely used antipyretic and analgesic drugs worldwide, especially as the risk of gastrointestinal bleeding events are lower in comparison to NSAIDs[61]. It is available over the counter in many countries[62]. However, in supra-therapeutic doses depletion of endogenous glutathione occurs, resulting in paracetamol metabolism shunting to toxic pathways causing severe, even fatal, hepatotoxicity[63,64]. To date, the mechanisms of analgesia by paracetamol remain unclear despite of extensive investigations[65]. A plethora of mechanisms have been postulated including activation of the endocannabinoid pathway[66,67], inhibition of the nitric oxide synthase[68,69], and indirect activation of descending serotonergic pathways[70-72]. Additionally, inhibition of cyclooxygenases in a direct-[73-75], or indirect (by converting to their oxidized, inactive form[76]) way has been described. Current opinion suggests that paracetamol performs its analgesic actions by multiple mechanisms predominantly in the central nervous system[65].

In-vitro addition of paracetamol to human platelets was reported to inhibit collagen, epinephrine and arachidonic acid induced platelet aggregation and TX formation[77]. Accordingly, in healthy individuals a reduced arachidonic acid-induced TX formation one hour after single dose of paracetamol was shown. However an effect on platelet aggregation was observed in only one of five investigated individuals[77]. Munsterhjelm *et al*[78] detected an inhibition of platelet aggregation in healthy individuals 10 min after ingestion of paracetamol. Already 90 min after intake of paracetamol, platelet aggregation was restored. Additionally, a combination of paracetamol and diclofenac exhibits an additive effect on platelet inhibition. In comparison to diclofenac treatment in healthy individuals alone, addition of paracetamol preserves inhibition of platelet aggregation and TX formation 90 min after intake. Nevertheless, platelet function normalized after 24 h[52]. In patients, a single dose of paracetamol reduced arachidonic acid induced TX formation, but did not inhibit platelet aggregation in patients[54]. Molecular modelling and docking analyses revealed that paracetamol forms only one single hydrogen-bond to arginine 120 in the hydrophobic channel of COX-1[27]. No aspirin interaction resulting in inhibition of aspirin antiplatelet effects was seen, suggesting that one hydrogen-bond might not be sufficient to induce impairment of aspirin antiplatelet effects[27]. These findings were supported by the results of Catella-Lawson *et al*[33] and Rao *et al*[79], both did not observe altered aspirin antiplatelet effects in presence of paracetamol, either. However an increased incidence of first cardiovascular event in patients with frequent use of paracetamol was observed[80]. Potential reasons for this observation may be a dose dependent risk of renal insufficiency of paracetamol[81] which is a predictor of cardiovascular events[82]. Secondly, an increased blood pressure in patients with paracetamol usage has been described[83-86]. Also, an impairment of endothelial function by depletion of glutathione is thinkable to induce this enhanced risk of cardiovascular events[87].

DIPYRONE (METAMIZOLE)

Dipyrone is a pyrazolinone analgesic with favorable analgesic, spasmolytic and antipyretic effects. Gastrointestinal complications are rare in comparison to NSAIDs like ibuprofen or diclofenac[88]. Due to the risk of agranulocytosis, it has been withdrawn in many countries including the United States. Nevertheless, it is extensively used in Central- and South America and freely available over the counter in Mexico. Therefore despite of the withdrawal by the Food and Drug Administration, there is a wide spread use in the United States as well[89]. Moreover, it is freely available and the most used analgesic in Eastern European countries like Bulgaria[90]. Guidelines of the European Society of Cardiology do not recommend the use of NSAIDs in patients with cardiovascular diseases[91,92]. This may be one of the reasons why dipyrone daily doses tripled during the last decade in European countries like Germany[93]. The exact mechanism of its analgesic effects is complex and not completely understood, yet. Besides COX inhibition, an activation of opioidergic- and cannabinoid system in combination with inhibition of central COX-3 appears to contribute to its analgesic effects. Comedication with opioids causes superadditive analgesic effects. It inhibits both prostaglandin dependent and - independent pathways of fever and exhibits its spasmolytic effects by inhibition of intracellular calcium release[94]. Dipyrone inhibits all COX isoforms. It reversibly binds near the active site of COX, forming hydrogen bonds to tyrosin 385 and serine 530[27]. Dipyrone sterically hinders aspirin access to the active site and serine 530 of COX-1. Plasma half-life of dipyrone is about 2.5 h. Therefore it is 7.5 fold longer available than aspirin with a plasma half-life of only 20 min[95]. *In-vitro* experiments revealed that dipyrone active metabolite impairs ASA induced inhibition of microsomal platelet COX. The active metabolite of dipyrone in therapeutically relevant (low micromolar) concentrations showed little inhibition of platelet aggregation and TX formation. However, it prevented ASA dependent inhibition of platelet aggregation and thromboxane formation caused by arachidonic acid as well as collagen. The effect was reproducible in terms of microsomal platelet COX activity and p-selectin expression as well[96]. Increasing ASA concentrations *in-vitro* overcame this effect[97]. Additionally, previous incubation with ASA before addition of dipyrone preserves ASA antiplatelet effects[98].

In healthy individuals, aspirin intake sufficiently inhibits platelet aggregation, seven days of additional

Table 1 Risk and benefits of non-opioid analgesics

Substance	Platelet inhibition	Aspirin interaction	Benefits	Risks
Aspirin	Irreversible	-	Analgesic, antipyretic, anti-inflammatory Reduction of cardiovascular events and death	Bleeding events
Ibuprofen	Reversible (half-life 1-4 h)	Yes	Analgesic, antipyretic, anti-inflammatory	Death Cardiovascular events Bleeding events
Naproxen	Reversible (half-life 12-24 h)	Yes	Analgesic, antipyretic, anti-inflammatory Reduction of cardiovascular events (?)	Bleeding events
Diclofenac	Reversible (half-life 1-2 h)	No	Analgesic, antipyretic, anti-inflammatory	Death Cardiovascular events Bleeding events
Celecoxib	Reversible (half-life 8-13 h)	Yes	Analgesic, antipyretic, anti-inflammatory Less gastrointestinal events	Death Cardiovascular events
Paracetamol	Reversible (half-life 1-4 h)	No	Analgesic, antipyretic Less gastrointestinal events	Cardiovascular events
Dipyrone	Reversible (half-life 2-4 h)	Yes	Analgesic, antipyretic, anti-inflammatory Less gastrointestinal events	Risk of death and cardiovascular events not investigated

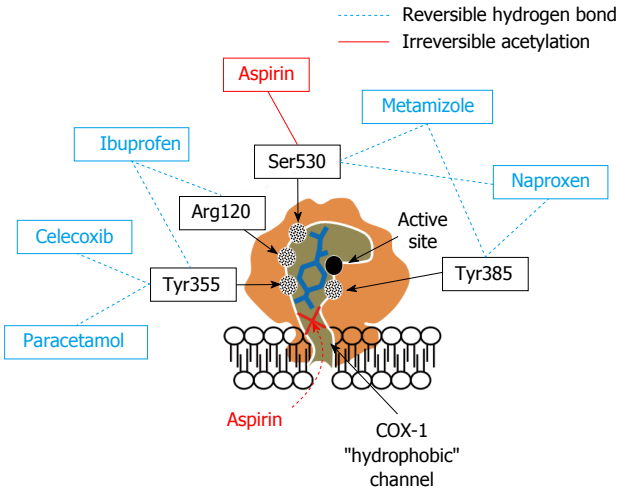

Figure 1 Graphical abstract. Non-opioid analgesics form reversible hydrogen bonds near the active centrum of cyclooxygenase (COX)-1. This prevents (1) aspirin entrance to the hydrophobic channel; (2) irreversible acetylation of Ser530; and (3) platelet inhibition for the remainder of the platelets life-span.

dipyrone intake completely blunts aspirin antiplatelet effects. This effect was reversible within three days of continued aspirin administration after termination of dipyrone intake. However, multiple daily doses of dipyrone were not tested[97]. Interestingly, Börgermann *et al*[99] reported that there was no impaired pharmacodynamic response to aspirin in dipyrone treated healthy individuals. However the duration of aspirin and dipyrone co-treatment was only two days. As aspirin antiplatelet effects are irreversible and persist for the remainder of the affected platelets life-span, it is not surprising, that no relevant differences were observed after two days of additional dipyrone treatment. A partial inhibition of aspirin antiplatelet effects has been described after four days of concomitant intake and complete inhibition after seven days[100]. Furthermore, it has been shown that aspirin intake prior to dipyrone preserves aspirin antiplatelet effects, whereas dipyrone intake prior to aspirin completely blunts aspirin antiplatelet effects measured by platelet aggregation in healthy individuals[97].

In patients with coronary artery disease, residual platelet reactivity despite of aspirin was detected in 50% of dipyrone comedicated patients[101]. Residual platelet TX formation in patients with coronary artery disease correlated with the concentration of dipyrone metabolites. Additionally, in dipyrone treated patients after cardiac surgery, the incidence of HTPR to aspirin nearly tripled postoperatively[99]. The impact of this *in-vitro* and *ex-vivo* effects on clinical outcome has not been investigated yet.

CONCLUSION

The optimal analgesic regimen in patients with pain is challenging. Considering laboratory and clinical data, naproxen and paracetamol seem to display the most favourable benefit/risk ratio. However, increased incidence of adverse events has been described with these analgesics as well. Alternatively, aspirin would be a possible alternative to relieve pain and inhibit platelet function. Yet it is well known, that analgesic doses of aspirin increase the risk of gastrointestinal complications (Figure 1 and Table 1). If medication with non-opioid analgesics is considered indispensable, a strict order of intake, with aspirin medication at least two hours prior to analgesic medication is advisable. However, the optimal analgesic and antiplatelet regimen in patients with increased risk of cardiovascular disease is still unknown and requires further investigation.

Abstract

The current models of cardiorenal syndrome (CRS) are mainly based on a cardiocentric approach; they assume that worsening renal function is an adverse consequence of the decline in cardiac function rather than a separate and independent pathologic phenomenon. If this assumption were true, then mechanical extraction of fluid (*i.e.*, ultrafiltration therapy) would be expected to portend positive impact on renal hemodynamics and function through improvement in cardio-circulatory physiology and reduction in neurohormonal activation. However, currently available ultrafiltration trials, whether in acute heart failure (AHF) or in CRS, have so far failed to show any improvement in renal function; they have reported no impact or even observed adverse renal outcomes in this setting. Moreover, the presence or absence of renal dysfunction seems to affect the overall safety and efficacy of ultrafiltration therapy in AHF. This manuscript briefly reviews cardiorenal physiology in AHF and concludes that therapeutic options for CRS should not only target cardio-circulatory status of the patients, but they need to also have the ability of addressing the adverse homeostatic consequences of the associated decline in renal function. Peritoneal dialysis (PD) can be such an option for the chronic cases of CRS as it has been shown to provide efficient intracorporeal ultrafiltration and sodium extraction in volume overloaded patients while concurrently correcting the metabolic consequences of diminished renal function. Currently available trials on PD in heart failure have shown the safety and efficacy of this therapeutic modality for patients with chronic CRS and suggest that it could represent a pathophysiologically and conceptually relevant option in this setting.

Key words: Cardiorenal syndrome; Peritoneal dialysis; Heart failure; Ultrafiltration

Core tip: This article briefly reviews the clinical significance of renal dysfunction in heart failure and evaluates the results of the ultrafiltration studies in acute heart failure and cardiorenal syndrome (CRS). It concludes that peritoneal dialysis could represent an

efficacious option for chronic CRS due to its ability to simultaneously address renal and cardiac dysfunction in these patients. Recent technical advances such as possibility of initiating peritoneal dialysis (PD) in the acute setting and placement of the PD catheter by interventional radiology could make this home-based therapeutic option even more accessible and intriguing.

INTRODUCTION

Renal dysfunction is a prevalent feature of heart failure (HF) and portends adverse impact on its potential management options, course, and outcomes. Although several therapeutic strategies have so far been evaluated for patients who present with simultaneous dysfunction of the heart and the kidney [*i.e.,* cardiorenal syndrome (CRS)], the optimal therapy for "chronic" CRS remains largely unknown. This could reflect the paucity of data on the precise mechanisms underlying this syndrome, which is unfortunately unlikely to resolve soon due to its complexity. The contemporary question for clinicians providing care for patients with chronic CRS is whether there exists a safe management strategy that could provide this group of patients with improved outcomes and quality of life compared with conventional therapies. The answer might paradoxically lie in the lessons learned from trials on "acute heart failure" (AHF).

ULTRAFILTRATION FOR HF AND CRS
