### Abstract

Ostial lesions present unique challenges for percutaneous coronary intervention (PCI). These lesions are often more calcified, fibrotic, rigid, and more prone to elastic recoil. Intervention on these lesions is associated with higher procedural complications and higher rates of restenosis. Ostial lesions require precise stent placement in the ostium with the absence of side branch compromise. Accurate stent placement in the ostium without side branch compromise is difficult to accomplish with angiography alone. The Szabo technique uses two coronary guidewires for the correct placement in the aorto-ostial or bifurcation lesion. One guidewire is passed through the final cell of the stent strut and acts as the anchor wire. It helps to prevent migration of the stent beyond the ostium and facilitates the precise stenting at the ostium. This technique has several advantages including less reliance on angiography, lower rates of stent malposition and lower rates of incomplete stent coverage. Potential disadvantages include stent distortion and dislodgement from stent manipulation. We describe two cases of successful PCI to bifurcation lesions using the Szabo technique and confirmation of correct placement in the ostium with optical coherence tomography.

**Core tip:** Percutaneous intervention of ostial and bifurcation lesions is associated with higher rates of restenosis and procedural complications. Vessel anatomy, histology, and the variable angle of takeoff of ostial lesions contribute to the challenging nature of intervention. Lesion histology demonstrates greater calcification, rigidity, eccentricity as well as thicker muscular and

elastic tissue, which contribute to greater elastic recoil. The Szabo two-wire technique provides accurate and complete stent positioning within the ostium, with less dependence on angiography. Intravascular imaging such as with intravascular ultrasound and optical coherence tomography (OCT) can confirm proper stent positioning. We describe two cases of successful percutaneous coronary intervention to bifurcation lesions using the Szabo technique and confirmation of correct placement in the ostium with OCT.

Three-dimensional optical coherence tomography reconstruction of bifurcation stenting using the Szabo anchor-wire technique. *World J Cardiol* 2017; 9(4): 384-390 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/384.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.384>

## INTRODUCTION

The Szabo or anchor-wire technique utilizes two coronary guidewires for the precise placement of stents in aorto-ostial or bifurcation lesions. One guidewire is placed in the main artery, while the second wire is placed in the side branch or aorta and threaded through the most proximal strut of the stent<sup>[1,2]</sup>. Gutiérrez-Chico *et al.*<sup>[3]</sup> evaluated it in a retrospective study in 2010 that showed reduction in incidence of angiographic malpositioning in bifurcation and aorto-ostial lesions without increasing complications. Others have concluded that the technique is imprecise with stent protrusion into the proximal main vessel after evaluation with intravascular ultrasound (IVUS) or stent dislodgement<sup>[4,5]</sup>. We present two such cases of evaluation of stent placement by the Szabo technique using optical coherence tomography (OCT).

## CASE REPORT

### Case 1

A 27-year-old female with CREST syndrome, limited scleroderma, interstitial lung disease, mild pulmonary hypertension, and chronic kidney disease (CKD) from scleroderma renal crises presented with intermittent atypical chest pain. It was midsternal, not worsened with exercise or relieved with rest, but relieved with nitroglycerin. During one episode of chest pain, she had an elevated troponin to 5.0 ng/mL. She was initially managed conservatively due to her CKD and equivocal nuclear stress test findings. She continued to have daily angina that was responsive to nifedipine so a coronary angiography was performed.

Her angiogram revealed a severe stenosis of the proximal left anterior descending (LAD) distal to the bifurcation of a high diagonal vessel (Figure 1) with associated collaterals from the right coronary artery and slow flow. The right coronary artery and left circumflex were normal. The patient had chest pain during the angiogram. Nitroglycerin relieved her symptoms and

improved the angiographic flow of the LAD, but the stenosis distal to the takeoff of the diagonal was persistent.

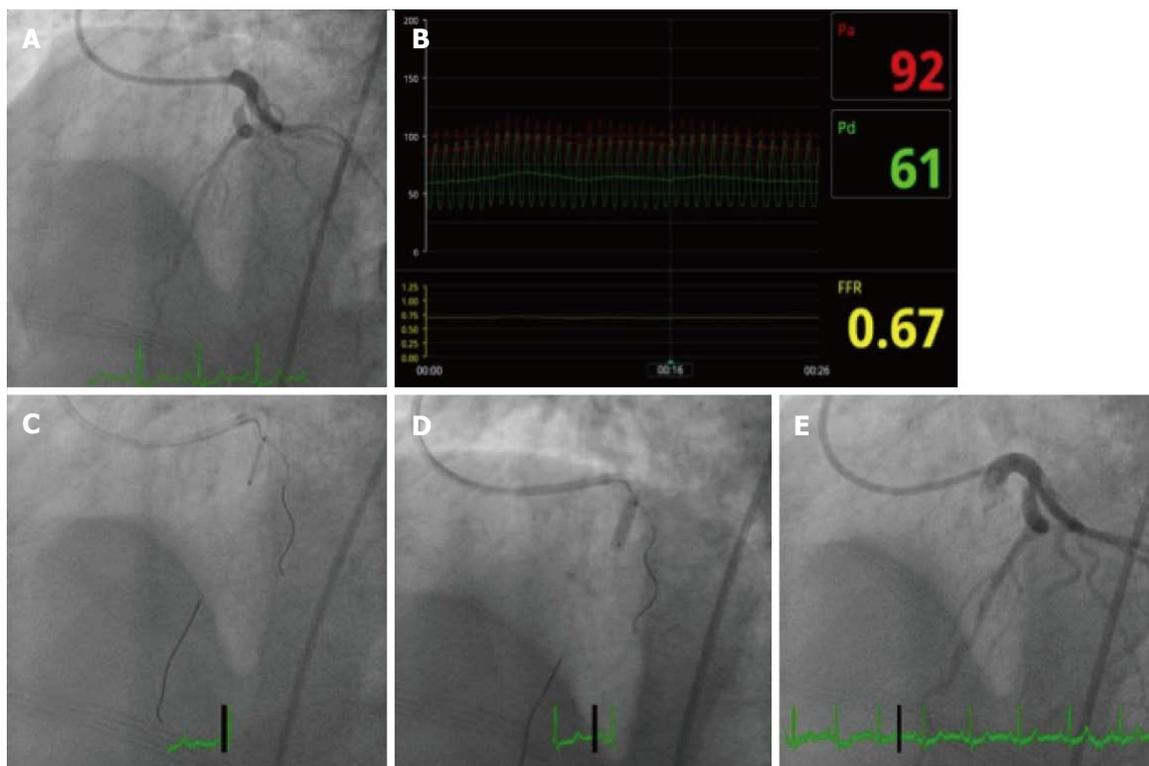

Using an XB 3.5 guide catheter, a pressure wire (PressureWire Aeris, St. Jude Medical, St. Paul, MN, United States), was advanced across the LAD lesion and the resting Pd/Pa ratio was found to be ischemic at 0.67. A HiTorque Whisper MS wire (Abbott Vascular, Temecula, CA, United States) was advanced past the lesion in the LAD and the PressureWire was removed. A second wire, PT 2 (Boston Scientific, Natick, MA), was advanced into the high diagonal. The LAD lesion was pre-dilated with a 2.0 mm × 12 mm compliant balloon. Coronary stent placement was performed using the Szabo technique with a 3.0 mm × 15 mm drug eluting stent. Post-dilation was performed with a 3.0 mm × 8 mm non-compliant balloon. Intravascular imaging with OCT was performed from the LAD, and showed stent malapposition and insufficient expansion of the distal portion of the stent, but also demonstrated optimal stent positioning with only a single stent strut visible beyond the ostium of the main branch of the LAD. Repeat OCT from the diagonal artery showed no stent struts encroaching on the diagonal artery. Other notable OCT findings were the absence of atherosclerotic disease and the presence of intimal medial hypertrophy in the proximal LAD rather than atherosclerosis. Following OCT images, the stent was post-dilated with a 4-0 noncompliant balloon with excellent results (Figure 2).

### Case 2

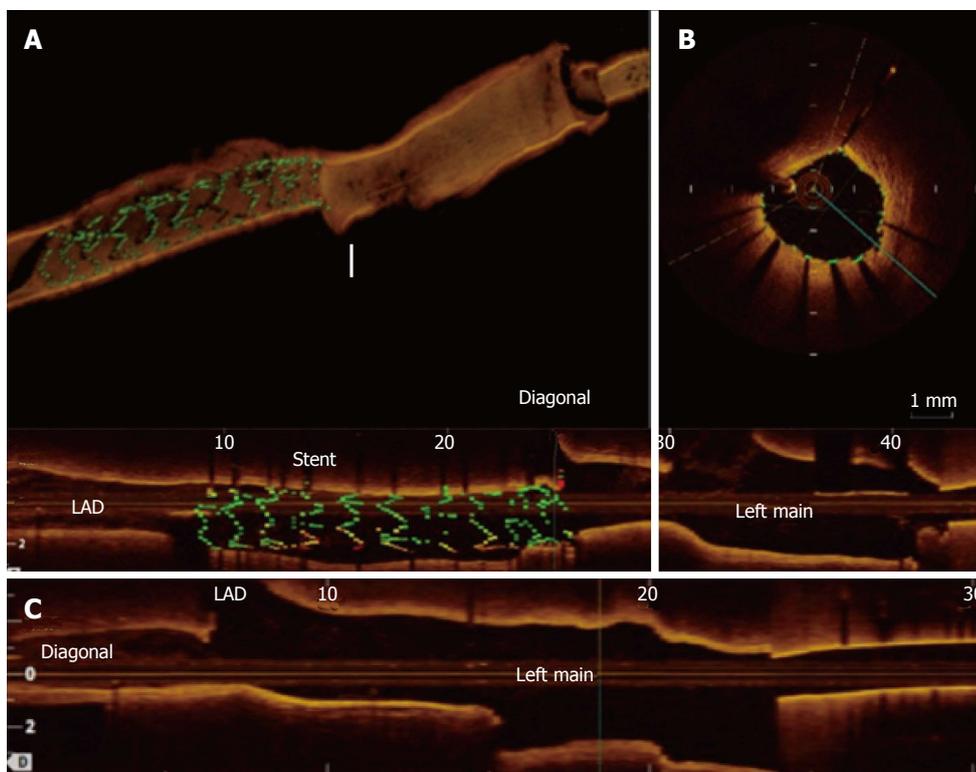

A 65-year-old man with atypical chest pain underwent stress echocardiography, which demonstrated ischemia in the LAD territory. Angiography showed separate ostia of the LAD and left circumflex artery (LCx) and proximal moderate to severe LAD stenosis (Figure 3). Percutaneous coronary intervention (PCI) using the anchor wire technique was performed. An IL 3.5 guide catheter was used to engage the LAD. A Balanced Middleweight 0(Abbott).014" coronary guidewire was placed across the lesion. A Whisper MS wire (Abbott) was backloaded through the proximal stent strut and across the LCx artery. A Vision 3.5 × 23 bare metal stent (Abbott) was deployed in the proximal LAD, anchored by the LCx wire. OCT of the LAD revealed adequate stent apposition. OCT of the LCx did not show any protrusion of stents into the branch vessel (Figure 4).

## DISCUSSION

Precise stent placement in ostial and bifurcation lesions can be technically challenging. Proper stent placement is essential as a stent placed too proximally may obstruct side branches or make future interventions difficult by preventing guiding catheter engagement. A stent placed too distally results in the use of additional stents leading to stent overlap and an increased risk of stent restenosis and adverse outcomes. Angiography alone has inherent limitations in visualizing bifurcation and ostial lesions of due to foreshortening, vessel overlap,

and poor resolution. Intravascular imaging with OCT or IVUS are essential in such cases.

**Figure 3** Angiographic images for case 2. Coronary angiography showed separate ostia of the LAD and left circumflex artery (LCx) and proximal moderate to severe LAD stenosis. RAO caudal (left) and LAO caudal (right) images with diagnostic images (top), Szabo technique (center three panels) and final images (bottom). LAD: Left anterior descending; LCx: Left circumflex artery.

**Figure 4** Optical coherence tomography images for case 2. A: Three-dimensional OCT of LAD shows excellent stent apposition; B: OCT of left circumflex does not show protrusion of stent struts. LAD: Left anterior descending; OCT: Optical coherence tomography.

Several different interventional techniques have been developed to treat ostial or bifurcation lesions. Many operators attempt to optimize placement with careful fluoroscopic views, but this is associated with a significant risk of geographic miss and restenosis. PCI with a single stent approach extending across the side branch can be reasonable when there is no significant disease in the side branch and the side branch is comparably small. Side branch wiring without anchoring the stent strut can be used to mark the bifurcation but has limited accuracy. Bifurcation stenting with a two-stent strategy would have been inappropriate for these Medina 0, 1, 0 lesions because there was no disease in the side branch and five-year outcome data from the Nordic bifurcation study confirmed an absence of benefit and an increase in complications with an empiric two-stent strategy<sup>[6]</sup>.

We performed PCI using an anchor wire technique in both cases because the side branches were comparably large and without disease. With the anchor wire technique, both the main and side branch vessel are wired. The stent is loaded onto the main branch wire and the

back end of the side branch wire (aka anchor wire) is carefully inserted through the final cell of the stent. This can be done by partially flaring the back of the stent using a partial inflation of the balloon while the stent cover is still in place. The stent is then manually re-crimped onto the balloon and advanced gently over both wires. The stent is pushed across the lesion, until the anchor wire prevents further forward motion. The stent is then deployed, the anchor wire removed, and the stent post-dilated. The advantages of this technique are decreased dependence on angiographic localization and avoidance of proximal protrusion or side branch compromise (Figure 5).

The Szabo technique has been evaluated by angiography and intravascular ultrasonography<sup>[7]</sup>. A series of 26 patients using the Szabo technique demonstrated a success rate of only 88% by angiography with a few cases of stent dislodgment and deformation<sup>[4]</sup>. In a series of 41 patients, PCI at the ostial lesion by the Szabo technique showed success rate 97.6% by IVUS<sup>[8]</sup>. In our experience, there are several ways to minimize complications. First, this technique is probably safest for

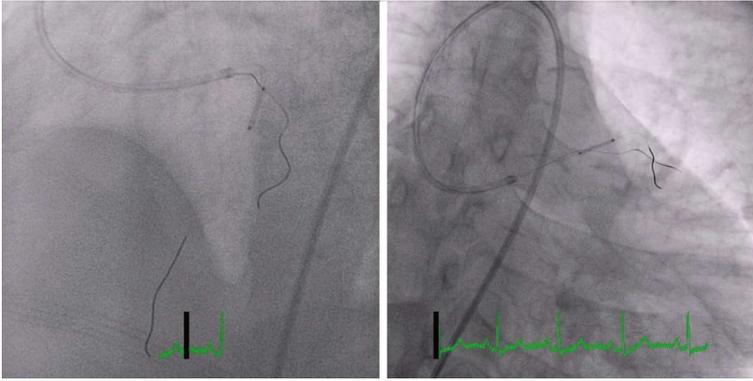

Figure 5 Angiographic images illustrate the position of the stent and the side branch anchor during this technique.

aorto-ostial lesions where the stent does not need to traverse any part of the coronary artery before reaching the lesion. Second, the side branch wire should be stiff to allow for resistance to stent advancement and should not have a polymer coating that may be stripped off as the wire is removed through the stent struts. Third, balloon expansion when backloading the wire onto the stent should be minimized or even avoided as any stent deformation may interfere with stent advancement and recovery. Lastly, testing the advancement of the stent into the main branch without the anchor wire will ensure that the stent will advance smoothly and reduce the risk of stent dislodgement upon attempted withdrawal.

While the Szabo technique has been evaluated by angiography and intravascular ultrasonography, it has not been studied with OCT. OCT has a resolution of 10-15  $\mu$ m and provides excellent images of a stented vessel, especially the adequacy of stent apposition and positioning. OCT of the non-stented vessel can also provide excellent visualization of stent struts, which may be deformed or protruding into the side-branch. This technology provides more definitive evidence of successful stent placement as compared to angiography alone as individual stent struts are easily imaged with OCT. Advances in image processing capabilities have enabled three-dimensional OCT reconstruction of the artery and the stent position within the artery. This allows for even finer evaluation of individual stent struts for deformation, malapposition, or side-branch encroachment.

These two cases demonstrate that the anchor wire method can provide complete ostial coverage and optimal placement for ostial lesions as documented by OCT. Prospective evaluation of the anchor wire technique combined with three-dimensional OCT may further elucidate factors that can contribute to suboptimal long-term outcomes and adverse events.

## COMMENTS

### Case characteristics

A woman with CREST syndrome and a man with risk factors for coronary artery disease present with chest pain.

### Clinical diagnosis

The woman from case 1 developed elevated troponin and the man from case 2

had a positive stress echocardiogram.

### Differential diagnosis

Gastroesophageal reflux disease, coronary vasospasm, musculoskeletal chest pain.

### Laboratory diagnosis

The woman with CREST syndrome developed a troponin of 5 ng/mL and had a chronically elevated BUN/Cr due to chronic kidney disease.

### Imaging diagnosis

The woman from case 1 had a severe stenosis of the proximal left anterior descending artery (LAD) distal to the bifurcation of a high diagonal vessel, and the man from case 2 had separate ostia of the LAD and left circumflex artery (LCx) and proximal moderate to severe LAD stenosis.

### Pathological diagnosis

Optical coherence tomography of the woman with CREST syndrome showed intimal medial hypertrophy, and the man from case 2 had atherosclerotic coronary artery disease.

### Treatment

After percutaneous coronary intervention, both patients were treated with dual antiplatelet therapy.

### Related reports

There are different interventional techniques to treat ostial and bifurcation lesions. The accuracy of the Szabo technique has been evaluated by both angiography and intravascular ultrasonography.

### Term explanation

An ostial lesion begins within 3-5 mm of the origin of a major epicardial artery. The Szabo technique uses two coronary guidewires for the correct placement in the aorto-ostial or bifurcation lesion.

### Experiences and lessons

Precise stent placement in ostial and bifurcation lesions can be technically challenging, but the anchor wire method can be used to provide complete ostial coverage and optimal placement.

### Peer-review

It is a fine case presentation with new stenting technique. The manuscript is well-written and deserves publication.

### Abstract

Aortic root rupture and cardiac tamponade during

transcatheter aortic valve implantation is a frightening complication with high mortality rate. A conservative management of this complication could represent an initial strategy, especially in high-risk patients, to avoid emergent cardiac surgery. This conservative management includes: Immediate detection of pericardial effusion by echocardiography, a fast instauration of pericardial drainage, auto-transfusion and anticoagulation reversal. We describe two cases of patients who suffered this complication and were treated successfully with this initial approach.

**Key words:** Aortic valve stenosis; Catheters; Heart valve prosthesis; Prosthesis implantation; Cardiac tamponade

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Aortic root rupture during transcatheter aortic valve implantation is a rare but severe complication with high mortality rate. We described two cases of aortic root rupture where we realized a conservative management with rapid anticoagulation reversal and pericardial drainage with blood auto-transfusion. These cases highlight the utility of rapid identification of aortic root hematoma and pericardial effusion by transesophageal echocardiography. Immediate detection of this complication allows to stabilize the patient avoiding further urgent interventions.

Conservative management of aortic root rupture complicated with cardiac tamponade following transcatheter aortic valve implantation. *World J Cardiol* 2017; 9(4): 391-395 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/391.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.391>

### INTRODUCTION

Transcatheter aortic valve implantation (TAVI) is gaining ground for the treatment of severe aortic stenosis (AS)

in patients with high risk of surgery or contraindications. However, it is a technical and complex procedure with intra and periprocedural risks of complications that could eventually need emergent cardiac surgery (ECS). Among the potential complications, aortic root rupture with subsequent cardiac tamponade is one of the most feared. No data are available about the best management of cardiac tamponade secondary to aortic root rupture during TAVI. Nevertheless, it is well known that ECS, especially in patients with cardiac tamponade, entails a high mortality rate<sup>[1]</sup>. Pericardiocentesis followed by conservative management of cardiac tamponade secondary to aortic root rupture during TAVI could be an initially effective approach to this complication if the prosthetic valve function is preserved.

We herein present two cases of conservative management of cardiac tamponade following aortic root rupture during TAVI.

## CASE REPORT

### Case 1

An 89-year-old lady with symptomatic severe AS was scheduled for a TAVI. Transthoracic echocardiography (TTE) showed a severe AS (mean gradient: 48 mmHg; aortic valve area of 0.5 cm<sup>2</sup>, with preserved ejection fraction, 55%). Computed tomography scanner (CT-scan) showed severe calcification of the valve and the following measurements: Minimum/maximum annulus transverse diameter of 23 mm/26 mm, aortic root perimeter of 83 mm and aortic root area of 5 cm<sup>2</sup>. She was rejected for surgical aortic valve replacement because of high surgical risk related to advanced age (Charlson score: 6; Barthel Score: 100; Logistic Euroscore: 13.57%).

General anaesthesia and mechanical ventilation support were used to allow trans-esophageal echocardiography (TEE) guidance. TEE showed an aortic annulus diameter of 22-mm (Figure 1A and B). Anticoagulation with unfractionated heparin adjusted for body weight was administered before the implantation. Aortic valve pre-dilatation under fast ventricular pacing was performed without complications and a 26-mm Edwards Sapien XT valve (Edwards Lifesciences, Irvine, California) was implanted.

Immediately after implantation, the patient presented sudden hypotension and TEE showed an expanding aortic root hematoma (Figure 1C and D); with progressively formation of pericardial effusion with signs of cardiac tamponade (Figure 1C, E and F). Percutaneous pericardiocentesis was performed, draining 200 mL of blood that were re-infused. Volume replacement and coagulation reversal with protamine were also performed with initial patient stabilization.

ECS was dismissed because of the high surgical risk and a conservative management was decided. During the first 72 h the patient persisted with hemodynamic instability controlled with volume load (fluid and blood) and repeated pericardial drainages to maintain a mean arterial pressure > 60 mmHg. Finally, the weaning from

mechanical ventilation was successfully performed and the patient could be transferred to the conventional ward and discharged one month after the procedure.

At one-year follow-up the patient was almost fully independent for basic activities of daily living (Barthel Score: 95).

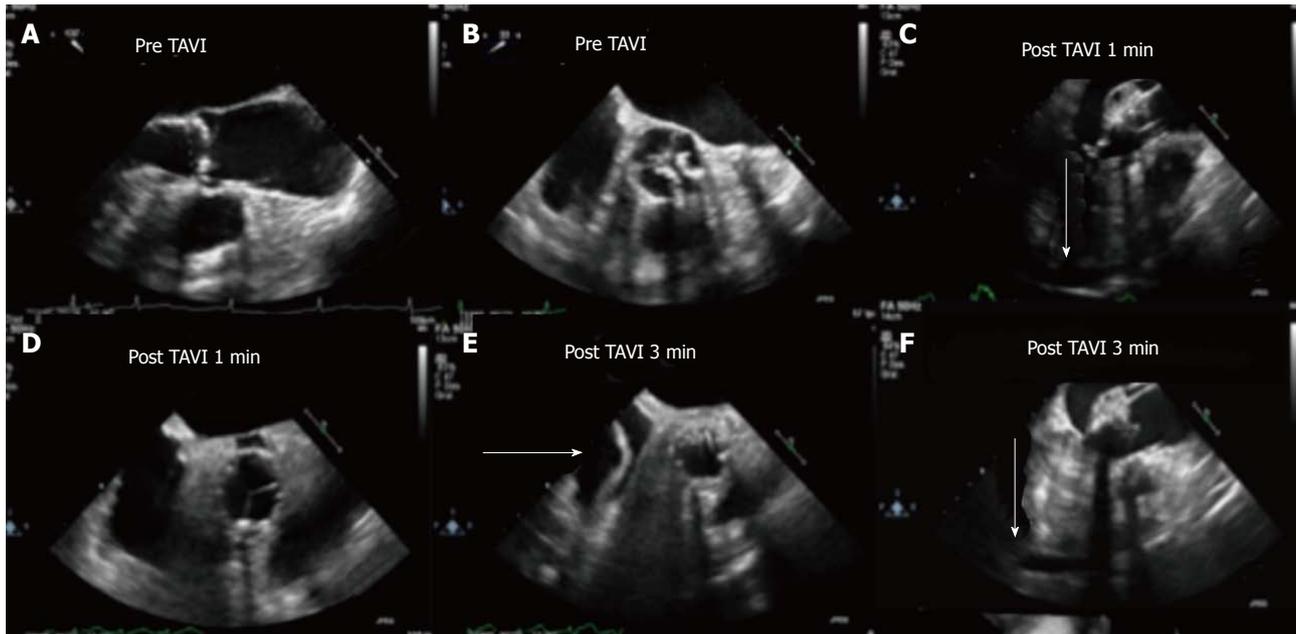

### Case 2

An 81-year-old woman with hypertension, renal impairment with glomerular filtration rate < 30 mL/min and severe AS (TTE mean gradient: 55 mmHg; aortic valve area of 0.78 cm<sup>2</sup>) with preserved ejection fraction (65%) was referred to TAVI. The patient had refused surgical treatment, after a complete evaluation by the Heart Team a TAVI procedure was proposed and finally accepted. TEE showed a severe calcified AS (mean-maximum transvalvular gradient were 58/100 mmHg, respectively) with an aortic annulus diameter of 22 mm. CT-scan measures (minimum/maximum annulus transverse diameters 22 mm and 27 mm, respectively; aortic root perimeter of 80 mm with an area of 4.7 cm<sup>2</sup>) and TEE lead to the selection of a 26 mm Edwards Sapien XT valve (Edwards Lifesciences, Irvine, California). Anticoagulation was reached with unfractionated heparin adjusted for body weight. Aortic valve predilatation under fast ventricular pacing was performed without complications; and the 26 mm valve was implanted. TEE immediately after TAVI showed a minimal paravalvular leak with normofunctional prosthetic valve.

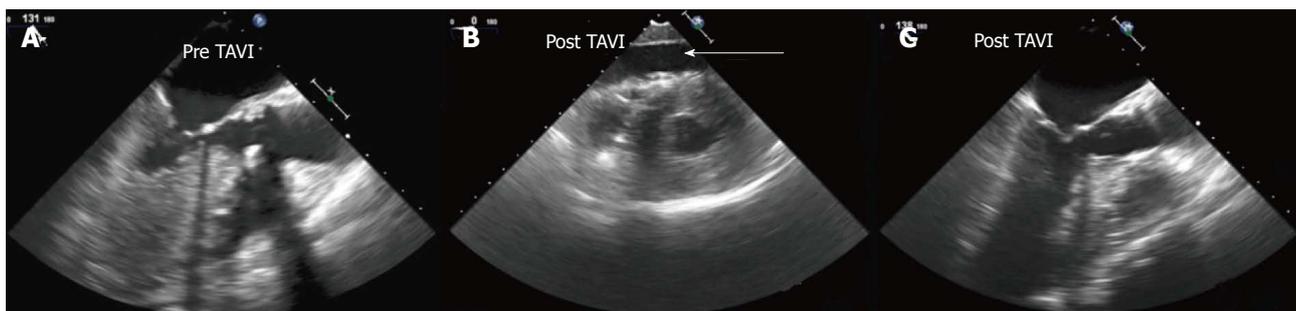

However, one minute later, the patient presented sudden hypotension, and pericardial effusion and signs of cardiac tamponade appeared evident on TEE without signs of aortic root hematoma or dissection (Figure 2). Percutaneous pericardiocentesis was performed draining 300 mL of blood that were reinfused into the patient and coagulation was reversed with protamine. The patient was hemodynamically stabilized and was transferred to the acute cardiac care unit.

Pericardial drainage was performed every eight hours during two days to maintain mean arterial pressure > 60 mmHg. After successful weaning from the ventilator, the patient was dismissed from the coronary intensive care unit and was finally discharged home at day 19 after TAVI procedure.

At one month follow-up, the patient presented new onset symptoms of heart failure. A TEE showed a severe aortic regurgitation with three different jets: One main central jet (apparently secondary to valve geometry alteration with an eccentric closure of valves) and two perivalvular leaks, with minimal pericardial effusion. The patient did not respond to optimal medical treatment and persisted in functional class NYHA IV. Finally, the heart team decided a surgical approach for TAVI replacement. A biologic valve prosthesis Mitroflow 19 mm (Sorin Group Inc.) was successfully implanted and aortic root rupture was confirmed. However, the patient suffered from several postoperatively complications including septic shock that resulted in death 1 mo after second procedure.

**Figure 1 Aortic root rupture and aortic root hematoma (Case 1).** A and B: Aortic valve assessment before TAVI, TEE mid esophageal long axis view (A) and short axis view (B); C and D: Aortic valve assessment post TAVI 1 min; E and F: Aortic valve assessment post-TAVI 3 min. We can observe the development of the aortic root hematoma and the pericardial effusion (arrowhead). TAVI: Transcatheter aortic valve implantation; TEE: Trans-esophageal echocardiography.

**Figure 2 Aortic root rupture and cardiac tamponade (Case 2).** A: Aortic valve assessment before TAVI, TEE mid esophageal long axis view; B: Aortic valve assessment after TAVI, TEE transgastric mid-ventricular short axis. Severe pericardial effusion is evidenced (arrow); C: Aortic valve assessment after TAVI, TEE mid esophageal long axis view. No signs of aortic root hematoma were observed in this case. TAVI: Transcatheter aortic valve implantation; TEE: Trans-esophageal echocardiography.

## DISCUSSION

An initially conservative management of aortic root rupture and cardiac tamponade during TAVI procedures may represent an appropriate approach in this high-risk population. Although uncontained aortic root rupture affects only to 0.5%-1% of the patients treated with a TAVI intervention, a contained rupture could occur in up to 5% of procedures<sup>[1]</sup>. Otherwise, as mentioned above, it is well known the increased risk of mortality of ECS in patients with cardiac tamponade<sup>[2]</sup>. Data on the need of ECS after TAVI is scarce, but it has been reported an incidence of about 1%<sup>[2]</sup>. In this regard, 30-d mortality rate in TAVI patients who need ECS may exceed 50%<sup>[2]</sup>. This is especially true in patients complicated with cardiac tamponade or annulus rupture in whom mortality rate may range between 60% and 100%<sup>[2-4]</sup>.

There are several issues to be taken into account

during the conservative management of this complication. First, it is mandatory to immediately identify the root rupture during the procedure. In this regard, intraoperative TEE is useful as aortic root hematoma could represent the first sign of aortic root rupture and may precede the development of hemodynamic instability and pericardial effusion. Aortic root hematoma was identified only in the first case. In the second case, the evidence of pericardial effusion on TEE allowed the diagnosis that was confirmed during valve-replacement surgery. Secondly, the rapid reversal of coagulation with protamine sulfate may help avoid progression of the hematoma. Finally a rapid percutaneous pericardial drainage and blood auto-transfusion connecting a drainage catheter directly into a central line is mandatory to stabilize hemodynamics of the patient.

Although it is well known that patients who need ECS present poor prognosis<sup>[2-5]</sup>, except for tamponade

secondary to right ventricular tears<sup>[6]</sup>, it is not clear whether the patient with cardiac tamponade secondary to aortic root rupture could benefit from an invasive management.

Several mechanisms could be involved in the development of this complication. The extensive calcification of left ventricular outflow tract (LVOT), the mismatches between the aortic root and the prosthesis (TAVI oversizing) and the ellipsoid geometry of aortic root have been proposed as potential predictors of this ominous complication<sup>[1,7,8]</sup>.

In the above-mentioned cases, the aortic annulus measured with CT-scan revealed an ellipsoid geometry (26 mm × 23 mm and 26 mm × 22 mm), with an eccentricity indexes of 0.12 and 0.15, respectively that did not exceed the normal value described in previous series<sup>[7]</sup>. The combination of ellipsoid geometry and the presence of severe and extensive calcification could be the cause of aortic root injury. Oversizing was calculated in 6% and 13% in our first and second case, respectively. A significant area-oversizing threshold > 20% was associated with aortic rupture<sup>[7]</sup>. However, it is plausible that an oversizing that exceeds 10% may still entail a higher risk of aortic root rupture.

An extensive study of the aortic root area with measurement of the perimeter, diameter, geometry and annulus-LVOT calcification with CT-scan, may help avoid excessive prosthesis oversizing and identify geometry incompatibility between prosthesis and landing zone because of its irregular geometry.

This initial conservative management could stabilize both patients and as a matter of fact, they were successfully discharged home. In the second case, however, further alteration of valve geometry caused severe prosthetic dysfunction and a surgical procedure was required. Eventually, the patient suffered from postoperatively complications and finally died. Nevertheless, the initial conservative management could allow further surgery in a more stable condition with higher chances of survival.

In conclusion, the risk of aortic root rupture during TAVI is difficult to predict despite an extensive study by TEE and CT-scan. Immediate detection of this complication during the TAVI procedure may allow rapid instauration of measures (anticoagulation reversal and pericardial drainage with auto-transfusion) that lead to stabilize the patient and avoid further ECS. Further investigation is needed to predict, avoid and manage the aortic root rupture in TAVI patients.

## ACKNOWLEDGMENTS

We are grateful to Dr. Susanna Prat for her contribution, analysis and interpretation of CT-scan images, and to the Acute Cardiac Care Unit staff and to the Transcatheter Aortic Valve Implantation Heart Team of our center for their collaboration.

## COMMENTS

### Case characteristics

The authors describe two cases of post-transcatheter aortic valve implantation (TAVI) cardiac tamponade with successful initial conservative management.

### Clinical diagnosis

Sudden hypotension and hypoperfusion.

### Differential diagnosis

Acute bleeding (retroperitoneal, TAVI-access site bleeding), heart-block, prosthetic-valve dysfunction.

### Laboratory diagnosis

Transesophageal echocardiography and invasive hemodynamics are the main diagnostic tools.

### Imaging diagnosis

Transesophageal echocardiography confirmed cardiac tamponade in both cases. In the case 1 showed an aortic root hematoma and pericardial effusion, in the case 2 did not identify signs of aortic root injury but identified progressive pericardial effusion.

### Treatment

Immediate anticoagulation reversal and pericardial drainage with autotransfusion that lead to stabilize the patient may avoid further emergency cardiac surgery.

### Related reports

Uncontained aortic root rupture is a rare post-TAVI complication (0.5%-1%) but with high mortality rate. TAVI patients who need emergency cardiac surgery with cardiac tamponade or aortic root rupture present a mortality rate between 60% and 100%. The data among conservative management are scarce.

### Term explanation

The aortic root is a complex structure that connects the heart to the systemic circulation, it is composed of distinct parts extremely sensitive to injury during TAVI: Valve leaflets (with the commissure and leaflet attachment), inter leaflet triangle, the sino tubular junction and the ventriculo-aortic junction.

### Experiences and lessons

Immediate detection of cardiac tamponade during TAVI procedure may allow rapid instauration of measures (anticoagulation reversal and pericardial drainage with auto-transfusion) that lead to stabilize the patient and that can avoid further interventions. Transesophageal echocardiography is the main diagnostic tool.

### Peer-review

The case report was well written, and may give rise to an interesting discussion on the described problem.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Gergely Feher, MD, PhD, Assistant Professor, Department of Neurology, Medical School, University of Pecs, Pecs, Baranya 7623, Hungary

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

diet, smoking, and sleep, play a major role in preventing the development and progression of cardiovascular disease (CVD). Among these behaviors, sleep may play a pivotal role, yet it has been studied somewhat less than other behaviors and there have been few well-designed sleep intervention studies targeting CVD. Furthermore, despite the fact that these behaviors are often inter-related, interventions tend to focus on changing one health behavior rather than concurrently intervening on multiple behaviors. Psychological constructs from depression to positive affect may also have a major effect on these health behaviors and ultimately on CVD. In this review, we summarize the existing literature on the impact of sleep and other cardiac health behaviors on CVD onset and prognosis. We also describe interventions that may promote these behaviors, from established interventions such as motivational interviewing and cognitive behavioral therapy, to more novel approaches focused on mindfulness and other positive psychological constructs. Finally, we outline population-health-level care management approaches for patients with psychiatric conditions (*e.g.*, depression) that may impact cardiac health, and discuss their potential utility in improving mental health, promoting health behaviors, and reducing CVD-related risk. Much work is still needed to better understand how sleep and other health behaviors may uniquely contribute to CVD risk, and additional high-quality studies of interventions designed to modify cardiac health behaviors are required to improve cardiovascular health in individuals and the population at large.

**Key words:** Sleep; Diet; Physical activity; Cardiovascular disease; Care management

**Core tip:** This manuscript discusses the link between modifiable health behaviors; including sleep, diet, activity, and their relationship to adult risk for cardiovascular disease. Despite knowing that these behaviors are

### Abstract

Numerous health behaviors, including physical activity,

often interrelated, interventions to date have primarily focused on changing one health behavior *vs* intervening on multiple behaviors simultaneously. Population health level care management approaches are outlined to aide providers in counseling their patients.

Kaar JL, Luberto CM, Campbell KA, Huffman JC. Sleep, health behaviors, and behavioral interventions: Reducing the risk of cardiovascular disease in adults. *World J Cardiol* 2017; 9(5): 396-406 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/396.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.396>

## INTRODUCTION

Recent guidelines for adequate sleep duration from the American Academy of Sleep Medicine and Sleep Research Society state that a typical adult needs at least 7 h of sleep each night to maintain optimal health<sup>[1,2]</sup>. Population-based studies estimate that one in three adults in the United States report sleeping fewer than 7 h per night<sup>[3,4]</sup>. This statistic is alarming as research has shown that individuals with insufficient sleep are at a significantly greater risk for many chronic diseases, including cardiovascular disease (CVD)<sup>[5-8]</sup>, which is responsible for one in four deaths in the United States<sup>[9]</sup>. Additional health behaviors beyond sleep, including poor diet, low levels of physical activity, and prolonged sedentary time, are also major risk factors for the development of CVD<sup>[6]</sup>. This review will discuss the current literature linking these modifiable health behaviors to an increased risk of CVD, and the evidence-based interventions that can modify them, in order to guide future intervention targets and strategies aimed at reducing CVD risk in adults.

## IMPORTANCE OF SLEEP IN REDUCING CVD RISK

In recent literature, both insufficient sleep duration (most often defined as fewer than 7 h) and long sleep duration (more than 9 h) have been associated with poor health outcomes and increased mortality risk<sup>[6,10]</sup>. In one such large, population-based study, individuals who reported fewer than 6 h of sleep had a 15% higher incidence of CVD compared to those who reported sleeping between 7-8 h<sup>[8]</sup>.

Many biomarkers related to CVD risk have been examined in relation to insufficient sleep duration. The relationship between short sleep duration and hypertension is well documented, extending from experimental studies to longitudinal epidemiological studies and intervention studies<sup>[11-13]</sup>. Short sleep duration (collected *via* self-report questionnaire) has been associated with higher blood pressure in cross-sectional studies and greater overall incidence of hypertension in population studies. Studies tend to vary in their definition

of short sleep duration, but overall conclude that 5 or fewer hours of sleep each night is related to the worst blood pressure outcomes. These poor blood pressure outcomes are reported to be most common in women and adults who are less than 65 years old. Racial/ethnic differences have been found showing that relationships between short sleep duration (fewer than six hours per night) and hypertension are strongest in non-Hispanic whites, blacks, and Hispanics/Latinos populations<sup>[5]</sup>.

Insufficient sleep has also been associated with other conditions linked with CVD, such as obesity and type 2 diabetes mellitus (T2DM). Short sleep duration has been strongly linked to an increased risk of obesity across all populations<sup>[14]</sup>, and, conversely, for each additional hour of sleep an individual's body mass index (BMI) decreases by 0.35 units<sup>[14]</sup>. Racial/ethnic differences have been found, with the strongest relationship of very short sleep (less than five hours per night) and obesity in individuals who identify as African American/black<sup>[5]</sup>. Further research has shown that women who reported sleeping less than 6 h per night over the course of 16 years gained significantly more weight compared to women that slept at least 7 h<sup>[15]</sup>. Individuals with short sleep duration (fewer than 6 h per night) have also been shown to have an increased risk of T2DM<sup>[16,17]</sup>. It remains unclear whether this increased risk is mediated by obesity or if there are other mechanisms, including glucose metabolism, that may explain the increased risk of T2DM.

There is less data on the connection between short sleep duration and other biological markers of health<sup>[6]</sup>. Regarding inflammatory markers, when sleep is experimentally restricted to fewer than four hours per night, increases in C-reactive protein and interleukin-1 receptor have resulted<sup>[18,19]</sup>. Studies examining the effects of short sleep duration and insulin resistance are also rare. Self-report of fewer than 6 h of sleep per night has been associated with increased insulin and hemoglobin A1C (HbA1c), but this result was attenuated when BMI was added to the model<sup>[20]</sup>. Studies of sleep restriction (fewer than 6 h in bed) have found an increase in insulin resistance<sup>[21,22]</sup>; however, these studies were limited to healthy, young males. Therefore, the relevance of these associations to the general population remain unclear.

### **Importance of other health behaviors in reducing CVD risk**

Dietary intake, physical activity, and sedentary time have also been associated with CVD risk in adults. The effects of numerous dietary components on CVD risk have been examined<sup>[23]</sup>. For example, adherence to a Mediterranean diet, consisting of a high intake of fruits and vegetables, fish, olive oils, and dairy, has been associated with a lower risk of CVD events including myocardial infarction and stroke as well as lower cardiovascular mortality<sup>[24]</sup>. A similar dietary eating pattern, the DASH eating plan, consisting of fruits and vegetables, low-fat dairy, whole grains, poultry, fish, and nuts, has also been found to lower incidence of adverse cardiovascular events<sup>[25]</sup>. Specific dietary components have also been associated

with a reduced risk of CVD. Diets high in polyunsaturated fatty acids and low in sodium have are linked to fewer cardiovascular events<sup>[23]</sup>. Increasing physical activity levels, at any intensity level, has been shown to lower CVD risk. Individuals with higher daily overall physical activity (measured *via* accelerometer) and moderate-vigorous physical activity have been shown to have lower CVD mortality<sup>[26]</sup>. Although reducing sedentary time appears important to overall health, sedentary time has generally not been associated with CVD mortality<sup>[26]</sup>.

## POTENTIAL RELATIONSHIPS BETWEEN MULTIPLE HEALTH BEHAVIORS IN REDUCING CVD RISK

Despite the strong evidence of increased CVD risk associated with each of the above behaviors on poor health outcomes, an important issue in this line of research is detangling the effects of these health behaviors from one another, as they tend to be strongly correlated within individuals. Due to this, it can be difficult to discern which health behaviors independently contribute to improved health outcomes. For example, there is limited data regarding how sleep combines with the other behaviors. Additional evidence is needed to define how these behaviors may cluster or pattern together resulting in an increased risk of disease; such knowledge can help to inform future public health intervention guidelines and policy in this area. Intervention and policy strategies to date have focused on changing individual behaviors, with very few strategies attempting to target multiple lifestyle behaviors simultaneously<sup>[27]</sup>. A study in over 500000 United Kingdom adults aged 37-63 years found that individuals with CVD were more likely to report low levels of physical activity, more than 3 h of TV viewing per day, and fewer than 7 h of sleep per night, compared to individuals without CVD<sup>[27]</sup>. The clustering of these behaviors was termed a “unhealthy phenotype” and individuals with this unhealthy phenotype had poorer disease outcomes.

Multiple health behavior interventions have been shown to have improved health outcomes, such as blood pressure, cholesterol, and glucose, when changes to both diet and activity are changed simultaneously<sup>[28]</sup>. However, there is very limited evidence to date that these types of interventions directly impact CVD events or mortality<sup>[28]</sup>.

## STANDARD HEALTH BEHAVIOR INTERVENTIONS AND THEIR IMPACT IN CVD RISK POPULATIONS

### **Cognitive-behavioral therapy**

Cognitive-behavioral therapy (CBT) is an evidence-based intervention for improving cardiac health behaviors and outcomes. It is a short-term skills-based psychotherapy that teaches cognitive (*e.g.*, cognitive restructuring,

probability estimation) and behavioral strategies (*e.g.*, behavioral exposures, behavioral activation) to reduce emotional distress, improve well-being, and promote healthy behavioral choices. Originally developed for treating emotional problems, CBT is often most useful for improving health behaviors among patients with or at risk for chronic medical conditions who may be more motivated for change, and psychiatric symptoms among individuals with mental health disorders who have the greatest room for symptom improvement. For example, in a study of CBT for improving sleep in healthy college students, only those with poor sleep at baseline showed significant improvement (Trockel *et al.*, 2011). Thus, much of the work on CBT and cardiac risk factors has been aimed at improving sleep and other health behaviors and psychiatric symptoms in patients with insomnia, mental health problems, or those with or at risk for CVD. Table 1 shows representative studies examining the effects of standard health behavior interventions on health outcomes.

CBT is useful for improving sleep and other health behaviors in patients with or at risk for CVD. A recent review of CBT for insomnia (CBT-I) in CVD patients found that there is limited but promising evidence for CBT-I to improve sleep characteristics (*e.g.*, sleep efficiency and quality), CVD biomarkers, symptom burden, functional impairment, and quality of life<sup>[29,30]</sup>. CBT has also been shown to improve health behaviors including diet (*e.g.*, reduced sugar, increased fruits/vegetables), physical activity, and smoking cessation in some studies of healthy adults and those with or at risk for CVD<sup>[31-35]</sup>.

In line with the original aim of CBT, much of the research on CBT and cardiac health has focused on the efficacy of CBT in improving psychosocial problems in CVD patients given that these problems have a significant negative impact on cardiac morbidity and mortality<sup>[36,37]</sup>. The results of several randomized clinical trials (RCT) support the efficacy of CBT in improving depression, anxiety, and quality of life in CVD patients, patients suffering an acute coronary syndrome (ACS), heart surgery patients, and heart failure patients<sup>[38-44]</sup>. A systematic review and meta-analysis of psychological interventions for depression in CVD found that CBT had the strongest effects<sup>[45]</sup>, and the American Heart Association specifically recommends CBT for treating depression in CVD patients<sup>[46]</sup>. CBT is also associated with improved psychosocial outcomes among individuals at risk for CVD including those with type 2 diabetes, hypertension, and overweight and obesity<sup>[31,34,47]</sup>.

Evidence for direct effects of CBT on physical health outcomes is less consistent. A Cochrane review of 64 RCTs found that psychological interventions produced small-moderate improvements in depression and anxiety and a small effect on cardiac mortality in CVD patients, but no effect on total death or cardiac events<sup>[44]</sup>. Another systematic review found improvements in depression symptoms but no effect on all-cause mortality, cardiac mortality, or cardiac events<sup>[43]</sup>. In the Enhancing Recovery in Coronary Heart Disease Patients trial, a randomized trial of 2481 post-ACS patients, CBT was asso-

**Table 1** Representative studies examining the effects of cognitive behavioral therapy and motivational interviewing on health-related outcomes

Ref.	Population	Intervention	Outcome
Tsiros <i>et al</i> <sup>[33]</sup> , 2008	<i>n</i> = 47 adolescents with overweight or obesity	CBT <i>vs</i> no-treatment	Greater improvements in weight, BMI, body fat, sugar intake (soft drinks) in CBT group at 20-wk follow-up
Welschen <i>et al</i> <sup>[34]</sup> , 2013	<i>n</i> = 154 diabetes patients	CBT <i>vs</i> managed care	Greater improvement in physical activity, quality of life, and depression in CBT group at 6-mo follow-up; no group differences at 12-mo follow-up
Freedland <i>et al</i> <sup>[39]</sup> , 2009	<i>n</i> = 123 CABG patients with depression	CBT <i>vs</i> supportive stress management	Greater depression remission in CBT than supportive stress management group at 3-mo and 9-mo follow-up
Berkman <i>et al</i> <sup>[48]</sup> , 2003	<i>n</i> = 2481 MI patients	CBT <i>vs</i> usual care	Greater improvement in depression and social support in CBT group at 6-mo follow-up; no group differences in survival at 29-mo follow-up
Woollard <i>et al</i> <sup>[55]</sup> , 1995	<i>n</i> = 166 patients with hypertension	MI low dose <i>vs</i> MI high dose <i>vs</i> usual care	Greater improvements in alcohol and salt intake in low-MI <i>vs</i> usual care; greater improvements in weight and blood pressure in high-MI <i>vs</i> usual care at 18-wk follow-up
Ma <i>et al</i> <sup>[59]</sup> , 2014	<i>n</i> = 120 Chinese patients with hypertension	MI <i>vs</i> usual care	Greater improvements in treatment adherence and blood pressure in MI group
Ogedegbe <i>et al</i> <sup>[60]</sup> , 2008	<i>n</i> = 190 African American patients with hypertension	MI <i>vs</i> usual care	Greater improvements in medication adherence and blood pressure in the MI group at 12-mo follow-up
Cain <i>et al</i> <sup>[68]</sup> , 2011	<i>n</i> = 104 adolescents	MI and sleep education <i>vs</i> no intervention	Greater improvements in sleep knowledge and out-of-bed time in MI group; improvements in sleep and daytime functioning in both groups

BMI: Body mass index; CABG: Coronary artery bypass graft; CBT: Cognitive behavioral therapy; MI: Motivational interviewing.

ciated with improvements in depression symptoms, but did not affect survival or cardiac events at 6-mo follow-up<sup>[48]</sup>. It is possible that longer-term follow-up is needed to identify physical health benefits of CBT, which may take time to develop and require continued use of CBT skills<sup>[49,50]</sup>.

Recent studies have explored telephone-based and web-based CBT interventions for improving psychosocial outcomes in patients with CVD. These studies have shown mixed but promising results. For example, a RCT of telephone-delivered CBT for post-ACS patients with depression found greater improvements in depression symptoms following CBT as compared to usual care, with effects maintained up to one year later<sup>[42]</sup>. A pilot study of web-based CBT for heart failure patients also found improvements in depression symptoms though there were no significant between-group differences<sup>[51]</sup>. In a study of post-transplant patients, however, telephone-delivered CBT was not found to be acceptable, and while patients who did participate showed significant reductions in anxiety and depression symptoms, most (67%) continued to show elevated scores<sup>[52]</sup>. Given that there is evidence of potential feasibility and efficacy, and mobile health interventions have the potential to improve access to mental health care for CVD patients<sup>[53]</sup>, further controlled studies should explore virtual CBT interventions

### **MI based interventions and their impact in CVD risk population**

An even more traditional approach to health behavior change is motivational interviewing (MI). Over 30 years of research have established MI, a patient-centered method for identifying and enhancing intrinsic motivation, as an effective and straightforward technique for promoting behavioral change<sup>[54,55]</sup>. MI is effective and can

be delivered remotely by different avenues with good fidelity<sup>[56,57]</sup>. MI interventions have led to improved health behaviors in patients with cardiac risk factors, including increased physical activity in patients with diabetes<sup>[58]</sup> and hypertension<sup>[59]</sup>. Additional studies have demonstrated improved medication adherence and significant reductions in systolic blood pressure in patients with hypertension<sup>[60-62]</sup>. Furthermore, a Cochrane review of MI for smoking cessation showed a modest but significant increase in quitting compared to usual care<sup>[63]</sup>. There are several ongoing trials assessing the potential of different MI-based interventions to improve other health behaviors and cardiac risk factors, including improving statin adherence in patients with hypercholesterolemia<sup>[64]</sup>, optimizing risk factors in patients undergoing cardiovascular procedures<sup>[65]</sup>, and comparing group-based to individual MI interventions in patients at high risk for CVD<sup>[66]</sup>. Although few interventions have used MI to modify sleep behaviors<sup>[67,68]</sup>, MI may be well-suited to address sleep in a manner similar to that used for other health behaviors. Further, despite MIs extensive use in research studies and clinical care, the effects of solely MI-based interventions for activity promotion in patients with T2D<sup>[58]</sup> and other major cardiac risk factors may not be significant enough to prevent CVD or major cardiac events, raising the possibility that additional interventions may be necessary in these patients.

## **NOVEL INTERVENTIONS TO TARGET HEALTH BEHAVIORS AND CARDIAC OUTCOMES**

### **Mindfulness and mind-body interventions**

Mindfulness and other mind-body interventions have

received increased attention for improving cardiac health behaviors and outcomes. Mind-body interventions encompass a range of techniques that aim to unite the body and mind to promote well-being, such as progressive muscle relaxation, meditation, yoga, and tai chi. Mindfulness is a specific approach that involves paying attention to present moment experiences with an attitude of openness, non-judgment, and curiosity<sup>[69]</sup>. A large body of research supports the efficacy of mind-body interventions, particularly mindfulness-based interventions that incorporate elements of CBT (*e.g.*, mindfulness-based stress reduction, mindfulness-based cognitive therapy) for improving a range of physical and mental health outcomes (*e.g.*, Hofmann *et al.*<sup>[70]</sup>, 2010).

Mindfulness-based interventions may improve cardiac health behaviors. Recent systematic reviews have concluded that mindfulness interventions promote smoking cessation<sup>[71]</sup> and healthy eating<sup>[72]</sup>. Evidence for improvements in sleep are somewhat limited, with a systematic review finding few randomized controlled trials and no significant between-group differences in sleep outcomes, but a significant correlation between amount of mindfulness meditation practice and improved sleep<sup>[73]</sup>. Subsequent RCTs, however, have found significant effects of mindfulness training on insomnia<sup>[74]</sup>. There has been less research using mindfulness-based interventions to promote physical activity, though there is some evidence to suggest that mindfulness training can increase physical activity in healthy young adults<sup>[75]</sup> and CVD patients<sup>[76]</sup>, and that the ability to be mindful during daily life in general (*i.e.*, trait mindfulness) might increase physical activity levels by making activity seem more satisfying<sup>[77]</sup>.

Mindfulness-based interventions have also been associated with improved health outcomes in patients with and at risk for CVD. Research suggests that mindfulness training can promote weight loss among patients with obesity<sup>[78]</sup>; improve disease management and HbA1c levels among patients with diabetes<sup>[79]</sup>; and improve coping and blood pressure in patients with hypertension<sup>[80]</sup>. A systematic review among individuals with CVD or other risk factors (*e.g.*, hypertension and diabetes patients) found significant improvements in stress, depression, anxiety, and quality of life following mindfulness interventions; however, similar to studies of CBT, effects on physical health outcomes were less consistent<sup>[49]</sup>. Among CVD patients specifically, a systematic review of 11 RCTs of mind-body practices found significant improvements in depression, anxiety, and QoL, though these studies were found to be of overall low quality<sup>[81]</sup>. Mindfulness-based interventions have also been integrated into cardiac rehabilitation programs<sup>[82]</sup>, and several studies suggest that meditation, tai chi, and yoga may be useful for improving health outcomes in heart failure patients<sup>[83-85]</sup>. Indeed, a systematic review of 29 trials (9 RCTs) found that tai chi is associated with reduced blood pressure and exercise capacity in patients with CVD and risk factors<sup>[86]</sup>. Further research on mind-body interventions for CVD risk

behaviors and outcomes is needed, though providers should be aware that existing mind-body approaches may be useful for cardiovascular outcomes.

### **Positive psychological interventions for health behavior and cardiac outcome improvement**

There has been increasing interest in the use of positive psychology (PP) interventions that aim to boost positive emotional experiences and cognitive processes through the use of simple tasks focusing on positive psychological constructs, such as optimism and positive affect. These positive constructs have been shown to correlate with improved adherence to cardiac health behaviors, such as physical activity<sup>[87,88]</sup>, diet<sup>[89,90]</sup>, and medication adherence<sup>[91]</sup>. They have further been associated with improved rates of heart disease and cardiac mortality<sup>[92-94]</sup>. Specific PP exercises found effective in medically healthy persons include recalling and discussing positive events, identifying and deliberately using personal strengths, and planning and performing acts of kindness<sup>[95,96]</sup>.

PP interventions are simple for patients and do not require extensive provider training, raising the attractive possibility of a cost-effective and efficient means of improving mood and cardiac health behaviors. Despite this, there has been limited study of PP-based interventions to promote health behaviors, improve sleep, or reduce cardiac events or mortality. PP interventions have been applied in studies of T2D<sup>[97]</sup> and immunodeficiency virus<sup>[98]</sup>, and a meta analysis has shown that their successful implementation leads to improvements in psychological outcomes<sup>[99]</sup>. Positive psychology interventions focused on gratitude have also promoted improvement in sleep hours and quality in patients with neuromuscular disease<sup>[100]</sup>.

Among patients with existing CVD, there is a small literature on PP interventions<sup>[101-103]</sup>, generally finding that such interventions are well-accepted and have beneficial effects on both positive and negative psychological states<sup>[101-106]</sup>. Additionally, randomized controlled trials of positive affect interventions have shown increased medication adherence in hypertensive patients<sup>[104]</sup> and improved physical activity in patients post-percutaneous coronary intervention<sup>[105]</sup>. Furthermore, combining PP with established health behavior interventions could provide additional benefit, building on the literature showing that PP exercises lead to increases in self-efficacy, confidence, and interpersonal connectedness<sup>[106-108]</sup> and findings that these same characteristics can improve engagement in health behavior interventions<sup>[109,110]</sup>.

### **Management of mental health conditions/care management**

Additional novel approaches to modifying health behaviors *via* mental health-related interventions may include care management programs for patients with psychiatric conditions. Depression and other psychiatric syndromes are common in patients with, or at risk for,

CVD<sup>[111,112]</sup>, and they can be identified *via* systematic screening in clinical cardiology settings<sup>[113]</sup>. Patients with depression and related conditions are at substantially elevated risk for nonadherence, including nonadherence to cardiac health behaviors<sup>[114-116]</sup>. Given the high prevalence and substantial impact of these psychiatric conditions, utilizing population-based interventions to efficiently manage these conditions is a promising approach to improving psychiatric symptoms, health behavior adherence, and overall cardiac risk in the greatest number of patients. For example, “collaborative care” interventions utilize a non-physician care manager (often a nurse) to assess and longitudinally monitor psychiatric conditions for patients in inpatient and outpatient medical settings<sup>[117,118]</sup>. The care manager can also provide psychotherapeutic interventions and support to patients, and receives psychiatric medication recommendations when indicated from a team psychiatrist. These medication recommendations are conveyed to primary care physicians, who then prescribe all medications. This allows a large number of patients to receive ongoing and expert management of psychiatric care, while maintaining such care within their existing medical home.

Collaborative care interventions have been found to be effective in improving psychiatric symptoms in over 90 prior trials<sup>[117]</sup>. This includes several prior trials in patients with CVD or cardiac risk factors (*e.g.*, diabetes)<sup>[118-124]</sup>, with beneficial effects on depression and/or anxiety symptoms. They have not typically included specific interventions to improve sleep or other health behaviors, and they have had more mixed effects on adherence, with some trials finding improvement in adherence to health behaviors (*e.g.*, diet, exercise, and medication adherence)<sup>[120,125]</sup>, while others have not measured effects on adherence or found no significant change. Effects on cardiovascular outcomes have similarly been mixed, though an analysis of the large IMPACT trial of collaborative care found that the intervention was associated with lower risk of cardiovascular events among those participants with no CVD at the outset of the trial<sup>[126]</sup>.

One promising approach to improving behavioral and cardiovascular outcomes is a “blended” collaborative care management approach that utilizes a nurse care manager to address depression, health behaviors, and medical targets (*e.g.*, blood pressure) in patients with medical illness. The TEAMCare randomized trial tested such an approach in patients with diabetes or coronary artery disease, and found that such an intervention led to improved medical outcomes, including hemoglobin A1c and blood pressure, using this combined psychiatric, behavioral, and medical approach<sup>[127]</sup>. The COMPASS project then implemented this intervention in 172 real-world clinics among 3609 patients<sup>[128,129]</sup>. Overall 40% had depression remission or response, one-quarter met criteria for control of blood glucose, and nearly 60% met criteria for blood pressure control, impressive findings for real-world implementation in a

complex population.

## CONCLUSION

The importance of sleep as a health behavior to lower the risk of CVD in adults has not been widely studied. With recent guidelines shedding light on the importance of adults maintaining adequate sleep (defined as at least seven hours) for optimal health and the growing number of Americans not meeting this recommendation, future research needs to include sleep when assessing CVD risk factors and intervention targets. Research to date has primarily focused on other health behaviors including diet, physical activity, and sedentary time. Many of these interventions have focused on one health behavior, rather than changing multiple behaviors, despite the fact that these behaviors tend to be inter-related. The same theories and intervention strategies used to change individual health behaviors, including CBT, MI, mindfulness and mind-body interventions, and PP-based interventions, could be adapted to promote all relevant health behaviors as we have outlined in this review. Further, moving toward blended collaborative care models may be a promising approach to improve health behaviors in those with psychiatric conditions. Such interventions that focus on psychological status, health behaviors, and medical targets may indeed hold substantial promise to modify sleep and other health behaviors to reduce cardiac risk.

### Abstract

Myocardial infarction (MI) remains the most common cause of heart failure (HF) worldwide. For almost 50 years HF has been recognised as a determinant of

adverse prognosis after MI, but efforts to promote myocardial repair have failed to translate into clinical therapies. Primary percutaneous coronary intervention (PPCI) has driven improved early survival after MI, but its impact on the incidence of downstream HF is debated. The effects of PPCI are confounded by the changing epidemiology of MI and HF, with an ageing patient demographic, an increasing proportion of non-ST-elevation myocardial infarction, and the recognition of HF with preserved ejection fraction. Herein we review the mechanisms of HF after MI and discuss contemporary data on its incidence and outcomes. We review current and emerging strategies for early detection of patients at risk of HF after MI, with a view to identification of patient cohorts for novel therapeutic agents.

**Key words:** Angioplasty; Heart failure; Myocardial infarction; Percutaneous coronary intervention; ST-elevation myocardial infarction

**Core tip:** Heart failure (HF) is a major cause of late morbidity and mortality after myocardial infarction. Several approaches exist for early identification of patients at risk of HF, including clinical and angiographic scoring, cardiac imaging, and invasive coronary physiology, but these are currently poorly integrated. Here we provide an overview of the incidence, mechanisms, and outcomes of HF following myocardial infarction in the era of primary percutaneous coronary intervention, and discuss HF risk-stratification for the individual patient. Looking ahead, accurate and early prediction of HF will allow targeting of novel therapeutic agents to high-risk patients before ventricular remodelling and clinical HF have become established.

in the era of primary percutaneous coronary intervention: Mechanisms, incidence and identification of patients at risk. *World J Cardiol* 2017; 9(5): 407-415 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/407.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.407>

## INTRODUCTION

Primary percutaneous coronary intervention (PPCI) has revolutionised the management and outcome of acute myocardial infarction (MI)<sup>[1,2]</sup>. It is the reperfusion strategy of choice throughout the developed world, with 90000 procedures performed annually in the United States alone<sup>[3,4]</sup>. Contemporary PPCI in the United Kingdom is characterised by door-to-balloon times of < 60 min, radial access, second generation drug-eluting stents and tailored use of antiplatelet and antithrombotic agents<sup>[5,6]</sup>. The introduction of PPCI and adjunctive therapies have driven a reduction in inpatient mortality following acute MI from 20% in the late 1980s to approximately 5%-7% in contemporary series<sup>[7,8]</sup>.

Despite this success, coronary artery disease remains the commonest cause of heart failure (HF)<sup>[9]</sup>. HF after MI is the major driver of late morbidity, mortality and healthcare cost. The effect of PPCI on the incidence of HF is debated, with studies confounded by the changing definitions and epidemiology of both MI and HF. Targeted therapies to prevent HF after MI have lagged behind advances in reperfusion, with Entresto (valsartan/sacubitril) the only novel pharmacotherapy for HF to enter the mainstream market in over a decade. Despite the evident burden of HF, many MI trials have predominantly focused on thrombosis, bleeding and composite endpoints [e.g., major adverse cardiac events (MACE)] rather than HF events specifically.

In this review we outline the challenge of HF following MI in contemporary practice. We provide an overview of the mechanisms and definitions of HF after MI, and the data on temporal trends in HF incidence from the pre-thrombolysis era through to the modern day. We review current and emerging strategies to identify patients at risk of HF, including coronary physiology, cardiac magnetic resonance and hybrid imaging, and suggest how improved mechanistic understanding of HF can be used to inform the next generation of clinical trials for these patients.

## DEFINING HF AFTER MI

HF is defined as "a clinical syndrome resulting from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill or eject blood"<sup>[10]</sup>. This has been translated into several validated diagnostic criteria (e.g., the Framingham criteria<sup>[11]</sup> and the European Society of Cardiology criteria<sup>[12]</sup>), but the primary definition of HF as a clinical syndrome has led to differing clinical, imaging and biomarker definitions

coexisting in clinical practice and research. Unlike MI, there is no "universal definition" and consequently, the diagnosis of HF is often heterogeneous between studies and over time<sup>[13]</sup>.

Early studies of HF following MI used clinical criteria such as the Killip and New York Heart Association classifications<sup>[14,15]</sup>. While crude, Killip class has retained prognostic value in more recent cohorts such as the GRACE registry: Patients in Killip class I had an in-hospital mortality of 3%, rising to 20% for those in class III<sup>[16]</sup>. In the PPCI population, higher Killip class at presentation is an independent predictor of in-hospital and 6-mo mortality<sup>[17]</sup>. Clinical HF scores were refined by the development of echocardiography, which led to objective measurement of ejection fraction and ventricular volumes as an intrinsic part of a HF diagnosis<sup>[18]</sup>.

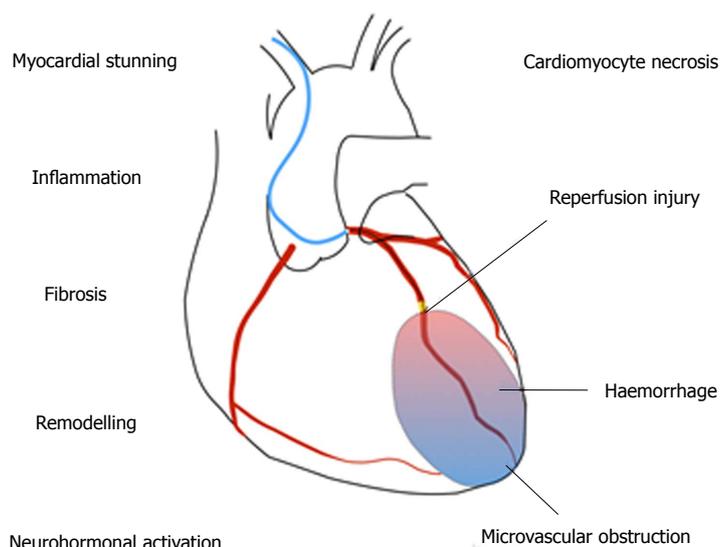

The timing of HF following MI is important clinically, mechanistically and for research. Three key time periods need to be distinguished: HF at the index MI presentation, during the course of the first admission, and after discharge. The timing of HF is often not well-defined by research studies, making comparison between studies challenging. From a statistical perspective, older studies failed to treat HF as a time-dependent, evolving covariate whose incidence was modifiable by the up-front treatment, meaning that late-onset HF after MI is less well characterised than HF at presentation<sup>[19]</sup>.

## PATHOPHYSIOLOGY OF HF AFTER MI

Several overlapping mechanisms contribute to HF after MI (Figure 1). HF during the index MI occurs due to a combination of myocardial stunning, myocyte necrosis, decompensation of pre-existing HF or acute mitral regurgitation due to papillary muscle dysfunction. HF during the hospitalisation may also be due to any of the above, compounded by fluid or contrast overload, renal dysfunction, or complications such as ventricular septal defect or cardiac tamponade. Late HF reflects the consequences of cardiomyocyte death and scar formation occurring alongside ventricular remodelling.

The cellular pathophysiology of MI has been clearly defined in animal models. Within 30 min of ischaemia, cardiomyocyte structural changes and oedema develop, leading to progressive cell death from three hours. Acute contractile dysfunction occurs due to oxidative stress and calcium overload, which is reversible if flow is restored<sup>[20]</sup>. Reperfusion itself causes a second wave of injury, by production of reactive oxygen species. Despite successful epicardial reperfusion, embolization of thrombotic debris, plugging by inflammatory cells and release of vasoactive mediators from damaged endothelium leads to ongoing microvascular dysfunction in up to 50% of patients<sup>[21]</sup>.

Myocardial injury leads to activation of a stereotyped inflammatory cascade, comprised of early neutrophil ingress followed by monocyte-macrophage infiltration.

**Figure 1** Mechanisms of heart failure after myocardial infarction.

Between days 3-5 following MI there is a transition from inflammation to repair, with activation of fibroblasts and progressive scar deposition<sup>[22]</sup>. Over time there is compensatory activation of the renin-angiotensin and sympathetic nervous systems and pathological remodelling, with changes to the ventricular geometry, wall thinning, ischaemic mitral regurgitation and further cardiomyocyte loss. The precise contribution of the different pathophysiological components (*e.g.*, microvascular dysfunction, inflammation) to injury is likely to be heterogeneous, and understanding mechanistic pathways in specific patient subgroups will be key to identifying novel therapeutic strategies<sup>[23]</sup>.

## TEMPORAL TRENDS IN HF AFTER MI

HF after MI was first described as an adverse prognostic feature by Killip in the 1960s<sup>[14]</sup>. HF was associated with large infarcts and multivessel disease, and the presence of impaired ventricular function was linked to worsening mortality<sup>[24,25]</sup>. Prior to thrombolysis, the incidence of in-hospital HF after ST-elevation myocardial infarction (STEMI) was approximately 40%<sup>[15]</sup>. This appeared to reduce after the introduction of thrombolysis, with HF present in approximately 3% of patients at presentation and 17% during admission<sup>[26]</sup>. Successful reperfusion was associated with improved LV function and long-term survival<sup>[27]</sup>. HF during admission remained an adverse prognostic feature, with 1-year mortality rates approximately 5 fold higher in those with HF<sup>[28]</sup>.

More recent studies have suggested a further reduction in HF rates with use of primary PCI. In an Italian cohort of 2089 MI patients treated exclusively by PPCI between 1995 and 2005, 17% presented in HF, but only a further 1% developed new onset HF during the hospital admission<sup>[29]</sup>. Similarly, in an analysis from the HORIZONS-AMI cohort of 3602 patients recruited between 2005-2007 treated with PPCI, 8.0% of patients

were in Killip class II-IV at presentation. At 30 d, only 4.6% of patients had developed a clinical HF syndrome (defined by NYHA/Killip class), rising to 5.1% at 2 years<sup>[30]</sup>.

These studies are not directly comparable, and reflect selected trial cohorts with a short duration of follow-up and differing methods of HF ascertainment. Several dedicated time trend analyses have now been performed. In Olmsted County, 1537 patients with an index MI between 1979 and 1994 were identified, spanning the introduction of thrombolysis in the late 1980s<sup>[31]</sup>. Over the study period the 5-year incidence of HF decreased from 40% to 33%. In a later study of 2596 MI patients between 1990 and 2010, there was increasing use of PPCI and a reduced risk of both early (0-7 d; HR = 0.67, 95%CI: 0.54-0.85) and late (8 d-5 years; HR = 0.63, 95%CI: 0.45-0.88) HF over time<sup>[32]</sup>. In patients with HF, mortality was higher for those with delayed vs early onset HF<sup>[33]</sup>.

A reduction in post-MI HF has also been seen in other studies. In a sample of 2.8 million MI hospitalisations (in Medicare beneficiaries) between 1998-2010, there was a reduction in the incidence of subsequent HF hospitalisation from 16 to 14 per 100 person-years<sup>[34]</sup>. In a Danish cohort, the incidence of HF at 90 d post-MI reduced from 24% to 20% alongside a an increase in PCI from 2.5% to 38% between 1997 and 2010<sup>[35]</sup>. Similarly, in Western Australia there was a reduction in the prevalence of HF at 90 d from 28% to 17% between 1996 and 2007<sup>[36]</sup>. Finally, in the SWEDEHEART registry of 19851 patients admitted with an MI between 1996 and 2008, there was a reduction in the incidence of clinical HF (albeit measured during the index hospitalization) from 46% to 28% alongside increasing use of PPCI<sup>[37]</sup>.

In contrast, data from Framingham Heart Study shows an increase in HF over time<sup>[38,39]</sup>. In 676 patients who developed a first MI between 1970 and 1999, both the 30-d and 5-year incidence of HF increased. At

Infarct size/characterisation		Salvage/repair

**Figure 2 Heart failure after myocardial infarction - strategies for prediction of infarct size and salvage.** BNP: B-type natriuretic peptide; CFR: Coronary flow reserve; CK: Creatine kinase; IMR: Index of microcirculatory resistance; LAD: Left anterior descending; MBG: Myocardial blush grade; MVO: Microvascular occlusion; PET: Positron emission tomography; PCI: Percutaneous coronary intervention; TIMI flow: Thrombolysis In Myocardial Infarction flow score; Tnl: Troponin I; WMSI: Wall motion score index.

5 years, the incidence of HF was 28% in 1970-1979 and 32% in 1990-1999, which remained significant after multivariate adjustment, with a risk ratio of 1.74 (95%CI: 1.07-2.84) for HF in 1990-1999 compared with 1970-1979<sup>[39]</sup>. Similarly, the Worcester Heart Attack Study showed an increasing incidence of HF between 1975 and 2001, and in the Alberta Elderly MI cohort, there was a 25% increase in the incidence of in-hospital HF between 1994-2000, from 31% to 39%<sup>[40,41]</sup>.

In the face of conflicting data from a relatively small number of studies, it remains difficult to draw firm conclusions on the impact of PPCI on the incidence of HF. There are key differences between studies in the definition of HF and MI, the validation of these diagnoses, the timing of ascertainment and the duration of follow-up. While the majority appear to suggest that PPCI is associated with reduced HF incidence, for many the duration of follow-up is short. Some studies have not differentiated between incident and prevalent cases. Reconciling these differences will require further studies with long term follow-up. If increasing survival from MI is leading to a rise in HF, this may only be seen in updated analyses, as interventionalists take on increasingly frail and elderly patients who previously were not surviving<sup>[42]</sup>.

## RISK STRATIFICATION FOR HF AFTER MI

Given the ongoing contribution of HF to morbidity and mortality after MI, early risk stratification and preventative therapeutic strategies are required. Although a number of clinical, angiographic, physiological, imaging and biomarker approaches to HF risk stratification following MI have been proposed (Figure 2), few are in routine clinical use. In addition to prognostication,

emerging hybrid imaging and coronary physiology approaches are shedding light on the mechanisms driving HF in different patient subgroups, and might also be used as early surrogate endpoints for trials. Given the historical failure of generic approaches targeting processes such as inflammation, it seems likely that tailored therapies for specific patient groups will be required.

### Clinical evaluation

Infarct size is the major determinant of downstream HF and prognosis<sup>[43]</sup>. Predictors of HF on admission are related to underlying LV function (*e.g.*, prior MI), markers of coronary artery disease severity (*e.g.*, diabetes mellitus) and features of an extensive infarct (*e.g.*, anterior location, increasing duration from symptom onset to reperfusion)<sup>[29]</sup>. Clinical predictors of late HF are of greater use for risk stratification. In the HORIZONS-AMI cohort, predictors of new-onset HF at 2 years were a history of MI (OR = 1.81, 95%CI: 1.22-2.67), ejection fraction (per 10% decrease OR = 1.35, 95%CI: 1.21-1.5), female sex (OR = 1.34, 95%CI: 1.1-1.51) and insulin-treated diabetes (OR = 1.68, 95%CI: 0.96-2.65)<sup>[30]</sup>. Similarly, in the CARE and VALIANT studies of MI survivors, predictors of late HF were age, diabetes, renal insufficiency, LVEF post-MI, and Killip class at index MI  $\geq 2$ <sup>[44,45]</sup>. A dedicated scoring system for prediction of late HF which integrated these parameters would be of value. Although not designed for HF events, the GRACE score, originally developed for ACS risk stratification, has recently been shown to predict late HF events after both STEMI and NSTEMI<sup>[46]</sup>.

### Coronary angiography and haemodynamics

Coronary angiography provides a number of patient-

specific markers for risk stratification, albeit often for MACE rather than HF specifically (Figure 2). The presence of multivessel disease and lack of normal flow in the infarct related artery are key adverse prognostic features after PPCI<sup>[47,48]</sup>. TIMI flow in the infarct related artery pre and post-procedure predicts outcome, with post-procedural  $\leq$  TIMI 2 flow associated with a HR of 3.8 (95%CI: 2.5-5.7) for 1-year mortality<sup>[49]</sup>. Impaired microvascular perfusion, assessed angiographically using the TIMI myocardial blush grade, also predicts 1-year mortality, which rises from 1.4% in patients with normal blush to 6.2% in patients with absent blush<sup>[50]</sup>. Patients with no-reflow have a higher incidence of arrhythmia, remodelling, HF and mortality<sup>[21]</sup>.

Recent attempts to categorise no-reflow have focused on the upstream causes, including distal embolisation of thrombus, new thrombus formation mid-procedure, and intraprocedural stent thrombosis, collectively badged as intraprocedural thrombotic events (IPTE). The incidence of IPTE was 12.2% in a recent STEMI cohort, with each IPTE component independently associated with 30-d death and MACE<sup>[51]</sup>. Beyond angiography, invasive hemodynamic measurement in the cath lab can provide further risk stratification: Measurement of LV end-diastolic pressure is an independent predictor of mortality at 2 years, even after adjustment for baseline LV function<sup>[52]</sup>.

### Coronary physiology

Invasive coronary physiology provides a highly sensitive readout of microcirculatory function, and has demonstrated significant value in prediction of myocardial recovery after MI. The index of microcirculatory resistance (IMR) is the ratio of distal coronary pressure to the inverse of the mean transit time during maximal hyperaemia. Measured after PPCI, IMR is a predictor of ejection fraction and infarct volume at 3 mo post-MI<sup>[53]</sup>. An IMR > 40 is associated with increased risk of death or rehospitalisation for HF (HR = 2.1,  $P = 0.034$ )<sup>[54]</sup>. IMR is now being used as a surrogate endpoint in ongoing trials of aspiration thrombectomy and intracoronary GpIIb/IIIa agents<sup>[55]</sup>. Hyperaemic microvascular resistance (HMR), another specific read-out of microcirculatory function, is also predictive of CMR-defined microvascular occlusion (MVO), and impaired local blood flow as measured by PET<sup>[56]</sup>.

Invasive measurement of coronary flow reserve (CFR), zero-flow pressure (Pzf), and fractional flow reserve (FFR) may also have a role in risk stratification following PPCI. CFR is the ratio of ratio of hyperaemic to resting coronary flow and incorporates both the epicardial and microvascular circulations. In 44 patients undergoing PPCI, the change in CFR between presentation and day 1 post-PPCI was predictive of the degree of myocardial salvage and ejection fraction at 6 mo<sup>[57]</sup>. Pzf, derived from pressure-velocity loop analysis, is the distal coronary pressure at which the flow in a coronary artery would theoretically cease and represents extra-vascular compression of the microcirculation by oedema

or haemorrhage. Pzf correlates with HMR, and also predicts residual scar at 6 mo post-MI with an AUC of 0.94<sup>[56,58]</sup>. FFR, the ratio of myocardial blood flow at maximal hyperaemia in comparison to normal proximal myocardial flow, is also predictive of adverse outcome, with an FFR of  $\leq 0.8$  associated with an HR of 3.24 for MACE<sup>[58]</sup>. The utility of coronary physiology in day-to-day practice, and the optimal index for HF risk stratification remains to be established.

### Imaging

Complimentary imaging modalities are providing increasingly detailed phenotyping of myocardial injury, function and healing. Standard echocardiographic indices including ejection fraction, LV volumes, wall motion score index, E/E' ratio and right ventricular function provide prognostic information after MI<sup>[59]</sup>. More recently, longitudinal and circumferential strain rate have been shown to be predictive of death or hospital admission for HF, with longitudinal strain rate adding significant incremental value in the prediction of all-cause mortality beyond clinical variables, LVEF, and wall motion score index<sup>[60]</sup>.

Cardiac MRI offers a broad armamentarium for tissue and functional characterisation, including quantification of the area at risk, infarct size, salvage index, microvascular obstruction, haemorrhage, heterogeneity and scar. Several indices are independently predictive of late outcome, including CMR-determined infarct size, myocardial salvage index and extent of microvascular obstruction<sup>[61-63]</sup>. In a study of 249 patients, CMR measurement of MVO was the strongest predictor of MACE over a 6-year follow-up<sup>[64,65]</sup>. CMR characterisation of infarct core characteristics, including identification of infarct haemorrhage (by T2W and T2\*) or native T1 signal, are recently-described predictors of adverse remodelling and clinical outcome<sup>[66-68]</sup>.

Combining metabolic imaging by <sup>18</sup>F-fludeoxyglucose (<sup>18</sup>F-FDG) with MRI has the potential to provide further characterisation of myocardial injury and repair. <sup>18</sup>F-FDG accumulates in monocyte-macrophages and other highly metabolically active tissues<sup>[69]</sup>. In a study of 49 patients hybrid <sup>18</sup>F-FDG PET-MRI was performed at a median 5 d following MI. The intensity of <sup>18</sup>F-FDG signal correlated with infarct size and predicted cardiac function at 6-9 mo follow-up. Interestingly, FDG signal remained an independent predictor after multivariate analysis, providing the first clue that imaging of inflammatory response can be used to risk stratify patients<sup>[70]</sup>. Recently, PET imaging of CXCR4, a receptor expressed on leucocytes and haematopoietic stem cells was demonstrated in human patients after MI. This type of approach holds great potential for understanding the biological heterogeneity in the healing response *in vivo*<sup>[71]</sup>.

### Biomarkers

Cardiac biomarkers such as troponin and BNP have established core use for the diagnosis of MI and HF,

and also demonstrate prognostic value for long-term outcome<sup>[72]</sup>. A recent study shows that combining serial measurement of traditional biomarkers (*e.g.*, NT-proBNP, hs-cTnT, aspartate transferase, alanine transaminase, lactate dehydrogenase and high-sensitivity C-reactive protein) gives an area under the curve of 0.85 for prediction of LV remodelling<sup>[73]</sup>. Looking forward, the field needs biomarkers which define specific biological groups at risk of HF who can be targeted with novel therapeutic agents. These might include biomarkers of inflammation, persistent fibrosis or matrix remodelling. There are data which highlight the potential value of measuring the inflammatory cascade for risk stratification: For example, the ratio of neutrophil:lymphocyte count predicts mortality after NSTEMI and STEMI, which may reflect the functional transition from inflammation to repair<sup>[74,75]</sup>.

There are a number of emerging potential biomarkers for future HF, including tenascin-C, myeloperoxidase, cytokines, matrix metalloproteinases and growth factors<sup>[76]</sup>. Tenascin-C is an extracellular matrix glycoprotein which is not normally expressed in the heart, but is upregulated following MI, or in myocarditis. In patients with acute MI, peak tenascin-C level measured at day 5 is independently predictive of LV remodelling, HF and MACE, and provides additive value to TIMI score and BNP<sup>[77,78]</sup>. Copeptin, the C-terminal portion of proavopressin, was the strongest marker of HF after MI from the OPTIMAAL study: A doubling of copeptin was related to a 1.83 fold (1.26-2.64) increased risk of mortality ( $P < 0.0001$ )<sup>[79,80]</sup>. Galectin-3 has shown some promise as a marker of matrix and fibrosis, but has not been found to be an independent predictor of LV remodelling<sup>[81]</sup>.

## CONCLUSION

HF remains a major challenge after MI. Despite the difficulties of interpreting incidence over time, HF indisputably drives much of the late mortality after successful revascularisation and therapeutic interventions to prevent HF in patients at high risk would be hugely valuable. Trials would be facilitated by consensus definitions for HF events and imaging endpoints (*e.g.*, oedema, myocardial salvage and remodelling). Given the long follow-up required for HF events, use of surrogate markers of HF risk (*e.g.*, IMR) could be used for early translational studies. To date, despite an attractive window of opportunity to target myocardial healing, therapies in this field have failed to translate. In part this may reflect divergent mechanisms of HF in different patients, with varying contributions from microcirculatory dysfunction, inflammation, haemorrhage, oedema and remodelling. Coronary physiology and CMR imaging can be used to identify discrete subsets of patients, for example those with MVO, for targeted therapies. For risk stratification, the optimal combination of predictive modalities needs to be defined. Looking ahead, there are three key questions: What is the risk of downstream HF, what mechanisms can be identified, and what therapies

can we trial?

### Abstract

In the last 25 years, the very existence of carotid artery stenting (CAS) has been threatened on a number of occasions. The initial disappointing results that even lead to the discontinuation of an early randomized controlled trial have improved considerably with time. Novel devices, advanced stent and equipment technology, alternative types of access and several types of filters/emboli protecting devices have been reported to reduce stroke/death rates during/after CAS and improve CAS outcomes. The present review will provide a description of the various technology advances in the field that aim to reduce stroke and death rates associated with CAS. Transcervical access, reversal of flow and mesh-covered stents are currently the most promising tools in the armamentarium of CAS.

**Key words:** Carotid artery stenting; Stroke; Carotid artery stenosis; Filters

**Core tip:** Carotid artery stenting (CAS) has improved considerably in the last few years. This comprehensive review provides the various technology advances in the field that aim to reduce stroke and death rates after CAS. These include transcervical access, reversal of flow and mesh-covered stents.

## INTRODUCTION

During its evolution, carotid artery stenting (CAS) has often gone through some difficult times. One of the first randomized controlled trials comparing CAS with carotid endarterectomy (CEA), the Leicester trial, had to be stopped prematurely after randomizing less than 20 patients<sup>[1]</sup>. All 10 patients that were randomized to CEA proceeded without complications. On the other hand, 5 of the 7 patients who were randomized to CAS suffered a stroke ( $P = 0.0034$ ), three of which were disabling at 30 d<sup>[1]</sup>.

Fortunately, CAS outcomes have improved considerably since then and continue to improve constantly. Technological advances such as proximal/distal embolic protection devices (EPDs), flow reversal, transcervical/transradial access and double layer mesh stent technology are adjuncts that have been developed to improve CAS outcomes. The current article presents an overview of these technological advances.

## EPDS

Proximal and distal EPDs are commonly utilized with CAS with the aim of preventing atherosclerotic debris from embolizing to the brain. Catheter manipulation within the aorta and supra-aortic arteries causes plaque embolization. Up to 90% of CAS procedures can be complicated by embolic events and EPDs may capture these embolized particles<sup>[2]</sup>. Although some studies report good outcomes for various distal EPDs (also known as filtering devices)<sup>[3-5]</sup>, others studies argue that distal filters may not be able to prevent all perioperative emboli<sup>[6-9]</sup>. The pore size of most available filter devices is  $> 80 \mu\text{m}$ <sup>[3]</sup>, but many emboli are  $< 80 \mu\text{m}$  in size<sup>[10,11]</sup>. Furthermore, due to the rigidity of many filter devices and a required minimal distal landing zone depending on the length of the basket of the filter device, the vessel wall apposition may not be optimal (especially in tortuous vessel segments) and could therefore allow cerebral embolization<sup>[12]</sup>. These studies have supported that, compared with distal EPDs, proximal EPDs reduce the perioperative microembolic signals detected by transcranial Doppler and the number of new ischemic lesions<sup>[6-9]</sup>.

A study from Milan, Italy compared the rate of cerebral microembolization during CAS with a proximal EPD [Mo.Ma system (Invatec, Roncadelle, Brescia, Italy);  $n = 26$ ] vs distal protection with a filter [FilterWire EZ (Boston Scientific Corporation, Santa Clara, California);  $n = 27$ ] in patients with high-risk, lipid-rich plaques<sup>[7]</sup>. Compared with use of the FilterWire EZ, the Mo.Ma system significantly reduced mean microembolic signal counts during lesion crossing (mean: 18 vs 2, respectively;  $P < 0.0001$ ), stent crossing (mean: 23 vs 0, respectively;  $P < 0.0001$ ), stent deployment (mean: 30 vs 0, respectively;  $P < 0.0001$ ), stent dilation (mean: 16 vs 0, respectively;  $P < 0.0001$ ) and total microembolic signals (mean: 93 vs 16, respectively;  $P$

$< 0.0001$ )<sup>[7]</sup>.

The Mo.Ma proximal EPD is a safe and effective neuro-protection system during CAS that achieves very low periprocedural stroke rates. A registry of 1300 patients undergoing CAS using the Mo.Ma device reported very low major adverse cardiac or cerebrovascular events including 5 deaths (0.38%), 6 major strokes (0.46%), 5 minor strokes (0.38%) and 0 myocardial infarctions (MIs)<sup>[13]</sup>. The incidence of postprocedural events did not increase even in the presence of theoretical anatomical contraindications to proximal endovascular occlusion (*e.g.*, contralateral carotid occlusion). The excellent results reported for the Mo.Ma device suggest that it is a promising technique for the achievement of low stroke rates after CAS.

A prospective randomized study, the Prevention of Cerebral Embolization by Proximal Balloon Occlusion Compared to Filter Protection During Carotid Artery Stenting study, compared the embolic load of filter-protected ( $n = 31$ ) vs proximal balloon-protected CAS ( $n = 31$ )<sup>[9]</sup>. Proximal balloon occlusion lead to a considerable reduction in the percentage of new cerebral ischemic lesions (45.2% vs 87.1%, for proximal balloon occlusion vs filter protection, respectively;  $P = 0.001$ ). Proximal balloon occlusion reduced both the number [median (range): 2 (0-13) vs 0 (0-4);  $P = 0.0001$ ] and the volume [0.47 (0-2.4)  $\text{cm}^3$  vs 0 (0-0.84)  $\text{cm}^3$ ;  $P = 0.0001$ ] of new cerebral ischemic lesions. Furthermore, contralateral hemisphere lesions were detected in 29.0% vs 6.5% of patients receiving a filter vs balloon occlusion, respectively ( $P = 0.047$ ). Finally, the 30-d major adverse cardiovascular and cerebral events rate was 3.2% for filter protection vs 0% for balloon occlusion, respectively ( $P = \text{not significant}$ )<sup>[9]</sup>.

A meta-analysis ( $n = 8$  studies; 357 patients) evaluated and compared the results of filter cerebral protection vs proximal balloon occlusion in preventing embolization during CAS as evaluated by diffusion-weighted magnetic resonance imaging (DW-MRI)<sup>[14]</sup>. The incidence of new ischemic lesions after CAS/patient detected by DW-MRI (effect size: -0.43; 95%CI: -0.84 to -0.02;  $I^2 = 70.08$ ;  $Q = 23.40$ ) and the incidence of contralateral site lesions (effect size: -0.50; 95%CI: -0.72 to -0.27;  $I^2 = 0.00$ ;  $Q = 3.80$ ) were both significantly lower in the proximal balloon occlusion group<sup>[14]</sup>. The results of this meta-analysis support the superiority of proximal balloon occlusion as compared with filter cerebral protection with respect to the degree of CAS-related brain embolization<sup>[14]</sup>.

Others, however, have supported that proximal EPDs have similar results with distal filter EPD<sup>[15]</sup>. The lack of difference in proximal occlusion vs distal filter EPD results was also verified in a meta-analysis<sup>[16]</sup>. This meta-analysis included 7 studies ( $n = 392$  patients; 193 with proximal occlusion; 199 with distal filters). The use of proximal occlusion vs distal filter did not reduce the risk of new cerebral lesions (OR = 0.65; 95%CI: 0.28-1.52;  $P = 0.32$ ) or the risk of death/cerebrovascular event (OR = 0.59; 95%CI: 0.22-1.60;  $P = 0.30$ )<sup>[16]</sup>. A more

recent meta-analysis verified the equipoise in clinical outcomes between proximal balloon occlusion and distal filter protection<sup>[17]</sup>. This meta-analysis ( $n = 18$  studies; 12281 patients) did not demonstrate any significant difference between the two modalities in terms of the risk of stroke or mortality, nor was there any difference in the incidence of new cerebral lesions on DW-MRI or contralateral DW-MRI lesions. The conclusion reached was that both proximal and distal EPDs provide similar levels of protection from periprocedural stroke and 30-d mortality<sup>[17]</sup>. Finally, a national cardiovascular data registry analysis from the United States compared stroke/death rates between proximal EPDs and distal filter EPDs in 10,246 consecutive elective CAS procedures. Both EPDs were associated with similar 30-d adverse event rates (2.7% vs 4.0%, after proximal vs distal filter EPDs, respectively;  $P = 0.22$ )<sup>[18]</sup>.

## TRANSCERVICAL ACCESS WITH FLOW-REVERSAL

The first description of flow reversal as a cerebral protection device was in 2000<sup>[19]</sup>. Although initially CAS with flow reversal was performed *via* the transfemoral approach<sup>[19]</sup>, a subsequent modification was the use of transcervical approach for CAS with flow reversal<sup>[20]</sup>. This technique is described in detail elsewhere<sup>[20]</sup>. Several independent studies have published very low 30-d stroke/death/MI rates and low incidence of complications for transcervical CAS with flow reversal<sup>[21-25]</sup>. It was recently demonstrated that transcervical CAS with flow reversal demonstrates embolization rates comparable with CEA<sup>[26]</sup>. Transcervical CAS with flow reversal thus seems a promising method for the reduction of strokes associated with CAS<sup>[27]</sup>.

Elderly patients (> 70 years) have inferior outcomes with transfemoral CAS compared with CEA<sup>[28]</sup>. The poor outcome of transfemoral CAS in this age group may be explained by the anatomic characteristics of the aortic trunk and supra-aortic vessels as well as by a high prevalence of aortic arch atheromatosis<sup>[21]</sup>. Transcervical CAS with flow reversal for cerebral protection avoids these unfavorable characteristics. An early study reported a 2.2% 30-d combined stroke/death/MI rates in 219 patients > 70 years of age (55.7% asymptomatic; 44.3% symptomatic)<sup>[21]</sup>. Symptomatic patients had a 5.1% combined stroke/death/MI rates whereas asymptomatic patients had a 0% rate<sup>[21]</sup>. Thus, transcervical CAS with flow reversal may be the preferred option for this age group.

Not long ago, the Reverse Flow Used During CAS Procedure (ROADSTER) multicenter trial reported its results from the evaluation of the safety and efficacy of the ENROUTE Transcarotid NPS (Silk Road Medical Inc, Sunnyvale, Calif), a novel transcarotid neuroprotection system that provides direct surgical common carotid access and cerebral embolic protection *via* high-rate flow reversal during CAS<sup>[29]</sup>. This study reported an

overall stroke rate of 1.4%, which is the lowest reported for any prospective multicenter clinical trial of CAS. The stroke/death rates (2.8%) and the stroke/death/MI rates (3.5%) reported were also similarly low<sup>[29]</sup>.

Direct percutaneous carotid access is an alternative access that has been described for CAS. This access can be used in individuals with difficult anatomies, high-risk patients and certain emergent situations that warrant easy and rapid access to the CCA<sup>[30]</sup>. A systematic review ( $n = 12$  studies; 739 CAS procedures) showed that direct CAS with transcervical access (filter protected or unprotected;  $n = 250$  patients) and CAS with transcervical access under reversed flow (with arteriovenous shunt in most cases;  $n = 489$  patients) are both associated with a low incidence of stroke and complications<sup>[31]</sup>. The incidence of stroke, MI and death was 1.1%, 0.14% and 0.41%, respectively. The incidence of stroke was 1.2% (3 of 250) in direct CAS with transcervical access and 1.02% (5 of 489) in CAS under reversed flow ( $P =$  not significant). Transient ischemic attack occurred in 20 patients (2.7%)<sup>[31]</sup>.

## HEAD-TO-HEAD COMPARISON/ COMBINATION OF STRATEGIES

Several studies have compared/combined the various proposed adjuncts to improve CAS outcomes in an attempt to identify those measures that would help improve CAS results to a greater extent. A study from Argentina compared transradial vs transfemoral CAS<sup>[32]</sup>. A total of 775 consecutive patients undergoing CAS during 16 years were included (101 transradial vs 674 transfemoral). The primary combined end-point was in-hospital major adverse cardiac and cerebral events, whereas secondary end-points included angiographic outcome after the procedure and cross-over rate to another puncture site. Angiographic success was achieved in all 775 patients. There was a significant difference in cross-over rate (4.9% vs 0%, for the transradial vs the transfemoral approach, respectively;  $P < 0.05$ ), but not in the incidence of in-hospital major adverse cardiac and cerebral events (2% vs 3.6%, for the transradial vs transfemoral approach, respectively;  $P =$  not significant)<sup>[32]</sup>. It was concluded that both approaches are safe and efficacious. These results verified the results of an earlier study<sup>[33]</sup>.

An earlier study from Atlanta, Georgia, United States compared revascularization outcomes after CEA ( $n = 226$ ) vs CAS with a distal filter EPD ( $n = 216$ ) vs CAS with a proximal flow reversal system ( $n = 53$ )<sup>[34]</sup>. The 3 groups did not differ in the overall composite end-point of death, cerebrovascular accident and MI (4% vs 5.1% vs 0%, respectively;  $P = 0.1$ ) or any individual major adverse event<sup>[34]</sup>. Overall, patients undergoing CAS with EPD had a greater incidence of minor cerebrovascular accidents than CEA patients (6 vs 1, or 3.4% vs 0.5%, respectively;  $P = 0.031$ ). This was driven by the increased risk for a cerebrovascular accident for

asymptomatic patients. Of note, patients undergoing CAS with flow reversal ( $n = 53$ ) had zero adverse events (minor/major stroke, MI or death)<sup>[34]</sup>.

A study from Japan evaluated the effectiveness of the combined use of distal filter protection device [FilterWire EZ (Boston Scientific, Natick, MA)] and the Mo.Ma Ultra (Medtronic, Minneapolis, MN)<sup>[35]</sup>. The Mo.Ma Ultra is an EPD for interrupting the antegrade blood flow to the internal carotid artery. This study demonstrated that the combined use of a distal filter protection device and Mo.Ma Ultra could provide a more reliable embolic protection in CAS<sup>[35]</sup>.

A study from Italy reported the outcomes of 214 patients undergoing CAS *via* a transradial ( $n = 154$ ) or a transbrachial ( $n = 60$ ) approach with either the Mo.Ma proximal protection ( $n = 61$ ) or the distal filter protection ( $n = 163$ )<sup>[36]</sup>. As a result of technical difficulties in catheterizing the target vessel, crossover to a femoral approach was required in 11 of 153 (7.1%) filter patients, but only in 1 of the 61 (1.6%) Mo.Ma patients. On the other hand, 5 Mo.Ma patients developed acute intolerance to proximal occlusion (4 were subsequently shifted to filter protection). One patient undergoing CAS *via* the transradial approach was shifted to filter because the Mo.Ma system was too short. Overall, CAS was technically successful in 55 of the 60 (90%) Mo.Ma patients and in 142 of the 154 (93%) filter patients. The 30-d major adverse cardiovascular/cerebrovascular events rate did not differ significantly between the 2 groups (0% for Mo.Ma patients vs 2.8% for filter patient;  $P = 0.18$ ). There was similarly no difference in radiation exposure between the 2 groups. Major vascular complications occurred in 1 of the 61 (1.6%) Mo.Ma patients and in 3 of the 153 (1.96%) filter patients, respectively ( $P = 0.18$ ). All these complications occurred during the early learning phase of the transbrachial approach. After a mean follow-up of  $8.1 \pm 7.5$  mo, chronic radial artery occlusion was detected by Doppler ultrasound in 2 of the 30 (6.6%) Mo.Ma patients and by clinical assessment in 4 of 124 (3.2%) filter patients ( $P = 0.25$ ). The conclusion reached was that CAS with proximal protection *via* a transradial or a transbrachial approach is a safe, feasible and effective technique with low rate of vascular complications<sup>[36]</sup>.

A study from Japan compared the effectiveness of the embolization prevention mechanism of 2 types of EPDs - a distal protection balloon ( $n = 82$  patients) and a distal protection filter ( $n = 82$  patients)<sup>[37]</sup>. Positive findings on postoperative diffusion-weighted imaging were found in more patients with distal protection balloon compared with the distal protection filter (34 vs 22 patients, or 41.4% vs 26.8%, respectively). Furthermore, in the distal protection balloon group there were more strokes than in the distal protection filter group (2 minor and 2 major strokes vs 0 strokes, respectively)<sup>[37]</sup>. A combination of flow reversal and distal filter may be more effective than either modality alone<sup>[38]</sup>.

Controversial results were reported in a small study from Brazil<sup>[39]</sup>. This study compared flow reversal vs filter protection in 40 patients undergoing CAS using a femoral approach. Compared with flow reversal ( $n = 21$ ), filter protection ( $n = 19$ ) resulted in a reduction in the incidence (15.8% vs 47.6%, respectively;  $P = 0.03$ ), number (0.73 vs 2.6, respectively;  $P = 0.05$ ) and size (0.81 mm vs 2.23 mm, respectively;  $P = 0.05$ ) of new ischemic brain lesions<sup>[39]</sup>. Flow reversal was associated with a tendency toward increased incidence of ipsilateral ischemic lesions more than those who had filter protection (70% vs 0.0%, respectively;  $P = 0.07$ ). In addition, flow reversal showed a greater tendency toward increased incidence of ipsilateral lesions than bilateral (70% vs 30%, respectively;  $P = 0.07$ )<sup>[39]</sup>. As the authors mentioned, this trial was the first to show better results using filter protection than a proximal protective technique during CAS. The authors attributed these good results to their considerable operator experience with CAS, the general anesthesia (which minimized the risk of movement accidents) and to the filter protection device profile<sup>[39]</sup>.

## ADVANCES WITH STENT DESIGN

Several important advances in stent design have also lead to improved CAS outcomes. For instance, the Inspire MD technology (Tel Aviv, Israel) includes a bare-metal stent (Inspire MD C-Guard stent) covered by a micron level mesh (MicroNet). Preliminary results appear encouraging<sup>[40]</sup>. A prospective multicenter study, the C-Guard CARotid Embolic protection using microNET trial evaluated the feasibility of the C-Guard carotid embolic protective stent system<sup>[41]</sup>. This is a novel thin-strut nitinol stent combined with a polyethylene terephthalate mesh covering. This study reported a 0% 30-d major adverse cardiac or cerebrovascular events rate in 30 patients<sup>[41]</sup>. Another stent that has demonstrated promising results is the double-layer CASPER-RX stent<sup>[42]</sup>. Finally, the Roadsaver Micromesh stent is a novel nitinol double-layer micromesh stent. Preliminary results from high-volume centres showing a low incidence of embolic events and new ipsilateral ischemic brain lesions are encouraging<sup>[43,44]</sup>.

During CAS, debris is often trapped in stent interstices. When flow is restored following CAS, the trapped debris may prolapse through the stent struts and result in delayed cerebral embolization<sup>[45]</sup>. Three companies (Roadsaver™ Micromesh Carotid Stent, Terumo, Japan; C-Guard™ MicroNet-Covered Embolic Prevention Stent System, InspireMD, Boston, MA, United States; and Scaffold Stent, W.L. Gore and Associates, Flagstaff, AZ, United States) are evaluating membrane or mesh covered carotid stents with smaller interstices to prevent such delayed strokes<sup>[45]</sup>.

The advances in carotid stent material and the new types of stents introduced in the market are beyond the scope of this review and are more extensively described elsewhere<sup>[46]</sup>.

## CONCLUSION

The battle for CAS is not lost<sup>[47]</sup>. The long-term results of the Carotid Revascularization Endarterectomy vs Stenting Trial did not show a significant difference in periprocedural stroke, MI or death and subsequent ipsilateral stroke between symptomatic and asymptomatic patients undergoing CAS or CEA<sup>[48]</sup>. Similarly, the Asymptomatic Carotid Trial demonstrated non-inferiority for CAS compared with CEA for asymptomatic patients with respect to the primary composite end-point of 30-d death, stroke or MI and ipsilateral stroke within 1 year<sup>[49]</sup>. New devices, membrane- and mesh-covered stents, alternative approaches and a combination of EPDs are tools in the armamentarium of CAS to improve its results. There is more to see in the future and we will all be awaiting the results of new trials incorporating the advances in CAS technology.

### Abstract

Ischaemic stroke is one of the commonest causes of morbidity and mortality worldwide and around a fifth of events can be attributed to a cardioembolic source. This is typically due to atrial fibrillation (AF), the most common sustained cardiac arrhythmia. However, AF can, at times, be difficult to detect due to a relative lack of symptoms and the fact that it can be paroxysmal in nature. Studies have shown that diagnosis of AF improves as the length of cardiac monitoring increases. However, prolonged cardiac monitoring is not a cost-effective way of diagnosing AF. Therefore, an alternative approach may be to empirically anticoagulate individuals who are at high risk of stroke. This article summarises current evidence surrounding stroke risk prediction, the use of anticoagulation in the secondary prevention of stroke and its use in the primary prevention of stroke in high risk groups with the aim of determining whether empirical anticoagulation is a safe and effective strategy.

**Key words:** Anticoagulation; Ischaemic stroke; Atrial fibrillation; CHA<sub>2</sub>DS<sub>2</sub>-VASc; CHADS<sub>2</sub>; Heart failure; Coronary artery disease; Peripheral arterial disease

**Core tip:** This is a contemporary review exploring issues related to the risk of stroke and use of anticoagulation in patients who are in sinus rhythm (SR). It examines the prediction of stroke in patients without known atrial fibrillation (AF), the identification of AF in patients following stroke and the use of anticoagulation in post-stroke patients seemingly in SR or those at high-risk of stroke. The main findings are: (1) prolonged cardiac monitoring increases the rate of AF diagnosis but is not cost-effective; (2) current risk stratification schemes such as CHA<sub>2</sub>DS<sub>2</sub>-VASc can identify those in sinus rhythm who are at risk of stroke; and (3) further research is required to determine whether individuals at high-risk of stroke would benefit from anticoagulation.

Empirical anticoagulation for patients in sinus rhythm at high risk of ischaemic stroke: A review of current literature. *World J Cardiol* 2017; 9(5): 422-428 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/422.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.422>

## INTRODUCTION

Ischaemic stroke is a leading cause of morbidity and mortality worldwide<sup>[1]</sup> and, following a first event, around a quarter of patients will go on to have a recurrent stroke<sup>[2,3]</sup>. Atrial fibrillation (AF), a common cause of stroke, is the most common sustained cardiac arrhythmia with an estimated prevalence approximately 3% in adults aged 20 years or older<sup>[4]</sup>, a figure that is expected to double over the next 50 years<sup>[5]</sup>. This arrhythmia carries a five-fold risk of stroke and patients who experience an AF-related stroke often suffer the most severe forms of the condition<sup>[6]</sup>.

Risk scores such as CHADS-2 and, more recently, CHA<sub>2</sub>DS<sub>2</sub>VASc have been developed in order to identify those patients with AF and an increased risk of stroke who would potentially benefit from anticoagulation. However, these risk scores are currently used only in patients with a confirmed diagnosis of AF, a condition which is underdiagnosed due to the fact it can be asymptomatic and paroxysmal. Therefore, given that 45% of all AF-related strokes occur in patients with previously undetected AF<sup>[7]</sup>, many more patients could potentially benefit from empirical anticoagulation therapy and there may be a role for using these risk scores in patients without known AF but with risk factors for developing stroke.

In view of the fact that AF can be difficult to detect, a number of studies have attempted to determine whether it is appropriate to give empirical anticoagulation to patients in sinus rhythm (SR) with risk factors for stroke. This article aims to summarise these studies and determine whether there are clinically relevant scenarios where anticoagulating patients in SR may be appropriate to reduce their risk of stroke.

## LITERATURE SEARCH AND METHOD

A Medline and Embase search was performed in August 2016 using the following terms: CHADS-2, CHA<sub>2</sub>DS<sub>2</sub>VASc, anticoagulation, vitamin K antagonist, warfarin, Coumadin, novel oral anticoagulant, direct oral anticoagulant, apixaban, eliquis, dabigatran, pradaxa, rivaroxaban, xarelto, edoxaban, lixiana, sinus rhythm, non-atrial fibrillation, normal heart rhythm, "without atrial fibrillation", stroke, cerebrovascular accident, cerebrovascular event, transient ischaemic attack (TIA), mini-stroke, heart failure, cardiac failure, left ventricular failure, left ventricular impairment, left ventricular dysfunction, impaired ventricle, coronary artery disease,

coronary heart disease, myocardial ischaemia, myocardial infarction, acute coronary syndrome, peripheral arterial disease and peripheral vascular disease.

## STROKE RISK PREDICTION IN A GENERAL POPULATION WITHOUT AF

In patients without known AF, risk assessment tools currently focus on overall cardiovascular risk rather than determining their specific risk of stroke. However, could risk scores such as CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc be used within this patient group to determine their cerebrovascular event risk?

An analysis of the Chin-Shan Community Cohort Study tested a number of risk stratification schemes which are currently used to predict thromboembolic risk in AF, including CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc, in a Chinese population without known AF<sup>[8]</sup>. This showed a modest predictive value of these risk stratification schemes in predicting stroke in non-AF patients with a C-statistic value ranging from 0.658 to 0.728, values which were broadly similar to those seen in an exploratory analysis of patients with AF within the same community.

Similar results were found in a meta-analysis performed by Santos *et al* who examined the use of the CHADS-2 score at predicting cerebrovascular events<sup>[9]</sup>. They found that CHADS-2 was able to identify patients at risk of stroke, regardless of whether AF was present or not.

More recently, Saliba *et al*<sup>[10]</sup> assessed the performance of CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc within a large Israeli population over a three year follow-up period. In individuals without AF, the C-statistic values were 0.718 and 0.714 for CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc respectively and in individuals with AF, the C-statistic values were 0.606 and 0.610 respectively. The authors concluded that these risk tools had a relatively high performance at predicting thromboembolism in patients without AF.

In all of these studies, the results suggest that current risk stratification schemes used in AF patients to predict thromboembolism could also be used in patients without AF as a screening tool to predict their risk of stroke. It remains unclear, however, as to whether anticoagulating these patients is a superior strategy to giving antiplatelet therapy.

## SECONDARY PREVENTION OF ISCHAEMIC STROKE/TIA

Around a fifth of ischaemic strokes are cardioembolic in origin<sup>[11]</sup> and these patients typically receive oral anticoagulants to reduce their risk of future events. However, around a third of ischaemic strokes are termed cryptogenic<sup>[12]</sup>, or without an attributable cause despite extensive work-up. The majority of these cases are likely to have an embolic mechanism and a significant proportion are likely to be related to undiagnosed AF.

**Table 1** Randomised control trials which show an increased yield of atrial fibrillation detection with extended cardiac monitoring

Ref.	Design	No. of patients	Inclusion/exclusion criteria	Type of monitoring	Outcome	Comments
Higgins <i>et al</i> <sup>[14]</sup> (2013)	RCT	100	Inclusion: Ischaemic stroke within 7 d; Exclusion: History of AF	7-d event recorder <i>vs</i> 24-h ECG (control)	Detection of AF: Sustained (> 20 s) and non-sustained (minimum 6 beats)	Sustained AF detected in 18% (control 2%); Non-sustained AF in 44% (control 4%)
Gladstone <i>et al</i> <sup>[15]</sup> (2014)	RCT	572	Inclusion: Cryptogenic stroke, Age ≥ 55 yr; Exclusion: History of AF	30-d triggered event recorder <i>vs</i> 24-h ECG (control)	Detection of AF (> 30 s)	AF detected in 16.1% (control 3.2%)
Sanna <i>et al</i> <sup>[16]</sup> (2014)	RCT	441	Inclusion: Cryptogenic stroke, Age ≥ 40 yr; Exclusion: History of AF	Insertable cardiac monitor <i>vs</i> Standard care (control)	Detection of AF (> 30 s)	At 6 mo, AF detected in 8.9% (control 1.4%) At 12 mo, AF detected in 12.4% (control 2.0%)
Brachmann <i>et al</i> <sup>[17]</sup> (2016)			Exclusion: History of AF (including 24-h ECG)			At 36 mo, AF detected in 30% (control 3.0%)

AF: Atrial fibrillation; RCT: Randomized controlled trial.

Ziegler *et al*<sup>[13]</sup> analysed data from patients at risk of thromboembolism (stroke/TIA) who had implantable cardiac devices capable of recording atrial arrhythmias. They identified newly detected episodes of atrial fibrillation/tachycardia in 28% of patients over a 1-year follow-up period.

Multiple studies have shown that the yield of detecting AF increases as the length of ambulatory monitoring increases (Table 1)<sup>[14-17]</sup>. A systematic review and meta-analysis performed by Dussault *et al* assessed the relationship between the duration of ECG monitoring and the incidence of AF detection in patients who had suffered a cerebrovascular event, using data from 31 studies<sup>[18]</sup>. They found that extending monitoring from 24 h to 30 d improved AF detection from 4.38% to 15.2% and if this monitoring was extended out to 180 d, detection rates increased to 29.15%.

Studies have also shown that in patients with implantable electronic devices, asymptomatic episodes of AF can be associated with an increased risk of thromboembolic events<sup>[19-25]</sup>, with a hazard ratio ranging from 2.2 to 9.4<sup>[26]</sup>. The length of each episode that is required to increase overall stroke risk varies in these studies, from a minimum of 5 min in the Ancillary MOde Selection Trial<sup>[19]</sup> to a maximum of 24 h in the Italian AT500 Registry<sup>[20]</sup>. At present, the episode duration and burden of asymptomatic AF that best predict future thromboembolic events are still matters of debate and need to be addressed by future studies.

A more recent systematic review performed by the Canadian Agency for Drugs and Technologies in Health examined not only the clinical effectiveness of cardiac monitoring in patients who had recently experienced a stroke or TIA, but also the cost effectiveness<sup>[27]</sup>. They showed that there was a substantial increase in the detection of AF when monitoring was performed for more than 24 h. Monitoring beyond 30 d increased this detection further although these improvements were modest. From an economic point of view, they

concluded that in patients who were admitted with a cerebrovascular event and did not receive in-patient continuous cardiac monitoring, 7 d cardiac monitoring was likely to identify significantly more cases of AF compared with current 24 h monitoring, with an acceptable increase in cost [CAN\$ 50000-80000/QALY (£ 28000-46000/QALY) gained]. Cost-effectiveness could be improved further by targeting stroke survivors who were relatively healthy and in whom there was a higher suspicion of underlying AF. However, they also concluded that extending monitoring beyond 7 d was unlikely to be cost-effective [ > CAN\$ 85000/QALY (>£ 49000/QALY) gained].

Current guidance continues to recommend long-term cardiac monitoring in patients who have a stroke with an undiagnosed cause with the AHA/ACC/HRS specifying at least 30 d. In view of the fact that this may not be cost-effective, would it be more appropriate to use current risk stratification schemes to identify those patients who may be at risk of further cerebrovascular events?

A trial by Ntaios *et al*<sup>[28]</sup> examined whether CHADS<sub>2</sub> and CHA<sub>2</sub>DS<sub>2</sub>VASc scores could be used to predict long-term outcomes in non-AF stroke patients. They divided patients into low, intermediate or high risk sub-groups, dependent upon their pre-stroke CHADS<sub>2</sub> and CHA<sub>2</sub>DS<sub>2</sub>VASc score. In both the CHADS<sub>2</sub> and CHA<sub>2</sub>DS<sub>2</sub>VASc sub-groups, they found that there were significant differences in stroke recurrence, cardiovascular events and 5-year mortality. They also demonstrated that compared with the low-risk sub-group, patients in the high-risk sub-group had a higher risk of stroke recurrence [CHADS<sub>2</sub>, hazard ratio (HR): 1.71; CHA<sub>2</sub>DS<sub>2</sub>VASc, HR: 2.93]. These results suggest that current clinical risk scores can be used to predict future events in patients who have had a stroke or TIA.

To improve the accuracy of these risks scores in post-stroke patients further, modification of certain variables may be helpful. Thijs *et al*<sup>[29]</sup> assessed

patients who had suffered a cryptogenic stroke or TIA and had an insertable cardiac monitor to determine whether there were specific factors which could predict the development of AF in this population. Following multivariate analysis, they found that increasing age [HR per decade 1.9 (1.3-2.8),  $P = 0.0009$ ] and PR interval prolongation [HR per 10 ms: 1.3 (1.2-1.4),  $P < 0.0001$ ] were independently associated with an increased incidence of AF. Therefore, in non-AF stroke/TIA patients, the addition of PR interval duration and placing further emphasis on age may help improve the accuracy of current risk scores.

Nevertheless, despite the fact that CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>-VASc may help to predict future events in non-AF stroke/TIA patients, more evidence is required to determine whether those within an intermediate or high-risk group should be offered anticoagulation.

## PRIMARY PREVENTION OF ISCHAEMIC STROKE/TIA IN SPECIFIC GROUPS

### Heart failure

It has long been established that heart failure (HF) is associated with an increased risk of thromboembolism and in particular, stroke. A systematic review performed by Witt *et al* analysed stroke rates in heart failure patients and found the risk of stroke to be 1.8% in the first year of HF diagnosis, rising to 4.7% at 5 years<sup>[30]</sup>. Multiple studies have attempted to clarify whether HF patients in SR would benefit from anticoagulant therapy. Initial trials suffered from poor recruitment and underpowered results and so it is not surprising that they failed to demonstrate an overall benefit of anticoagulation in this population<sup>[31-33]</sup>. One of these studies, the Warfarin and Antiplatelet Therapy in Chronic Heart Failure (WATCH) trial, did however show a significant reduction in non-fatal ischaemic strokes in patients on warfarin compared with aspirin or clopidogrel ( $P < 0.01$ )<sup>[33]</sup>. This was at the expense of a higher rate of major bleeding events.

More recently, the Warfarin vs Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial compared warfarin and aspirin in patients with HF in SR, using the primary endpoints of ischaemic stroke, intracerebral haemorrhage or death from any cause<sup>[34]</sup>. Although there was no overall difference in the combined primary endpoints between the two treatments ( $P = 0.4$ ), warfarin was associated with a significant reduction in the rate of ischaemic stroke (2.5% vs 4.7%,  $P = 0.005$ ) without a significant difference in the rate of intracerebral or intracranial haemorrhage ( $P = 0.82$ ). Once again, the rate of major bleeding was higher (warfarin 5.8% vs aspirin 2.7%,  $P < 0.001$ ).

One limitation of the WARCEF study was the time in therapeutic range (TTR) among patients in the warfarin group which was relatively low at 63% (high-quality warfarin treatment is defined as a TTR > 70%<sup>[35]</sup>). Low TTRs are strongly associated with adverse outcomes

such as major haemorrhage and thromboembolic events<sup>[35]</sup>. The higher bleeding risk with warfarin may, in part, be related to this low TTR. One solution to this could be use of direct oral anticoagulants (DOACs) which, in the absence of compliance issues, provide a much more consistent level of therapeutic anticoagulation. DOACs have already been shown to be non-inferior, and in some cases, superior to warfarin with respect to stroke and major bleeding risk reduction<sup>[36-39]</sup>. Further research exploring the use of DOACs in HF patients is needed to determine whether they can reduce thromboembolic risk without significantly increasing bleeding risk.

In terms of estimating stroke risk within HF patients without AF, current clinical risk scores have been assessed. A recent prospective cohort study investigated whether CHA<sub>2</sub>DS<sub>2</sub>-VASc could be used to predict the risk of ischaemic stroke in HF patients without AF<sup>[40]</sup>. It performed moderately at predicting ischaemic stroke at 1- and 5-year follow-up (C-statistics 0.67 and 0.69 respectively) and performed well at identifying those at low risk of ischaemic stroke with a negative predictive value of 92%. Additionally, the authors found that those with a CHA<sub>2</sub>DS<sub>2</sub>-VASc score of  $\geq 2$  had a stroke risk of > 1% per year. To put this into context, patients with AF are typically offered anticoagulation once their annual stroke risk exceeds 1%. This would suggest that the CHA<sub>2</sub>DS<sub>2</sub>-VASc score may have a use in identifying those HF patients without AF who are at risk of stroke. Whether these patients would gain benefit from anticoagulation remains to be seen and clinical trials are needed to clarify this.

### Coronary artery disease

Coronary artery disease (CAD) has been identified as an independent risk factor for stroke<sup>[41]</sup> and co-existent vascular disease, such as coronary or peripheral artery disease, is present in around 40% of stroke patients<sup>[42]</sup>. Studies have previously examined the addition of warfarin to antiplatelet therapy in patients with acute coronary syndrome (ACS). These were performed in an era before the widespread use of dual antiplatelet therapy. A meta-analysis of the studies found that the addition of warfarin led to reduction in major adverse cardiovascular events {MACE: death, non-fatal MI, non-fatal ischaemic stroke; [OR = 0.73 (0.63-0.84),  $P < 0.0001$ ]} but this was at the expense of an increased risk of major bleeding [OR 2.32 (1.63-3.29),  $P < 0.00001$ ]<sup>[43]</sup>. As a result, anticoagulation is not routinely given to patients following ACS. However, a proportion of these patients will be at significant risk of thromboembolic events and if a clinical risk score could accurately identify this sub-group, they might well benefit from anticoagulation.

A prospective registry study by Mitchell *et al*<sup>[44]</sup> assessed the accuracy of CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>-VASc at predicting cerebrovascular events in non-AF patients who had suffered an ACS. They found that the incidence of stroke increased with increases in each risk score and

that a CHADS-2 score  $\geq 3$  or a CHA<sub>2</sub>DS<sub>2</sub>VASc score  $\geq 4$  was associated with an annual stroke incidence of  $\geq 1\%$ . Both CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc performed moderately at predicting ischaemic stroke [C-Statistics (0.68 and 0.71 respectively)].

Similar results were found in a prospective cohort study which assessed the accuracy of CHADS-2 at predicting cerebrovascular events in non-AF patients who had stable CAD<sup>[45]</sup>. Those with a CHADS-2 score of 2-3 had a 2.7 times higher rate of stroke and those with a CHADS-2 score of 4-6 had a 4.6 times higher rate of stroke. They concluded that stable CAD patients with a CHADS-2 score of 5-6 had a comparable stroke rate to AF patients with a CHADS-2 score of 2-3, the level at which anticoagulation is felt to be beneficial.

In both of these studies, cerebrovascular events occurred despite antiplatelet therapy. They indicate that in patients with CAD, high CHADS-2 or CHA<sub>2</sub>DS<sub>2</sub>VASc scores can predict those at risk of stroke or TIA. These patients may therefore benefit from the addition of anticoagulation and further studies are required to clarify this.

### Peripheral arterial disease

The presence of peripheral arterial disease (PAD) is a significant predictor of stroke and in one study was found to be present in 14.4% of major ischaemic strokes and 8.9% of minor ischaemic strokes<sup>[46]</sup>. Warfarin has also been evaluated for the use in this patient group. A meta-analysis which assessed the use of anticoagulation in PAD patients provided inconclusive results<sup>[47]</sup> and led to the development of the Warfarin Antiplatelet Vascular Evaluation (WAVE) Trial<sup>[48]</sup>. This compared oral anticoagulation plus antiplatelet therapy vs antiplatelet therapy alone. They found no significant difference in MACE events (relative risk: 0.92; 95%CI: 0.73-1.16;  $P = 0.48$ ). However, those receiving combination therapy had a significantly higher rate of major bleeding rate (4.0%), compared with in those receiving antiplatelet monotherapy (1.2%). There is some evidence that patients undergoing vein graft bypass surgery gain benefit from warfarin monotherapy<sup>[49]</sup> and this is the only sub-group of PAD patients in which anticoagulation is currently indicated.

To date, there is only one trial which has examined the use of clinical risk scores to predict thromboembolic events in patients with PAD. Yang *et al*<sup>[50]</sup> assessed the accuracy of CHADS-2 and CHA<sub>2</sub>DS<sub>2</sub>VASc in predicting 5-year cumulative ischaemic stroke risk in PAD patients. They found that each increase in the risk scores led to an increased stroke risk, and both scores performed well at predicting 5-year cerebrovascular events (C-statistics 0.92 for CHADS-2, 0.862 for CHA<sub>2</sub>DS<sub>2</sub>VASc). In multivariate analysis, each increment of the CHADS-2 or CHA<sub>2</sub>DS<sub>2</sub>VASc score was associated with around a three-fold increase in stroke risk.

As with CAD, current risk scores appear to be able to identify those PAD patients who are at high-risk of cerebrovascular events and this sub-group may also

benefit from anticoagulation therapy. More clinical evidence is required to confirm this.

## CONCLUSION

Cerebrovascular disease remains one of the leading causes of death throughout the world. Those that survive are commonly left with serious long-term disability and are at an increased risk of recurrent events. AF is a common cause of stroke/TIA but because the arrhythmia can be paroxysmal and asymptomatic, it remains a challenge to detect. Long-term ambulatory monitoring has not been shown to be a cost-effective way of diagnosing the arrhythmia. Additionally, the duration of AF which represents an increased risk of thromboembolism is still to be determined.

An alternative strategy is to use current risk stratification schemes such as CHADS-2 or CHA<sub>2</sub>DS<sub>2</sub>VASc. There is evidence to suggest that these scores can identify those at significant risk of thromboembolic events, not only in the general population but more specifically in those that have suffered a cerebrovascular event or have co-existent HF, CAD or PAD.

At present, it remains unclear as to the most appropriate way of treating these high-risk patients once they have been identified. With the dawn of DOACs, which can provide a more steady-state of anticoagulation and potentially have a better bleeding profile, there are now therapeutic options which may benefit high-risk groups. Future trials should use risk scores to identify high-risk groups in a variety of clinical settings to determine whether anticoagulation therapy can reduce the burden of cerebrovascular disease.

### Abstract

Implantable cardioverter defibrillator (ICD) programming

involves several parameters. In recent years antitachycardia pacing (ATP) has gained an increasing importance in the treatment of ventricular arrhythmias, whether slow or fast. It reduces the number of unnecessary and inappropriate shocks and improves both patient's quality of life and device longevity. There is no clear indication regarding the type of ATP to be used, except for the treatment of fast ventricular tachycardias (188 bpm-250 bpm) where it has been shown a greater efficacy and safety of burst compared to ramp; 8 impulses in each sequence of ATP appears to be the best programming option in this setting. Beyond ATP use, excellent clinical results were obtained with programming standardization following these principles: extended detection time in ventricular fibrillation (VF) zone; supraventricular discrimination criteria up to 200 bpm; first shock in VF zone at the maximum energy in order to reduce the risk of multiple shocks. The MADIT-RIT trial and some observational registries have also recently demonstrated that programming with a widespread use of ATP, higher cut-off rates or delayed intervention reduces the number of inappropriate and unnecessary therapies and improves the survival of patients during mid-term follow-up.

**Key words:** Implantable cardioverter defibrillator programming; Antitachycardia pacing; Ventricular tachycardia; Electrical antitachycardia therapy

## INTRODUCTION

The efficacy of implantable cardioverter-defibrillator (ICD) in reducing sudden death and total mortality is well documented<sup>[1]</sup>, initially in secondary prevention<sup>[2-4]</sup>, more recently also in primary prevention<sup>[5,6]</sup>. In particular, two big trials, MADIT II<sup>[5]</sup> and SCD-HeFT<sup>[6]</sup>, helped to define high risk patients after a myocardial infarction (MI) or with heart failure (HF) associated with reduced left ventricle ejection fraction.

These studies showed that the overall survival rate was higher in patients with ICD compared with those who received conventional medical therapy<sup>[5,6]</sup>.

In the last decade, ICD implants have grown exponentially<sup>[7]</sup>, leading manufacturers to heavily invest in this field to improve therapies and develop sophisticated algorithms with high sensitivity and specificity for arrhythmias discrimination. Once detected, the ICD can treat ventricular arrhythmias with high-energy shocks or antitachycardia pacing (ATP).

Although ICDs are usually well accepted by most patients, there are several clinical reports of anxiety and depression after implantation<sup>[8,9]</sup>. Quality of life can, in fact, be negatively influenced when receiving painful shocks, especially if multiple<sup>[10]</sup>. The main benefit of ATP therapy, from the patient's point of view, is to avoid painful shocks; actually, ATP is rarely noticed by patients and therefore well tolerated. Moreover, battery life of the device is extended if the high-energy shock therapy is avoided. Even more important, it has also been demonstrated that shock therapy is associated with a higher risk of mortality compared to ATP sequences only<sup>[11]</sup>.

With the increase in ICD indications, the choice of an optimal device programming, both for discrimination and therapy, is becoming increasingly important. A critical analysis of the most important clinical studies in this field is crucial in order to achieve an effective and safe therapy that improves patient's outcome without adversely affecting quality of life.

## WHAT IS ATP?

ATP consists of one or more trains of pacing stimuli

(usually 8 impulses for each train) conventionally expressed as a percentage of the tachycardia cycle length for a given RR interval, from the onset of the preceding R wave. Pace stimulation delivered at very short coupling intervals (*i.e.*, < 84%) is more likely to enter a reentrant circuit but also accelerate the arrhythmia. Unlike shock therapy, the locations of the ICD generator and shocking coils do not affect ATP efficacy. ATP is usually delivered from the right ventricular apex (RVA), but efficacy is similar also when pacing from outflow tract. ATP from RVA is less effective in terminating ventricular tachycardia (VT) with a basal exit site<sup>[1]</sup>.

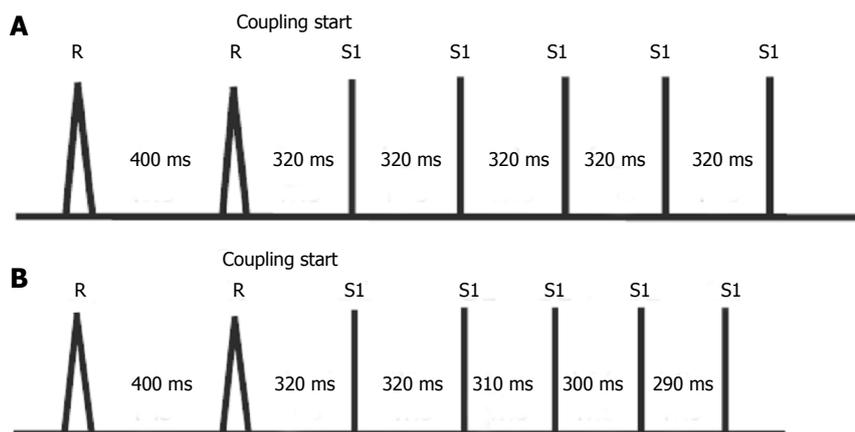

The rationale for ATP efficacy relies on the fact that monomorphic VT can be interrupted with appropriately timed pacing stimuli delivered into the excitable gap of a reentrant circuit. The chance of arrhythmia interruption depends on several factors: The conduction time from pacing stimulus site to the reentrant circuit; the duration of the excitable gap; the presence of anatomic/functional barriers; the state of the sympathetic nervous system. For example, beta-blockers drugs increase the duration of excitable gap, thus increasing ATP efficacy<sup>[10]</sup>.

VT with spontaneous RR interval variability are more likely to be ATP responsive, while those with greater variation in QRS morphology are less responsive. This is the reason why polymorphic VT and ventricular fibrillation (VF), usually lacking an organized reentry, are rarely interrupted by pacing.

ICDs allow delivering different ATP therapy types, in particular the two most important are: (1) burst with impulse trains at constant coupling in a programmable number; and (2) ramp with autodecremental coupling (Figure 1).

## WHEN SHOULD WE PROGRAM ATP?

Schaumann *et al.*<sup>[12]</sup>, in 1998, evaluated whether ATP could be safely used even in those patients in whom ATP testing on induced VT was not performed. All devices were programmed with the same ATP scheme in the VT zone (< 200 bpm): 3 ramps from 8 to 10 impulses, with 8 ms decrease and 81% coupling. The study enrolled 200 patients divided in two groups: The first included subjects in whom efficacy of ATP was demonstrated on sustained VT induced in the electrophysiology laboratory (Tested group); in the second group ATP was programmed empirically (Empirical group). During the follow-up period (20 ± 11 mo) ATP therapy proved to be highly effective in both groups. In particular, success rate was 95% in the T group and 90% of the E group. Moreover, this study provided a strong response to one of the most frequent criticisms to pacing therapy, the risk of tachycardia acceleration. Acceleration after ATP occurred only in 2% in group T and 5% in group E. The conclusions of the study were, therefore, that the success rate of ATP therapy was not dependent on efficacy testing and ATP was recommended for VT

**Figure 1** Examples of antitachycardia pacing patterns. A: Burst with 5 impulses and coupling at 80%; B: Ramp with 5 impulses, coupling at 80% and with a 10 ms decrease.

treatment in any patient with ICD.

During the 90s other studies were published about the efficacy and the safety of the ATP therapy. These studies reported that ATP sequences successfully interrupted 78%-94% of slow VT (< 188 bpm), with an acceleration rate between 2% and 4%<sup>[13-15]</sup>. Based on these results the ATP was conventionally programmed only for slower VT, presumably hemodynamically well tolerated.

Fast VTs (from 188 to 250 bpm) were, instead, still treated like VF, with high energy shocks. Faster VTs have a shorter excitable gap that is more difficult to be penetrated and interrupted by a pacing stimulus.

Nevertheless, in 2001, Wathen *et al.*<sup>[16]</sup> with the PainFREE Rx I trial showed, for the first time, that ATP therapy was also effective for fast VT (FVT). This trial, however, had many limitations: Only patients with coronary artery disease were included; it was nonrandomized; ICDs were programmed with a short detection interval (12 of 16 beats), which could imply that many treated arrhythmias were non-sustained VTs, destined to run out on their own.

In 2004, the same authors published a prospective, single-blinded trial, the PainFREE Rx II<sup>[17]</sup>, which exceeded the limits of the first study. This trial enrolled 637 ICD patients randomized to ATP ( $n = 315$ ) or shock therapy ( $n = 322$ ) to evaluate episode duration between the two arms (primary endpoint). Baseline clinical variables were similar between the 2 groups, in particular age (average, 67 years), ejection fraction (average, 32%), sex (male 77%), coronary artery disease (85%), syncope (35%). Both groups received similar pharmacological therapies. Primary prevention indication for ICD involved 44% of patients. Fast VT was defined as a zone between 240 and 320 ms (188-250 bpm); faster rates were considered as VF. In the first group the initial therapy in the FVT zone was ATP (8 impulses burst at 88% of arrhythmia cycle length), while in the second group shock was directly delivered at the defibrillation threshold (DFT) + 10 J. The detection for FVT, as well as for VF, was 18 of 24 beats. The

first important result was that the FVTs represented 76% of all ventricular arrhythmias. In the ATP group the bursts resulted effective in 77% of the FVTs; when it failed, shocks were effectively delivered to interrupt the arrhythmia. There was no significant difference between percentage (and number) of patients who had fast VT in either the ATP or shock arms (15% vs 16% respectively). In addition, after accounting for 2 patients in the ATP arm who together had 131 episodes, numbers of fast VT in the ATP and shock arms were similar (151 vs 144, respectively). Moreover, there was no significant difference in episode duration between the shock and ATP arms (10 s vs 9.7 s, respectively). Not all patients with fast VT episodes received shock therapy in the shock arm (only 67% of episodes being shocked) and 30% of fast VT episodes self-terminated after detection. In comparison, only 20% of patients in the ATP arm received shocks. The acceleration was rare, with 2% incidence in the ATP arm and 1% the shock arm. Syncopal events were also low and comparable between the two groups. It is interesting to note that the success rate of the first shock (92%) was identical in both groups, even if delivered after an ineffective ATP. In conclusion, this study showed that ATP therapy was safe and effective compared to shocks also for the treatment of FVT, with a 70% relative reduction of shocks in the ATP group.

After these studies, scientific community started to consider ICDs as stimulation devices with a defibrillation backup, only as a security option, with a consequent improvement in patient's quality of life. It is noteworthy that these trials used bursts coupled to 88% of arrhythmia cycle: This was a "little aggressive" therapy, so the risk of arrhythmias acceleration was low<sup>[18]</sup>.

In order to avoid significant delays in the delivery of shock therapy (in case of ATP failure) algorithms of ATP sequences during or before capacitor charging were soon implemented in the VF zone for most manufacturers; this strategy has been subsequently clinically validated as safe and effective<sup>[11]</sup>.

## WHICH PATTERN OF ATP SHOULD BE PREFERRED?

The importance of the ATP therapy in the context of ICD programming is well documented, but we should understand if there is a specific pacing pattern to prefer, especially in relation to the type of ventricular arrhythmia.

Several studies comparing the efficacy of two different types of ATP pattern (burst and ramp) on induced VTs did not show significant differences in the percentage of success: Gills *et al.*<sup>[19]</sup> reported 76% efficacy for burst and 68% for ramp in a study with 21 patients enrolled; Calkins *et al.*<sup>[20]</sup> reported a success rate of 70% for burst and 72% for ramp (44 patients); Kantoch *et al.*<sup>[21]</sup> reported a 69% success for burst and 72% for ramp in 31 patients. The rate of acceleration was low and did not change significantly between the two patterns.

Burst vs Ramp were evaluated also in the setting of spontaneous VTs: Gills *et al.*<sup>[19]</sup> found, in this case, a success rate of 96% for burst and 93% for ramp; Ardashev *et al.*<sup>[22]</sup> reported 61% efficacy for burst and 76% for ramp with 54 patients enrolled. The latter study, therefore, was the only indicating a significant difference in efficacy between the two techniques ( $P < 0.01$ ), in favor of the ramp.

Overall, from the analysis of several studies, there was not a clear difference in the efficacy of burst and ramp for treatment of non-FVT, in ischemic and non-ischemic cardiomyopathies. The choice of the pattern was, therefore, left to the clinician's experience and to an empirical case-by-case approach<sup>[18]</sup>. An important exception is represented by patients with arrhythmogenic right ventricular dysplasia: The success rate of ramp fell down to 25%, with an acceleration rate of 24%, while the burst resulted in a better outcome<sup>[22]</sup>.

Different considerations have to be made for FVT in which burst seems to be better. The PITAGORA ICD<sup>[23]</sup> trial was a randomized Italian study that aimed to compare two ATP strategies (burst and ramp) in terms of efficacy, arrhythmia acceleration and syncope on FVT episodes. Two hundred and six patients were randomized into two groups, with two different therapies: 88% coupling-8 impulses burst vs 91% coupling-8 impulses ramp with 10 ms decrement. The FVT zone was programmed between 188 and 250 bpm, with a detection of 18 of 24 beats. The study demonstrated that burst was significantly more effective than ramp (75% vs 54%;  $P = 0.015$ ) to interrupt FVT episodes. Regarding safety, burst was associated with a lower percentage of acceleration compared to ramp (2% vs 7%), although this difference was not statistically significant. The overall incidence of syncope was 1%. The adopted strategy, with ATP as the first therapy and prolonged detections (18 of 24 compared to 12 of 16), allowed the end of the arrhythmic episode before shock delivery in 81% of the cases<sup>[23]</sup>.

In 2010, the results of the trial ADVANCED-D<sup>[24]</sup> were

published. This study aimed to compare 8 impulses burst with 15 impulses burst on FVT. Nine hundred and twenty-five patients were enrolled and randomized into two groups treated with the two different sequences of ATP. The window of FVT remained between 188 and 250 bpm and detection 18 of 24 beats. No significant difference was detected between the two sequences, 8 pulses burst terminated 64% of episodes compared to 70% of 15 pulses burst. Moreover, there were not significant differences also regarding syncope or rate of acceleration. The sequence of 15 pulses was more effective only in patients with no history of HF ( $P = 0.014$ ) and with left ventricular ejection fraction  $> 40\%$  ( $P = 0.016$ ). The conclusion of the study was that an ATP sequence of 15 pulses can be considered effective, but also safe, in FVT comparable with a sequence of 8 pulses.

## ATP IN BIVENTRICULAR ICD

Thanks to the coronary sinus lead which stimulates the left ventricle, cardiac resynchronization therapy devices equipped with a cardioverter defibrillator (CRTD) offer the potential for alternative sites for ATP. The possibility to deliver therapy from either the left ventricular lead (LV-ATP) or the left and the right ones simultaneously (BiV-ATP) may theoretically increase the rate of success compared to right ventricular stimulation (RV-ATP). Several studies reported an increased efficacy of BiV-ATP configuration compared to the RV-ATP for termination of VT events both slow and fast<sup>[25]</sup>. However, the ADVANCED CRT-D<sup>[26]</sup> trial demonstrated a significant superiority of BiV-ATP only in ischemic patients with FVTs. Moreover, few papers compared LV-ATP with the other configurations. In this context, a study by Haghjoo *et al.*<sup>[27]</sup> compared efficacy and safety of the three ATP therapy sites (RV, LV and BiV) for VT treatment in patients with a CRTD device. The study enrolled 89 patients (with ischemic and non-ischemic etiologies) divided into 3 groups with 3 different pacing sites during ATP. The mean follow-up was 38 mo with 259 detected VT episodes in 46 patients. The results showed: (1) greater efficacy of BiV-ATP compared to both LV-ATP and RV-ATP for the treatment of FVT (188-250 bpm); (2) higher success rate and lower acceleration rate of both LV-ATP and BiV-ATP compared to RV-ATP for slower VTs ( $< 188$  bpm)<sup>[27]</sup>. Therefore, left ventricular lead allows further possibilities to increase the success of ATP; in patients with CRTD it is recommended to set either biventricular or left ventricular ATP therapy for the slowest therapy zone ( $< 188$  bpm), while biventricular ATP should be programmed for faster arrhythmias.

## THE STANDARDIZATION OF THE ICD PROGRAMMING

The therapeutic programming of an ICD involves several

parameters. It is worthwhile to understand if a strategic standardized choice can be as effective and safe as a patient-tailored programming, which is inevitably time-consuming for the physician. Indeed, the customization of the ICD setting is useful only if it provides improvements in clinical outcomes or in patient's quality of life; otherwise both the simplification and the standardization of the therapy can be convenient and minimize the risk of random errors.

In this framework, EMPIRIC trial<sup>[10]</sup> randomized 900 patients with ICDs (48% implanted for primary prevention, 52% for secondary prevention) to a standardized (EMPIRIC group) or a physician-tailored (TAILORED group) VT/VF programming and followed them for 1 year. The EMPIRIC programming (Table 1) was created by taking into account some key strategies to safely reduce the number of shocks for VT/VF and supraventricular tachycardias (SVTs) and to avoid untreated slow VT: (1) three attempts of ATP for VT < 200 bpm. In particular, 2 burst of 8 intervals coupled at 88% with 20 ms decrement and 1 ramp of 8 intervals coupled at the 81% with 10 ms decrement; (2) a sequence of ATP for FVT between 200 bpm and 250 bpm. In particular, 1 burst of 8 intervals coupled at the 88% (as in the PainFREE Rx II); (3) long detection time (18 out of 24) in VF and FVT (as in the PainFREE Rx II, PITAGORA ICD e ADVANCED-D trials); (4) first shock at the maximum energy in VF and FVT zones to reduce the risk of multiple shocks; and (5) discrimination criteria for SVT in the VF zone.

The results of the study reported no significant differences in the number of deaths, syncope events and arrhythmias acceleration between the two groups of patients. Moreover, the rate of hospitalization was significantly lower ( $P = 0.001$ ) in the EMPIRIC group<sup>[10]</sup>. The overall ATP efficacy was 92%; consequently, a significant reduction of VT shocks was reported in the EMPIRIC group compared to the TAILORED group ( $P < 0.001$ ). It is interesting to observe that the EMPIRIC group had a threshold for the VT zone of 150 bpm, value which is lower than the average in the TAILORED group (171 bpm). Nevertheless, the study did not show an increase of the SVTs inappropriately treated, thanks to the discrimination algorithms. To conclude, EMPIRIC study entails that a simplified and standardized programming is possible, without reducing efficacy and safety of the therapy.

The PREPARE study<sup>[1]</sup> analyzed a different standardized setting with the aim of reducing shocks occurrence, syncopes and untreated symptomatic VT in patients with ICDs for primary prevention<sup>[28]</sup>. The PREPARE programming was developed on the basis of some key strategies: (1) to detect only fast tachycardias (> 182 bpm); (2) to discriminate only sustained tachycardias (discrimination set to 30 of 40 in the FVT and FV zones); (3) to deliver ATP as the first therapy for FVT; (4) to always deliver the high-energy shock (at least 30 J); and (5) to use discrimination criteria for SVT up to 200 bpm.

The PREPARE programming (Table 2) provided a lower mortality ( $P = 0.01$ ) compared to a control cohort of patients from the EMPIRIC<sup>[10]</sup> the MIRACLE ICD (Multicenter InSync Implantable Cardioverter Defibrillators Trial) studies. The extension of the detection duration (30 out of 40 beats), fast rate cutoffs for the therapy (182 bpm), the use of SVT discrimination criteria reduced the number of shocked episodes. Moreover, at 12 mo follow up the incidence of syncopal events was 1.6% and mortality 4.9%. This study demonstrated how a strategically chosen tachycardia detection and conservative therapy options, can make the device more acceptable by the patient without negatively affecting its efficacy and safety.

In 2012 a large randomized multicenter study, Multicenter Automatic Defibrillator Implantation Trial-Reduce Inappropriate Therapy (MADIT-RIT)<sup>[29]</sup>, was published in the New England Journal of Medicine. The aim of this study was to test two ICD programming strategies in patients with an ICD implanted for primary prevention. In particular, the first strategy was characterized by therapies only for high heart rates (> 200 bpm) while the second was to increase of the detection delay duration before the initiation of therapies, with values variable in relation to the heart rate (60 s delay for rates between 170 bpm and 199 bpm, 12 s delay for rates between 200 bpm and 249 bpm, 2.5 s delays for higher rates). As explained by the authors, the MADIT-RIT study was based on the hypothesis that these two strategies would have reduced the number of patients receiving appropriate and inappropriate shocks and ATPs, compared to a conventional programming, without increasing mortality and morbidity. The study involved 98 centers in the United States, Canada, Europe, Israel and Japan, enrolling a total of 1500 patients with either ischemic or non-ischemic heart disease and indicated for implantation of an ICD or a CRTD in primary prevention. Patients with atrial fibrillation were excluded. The first episode of inappropriate therapy represented the primary endpoint of the study: This outcome was evaluated by comparing each treatment group with the control group. The rates of both syncope and mortality (for any cause) were secondary endpoints. A significant reduction in the risk of any inappropriate therapy was observed in the two groups with "unconventional" programming in a follow-up of 1.4 years: The results showed a 79% relative risk reduction for patients with "High-Rate Therapy" and a 76% risk reduction for those with "Delayed Therapy" (HR of "High-Rate therapy" vs conventional therapy: 0.21, 95%CI,  $P < 0.001$ ; HR of "Delayed Therapy" vs conventional therapy: 0.24, 95%CI,  $P < 0.001$ ). Another significant result of the MADIT-RIT regarded one of the secondary endpoints of the study. The "High-Rate Therapy" programming reduced the risk of death from any cause (HR = 0.45,  $P = 0.01$ ) by a factor of 55% compared to conventional therapy. The group with "Delayed Therapy" showed a 44% reduction of the mortality risk, but it did not reach statistical significance compared to the conventional therapy group (HR = 0.56,

**Table 1** EMPRIC programming

Detection	Threshold (bpm)	Beats to detect	Therapies
VF	250	18 out of 24	30 J × 6
FVT	200	18 out of 24	1 × burst, 30 J × 5
VT	150	16	2 × burst, 1 × ramp, 30 J × 3

Burst: 8 impulses coupled at the 88% with 20 ms decrement; Ramp: 8 intervals coupled at the 81% with 10 ms decrement. VF: Ventricular fibrillation; FVT: Fast ventricular tachycardia; VT: Ventricular tachycardia.

$P = 0.06$ ). Concerning syncopal episodes, no difference among the three groups was observed.

Recently, the OBSERVational registry on long-term outcome of ICD patients<sup>[30]</sup> confirmed, in a “real world setting”, the results of MADIT-RIT trial. OBSERVO-ICD was a multicenter, retrospective, registry enrolling (from 2010 to 2012) all consecutive patients undergoing ICD implantation in 5 Italian centers. The aim of the study was to test whether a too aggressive ICD programming could be associated with electrical storms (ES). A total of 1319 patients were enrolled, both primary and secondary prevention. During follow up (median 39 mo) 4.7% of patients experienced at least 1 ES episode. Patients with ES presented with significantly lower VF detection zone ( $P = 0.002$ ), more frequently had ATP therapies during capacitor charging programmed off ( $P = 0.001$ ), and less frequently had delayed therapies for VT zone ( $P = 0.042$ ) and VF zone ( $P = 0.036$ ). Patients with ES had a significantly higher incidence of death and HF-related death compared to patients with no VTs and patients with unclustered VTs/VFs ( $P = 0.025$  and  $P = 0.001$ , respectively). In conclusion, patients with less aggressive ICD programming (higher VF detection rates, higher detection times, ATP therapies during capacitor charging turned on) had a decreased likelihood of ES and lower risk of death.

## CONCLUSIONS AND “TAKE HOME MESSAGES”

ATP is a safe, effective and painless therapy for VTs with large clinical evidence supporting its routine use in primary and secondary ICD patients<sup>[31,32]</sup>.

ATP therapy is effective in interrupting VTs, both slow and fast, with a consequent reduction of unnecessary shocks and an improvement of clinical outcome, patients’ quality of life and device longevity<sup>[12,16,17,31]</sup>.

In a recent expert consensus document on ICD programming, from the most important world leading arrhythmological societies<sup>[32]</sup>, it was stated that “in all patients with structural heart disease... that ATP therapy be active for all ventricular tachyarrhythmia detection zones to include arrhythmias up to 230 bpm, to reduce total shocks except when ATP is documented to be ineffective or proarrhythmic”.

In patient with inherited cardiac channelopathies

**Table 2** PREPARE programming

Detection	Threshold (bpm)	Beats to detect	Therapies
VF	250	18 out of 24	30 J/35 J × 6
FVT	182	18 out of 24	1 × Burst, 30 J/35 J × 6
VT	167	32	Off

Burst: 8 impulses coupled at the 88%. VF: Ventricular fibrillation; FVT: Fast ventricular tachycardia; VT: Ventricular tachycardia.

(Brugada syndrome, Long and Short QT syndrome, catecholaminergic polymorphic VT, early repolarization syndromes) the index clinical arrhythmia is polymorphic VT or VF: These arrhythmias usually lack an organized reentry and are rarely interrupted by pacing, so ATP should not be routinely programmed<sup>[31,32]</sup>.

As concerns the type of ATP to be used, clear conclusions cannot be drawn, except for the treatment of fast TV (188 bpm–250 bpm) for which greater efficacy and safety of burst was showed compared to ramp<sup>[23,31,32]</sup>. So, as a first choice, it is indicated to program burst in preference to ramp. Ramp should be reserved for patients in whom burst fails and ramp is proven to be effective. A “little aggressive” burst programming (several studies used impulses coupled at the 88%) seems to be related to lower rates of arrhythmia acceleration<sup>[18]</sup>. Moreover, the optimal number of impulses in each sequence of ATP has been proved to be minimum 8<sup>[24,32]</sup>.

In patients with biventricular devices the lead placed in the coronary sinus offers further opportunities for a successful ATP therapy, due to biventricular pacing (ATP-BiV) or left ventricular only pacing (LV-ATP)<sup>[25-27]</sup>.

In the last years, a great effort has been devoted to standardize the ICD programming, particularly in the primary prevention. Two studies provided excellent results in this field: EMPERIC<sup>[10]</sup> and PREPARE<sup>[1]</sup>. The fundamental principles of these programming strategies were: (1) prolonged detection for the VF zone (18 out of 24 and 30 out of 40); (2) delayed detection time in any window; (3) SVT discrimination criteria up to 200 bpm; (4) ATP as first therapy for FVT; and (5) first shock at maximum energy in the VF zone to reduce the risk of multiple shocks.

The MADIT-RIT<sup>[29]</sup> trial and the OBSERVO-ICD registry<sup>[30]</sup> have recently confirmed this programming philosophy, showing that higher cut-off rates, more prolonged detections and ATP during capacitor charging reduce the number of inappropriate and unnecessary therapies compared to a more “conventional” programming. This reduction translates in a better clinical outcome in terms of morbidity and even mortality. The results of these studies add new chapters in the development of the ICD therapy, especially in primary prevention patients.

More studies are needed, instead, in a secondary prevention setting to design effective ATP strategies. Secondary prevention patients can represent an

opportunity to a more “tailored” approach compared to primary prevention, on the basis of the knowledge of arrhythmia history (ECG morphology, cycle length, arrhythmia mechanism, patient’s tolerance, hemodynamic impact)<sup>[31]</sup>. In patients with prior known VTs the device must be programmed to cover all clinical arrhythmias; slower monomorphic and better tolerated VTs should be treated with at least 2-3 sequences of ATP and at least 8 impulses. A second burst of ATP increases efficacy from 64% to 83% in FVT range, although programming > 2 bursts usually does not add further benefit<sup>[31,32]</sup>.

## Abstract

### AIM

To investigate the characteristics and outcomes of octogenarians who presented with ST-elevation myocardial infarction (STEMI) compared to non-octogenarians and to investigate the outcomes of octogenarians that received primary percutaneous coronary intervention (PCI) compared to those managed conservatively.

### METHODS

We performed a single center retrospective case controlled study. All octogenarians who presented with STEMI to a tertiary referring hospital between 2007 and 2012 were included. The subsequent non-octogenarian patient who presented with a STEMI following the octogenarian patient was assigned to the control group in a 1:1 manner. The outcomes measured were peri-procedural cardiac arrest, death on table, cerebrovascular accidents (CVA), in-hospital and 30-d mortality.

### RESULTS

A total of 146 patients were analyzed. The octogenarian group had a higher percentage of females, higher overall comorbidities, higher Charlson Comorbidity Index score, worse renal function and were more likely to require residential care and home help. The octogenarian group were also less likely to have PCI attempted and had a longer symptom onset to PCI

time. Mortality rate was high amongst octogenarians who presented with STEMI. However, those managed conservatively had a higher in-hospital and 30-d mortality rate

### CONCLUSION

Octogenarians who presented with STEMI that were managed conservatively had a higher mortality rate compared to those who had primary PCI. Therefore, we propose that revascularization may be beneficial to patients in this age group.

**Key words:** Coronary disease; Acute coronary syndrome; Myocardial infarction; Percutaneous coronary intervention; Aged 80 and over

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The octogenarian group represents a complex population with multiple comorbidities. Percutaneous coronary intervention in this group is challenging and is associated with a high rate of failure and complications. This study shows that the mortality rate amongst octogenarians presenting with ST elevation myocardial infarction is high. However, there may be a mortality benefit in those treated with percutaneous coronary intervention, compared to those managed conservatively.

Sim WL, Mutha V, Ul-Haq MA, Sasongko V, Van-Gaal W. Clinical characteristics and outcomes of octogenarians presenting with ST elevation myocardial infarction in the Australian population. *World J Cardiol* 2017; 9(5): 437-441 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/437.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.437>

## INTRODUCTION

Advanced age is associated with increased risk of acute coronary syndrome (ACS) and cardiovascular comorbidities<sup>[1]</sup>. The octogenarian population (age  $\geq$  80 years) is a fast growing segment of the population worldwide, and represent a high risk group for procedural complications during percutaneous coronary intervention (PCI) particularly in the settings of ST-segment elevation myocardial infarction (STEMI)<sup>[2]</sup>. These patients are underrepresented in randomized clinical trials evaluating primary PCI for STEMI and a high mortality has been reported<sup>[3,4]</sup>. These patients are typically treated less aggressively than are younger patients, due partly to the increased risk of adverse events and PCI related complications, and partly to a lack of standard management guidelines. Evidence based management of octogenarian patients with STEMI thus remains suboptimal despite the high mortality<sup>[2]</sup>. The overseas observational trials have suggested that despite the recommendations being

that age should not influence the decision of reperfusion strategy in STEMI patients, older age remains one of the strong predictors of not receiving it. There is paucity of Australia data on outcomes of octogenarian who present with STEMI. In this context, the aim of our study was to assess the clinical characteristics and outcomes of octogenarians presenting with STEMI, as compared with non-octogenarian patients (age < 80 years), as well as the outcomes of octogenarians who received primary PCI, compared to those that were managed conservatively.

## MATERIALS AND METHODS

This study is a single center retrospective case controlled study including all octogenarians who presented with STEMI between 2007 and 2012 in a tertiary Australian hospital. The subsequent non-octogenarian patient who presented with STEMI following an octogenarian STEMI was assigned to the control group in 1:1 manner. Detailed data on baseline and procedural characteristics and patient comorbidities were obtained through electronic medical records, and compared between octogenarian and non-octogenarian STEMI patients. The charlson comorbidity index (CCI) was calculated based on the patient's comorbidities. CCI predicts long-term survival according to a patient's medical condition<sup>[5]</sup>. STEMI was defined as persistent angina for 20 min in conjunction with either: (1) an ST-segment elevation at the J point of 0.25 mV in men aged < 40 years or 0.2 mV in men aged > 40 years or 0.15 mV in women in the precordial leads V2 to V3, and 0.1 mV in all other leads; or (2) the presence of a new left bundle branch block<sup>[6]</sup>. PCI success was defined as TIMI 2 or 3 flow post intervention. Left ventricular ejection fraction (EF) was derived either from the echocardiogram performed following the presentation or coronary angiogram during the index admission. Outcomes compared between the two groups included peri-procedural cardiac arrest, death on table, cerebrovascular accident (CVA), in-hospital and 30-d mortality. CVA was defined a clinical evidence of neurological deficit leading to a documented diagnosis of transient ischaemic attack or stroke. Subgroups of octogenarian STEMI patients who received PCI vs who did not (conservatively managed) were also compared for baseline and clinical characteristics. In-hospital and 30-d mortality was compared between all subgroups and independent predictors calculated.

All data were analyzed using IBM SPSS v22 and presented as percentages or mean value  $\pm$  standard deviation (SD). Independent *t* test was used to compare continuous while  $\chi^2$  and Fisher's exact tests were performed for categorical data. Logistic regression and multivariate analysis were performed to identify independent predictors. A two tailed *P* value of < 0.05 was considered statistically significant. The statistical methods of this study were reviewed by our biostatistics expert Dr. Asrar Ul-Haq, MBBS.

## RESULTS

### Octogenarians vs non-octogenarians

A total of 146 patients were analysed (octogenarians = 73; non-octogenarians = 73). The mean age was 85.2 ± 4.1 years in the octogenarian group and 67.1 ± 5.3 years in the control group (Table 1). The octogenarian group had a higher percentage of females (56% vs 29%, *P* < 0.005), higher overall comorbidities, a higher CCI score (3.2 ± 2.3 vs 1.7 ± 2.2, *P* < 0.001), were more likely to require residential care (23% vs 2.7%, *P* < 0.001) as well as home help (25% vs 0%, *P* < 0.001), and had worse renal function (eGFR 48.7 ± 19.9 vs 68.1 ± 20.3 mL/min per 1.73 m<sup>2</sup>, *P* < 0.001).

Octogenarians were less likely to have PCI attempted compared to the non-octogenarians (47% vs 84%, *P* < 0.001). The rate of symptom onset-to-PCI of < 6 h was significantly lower in octogenarians (16% vs 45%, *P* < 0.001). The rate of PCI success was high in both groups (91% vs 99%, *P* = 0.1). Reasons PCI was not attempted in non-octogenarians include: No culprit found (3), embolic event (1), recent CVA (1), known or new triple vessel disease/complex anatomy (2), other comorbidities (5); and in octogenarians: No culprit found (9), embolic event (2), recent CVA (4), known or

**Table 2** Baseline characteristics and outcomes of octogenarians who received percutaneous coronary intervention compared to conservatively managed octogenarians (no-percutaneous coronary intervention)

	PCI (n = 34)	No-PCI (n = 39)	P

Outcomes			
Inhospital mortality	18	37	0.1
30-d mortality	29	59	< 0.05

Data are means ± SD or n (%). LLC: Low level care; HLC: High level care; PVD: Peripheral vascular disease; EF: Ejection fraction; PCI: Percutaneous coronary intervention; MI: Myocardial infarction.

new triple vessel disease/complex anatomy (13), other comorbidities (11). Octogenarians had a significantly higher overall in-hospital mortality (28% vs 7%, *P* < 0.005) and 30-d mortality (45% vs 12%, *P* < 0.001).

The independent predictors of 30-d mortality in octogenarians included age (OR 1.20/year of advancing age, *P* < 0.01), place of residence (OR = 4.4, *P* < 0.01 for nursing home), conservative management (No intervention - OR 2.77, *P* < 0.05), and declining renal function (OR = 0.9, *P* < 0.05).

### PCI vs conservatively managed octogenarians

The 39 (53%) octogenarians who did not receive PCI were older (86 ± 4.3 years vs 84 ± 3.4 years, *P* < 0.05) and were more likely to be in residential care (41% vs 3%, *P* < 0.001), had higher CCI score (3.8 ± 2 vs 2.52 ± 2, *P* < 0.05) and worse renal function (eGFR 44 ± 16 mL/min vs 54 ± 23 mL/min per 1.73 m<sup>2</sup>). Type of myocardial infarction was not different as compared to octogenarians who received PCI (Table 2).

Mortality rate was high among octogenarians who presented with STEMI. However, those who were managed conservatively had a higher in-hospital and 30-d mortality (37% vs 18%, *P* = 0.1; and 59% vs 29%, *P* < 0.05 respectively).

Independent predictors of intervention in octogenarians included younger age (OR = 0.86, *P* < 0.05), place of residence (OR = 0.1, *P* < 0.05 for nursing home), lower CCI (OR = 0.7, *P* < 0.05), and renal

function (OR = 1.03,  $P < 0.05$ ).

## DISCUSSION

### **High mortality**

Our study demonstrated that mortality rate amongst octogenarians presenting with STEMI is high in Australian population despite the offered treatment, although much worse when treated conservatively. This appears to be associated with higher overall comorbidities, higher CCI score, worse renal function, and need for residential care or home help (which maybe the indirect measure of overall comorbidities and physical state). These findings are consistent with overseas studies looking at similar age groups<sup>[7-9]</sup>. Some factors reported to affect the mortality in these studies include heart failure, multiple co-morbidities, cachexia, cognitive state, history of intra-cranial bleeding and pre-hospital physical activity status<sup>[10,11]</sup>. Furthermore, it has been shown that the elderly are less likely to receive evidence based medical treatment such as aspirin, clopidogrel, beta-blockers, statins or glycoprotein IIb/IIIa inhibitors<sup>[7,8]</sup>. This may be due to concerns with regards to potential side effects in this age group. Previous studies have also shown that the elderly is associated with a higher rate of PCI failure. However, this is not reflected in our study, likely because the candidates for treatment were carefully selected.

### **Underuse of invasive treatment**

Our study suggested that despite having a higher mortality rate, octogenarians are less likely to have PCI attempted as compared to non-octogenarians. Frailty, co-morbidities and time delays have been shown to contribute to the underuse of invasive therapies. In our study, the proportion of those who received PCI in less than 6 h was significantly lower in the octogenarian group. This might reflect difficulty in decision-making with regards to reperfusion strategy. Atypical clinical presentation is also more common in the elderly and could contribute to time delay as well as the higher prevalence of cardiac failure. In addition, female gender was more prevalent in the octogenarian group. Previous studies have shown that female gender is associated with lower use of invasive therapies, especially in the elderly<sup>[12]</sup>.

### **Invasive treatment appears beneficial**

Another major finding of our study is that despite a relatively poor prognosis, octogenarians who received primary PCI had a significantly lower 30-d mortality. This however maybe related to the selection bias, a limitation of observational study design. Patients managed conservatively in our study were older, more likely to be in residential care, had a higher CCI score and worse renal function, and this represents a group with higher risk profile. The most common reasons PCI was not performed in the elderly were triple vessel disease/complex anatomy, other co-

existing comorbidities and the absence of a clear culprit lesion. There was no significant difference in in-hospital mortality between those managed who received intervention and those managed conservatively. Other factors affecting 30-d mortality included age, place of residence and declining renal function, highlighting the complexity of this patient population.

### **Limitations**

Our study is not randomized, and therefore limited by selection bias. However, it is an "all comers" registry which reflects "real world" data on management and outcomes of elderly patients who presents with STEMI. A randomised trial in this particular group is not viable. Propensity score matching would be the next best option and requires larger studies. Furthermore, we did not evaluate long term mortality and re-infarction rates, which may provide incremental information and a better picture of the utility of invasive management in this group.

In conclusion, this study is the first Australian report on the outcomes of octogenarians who present with ST-elevation myocardial infarction. This group represents a complex population with multiple medical comorbidities and PCI is challenging, associated with high failure and complication rates. Consequently, mortality is high in this group. However, the detrimental prognosis of conservatively managed octogenarians and relative mortality benefit associated with PCI suggests that revascularization therapy may benefit this age group.

## COMMENTS

### **Background**

The elderly have an increased risk of acute coronary syndrome. However, there are more likely to be managed conservatively compared to the younger cohort. This is due to concerns regarding procedural complications and success. The elderly is also under-represented in major clinical trials evaluating primary percutaneous coronary intervention (PCI). Recognizing this there have been recent overseas studies evaluating the elderly and primary PCI.

### **Research frontiers**

This study is the first to evaluate the characteristics and outcome of octogenarians who presents with ST-elevation myocardial infarction (STEMI) in an Australian setting. The authors also evaluated the outcomes of octogenarians who received primary PCI compared to those that were managed conservatively.

### **Innovations and breakthroughs**

This paper showed that despite poor prognosis among octogenarians who presents with STEMI, primary PCI may offer some benefit, with significantly lower 30 d mortality in the group that received it.

### **Applications**

Primary PCI should be considered in octogenarians who presents with STEMI. The patient's co-morbidities, quality of life and life expectancy should be taken into account when making this decision.

### **Terminology**

Primary PCI consists of urgent balloon angioplasty (with or without stenting), without the previous administration of fibrinolytic therapy or platelet glycoprotein IIb/IIIa inhibitors, to open the infarct-related artery during an acute myocardial infarction with ST-segment elevation.

**Peer-review**

This is an interesting and well-written article dealing with care on octogenaries after acute myocardial infarction. The authors have found worse clinical characteristics in octogenaries in comparison with non octogenaries, as well as lower referral for interventional procedures.

**Abstract****AIM**

To study the relationship of jailed polymer jacketed guide wires (PGW) with procedural myocardial infarction (PMI) after bifurcation coronary interventions.

**METHODS**

Consecutive bifurcation interventions performed from January 2010 to October 2014 were included in the study. Chart review was performed to obtain demographic, clinical and procedural data. PMI was defined as Creatine Kinase MB > 3 × upper reference limit of normal. Multivariate logistic regression was used to ascertain relationship of PGW use with PMI.

**RESULTS**

Two hundred and ninety-three patients (age 63.5 ± 12.3 years; 33.8% diabetic) were included in the study. Eighty point two percent ( $n = 235$ ) were true bifurcation lesions use of PGW was associated with PMI on univariate analysis (OR = 4.1;  $P = 0.002$ ). This association remained significant after adjusting for other possible risk factors (OR = 3.5;  $P = 0.02$ ).

## CONCLUSION

Our results suggest that PGW use for side branch protection may be associated with PMI. Randomized studies are needed to validate these findings.

**Key words:** Coronary bifurcation lesions; Percutaneous coronary intervention; Procedural myocardial infarction; Jailed guidewire; Polymer shearing

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This is a retrospective study aiming to investigate the relationship of jailed polymer jacketed guide wires (PGW) with procedural myocardial infarction (PMI) after a bifurcation coronary intervention. There is concern that this causes polymer shearing and distal micro-embolization. Our data suggests that jailed PGW are strongly associated with PMI, even after adjusting for pertinent risk factors. Thus caution should be exercised in routinely jailing PGW until further definitive data are available.

Jailing polymer jacketed guide-wires during bifurcation coronary interventions is associated with procedural myocardial infarction. *World J Cardiol* 2017; 9(5): 442-447 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/442.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.442>

## INTRODUCTION

Coronary bifurcation lesions (CBL) are a challenging subset of day to day coronary interventions with a higher adverse event profile as compared to non-bifurcation lesions<sup>[1]</sup>. In the past decade, multiple studies have investigated the optimum approach to bifurcation lesions *vis-à-vis* simple (provisional side branch stenting only) vs complex (mandatory main and side branch stenting) approaches<sup>[2-4]</sup>. These have led to a widespread consensus that the simple approach should be preferred in majority of CBLs as the complex strategy showed higher incidence of adverse cardiac events, mainly myocardial infarction<sup>[5]</sup>.

In the simple approach, a coronary guidewire is frequently inserted into the side-branch (SB) as a strategy to prevent occlusion. This is considered to be an important step as side branch compromise is associated with higher incidence of myocardial infarction and death<sup>[6,7]</sup>. Stent deployment in the main vessel (MV) "jails" this guidewire which then has to be pulled from underneath the stent struts. Polymer jacketed guidewires (PGW) have the advantage of maximum lubricity which allows them to be easily withdrawn from a jailed position. However there are concerns over wire damage and shearing of the polymer jacket<sup>[8]</sup> and hence these are not universally recommended for

jailing<sup>[9]</sup>. In addition, studies of pathological specimens have revealed evidence of embolized polymer in the myocardium<sup>[10,11]</sup>. Guidewires with no or minimal polymer coatings are felt to be safer but run a risk of wire fracture during attempts at withdrawal<sup>[12]</sup>. In a pilot study using scanning electron microscopy (SEM) at our institution, it was established that polymer shearing is a real phenomenon and that the amount of polymer sheared is weakly correlated with biomarker release post procedure<sup>[13]</sup>. These studies have posed a question regarding an incremental risk of myonecrosis and possibly procedural myocardial infarction (PMI) with jailing of PGW and polymer shearing.

To try and answer this question, we performed a retrospective analysis of consecutive CBL interventions at our institution to determine if there is any association between type of guidewire jailed and PMI.

## MATERIALS AND METHODS

All coronary interventions performed between January 2010 and October 2014 at our institution were reviewed to identify CBL interventions. Inclusion criteria were: CBL requiring percutaneous coronary intervention (PCI), MV diameter  $\geq 2.5$  mm and side branch diameter  $\geq 2$  mm. Criteria for exclusion were PCI for chronic total occlusions, cases where dual antiplatelet therapy was started after PCI and unavailability of biomarker levels at least 12 h after PCI. The Institutional Review Board of the University of Alabama at Birmingham approved the study. Chart review was performed to extract demographic and clinical parameters. Patients were divided into two groups based on occurrence of PMI as defined below.

### Angiographic definitions

Angiograms were reviewed and quantitative measurements made using the CAAS system. A CBL was defined as a lesion located at a major coronary bifurcation point. Lesions were classified according to the Medina classification with a score of "1" or "0" being given to the proximal MV, distal MV and the SB components if they had  $\geq 50\%$  diameter stenosis. Lesions were also classified as true bifurcation lesions (Medina type 1,1,1; 1,0,1 or 0,1,1) vs non-true bifurcation lesions (Medina type 1,0,0; 0,1,0 or 0,0,1).

### Definition of procedural myocardial infarction

PMI was defined as creatine kinase (CK) MB  $> 3 \times 99^{\text{th}}$  percentile of upper limit of normal post procedure if the pre-procedure levels were normal or a  $> 20\%$  increase if pre-procedure levels were abnormal but stable or down-trending. If there were any unrelated cause for biomarker elevation, *e.g.*, acute stent thrombosis, no reflow, SB occlusion,  $<$  TIMI 3 flow in MV or SB, shock or hypotension in the immediate 24 h post PCI, acute kidney injury, stroke, bleeding requiring transfusion, pulmonary embolism, access complication causing limb

**Table 1** Demographic and clinical characteristics of the study population

	No PMI (n = 270)	PMI (n = 23)	P value
Age (yr)	63.6 ± 12.1	62.9 ± 14.4	0.80
Male sex	68.1%	60.9%	0.49
Smoking	55.6%	52.2%	0.86
Diabetes mellitus	33.0%	43.5%	0.36
Hypertension	78.1%	65.2%	0.33
Hyperlipidemia	73.7%	78.3%	0.87
Acute coronary syndrome	45.6%	52.2%	0.66

PMI: Procedural myocardial infarction.

ischemia or sustained arrhythmia these cases were classified as not having PMI. This was done to focus only on cases without a clear explanation for cause of PMI.

### Statistical analysis

Continuous variables are represented as mean ± SD and compared using the Welch's *t* test as the sample sizes are unequal. Categorical variables were compared using the Fisher's exact test. Statistical analyses were carried out using SPSS v 22.0 (SPSS, Chicago, Illinois). Multivariate logistic regression was used to ascertain relationship of the following variables with PMI: Age, Diabetes Mellitus, severe lesion calcification, true bifurcation lesion, use of newer antiplatelet agent (Ticagrelor and Prasugrel), Bivalirudin use, upstream Glycoprotein IIb/IIIa use, use of preplanned two stent technique, SB protection with any guidewire and SB protection with PGW.

## RESULTS

A total of 293 consecutive patients undergoing CBL interventions were included in the study. Seven point eight percent (*n* = 23) patients were classified as having had a PMI. Demographic and clinical characteristics of the patients broken down into two groups depending on whether or not PMI occurs are shown in Table 1. There were no statistically significant differences between the two groups. Table 2 shows the angiographic and procedural characteristics of patients with and without PMI. The most common bifurcation lesions included were left anterior descending/diagonal and left circumflex/marginal branch respectively. Proportion of true bifurcation lesions was higher and Bivalirudin use lower in the PMI group but these differences did not reach statistical significance. Seventy-four point four percent of total patients had a wire placed in the side branch and jailed with no difference amongst the two groups. However a jailed PGW was much more common in the PMI group (43.4% vs 15.9%, *P* = 0.003). There were no instances of wire entrapment or wire rupture in either group. The most common PGW jailed was a Hi Torque Whisper (Abbot Vascular, Abbott Park, IL, United States) while non PGW jailed were Runthrough NS

**Table 2** Angiographic and procedural characteristics

	No PMI (n = 270)	PMI (n = 23)	P value
Vessels involved			0.68
LM bifurcation	15.9%	21.7%	
LAD/Diagonal	40.0%	47.8%	
LCX/OM	34.8%	21.7%	
RPDA/RPLA	8.8%	4.3%	
RCA/RV marginal	0.003%	0%	
Severe calcification	57.4%	65.2%	0.52
True bifurcation (Medina 1,1,1; 1,0,1; 0,1,1)	79.3%	91.3%	0.27
Main vessel diameter (mm)	3.3 ± 0.5	3.3 ± 0.4	0.4
Side branch diameter (mm)	2.6 ± 0.5	2.6 ± 0.4	0.94
Antiplatelet therapy			0.97
Plavix	73.7%	69.6%	
Prasugrel	7.0%	8.7%	
Ticagrelor	19.3%	21.7%	
Anticoagulant			0.08
Heparin	45.2%	65.2%	
Bivalirudin	54.8%	34.8%	
Upstream GpIIb/IIIa use	11.5%	13.0%	0.74
Planned 2 stent approach	28.1%	39.1%	0.34
Final kissing balloon angioplasty	45.9%	56.5%	0.39
SB protected	73.3%	87%	0.21
PGW jailed	15.9%	43.4%	0.003

PMI: Procedural myocardial infarction; PGW: Polymer jacketed guide wires.

(Terumo Interventional Systems, Somerset, NJ, United States), Cougar LS (Medtronic, Minneapolis, MN, United States) and HT Balance Middle Weight (BMW, Abbot Vascular, Abbott Park, IL, United States).

Univariate logistic regression analysis did not reveal any significant association of PMI with age, Diabetes, lesion calcification, use of newer antiplatelet agents, use of Bivalirudin, upstream use of Gp IIb/IIIa use, SB protection, pre-planned use of complex 2 stent strategy or Medina classification as true bifurcation lesion. The use of jailed PGW was strongly associated with PMI with an odds ratio of 4.1 (95%CI: 1.7-9.9; *P* = 0.002). Performing multivariate logistic regression to adjust for all the aforementioned factors still showed a strong association between jailing of PGW and PMI (Figure 1, Odds ratio 3.5; 95%CI: 1.2-9.9; *P* = 0.02).

## DISCUSSION

SB protection is of considerable importance during CBL interventions. Occlusion of a SB > 1.0 mm has been associated with a 14% risk of MI<sup>[6]</sup>. In a large series of 2227 CBL interventions, Hahn *et al*<sup>[7]</sup> reported a SB occlusion rate of 8.4% and this increased the rate of major adverse cardiovascular events. The only protective factor found to prevent SB occlusion was the presence of a jailed guide-wire. Similar findings were reported in the Nordic study illustrating the importance of the jailed SB wire<sup>[14]</sup>. The jailed guide wire provides a physical impediment to closure of the SB ostium and also facilitates re-wiring of the vessel by making the angle between the MV and the SB wider<sup>[15]</sup>. Thus jailing

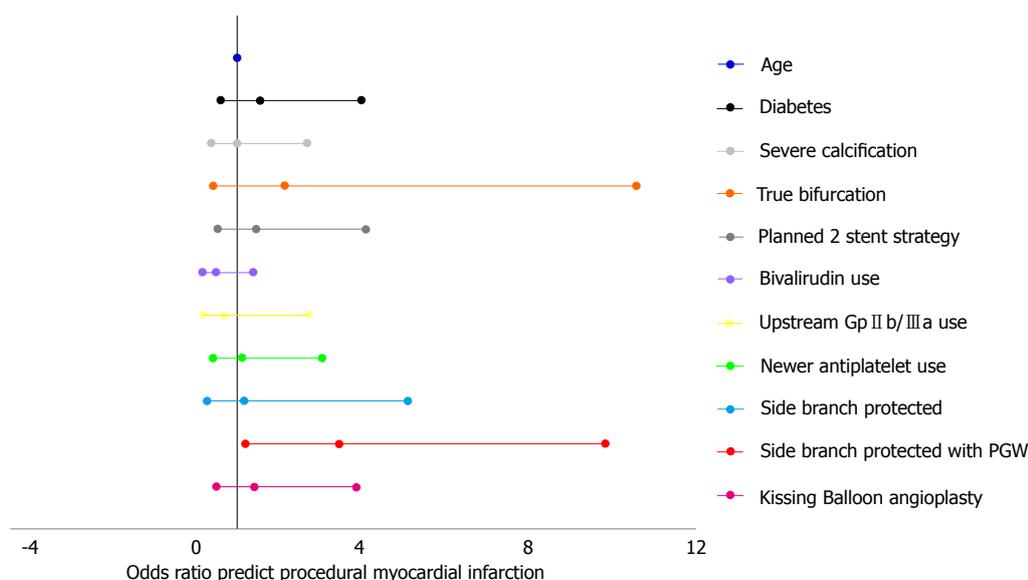

Figure 1 Multi-variate Odds ratios for various factors in predicting procedural myocardial infarction. PGW: Polymer jacketed guide wires.

a wire in the SB during MV stenting is a widely accepted practice for CBL interventions. However there is less consensus on the type of guide-wire to jail.

All coronary guide-wires have some degree of polymer coating on them with varying degrees of polymer cover or jacket. Based on the latter, guide-wires are broadly classified into three categories: (1) Wires with no polymer jacket - minimum lubricity, *e.g.*, HT BMW, Prowater and HT Floppy II; (2) Wires with intermediate polymer jacket - lack polymer jacket at the very distal end only; medium lubricity, *e.g.*, HT BMW Universal, Runthrough NS, Cougar LS; and (3) Wires with full polymer jacket - polymer jacket throughout the length of the wire; maximum lubricity; *e.g.*, HT Whisper, HT Pilot, HT Fielder XT.

PGW (3<sup>rd</sup> category) offer the attractive quality of lubricity and are easily withdrawn from underneath stent struts. However the interventional community has been wary of these as the initial reports of wire rupture were consistently with hydrophilic PGW<sup>[8]</sup>. Since then multiple reports of non hydrophilic wires being entrapped have been published as well<sup>[16-19]</sup>. With the lesser degree of lubricity of a non PGW, greater force may be required to extract the wire and hence risk deep intubation of the guide catheter and injury to the vessel as well.

Some reports have also raised the possibility of shearing of the polymer jacket during extraction of the jailed PGW<sup>[20]</sup>. Grundeken *et al*<sup>[11]</sup> examined the possibility of distal polymer embolization in two ways - they examined the aspirate from patients undergoing aspiration thrombectomy and reported that 45% samples had polymer material in them. Also, examination of autopsy specimens from patients who had undergone PCI showed intramyocardial polymer in 10% subjects. The amount of polymer detected increased as the polymer jacket increased with the maximum embolization noted in cases using HT Whisper

wires. This study is especially concerning because polymer embolization occurred even without jailing the guide-wire. It is notable that distal embolization of athero-emboli is considered an important contributor in the etiology of PMI<sup>[21]</sup> - hence embolization of non-degradable polymer is a plausible hypothetical cause for PMI as well.

To try and quantify the extent of polymer shearing and embolization, we have previously performed a small study examining jailed HT Whisper and Runthrough NS wires with SEM<sup>[13]</sup>. This revealed polymer shearing in both types of wires but up to 5 fold higher in the HT Whisper, a PGW. Amount of polymer shearing was also weakly correlated with the level of CK MB post procedure. Pan *et al*<sup>[22]</sup> randomized 235 patients who underwent CBL interventions with the jailed wire technique to use of PGW or non PGW and examined the jailed wires using an optical microscope. They reported more structural damage to non PGW although no wire fracture was noted. It should be noted though that the study used magnification up to 6.3X only, which is insufficient to detect shearing of polymer and also used wires with no polymer cover as the comparison group, the use of which has gone down in comparison to wires with intermediate polymer cover. Also, the rate of PMI was not different in the two groups.

In this respect, our study is the second study to investigate the relationship of type of wire jailed to PMI. Our results show a strong association of jailed PGW to PMI which are contrary to the results of Pan *et al*<sup>[22]</sup>. One reason may be that there are varied reasons why patient have elevated cardiac biomarkers post PCI. Some of these may be no reflow phenomenon, distal athero-embolization, occlusion of SB, coronary perforation, development of cardiogenic (or other types of) shock, access complications causing limb ischemia, arrhythmias, bleeding causing hemodynamic instability,

*etc.* These, at least by our current knowledge of PMI are more likely to be contributors than polymer embolization from jailed PGW. Hence we meticulously excluded all cases which may have had any confounding factor causing a biomarker elevation and categorized these cases as having no PMI. This further strengthens our belief in the credibility of our results.

### Limitations

Our study has all the limitations of a retrospective analysis and the inherent biases. However we have attempted to correct these biases by careful data acquisition, exclusion of cases with potential confounding factors and a multivariate logistic regression analysis. We also note that the definition of PMI used is inconsistent with the 3<sup>rd</sup> universal definition of MI consensus document<sup>[23]</sup> which defines PMI as  $> 5 \times$  ULN of cardiac Troponin (cTn) along with symptoms, electrocardiographic, imaging or angiographic evidence of ischemia. Multiple studies have been done that question the relevance of the  $5 \times$  ULN of cTn criterion as a  $> 3 \times$  ULN of CK-MB cut-off is better correlated with mortality<sup>[24]</sup> and evidence of new myocardial injury as detected by cardiac MRI<sup>[25]</sup>. In fact, a cut off of  $3 \times$  ULN of CK-MB is equivalent to a cut-offs of  $20 \times$  cTn for mortality and  $40 \times$  cTn for MRI proven new myocardial injury. Hence while the updated definition is valid in conjunction with clinical evidence of ischemia, CK MB may be a better choice for isolated biomarker analyses.

In conclusion, our study shows that jailed PGW may be associated with a threefold higher risk of PMI. Given the retrospective design, this finding should be treated as hypothesis generating and hopefully will trigger prospective analysis to confirm or refute this association. The etiology for this risk is believed to be polymer shearing and micro-embolization which has been proven by multiple small but rigorously conducted studies<sup>[11,13]</sup>. We believe that much has to be learned about the potential role of polymer shearing and embolization in myonecrosis post CBL intervention. There is also a need to determine if the wires with intermediate polymer cover may be the best middle path compromise in the argument of lubricity vs fracture and polymer shearing.

## COMMENTS

### Background

Polymer jacketed guide wires (PGW) are frequently used for side branch protection during bifurcation coronary interventions. Their lubricity is an attractive property for this use as it makes them easy to retract from underneath stent struts. However, microscopic shearing of polymer from jailed guide wires has been reported and may be a potential cause of procedural myocardial infarction (PMI) as this may cause distal micro-embolization. Hence, the authors performed a retrospective analysis of bifurcation interventions at this institution to ascertain relationship of PGW use with PMI.

### Research frontiers

PMI has important prognostic implications in patients undergoing percutaneous coronary intervention. Thus it is important to understand if any procedural factors such as use of PGW have any effect on PMI.

### Innovations and breakthroughs

This is only the second study to ascertain if there is a relationship between use of jailed PGW and PMI. In their data there is a strong association of these which translates to a three fold higher risk of PMI if a PGW is jailed.

### Applications

These results should caution interventional cardiologists from adopting PGW as their go to wire for jailing until prospective data comparing different types of wires are available. Randomized studies are needed to compare newer generation non polymer jacketed, intermediate polymer jacketed and full polymer jacketed coronary guide wires.

### Terminology

PGW: Polymer jacketed guide wires; PMI: Procedural myocardial infarction.

### Peer-review

This is an interesting manuscript about the relation of jailing PGW to PMI. The authors demonstrated that jailed PGW might be associated with PMI. This manuscript is nicely structured and well written.

**Abstract****AIM**

To evaluate novel risk factors and biomarkers of cardiovascular disease in celiac disease (CD) patients compared with healthy controls.

**METHODS**

Twenty adult patients with recent diagnosis of CD and 20 sex, age and body mass index-matched healthy controls were recruited during a period of 12 mo. Indicators of carbohydrate metabolism, hematological parameters and high sensitive C reactive protein were determined. Moreover, lipoprotein metabolism was also explored through evaluation of the lipid profile and

the activity of cholesteryl ester transfer protein and lipoprotein associated phospholipase A2, which is also considered a specific marker of vascular inflammation. The protocol was approved by the Ethic Committee from School of Pharmacy and Biochemistry, University of Buenos Aires and from Buenos Aires Italian Hospital, Buenos Aires, Argentina.

## RESULTS

Regarding the indicators of insulin resistance, CD patients showed higher plasma insulin levels [7.2 (5.0-11.3) mU/L *vs* 4.6 (2.6-6.7) mU/L,  $P < 0.05$ ], increased Homeostasis Model Assessment-Insulin Resistance [1.45 (1.04-2.24) *vs* 1.00 (0.51-1.45),  $P < 0.05$ ] and lower Quantitative Sensitive Check index [0.33 (0.28-0.40) *vs* 0.42 (0.34-0.65),  $P < 0.05$ ] indexes. Folic acid concentration [5.4 (4.4-7.9) ng/mL *vs* 12.2 (8.0-14.2) ng/mL,  $P < 0.01$ ] resulted to be lower and High-sensitivity C reactive protein levels higher ( $4.21 \pm 6.47$  mg/L *vs*  $0.98 \pm 1.13$  mg/L,  $P < 0.01$ ) in the patient group. With respect to the lipoprotein profile, CD patients showed lower high density lipoprotein-cholesterol (HDL-C) ( $45 \pm 15$  mg/dL *vs*  $57 \pm 17$  mg/dL,  $P < 0.05$ ) and apo A-I ( $130 \pm 31$  mg/dL *vs*  $155 \pm 29$  mg/dL,  $P < 0.05$ ) levels, as well as higher total cholesterol/HDL-C [4.19 (3.11-5.00) *vs* 3.52 (2.84-4.08),  $P < 0.05$ ] and apo B/apo A-I (0.75  $\pm$  0.25 *vs* 0.55  $\pm$  0.16,  $P < 0.05$ ) ratios in comparison with control subjects. No statistically significant differences were detected in lipoprotein-associated lipid transfer protein and enzymes.

## CONCLUSION

The presence and interaction of the detected alterations in patients with CD, would constitute a risk factor for the development of atherosclerotic cardiovascular disease.

**Key words:** Inflammation; Cardiovascular disease; High density lipoprotein-cholesterol; Lipoproteins; Celiac disease

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Given that data about the presence of metabolic alterations and atherogenic risk factors in celiac disease are scarce and contradictory, we aimed to investigate carbohydrate metabolism, lipoprotein profile and inflammatory status in patients with celiac disease (CD). Patients presented higher insulin levels, Homeostasis Model Assessment-Insulin Resistance index, apo B/apo A-I ratio and High-sensitivity C reactive protein concentration, as well as lower Quantitative Sensitive Check index index, high density lipoprotein-cholesterol and apo A-I levels in comparison with sex and aged-matched healthy controls. Persistence of these alterations through long periods of time in a chronic pathologic condition, as it is the case with CD, would constitute a high risk of developing atherosclerotic cardiovascular disease.

Tetzlaff WF, Meroño T, Menafrá M, Martín M, Botta E, Matoso MD, Sorroche P, De Paula JA, Boero LE, Brites F. Markers of inflammation and cardiovascular disease in recently diagnosed celiac disease patients. *World J Cardiol* 2017; 9(5): 448-456 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/448.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.448>

## INTRODUCTION

Celiac disease (CD) is a multisystemic disease which mainly affects the digestive system, though not exclusively. Its main trait is chronic and diffuse inflammation of the mucosa of the small intestine and it can present a wide variety of clinical symptoms<sup>[1]</sup>. Thus far, the only available therapy for CD consists of the implementation of a gluten free diet (GFD), whose efficacy depends on strict adherence.

It is remarkable that most cases of CD lack typical gastrointestinal symptoms and are, instead, very frequently associated with presentations known as atypical or extra-intestinal. Thus, its diagnosis represents one of the main challenges for health professionals<sup>[2]</sup>.

Commonly, CD has been associated with certain physiopathological conditions (type 1 diabetes, Hashimoto thyroiditis, *etc.*) which are not directly related to gluten ingestion<sup>[3]</sup>. Among these conditions, it is worth noting that the evidence linking CD and atherosclerotic cardiovascular disease (CVD) is scarce. It is well known that CD patients do not show classical CVD risk factors. In fact, hypertension and hypercholesterolemia are less frequent in CD patients than in the general population<sup>[4]</sup>. However, previous studies have failed to show lower CVD risk in CD patients than in healthy subjects<sup>[4,5]</sup>. Furthermore, an important study carried out in Sweden in approximately 14000 hospitalized CD patients showed higher risk of acute myocardial infarction, chest angina, cardiac insufficiency, brain hemorrhage and ischemic stroke when compared to sex and age-paired healthy controls<sup>[6]</sup>.

These facts suggest that CD would be associated with novel atherogenic risk factors or even with other non-identified risk factors. In fact, inflammation and anemia, among other signs that characterize CD, could represent a link between this pathology and CVD<sup>[7,8]</sup>.

Atherosclerosis is presently understood as a chronic inflammatory disease in which endothelial dysfunction and biomarkers of inflammation are present since the early stages of the pathology<sup>[9]</sup>. So far, the inflammatory process typical of CD has not been described in relation to increased risk of CVD.

The aim of the present study was to evaluate novel risk factors and biomarkers of CVD in CD patients in comparison to sex, age and body mass index (BMI)-matched healthy controls. In addition, the metabolic differences between patients with typical and atypical presentations of the disease were also analyzed.

## MATERIALS AND METHODS

### Subjects

Twenty patients with CD were consecutively recruited from the service of gastroenterology, Buenos Aires Italian Hospital, during a period of 12 mo. The inclusion criteria were adult age and recent diagnosis of CD (< 3 mo) based on histopathological findings and serological markers (anti-gliadin IgG and IgA and anti-transglutaminase IgA). Patients were not treated and they had not still started a GFD. All individuals presenting any other intestinal inflammatory disease, IgA deficiency, malignant diseases, chronic infections, pregnancy, thyroid, renal or hepatic alterations, history of CVD, smoking, alcohol consumption > 40 g/d, and treatment with drugs known to affect lipid and/or carbohydrate metabolism were excluded. Patients were classified according to the presence of gastrointestinal (typical presentation) or extra-digestive symptoms (atypical presentation)<sup>[2]</sup>. Gastrointestinal manifestations analyzed were: Diarrhea, abdominal distention, weight loss, and malabsorption syndrome. Extra-digestive alterations considered were: Anemia, mouth ulcers, osteoporosis, and modifications of liver function tests. Employing these criteria, 11 out of the 20 CD patients showed gastrointestinal symptomatology and 9 showed only extradiigestive symptoms. The group of CD patients was compared with a sex, age and BMI-matched group of healthy volunteers ( $n = 20$ ). Weight, height and waist circumference were registered in all subjects and an exhaustive anamnesis was performed. All participants in the study signed an informed consent. The protocol was approved by the Ethical Committees from School of Pharmacy and Biochemistry, University of Buenos Aires and from Buenos Aires Italian Hospital. Buenos Aires, Argentina.

### Study protocol and samples

Blood samples were obtained from the antecubital vein after 12 h of fasting. Serum and EDTA plasma (final EDTA concentration 1 mg/mL) were prepared from venous blood collected into sterile, evacuated tubes. The former was centrifuged at 1500 g for 15 min at 4 °C. Serum was isolated and stored at 4 °C and -70 °C.

### Determination of general biochemical parameters

Plasma concentrations of glucose, urea, uric acid, total bilirubin, folic acid and vitamin B12, as well as aspartate aminotransferase (ASAT), alanin aminotransferase and alkaline phosphatase activities, and hemogram were determined by standardized methods. Insulin levels were measured by radioimmunoassay (Diagnostics Products Corp., Los Angeles CA, United States). Homeostasis Model Assessment-Insulin Resistance (HOMA-IR) was calculated using the formula  $[\text{glucose (mmol/L)} \times \text{insulin (uU/mL)}] / 22.5$  and Quantitative Sensitive Check index (QUICKI) using the formula  $1 / [\ln \text{Glucose (mmol/L)} + \ln \text{Insulin (mU/L)}]$ <sup>[10,11]</sup>. High-sensitivity

C reactive protein (hsCRP) levels were determined by immunoturbidimetry (Roche, Mannheim, Germany) in a Hitachi 917 autoanalyzer (Tokyo, Japan).

### Determination of the lipid, lipoprotein and apolipoprotein profile

Plasma levels of total cholesterol (TC) and triglycerides were quantified by standardized methods (Roche, Mannheim, Germany) in a Hitachi 917 autoanalyzer (Tokyo, Japan). High density lipoproteins (HDL) were isolated from the supernatant obtained after selective precipitation of apolipoprotein (apo) B-containing lipoproteins using 0.44 mmol/L phosphotungstic acid in presence of magnesium ions<sup>[12]</sup>. Cholesterol (C) of low density lipoprotein (LDL) was estimated as the difference between TC and the cholesterol contained in the supernatant obtained after selective precipitation of LDL with 10 g/L polyvinil sulfate in poliethilenglicol (600 Da; 2.5 w/v; pH = 6.7)<sup>[13]</sup>. Non HDL-C was calculated as the difference between TC and HDL-C. Very low density lipoprotein cholesterol (VLDL-C) was calculated as the difference between the supernatants of the LDL-C and HDL-C precipitations. Apo B and apo A-I levels were quantified by immunoturbidimetry (Roche, Mannheim, Germany) in a Hitachi 917 autoanalyzer (Tokyo, Japan). Results were expressed as mg/dL. The following ratios were calculated: TG/HDL-C, TC/HDL-C and apo B/apo A-I.

### Determination of cholesteryl ester transfer protein activity

Cholesteryl ester transfer protein (CETP) activity was evaluated in serum samples following the radiometric method previously described with minor modifications<sup>[14]</sup>. Briefly, the capacity of the serum to promote the transfer of tritiated esterified cholesterol (EC) from the biosynthetically marked HDL3 subfraction (<sup>3</sup>H-EC-HDL3) (NEN Life science products, Boston, United States) to apo B containing lipoproteins present in the serum. Serum samples were incubated with <sup>3</sup>H-CE-HDL3 (50 μmol/L cholesterol) with iodoacetate (1.5 mmol/L) in TBS buffer (pH = 7.4) during 3 h at 37 °C. After incubation, apo B-containing lipoproteins were separated from HDL by selective precipitation with phosphotungstic acid (0.44 mmol/L) in the presence of magnesium ions. Radioactivity was measured in the reaction cocktail and in the supernatant containing the HDL subfraction in a liquid scintillation counter (Packard 210 TR, Packard Instruments, Meridians, CT, United States). Results were expressed as the percentage of tritiated EC transferred from HDL3 to apo B-containing lipoproteins, per ml, per hour. All samples were processed in the same assay.

### Determination of lipoprotein associated phospholipase A2 activity

Lipoprotein associated phospholipase A2 activity (Lp-PLA2) was evaluated employing the radiometric assay described by Blank *et al.*<sup>[15]</sup> with minor modifications.

**Table 1** Clinical and biochemical characteristics from patients with celiac disease and control subjects

	Patients with celiac disease (n = 20)	Control subjects (n = 20)	P
Age (yr)	50 (25-58)	47 (28-60)	ns
Men/woman	5/15	5/15	ns
BMI (kg/m <sup>2</sup> )	22.8 (20.4-26.2)	23.0 (21.0-24.7)	ns
Glucose (mg/dL)	87 ± 11	86 ± 12	ns
Insulin (mU/L)	7.2 (5.0-11.3)	4.6 (2.6-6.7)	< 0.05
HOMA-IR	1.45 (1.04-2.24)	1.00 (0.51-1.45)	< 0.05
QUICKI	0.33 (0.28-0.40)	0.42 (0.34-0.65)	< 0.05
Urea (mg/dL)	27 (21-34)	35 (34-39)	< 0.01
Creatinine (mg/dL)	0.74 (0.63-0.88)	0.80 (0.75-1.10)	< 0.05
Uric acid (mg/dL)	5.0 ± 1.2	4.3 ± 1.6	ns
Bilirubin (mg/dL)	0.7 (0.5-0.8)	0.6 (0.6-0.8)	ns
ASAT (U/L)	26 (20-35)	14 (12-20)	< 0.01
ALAT (U/L)	22 (17-39)	18 (16-22)	ns
ALP (U/L)	80 (59-102)	124 (67-219)	ns

BMI: Body mass index; HOMA-IR: Homeostasis Model Assessment insulin resistance; QUICKI: Quantitative insulin sensitivity check index; ASAT: Aspartate-amine transferase; ALAT: Alanine-amine transferase; ALP: Alkaline phosphatase; ns: Non significant. Data are shown as mean ± SD or median (interquartile range) according to data distribution.

The extraction of the marked acetate was performed using chloroform and the radioactivity of the aqueous phase was measured in a liquid scintillation counter (Packard 210 TR, Packard Instruments, Meridians, CT, United States). The radioactivity of the reaction buffer was also measured. Results were expressed as µmol of acetate liberated, per millilitre, per hour. All samples were processed in the same assay.

### Statistical analysis

The sample size was calculated based on previous studies carried out in our laboratory. The outcome variables chosen to perform the sample size calculation for this study were HDL-C, CETP and Lp-PLA2. Having defined a 0.8 power, an effect size of 1.0 and a significance level of 0.05, the number of patients to be included in the present study was at least 17. Data distribution was analyzed with the Shapiro-Wilks test and data was expressed as mean ± SD, if distribution was found to be parametric, or as median (interquartile range) if distribution was non-parametric. To assess differences between groups, both parametric and non-parametric methods were employed. Correlation analyses were performed using Spearman or Pearson tests depending on variable distribution. When partial correlations, linear regressions or adjusted group differences were performed, all non-parametric variables were normalized prior to be included in the analysis. Statistical significance was defined as  $P < 0.05$ . A statistical review of the study was performed by a biomedical statistician. For the statistical analysis, the programs Infostat (Universidad Nacional de Cordoba, Argentina) and SPSS 19.0 (IBM, Chicago, United States) were used.

**Table 2** Hematological parameters from patients with celiac disease and control subjects

	Patients with celiac disease (n = 20)	Control subjects (n = 20)	P
Erythrocytes (10 <sup>6</sup> /mL)	4.40 ± 0.48	4.58 ± 0.27	ns
Hematocrite (%)	38.5 ± 4.0	40.1 ± 2.6	ns
Hemoglobin (g/dL)	13.0 ± 1.4	13.3 ± 0.9	ns
Serum iron (µg/dL)	73 ± 35	105 ± 61	ns
Ferritin (ng/mL)	33 (13-110)	92 (43-117)	ns
Transferrin (mg/dL)	261 ± 62	293 ± 59	ns
Transferrin Sat. (%)	25 ± 14	29 ± 14	ns
Vitamin B12 (pg/mL)	337 (251-482)	315 (265-393)	ns
Folic acid (ng/mL)	5.4 (4.4-7.9)	12.2 (8.0-14.2)	< 0.01

ns: Non significant; Sat.: Saturation. Data are shown as mean ± SD or median (interquartile range) according to data distribution.

## RESULTS

As expected, CD patients and control subjects did not show any difference in age, sex distribution and BMI (Table 1). Nevertheless, CD patients had significantly higher insulin levels and HOMA-IR, as well as lower QUICKI (Table 1). Both urea and creatinine concentrations were lower in the patient group, though individual results were comprised within the reference values. Additionally, ASAT activity was significantly increased in patients compared to controls.

The evaluation of hematological parameters showed no significant decrease in hemoglobin concentration in patients. Furthermore, only one woman met the criteria for anemia diagnosis (hemoglobin < 12 g/dL for women and < 13 g/dL for men). Similarly, there were no differences in total iron content, transferrin saturation or concentrations of ferritin, transferrin and vitamin B12. Only folic acid concentration was found to be significantly lower in patients (Table 2). Employing the reference values established by the World Health Organization<sup>[16,17]</sup>, the prevalence of folic acid deficiency resulted to be 10% (< 4 ng/dL), of iron deficiency 15% (ferritin < 15 ng/dL) and of low vitamin B12 7.5% (< 203 pg/mL).

Regarding the lipid and lipoprotein profile, no differences were detected in TG, TC, LDL-C and apo B levels. However, statistically significant decreases in HDL-C and apo A-I concentrations were observed (Table 3). Furthermore, both parameters showed a strong positive correlation between them ( $r = 0.78$ ;  $P < 0.0001$ ). TC/HDL-C and apo B/apo A-I ratios, both of which possess high predictive value for CVD, were significantly higher in patients, whilst TG/HDL-C showed no difference between groups. On the other hand, CETP activity was similar in patients and controls (145% ± 32%/mL.h vs 132% ± 33%/mL.h,  $P > 0.05$ ) and exhibited direct correlations with TG levels ( $r = 0.52$ ;  $P < 0.005$ ) and apo B/apo A-I ratio ( $r = 0.48$ ;  $P < 0.005$ ), and negative ones with HDL-C ( $r = -0.58$ ;  $P < 0.0001$ ) and apo A-I ( $r = -0.40$ ;  $P < 0.005$ ).

**Table 3** Lipid, lipoprotein and apolipoprotein profile from patients with celiac disease and control subjects

	Patients with celiac disease (n = 20)	Control subjects (n = 20)	P
TG (mg/dL)	81 (65-119)	78 (60-114)	ns
TC (mg/dL)	185 ± 37	194 ± 39	ns
VLDL-C (mg/dL)	18 ± 8	17 ± 7	ns
LDL-C (mg/dL)	139 (89-149)	107 (95-147)	ns
HDL-C (mg/dL)	45 ± 15	57 ± 17	< 0.05
Non-HDL-C (mg/dL)	153 (105-167)	137 (112-167)	ns
Apo A-I (mg/dL)	130 ± 31	155 ± 29	< 0.05
Apo B (mg/dL)	93.6 ± 23.8	83.5 ± 20.7	ns
TG/HDL-C	2.09 (1.13-2.98)	1.29 (1.06-1.93)	ns
TC/HDL-C	4.19 (3.11-5.00)	3.52 (2.84-4.08)	< 0.05
ApoB/apo A-I	0.75 ± 0.25	0.55 ± 0.16	< 0.01

TG: Triglycerides; TC: Total cholesterol; VLDL: Very low density lipoprotein; LDL: Low density lipoprotein; HDL: High density lipoprotein; apo: Apolipoprotein; ns: Non significant. Data are shown as mean ± SD or median (interquartile range) according to data distribution.

Evaluation of inflammation markers showed an increase in hsCRP levels in CD patients (Figure 1), which also correlated with apo B/apo A-I ratio ( $r = 0.42$ ;  $P < 0.01$ ). Even though white blood cell count (WBC) showed no differences between the two groups ( $6.11 \pm 1.31 \cdot 10^3/\text{mL}$  vs  $6.17 \pm 1.15 \cdot 10^3/\text{mL}$ ), it was directly associated with several parameters of the lipid profile ( $r/p$ ; TG,  $0.33 < 0.05$ ; HDL-C,  $-0.34 < 0.05$ ; apo B,  $0.42 < 0.05$ ; TG/HDL-C,  $0.37 < 0.05$ ; TC/HDL-C,  $0.44 < 0.01$ ; and apo B/apo A-I,  $0.51$ ;  $< 0.005$ ). Lastly, Lp-PLA2 activity was similar between patients and controls ( $7.20 \pm 1.28 \mu\text{mol/mL.h}$  vs  $7.91 \pm 2.02 \mu\text{mol/mL.h}$ ) and was positively associated with LDL-C, main carrier of the enzyme in circulation ( $r = 0.50$ ;  $P < 0.005$ ).

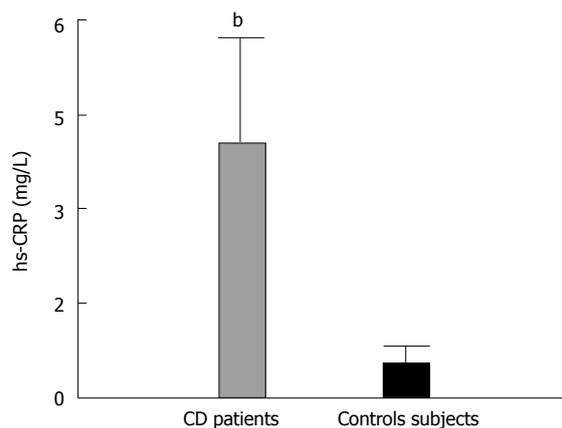

Moreover, folic acid level was significantly associated with several parameters of the lipid profile ( $r/p$ ; HDL-C,  $0.52 < 0.05$ ; apo A-I,  $0.45 < 0.01$ ; TG/HDL-C,  $-0.36 < 0.05$ ; and apo B/apo A-I,  $-0.34 < 0.05$ ) and with hsCRP concentration ( $r = -0.42$ ;  $P < 0.05$ ).

When comparing patients according to the clinical features, no differences were detected between patients with typical and atypical presentation of the disease in any of the parameters analyzed (data not shown).

## DISCUSSION

Patients with CD showed a slight alteration in carbohydrate metabolism, decreased folic acid levels, a more atherogenic lipoprotein profile and an increase in the inflammatory marker hsCRP, with no difference evidenced between typical and atypical presentation of the disease. Likely, in both groups, the severity of duodenal lesion would not be a determining factor in the metabolic alterations nor in the increase of hsCRP observed in this study.

Unlike other pathologies characterized by the presence of systemic inflammation, such as lupus erythematosus and rheumatoid arthritis, in which patients

**Figure 1** Levels of high sensitive C-reactive protein in patients with celiac disease (n = 20) and control subjects (n = 20). <sup>b</sup> $P < 0.01$ . hsCRP: High sensitive C reactive protein; CD: Celiac disease.

show higher CVD morbidity and mortality<sup>[18,19]</sup>, available evidence for CD appears less solid and more controversial. Even though some studies have described an increase in CVD risk compared with the general population<sup>[20-22]</sup>, this has not been the case in other reports<sup>[4,23]</sup>. A group of CD patients, retrospectively studied in comparison with data from general population<sup>[24]</sup>, showed less CVD risk employing the Framingham score. Nevertheless, assessment of cardiac functionality, specifically of the left ventricle<sup>[25]</sup>, and the study of the presence of subclinical atherosclerosis, analyzed through aortic stiffness, aortic strain, and aortic distensibility<sup>[26,27]</sup>, evidenced a clear association between CD and CVD. Moreover, a previous study showed higher carotid intima media thickness (an established marker of generalized atherosclerosis that correlates with the extent of coronary artery disease and predicts future cardiovascular events) in CD patients compared to healthy controls and similar to that of patients with type 1 diabetes<sup>[28]</sup>. Lastly, it is worth noting that a recent meta-analysis<sup>[29]</sup>, based on ten studies performed in CD patients, showed a slight increase in the risk of stroke, acute myocardial infarction, and cardiovascular death, though only in the first case this increase reached statistical significance. As evidenced by the bibliography, the subject remains highly controversial.

In CD patients, a systemic pro-inflammatory status was evidenced through an increase in plasma hsCRP levels. According to the guides of the American Heart Association<sup>[30]</sup>, values above 3 mg/dL, such as those observed in the group of the CD patients studied, would be indicative of high CVD risk. Even though Lp-PLA2 activity, considered a specific marker of vascular inflammation<sup>[31]</sup>, showed no differences between patients and controls, there is solid evidence about the increase of other inflammation markers in CD. In this regard, a previous study reported an increase in tumor necrosis factor (TNF)- $\alpha$ -producing innate lymphoid cells in the intestinal mucosa of untreated CD patients in comparison with treated patients and healthy controls<sup>[32]</sup>.

Moreover, an increase in TNF- $\alpha$  and interleukin (IL)-6 levels has been reported in the epithelium and the lamina propria of the intestinal mucosa of untreated CD patients<sup>[33,34]</sup>. Additionally, higher levels of IL-6 have been observed in the plasma of untreated CD patients compared to treated ones and healthy controls<sup>[35,36]</sup>.

Regarding markers of carbohydrate metabolism, even though insulin levels and HOMA-IR were increased and QUICKI diminished, the analysis of the individual values did not allow the diagnosis of insulin resistance in any of the patients included in the present study. In fact, the results obtained were below the values reported for patients with metabolic syndrome or type 2 diabetes, though above those reported for the general population<sup>[37-40]</sup>. Nevertheless, even the presence of a subtle alteration in carbohydrate metabolism in untreated CD patients would possess great clinical impact. Actually, GFD, the only available treatment for CD, contains higher caloric density than similar diets based on gluten containing foods, and its implementation could, as a result, increase the risk of developing obesity, and, consequently, metabolic syndrome and diabetes<sup>[41-43]</sup>. Therefore, assessment of fasting glucose and insulin in patients diagnosed with CD before and during the introduction of GFD should be performed. However, the subject is still controversial. Kabbani *et al.*<sup>[44]</sup> reported lower prevalence of metabolic syndrome and type 2 diabetes in patients under GFD treatment, regardless of treatment duration. Moreover, experiments carried out in C57BL/6 mice fed on a hyper fat diet with and without gluten showed that GFD reduced insulin resistance, adiposity and inflammation<sup>[45]</sup>, although it is necessary to consider that these mice did not present CD. In the present study, the finding of significantly higher insulin levels and HOMA-IR and lower QUICKI than in controls suggests the presence of a slightly altered carbohydrate metabolism, which could be related to the pro-inflammatory status described in CD patients and evidenced in our study by higher hsCRP levels. It has been previously proposed that inflammation could be a causative agent for alterations in carbohydrate metabolism through the action of cytokines such as TNF- $\alpha$ , IL-6 and IL-1 $\beta$ , among others<sup>[46,47]</sup>.

Studying lipoprotein profile in CD patients appears interesting, since there is evidence for both a decrease in cholesterol absorption and an increase in its synthesis<sup>[48-50]</sup>. In the current study, patients showed TC and LDL-C levels similar to controls. These findings are in disagreement with the decrease in both parameters previously reported for CD patients<sup>[5,51,52]</sup>. Patients evaluated in this study also presented lower HDL-C levels. There is prior evidence showing a 12% prevalence of CD in patients with low HDL-C concentration<sup>[53]</sup>, much higher than that reported for the general population, which implies a causal relationship between the presence of CD and the decrease in HDL-C. Unlike in the case of patients with insulin resistance<sup>[54,55]</sup>, this decrease was not found to be associated with higher CETP activity. Therefore,

this alteration could result from a lower synthesis and secretion of apo A-I<sup>[56]</sup>. Furthermore, longitudinal studies described an increase in HDL-C and apo A-I values after initiation of treatment with GFD<sup>[51]</sup>. In addition, CD patients presented an increase in TC/HDL-C and apo B/apo A-I ratios<sup>[57]</sup>, which reflect an imbalance between proatherogenic and antiatherogenic lipid factors. Another possibility that could explain HDL-C decrease is that HDL particles from CD patients would possess less capability to promote cholesterol efflux from cells. In fact, apo A-I has not only got a structural role in HDL particles, but it is also involved in multiple antiatherogenic functions including cholesterol efflux promotion<sup>[58]</sup>. Due to the decrease in intestinal apo A-I synthesis, the number of circulating HDL particles would be diminished and, in turn, each particle would be depleted in this apolipoprotein. As a matter of fact, in other inflammatory pathologies such as rheumatoid arthritis, alterations in HDL functionality have been associated with higher risk of CVD<sup>[59]</sup>. Study of HDL functions in affected patients could provide important evidence linking CD and CVD risk.

Regarding hematological parameters, only folic acid was decreased in CD patients. This finding is consistent with previous reports that show a decrease in folic acid levels as a consequence of impaired intestinal absorption, resulting from the damage to the intestinal epithelium caused by the inflammatory process<sup>[60]</sup>. This folic acid deficiency persists, in many cases, even after the initiation of treatment with GFD<sup>[61]</sup>. It is worth noting that a decrease in folic acid levels may lead to an increase in homocysteine concentration. One of the main homocysteine clearance pathways consists of its re-methylation and recycling to methionine, a process catalyzed by the methionine synthase (MTR) enzyme, which links the folate cycle with homocysteine metabolism<sup>[62]</sup>. In fact, different studies showed higher homocysteine levels in CD patients<sup>[26,63,64]</sup>. Importantly, this increment was independently associated with increased risk and severity of coronary artery disease<sup>[65]</sup>. Moreover, high homocysteine levels were also identified as independent predictors of a suboptimal response to antiplatelet therapy with acetyl salicylic acid, thus favouring thrombotic complications in patients with coronary artery disease<sup>[66]</sup>. In addition, in a meta-analysis of randomized controlled trials, Liu *et al.*<sup>[67]</sup> demonstrated that folic acid supplementation could improve the endothelial dysfunction observed in patients with coronary artery disease. Nevertheless, studies on homocysteine-lowering interventions with vitamin B6, folic acid (vitamin B9) or vitamin B12, administered alone or in combination with the purpose of preventing cardiovascular events, failed to consistently demonstrate their efficacy<sup>[68]</sup>. Therefore, consideration of increased homocysteine levels as a risk factor for CVD is still a controversial topic<sup>[69]</sup>.

In the present study, newly diagnosed CD patients, who were not following a GFD, presented higher insulin

levels, HOMA-IR index, apo B/apo A-I ratio and hsCRP concentration, as well as lower QUICKI index, HDL-C and apo A-I levels in comparison with sex and aged-matched healthy controls.

### Limitations

The main limitation of the present study is that, due to its cross-sectional design, it only provides a “snapshot” of the outcome and the characteristics associated with it, at a specific point in time. Then, only associations that may exist and are therefore useful in generating hypotheses for future research may be established. Another limitation is the sample size, which may be attributed to the fact that this study only included newly diagnosed CD patients, but that hampered the search for a possible correlation between intestinal inflammation factors and the risk of atherosclerosis.

### Conclusions

According to the results reported in the current study, untreated CD patients would present modifications in carbohydrate and lipoprotein metabolism and a pro-inflammatory status. Even though the magnitude of the alterations here described is not major, their presence and interaction through long periods of time in a chronic pathologic condition, as it is the case with CD, would constitute a high risk of developing atherosclerotic CVD.

## COMMENTS

### Background

Celiac disease (CD) is a multisystemic disease which main trait is chronic and diffuse inflammation of the mucosa of the small intestine. The only available therapy for CD consists of the implementation of a gluten free diet (GFD). It is well known that CD patients do not show classical cardiovascular disease (CVD) risk factors suggesting that CD would be associated with novel atherogenic risk factors or even with other non-identified risk factors such as inflammatory markers.

### Research frontiers

The role of novel atherogenic risk factors or inflammatory markers for CVD in CD patients has been poorly studied. The research hotspot is to assess which factors or markers for cardiovascular disease are found in CD patients in order to be able to prevent or treat them.

### Innovations and breakthroughs

It is well known that CD patients do not show classical CVD risk factors. Therefore in these patients, detection of novel atherogenic risk factors would be crucial to reduce the risk of CVD.

### Applications

The detection of CVD risk factors in CD patients is an important tool for the implementation of an adequate treatment.

### Terminology

CD is a disease which mainly affects the digestive system. Its main trait is chronic and diffuse inflammation of the mucosa of the small intestine and it can present a wide variety of clinical symptoms. It is remarkable that most cases of CD lack typical gastrointestinal symptoms and are, instead, very frequently associated with presentations known as atypical or extra-intestinal. Thus, its diagnosis represents one of the main challenges for health professionals

### Peer-review

This is an interesting study showing that patients with CD do have an atherogenic lipoprotein profile that may dispose them to develop CVD.

**Abstract****AIM**

To investigate feasibility of combined assessment of biochemical and electrophysiological myocardial impairment markers risk-stratifying patients with chronic heart failure (CHF).

**METHODS**

Serum levels of heart-type fatty acid binding protein (H-FABP) as a marker of ongoing myocardial damage and QRS duration on electrocardiogram were measured at admission in 322 consecutive patients with CHF. A prolonged QRS duration was defined as 120 ms or longer. The cut-off value for H-FABP level (4.5 ng/mL) was determined from a previous study. Patients were prospectively followed during a median follow up period of 534 d. The primary endpoint was cardiac deaths and rehospitalization for worsening CHF.

**RESULTS**

There were 117 primary events, including 27 cardiac deaths and 90 rehospitalizations. Patients were stratified into four groups according to H-FABP level and QRS duration ( $\geq 120$  ms). Multivariate analysis demonstrated that high H-FABP levels [hazard ratio (HR) = 1.745,  $P = 0.021$ ] and QRS prolongation (HR

1.612,  $P = 0.0258$ ) were independent predictors of cardiac events. Kaplan-Meier analysis demonstrated that the combination of high H-FABP levels and QRS prolongation could be used to reliably stratify patients at high risk for cardiac events (log rank test  $P < 0.0001$ ).

### CONCLUSION

Combined assessment of myocardial damage and electrical disturbance can be used to risk-stratify patients with CHF.

**Key words:** QRS prolongation; Heart-type fatty acid binding protein; Heart failure; Prognosis

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This was a prospective single center study with 322 consecutive patients with chronic heart failure (CHF) seeking to evaluate the feasibility of combined assessment of biochemical and electrophysiological markers of myocardial impairment for risk-stratifying patients with CHF. QRS prolongation and high heart-type fatty acid binding protein levels are independently associated with cardiac events in patients with CHF.

Combined assessment of myocardial damage and electrical disturbance in chronic heart failure. *World J Cardiol* 2017; 9(5): 457-465 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i5/457.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i5.457>

## INTRODUCTION

Chronic heart failure (CHF) is a major health problem with high mortality despite advance in medical therapy<sup>[1-3]</sup>. Various pathophysiological changes are reportedly associated with initiation and progression in CHF<sup>[4]</sup>. The role of biomarkers continues to increase in importance to evaluate and risk-stratify CHF patients<sup>[5]</sup>.

Heart-type fatty acid binding protein (H-FABP) is a small molecule protein (14-15 kDa), abundant in cytoplasm of cardiomyocytes and easily leaks to the circulation from damaged myocardium<sup>[6-8]</sup>. H-FABP is a potential myocardial damage marker. We and others reported that elevated serum H-FABP levels can predict poor outcomes in patients with CHF<sup>[9,10]</sup>. Progression of CHF is associated with persistent loss of cardiomyocytes, which can be clinically detected as a continuous increase in serum H-FABP levels<sup>[11]</sup>.

Electrocardiography (ECG) is routinely performed and is useful for evaluating the etiology of heart failure. Several electrocardiographic parameters were reported to predict poor outcome in HF patients<sup>[12-14]</sup>. QRS prolongation indicated electrical disturbance and is associated with left ventricular dyssynchrony and poor cardiac prognosis in patients with CHF<sup>[15-17]</sup>. Not

surprisingly, due to the complex pathogenesis of CHF, a single biomarker cannot be used to predict the absolute risk of future cardiac events. Therefore, the purpose of the present study was to investigate whether a combined measurement of a myocardial damage marker and electrical disturbance can be used to risk-stratify CHF patients.

## MATERIALS AND METHODS

### Study population

We prospectively studied 322 patients with CHF, who were admitted to our hospital for the diagnosis or treatment of CHF. The diagnosis of CHF was made by two cardiologists who used the generally accepted Framingham criteria, including a history of dyspnea and symptomatic exercise intolerance, signs of pulmonary congestion, peripheral edema, and radiologic or echocardiographic evidence of left ventricular enlargement or dysfunction. Demographic and clinical data including age, gender, New York Heart Association (NYHA) functional class, and medications at discharge were obtained from hospital medical records and interviews with patients. The diagnoses of hypertension, diabetes mellitus and hyperlipidemia were ascertained from the medical records or current or previous medical therapy. Glomerular filtration rate (GFR) was estimated using the modification of diet in renal disease equation with the Japanese coefficient, as previously reported<sup>[18]</sup>. The exclusion criteria for the present study were acute coronary syndrome, bundle branch block, pace maker implantation, a serum creatinine concentration  $> 2.0$  mg/dL, and implantation of a heart valve prosthesis.

### Electrocardiographic and echocardiographic studies

Standard 12-lead ECG was performed at admission. QRS duration was measured by averaging of all heartbeats all leads. A normal QRS duration was defined as less than 120 ms and a prolonged QRS as 120 ms or longer. Transthoracic echocardiography was performed by physicians who were blinded to the biochemical data.

### Assay of H-FABP and brain natriuretic peptide concentrations

Venous blood samples were obtained at admission for measurements of serum H-FABP levels. These samples were immediately centrifuged at 2500 G for 15 min at 4 °C. The clarified serum samples were frozen, stored at -70 °C, and thawed just before assay. H-FABP concentration was measured using a two-step sandwich enzyme-linked immunosorbent assay kit (MARKIT-M HFABP, Dainippon Pharmaceutical Co Ltd, Tokyo, Japan) as previously reported<sup>[19,20]</sup>. The cut-off value for H-FABP concentration (4.5 ng/mL) was determined from a previous study<sup>[21]</sup>. The same blood samples were used for measurement of plasma brain natriuretic peptide (BNP) concentrations. The samples were transferred to chilled tubes containing of ethylene diamine tetraacetic acid disodium salt (4.5 mg) and aprotinin (500 U/mL),

and immediately centrifuged at 1000 G for 15 min at 4 °C. The clarified plasma samples were frozen, stored at -70 °C and thawed just before assay. BNP concentrations were measured using a commercially available specific radioimmunoassay for human BNP (Shiono RIA BNP assay kit, Shionogi Co Ltd, Tokyo, Japan). The analytical ranges, and intra- and inter-assay coefficients of variation for the H-FABP and BNP assays were, 1.1-250 ng/mL, 3% and 3.5%, and 4.0-2000 pg/mL, 10.9% and 10.6%, respectively.

### End points and follow-up

Patients were prospectively followed for a median period of 534 d (range 203-1014). Patients were followed in our hospital outpatient clinic every month. The other patients were followed by telephone twice a year until 2555 d after discharge. The end points were cardiac death, defined as death due to progressive heart failure, myocardial infarction or sudden cardiac death, and progressive heart failure requiring rehospitalization. Sudden cardiac death was defined as death without definite premonitory symptoms or signs, and was established by the attending physician. The study was approved by the Institutional Ethics Committee, and all patients gave written informed consent prior to participating. The study was performed in accordance with the Helsinki Declaration.

### Statistical analysis

Results are presented as the mean values  $\pm$  SD for continuous variables and as percentages of the total number of patients for categorical variables. The independent samples *t* test and  $\chi^2$  test or linear regression analysis were used for comparison of continuous and categorical variables, respectively. A Cox proportional hazard analysis was performed to assess the independent predictors for cardiac events in the entire population. Statistical significance was defined as  $P < 0.05$ . Variables identified as significant by univariate analysis were entered into the multivariate analysis. The cardiac event-free curve was computed according to the Kaplan-Meier method, and comparison of cardiac event-free survival between subgroups was performed using the log-rank test. Receiver operating characteristic (ROC) curve analysis, as well as area under the curve (AUC) was used as measures of the predictive accuracy of traditional prognostic factors for cardiac events. In addition, the net reclassification improvement (NRI) and integrated discrimination improvement (IDI) were calculated in order to quantify the improvement for the corrected reclassification and sensitivity after inclusion of high H-FABP levels and QRS prolongation in the model. Statistical analyses were performed using a standard software package (JMP version 8; SAS Institute Inc., Cary, NC, United States) or R 3.0.2 with additional packages (Rcmdr, Epi, pROC and PredictABEL).

## RESULTS

### Patient characteristics

Table 1 shows that clinical characteristics of the study patients. The mean age of the patients was  $69 \pm 13$  years. There were 175 patients in NYHA functional class II, 105 in NYHA class III, and 42 in NYHA class IV. Diabetes mellitus, dyslipidemia, and hypertension were identified in 117 (36%), 87 (26%), and 217 (67%) of the CHF patients, respectively. The etiology of heart failure was dilated cardiomyopathy in 80 (25%) patients, hypertensive heart disease in 14 (4%), hypertrophic cardiomyopathy in 21 (7%), ischemic heart disease in 65 (20%), valvular heart disease in 80 (25%), arrhythmia in 24 (7%), and other etiologies in 38 (12%) patients. The median H-FABP and BNP levels were 4.7 (3.3-7.6) ng/mL and 397 (135-853) pg/mL, respectively. The mean QRS duration was  $107 \pm 20$  ms and 61 patients (19%) showed QRS prolongation. Simple linear regression analysis showed that QRS duration was not correlated with H-FABP level ( $r = 0.091$ ,  $P = 0.1019$ ) or BNP level ( $r = 0.066$ ,  $P = 0.2356$ ) as shown in Figure 1.

### Clinical outcomes

During the follow-up period, there were 117 primary events, including 27 cardiac deaths and 90 re-admissions for worsening CHF. Among 27 cardiac deaths, there were 21 deaths from worsening CHF, 2 fatal acute myocardial infarction, and 4 sudden cardiac deaths. The patients with cardiac events were older and had a more severe NYHA functional class compared to those who did not (Table 1). Furthermore, higher BNP and H-FABP levels, and a higher prevalence of QRS prolongation were observed in patients who experienced cardiac events, compared with those who did not. Patients who experienced cardiac events also had a lower estimated GFR (eGFR) compared with those who did not. There was no difference in gender, prevalence of atrial fibrillation, hypertension, diabetes mellitus or hyperlipidemia between CHF patients with and without cardiac events. Patients who experienced cardiac events took loop diuretics more frequently than patients who were event-free.

### Independent predictors of cardiac events

To investigate the risk factors for cardiac events, Cox proportional hazards regression analyses were performed (Table 2). In the univariate analysis, high H-FABP levels and QRS prolongation were significantly associated with cardiac events. Further, age, NYHA functional class, BNP levels, and eGFR were significantly associated with cardiac events. In the multivariate analysis, NYHA functional class, eGFR, high serum H-FABP levels, and prolonged QRS duration were independently associated with cardiac events.

HR: Hazard ratio; SD: Standard deviation; BNP: Brain natriuretic peptide; eGFR: Estimated glomerular filtration rate; NYHA: New York Heart Association.

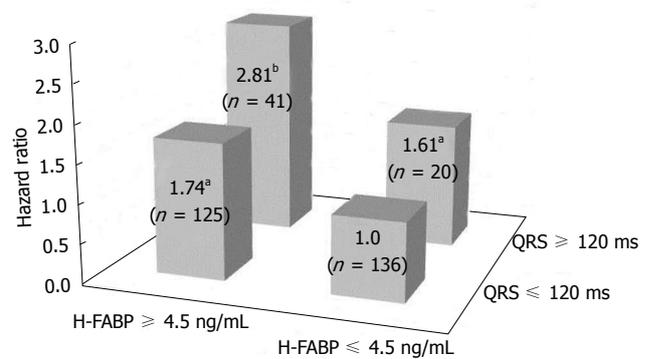

**Figure 1** Relationship between QRS duration and heart-type fatty acid binding protein levels (A) and brain natriuretic protein levels (B). BNP: Brain natriuretic peptide; H-FABP: Heart-type fatty acid-binding protein.

**Figure 2** Cardiac mortality and all cardiac events among the four groups based on heart-type fatty acid-binding protein level and QRS duration. Normal group ( $n = 136$ ), H-FABP  $\leq 4.5$  ng/mL and QRS duration  $< 120$  ms; QRS prolongation group ( $n = 20$ ), H-FABP  $\leq 4.5$  ng/mL and QRS duration  $\geq 120$  ms; high H-FABP group ( $n = 125$ ), H-FABP  $> 4.5$  ng/mL and QRS duration  $< 120$  ms; and high H-FABP + QRS prolongation group ( $n = 41$ ), H-FABP  $> 4.5$  ng/mL and QRS duration  $\geq 120$  ms. H-FABP: Heart-type fatty acid-binding protein.

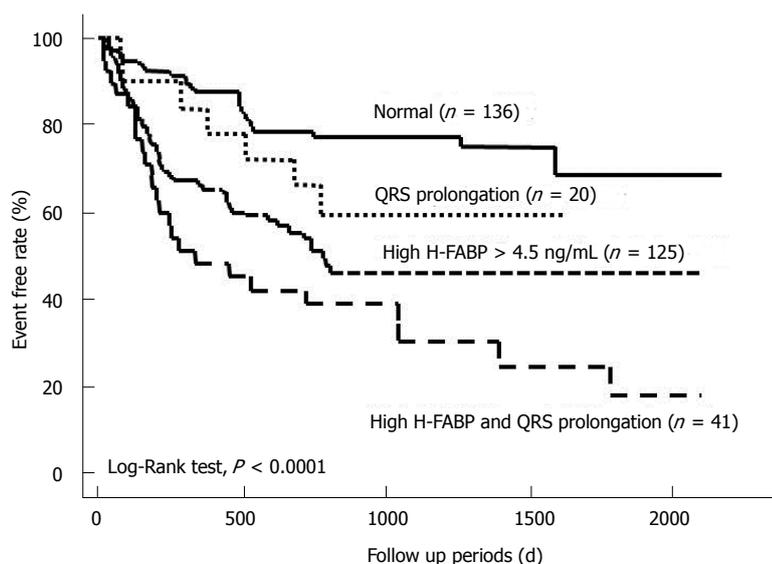

**A combined assessment of QRS duration and H-FABP level**

Simple linear analysis demonstrated that QRS duration was not correlated with H-FABP or BNP levels in patients with CHF (Figure 1). The patients were divided into four groups based on QRS prolongation and H-FABP cutoff values as shown in Figure 2: (1) normal group ( $n = 136$ ), H-FABP  $\leq 4.5$  ng/mL, QRS duration  $< 120$  ms; (2) QRS prolongation group ( $n = 20$ ), H-FABP  $\leq 4.5$  ng/mL, QRS  $\geq 120$  ms; (3) high H-FABP group ( $n = 125$ ), H-FABP  $> 4.5$  ng/mL, QRS duration  $< 120$  ms; and (4) high H-FABP + QRS prolongation group ( $n = 41$ ), H-FABP  $> 4.5$  ng/mL, QRS duration  $\geq 120$  ms. High serum H-FABP + QRS prolongation group showed the highest rates of cardiac deaths and cardiac events ( $P < 0.001$ ). Multivariate Cox hazard analysis revealed that after

**Figure 3** Hazard ratios relative to the normal group after adjustment for age, New York Heart Association functional class, brain natriuretic peptide level and estimated glomerular filtration rate. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs normal group. H-FABP: Heart-type fatty acid-binding protein.

adjustment for age, NYHA functional class, BNP levels and eGFR, the QRS prolongation, high H-FABP, and high H-FABP + QRS prolongation groups had 1.61-fold ( $P < 0.05$ ), 1.74-fold ( $P < 0.05$ ), and 2.81-fold higher risks of cardiac events ( $P < 0.01$ ), respectively, compared with the normal group (Figure 3). The characteristics of these four groups are presented in Table 3. The QRS prolongation group had lower BNP levels than the high H-FABP and high H-FABP + QRS prolongation groups. The QRS prolongation group also had the lowest left ventricular (LV) ejection fraction and largest LV end-diastolic diameter among 4 groups. Kaplan-Meier analysis demonstrated that the high H-FABP + QRS prolongation group had a significantly higher rate of cardiac events than the other groups (Figure 4). In order to examine whether model fit and discrimination improved with the addition of high H-FABP levels and QRS prolongation to the traditional prognostic factors of age, BNP level, NYHA functional class and eGFR, the differences in area under the ROC curves, and the improvement in NRI and IDI were evaluated for two models: With (group 2) or without (group 1) a high H-FABP level and QRS prolongation. The area under the ROC curve for predicted cardiac events was significantly

Normal group (n = 136): H-FABP ≤ 4.5 ng/mL and QRS duration < 120 ms; QRS prolongation group (n = 20): H-FABP ≤ 4.5 ng/mL and QRS duration ≥ 120 ms; High H-FABP group (n = 123): H-FABP > 4.5 ng/mL and QRS duration < 120 ms; and High H-FABP and QRS prolongation group (n = 41): H-FABP > 4.5 ng/mL and QRS duration ≥ 120 ms. ACE: Angiotensin-converting enzyme; ARB: Angiotensin receptor blocker; BNP: Brain natriuretic peptide; eGFR: Estimated glomerular filtration rate; H-FABP: Heart-type fatty acid-binding protein; LV: Left ventricular; NYHA: New York Heart Association.

**Table 4** Statistics for model fit and improvement with the addition of high heart-type fatty acid-binding protein and QRS prolongation predicted on the prediction of cardiac events

	Group 1	Group 2	P value
AUC of ROC curve	0.668	0.706	0.029
NRI (95%CI)	Ref	0.223 (0.073-0.372)	0.003
IDI (95%CI)	Ref	0.036 (0.015-0.056)	0.016

AUC: Area under the curve; CI: Confidence interval; IDI: Integrated discrimination improvement; NRI: Net reclassification improvement; ROC: Receiver operator characteristics. Group 1: Age + BNP + NYHA + eGFR; Group 2: Group 1 + H-FABP > 4.5 ng/mL + QRS duration  $\geq$  120 ms. BNP: Brain natriuretic peptide; eGFR: Estimated glomerular filtration rate; H-FABP: Heart-type fatty acid-binding protein; NYHA: New York Heart Association.

greater for group 2 than group 1 (Table 4). Further, the group 2 model improved the NRI and IDI values for predicting cardiac events compared with the group 1 model.

## DISCUSSION

In the present study, we demonstrated that QRS prolongation as a marker of electrical disturbance, and high H-FABP levels as a marker of ongoing myocardial damage are significantly related to cardiac events in CHF patients. The inclusion of high H-FABP level and QRS prolongation with BNP level, NYHA functional class and eGFR in the model for predicting cardiac events improved the NRI and IDI values, indicating effective reclassification and discrimination. Therefore, a combined measurement of H-FABP levels and QRS duration is a promising strategy for risk stratification for future cardiac events in CHF patients.

There are several markers of myocardial damage, including troponin T, troponin I and H-FABP<sup>[9,22]</sup>. Since H-FABP is a small cytosolic protein, it is readily released into the circulation when cardiomyocytes are injured. The mechanism by which serum levels of H-FABP are increased in CHF has been reported to be related to cardiomyocyte necrosis, apoptosis, chronic inflammation and microcirculatory disorder<sup>[8,23]</sup>. In this study, elevated levels of H-FABP were significantly associated with cardiac events, which are consistent with previous reports<sup>[19,24]</sup>.

QRS duration reflects LV conduction disturbance, LV systolic dysfunction and LV dilation<sup>[25]</sup>. In this study, the QRS prolongation group had the lowest LV ejection fraction and the greatest LV end-diastolic diameter compared with the other groups. Since left bundle branch block is an unfavorable prognostic marker in CHF patients<sup>[26,27]</sup>, patients with bundle branch block were excluded from the present study. Therefore, QRS prolongation is an independent risk factor for cardiac events in patients with CHF, irrespective of bundle branch block. Recently, it was reported that cardiac resynchronization therapy (CRT) can improve the cardiac prognosis in patients with QRS prolongation<sup>[28,29]</sup> and

measurement of QRS duration has attracted widespread interest.

The present study showed that there was no correlation between QRS duration and H-FABP or BNP levels in patients with CHF. These results suggest that H-FABP and BNP levels and QRS duration reflect different pathophysiological backgrounds. In the multivariate analysis, high H-FABP levels and QRS prolongation were independent predictors of cardiac events. In addition, multivariate Cox hazard analysis revealed that the combination of elevated H-FABP levels and QRS prolongation was associated with the highest increase in risk for cardiac events (2.81-fold) compared with the normal group.

Taniguchi *et al.*<sup>[30]</sup> reported that the combined measurement of BNP levels and QRS duration can be used to predict cardiac events in heart failure patients. We recently determined that the AUC for prediction of cardiac events in heart failure was greater for H-FABP level than for BNP level<sup>[10]</sup>. Both the sensitivity and the specificity for predicting cardiac events were significantly greater for H-FABP level than for BNP level, indicating that H-FABP level is superior to BNP level for predicting cardiac events in CHF patients<sup>[10]</sup>. In this study, BNP level was not associated with cardiac events in the multivariate analysis. A weak correlation between H-FABP levels and BNP levels was observed (data not shown), which was consistent with the results from a previous study<sup>[10]</sup>. H-FABP and BNP reflect different pathophysiological backgrounds as markers of left ventricular overload. Combined assessment of H-FABP as a biochemical marker of myocardial damage and QRS prolongation as an electrophysiological marker of myocardial impairment is a potentially useful method for risk-stratification in CHF patients.

This study has several limitations. The effect of changes in QRS duration and H-FABP level between the time of hospitalization and discharge were not evaluated. However, it was reported that QRS duration in patients with CHF did not change significantly over two years<sup>[31]</sup>. On the other hand, although H-FABP level is usually decreased at discharge, persistently elevated H-FABP levels were reported to be associated with adverse outcomes in patients with CHF<sup>[32]</sup>. Therefore, further research is needed to elucidate whether the combined assessment of H-FABP level at discharge and QRS prolongation can be used to more precisely predict the cardiac prognosis of patients with CHF.

In conclusion, the combined assessment of markers of ongoing myocardial damage and electrical disturbance can be used to risk-stratify patients with CHF.

## ACKNOWLEDGMENTS

The authors would like to express their gratitude to the staff at the Department of Cardiology, Pulmonology, and Nephrology, Yamagata University School of Medicine, Yamagata, Japan, for their cooperation while we conducted this study.

## COMMENTS

### Background

Despite advancing medical therapy, chronic heart failure (CHF) is a major health problem with high morbidity and mortality. It is important to risk-stratify patients with CHF.

### Research frontiers

Prolonged QRS duration reflects intraventricular conduction disturbance caused by left ventricular fibrosis and cardiac myocyte loss, and is associated with cardiac prognosis in patients with CHF. However, there are CHF patients with narrow QRS duration showing poor prognosis. Biochemical myocardial damage markers are also useful for predicting prognosis in addition to electrophysiological myocardial impairment markers in CHF patients.

### Innovations and breakthroughs

The combined assessment of markers of ongoing myocardial damage and electrical disturbance can risk-stratify patients with CHF.

### Applications

It may be difficult to predict prognosis of CHF patients using a single biomarker precisely. The combined assessment of commonly used biomarkers is easily applicable to clinical practice.

### Terminology

Since heart-type fatty acid binding protein (H-FABP) is a low molecular weight protein and abundant in the cytosolic fraction of cardiomyocytes, it is rapidly released into the circulation from damaged myocardium. Therefore, H-FABP is a potential marker of ongoing myocardial damage.

### Peer-review

The manuscript was very easy to follow and well written.

lung adenocarcinoma who presented with shortness of breath and frequent episodes of cough-induced syncope. A large pericardial effusion was found on echocardiogram suggestive of cardiac tamponade. Pericardiocentesis was done which improved the dyspnea and eventually resolved the syncope. There are only two other cases reported in the literature with cough-induced syncope in the setting of pericardial effusion or cardiac tamponade. Our clinical vignette also highlights the importance of pulsus paradoxus identification in patients with cough induced syncope to rule out cardiac tamponade since this is the most sensitive physical finding for its diagnosis.

**Key words:** Cardiac tamponade; Cough-induced syncope; Pericardial effusion

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Cough-induced syncope should be a hint towards the consideration of either pericardial effusion or cardiac tamponade. Aside from the medical history and the diagnostic imaging modalities to include echocardiogram and chest computed tomography, clinical evaluation to explore pulsus paradoxus is imperative which has a high sensitivity in the diagnosis of cardiac tamponade. Timely diagnosis of cardiac tamponade because of these clues translate into prompt intervention to prevent the deleterious complications associated with it.

### Abstract

We report a case of a 75-year-old male with history of

### INTRODUCTION

Cough-induced syncope is a validated rare phenomenon

**Figure 1** Transthoracic echocardiogram showing a large pericardial effusion with right ventricular diastolic indentation and collapse suggestive of tamponade.

which denotes cough as the etiology of the syncope and has been linked with chronic obstructive disease and constrictive pericarditis. It is very rare to have cough-induced syncope in a case of pericardial effusion or cardiac tamponade with only two other reported cases in the literature. Therefore, we describe a case of cough-induced syncope in an elderly gentleman with cardiac tamponade, elaborating further the pathophysiology behind this rare occurrence.

## CASE REPORT

A 75 years old male with known history of stage 4 adenocarcinoma of the lung with recent right lung biopsy, chronic obstructive pulmonary disease, hypertension, diabetes mellitus, hyperlipidemia and peripheral vascular disease presented with symptoms of increased shortness of breath for several days before hospitalization accompanied by cough with subsequent syncopal episodes. He had three syncopal episodes, two of them witnessed and were associated with coughing spells, lasting for 30 s to 1 min with complete recovery thereafter. No seizure-like activity was noted during the syncopal event. Prior to this presentation, he had never had a syncopal episode. The patient's syncope was not associated with other precipitants including laughter and micturition. On admission to the hospital, he was hypertensive with a blood pressure of 151/88 mmHg and with a pulse rate of 100. General appearance was apparent for occasional cough with no signs of cyanosis nor worsening shortness of breath. Further examination revealed mild diminished breath sounds at the bases. Cardiac evaluation showed sinus tachycardia with a soft 2/6 systolic murmur at the apex and a pulsus paradoxus of 16 mmHg but no note of muffled heart sounds, distended neck veins or peripheral edema.

Neuroexamination was intact and nonfocal. Pericardial effusion was considered immediately on admission because of his medical history, his symptoms, and the pulsus paradoxus which was confirmed later on by imaging studies. Hemogram revealed mild anemia (12.5 g/dL) and leukocytosis (12.8/nL). Electrocardiogram demonstrated sinus tachycardia (103 bpm) with intraventricular conduction delay but no low voltage complexes. No evident electrical alternans appreciated. Carotid ultrasound was done during his hospitalization which demonstrated no evidence of hemodynamically significant stenosis of the carotid system bilaterally and with normal antegrade flow of the vertebral arteries. Chest radiograph showed right pleural effusion. Chest computed tomography confirmed worsening bilateral pleural effusion as well as pericardial effusion but with no pulmonary embolus. Transthoracic echocardiography revealed a large pericardial effusion with right ventricular diastolic indentation and collapse suggestive of tamponade (Figure 1) which was also evident on the M-mode (Figure 2). Mitral valve inflow E wave velocity showed greater than 25% respiratory variation also suggestive of tamponade physiology (Figure 3). The cardiothoracic surgery team was involved to move forward with a pericardial window. Pericardiocentesis was done and drained 600 mL of hemorrhagic fluid. Subsequently, thoracentesis was performed and drained 500 mL of serosanguineous pleural fluid. Pericardial and pleural fluid cytology revealed adenocarcinoma. After drainage of both pericardial and pleural effusion, his dyspnea improved significantly and subsequently his cough-induced syncope resolved.

## DISCUSSION

Cough-induced syncope is a well-recognized but uncom-

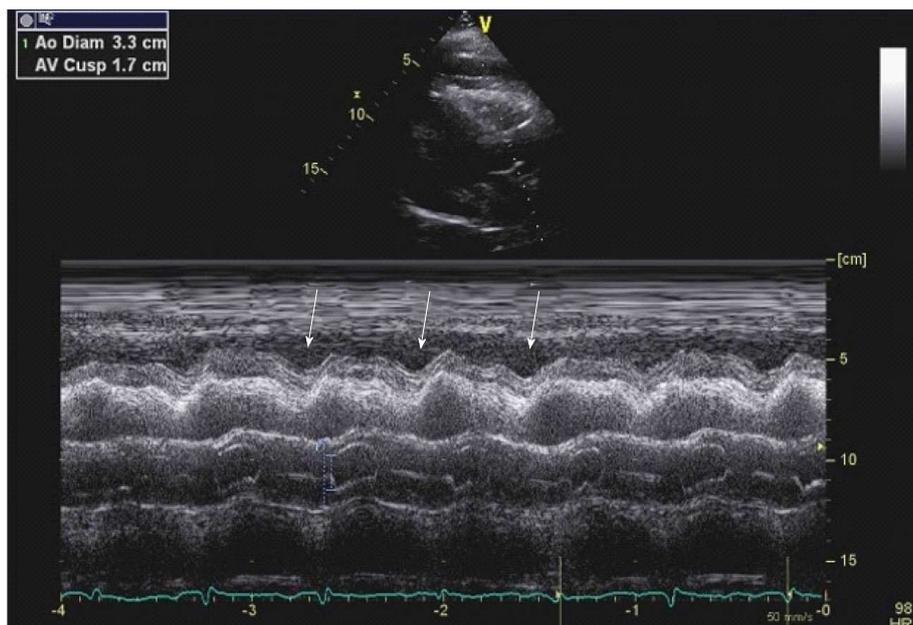

Figure 2 M-mode showing right ventricular diastolic indentation.

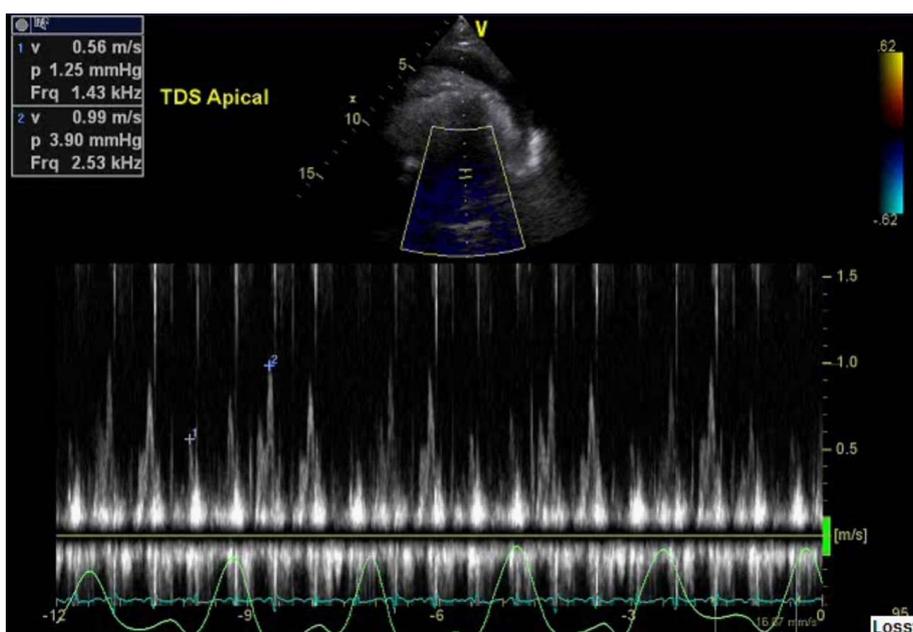

Figure 3 Transthoracic echocardiogram showing a mitral valve inflow E wave velocity greater than 25% respiratory variation suggestive of tamponade physiology.

mon phenomenon in which the cough is the main culprit of the syncope<sup>[1]</sup>. It is associated with chronic obstructive pulmonary disease and constrictive pericarditis<sup>[2]</sup>, although it is very rare to have cough induced syncope in a case of pericardial effusion or cardiac tamponade<sup>[3]</sup>. The proposed pathophysiology is multifactorial wherein there is a more exaggerated drop in blood pressure in response to cough compared to patients with other causes of syncope<sup>[4]</sup>. Also, the cough increases intrathoracic pressure, which decreases blood return to the heart and cardiac output, which is already reduced by the cardiac tamponade or moderate/large pericardial

effusion. This phenomenon has been reported with even small pericardial effusions<sup>[5]</sup>. The combination of these events leads to cerebral hypoperfusion resulting to syncope. In subacute cardiac tamponade, these events occur over days to weeks and is usually associated with neoplastic, uremic or idiopathic pericarditis; it may be asymptomatic early in the course, but once intracardiac pressures reach a critical value, the patients develop symptoms of increased filling pressures and limited cardiac output and syncopal events<sup>[6]</sup>. There are two reported cases in the literature of moderate pericardial effusion associated with cough-induced syncope which

also presented with pulsus paradoxus with a drop of > 15 mmHg systolic blood pressure but no evidence of echocardiographic criteria for tamponade<sup>[1,3]</sup>. Pulsus paradoxus greater than 10 mmHg with a pericardial effusion increases the likelihood of tamponade (likelihood ratio, 3.3; 95%CI: 1.8-6.3), while a pulsus paradoxus of 10 mmHg or less lowers the likelihood (likelihood ratio, 0.03; 95%CI: 0.01-0.24)<sup>[7]</sup>. Sensitivity of pulsus paradoxus for tamponade exceeds 80% and is higher than any other single physical finding although its specificity is only 70%<sup>[8]</sup>. Echocardiogram's sensitivity is not significantly superior than clinical examination with reported sensitivity of the echocardiographic findings of right atrial collapse ranging from 50% to 100% and specificity ranging from 33% to 100%. Its sensitivity in identifying right ventricular collapse ranges from 48% to 100% whereas specificity ranges from 72% to 100%<sup>[9,10]</sup>. In one of the reported cases of cough induced syncope, the pericardial effusion was from metastatic non-small cell carcinoma, while the other case was secondary to suspected viral pericarditis in which pericardiocentesis of both cases afforded complete resolution of cough-syncope syndrome cycle<sup>[1,3]</sup>.

It is important to consider either pericardial effusion or cardiac tamponade in any case of cough-induced syncope. Pulsus paradoxus has a high sensitivity in the diagnosis of cardiac tamponade and should therefore be checked in every patient with cough-induced syncope, consequently, can provide early diagnosis and intervention.

## COMMENTS

### Case characteristics

This is an interesting clinical vignette on syncope that was precipitated by cough which may serve as a clue to consider the diagnosis of pericardial effusion or cardiac tamponade.

### Clinical diagnosis

The patient presented with progressive shortness of breath accompanied by cough with subsequent syncopal episodes, noted clinically to have pulsus paradoxus, and was found out to have a pericardial effusion with tamponade physiology on echocardiogram.

### Differential diagnosis

Cerebrovascular accident, vasovagal syncope, seizure.

### Laboratory diagnosis

Pericardial and pleural fluid cytology revealed adenocarcinoma.

### Imaging diagnosis

Chest computed tomography showed both pericardial effusion and bilateral pleural effusion but with no pulmonary embolus while transthoracic echo-

cardiography revealed a large pericardial effusion with tamponade.

### Treatment

Surgical drainage of the pericardial and pleural fluid afforded significant improvement of dyspnea and resolution of cough-induced syncope.

### Related reports

Cough-induced syncope is a very rare occurrence that has been associated with evolving pericardial effusion or cardiac tamponade with only two similar cases reported in the literature.

### Term explanation

Pulsus paradoxus is a drop in systolic blood pressure of more than 10 mmHg during inspiration which is a sign of cardiac tamponade or pericarditis.

### Experiences and lessons

Pericardial effusion or cardiac tamponade should be considered in patients with cough-induced syncope especially if accompanied by pulsus paradoxus which has a high sensitivity in such case.

### Peer-review

The report has clinical interest.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Dr. Joaquin De Haro, MD, PhD, Professor, Staff Physician, Surgeon, Angiology and Vascular Surgery Department, Hospital Universitario Getafe, 28905 Madrid, Spain

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Intense exercise may cause heart remodeling to compensate increases in blood pressure or volume by increasing muscle mass. Cardiac changes do not involve only the left ventricle, but all heart chambers. Physiological cardiac modeling in athletes is associated with normal or enhanced cardiac function, but recent studies have documented decrements in left ventricular function during intense exercise and the release of cardiac markers of necrosis in athlete's blood of uncertain significance. Furthermore, cardiac remodeling may predispose athletes to heart disease and result in electrical remodeling, responsible for arrhythmias. Athlete's heart is a physiological condition and does not require a specific treatment. In some conditions, it is important to differentiate the physiological adaptations from pathological conditions, such as hypertrophic cardiomyopathy, arrhythmogenic dysplasia of the right ventricle, and non-compaction myocardium, for the greater risk of sudden cardiac death of these conditions. Moreover, some drugs and performance-enhancing drugs can cause structural alterations and arrhythmias, therefore, their use should be excluded.

**Key words:** Athlete's heart; Cardiac damage; Fibrosis; Intense exercise; Arrhythmogenic dysplasia of the right ventricle; Atrial fibrillation; Doping; Anabolic-androgenic steroids; Hypertrophic cardiomyopathy

**Core tip:** Athlete's heart is a physiological condition that in some cases can simulate pathological disease,

sometimes due to the use of doping drugs. Furthermore, exercise can induce atrial dilation and arrhythmias. Our objective is to analyze the current literature and to review the most important changes in the heart of athletes, from the different molecular pathways to the structural anomalies.

## INTRODUCTION

High-intensity exercise training leads to morphological, functional, and electrical remodeling of the heart, which are included in the "athlete's heart", characterized by increased left ventricular mass (LVM), cavity dimensions and wall thickness<sup>[1]</sup>. Athletes with left ventricular (LV) hypertrophy generally have normal cardiac function and normal systolic and diastolic function<sup>[2]</sup>. Athletes exhibit an improvement in myocardial diastolic indices and supernormal LV diastolic function<sup>[3]</sup>. Recent studies have documented decrements, especially in right ventricular (RV) function, during intense endurance exercise<sup>[4,5]</sup>. Actual evidence suggests that there may be some overlap between physiological and pathological conditions, such that a modest amount of fibrosis may be present in cardiac remodeling associated with lifelong endurance training and then acts as a substrate for arrhythmias<sup>[6]</sup>.

Our objective is to describe the mechanisms of cardiac remodeling in athletes and to delineate the most important differences, from the molecular mechanisms to the structural changes, between athlete's heart and pathological conditions, taking into account the most important cardiomyopathy, arrhythmias and the abuse of performance-enhancing drugs.

## PHYSIOLOGICAL VS PATHOLOGICAL CARDIAC HYPERTROPHY: FROM PHYSICAL PRINCIPLES TO MOLECULAR MECHANISMS

Cardiac hypertrophy is an adaptive response to the increased cardiac loading that normalizes wall stress, according to Laplace relationship (Figure 1). Unfortunately, long-term maladaptive remodeling of reactive hypertrophy in various cardiovascular diseases (*e.g.*, valvular heart disease, myocardial ischemia, coronary artery disease, hypertension, and cardiomyopathy) is associated with gradual ventricular dilation, due to loss of myocytes and cardiac fibrosis<sup>[7]</sup>. Physiological hypertrophy, such as athlete's heart, is typically not associated with myocyte

death, although recent studies have shown myocardial damage during intense exercise and RV inflammation and fibrosis in long term endurance athletes<sup>[4,8]</sup>. The shift from compensated pathological hypertrophy to failure of myocardium includes cellular and molecular events, such as myocyte death, with three different mechanisms: Apoptosis, necrosis and autophagic cell death<sup>[9,10]</sup>. Cardiomyocyte replacement and myocardial fibrosis are representative of all types of pathological hypertrophy and proceed along with functional decompensation. To explain fibrosis and necrosis in athlete's heart, interesting is the "ischemic core" hypothesis: Hypertrophic cardiomyocyte becomes ischemic when his surface exceeds the distance across which oxygen can diffuse down its concentration gradient from adjacent capillaries, with contractile depression and cellular death<sup>[11]</sup>. Physiological hypertrophy is associated with a normal or increased number of myocardial capillaries, due to the activation of VEGF pathway<sup>[9]</sup>. Akt is a serine/threonine protein kinase responsible for the cellular growth in multiple cell types, which can be activated by exercise. Recent data suggest that Akt pathway might be implicated both in physiological and pathological cardiac growth. In animal models, myocardial expression of Akt pathway caused reversible hypertrophy after 2 wk of strenuous exercise, but an irreversible cardiomyopathy with decreased capillary density and fibrosis after 6 wk of intense training. It seems that myocardial angiogenesis is more intense in the acute phase of heart hypertrophy but insufficient in the advanced phase: Excessive "physiological" hypertrophy might be associated with poor angiogenesis and consequently with heart failure<sup>[12]</sup>.

Autocrine and paracrine triggers are released in response to hemodynamic overload, and definite substances are preferentially released for pathological or physiological stimuli. Insulin like growth factor 1 (IGF1) is released in the course of postnatal development and during exercise training and is increased in swim-trained rats and in veteran athletes compared with controls<sup>[13]</sup>, whereas elevated levels of angiotensin II (Ang II), catecholamine and endothelin-1 (ET-1) were observed in pathological hypertrophy and in heart failure subjects<sup>[14]</sup>. IGF1 promotes the PI3K-Akt molecular pathway to induce physiological cardiac hypertrophy, whilst the mitogen activated protein kinase (MAPK) pathway and calcineurin system are activated by Ang II and ET-1 in pathological hypertrophy (Table 1)<sup>[15]</sup>.

In conclusion, familial hypertrophic cardiomyopathy<sup>[16]</sup> is associated with sarcomeric protein mutations, such as cardiac troponin I or T,  $\beta$ -MHC,  $\alpha$ -MHC, myosin light chain,  $\alpha$ -tropomyosin, titin, and actin, with loss of contractile filaments and proteins of sarcomeric skeleton<sup>[17]</sup>.

## CARDIOMYOCYTE DAMAGE DURING INTENSE EXERCISE

After intense exercise, acute increases in troponin (cTn) and B-type natriuretic peptide have been detected in

**Table 1 Differences in between physiological and pathological hypertrophy**

Physiological hypertrophy	Pathological hypertrophy
Angiogenesis, release of VEGF	Perivascular fibrosis and inflammation
Activation of IGF-1 pathway (IGF-1- > PI3K- > Akt)	Activation of Angiotensin II, Catecholamine and Endotelin-1
No fibrosis	MAPK and Calcineurin pathway
Normal gene expression	Fibrosis, myocyte necrosis and apoptosis
Proportional chamber enlargement	Cardiac dysfunction

The table summarizes the differences in the cellular and molecular pattern between physiological and pathological hypertrophy. VEGF: Vascular endothelial growth factor; IGF-1: Insulin like growth factor; PI3K: Phosphoinositide 3-kinase; MAPK: Mitogen-activated protein kinase.

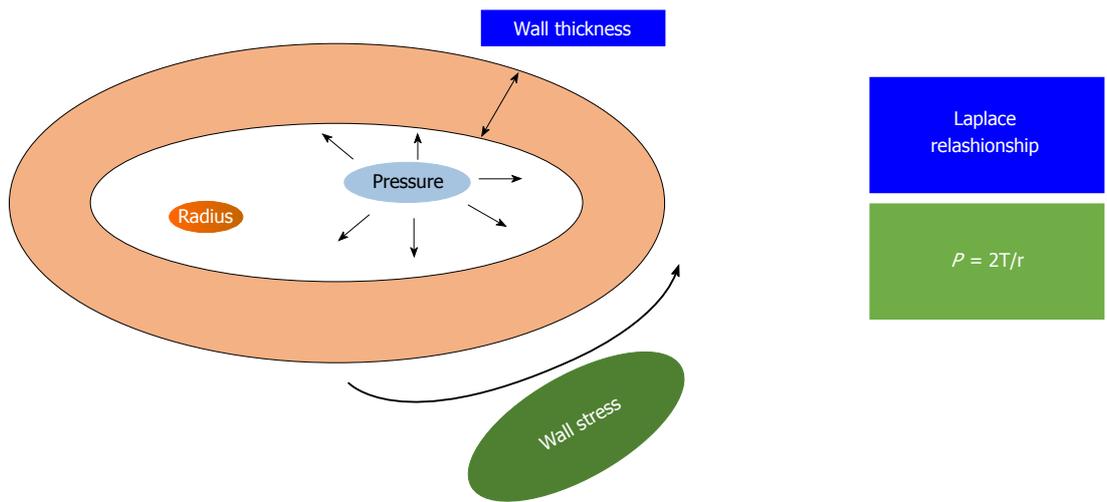

Figure 1 The figure shows the Laplace relationship: The pressure (P) generated in a sphere is directly proportional to the wall tension (T) and inversely related to the radius of the sphere (r).

athletes<sup>[18]</sup>. These are specific markers of myocyte injury and strain, but do not indicate a permanent injury. Potential mechanisms have been showed to elucidate cTn elevation after intense exercise, but actually, the elevation of cTn levels in healthy individuals cannot be explained by any of these theories<sup>[18]</sup>. It is possible that exercise induces an increase in myocardial sarcolemma permeability, due to mechanical stress on the cardiomyocytes and to increased production of oxidative radicals or altered acid base balance exercise, with passive diffusion of cTn from the intra- to extra-cellular compartment<sup>[18]</sup>. Cellular stretching might cause transient disruption of the myocardial plasma membrane and then, the release of cTn<sup>[19]</sup>. Furthermore, it can stimulate integrins, mediating the transport of entire cTn molecules out of viable cardiomyocytes<sup>[20]</sup>. Increased levels of cTn are more common in cycling or triathlon and depend on the exercise intensity<sup>[21]</sup>.

Case reports have shown myocardial fibrosis and late gadolinium enhancement, associated with cTn elevation post-exercise, in a small number of veteran athletes, but the pathogenesis of these cases remains unclear<sup>[18]</sup>.

## EXERCISE-INDUCED MYOCARDIAL FIBROSIS

Despite the widely recognized benefits of regular physical

activity, high-level exercise training may be associated with increased arrhythmia risk and even with sudden cardiac death<sup>[22]</sup>.

The athlete's heart is a benign condition, representing a normal adaptation to chronic exercise, in which loss of myocytes and abnormal deposition of collagen do not usually occur<sup>[15]</sup>. Pathological hypertrophy is associated with apoptosis and necrosis; in this case, the loss of myocytes is replaced with excessive collagen deposition. Excessive collagen deposition increases the stiffness of the ventricles, with consequent impaired contraction and relaxation, electrical conduction system fibrosis and reduced capillary density, leading to myocardial ischemia and the transition from hypertrophy to failure<sup>[15]</sup>. Interestingly, recent studies have shown myocardial inflammation and fibrosis in animal models of long term, intensive exercise. Chen *et al*<sup>[23]</sup> forced rats to swim strenuously and found histological evidence of localized myocyte damage, myocardial necrosis and inflammatory infiltrates. Benito *et al*<sup>[24]</sup> instituted an intensive treadmill running protocol in rats and demonstrated an increase in atrial and ventricular inflammation and fibrosis and a greater risk of ventricular arrhythmias in the "marathon rats". Fibrosis and inflammatory infiltrates have been identified in well-trained athletes who underwent cardiac biopsy for high probability of identifying a cardiac pathology<sup>[25]</sup>. Histology offers the tangible evidence of fibrosis, but inflammatory infiltrates and fibrosis are

non-specific and their etiology can be supposed only by other clinical factors. Furthermore, cardiac biopsy is an invasive procedure with significant risks and it is not applicable in the absence of high suspicion of heart disease. An accurate, non-invasive surrogate tool for detecting fibrosis is cardiac magnetic resonance (CMR) imaging with gadolinium contrast. Gadolinium-based extracellular paramagnetic contrast agents concentrate in areas of fibrosis and thus can be used to characterize injured myocardium. Using gradient-echo inversion recovery imaging, fibrosis appears as bright signal, with a prolonged wash-out time for gadolinium [delayed gadolinium enhancement (DGE)], contrasting with the normal myocardium, which looks black<sup>[6]</sup>. Several studies have identified the presence of DGE in the heart of extensively trained veteran athletes. In most cases, the patches of DGE were very small and sited in the septum and in RV insertion points, regions subjected to local stretching during exercise<sup>[6]</sup>. More recently, La Gerche *et al.*<sup>[4]</sup> have shown myocardial fibrosis by CMR and a reduction in RV systolic function in athletes with long-term exercise, suggesting that the heart has a limited capacity to tolerate the overload exercise. The patches of cardiac fibrosis may be the substrate for ventricular tachycardia and sudden death, in predisposed individuals<sup>[4]</sup>. Some authors have recently suggested a new entity, the so called Phidippides cardiomyopathy: Long term strenuous exercise can induce cardiac dilation and also activates resident macrophages, pericytes, and fibroblasts, resulting in the deposition of collagen and fibrosis<sup>[26,27]</sup>. CMR can also specifically detect intra-myocardial fibrofatty infiltration of the RV wall, typical of the arrhythmogenic right ventricular cardiomyopathy (ARVC), which often leads to ventricular arrhythmias and usually appears in young adulthood and affected asymptomatic or minimally symptomatic individuals<sup>[27]</sup>. In conclusion, it is possible that the RV is more susceptible to fatigue than the left ventricle after prolonged exercise. It needs more studies to identify a probable effect of exercise "dose" and their implication in the development of heart failure.

## IS CARDIAC REMODELING IN ATHLETES ALWAYS BENIGN?

Cardiac adaptations to exercise not involve only the left ventricle, but all the heart chambers. Often these changes are absolutely physiological, but in some cases, they can predispose to pathological conditions, such as arrhythmias. Below, we report the main morpho-functional changes of the different cardiac structures in athletes and their implications in the pathogenesis of cardiovascular diseases.

## ATHLETE'S ATRIA FUNCTION AND DYSFUNCTION

Atrial abnormalities can be present in athletes, such as

a mild increase in atrial volume and diameter, and may be considered a physiological adaptation to exercise<sup>[28]</sup>. The pathophysiological mechanisms are not well defined. Studies in animal models have shown that, in rats, prolonged and vigorous exercise resulted in eccentric hypertrophy and diastolic dysfunction with atrial dilatation and fibrosis, especially in the atria and the right ventricle, and increased fibrotic mRNA compared with controls<sup>[24]</sup>. A recent meta-analysis of 7189 adult elite athletes have shown that exercise causes an increase in left atrium (LA) dimensions, compared with controls, evaluating both diameter and volume, corrected for body surface area. The endurance athletes reported the largest average LA diameters<sup>[29]</sup>. Since pre-adolescence, the long-term endurance exercise results in considerable bi-atrial remodeling and enlargement compared with sedentary subjects of the same age, with a preserved cardiac function<sup>[30,31]</sup>. LA enlargement could be considered part of athlete's heart, considering that the LA pressure rises during ventricular diastole more than in sedentary subjects, to maintain adequate filling whereas LV stiffness or pressure are increased<sup>[32]</sup>. On the other hand, there is evidence that the endurance exercise increases the risk of developing atrial fibrillation (AF) and atrial flutter in the middle age, in subjects without any clinical or echocardiographic signs of cardio-pulmonary pathologies or hypertension<sup>[33]</sup>. The mechanisms responsible for these arrhythmias might be: The major incidence of atrial ectopic beats in this population, as a consequence of physical activity; the influence of autonomic nervous systems, and in particular the vagal system, responsible for the "vagal AF"<sup>[34]</sup>; the atria dilatation, fibrosis, and inflammation induced by high exercise training and the atrial remodeling<sup>[33]</sup> (Table 2). In mice, exercise can induce TNF $\alpha$ -dependent activation of both NF- $\kappa$ B and p38MAPK, increasing inflammation and AF susceptibility<sup>[35]</sup>.

Moreover, AF might be closely connected with oxidative cellular changes and redox imbalance in the atrium. The oxidative species, generated from cardiomyocytes in stress conditions such as strenuous exercise, can increase inflammation and activate downstream molecular pathways, promoting morphological and electrical modeling. Recently, Mont *et al.*<sup>[36]</sup> have shown that loss of Nrf2, a gene with antioxidant function in the atria, could be associated with atrial hypertrophy and AF, suggesting that the preservation of the redox state is essential for the atrium health.

Finally, in athletes AF appears as some symptomatic and paroxysmal episodes that could become more frequent and progress to persistent AF. The GIRAFA study has showed that the crisis appears in the night or after the meal, related to an increased vagal tone<sup>[36]</sup>.

Data about right atrial (RA) function in top level athletes are lacking. Previously, our group has delineated the upper limits of RV and RA dimensions in highly-trained athletes and showed that right heart dimensions were greater in elite endurance-trained athletes than in age- and ex-matched strength athletes and controls<sup>[37]</sup>. Then, D'Ascenzi *et al.*<sup>[38]</sup> investigated the RA function and dimension in 100

top level athletes by standard echocardiography and 2D speckle tracking echocardiography and showed that RA area, volume, volume index, and inferior vena cava were significantly greater in athletes than in controls and the peak atrial longitudinal strain and peak atrial contraction strain values were lower in athletes than in controls. This strain reduction should not represent a real dysfunction, but only a physiological phenomenon, and can be included in the "athlete's heart"<sup>[38]</sup>.

## LV CHANGES IN EXERCISE RELATED AND PATHOLOGICAL CONDITIONS

In some highly-trained athletes, the LV wall thickness may be increased, mimicking a hypertrophic cardiomyopathy (HCM). The thickening is usually mild, but in some cases, it may be significant and creates difficulties to differentiate athlete's heart and hypertrophic cardiomyopathy, especially in the ambiguous "gray zone", when the wall thickness is of 13 to 15 mm (12 to 13 mm in women)<sup>[39]</sup>. This differential diagnosis is important, since most cases of sudden death in athletes are probably due to HCM<sup>[40]</sup>. Echocardiography plays an important role in the differential diagnosis: HCM is probable with LV end-diastolic cavity < 45 mm, evidence of pathogenic sarcomere mutation, family history of HCM, abnormal LV diastolic function, left atrial dilatation, and late gadolinium enhancement on contrast-enhanced CMR imaging. Usually athlete's heart is characterized by LV cavity enlargement (> 55 mm), peak VO<sub>2</sub> > 110% of expected, and thickness or mass decreases with short periods of detraining<sup>[41,42]</sup>. Pelliccia *et al.*<sup>[43]</sup> have shown that LV wall thickness ≥ 13 mm is mostly present in elite rowers and cyclists, and the upper limit appeared to be 16 mm (Figure 2).

Other conditions that can cause cardiac hypertrophy include valve disease, hypertension and non-compaction myocardium. Despite the prevalence of hypertension is approximately 50% lower in athletes compared with the general population, it is also the most common cardiovascular condition in athletes. The pharmacological therapy can be difficult for the competition regulations and potential adverse effects<sup>[44]</sup>. It is important to

diagnose this condition, because it is associated with an increased risk of developing heart failure. Recently, an elevated prevalence of LV noncompaction (LVNC) has been reported in athletes, phenotypically characterized by a more thick endocardial noncompact layer, increased trabeculations and deep recesses<sup>[45]</sup>. Caselli *et al.*<sup>[46]</sup>, in a recent study, have shown that in a large population of athletes, only a small subgroup presented LVNC. The increased trabeculations may represent a LV variant of athlete's heart without any clinical significance<sup>[46]</sup>.

Figure 3 summarizes the different characteristics of physiological remodeling and pathological condition of LV.

## EXERCISE-RELATED RIGHT VENTRICLE REMODELING

Strenuous and prolonged exercise can cause RV dysfunction, usually transient, with evidence of increased biomarkers of cardiac damage. On the other hand, repeated bouts of exercise can lead to RV structural remodeling and arrhythmias and can lead to a syndrome similar to familial ARVC, without an identifiable genetic predisposition<sup>[47,48]</sup>. ARVC is present in 4% to 22% of athletes with sudden cardiac death<sup>[49,50]</sup>. As mentioned above, the RV function may be more interested by intense endurance training, therefore the diagnostic criteria for ARVC should be nonspecific in athletes with electrocardiographic anomalies and biventricular dilation.

Marcus *et al.*<sup>[51]</sup> in a multi-center study of 108 probands with ARVD/C showed that 34% were athletes. Vigorous or long term athletic exercise might facilitate the phenotypic expression of ARVC due to the repetitive stretch of the RV with an underlying genetic desmosomal protein anomaly<sup>[51]</sup>.

Signs of RV dysfunction seem to include: Syncope; Q waves in precordial leads; augmented QRS duration; three abnormal signal averaged electrocardiography parameters; delayed gadolinium enhancement; RV ejection fraction < 45% or wall motion anomalies at CMRI; > 1000 ventricular extra-systoles (or > 500 non-RV outflow tract) per 24 h; ventricular tachyarrhythmia or abnormal blood pressure response during exercise (Table 3)<sup>[52,53]</sup>. RV cavity size is not significantly larger in ARVC patients compared with athletes, whereas RV outflow tract is larger in ARVC subjects than in athletes<sup>[53]</sup>. The thickened and high reflective moderator band, commonly considered typical of ARVC, are present also in athletes and could be due to RV dilatation<sup>[53]</sup> (Figure 4). Further studies regarding the differential diagnosis between ARVC and physiological remodeling in athletes are needed to create useful clinical diagnostic algorithms.

## PERFORMANCE-ENHANCING DRUGS AND CARDIAC DAMAGE

Some banned athletic performance-enhancing drugs

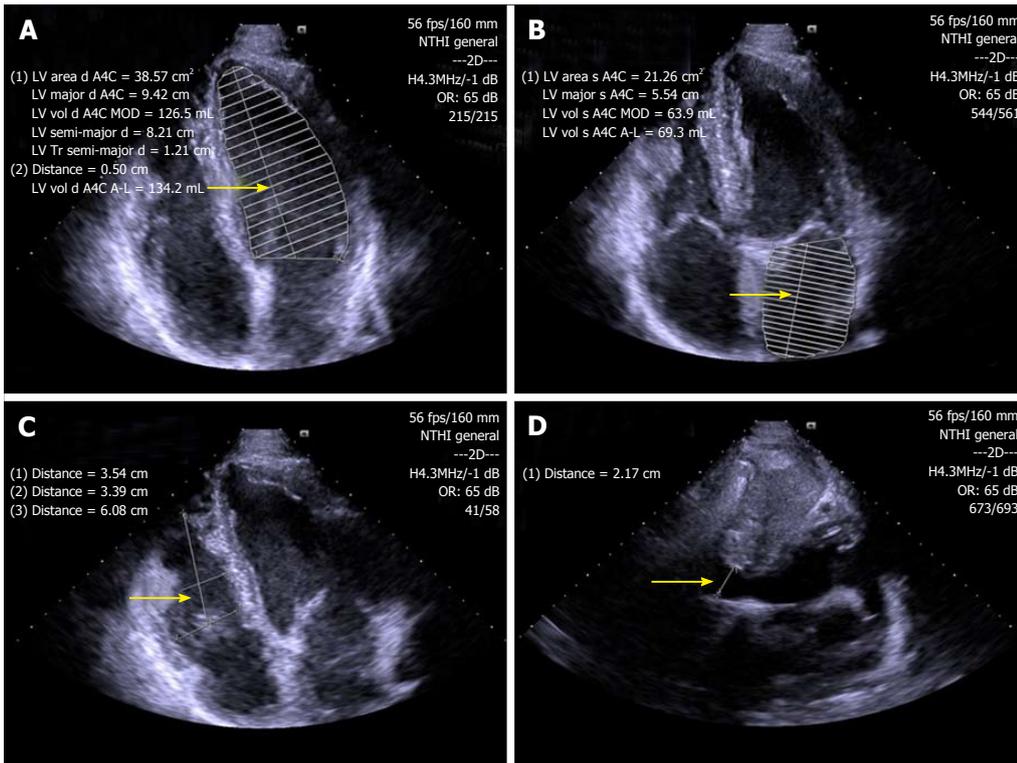

Figure 2 Standard B-mode echocardiography of endurance athlete showing enlargement of left ventricular (A), left atrial (B) and right ventricular (C) chambers, as well as inferior vena cava dilatation (D) (arrows). LV: Left ventricular.

might have cardiac toxic effects, such as anabolic-androgenic steroids (AASs) and growth hormone (GH).

Healthy athletes abusing AASs may exhibit LV hypertrophy with both systolic and diastolic myocardial dysfunction and focal areas of DGE at CMR, with non-ischemic distribution<sup>[54]</sup> (Figure 5). AASs have direct toxicity on myocardial structures, with increased collagen deposition, fibrosis, and intimal hyperplasia of the intra-

mural coronary vessels with chronic ischemic damage and microcirculation alterations. Moreover, testosterone might inhibit the extra-neuronal uptake of neuroamine and consequently result in vasospasm due to an abnormal vascular response to norepinephrine<sup>[55]</sup>. Post-mortem studies of athletes who used AASs have found infiltration of eosinophils into myocardial cells, as well as destruction of myofibrils. Endothelial dysfunction was

also observed<sup>[56]</sup>.

GH abuse has tainted many sports, including baseball, cycling, and track and field, for promoting an increase in muscle mass, though its effects on physical performance are not completely supported by the literature<sup>[57]</sup>. GH promotes cellular growth by stimulating protein synthesis, inhibiting catabolism, and inducing IGF-1 production. At the molecular level, GH binds its receptor and induces subsequent expression of growth-promoting molecules<sup>[58]</sup>. GH, both in excess or in deficient states, is related to increased cardiovascular mortality. The excess, like in acromegaly or in doping, results in cardiac hypertrophy and an increase in collagen, fibrosis, and cellular infiltration. *In vivo* studies on healthy mice demonstrated that increased GH levels induce significant LV hypertrophy and an increase in concentric anterior and posterior wall thicknesses, LV diastolic diameters and volumes, and cardiac output<sup>[59]</sup>. Unfortunately, the majority of conclusions about GH abuse and its cardiac effects result from data regarding acromegaly and not from direct data, which are lacking.

Also, erythropoietin (EPO), which increases hematocrit levels and thus improves aerobics capacity, may lead to cardiac dysfunction, increasing blood viscosity and cardiac afterload, and predisposes to hypertension and thromboembolism. Experimental studies have shown hypertension, cardiac hypertrophy and fibrosis after administration of high doses of EPO<sup>[60]</sup>.

Thyroxine is used, generally, by athletes to promote weight loss. Thyroid hormones (TH) play an important role in cardiac growth and might cause cardiac hypertrophy and also heart failure if they are in excess. High levels of TH might result in elevated heart rate, decreased total peripheral resistance, widened pulse pressure, blood volume expansion, increased LVM and cardiac output, with improved contractile function and hemodynamic parameters in the short term. Long-standing hyperthyroidism can lead to dilatation of cardiac chambers and heart failure. Interestingly, the diminished cardiac function is often reversible when euthyroidism is re-established<sup>[61]</sup>. Weltman *et al*<sup>[61]</sup> showed that hyperthyroid rodents had important cardiac hypertrophy and adverse cardiac remodeling with chamber dilatation, LV systolic and diastolic dysfunction, decreased relative

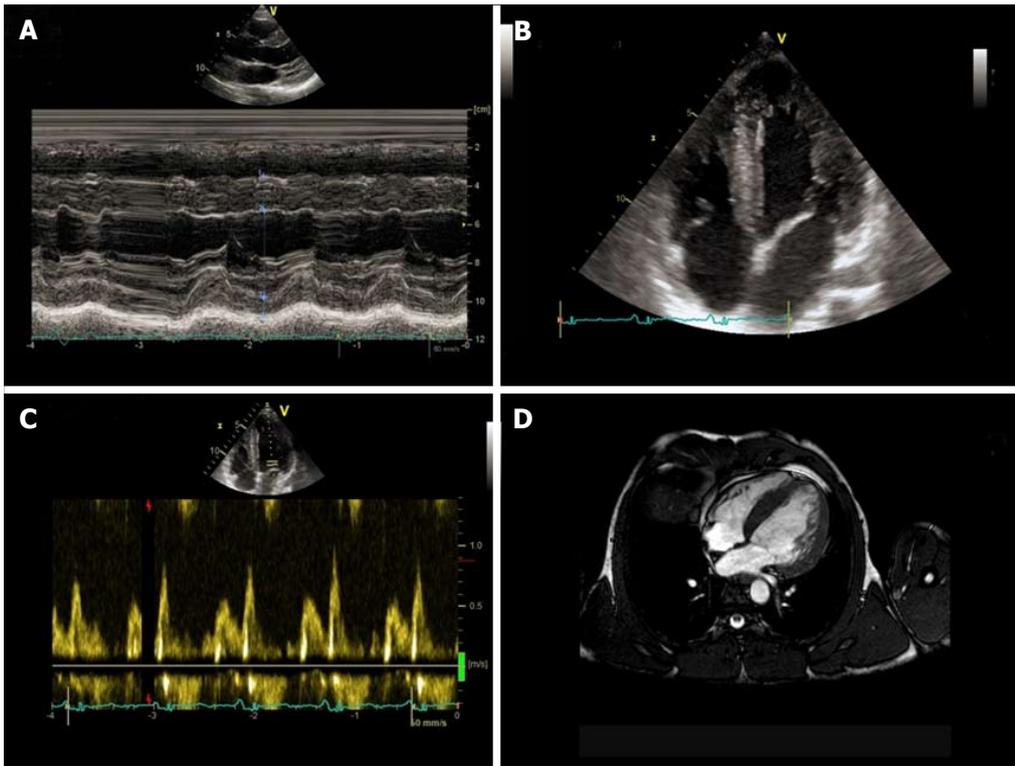

**Figure 4** Cardiac magnetic resonance depicting in short-axis (A) and long-axis (B) view balanced biventricular enlargement in endurance athlete.

wall thickness, and fibrosis<sup>[61]</sup>. Few data in the literature are about the cardiac consequences of the prolonged use of thyroxine treatment. Thyroxine treatment, in high doses which suppress serum thyrotropin to below normal, has been associated with LV hypertrophy (in the absence of significant changes in heart rate, stroke volume, blood pressure, and LV systolic function), but untreated thyrotoxicosis resulted in more pronounced cardiovascular changes than thyroxine treatment<sup>[62]</sup>. Further studies are necessary to evaluate the cardiovascular risk in patients treated with thyroxine.

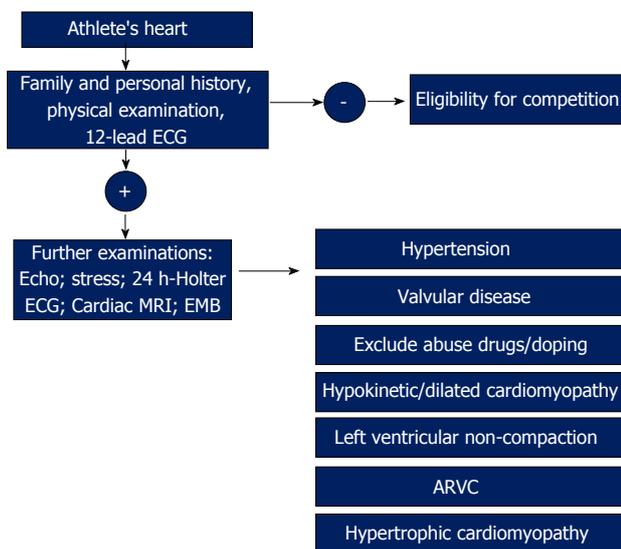

Many other drugs are responsible for heart failure in athletes, such as corticotrophin, beta 2 agonists, amphetamines and cocaine. Often athletes use combinations of different banned drugs, resulting in additive effects on cardiac remodeling. Cardiac alterations may lead to arrhythmias, heart failure and sudden death. It is important to exclude the abuse of these drugs, when athletes with heart dysfunction come to our attention. Figure 6 shows a flow chart to differentiate athlete's heart from pathological conditions.

## ENERGY DRINK CONSUMPTION AND HEMODYNAMIC EFFECTS

A growing number of case reports of cardiovascular adverse events associated with energy drinks (EDs) are present in the literature. The use of EDs is more common in young students and in athletes. The consumption of EDs negatively affects the hemodynamic system. Important changes in arterial pressure and heart rate may occur with the ingestion of only one can (355 mL drink volume). Furthermore, it seems that EDs may diminish cerebral blood velocity, increasing breathing frequency<sup>[63]</sup>. Caffeine and sugar appear to be the ingredients underlying hemodynamic impact of EDs. Taurine and vitamin B complex play a minor role<sup>[64]</sup>. Genetic polymorphisms in cytochrome P-450 enzymes and variations of adenosine receptors play a role in the different responses to the caffeine<sup>[65]</sup>. Caffeine improves athletic performance in rowing<sup>[66]</sup>, swimming<sup>[67,68]</sup>, soccer<sup>[69]</sup> and hockey<sup>[70]</sup>. On the other hand, EDs can cause many cardiovascular adverse

**Figure 5 Non-invasive evaluation of power athlete abusing of steroids.** Standard M-mode (A) and 4-chamber view B-mode (B) echocardiography, evidencing severe left ventricular hypertrophy, with diastolic dysfunction (C) underlined by Doppler transmittal flow pattern. effects (Table 4), such as hypertension, palpitations, ischemic stroke, epileptic seizure<sup>[71]</sup> and myocardial ischemia, with no additional trigger<sup>[72]</sup>. The possible mechanism is related to the caffeine interaction with the G-protein coupled receptors on the cardiomyocytes that leads to an increase in intracellular cyclic-AMP and calcium concentrations with chronotropic and inotropic

effects<sup>[73]</sup>. Large studies regarding EDs and their effects on the cardiovascular system are necessary, especially for the widespread consumption of these substances in recent years.

## CONCLUSION

The exact clinical significance and prognostic value of cardiac injury and fibrosis in athletes are unknown. Physiological remodeling is characterized by specific molecular activation and gene expression. More large studies are needed to gain a better understanding of these conditions and the pathological changes in the heart structure in athletes and to investigate the cardiac effects of performing-enhanced drugs and EDs in this population.

### Abstract

Aortic valve disease [aortic stenosis (AS) and aortic regurgitation (AR)] represents an important global health

problem; when severe, aortic valve disease carries poor prognosis. For AS, aortic valve replacement, either surgical or interventional, may provide definite treatment in carefully selected patients. For AR, valve surgery (either replacement or - in selected cases - aortic valve repair) remains the gold standard of care. To properly identify those patients who are candidates for surgery, the clinician has to carefully assess the severity of valve disease with an understanding of the potential pitfalls involved in these assessments. This review focuses on the practical issues concerning the evaluation of patients with AS and AR from a general cardiologist's perspective. The most important issues regarding the documentation of the severity of AS and AR are summarized. More specific issues, such as the role of stress echocardiography, other imaging techniques and details regarding the treatment options (medical, surgical, or interventional), are mentioned briefly.

**Key words:** Echocardiography; Aortic stenosis; Aortic regurgitation; Treatment; Evaluation

## INTRODUCTION

Aortic valve disease [aortic stenosis (AS) and aortic regurgitation (AR)] represents an important global health problem. The data on the exact prevalence of AS and AR in the general population are lacking, but studies performed in Western populations estimate that 3% to 4% of the adult population suffers from moderate or severe aortic valve disease. The prevalence of AS and AR increases with age; it is estimated that 1% of persons aged < 55 years and 6% of persons aged > 75 years suffer from moderate or severe AS/AR<sup>[1,2]</sup>.

This review focuses on the practical issues concerning the evaluation of patients with AS and AR from a general cardiologist's perspective. The most important issues regarding the documentation of the severity of AS and AR using echocardiography are summarized. More specific issues, such as the role of stress echocardiography, other imaging techniques and details regarding the treatment options (medical, surgical, or interventional), are mentioned briefly. For more detailed information on these topics, the reader is referred to several recent excellent reviews, mostly regarding AS<sup>[3-11]</sup>.

## AS

AS is defined as a narrowing of the surface area of the aortic orifice [aortic valve area (AVA)] below the normal value (approximately 3 cm<sup>2</sup>). AS becomes significant [*i.e.*, determines a significant increase in left ventricular (LV) afterload] only after the AVA decreases by more than half. In general, the accepted criteria for the definition of severe AS is an AVA ≤ 1 cm<sup>2</sup> (or ≤ 0.6 cm<sup>2</sup>/m<sup>2</sup> of body surface area). These cut-off values have been used in clinical studies but are patient-dependent and do not completely overlap with other indices that are also used to define severe AS (*e.g.*, transaortic pressure gradients - see below).

### Etiology

In Western countries, AS has the following two major causes: Degenerative (calcific) and congenital. Calcific AS is predominant in the elderly population, shares common pathological features and is commonly associated with atherosclerosis. Congenital AS [> 90% represented by bicuspid aortic valve (BAV)] manifests clinically 10 to 20 years earlier than calcific AS. Contemporary data from 932 isolated aortic valves excised from adults aged 26 to 91 years between 1993 and 2004 suggest that 54% of these cases were congenital in origin<sup>[12]</sup>.

AS is a slowly progressive disease. Almost 50 years ago, Ross and Braunwald highlighted that the appearance of symptoms marks a sharp decline in survival with nearly universal death within 5 years<sup>[13]</sup>. The types of symptoms are important, as follows: The mean survival after the

appearance of angina was 5 years, 3 years after syncope and 2 years after the appearance of heart failure. When these data were published, the predominant etiology was rheumatic heart disease, and the mean patient age was 63 years old<sup>[14]</sup>. Thus, the contemporary application of these data is limited. Recent data suggest that the presence of AS is associated with a 68% increased risk of coronary events, a 27% increased risk of cerebrovascular events, and a 36% increased risk of mortality<sup>[15]</sup>. The data from the PARTNER study in elderly patients with severe calcific AS suggest an annual mortality of 50% with conservative treatment<sup>[16]</sup>.

### Evaluation of AS

The evaluation of patients with AS must define the following 2 issues: (1) identification of patients with severe AS; and (2) in patients with severe AS, identification of patients whose prognosis will be improved by aortic valve replacement (AVR) (surgical or interventional).

**Identifying patients with severe AS:** The clinical (presence of symptoms, grade ≥ 4/6 ejection murmur, and "tardus et parvus" peripheral pulse), electrocardiographical (left ventricular hypertrophy) or radiological (valve calcification) criteria for severity have high sensitivity but low specificity in identifying patients with severe AS. Therefore, objective assessment of AS severity is needed.

Historically, invasive direct measurement of transaortic pressure gradients was performed, and the aortic valve area was calculated using the Gorlin formula. This practice was abandoned because of the following important drawbacks: (1) invasively measured pressure gradients (mean transaortic pressure gradient and the difference between peak aortic pressure and peak LV systolic pressure) do not overlap with the Doppler estimation of transaortic pressure gradients. This is because Doppler echocardiography measures instantaneous velocities and through the use of Bernoulli equation estimates instantaneous pressure gradients, whereas peak LV pressure occurs before peak aortic pressure (the invasively measured peak-to-peak transaortic pressure difference is not instantaneous); and (2) the risk of atherosclerotic cerebral embolism during the transaortic passage of the pressure catheter may reach 20%<sup>[17]</sup>. Thus, today, objective assessment of AS severity almost completely relies on proper performance and interpretation of Doppler echocardiography.

The currently used criteria for the definition of severe AS by echocardiography are listed in Table 1<sup>[18]</sup>. These criteria have advantages and disadvantages.

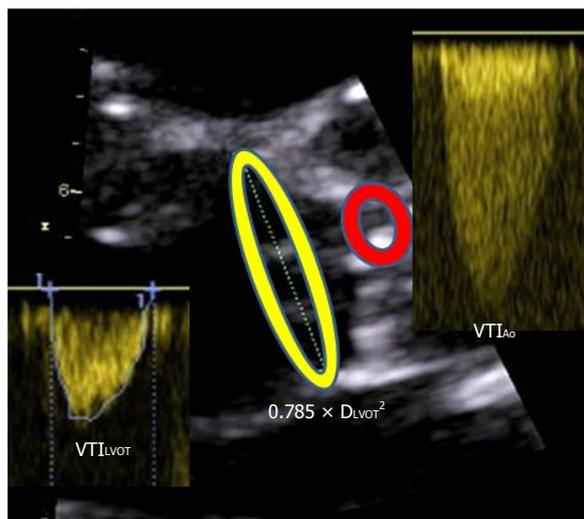

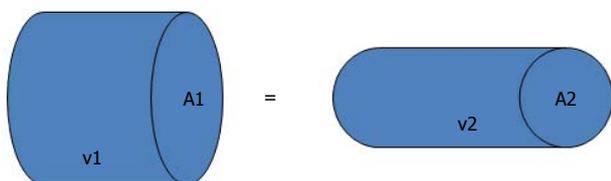

It is of critical importance that the echocardiographic evaluation of AS is based on correctly performed measurements, using an integrative approach, because the echocardiographic criteria for the definition of severe AS are not interchangeable, and the criteria based on pressure gradients and velocities are highly dependent on blood flow.

The most robust and reproducible estimation of AVA

**Table 1 Echocardiographic criteria for the definition of severe aortic stenosis: Advantages and disadvantages<sup>[18]</sup>**

Criteria	Severe AS	Advantages	Disadvantages
Aortic surface area	$\leq 1.0 \text{ cm}^2$	Measures effective AVA. However, this may also constitute a disadvantage because it does not measure anatomical AVA Less flow-dependent compared with other measurements	Very sensitive to measurement errors
Indexed AVA to body surface area	$\leq 0.6 \text{ cm}^2/\text{m}^2$	Useful for extreme heights/weights	Very sensitive to measurement errors
Mean transaortic pressure gradient	$\geq 40 \text{ mmHg}$		Flow-dependent Requires correct alignment of Doppler signal with the flow direction
Peak transaortic flow velocity	$\geq 4.0 \text{ m/s}$	Measures instantaneous velocity Best predictor of adverse events	Flow-dependent Requires correct alignment of Doppler signal with the flow direction
Ratio between peak transaortic flow velocity and peak LVOT velocity	$\leq 1/4$	Good reproducibility (compared with AVA calculation)	Limited data on prognostic utility

AS: Aortic stenosis; AVA: Aortic valve area; LVOT: Left ventricular outflow tract.

$$A_{LVOT} \times VTI_{LVOT} = AVA \times VTI_{Ao} \rightarrow AVA = A_{LVOT} \times VTI_{LVOT}/VTI_{Ao}$$

where  $A_{LVOT} = (\pi \times D_{LVOT}^2)/4 = 0.785 \times D_{LVOT}^2$

**Figure 1 Relationship between flow, area and velocity.** Calculation of the aortic valve area (AVA) based on the continuity equation. Flow (mL) equals the cross-sectional area (cm<sup>2</sup>) of the vessel multiplied by the mean flow velocity through that cross-sectional area during a period of time [measured as velocity-time-integral, VTI (cm)]. The flow is constant throughout the length of the vessel without ramifications. Thus, at the aortic valve level, the flow below the valve (in the left ventricular outflow tract, LVOT) equals flow through the aortic valve. Therefore, the AVA equals the LVOT area multiplied by the mean flow velocity through the LVOT area during ejection [LVOT velocity-time-integral, VTI<sub>LVOT</sub> (cm)] divided by the transaortic mean flow velocity during ejection [transaortic velocity-time-integral, VTI<sub>Ao</sub> (cm)]. The LVOT area, given the theoretical circular shape of the LVOT, is calculated by measuring its internal diameter [D<sub>LVOT</sub> (cm)]. A: Area; V: Velocity; D<sub>LVOT</sub>: Left ventricular outflow tract diameter; VTI: Velocity-time-integral.

is based on the continuity equation (Figure 1).

To calculate the AVA, it is essential to perform correct

measurements, especially for the left ventricular ejection tract diameter (D<sub>LVOT</sub>) and velocities.

Any error in the measurements of D<sub>LVOT</sub> will be squared when calculating AVA using the continuity equation. Thus, for a correct measurement of D<sub>LVOT</sub>, the following technical requirements are suggested: (1) use of the “zoom” function on the echocardiograph to focus and enlarge the LVOT; (2) decrease the grey-scale gain towards the minimum; (3) D<sub>LVOT</sub> measurement is performed from the inner anterior edge to the inner posterior edge of the LVOT in mid-systole (“inner-edge to inner-edge”), which is immediately under the aortic valve. The maximal visualized D<sub>LVOT</sub> is considered, using an echocardiographic section that passes through the center of the LVOT and is not excentric because an excentric slice will underestimate the true maximal diameter. The measured D<sub>LVOT</sub> should be compatible with the patient’s height and weight. A D<sub>LVOT</sub> < 16 mm is extremely rarely seen in adults and should raise suspicion of measurement errors<sup>[19]</sup>.

It is important to realize that the true shape of the LVOT is not circular but oval; thus, echocardiographically determined AVA will always be an estimation and not a true measurement.

The correct measurement of transaortic velocities and gradients requires the use of the following multiple echo windows: Modified apical 5 chamber view towards the axilla; apical long axis view; 4<sup>th</sup> right intercostal space; and suprasternal window. Given these views, the following precautions should be applied: (1) the full envelope of the Doppler signal should be measured to avoid noise and/or aliasing; (2) measurements should not be made on post-extrasystolic beats; (3) correct measurement of the LVOT velocity-time-integral (VTI<sub>LVOT</sub>) should be made. The sample area should be placed immediately under the aortic valve in the middle of the LVOT where the velocity is maximal. In this location, the signal should record the clear click of the aortic valve closure without the click of the aortic valve opening; and (4) for the correct assessment of AVA using the simplified Bernoulli equation (automatically given by the echocardiograph), the measured VTI<sub>LVOT</sub> should be < 1.5 m/s. When the

$VTI_{LVOT}$  is  $\geq 1.5$  m/s (e.g., increased LVOT flow due to severe AR, etc.), the simplified Bernoulli equation cannot be used because it will overestimate the transaortic pressure gradient and AS severity based on the continuity equation and calculated AVA.

In conclusion, a correct and complete echocardiographic assessment of AS severity should report on the overall context of the cardiac pathology, LV volumes and LVEF, stroke volume (based on Doppler, not volumetric measurements), grade of calcification of the aortic valve (is it compatible with the measured severity?), associated abnormalities, estimation of pulmonary pressures, dimensions of right heart chamber, and estimation of right ventricular function.

The echocardiographic criteria for the definition of severe AS are not interchangeable. For example, a recent study on the correlation between mean transaortic pressure gradient and AVA in patients with AS and normal LVEF proved that for a mean pressure gradient of 40 mmHg, the corresponding AVA was  $0.8 \text{ cm}^2$  and not  $1 \text{ cm}^2$  as is the standard definition of severe AS<sup>[20]</sup>. Similarly, it is important to understand that a simple documentation of an AVA  $\leq 0.8 \text{ cm}^2$  does not prove the presence of severe AS because AVA is calculated using pressure gradients that are highly dependent on flow. Thus, when the transaortic flow is low, any valve (including normal ones) will appear "stenotic" because the orifice will not be fully opened. It has been proven that at transaortic flow rates  $< 125 \text{ mL/s}$  (corresponding to a cardiac output of approximately 3 L/min) the effective orifice area of any aortic valve, from mild anatomic AS to severe anatomic AS, will be  $\leq 1 \text{ cm}^2$ . Similarly, the mean transaortic pressure gradient will be  $\leq 40 \text{ mmHg}$  for any AS severity (from mild to severe, based on anatomical AVA) when the transaortic flow is  $< 175 \text{ mL/min}$ <sup>[21]</sup>.

Thus, the major problem in assessing AS severity rests with low-flow states. The prevalence of "low-flow, low-gradient" severe AS is approximately 25% of all severe AS cases. A low flow state is defined as an indexed stroke volume  $< 35 \text{ mL/m}^2$  of the body surface area. A low-flow/low-gradient state can appear in patients with both reduced LVEF due to myocardial systolic dysfunction or preserved LVEF due to small LV cavity size<sup>[22]</sup>. These 2 conditions will be detailed below.

**Low-flow, low-gradient, low-LVEF, severe AS:** Low-flow, low-gradient, low-LVEF, severe AS ("classical" low-flow, low-gradient severe AS) was described for the first time by Carabello *et al*<sup>[23]</sup> in 1980. It is defined as severe AS in the presence of systolic LV dysfunction (LV ejection fraction  $< 40\%$ ) with a mean transaortic pressure gradient  $< 40 \text{ mmHg}$  if estimated by echocardiography or  $< 30 \text{ mmHg}$  if measured invasively.

When the calculated AVA is  $\leq 1 \text{ cm}^2$  in low flow states, one should differentiate whether this is primarily due to the low flow (pseudo severe AS, where the anatomical AVA is  $> 1 \text{ cm}^2$ ) or if there is true severe AS (AVA remains fixed and  $\leq 1 \text{ cm}^2$  regardless of flow). Dobutamine stress echocardiography (DSE) is typically

performed to differentiate between the two conditions because it evaluates the response of AVA to increased transaortic flow. Figure 2 exemplifies the role of DSE in diagnosing low-flow, low-gradient, low-EF severe AS<sup>[24]</sup>.

Thus, when the calculated AVA is  $\leq 1 \text{ cm}^2$ , the mean transaortic pressure gradient is  $< 40 \text{ mmHg}$  and the LVEF is  $< 40\%$ , the DSE will help define the following parameters: (1) the severity of AS; and (2) the presence or absence of LV flow/contractile reserve, which is defined as an increase in LV stroke volume  $> 20\%$  compared with baseline at maximal dobutamine dose. Thus, the following 2 responses to dobutamine and 3 conditions associated with AS are seen when using DSE.

Low-flow, low-gradient, low-EF severe AS is diagnosed when there is increased flow/contractile reserve with a subsequent increase in transaortic pressure gradient to  $> 40 \text{ mmHg}$  while AVA remains  $\leq 1 \text{ cm}^2$ . AVR is indicated in these patients.

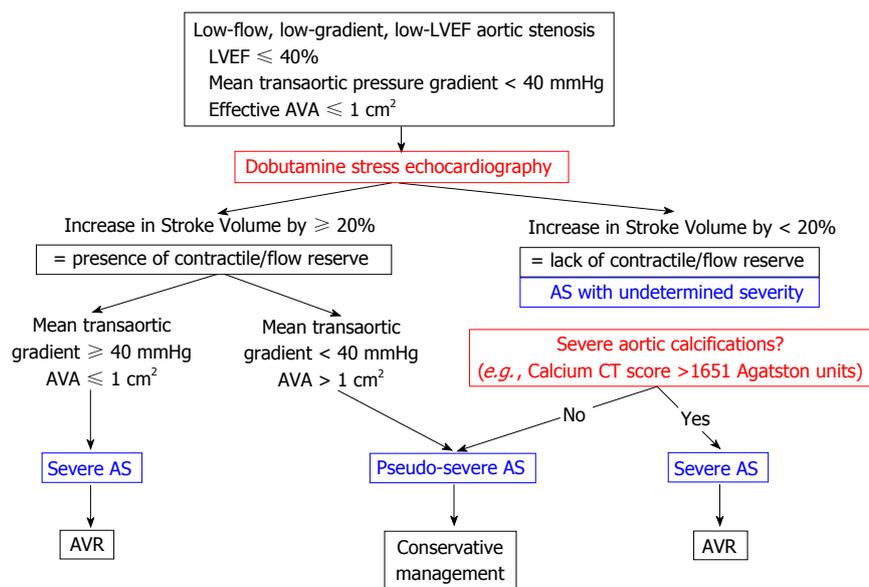

Pseudo-severe AS is diagnosed when there is flow (contractile) reserve, but the AVA increases in parallel with the flow to  $> 1 \text{ cm}^2$ . AVR is not indicated in these patients.

AS with undetermined severity is defined by the lack of flow/contractile reserve<sup>[25]</sup>. Even in this situation, identifying severe AS is important because the prognosis without AVR is grim, although surgical mortality is high. Identifying low-flow, low-gradient, severe AS without flow (contractile) reserve is based on the following: (1) statistical data - approximately 95% of low-flow, low-gradient, low-EF AS with undetermined severity have truly severe AS; and (2) objective data - evidence of severe aortic valve calcification (using echocardiogram, plain radiology or computed tomography) is highly specific for severe AS<sup>[26]</sup>. In this situation, a calcium score of  $\geq 1651$  Agatston units on computed tomography has an 82% sensitivity, 80% specificity, 88% negative predictive value and 70% positive predictive value for severe AS<sup>[27]</sup>. Of note, for the same hemodynamic severity of AS, women have lower aortic calcium load compared with men, so the thresholds should probably be lower in women compared with men<sup>[28]</sup>.

#### **Low-flow, low-gradient severe AS with preserved LVEF:**

Approximately 10% of patients with anatomically severe AS have low-flow/low-gradient characteristics despite preserved LVEF ("paradoxical" low-flow, low-gradient severe AS). This form of severe AS was first described by Hachicha *et al*<sup>[29]</sup> in 2007 and is characterized by the following features: (1) concentrically remodeled LV with preserved LVEF, severe diastolic dysfunction, impaired LV filling and low cardiac output (stroke volume  $< 35 \text{ mL/m}^2$ ); and (2) increased LV afterload generated by the AS and increased peripheral vascular resistance due to the rigid arterial system and frequent severe arterial hypertension in these patients.

Estimation of the global afterload faced by the LV (defined as the ventriculo-arterial impedance, Zva) is important because it is an independent negative prognostic factor and correlates with the appearance of symptoms

**Figure 2** The role of dobutamine stress echocardiography in diagnosing low-flow, low-gradient/low-ejection fraction severe<sup>[24]</sup>. LVEF: Left ventricular ejection fraction; CT: Computed tomography; AVR: Aortic valve replacement; AVA: Aortic valve area; AS: Aortic stenosis.

in these patients<sup>[30]</sup>. Zva is calculated according to the following formula:

$$Zva = [\text{Systolic blood pressure (mmHg)} + \text{mean transaortic pressure gradient (mmHg)}] / [\text{indexed stroke volume (mL/m}^2)].$$

Taking into account the transaortic flow and pressure gradients, severe AS with preserved LVEF has been recently classified into the following 4 forms<sup>[31]</sup>: (1) normal flow, low-gradient (NFLG) - representing approximately 1/4 of patients; (2) normal flow, high-gradient: Representing approximately 2/3 of patients; (3) low-flow, low-gradient (LFLG) - also known as "paradoxical" low-flow/low-gradient - representing 10% of patients; and (4) low-flow, high-gradient - representing the remaining 10% of patients.

The principle of this classification scheme can be extended to all forms of AS, regardless of LVEF<sup>[11]</sup>.

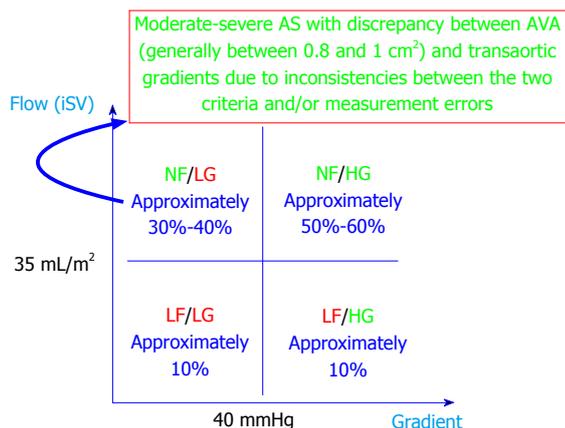

This classification has prognostic importance in patients with severe AS with preserved LVEF. The best prognosis [major adverse cardiovascular event (MACE) rate, 35% at 3 years] is carried by NFLG, and the most severe prognosis (MACE rate, 90% at 3 years) is carried by LFLG severe AS with preserved LVEF. The "high-gradient" forms have similar prognoses because they are intermediate forms between NFLG and LFLG<sup>[31]</sup>. However, this classification is limited by the fact that the existence of NFLG severe anatomical AS is counterintuitive. Indeed, the prognosis of these patients is similar to that for patients with moderate AS and is better than that for any other form of severe AS<sup>[32]</sup>. Thus, it is highly likely that what is known as NFLG severe AS with preserved LVEF is in fact moderate AS where the discrepancy between calculated AVA (which usually rests between 0.8 and 1 cm<sup>2</sup> in these cases) and transaortic gradients is a consequence of the inconsistency of the criteria used to define severe AS (see above) and/or measurement errors (Figure 3).

Thus, when one is faced with a discrepancy between the calculated AVA and measured gradients, the following elements should be taken into account: (1) measurement errors, especially of the  $D_{LVOT}$  diameter and  $VT_{LVOT}$  (underestimating flow); (2) extremes in body surface areas (very small or large individuals) - always use indexed measurements; and (3) inconsistency between the cut-off values used to define severe AS: An AVA of 1 cm<sup>2</sup> corresponds better to a transaortic pressure gradient of 30-35 mmHg and not 40 mmHg (see comments above for NFLG "severe" AS with preserved LVEF).

To establish a diagnosis of LFLG severe AS with preserved LVEF the following 3 criteria are recommended. First, confirmation of low-flow states by and indexed stroke volume < 35 mL/m<sup>2</sup>. Second, confirmation of increased global LV afterload (ventriculo-arterial impedance) by  $Zva \geq 4.5$  mmHg/mL per square meter. Third, confirmation of concentric LV remodeling by the following: (1) relative wall thickness (RWT)  $\geq 0.45$ . RWT is calculated using the following formula:  $RWT = (IVS + LVPW)/LVEDD$ , where IVS is the end-diastolic ventricular septal thickness; LVPW is the end-diastolic LV posterior wall thickness; and LVEDD is the end-diastolic LV diameter; (2) end-diastolic LV diameter < 47 mm; and (3) indexed end-diastolic LV volume < 55 mL/m<sup>2</sup>.

#### Identification of patients with severe AS who are candidates for aortic valve replacement:

After establishing the diagnosis of severe AS, the next step is to identify those patients who will benefit from AVR. The European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS) and the American Heart Association/American College of Cardiology (AHA/ACC) guidelines establish clear indications for AVR in patients with *symptomatic* severe AS (class I for normal flow/normal LVEF and for patients

**Figure 3** Classification of severe aortic stenosis with preserved left ventricular ejection fraction based on flow and transaortic pressure gradients<sup>[29]</sup>. iSV: Indexed stroke volume; NF: Normal flow; LF: Low flow; HG: High gradient; LG: Low gradient; AVA: Aortic valve area; AS: Aortic stenosis.

with normal flow/low LVEF and class IIa for patients with low-flow/low-gradient/low LVEF with true severe AS) and asymptomatic severe AS with LV systolic dysfunction or symptoms unmasked at stress tests (Table 2)<sup>[33,34]</sup>.

Establishing the presence or absence of symptoms can be difficult because many older patients (the majority of patients with AS) deny the presence of symptoms due to lifestyle adaptations to lower functional needs. Also, older patients refer symptoms that can be vague (e.g., fatigue), related to AS or to other comorbidities related with advanced age but not caused by AS. In these patients, unmasking the presence of symptoms (by treadmill or bicycle stress test) and/or LV systolic dysfunction (by stress echocardiography) establishes the indication for AVR<sup>[35]</sup>. The prognosis of patients with asymptomatic severe AS by positive stress test is identical to that for patients with symptomatic severe AS<sup>[36,37]</sup>.

The indication for AVR in patients with asymptomatic severe AS with preserved LVEF is highly controversial<sup>[38,39]</sup>. For a detailed discussion and extensive review of the literature on this highly important topic, the reader is referred to the excellent article by Génèreux *et al*<sup>[10]</sup>. The 1- and 5-year mortality rates for asymptomatic severe AS with preserved LVEF are 3% and 26.4%, respectively; also, 46% of initially asymptomatic patients develop symptoms during the next 5 years, and 20% develop heart failure<sup>[40]</sup>. Among patients with asymptomatic severe AS with preserved LVEF, those with very severe AS (defined as having a maximal transaortic velocity of  $\geq 5.5$  m/s) have twice the rate of MACE compared with that of patients with severe AS and a maximal transaortic velocity of 4 to 5 m/s (96% vs 39% at 4 years)<sup>[41]</sup>. Almost all patients (97%) with severe AS and a maximal velocity of  $\geq 5$  m/s suffered a MACE within 6 years of follow-up<sup>[41]</sup>. A recent registry study on patients with asymptomatic very severe AS, which compared 102 patients who had surgical AVR with 95 patients who were treated conservatively, showed that surgical AVR was

associated with an 86% reduction in mortality compared with the conservatively managed group after 6 years of follow-up (2% vs 32%; HR = 0.14, 95%CI: 0.03-0.6,  $P = 0.008$ )<sup>[42]</sup>. Based on these non-randomized, single-center data, current guidelines provide a class IIa ("is reasonable"; "should be considered") for AVR in patients with asymptomatic very severe AS with preserved LVEF (defined as having a maximal velocity of  $\geq 5.5$  m/s in the ESC/EACTS guidelines or  $\geq 5$  m/s in the AHA/ACC guidelines) only if the estimated perioperative mortality in that center is low<sup>[32,34]</sup>. Current guidelines also give a class IIa indication for AVR in patients with severe low-flow AS with preserved LVEF if the symptoms are judged to be secondary to AS only.

Observational and retrospective data suggest that several risk factors for MACE and poor prognosis may be useful to take into account in these cases (Table 3). However, it should be noted that the sensitivity and specificity of these parameters for the identification of patients with a good post-operative prognosis are only approximately 80%. Thus, implementation of these parameters to wide clinical practice cannot be recommended at present but can they can be useful for individual decision making in patients proposed for AVR. Among these parameters, the most widely studied are the prognostic role of aortic valvular calcifications and the hemodynamic response at stress echocardiography.

Eighty percent of patients with asymptomatic severe AS with preserved LVEF who have moderate or severe valvular calcifications develop MACE within the next 4 years, compared with only 20% of patients without moderate or severe calcifications<sup>[26,43]</sup>.

The response of transaortic pressure gradient to exercise has also been suggested to have prognostic importance. Thus, MACE event rate is highest (100% at 2 years) in patients with high resting transaortic pressure gradient ( $> 35$  mmHg) that increases by  $> 20$  mmHg during exercise, intermediate in patients where the transaortic pressure gradient increases by  $< 20\%$  during exercise (50% at 2 years for patients with high resting transaortic pressure gradient, and 20% at 2 years for patients with low transaortic pressure gradient), and lowest (10% at 2 years) in patients with low transaortic pressure gradient ( $\leq 35$  mmHg) that increases by  $< 20\%$  during exercise<sup>[44]</sup>.

Another study that evaluated 105 patients with asymptomatic severe AS with preserved LVEF showed that the inducibility of pulmonary hypertension during exercise (defined as an echocardiographically estimated systolic pulmonary arterial pressure  $\geq 60$  mmHg) was associated with twice the risk of MACE within 3 years of follow-up compared with patients with asymptomatic severe AS with preserved LVEF who did not develop pulmonary hypertension during exercise (22% vs 55%,  $P = 0.014$ )<sup>[45]</sup>. However, the incidence of MACE in both of these groups was very high. In addition, a recent meta-analysis of 4 observational studies with a total of 2486 patients reporting on the utility of AVR (21%

**Table 2** Indication for aortic valve replacement according to European Society of Cardiology/European Association for Cardio-Thoracic Surgery and American Heart Association/American College of Cardiology guidelines<sup>[33,34]</sup>

Criteria	Level of recommendation		Differences between guidelines
	ESC/EACTS	AHA/ACC	
Severe AS with any symptoms clearly due to AS, based on history or unmasked by stress test	I	I	"High-gradient" in AHA/ACC guidelines

Low-flow/low-gradient/low-LVEF severe AS with proof of contractile reserve presence	II a	II a	
Symptomatic low-flow/low-gradient/preserved LVEF severe AS after careful confirmation of severity	II a	II a	
Truly asymptomatic severe AS (no symptoms during treadmill test, no risk criteria) with preserved LVEF if the surgical risk is deemed low and the following criteria are also satisfied: Very severe AS (maximal velocity $\geq$ 5.5 m/s); Severe valvular calcification and increased maximal velocity by $\geq$ 0.3 m/s per year	II a	II a for velocity $\geq$ 5 m/s (see text)  II b for maximal velocity increase by $\geq$ 0.3 m/s per year	AHA/ACC guideline: Velocity $\geq$ 5 m/s or mean gradient $\geq$ 60 mmHg AND severe calcifications; velocity 4 to 4.9 m/s or mean gradient 40 to 59 mmHg AND severe valvular calcification AND stress test demonstrating reduced tolerance or drop in blood pressure
Truly asymptomatic severe AS (no symptoms during treadmill test, no risk criteria) with preserved LVEF if the surgical risk is deemed low and 1 or more of the following criteria are also satisfied: Severely increased BNP/Nt-ProBNP levels at serial determinations and without an alternative explanation; increased transaortic pressure gradient at stress echocardiography by > 20 mmHg; excessive LV hypertrophy without an alternative explanation	II b	-	This indication is not covered in the AHA/ACC guidelines
Low-flow/low-gradient/low-LVEF severe AS without contractile/flow reserve	II b	-	This indication is not covered in the AHA/ACC guidelines

Class I : It is indicated, it is recommended; Class II a: Should be considered, it is reasonable; Class II b: May be considered; Class III: It is not indicated, it is contraindicated; ESC: European Society of Cardiology; EACTS: European Association for Cardio-Thoracic Surgery; AHA/ACC: American Heart Association/American College of Cardiology; AS: Aortic stenosis; LVEF: Left ventricular ejection fraction; CABG: Coronary artery bypass graft.

**Table 3** Suggested high-risk criteria in asymptomatic severe aortic stenosis

Test	High risk criteria
Electrocardiogram	Presence of LV hypertrophy with secondary ST segment deviation ("LV strain")
Blood tests	Highly increased BNP/Nt-ProBNP levels
Stress test	Unmasked symptoms: Fatigability/dyspnea at < 75 W, syncope/near syncope; angina Lack of increase in systolic blood pressure by > 20 mmHg (or decrease) with exercise Inducible myocardial ischemia (ST segment depression $\geq$ 2 mm) Severe ventricular arrhythmias (sustained VT, polymorphic VT, VF)
Conventional Doppler echocardiography	Very severe AS (AVA $\leq$ 0.6 cm <sup>2</sup> ; maximal velocity $\geq$ 5 m/s) LVEF < 50% Severe LV hypertrophy ( $\geq$ 15 mm)? Reduced LV longitudinal strain Zva $\geq$ 4.5 mmHg/mL per square meters Lack of contractile reserve
Dobutamine stress echocardiography (in low-flow, low-gradient, low LVEF)	
Exercise echocardiography (ergometric bicycle)	Increase in transvalvular pressure gradient by > 20 mmHg during exercise
- any severe AS	Inducible pulmonary hypertension during exercise (systolic pulmonary pressure $\geq$ 60 mmHg)
Documentation of valvular calcification	Presence of severe valvular calcifications: Qualitatively (radiology, conventional echocardiography); quantitatively (computed tomography): Calcium score $\geq$ 1651 Agatston units (lower in women vs men)

LVEF: Left ventricular ejection fraction; AS: Aortic stenosis; AVA: Aortic valve area.

of patients) vs watchful waiting (until development of symptoms for a class I indication of AVR) (79% of patients) found that patients who were treated

medically had a 3.5-fold increase in mortality compared with those who underwent AVR, suggesting the benefit of early AVR in this population<sup>[10]</sup>. However, in these

observational studies, patients who were medically treated were older and sicker, and up to 50% of them developed a class I indication for AVR during follow-up but were refused for various reasons - suggesting they were too sick to undergo either surgical or interventional AVR<sup>[40]</sup>. Thus, there is urgent need for a randomized trial to directly compare the two strategies<sup>[46]</sup>.

Although the ESC/EACTS guidelines for valvular heart disease suggest the use of natriuretic peptide levels (Nt-ProBNP) for decisions regarding the need for AVR in patients with asymptomatic severe AS with preserved LVEF<sup>[33]</sup>, a recent study found that the discriminating value of Nt-ProBNP in identifying patients who need AVR is suboptimal (area under the curve, AUC 0.73)<sup>[47]</sup>. Further research is needed to establish the use of natriuretic peptides in these patients.

### **Aortic valve replacement**

In patients proposed for AVR, estimation of operative risk is essential. Currently, two risk scores are widely used. The EuroSCORE II (<http://www.euroscore.org/calc.html>) includes 12 predictors identified from a retrospective population of 14799 patients who underwent different cardiovascular surgical interventions (mainly coronary artery bypass graft) in Europe, in 1995. The STS score (Society of Thoracic Surgeons, <http://riskcalc.sts.org>) includes 24 predictors identified from a population of 64292 patients who underwent surgical intervention only for AS in the United States between 2002 and 2006. The STS score is widely used in the United States for evaluating surgical risk for AS.

Both the EuroSCORE II and the STS score are quite precise in identifying patients with low surgical risk, but they tend to overestimate the risk of patients with high surgical risk (EuroSCORE II more than STS). For example, a patient with a logistic EuroSCORE II > 20 has an estimated surgical mortality of 39%, which is much higher than the real-world mortality of 11%<sup>[43]</sup>. Importantly, both the EuroSCORE II and the STS score can be used in practice in surgical institutions where the operative mortality lies within 1 standard deviation from the mean calculated mortality for the respective surgical procedure. None of the scores include frailty, which is a major limitation. The AHA/ACC guidelines recommend that the overall surgical risk should be divided into 4 groups (low, intermediate, high, and prohibitive) based on the overall assessment of surgical risk (STS score), patient frailty (Katz score)<sup>[48]</sup>, presence of major comorbidities (e.g., severe LV systolic dysfunction, fixed pulmonary hypertension, severe chronic renal failure, respiratory failure, cerebral dysfunction, cancer, and liver cirrhosis), and anticipated difficulties for surgical intervention (e.g., porcelain aorta, thoracic deformities, previous radiotherapy, internal mammary artery crossing the mid-line, and arterial bypass grafts that adhere to the posterior thoracic wall)<sup>[34]</sup>. The ESC/EACTS guidelines do not have similar recommendations<sup>[33]</sup>.

Importantly, the overall decision regarding the relative risks vs benefits for AVR and the most appropriate

type of AVR in individual patients should be made by a multidisciplinary heart team, consisting of a general cardiologist, an interventional cardiologist, a cardiac and vascular surgeon, imaging specialists (echocardiography, computed tomography), and an intensive care specialist with expertise in cardiac anesthesia.

Currently, the most effective treatment for AS is AVR. Simple valvuloplasty has no role in the treatment of severe AS except as a short-term palliation or as a bridge to more definite treatments (e.g., patients with very severe AS who also have abdominal surgical emergencies). Surgical AVR remains the main treatment option, and either a mechanical valve (in younger patients or patients with other indications for long-term anticoagulant therapy) or a bioprosthesis (in older patients due to durability issues or patients with contraindications to life-long anticoagulant therapy) can be used<sup>[49]</sup>. For a detailed discussion regarding the choice of surgical prosthesis, the reader is referred to recent reviews<sup>[50,51]</sup>. The newer alternative of percutaneous transcatheter AVR (TAVR) is given a class I indication for patients who have an indication for AVR but are not candidates for surgery (e.g., porcelain aorta, severe frailty) and a class IIa indication for patients with high surgical risk scores<sup>[33,34,52]</sup>. The morbidity and mortality associated with TAVR have significantly decreased recently as the technique has matured and experience increased; thus, TAVR is currently being investigated for possible expansion to lower risk patients with an indication for a bioprosthesis because recent trials have suggested that TAVR compared favorably to SAVR in these groups<sup>[53]</sup>. For a detailed discussion regarding the selection of TAVR candidates, the reader is referred to excellent recent reviews<sup>[7,8]</sup>.

## **AR**

AR is defined as the presence of diastolic incompetence of the aortic valve with the subsequent regurgitation of blood back from the aorta into the LV. The generally accepted criteria for the definition of severe AR is a regurgitant volume > 60 mL/cardiac cycle or an effective regurgitant orifice area (EROA) > 0.3 cm<sup>2</sup>. However, these parameters are very difficult to measure; therefore, numerous alternative parameters are used to define AR severity. One should be careful when using these parameters because the cut-off values are not interchangeable, and their sensitivity and specificity are suboptimal. Similarly to any other valvular heart disease, the echocardiographic assessment has to use an integrative, complete and correct approach.

### **Etiology**

The prevalence of AR is much lower compared with that for AS, and thus, far fewer studies are available for AR diagnosis and management. AR can be acute or chronic. Acute AR appears primarily as a result of aortic dissection or infective endocarditis. The heart cannot adapt by compensatory dilatation; as a result, the clinical picture is

dominated by signs of low cardiac output (due to reduced effective circulating volume) and pulmonary edema (due to high LV filling pressures secondary to large regurgitant volume). The classical signs of severe chronic AR (diastolic murmur, peripheral signs due to wide pulse pressure) are absent in severe acute AR because the diastolic pressure gradient between the aorta and the LV quickly equalizes. For the same reason, some echocardiographic signs of severe AR may be absent (such as the Doppler signal aliasing in the LVOT); in these situations, documenting diastolic reversal flow in the descending aorta prevents missing the diagnosis of severe AR. The presence of severe acute AR should be considered in the differential diagnosis of any patient presenting with acute severe heart failure or cardiogenic shock in the absence of obvious causes (such as myocardial infarction)<sup>[54]</sup>.

Chronic AR is mostly due to BAV or aortic root dilatation. Degenerative aortic valve disease is also important, whereas other etiologies are rare. Patients remain asymptomatic for a long time, but irreversible LV dysfunction may appear before symptom onset.

Bicuspid aortic valve (BAV) is the most frequent congenital heart disease in humans (prevalence: 2% of the general population)<sup>[55]</sup>. Congenital abnormalities of the aortic valve, of which > 90% are represented by BAV, are at the base of > 50% of so-called "calcific" severe AS in adults with an indication for AVR<sup>[12]</sup>. BAV is probably a disease of the entire aortic root characterized by fragmentation of elastin fibers, alteration of the media and increased collagen deposition in the ascending aorta<sup>[56]</sup>. These alterations are frequently seen in patients with ascending aortic dilatation and increased risk for aortic dissection.

BAV is characterized by fusion of one of the aortic commissures, which results in two functional aortic cusps of different dimensions. The terminology used to classify BAV may be confusing. Depending on the commissure that is fused, the orientation of the abnormal orifice can be anterior-posterior (by fusion of the right with the left coronary cusps - encountered in 56% of cases) or right-left (by fusion of the non-coronary with the right coronary cusp - encountered in 44% of cases). Less than 2% of cases are characterized by fusion of the non-coronary with the left coronary cusp. Thus, the morphology of the BAV can be described by the orientation of the opening orifice (anterior-posterior, AP/right-left, RL)<sup>[57]</sup> or by the cusps that fuse (right - left coronary, RL/right coronary - non-coronary, RN)<sup>[58]</sup>.

Recently, in a study that used 4-dimension flow magnetic resonance imaging, Mahadevia *et al*<sup>[58]</sup> suggested that the type of BAV determines the pattern of dilatation of the ascending aorta through the direction of the systolic transaortic jet and subsequent differential pressures on the various regions of the ascending aortic walls. Thus, BAV type AP/RL is associated with an eccentric systolic jet and increased parietal pressures on the anterior and right ascending aortic wall and is frequently (87%) associated with dilatation of the root or the entire ascending thoracic aorta. Conversely, BAV type RL/RN determines increased

parietal pressures on the right and posterior ascending aortic wall and is rarely associated with aortic dilatation. The role of hemodynamic vs genetic factors in stratifying the risk associated with BAV and aortic root disease is unclear<sup>[59]</sup>.

### Evaluation of AR

The evaluation of AR severity follows the same principles as that for the other valvular heart disease and is primarily based on echocardiography. For AR, the following goals are to be achieved by the echocardiographic evaluation: (1) identification of patients with severe AR; (2) identification of patients with an indication for AVR (surgical); and (3) identification of patients with dilated ascending aorta (with or without aortic bicuspid valves).

**Identifying patients with severe AR:** The most important echocardiographic criteria for identification of severe AR are listed in Table 4. For AR patients, the impact of different flow states (normal vs low) has not been investigated and is not applicable for routine clinical practice. Studies that validated the echocardiographic criteria for AR severity have used angiography as the comparator<sup>[60,61]</sup>. Only one study has prospectively evaluated the role of echocardiographic AR severity criteria in relation to the long-term prognosis of patients with severe, asymptomatic AR<sup>[62]</sup>.

**Identifying patients who are candidates for AVR:** SAVR remains the gold-standard treatment for AR. In a few experienced centers, surgical aortic valve reconstruction may be an alternative for patients with favorable anatomy (*e.g.*, dilated aortic root, prolapsed aortic cusp)<sup>[63,64]</sup>. TAVR has a very limited role in treating AR and has only been used anecdotally in these patients<sup>[65]</sup>.

Unlike AS, the current recommendations for AR evaluation and management are based on far fewer data. Additionally, most of the data on the prognosis of AR come from studies published more than 2 decades ago, which used outdated evaluation techniques.

Severe acute AR is a surgical emergency. The current indications for surgery for chronic severe AR are summarized in Table 5<sup>[33,34]</sup>. Regarding patients with dilatation of the ascending aorta, there are considerable differences between different guidelines, and a summary is provided in Table 6<sup>[33,34,66]</sup>. This summary does not cover patients with connective tissue disorders (*e.g.*, Marfan syndrome). In these patients, a recent AHA/ACC statement tried to clarify the differences between the 2 guidelines published in 2014 by the AHA/ACC (the "2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease"), and in 2010 by other collaborating societies (the "2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM Guidelines for the Diagnosis and Management of Patients With Thoracic Aortic Disease")<sup>[67]</sup>.

The indications for surgery in AR are based on only a few small-medium sized prospective studies all of which were observational and published before 2000. Bonow *et al*<sup>[68]</sup> evaluated the long-term prognosis (mean follow-up, 8

**Table 4** Criteria for the diagnosis of severe aortic regurgitation

	Mild AR	Moderate AR	Severe AR
Ratio between the AR jet diameter and the LVOT diameter	< 25%	25%-64%	≥ 65%
Vena contracta (mm)	< 3	3-5.9	≥ 6
Regurgitant volume (mL/beat)	< 30	30-59	≥ 60
Regurgitant fraction	< 30%	30%-49%	≥ 50%
EROA (cm <sup>2</sup> )	< 0.1	0.1-0.29	≥ 0.3
Diastolic backflow in the descending thoracic and/or abdominal aorta	Minimal	Less than holodiastolic	Holodiastolic (especially for backflow documented in the abdominal aorta)
Angiographic	1+	2+	3-4+
LV dilatation	No	No	Yes (mandatory for chronic severe AR)

AR: Aortic regurgitation; LVOT: Left ventricular outflow tract; EROA: Effective regurgitant orifice area.

years) of 104 patients with severe AR and preserved LVEF recruited between 1973 and 1988. In these patients, the independent prognostic factors were age, the initial end-systolic LV diameter, and modification in time of the LVEF. In this study, patients with an end-systolic LV diameter > 50 mm and an end-diastolic LV diameter > 70 mm had a > 10%/year risk for death, development of symptoms or development of LV systolic dysfunction. The LV diameters were measured using simple, M-mode echocardiography, which has major limitations and is completely outdated today.

A second prospective observational study evaluated the prognosis of 104 patients with severe AR recruited beginning in 1979 and followed-up for an average of 7.3 years<sup>[69]</sup>. In this study, the most powerful prognostic factor was the rate of decline of LVEF (normalized to wall stress). Tornos *et al*<sup>[70]</sup> evaluated 101 patients with asymptomatic severe AR and normal LVEF, and followed-up these patients for up to 10 years. The rate of AVR was 12% at 5 years and 24% at 10 years. The independent prognostic factors required for AVR were an end-systolic LV diameter > 50 mm and an LVEF < 60% (determined by radionuclide cardiac scan); patients who needed AVR more frequently had progressive LV systolic dysfunction. Dujardin *et al*<sup>[71]</sup> evaluated 246 patients with severe AR included between 1985 and 1994, and followed-up these patients for an average of 10 years. The incidence of MACE during this period was very high (83%) as follows: 34% deceased; 47% developed heart failure and 62% received AVR<sup>[71]</sup>. In this study, the following were the independent predictors of survival: Age, New York Heart Association functional class, presence of co-morbidities, presence of atrial fibrillation, end-systolic LV indexed diameter > 25 mm/m<sup>2</sup>, and the LVEF. In a retrospective cohort study of 166 patients with asymptomatic severe AR and severe systolic dysfunction (LVEF < 35%), Kamath *et al*<sup>[72]</sup> showed that those who underwent surgery had much better prognosis compared with that of patients treated medically (HR = 0.59, 95%CI: 0.42-0.98, *P* = 0.04).

Importantly, AR severity in these studies was determined by angiographic and not echocardiographic criteria. Only one study evaluated the utility of echocardiographic indices in AR severity by identifying patients who will

need surgery. Detaint *et al*<sup>[62]</sup> evaluated 251 patients with asymptomatic severe AR with preserved LVEF (> 50%) recruited between 1991 and 2003 (a relatively contemporary population in comparison with previous studies). The independent prognostic factors required for AVR were severe AR as determined by quantitative echocardiographic indices and an end-systolic LV indexed volume > 45 mL/m<sup>2</sup> (as measured by the Simpson bi-plane method). Patients with severe AR and an end-systolic LV indexed volume > 45 mL/m<sup>2</sup> had an 87% risk of MACE at 10 years compared with only 40% of patients with severe AR and an end-systolic LV volume < 45 mL/m<sup>2</sup>. This study also showed that quantitative echocardiographic indices of AR severity had superior prognostic value compared with that of qualitative echocardiographic indices<sup>[62]</sup>.

These studies also suggested that patients with severe AR may have severe prognosis even before the appearance of symptoms or LV dysfunction. The mortality of patients with asymptomatic severe AR with preserved LVEF may reach 35% at 10 years<sup>[62,71]</sup>. However, there is insufficient prognostic data that can be used to identify patients at risk. The role of stress echocardiography in stratifying the risk of patients with severe AR has been much less studied compared with for patients with AS, but it may be used to evaluate the presence of contractile reserve<sup>[73]</sup>.

The role of myocardial deformation imaging in the selection of patients who may need AVR is also under investigation. A study of 64 patients with moderate or severe AR (regardless of symptoms and LVEF) showed that patients for whom AVR was eventually performed (*n* = 29) had lower values of LV strain, LVEF and higher LV volumes compared with patients who did not need surgery. However, the reported cut-off values for identifying patients who will need surgery had sensitivities and specificities that make them poorly applicable in clinical practice (area under the curve < 0.77)<sup>[74]</sup>.

B-type natriuretic peptide (BNP) levels may also play a role in predicting outcomes in patients with severe AR. Pizarro *et al*<sup>[75]</sup> studied 294 patients with severe asymptomatic AR and LVEF > 55%, and found that a BNP level > 130 pg/mL had 77% sensitivity and 94% specificity for predicting LV dysfunction symptoms

**Table 5** Indications for aortic valve replacement in chronic aortic regurgitation<sup>[33,34]</sup>

Criteria	Class of indication		Differences between guidelines
	ESC/EACTS	AHA/ACC	
Symptomatic severe AR (any LVEF)	I	I	
Asymptomatic severe AR with depressed LV function (LVEF < 50%)	I	I	
Severe AR in patients with another indication for cardiac surgery (e.g., CABG, thoracic aorta, another valve)	I	I	
Asymptomatic severe AR with normal LVEF (> 50%) but with severe LV dilatation	II a	II a	Definition of severe LV dilatation: ESC/EACTS guideline: End-diastolic LV diameter > 70 mm, or end-systolic LV diameter > 50 mm (or > 25 mm/m <sup>2</sup> ); AHA/ACC guidelines: End-systolic LV diameter > 50 mm
Moderate AR in patients with another indication for cardiac surgery (e.g., coronary bypass, thoracic aorta, another valve)	-	II a	This indication is not covered in the ESC/EACTS guidelines
Severe AR with normal LVEF (> 50%) but with progressive LV dilatation (end-diastolic LV diameter > 65 mm) if the surgical risk is low	-	II b	This indication is not covered in the ESC/EACTS guidelines

Class I : It is indicated, it is recommended; Class II a: Should be considered, it is reasonable; Class II b: May be considered; it is contraindicated; ESC/EACTS: European Society of Cardiology/European Association for Cardio-Thoracic Surgery; AHA/ACC: American Heart Association/American College of Cardiology; AR: Aortic regurgitation; LVEF: Left ventricular ejection fraction; CABG: Coronary artery bypass graft.

**Table 6** Indication for surgery in patients with bicuspid aortic valve and aortic root disease<sup>[33,34,66,67]</sup>

Class of indication	Guideline		Differences between guidelines
	ESC/ EACTS 2012	AHA/ACC 2016 Consensus on AHA/ACC 2014, and ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM 2010 Guidelines	
I	-	Asymptomatic bicuspid aortic valve with dilatation of Valsalva sinuses or the ascending thoracic aortic diameter > 55 mm	No class I indications in the 2012 ESC/EACTS guidelines
II a	Bicuspid aortic valve with an ascending thoracic aortic diameter > 50 mm if the patient also has at least one of the followings: Family history of aortic dissection; documented increase in the aortic diameter > 2 mm/yr (assessed using the same imaging method, at the same level, and with comparative images available); arterial hypertension; coarctation of the aorta	Bicuspid aortic valve AND dilatation of the Valsalva sinuses or of the ascending thoracic aorta (> 50 mm) AND at least one of the following Family history of aortic dissection Documented increase in aortic diameter > 5 mm/yr OR low surgical risk in an expert center	
	-	Replacement of the ascending aorta if the patient also has an indication for surgery for AS/AR, and the ascending aortic/Valsalva sinus diameter is > 45 mm	Not covered by the 2012 ESC guidelines

Class I : It is indicated, it is recommended; Class II a: Should be considered, it is reasonable; Class II b: May be considered; ESC: European Society of Cardiology; EACTS: European Association for Cardio-Thoracic Surgery; AHA/ACC: American Heart Association/American College of Cardiology; ACCF: American College of Cardiology Foundation; AHA: American Heart Association Task Force on Practice Guidelines; AATS: American Association for Thoracic Surgery; ACR: American College of Radiology; ASA: American Stroke Association; SCA: Society of Cardiovascular Anesthesiologists; SCAI: Society for Cardiovascular Angiography and Interventions; SIR: Society of Interventional Radiology; STS: Society of Thoracic Surgeons; SVM: Society for Vascular Medicine, North American Society for Cardiovascular Imaging; AR: Aortic regurgitation; AS: Aortic stenosis.

or death after  $38 \pm 9$  mo of follow-up. BNP level had additive prognostic value to echocardiographic prognostic indices<sup>[75]</sup>. Further studies are needed to establish the role of BNP levels for indication of surgery in patients with AR.

A recent study of 159 patients with moderate or severe AR without a formal indication for surgery according to current guidelines (LVEF > 50%, end-diastolic LV diameter  $\leq$  70 mm, end-systolic LV diameter  $\leq$  70 mm or  $\leq$  25 mm/m<sup>2</sup>) showed that 31% of these patients needed AVR within  $30 \pm 21$  mo of follow-up. The independent prognostic factors for early surgery were as follows: Global longitudinal LV strain, right ventricular longitudinal

strain, and tricuspid annular peak systolic excursion (TAPSE); the combination of these 3 factors had a higher discriminating power compared with each one taken individually ( $\chi^2 = 64.4$ ,  $P < 0.001$ )<sup>[76]</sup>. However, the individual variability of these indices was high, and their utility for clinical practice must be validated in prospective clinical studies. This study confirmed that patients with significant AR without an initial formal indication but who eventually needed AVR, developed progressive LV dilatation and LVEF decline during follow-up, despite similar degrees of LV dilatation and LVEF at baseline, when compared to patients who did not need AVR during follow-up<sup>[76]</sup>.

Cardiac magnetic resonance imaging (CMRI) is highly accurate in quantifying cardiac chamber volumes, aortic regurgitant volume and EROA. CMRI is recommended for patients with suboptimal echocardiography for whom the exact determination of AR severity is important and has therapeutic consequences (class II a indication, according to ACC/AHA guidelines)<sup>[34]</sup>.

A recent study of 113 patients with moderate and severe AR (as determined by echocardiography) followed-up for up to 9 years suggested that a regurgitant fraction > 33% as determined by CMRI had a high positive predictive value (93%) in identifying patients who will need AVR. Additionally, an end-diastolic LV volume > 246 mL was also useful in identifying these patients (positive predictive value for AVR, 88%)<sup>[77]</sup>. However, contrary to previous data, in this study, the CMRI-measured LVEF was not useful in identifying patients with asymptomatic severe AR who needed AVR. More studies are needed to establish the exact role of all these parameters in selecting patients with asymptomatic severe AR who will need AVR.

## CONCLUSION

AS and AR represent important health problems worldwide; when severe, they carry poor prognoses. For AS, both SAVR and TAVR may provide definite treatment in carefully selected patients. For AR, valve surgery (either SAVR or - in selected cases - aortic valve repair) remains the gold standard of care. To properly identify those patients who are candidates for surgery, the clinician has to carefully assess the severity of valve disease with an understanding of the potential pitfalls involved in these assessments. Thus, evaluation of aortic valve disease requires "a global view and a global understanding"<sup>[4]</sup>.

### Abstract

The adult congenital heart disease (ACHD) population continues to grow and most cardiologists, emergency room physicians and family doctors will intermittently come into contact with these patients. Oftentimes this may be in the setting of a presentation with atrial tachyarrhythmia; one of the commonest late complications of ACHD and problem with potentially serious implications. Providing appropriate initial care and ongoing management of atrial tachyarrhythmia in ACHD patients requires a degree of specialist knowledge and an awareness of certain key issues. In ACHD, atrial tachyarrhythmia is usually related to the abnormal anatomy of the underlying heart defect and often occurs as a result of surgical scar or a consequence of residual hemodynamic or electrical disturbances. Arrhythmias significantly increase mortality and morbidity in ACHD and are the most frequent reason for ACHD hospitalization. Intra-atrial reentrant tachycardia and atrial fibrillation are the most prevalent type of arrhythmia in this patient group. In hemodynamically unstable patients, urgent cardioversion is required. Acute management of the stable patient includes anticoagulation, rate control, and electrical or pharmacological cardioversion. In ACHD, rhythm control is the preferred management strategy and can often be achieved. However, in the long-term, medication side-effects can prove problematic. Electrophysiology studies and catheter ablation are important treatments modalities and in certain cases, surgical or percutaneous treatment of the underlying cardiac defect has a role. ACHD patients, especially those with complex CHD, are at increased risk of thromboembolic events and anticoagulation is usually required. Female ACHD patients of child bearing age may wish to pursue pregnancies. The risk of atrial arrhythmias is increased during pregnancy and management of atrial tachyarrhythmia during pregnancy needs specific consideration.

**Core tip:** This review highlights the importance of atrial tachyarrhythmia in adult congenital heart disease (ACHD) patients. It discusses causative mechanisms of arrhythmia, treatment of arrhythmia in the acute setting and on a long-term basis, including: Medications, catheter ablation, and anticoagulation. We include specific comments on the treatment of arrhythmias in ACHD patients who are pregnant.

## INTRODUCTION

With an estimated incidence of 9 per 1000 live births, congenital heart disease (CHD) is the most frequent major birth defect<sup>[1]</sup>. Improved diagnosis and management have led to recent rapid growth in numbers of adult survivors, particularly in the subset of patients with complex heart lesions<sup>[2]</sup>. Individuals with adult congenital heart disease (ACHD) often have residual cardiac lesions that promote abnormal hemodynamics and electrical disturbance. Electrical abnormalities are exacerbated by surgical scar, prosthetic patches and diffuse myocardial fibrosis and increasingly as these patients age, by the additional burden of traditional cardiovascular risk factors<sup>[3,4]</sup>. It is perhaps not surprising that arrhythmia is one of the most important problems faced by ACHD patients and has become the leading cause of ACHD hospitalization<sup>[5]</sup>. In this population, atrial arrhythmia is far more common than ventricular and is associated with substantial morbidity and mortality.

Atrial arrhythmia in ACHD occurs with a prevalence 3 times greater than that seen in the general population<sup>[6]</sup>. The risk increases with age<sup>[7]</sup> and varies according to underlying congenital cardiac anomaly (Table 1<sup>[8-16]</sup>). The prevalence is greatest in those with complex defects where it is estimated at > 50% by the age of 65 years<sup>[6]</sup>. Atrial arrhythmias in ACHD can herald adverse or declining intra-cardiac hemodynamics and their occurrence is a risk factor for other significant clinical events<sup>[6,17]</sup>. Prompt diagnosis and appropriate management may help avoid important complications, the risks of which are higher in specific ACHD subgroups. In patients with simple lesions<sup>[18]</sup>, atrial arrhythmia can be managed in a similar manner to arrhythmia in patients with structurally normal hearts. However, for patients with lesions of moderate or high complexity<sup>[18]</sup>, involvement of an ACHD specialist and/or electrophysiologist with subspecialty expertise is recommended<sup>[17,18]</sup>. Most ACHD patients with arrhythmia

will initially present locally, to general cardiologists, family physicians and emergency doctors and given population demographics, it is increasingly likely these care providers will encounter such patients. This review is intended to raise awareness of atrial arrhythmia as a complication of ACHD and of the necessary caveats to deliver care safely. It focuses on issues seen frequently in our day-to-day clinical practice and of importance to primary care providers. For a more comprehensive analysis and further reading we suggest the 2014 PACES/HRS Expert Consensus Statement on the Recognition and Management of Arrhythmias in Adult Congenital Heart disease<sup>[17]</sup>.

## CLINICAL IMPLICATIONS OF ATRIAL TACHYARRHYTHMIA IN ACHD

Given the retrospective and observational nature of most studies, teasing out "cause and effect" for the clinical implications of atrial arrhythmia in ACHD is challenging. However, it is certain that ACHD patients who develop atrial arrhythmia are at increased risk of other adverse clinical events. In their large ( $n > 38000$ ) analysis of Quebec's ACHD patients, Bouchardy *et al*<sup>[6]</sup> found patients with a history of atrial arrhythmia experienced a 50% increase in mortality, a 100% increase in stroke or heart failure and a 300% increase in the risk of cardiac interventions, as compared those with no history of atrial arrhythmia. These findings from a large and heterogeneous ACHD population are borne out by those from smaller studies of diagnosis-specific cohorts. Two large multi-center studies identified atrial arrhythmia as a powerful predictor of mortality and/or ventricular tachycardia in patients with tetralogy of Fallot (TOF)<sup>[19,20]</sup>. In a single-centre study of 321 Fontan patients "clinically relevant arrhythmia" was the strongest predictor of outcome, increasing the risk of death or transplant 6-fold<sup>[21]</sup>. In our own cohort of Mustard patients, patients who had experienced an atrial arrhythmia had worse subaortic right ventricular (RV) function and more tricuspid regurgitation than those who had not<sup>[22]</sup>.

## TYPES OF ATRIAL TACHYARRHYTHMIA IN ACHD AND THEIR MECHANISMS

Any type of atrial tachyarrhythmia can occur in ACHD patients. However, by nature of their underlying heart defects and previous surgeries, some subtypes are more frequently encountered than others. Intra-atrial reentry tachycardia (IART) is the sub-type encountered most frequently at the current time<sup>[23]</sup>. This may change as the ACHD patient population ages and increases in the incidence of atrial fibrillation have been already noted<sup>[24-26]</sup>. Atrioventricular nodal reentry, typical atrial flutter and focal atrial tachycardias<sup>[17,27]</sup> are also seen and atrial arrhythmia mediated by accessory pathway(s) is a particular idiosyncrasy of patients with Ebstein anomaly of the tricuspid valve<sup>[27]</sup>.

**Table 1 Summary of studies describing the prevalence of arrhythmia in adult congenital heart disease**

Ref.	Diagnosis	No. of patients in study	Duration of follow-up (yr)	Prevalence of atrial arrhythmia (%)
[8]	Fontan	94	11	41
[9]	Fontan	334	9	16
[10]	TGA: Mustard or Senning	86 Mustard	8	48
[11]	TGA: Mustard or Senning	60 Mustard	Mustard 16	Mustard 28.8
		62 Senning	Senning 11	Senning 11.9
[12]	TGA: Arterial switch	374	19	2
[13]	Ebstein anomaly	285	20	36
[14]	Tetralogy of Fallot	242	16	12
[15]	Repaired AVSD	300	11	14
[16]	Repaired ASD	213	4	14

TGA: Transposition of great arteries; AVSD: Atrio-ventricular septal defect; ASD: Atrial septal defect.

### ***Intra-atrial reentry tachycardia and atrial flutter***

Macro reentry circuits within the atria of people without CHD usually produce typical isthmus-dependent atrial flutter, which can also occur in patients with ACHD. However, the scarred, dilated and thickened atria of ACHD patients produce additional barriers to conduction and promote macro reentry pathways independent of the tricuspid valve-inferior vena cava isthmus with low voltage electrocardiogram (ECG) signals and without the typical saw-toothed p-wave appearance of flutter waves. We refer to this type of arrhythmia as IART. With atrial rates ranging from 150-200 per minute, IART is usually slower than typical flutter and has a stable cycle length and p wave morphology<sup>[27]</sup>. Although both IART and atrial flutter can occur in ACHD and may coexist in individual patients<sup>[28,29]</sup> in our experience IART is the more frequently encountered and so we use this term preferentially when discussing atrial macro reentry in ACHD patients.

IART is the most common arrhythmia in adults with an atrial redirection procedure (Mustard or Senning operation) for transposition of the great arteries (TGA) and also in those with a Fontan circulation<sup>[23]</sup>. IART is also prevalent in patients with repaired TOF and reported to be an important cause of morbidity<sup>[25,30]</sup>. While the occurrence of atrial arrhythmia in ACHD increases with time<sup>[6]</sup> and subaortic ventricular dysfunction is a generalized risk factor<sup>[11]</sup>, more specific risk factors for IART have been identified in some subgroups. In patients with TGA and an atrial redirection procedure identified IART risk factors include: A Mustard procedure<sup>[31]</sup>, the occurrence of perioperative bradyarrhythmia, need for reoperation and loss of sinus rhythm during follow-up<sup>[26]</sup>. Older age at operation, history of an atrial septectomy, and an atriopulmonary connection have been identified as risk factors for IART in the Fontan population<sup>[10,32]</sup>.

The propagation route for an IART circuit differs depending on the anatomic defect and type of surgical repair<sup>[33]</sup>. The pathway is often restricted to right atrial tissue, modified by regions of fibrosis from previous suture lines, patches, and baffles which act in combination with natural conduction barriers like crista terminalis, valve orifices, and the superior and inferior caval orifices to

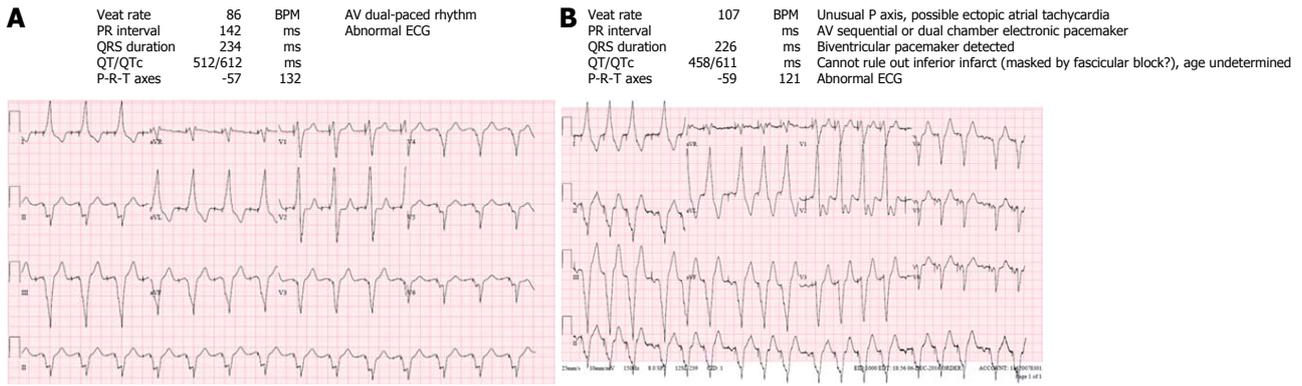

channel the wave front along a macroreentrant loop<sup>[34,35]</sup>. If a tricuspid valve is present, the isthmus between the valve ring and the inferior vena cava is often involved in such circuits, but in the absence of tricuspid valve or if there is a deformed valve, the circuit path is less predictable and can usually only be identified by electrophysiological mapping<sup>[36]</sup>. Multiple IART pathways can be present in the same patient<sup>[37]</sup>.

In the setting of a healthy AV node A:V conduction may occur 1:1. If so, the resultant fast ventricular rhythm can produce hypotension, syncope, or possibly cardiac arrest in ACHD patients who often have abnormal baseline hemodynamics or impaired ventricular function<sup>[36]</sup>. Rapid conduction is of particular concern in patients with atrial baffles (Mustard and Senning) who are unable to augment sub-aortic RV filling rates and stroke volume during tachycardia<sup>[38,39]</sup> and also in patients with a single ventricle physiology. The clinical picture of instability combined with tachycardia sometimes give rise to erroneous interpretation of the rhythm as being of ventricular origin. We see this mistake made most frequently in patients with TOF, since they usually have a baseline broad RBBB which persists during atrial tachycardia.

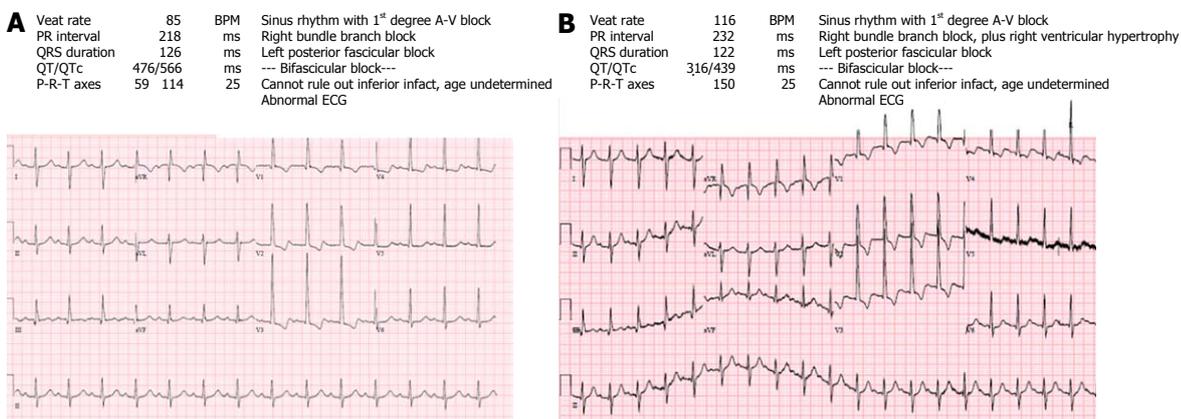

Conversely, in patients who remain clinically stable, IART with 2:1 or 3:1 conduction can easily be misinterpreted as sinus rhythm on the surface ECG of a patient with ACHD. This is not infrequently encountered in patients with a Fontan circulation or atrial redirection procedure for TGA. These patients often experience IART with a ventricular rate only slightly above their baseline rate and may have fractionated, difficult to see p-waves. Reviewing previous ECGs is often key to establishing the correct diagnosis. Hidden p-waves may be uncovered by vagal maneuvers or intravenous adenosine infusion, which can be useful when used with caution if still uncertain<sup>[36]</sup>. A high degree of clinical suspicion is required when interpreting the ECG in an adult CHD patient who presents with palpitations, especially if that patient has a Fontan or Mustard/Senning circulation (Figures 1 and 2).

### ***Atrial fibrillation***

Atrial fibrillation is the result of multiple micro reentry circuits and in ACHD is less prevalent than IART. A single-

**Figure 1** Electrocardiograms from a patient with an interatrial lateral tunnel Fontan for double inlet left ventricle. Patient has an epicardial DDI pacemaker for management of postoperative complete heart block. A: Atrio-ventricular sequentially paced rhythm. Patient feeling well; B: Grouped beating with V paced beats and intermittent p-waves. Underlying intra-atrial reentry tachycardia with AV Wenkebach demonstrated on device tracing (not shown). Patient complaining palpitations.

**Figure 2** Electrocardiograms from a patient with a Mustard procedure. A: Sinus rhythm with 1<sup>st</sup> degree heart block. Patient feeling well; B: Intra-atrial reentry tachycardia with 2:1 ventricular conduction, alternate p-waves not seen as overlapping with QRS complexes. Patient complaining palpitations initially. Within 3 h unable to lie flat, requiring oxygen for desaturation and with pulmonary edema on chest X-ray. Note incorrect automated diagnosis of sinus tachycardia.

centre study of 471 electrical cardioversions in 149 CHD patients found that 78% were for IART and 22% for AF<sup>[23]</sup>. However, the prevalence of AF is increasing as the ACHD population ages such that this diagnosis is becoming the most common atrial arrhythmia in older cohorts. A recent study of 4781 TOF patients across the age spectrum reported the average age of onset of IART as 27 years vs 44 years for AF<sup>[20]</sup>. In the same study, AF was the diagnosis in 10% of arrhythmias seen in patients born prior to 1961 vs < 1% patients born after 1981<sup>[20]</sup>. In another cohort of TOF patients AF was the most prevalent atrial arrhythmia after 55 years of age<sup>[25]</sup>. The increasing risk of AF with age relates to the underlying mechanism, which is usually chronic hemodynamic atrial stress and remodeling as well as increase in conventional risk factors such as hypertension, diabetes mellitus, obesity, and sleep apnea. Patients with residual AV valve regurgitation or left-sided obstructive lesions as well as those with unrepaired, palliated CHD are particularly vulnerable to AF<sup>[23,24]</sup>. Patients who have undergone ablation for IART may go on to experience late atrial fibrillation in follow-up. During follow-up approximately 30% of patients with surgically closed ASD who had previously undergone successful catheter ablation for IART develop AF<sup>[40]</sup>.

**Atrioventricular reentrant tachycardia**

Wolff-Parkinson-White syndrome (WPW) occurs in 20% of cases with Ebstein anomaly of tricuspid valve<sup>[41]</sup>. The accessory pathway in Ebstein anomaly is usually located along the posterior and septal aspect of the tricuspid ring where the valve leaflets are most abnormal, and about half of these patients have multiple accessory pathways<sup>[42,43]</sup>. Ebstein-like malformation of a left-sided tricuspid valve is common in congenitally corrected TGA and often associated with accessory pathway(s)<sup>[36]</sup>. Tachycardia events for Ebstein patients are of concern in adult years when there is increased likelihood of coexisting atrial fibrillation and 1:1 anterograde conduction over the accessory pathway<sup>[36]</sup>.

**MANAGEMENT OF ACUTE ATRIAL ARRHYTHMIAS IN ACHD PATIENTS**

Acute management of atrial tachyarrhythmia in hemodynamically stable patients includes anticoagulation to prevent thromboembolism, rate control, and cardioversion to restore sinus rhythm. In ACHD patients with simple anatomy and an atrial arrhythmia of ≥ 48 h or unknown duration, ≥ 3 wk of anticoagulation or transesophageal

echocardiography (TEE) is recommended prior to cardioversion to rule out intra-cardiac thrombus<sup>[17]</sup>. In moderate and complex patients who are at higher risk of thrombosis formation, TEE or 3 wk of anticoagulation is recommended prior to cardioversion, even if the IART or atrial fibrillation is less than 48 h in duration<sup>[17,44]</sup>. In our own practice, we are reluctant to leave Fontan patients or those with a systemic right ventricle in an atrial tachyarrhythmia for a prolonged period of time, for fear of deteriorating hemodynamics and/or ventricular function. Therefore we rarely choose to anticoagulate and wait three weeks. In high-risk patients we prefer to perform TEE or low dose cardiac CT promptly followed by cardioversion within a day or two of diagnosis. Pharmacologic rate control can be useful for those who have a rapid ventricular response during their tachyarrhythmia while cardioversion is being planned. Options include use of beta-blockers, calcium channel blockers, or amiodarone<sup>[45]</sup>.

Termination of atrial tachyarrhythmia can be achieved by electrical cardioversion, overdrive pacing, or drug therapy. Urgent electrical cardioversion is recommended in adults with ACHD who are hemodynamically unstable regardless of arrhythmia duration or anticoagulation status<sup>[45]</sup>. Anterior-posterior pad positioning increases cardioversion success in the face of marked atrial dilatation<sup>[17]</sup> and is important in the many ACHD patients who have a pacemaker. Patients with Fontan palliation, Mustard or Senning, and Glenn shunts, are at risk of sinus node dysfunction and may develop prolonged sinus pause following rhythm conversion<sup>[17,9,46]</sup>. The team planning a cardioversion needs to be prepared for this possibility. Patients with an extra-cardiac or interatrial lateral tunnel Fontan circulation do not have ready venous access to enable ventricular pacing. The back-up plan for these patients should include percutaneous pacing and/or use of medications such as atropine or isopretrenol. Electrical cardioversion of complex CHD patients is best performed in the coronary care unit with continuous monitoring of heart rhythm post cardioversion till rhythm stability is established. Overdrive pacing of IART can be attempted in patients with either atrial or dual chamber pacemakers or defibrillators. Immediate anti-tachycardia pacing is effective in up to 50% of cases<sup>[47]</sup>. In pacemaker dependent patients, it is important to maintain back up ventricular pacing during attempted atrial overdrive pacing<sup>[17]</sup>.

Pharmacologic cardioversion can be used to terminate atrial arrhythmias acutely, however, concerns include risk of torsades de pointes in Class III and ventricular tachycardia in Class IA and IC antiarrhythmic medications<sup>[17]</sup>. Amiodarone is the medication we use most often for acute termination of atrial arrhythmias in ACHD patients. Cardioversion can sometimes be achieved by following an intravenous bolus dose with a maintenance infusion for 24-48 h. Amiodarone may restore sinus rhythm, or assist in slowing the ventricular rate if cardioversion fails. There are currently no efficacy or safety data regarding the acute use of amiodarone in treatment of atrial tachy-

arrhythmia in ACHD patients<sup>[17]</sup>. Ibutilide and sotalol have also been shown as effective in acute treatment of atrial tachyarrhythmia<sup>[48,49]</sup>. When compared in a randomized study in non-ACHD population, ibutilide was superior to sotalol in conversion of atrial arrhythmia<sup>[50]</sup>. If using ibutilide, one must be cautious of torsades de pointes which is reported to occur in 2%-8% of non-ACHD patients<sup>[51]</sup>. In ACHD patients presenting with IART or atrial fibrillation, 1 to 2 mg of IV ibutilide over 10 min may be given if used with continuous heart monitoring where emergency defibrillation and resuscitation is available<sup>[17]</sup>.

Patients with WPW, orthodromic atrioventricular reentrant tachycardia and AVNRT, who are hemodynamically stable can be treated with intravenous adenosine, which may terminate the tachycardia and restore sinus rhythm. This is because adenosine slows AV nodal conduction and these tachycardias include the AV node as an obligatory part of their circuit. In contrast, the effects of adenosine on atrial flutter, IART and atrial ectopic tachycardia are inconsistent<sup>[52]</sup>. Adenosine will not generally terminate these arrhythmias and is more likely to produce transient or increased AV block, which can unmask atrial activity on an ECG and aid diagnosis. It is important that adenosine be given rapidly and in a sufficient dose to reach the coronary circulation. Adenosine administration is generally safe but rare proarrhythmic and potentially life-threatening effects have been reported<sup>[53]</sup>. It can precipitate atrial fibrillation, which as already stated, is a risk in patients with an accessory pathway where the atrial rate may be conducted 1:1 to the ventricles. Patients with pre-excited atrial fibrillation are usually treated with urgent electrical cardioversion because of the risk of cardiovascular collapse<sup>[54]</sup>.

---

## MANAGEMENT OF CHRONIC OR RECURRENT ATRIAL ARRHYTHMIAS IN ACHD PATIENTS

---

### *Medical management*

Rhythm control is generally recommended as the initial strategy for patients with moderate or complex forms of CHD<sup>[17]</sup>. This is because loss of sinus rhythm, even with a controlled heart rate can adversely and importantly impact both hemodynamics and ventricular function in ACHD patients<sup>[17,27]</sup>. However, once an ACHD patient has experienced atrial arrhythmia, recurrences are often seen. In our experience, the initiation of antiarrhythmic drugs, before further cardioversion may be beneficial to the chances of reestablishing sinus rhythm and/or reducing the frequency of recurrence.

The pro-arrhythmic risk of Class I (fast sodium channel blockers) antiarrhythmic drugs in patients with CHD includes ventricular arrhythmias<sup>[55,56]</sup>. In addition, they are not recommended for maintenance of sinus rhythm in patients with coronary artery disease or moderately to severe systolic dysfunction of either ventricle<sup>[17,45]</sup>.

In general cardiology practice, sotalol is used for

maintenance of sinus rhythm in patients with AF who have normal baseline QT interval (< 460 ms) and minimal or no structural heart disease<sup>[45]</sup>. While some retrospective studies have suggested safety and efficacy of sotalol in adults with CHD<sup>[57-59]</sup>, a meta-analysis of antiarrhythmic drugs for AF which included 12 clinical trials showed that sotalol doubles all-cause mortality<sup>[60]</sup>. Based on the current evidence, sotalol can be used with caution for maintenance of sinus rhythm in IART or AF in patients with ACHD<sup>[17]</sup>.

In non-ACHD populations, amiodarone is the most effective antiarrhythmic medication in maintaining sinus rhythm in AF and is considered drug of choice in heart failure patients<sup>[61,62]</sup>. Expert consensus suggests amiodarone as first line for maintenance of sinus rhythm in ACHD patients with IART and those with AF in presence of ventricular hypertrophy or dysfunction, or coronary artery disease<sup>[17]</sup>. It is the drug we use most often across the spectrum in ACHD, including in patients with impaired ventricular function. Unfortunately, long-term treatment with amiodarone (which is often necessary in this population) can be complicated by pulmonary and liver toxicity, thyroid dysfunction, photosensitivity, and corneal microdeposits<sup>[63]</sup>. In our experience the most frequent problems in ACHD patients are thyroid related. Torsades de pointes is seen in fewer than 1% of non-ACHD patients<sup>[64]</sup>.

Dofetilide has been shown to be safe in adult patients with recent myocardial infarction or heart failure<sup>[65]</sup>. The major concern is risk of torsade de pointes, which is seen in 0.9% to 3.3% of patients<sup>[66,67]</sup>. Dofetilide was studied in a multicenter series of 20 ACHD patients with refractory atrial arrhythmia and reasonable success was noted<sup>[68]</sup>. However, we rarely use this drug in our center and prefer the use of sotalol.

### **Catheter ablation**

Catheter ablation is now used as an early treatment strategy for IART in many centers and is preferred over the long-term pharmacological management<sup>[17,69]</sup>. Advances in 3D mapping for improved circuit localization and irrigated-tip or large-tip ablation catheters which help with effective lesion creation has led to 81% acute success rate<sup>[69-72]</sup>. Newly developed software permits rapid automatic annotation of signals using multi-electrode catheters. This allows large chambers to be mapped rapidly and with a huge number of points reducing procedure time and potentially increasing success rates of ablation<sup>[73]</sup>. These needs to be interpreted in the context of programmed settings on the mapping system including the window of interest and electrogram annotation the discussion of which is beyond the scope of this review<sup>[74]</sup>.

The acute success rate is lower in Ebstein anomaly with higher recurrence rate<sup>[75,76]</sup> due to challenges of distorted anatomic landmarks, difficulty identifying the true AV groove, extremely fractionated electrograms, and the high incidence of multiple pathways<sup>[31,75,76]</sup>. Recurrence

rates following ablation are 34%-54%, mostly occurring within the first year and are higher in atriopulmonary anastomosis of Fontan palliation compared to other CHD patients<sup>[72,77,78]</sup>. Gaining access to the atrial tissue is difficult in patients with an interatrial lateral tunnel or extra-cardiac Fontan palliation and conduit puncture may be required<sup>[79]</sup>. When planning ablation, consideration should be given to the location of the AV node in the underlying CHD and the risk of AV block due to ablation. For example, the AV node is typically located anterior in the AV junction in congenitally corrected-TGA<sup>[80]</sup>. The AV node is displaced postero-inferiorly in inlet VSDs<sup>[81]</sup>. These should be kept in mind when planning ablations in that region as for typical slow fast AVNRT. The AV node does not have an intracardiac signal. The His bundle signal is used as its surrogate marker. Locating and identifying the His is often challenging in ACHD as the conduction system is often displaced in many conditions like AV canal defects and congenitally corrected transposition of great arteries. In other conditions like an extracardiac Fontan, the His bundle is not accessible unless a puncture is performed. If located, the His signal can be tagged by using 3D electroanatomic mapping systems. This is especially important in patients with single ventricle palliation where the complication of heart block would often require management with epicardial pacing<sup>[82]</sup>.

Specific recommendations for AF ablation in CHD population have not yet been developed due to scarcity of published data on mechanism of arrhythmia, unclear ablation targets, and efficacy<sup>[27]</sup>. One study reported a success rate of 42% compared to 53% in controls without CHD. The value of repeat ablations and role of pulmonary vein isolation in complex CHD patients remains to be determined<sup>[40,83]</sup>. Limited experience is available on AV nodal ablation followed by permanent pacing in symptomatic patient with poor rate control<sup>[84]</sup>.

### **Surgical treatment and percutaneous intervention**

A disturbance of hemodynamics often underlies (or is a significant contributor to) atrial arrhythmia in ACHD. Sometimes the hemodynamic issues are amenable to treatment by surgery or a percutaneous intervention and if successful, such procedures may extinguish or ameliorate the patient's arrhythmia burden. Examples would be replacement of a regurgitant left atrioventricular valve in a patient with an atrioventricular septal defect, pulmonary valve replacement in a patient with repaired tetralogy of Fallot and severe pulmonary regurgitation and replacement of a stenosed conduit for pulmonary blood flow. The decision to surgically revise or upgrade a Fontan circulation as an intervention for recurrent arrhythmia can have excellent results but is a specific example with unique considerations<sup>[85-87]</sup>. When patients with ACHD experience atrial arrhythmia consideration should not only be given to correction of residual hemodynamic lesions but also to the role of specific arrhythmia surgery, which can be performed either in conjunction with

other procedures or in isolation. Mavroudis *et al.*<sup>[88]</sup> have published an excellent and detailed review of arrhythmia surgery in ACHD based on their own experience in 248 patients. Most of the surgical procedures described are for the treatment of atrial arrhythmia in patients with repaired TOF or a single ventricle circulation. Operative techniques described include, methods for increasing the safety of repeat sternal reentry, direct ablation (cryoablation or radiofrequency), right atrial and biatrial Cox-maze procedures, as well as excision of automatic foci. The paper describes the differing anatomical and electrophysiological variations which need to be taken into account for each congenital cardiac diagnosis and arrhythmia<sup>[88]</sup>.

### Anticoagulation

Thromboembolic prevention in ACHD patients is an important aspect of pharmacological treatment of atrial arrhythmia. The prevalence of thromboembolic events in ACHD patients is estimated to be 10 to 100-fold higher than age-matched controls in the general population due to dilated chambers with sluggish flow, intra-cardiac prosthetic material, pacing/defibrillation leads, intracardiac shunts, and associated hypercoagulable states<sup>[89,90]</sup>. In particular, the risk of stroke is 10-fold higher in ACHD patients, with atrial arrhythmia being one of the strongest predictors<sup>[91,92]</sup>. In a small series of ACHD patients who underwent TEE prior to electrical cardioversion of an atrial arrhythmia, atrial thrombus was seen in 37%<sup>[93]</sup>.

Risk scoring systems (CHA2DS2, CHA2DS2-VASc, and HAS-BLED) are widely used to guide anticoagulant prescription in non-ACHD patients, balancing the risks of thromboembolism against the risks of bleeding<sup>[94-96]</sup>. Initially, these scoring systems were not developed or tested in ACHD patients and did not include any component relating to the type or severity of congenital cardiac lesion<sup>[17]</sup>. For many years there has been controversy about whether or not they have any value in decision-making for ACHD patients. In 2015 a Dutch study of 229 ACHD patients with atrial arrhythmias attempted to address this issue<sup>[97]</sup>. The authors evaluated dichotomized CHA2-DS2-VASc and HAS-BLED scores in their ACHD cohort and reported that thrombotic and bleeding events can be predicted by using scoring systems<sup>[97]</sup>. In moderate/complex patients with IART or AF, long-term oral anticoagulation is recommended with vitamin K antagonist (VKA) however, in simple nonvalvular CHD, the decision of anticoagulation risk can be guided by CHA2DS2-VASc score<sup>[17,98]</sup>. Patients with CHA2DS2-VASc score of  $\geq 2$  need oral anticoagulation with VKA or novel oral anticoagulants<sup>[17]</sup>.

The new oral anticoagulants (NOAC) have been introduced as an alternative to VKA in non-valvular atrial fibrillation. These drugs are either direct thrombin (Dabigatran) or factor Xa (Rivaroxaban, Apixaban) inhibitors. Limited data is available regarding the use of NOACs in ACHD population. One prospective study included data from 75 ACHD patients without prosthetic

heart valves taking one of three NOACs<sup>[99]</sup>. Twenty-one percent of participants had complex CHD and the main indication was thrombosis prevention in atrial arrhythmia<sup>[99]</sup>. During a mean follow-up duration of 12 mo, there were no thrombotic or major bleeding events<sup>[99]</sup>. Results from further multi-centre studies are anticipated. However, it may be reasonable to consider NOAC in lieu of VKA in simple CHD and without prosthetic valves or hemodynamically significant valve disease<sup>[17,99]</sup>.

## ATRIAL ARRHYTHMIAS DURING PREGNANCY IN ACHD PATIENTS

The risk of atrial arrhythmia is known to increase during pregnancy due to anticipated adaptive hemodynamic, hormonal, and autonomic changes<sup>[100,101]</sup>. The incidence of AF/IART in patients with structural heart disease was reported at 1.3% by the Registry on Pregnancy and Cardiac Disease with the majority of arrhythmias occurring during second trimester<sup>[102]</sup>. The frequency of arrhythmia during pregnancy is higher than this in other studies and certain ACHD subgroups. In a systematic review by Drenthen *et al.*<sup>[103]</sup>, the highest risk of arrhythmia was reported in patients with Fontan palliation, atrial redirection for TGA (Mustard or Senning) and repaired atrio-ventricular septal defect. In a multi-centre study of 157 pregnancies in 74 women with repaired TOF the incidence of arrhythmia was 6.5% vs < 1% in controls<sup>[104]</sup>. In a study of women with valvular heart disease the rate of arrhythmia during pregnancy was 15% vs 0% in controls ( $P = 0.001$ )<sup>[105]</sup>. The following have been identified as risk factors for the occurrence of atrial arrhythmias during pregnancy: Arrhythmia before pregnancy, mitral valve disease, beta-blocker use before pregnancy, and left-sided cardiac lesions<sup>[101,102]</sup>. Atrial arrhythmias during pregnancy are associated with pregnancy-related mortality and morbidity. This may be due to severity of underlying heart disease and also to an increased risk of thromboembolic events<sup>[102]</sup>.

Electrical cardioversion can be used in all trimesters of pregnancy and must not be delayed in hemodynamically unstable patients<sup>[106]</sup>. The risk of inducing fetal arrhythmias is minimal but unless cardioversion is emergent, fetal monitoring should be performed<sup>[101,106,107]</sup>. Most antiarrhythmic drugs are United States Food and Drug Administration class C medications; *i.e.*, animal studies have shown risk to the fetus, there are no controlled studies in women or studies in women and animals are not available. This is a confusing classification, meaning that there is insufficient data to make a statement regarding safety. Use of these drugs must be carefully discussed with pregnant women to allow them the ability to weigh potential pros and cons. Beta-blockers (often metoprolol) are commonly used as first line rate control therapy. Atenolol is an FDA class D medication (positive evidence of fetal risk) and should be avoided due to association with low birthweight. Oral verapamil and digoxin (FDA Class C) are used for atrial arrhythmia in pregnancy

but should not be used when an accessory pathway is suspected<sup>[106]</sup>. Sotalol (FDA class B - animal studies show no risk, no studies in humans) can be used to maintain sinus rhythm although, its side effects include fetal bradycardia and long QT in the mother and therefore, close monitoring is required. Due to its side effects on fetal thyroid function, amiodarone should not be used during pregnancy unless other antiarrhythmic agents are contraindicated or ineffective. Flecainide (FDA class C) is a drug which crosses the placenta and is often used for treatment of fetal tachycardia, however there are proarrhythmic risks in patients with structural heart disease<sup>[108,109]</sup>. Pregnancy is a prothrombotic state and sustained atrial arrhythmia will further increase risk of thromboembolic events in pregnancy, therefore anticoagulation should be considered<sup>[100,110]</sup> and any decision about anticoagulation during pregnancy should be made with the input of specialist advice and in full consultation with the patient. Different regimens can be recommended depending on patient preference and the individualized balance of risks: Obstetric risks (miscarriage, retro-placental hematoma, bleeding during delivery) vs offspring risks (warfarin associated embryopathy, premature birth, inter-cranial bleeding) vs maternal risks (thrombosis and bleeding). The risk of maternal thrombosis and thromboembolism are highest in women who in addition to their atrial arrhythmia also have either mechanical valves or Fontan circulations.

## CONCLUSION

The ACHD population continues to expand and is also aging. Atrial arrhythmias are common in these patients and the cause of significant morbidity. They also associated with increased risk of subsequent mortality. A comprehensive understanding of the underlying anatomy, previous surgeries and mechanism of the arrhythmia is essential to optimal management of arrhythmias in this population and clear, open communication between ACHD specialists, electrophysiologists and primary care providers necessary.

### Abstract

Neural elements of the intrinsic cardiac nervous system transduce sensory inputs from the heart, blood vessels and other organs to ensure adequate cardiac function on a beat-to-beat basis. This inter-organ crosstalk is critical for normal function of the heart and other organs; derangements within the nervous system hierarchy contribute to pathogenesis of organ dysfunction. The role of intact cardiac nerves in development of, as well as protection against, ischemic injury is of current interest since it may involve recruitment of intrinsic cardiac ganglia. For instance, ischemic conditioning, a novel protection strategy against organ injury, and in particular remote conditioning, is likely mediated by activation of neural pathways or by endogenous cytoprotective blood-borne substances that stimulate different signalling pathways. This discovery reinforces the concept that inter-organ communication, and maintenance thereof, is key. As such, greater understanding of mechanisms and elucidation of treatment strategies is imperative to improve clinical outcomes particularly in patients with comorbidities. For instance, autonomic imbalance between sympathetic and parasympathetic nervous system regulation can initiate cardiovascular autonomic neuropathy that compromises cardiac stability and function. Neuromodulation therapies that directly target the intrinsic cardiac nervous system or other elements of the nervous system hierarchy are currently being investigated for treatment of different maladies in animal and human studies.

**Key words:** Intrinsic cardiac nervous system; Myocardial ischemia; Ischemic conditioning; Autonomic neuropathy; Coronary blood flow regulation

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Neural elements within the intrinsic cardiac nervous system are known to transduce sensory inputs from the heart, blood vessels and surrounding organs

to ensure beat-to-beat regulation of cardiac function. Development of autonomic neurophathies in patients with comorbidities compromises clinical outcomes. Myocardial ischemia also significantly affects cardiocytes as well as cardiac neurons; post-ischemic remodeling might affect neuronal function and thereby contribute to cardiac instability. Different protection strategies including ischemic conditioning and neuromodulation interventions that limit neural injury and help maintain cardiovascular function are the subject of ongoing investigations.

## INTRODUCTION

A dense network of parasympathetic, sympathetic and sensory neurons innervates the heart and cardiac conduction system; each population of neurons is distinct with respect to functional requirements of the heart. Increased attention is being focused on the complex anatomy and function of the cardiac neuroaxis and questions abound regarding the manner in which different neuronal populations communicate with each other and between different organ systems. Ardell *et al.*<sup>[1]</sup> recently made the case that the cardiac neural hierarchy functions as a distributive processor with multiple nested feedback control loops that involve peripheral and central aspects of the autonomic nervous system. Remodeling of the cardiac nervous system at morphological and phenotypic levels during disease development is also under scrutiny<sup>[2-5]</sup>; neural remodeling can cause electrical instability that increases the incidence of arrhythmogenesis. Neuromodulation-based treatments for cardiovascular disease are being investigated as evidenced by the increasing use of diverse cardiac sympathetic decentralization and bioelectric interventions<sup>[6]</sup>. Herein, we briefly discuss experimental and clinical findings that highlight a role for the intrinsic cardiac nervous system on cardiodynamics. We also discuss mechanisms relevant to diverse protection stratagems. Finally, we focus on autonomic neurophathies that accompany comorbidities (Figure 1). For this review, clinical and basic science reports were searched using MEDLINE, PubMed and Google Scholar with the keywords intrinsic cardiac nervous system, myocardial ischemia-reperfusion injury, heart and kidney disease, cardioprotection, preconditioning and combinations thereof. Findings from our own studies on this, and related subjects were also consulted.

### Developmental aspects

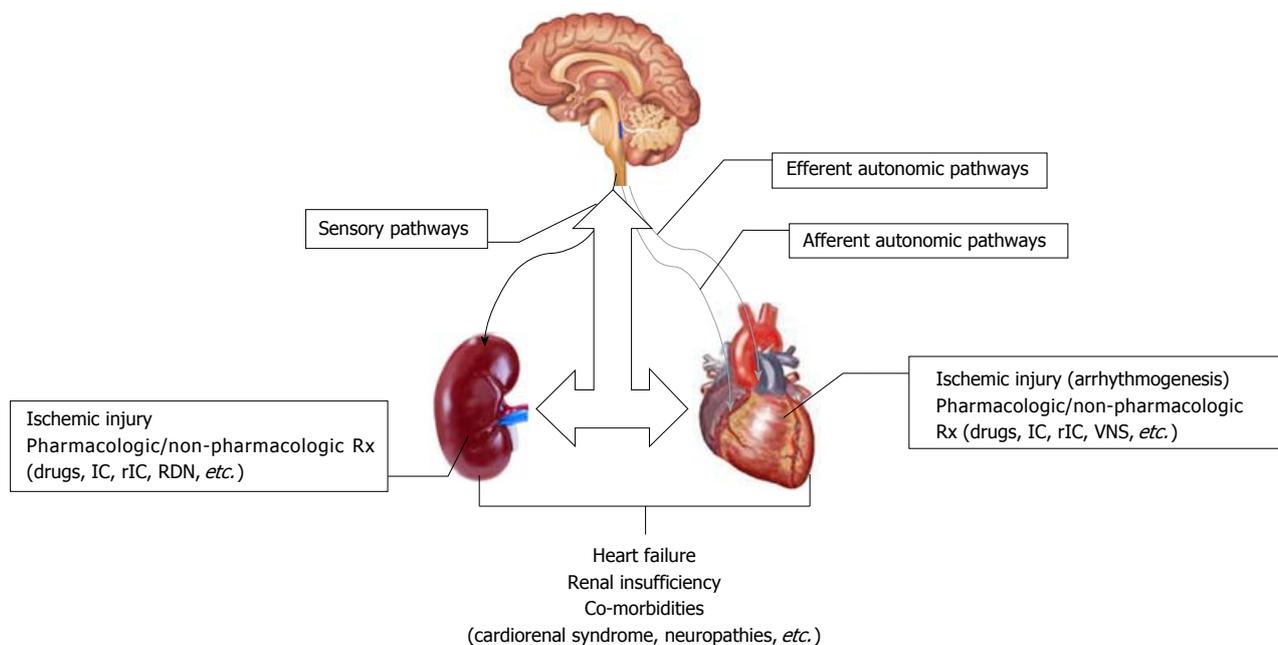

Development of the nervous and cardiovascular systems is synchronized during embryogenesis; neural crest cells in the dorsal neural tube form the parasympathetic and

sympathetic nervous systems that are important for cardiovascular function. Sympathetic interactions play a part in postnatal regulation of cardiocyte maturation; during life, cardiocytes remain quiescent and heart size increases by cellular hypertrophy<sup>[7]</sup>.

Cardiac neural crest cells furnish mesenchymal cells to the heart and great arteries that are involved in vascular remodeling and development of the cardiac conduction system<sup>[8-10]</sup>. The sympathetic component of the autonomic nervous system promotes cardiac conduction while the parasympathetic selectively exerts an inhibitory influence<sup>[11,12]</sup>. The integration of information for neurocardiac regulation involves the neuraxis that comprises the cortex, amygdala and various subcortical structures with an ability to modulate lower-level neurons within the hierarchy (for a detailed explanation see ref.<sup>[12]</sup>). Principal contacts between preganglionic neurons and the heart occur *via* the vagus nerves<sup>[2,13]</sup>. Neurons of the autonomic nervous system are: (1) characterized by chemical phenotyping (cholinergic, adrenergic, *etc.*); (2) located within intrathoracic extracardiac ganglia and intrinsic cardiac ganglia<sup>[14,15]</sup>; and (3) found within atrial epicardium and ganglionated plexi along major vessels and in the ventricular wall<sup>[16,17]</sup> depending on species<sup>[18]</sup>. Sensory neurons, interneurons and sensory fibers that originate from the nucleus ambiguus are also located therein<sup>[19,20]</sup>. Sensory information from all of these peripheral structures is integrated with higher central nervous system centers to coordinate regulation of cardiovascular responses. For example, descending signals from higher brain centers as well as afferent sensory signals from systemic arteries, cardiopulmonary regions and viscera have their first synapse in the nucleus tractus solarius (NTS) found in the dorsomedial region of the medulla<sup>[21]</sup>. Transmission of afferent inputs from other sources such as skin and skeletal muscle to medullary vasomotor centers occur *via* the spinal cord. Vagal outflow to the heart is mediated by NTS neurons that synapse to preganglionic parasympathetic neurons located in the dorsal motor nucleus. All of these neural inputs to medullary vasomotor centers are involved in autonomic control of the cardiovascular system, for example, the arterial baroreceptor reflex plays a major role in blood pressure homeostasis on a beat-to-beat basis and involves stretch receptors that can be found in the carotid sinus and aortic arch. Accordingly, afferent baroreceptor discharge is relayed from the carotid sinus (*via* glossopharyngeal nerve) and aorta (*via* vagus nerve) to the NTS that stimulates afferent baroreceptor discharge and promotes efferent sympathetic and parasympathetic outflow to the heart and blood vessels, this enables adjustments of cardiac output and vessel resistance and ultimately facilitates return of blood pressure to steady state levels.

## CORONARY BLOOD FLOW REGULATION AND MYOCARDIAL PERFUSION

Non-neural mechanisms (humoral, metabolic, mechanical,

**Figure 1** A schematic overview of efferent and afferent autonomic pathways on normal cardiac regulation, they also play a role in arrhythmogenesis caused by ischemic injury. Various pharmacologic/non-pharmacologic interventions that target autonomic pathways (IC: Ischemic conditioning; rIC: Remote IC; VNS: Vagus nerve stimulation) attenuate cardiac or renal symptoms. Sensory pathways are involved in renal regulation; injury (all cause) affects renal function that can be attenuated by different interventions (IC, rIC, RDN: Renal denervation). Inter-organ interactions also directly affect organ function; development of comorbidities is related to pathogenesis of disease in multiple organs (ex. heart-kidneys-brain, etc.). Pathology in one organ system can result in significant progression of disease in a distant organ; neuromodulation interventions may be beneficial to these patients.

etc.) that contribute to control of vascular regulation act independently from autonomic neural mechanisms. For example, under normal physiological conditions myocardial perfusion across the ventricles is uniform as long as coronary artery pressure is maintained within the range of autoregulation<sup>[22]</sup>. Shifts in the lower pressure limit are produced by changes in left ventricular pressure and volume as well as biochemical modifications by a host of endogenous compounds that exercise their effects on myocytes, conduction tissues, vascular smooth muscle, etc. The scientific literature that has examined coronary vasoregulation with a focus on cardiac nerve status is relatively sparse. Most studies have concentrated on control of regional cardiodynamics by the intrinsic cardiac nervous system in either normal or pathological conditions.

In healthy individuals during exercise, activation of the sympathetic nervous system stimulates metabolic vasodilatation due to increases in heart rate, cardiac contractility and ventricular work. Direct sympathetic stimulation of coronary vessels induces either vasoconstriction or vasodilatation depending on activation of either  $\alpha$ -, or  $\beta$ -adrenoreceptors, or vessel size. For example, large coronary vessels (> 100  $\mu\text{m}$ ) constrict when exposed to norepinephrine whereas small coronary vessels relax<sup>[23]</sup>; vasodilatation in arterioles permits coordination of oxygen delivery to myocardial oxygen demand<sup>[24]</sup>. On the other hand, simultaneous vasoconstriction in medium and large coronary arteries mediated by activation of  $\alpha$ -adrenoreceptors helps to preserve subendocardial blood flow when oxygen demand increases. In a canine study,

we examined myocardial perfusion following injection of select neuropeptides into active loci of the intrinsic cardiac nervous system and documented significant coronary vasodilatation secondary to increased myocardial metabolism and oxygen demand<sup>[25]</sup>. We also examined whether intact cardiac nerves were critical for coronary blood flow autoregulation; results confirmed a role for intrinsic cardiac neurons in autoregulatory control and myocardial perfusion even after ablation of extracardiac nerves from central nervous system control<sup>[26]</sup>. Ablation of external neuronal inputs to the heart also results in reduced myocardial efficiency that is consistent with impaired glucose utilization and depletion of cardiac catecholamine levels<sup>[27,28]</sup>; the latter directly affect myocardial oxygen demand<sup>[29-31]</sup>. Other animal studies reported that heterogeneity of myocardial perfusion is similar in innervated and denervated hearts<sup>[32-34]</sup>; possible explanations include: (1) the fact that regional denervation has little effect on vascular  $\alpha$ -adrenergic receptors (in part due to circulating catecholamines); or (2) preserved neural modulation and autoregulation at different levels of the microcirculation across the ventricular wall<sup>[35,36]</sup>.

Diverse central and peripheral elements within the cardiac nervous system act in sync to regulate cardiac function<sup>[20,37]</sup>; direct stimulation of intracardiac neurons occurs through central efferent neuronal inputs from the vagi or stellate ganglia<sup>[38]</sup>. G-protein coupled receptors are known to regulate cardiac function (see recent review by Capote *et al.*<sup>[39]</sup> on structure, function and signalling pathways solicited by G-protein-coupled receptors in the heart). Control of heart rate requires intricate

coordination between  $\beta$ -adrenergic and muscarinic cholinergic receptors found throughout the cardiac conduction system. Cardiac contraction controlled by  $\beta$ -adrenergic receptors are found in myocyte membranes while cardiac structure and morphology are coordinated by angiotensin II type 1 receptors in fibroblast and both endothelial cell and myocyte membranes<sup>[40,41]</sup>. Highly distinct processing capabilities of intracardiac neurons allow this complex network to respond to multiple inputs from all cardiac regions and major vessels near the heart. Disruption of these control networks by diverse cardiac pathologies ultimately increases the potential for sudden cardiac death<sup>[42-45]</sup>.

## MYOCARDIAL ISCHEMIA

Myocardial ischemia significantly influences cardiocytes as well as local and remote neurons that are involved in regulation of cardiac function<sup>[1,46]</sup>; the survival threshold of intra-/extra-cardiac sympathetic/parasympathetic neurons during development of coronary artery disease is not well established. However, viable nerves that course over an infarcted region tend to remain so oxygen and energy needs are fulfilled by an independent blood supply from extracardiac sources<sup>[47]</sup>. Reorganization of cardiocytes and nerves during development of diverse cardiac pathologies could occur in response to shifts of cardiac demand and function<sup>[3,48]</sup>. Mechanisms involved in the pathogenesis of cardiac dysfunction are multifactorial; a short list of possible factors include cardiac substrates, neural/cardiocyte interface, hormonal influences, inflammation and reflex responses between intra- and extra-cardiac nervous systems and their interactions with higher center neurons. Cardiocytes and cardiac neurons conceivably share common pathways for survival but this remains to be proven.

In the setting of transient ischemia, intact cardiac nerves are believed to play a key role on post-ischemic restoration of cardiac function<sup>[49]</sup>. Direct ischemic effects include progressive neuronal dysfunction and regional nerve terminal sprouting which ultimately diminishes local sensory and motor neurite function<sup>[50,51]</sup>. Indirect effects that modulate local neurite function are caused by local release of a host of endogenous chemicals (purinergic agents, peptides, hydroxyl radicals, *etc.*) that also affect neuronal function. Post-ischemic remodeling of cardiac neural networks could promote conflicts between central and peripheral reflexes that increases the risk of autonomic imbalances, arrhythmogenesis and sudden cardiac death<sup>[3,15,37,52]</sup>. A recent position paper by Ardell *et al.*<sup>[1]</sup> discussed the significance of remodeling of the cardiac neuronal hierarchy to cardiac arrhythmia induction. In addition, inotropic stimulation is deleterious to myocyte survival as it occasions an imbalance between oxygen demand and supply (*i.e.*, increased oxygen demand with limited coronary vascular reserve)<sup>[49,53]</sup>.

Acute occlusion of a coronary artery produces distinct alterations of myocyte pathology that lead to cell death unless blood flow is restored to the affected myocardium,

a transmural gradient of cell death occurs in relation to the duration of ischemia and degree of blood perfusion *via* coronary collateral vessels to the underperfused myocardium<sup>[54]</sup>. In animal models, necrosis is generally fully developed by 6 h after which tissue salvage is not possible (this time frame may not be the same for human myocardium) with currently available interventions. In addition, early restoration of blood flow to an infarct-related coronary vessel could cause "reperfusion injury" in already damaged or otherwise affected myocytes<sup>[55]</sup>. The physiopathology of ischemic, or reperfusion injury has been reviewed and discussed over the past several decades<sup>[56-59]</sup>; however, less attention has focused on the ability of the cardiac nervous system to accommodate the stress of ischemic, or reperfusion injury. Post-ischemic changes in peptide expression due to release of inflammatory cytokines combined with nerve damage could affect neuropeptide production in sympathetic cardiac neurons. In one study, Habecker *et al.*<sup>[60]</sup> documented extensive axon damage after infarction; they also reported a significant increase of galanin (promotes regeneration of sensory neurons<sup>[61]</sup>) in cardiac sympathetic neurons in the left ventricle. These findings indicate that cardiac sympathetic neurons retain a certain capability to respond to nerve growth factor which is increased during ischemia-reperfusion<sup>[62]</sup>.

While sympathetic dysinnervation has been reported secondary to myocardial infarction, the injury threshold of sympathetic and parasympathetic cardiac neurons within the ischemic region has not been established<sup>[63,64]</sup>. Several studies have documented that sympathetic impairment could exceed the area of underperfusion and necrosis<sup>[65,66]</sup>. Ischemic stress stimulates release of autocooids such as adenosine and bradykinin, along with nitric oxide and reactive oxygen species that can trigger cellular signal transduction pathways. These compounds can initiate responses in somata and axons within the intrinsic cardiac nervous system<sup>[37]</sup>. Indeed, oxidative stress, changes in growth factor expression and inflammatory cytokines released within the heart and vasculature contribute to neuronal remodelling<sup>[2,3,5,67]</sup>. As mentioned earlier, the regenerative capacity of cardiocytes is limited<sup>[68]</sup>; cardiocytes withdraw from the cell cycle early after birth and subsequently remain quiescent. Transition from proliferative to hypertrophic growth corresponds to the period of sympathetic growth into the heart tissues; *in vitro* studies with neonatal cardiocytes cultivated in the presence of innervating sympathetic fibers showed significant cellular proliferation<sup>[69]</sup> thereby confirming that early sympathetic signalling plays a role. In earlier *in vitro* studies, Horackova *et al.*<sup>[70]</sup> reported that adult ventricular myocytes co-cultured with intrathoracic neurons retained similar structural properties to those observed *in vivo*; cardiocytes and intrinsic cardiac neurons that were cultured alone displayed a variety of morphologies (unipolar, bipolar, multipolar).

Sympathetic regulation might also be involved in myocyte regeneration following ischemia, or reperfusion, injury; however, disruption of peripheral nerves inhibits

regeneration<sup>[71,72]</sup>. Chemical sympathectomy blocks early regeneration of damaged myocytes and increases tissue scarring<sup>[73]</sup>. Though additional studies are necessary, available data support the role of the intact cardiac nervous system on cardiocyte development and proliferation. On the other hand, post-ischemic regeneration and remodeling of the cardiac nervous system also merits further consideration and investigation. Rajendran *et al*<sup>[46]</sup> recently evaluated post-ischemic changes in neural signalling in a porcine model; they presented a “cardiac electroneurogram” between injured and adjacent non-injured myocardial tissue and reported: (1) that different intra-cardiac ganglia undergo morphological and phenotypic remodeling depending on the site of injury; (2) attenuation of afferent neural signals from the infarcted region to intra-cardiac neurons (activity in border and remote regions is apparently preserved); (3) maintenance of autonomic efferent inputs to the intrinsic cardiac nervous system; (4) augmented transduction capacity of convergent intrinsic cardiac local circuit neurons; and (5) reduced network connectivity within the intrinsic cardiac nervous system. The heterogeneity of afferent neural signals probably results from the presence of a “neural sensory border zone” (*i.e.*, analogous to the so-called myocardial border zone) caused by scar formation during post-ischemic myocardial healing. This infarct-induced asymmetry of afferent inputs probably contributes to reflex activation of the autonomic nervous system; recent findings from Wang *et al*<sup>[74]</sup> using resiniferatoxin (a potent agonist of transient receptor potential vanilloid 1) showed reductions in cardiac afferent nociceptive signalling, and sympatho-excitation along with preserved cardiac function in rat hearts.

The role of intact cardiac nerves in modulating responses to ischemia and post-ischemic ventricular function has been studied in a variety of experimental models. In a cardiac decentralized porcine model subject to acute coronary artery stenosis Huang *et al*<sup>[49]</sup> reported significant ventricular dysfunction accompanied by patchy subendocardial necrosis; they proposed that the impaired recovery of left ventricular function is mediated by nitric oxide (NO) and reactive oxygen species (ROS). Cardiac nerves may help to attenuate production of ROS and/or prevent conversion of NO to peroxynitrite (*via* release of still unknown mediators/scavengers); neurotransmitters from cardiac nerves could stimulate or upregulate different isoforms of nitric oxide synthase (*i.e.*, endothelial, neural)<sup>[75]</sup>. Myocardial perfusion-function relations are not altered by cardiac denervation<sup>[49]</sup>; this can be partly explained by the similarity between intact innervated and denervated hearts with regard to determinants of myocardial oxygen demand. In a recent study, we reported no significant change in coronary vascular reserve (intact cardiac nerves *vs* acute decentralized) in a canine model of ischemia-reperfusion injury<sup>[76]</sup>; these findings concur with most<sup>[77,78]</sup>, but not all, earlier studies<sup>[79]</sup>. Of particular note is that protection against ischemic injury occurred even when affected myocardium was disconnected from central command;

this suggests that local intrinsic cardiac neurons share common protection pathways to delay progression of cellular necrosis. Neurotransmitters that originate from cardiac nerves or intrinsic cardiac neurons might stimulate release of endogenous compounds that activate intracellular signalling pathways involved in cytoprotection; they could also inhibit peroxynitrite formation by modulating activation of various nitric oxide synthase isoforms. Indeed, many questions remain regarding the role of intact cardiac nerves within the context of cardioprotection against ischemia-reperfusion injury.

Myocardial ischemia also results in excessive activation of extracardiac cholinergic and adrenergic inputs of local circuit neurons within the intrinsic cardiac nervous system<sup>[38,80]</sup> that initiate cardiac arrhythmias<sup>[81]</sup>. A novel treatment for suppression of ventricular arrhythmias and treatment of refractory angina pectoris in current use in preclinical and clinical studies is spinal cord stimulation<sup>[80,82-84]</sup>; this intervention alters peripheral ganglia neural processing along the neural end-organ interface<sup>[85,86]</sup> and transduces neural signals to higher centers *via* the spinal cord<sup>[1,87,88]</sup>. Spinal cord stimulation influences autonomic reflexes within the neuroaxis and stimulates discharge of neuromodulators that limit release of select neurotransmitters and alter basal activity of sympathetic preganglionic neurons<sup>[89,90]</sup>. Intermittent spinal cord stimulation is suggested to stimulate neural memory and may be used for management of cardiac control and angina<sup>[91]</sup>; this could be akin to “electrical conditioning” and may be useful to limit cellular injury caused by ischemia. Vagus nerve stimulation is also being used to protect against ischemic injury and its consequences<sup>[92]</sup>; vagus nerve stimulation activates a host of signalling pathways and inhibits release of pro-inflammatory cytokines (see Ardell *et al*<sup>[1]</sup> for an up-to-date review). Vagus nerve stimulation might also affect myocardial energetics and maintain the equilibrium between energy supply and demand in the failing heart<sup>[93,94]</sup>. Interventions using vagus nerve stimulation favourably modulate cardiac disease as well as arrhythmogenesis; in several clinical studies this non-pharmacologic treatment is safe and well tolerated and is documented to improve cardiodynamics in patients with compromised ventricular function<sup>[95,96]</sup>.

## MYOCARDIAL PROTECTION

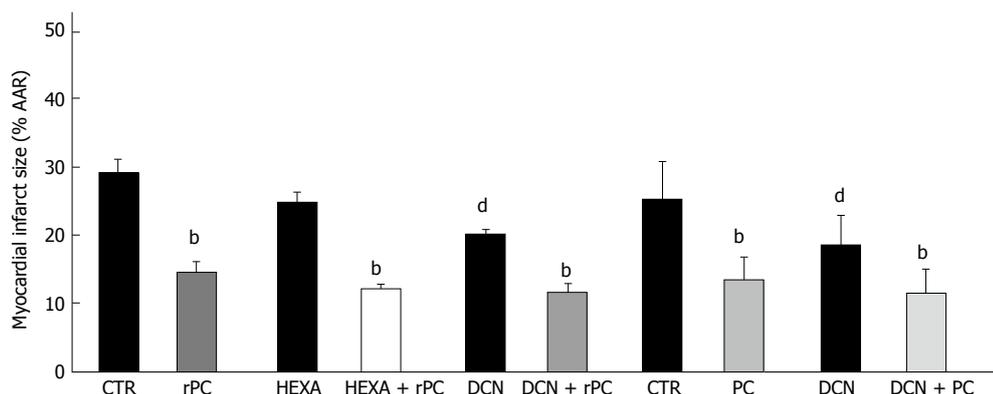

Sympathetic and parasympathetic nerves located near cardiocytes permit rapid crosstalk between cell types that may, or may not, activate cytoprotective pathways. Ischemic conditioning was first described by Murry *et al*<sup>[97]</sup> in 1986 in barbiturate-anesthetized dogs subjected to repeated episodes of sublethal coronary occlusion/reperfusion in advance of a prolonged period of acute ischemia. To date, ischemic conditioning has been reported to delay development of cellular necrosis in all organs examined in animals and in humans<sup>[98]</sup>; two distinct windows of cellular protection have been described but the causative mechanism(s) remain unanswered. The reader is referred to a recent review that summarizes

research into this cytoprotective intervention over the past 30 years<sup>[99]</sup>. Interestingly, Kudej *et al.*<sup>[100]</sup> showed that intact cardiac nerves were not required for first window protection in a porcine ischemia-reperfusion injury model; however, the presence of functional cardiac nerves was considered essential for development of second window protection. This delayed protection could occur through  $\alpha_1$ -adrenergic receptor pathways mediated by iNOS and COX-2<sup>[101]</sup>.

A host of conditioning strategies have been described in animal and clinical studies; however, the potential to translate conditioning-mediated protection in patients remains controversial<sup>[102,103]</sup>. Remote conditioning was first described in dogs subject to acute coronary occlusion and was referred to as "preconditioning at a distance"<sup>[104]</sup>. In that study, animals were subject to repetitive periods of non-lethal ischemia of the left circumflex artery vascular bed before exposure to a prolonged occlusion of the left anterior descending coronary artery; results demonstrated that a cytoprotective factor could be activated, produced, or transported from the heart or elsewhere to affected tissues to afford protection. Since the publication of these key findings numerous studies using remote conditioning either before, during or after coronary occlusion have been reported<sup>[105-109]</sup> but the mechanisms involved have not been established. An important but unanswered question that persists is how the protective signals are transferred from distant tissues to the target organ. Various hypotheses (not mutually exclusive) including: (1) communication *via* blood or perfusate borne humoral factors; (2) communication by neuronal stimulation and transmission; and (3) communication by systemic alteration of circulating immune cells have been proposed<sup>[106,110,111]</sup>. Intrinsic neural loops in the heart process sensory information from the myocardium that modulate efferent autonomic output from the intrinsic cardiac ganglia even in the absence of input from the central nervous system<sup>[37,38,93,112]</sup>. Transmission of sensory messages within intrinsic cardiac ganglia is regulated by release of acetylcholine into the synaptic cleft; nerve impulses are initiated by acetylcholine that activates specific receptors in post-ganglionic nerves<sup>[112-114]</sup>. The risk of injury or remodeling of these neural loops escalates during myocardial ischemia; studies with pharmacologic ganglionic blockade document abolition of remote conditioning-mediated cytoprotection and suggest that protective signals could transfer between organs *via* neural pathways<sup>[112,115-117]</sup>. Early preclinical studies in different experimental models (including heart failure) reported positive results with vagal nerve stimulation (VNS) with respect to ventricular remodeling, ejection fraction and biomarker levels<sup>[118-120]</sup>. In patients with advanced heart failure, VNS reportedly attenuates left ventricular contractile dysfunction<sup>[121]</sup> and may reduce ischemic injury<sup>[122-124]</sup>. Clinical studies show that diminished heart-rate responses and depressed sensitivity of vagal reflexes are associated with poor cardiovascular outcomes and cardiac-related mortality<sup>[125-127]</sup>. Smith *et al.*<sup>[127]</sup> recently reviewed efficacy of VNS for hypertension and heart failure in several small,

randomized clinical trials (ANTHEM-HF, NECTAR-HF, INOVATE-HF, *etc.*) and concluded that further studies are required; VNS titration studies are also needed to validate potential clinical benefits of these interventions<sup>[128]</sup>. Stimulation of vagal nerves activate a host of signalling pathways *via* increased release of acetylcholine that activates downstream receptors (cholinergic, muscarinic, *etc.*) to impact cardiodynamics and could also promote myocyte resistance to stress by improving myocyte energetics<sup>[93]</sup>. Cross-talk between humoral mediators and neural pathways could also produce cytoprotection by stimulation of local afferent nerves<sup>[129,130]</sup>; but it remains unclear whether intact, functional nerves are required to assure conditioning-mediated cytoprotection<sup>[131,132]</sup>. On the basis of data showing that intact sensory innervation of peripheral ischemic tissue is essential to remote conditioning protection, Mastitskaya *et al.*<sup>[133]</sup> proposed a "remote preconditioning reflex" that requires sensory input from remote ischemic tissue; recruitment of vagal pre-ganglionic neurons within the dorsal motor nucleus of the vagus nerve was considered to be critical for cytoprotection. While this data does not negate the concept that humoral factors are required for protection by remote conditioning, they strongly suggest that functional neurons within the parasympathetic nervous system are critical<sup>[134,135]</sup>. Bilateral vagotomy reportedly abolished protection afforded by remote conditioning<sup>[136]</sup>. On the other hand, findings from our laboratory (summarized in Figure 2) documented significant protection against ischemic injury independent of intact extrinsic cardiac nerves (note the similarity between groups with respect to reduction in infarct size) regardless of the conditioning protocol<sup>[76,137]</sup>. Briefly, in those studies isoflurane anesthetized dogs underwent remote conditioning (4 × 5-min renal artery occlusion/reperfusion) combined with/without treatment with the autonomic ganglionic blocker, hexamethonium (HEXA; 20 mg/kg, *IV*) or acute cardiac decentralization (DCN). Additional experiments were performed in dogs subject to classical preconditioning either before or after DCN. Based on these findings we suggested that neural pathways might not directly influence ischemic conditioning (either classical or remote) mediated cardioprotection. Moreover, others have brought forward the view that intact connections between the heart and central nervous system are not necessary for remote conditioning-mediated cardioprotection as long as recruitable parasympathetic neurons within a target organ can be activated. Use of remote conditioning as a potential therapeutic intervention for organ protection in man continues to merit investigation because it is non-invasive, cost-effective and easily applicable; however, the period for successful application of this intervention has yet to be determined and clinical strategies aimed at reducing myocardial damage by ischemic conditioning have been unsuccessful. While cellular protection by ischemic conditioning is possible in the presence of comorbidities, a stronger triggering stimulus appears necessary to assure cytoprotection<sup>[138]</sup>.

Understanding bidirectional interactions between

**Figure 2** Myocardial infarct size (% anatomic area at risk: AAR) is shown for different study groups subject to ischemia-reperfusion injury. Data are means  $\pm$  1SD; <sup>b</sup> $P \leq 0.01$  vs respective control (CTR), HEXA (hexmethonium; 20 mg/kg, IV), or DCN (acute cardiac decentralized) group; <sup>d</sup> $P \leq 0.01$  vs CTR groups. Group differences determined by ANOVA. PC: Ischemic preconditioning; rPC: Remote preconditioning. Data reported in earlier studies from our laboratory<sup>[76,137]</sup>.

elements of the nervous system and its remodeling during evolution of different comorbidities (senescence, kidney dysfunction, diabetes, *etc.*) is essential to help in the development of strategies to delay progression of disease not only in the heart but also in other organs. For instance, autonomic neuropathies defined by abnormalities of the sympathetic and parasympathetic nervous systems could be responsible for significant morbidity and mortality in patients; cardiovascular events are considered a primary risk factor for mortality. Cardiovascular autonomic dysfunction is the result of complex interplay between vascular, neural, cardiac, paracrine and endocrine entities; the outcome is tissue injury that compromises integrity of cardiac reflexes.

## HEART FAILURE

Heart failure subsequent to cardiac injury or chronic stress causes significant loss of contractile efficacy. Investigations into the role of autonomic imbalance between sympathetic and parasympathetic nervous systems and its contribution to pathogenesis of heart failure is ongoing for more than 25 years. Altered autonomic function also plays a role in other cardiac interrelated conditions such as hypertension, myocardial ischemia, cardiac arrhythmogenesis and sudden cardiac death<sup>[48]</sup>, see recent review by Florea and Cohn<sup>[139]</sup>. Dynamic interactions between cardiocytes and compensatory neurohumoral mechanisms allow the heart to maintain cardiac output; stimulation of the adrenergic nervous and renin-angiotensin-aldosterone systems along with activation of cytokines play a critical role to prevent progressive worsening of cardiac function associated with heart failure<sup>[140,141]</sup>. Lympelopoulous *et al.*<sup>[141]</sup> recently reviewed: (1) the actions of neurotransmitters on cell surface adrenergic and G-protein-coupled receptors; and (2) adrenergic receptor polymorphisms in the physiopathology of heart failure. They concluded that activation of the autonomic nervous system plays a critical role in compensatory responses to progressive cardiac dysfunction; however, excessive activation of these compensatory pathways could accelerate development

of heart failure. In addition, they examined various therapeutic approaches (*i.e.*, sympathomimetic drugs, activation of cardiac parasympathetic nervous system, increasing  $\beta$ -adrenergic receptor function using novel G-protein-coupled receptor blockade, *etc.*).

## CHRONIC KIDNEY DISEASE AND NEUROPATHY

Physiopathology of chronic kidney disease (CKD) is complex and results either from a primary renal disorder or from multisystem disorders related to various comorbidities such as diabetes. Indeed, diabetes is considered to be the most common cause of CKD in patients. Neurological derangements are a common occurrence in CKD<sup>[142]</sup>. The spectrum of CKD ranges from mild kidney damage (largely asymptomatic) to end-stage renal disease (potentially fatal); neurological complications that include cognitive dysfunction, stroke, as well as peripheral and autonomic neuropathy can markedly affect clinical outcomes<sup>[143]</sup>. Accumulation of urea, creatinine, parathyroid hormone in high concentrations provide a biochemical milieu that rapidly produces neurological dysfunction; however, most symptoms can be reversed with treatments such as hemodialysis<sup>[144]</sup>. Mechanisms responsible for increased cardiovascular risk in patients with CKD are multifactorial and include hypertension and diabetes<sup>[145]</sup>, along with increased oxidative stress, decreased bioavailability of nitric oxide, inflammation, abnormal calcium and phosphorous metabolism, overstimulation of the sympathetic nervous system, *etc.*<sup>[146-148]</sup>. Anemia is another major complication associated with both CKD and diabetes<sup>[149]</sup>; the latter may be present before overt evidence of symptoms of renal impairment<sup>[150]</sup>.

Essential structures of the kidneys (renal vessels, tubules, juxtaglomerular apparatus, *etc.*) are richly innervated. Renal afferent nerves transmit sensory information *via* chemo- and mechano-receptors to higher centers within the brain<sup>[151,152]</sup>, to maintain water retention, sodium reabsorption and blood flow. These

nerves might also play a role in renal inflammation and injury; suggested mechanisms include  $\beta$ -adrenergic receptor activation, release of neuropeptides (neuropeptide Y, vasoactive intestinal polypeptide, substance P, *etc.*), renin release from juxtaglomerular cells (increases plasma angiotensin II levels) and other pro-inflammatory cytokines (tumor necrosis factor, IL-1 $\beta$ , *etc.*).

Autonomic dysfunction is prevalent (> 60%) in CKD patients and is associated with vascular calcification, cardiac arrhythmias and sudden cardiac death<sup>[153]</sup>. Reduced sensitivity to baroreceptors in the vessel wall caused by autonomic dysfunction can modulate cardiac regulation and contribute to intradialytic hypotension (*i.e.*, no increase in heart rate to compensate the decrease in arterial pressure)<sup>[154]</sup>; these symptoms can be corrected with pharmaceuticals or, if necessary, renal transplantation.

## DIABETIC AUTONOMIC NEUROPATHY

Autonomic dysfunction is a recognized complication of diabetes mellitus; diverse contributory mechanisms to increased mortality includes medial hyperplasia at baroreceptor sites, impaired cardiac vagal function, left ventricular hypertrophy and endothelial dysfunction<sup>[155]</sup> due in part to oxidative stress and reduced availability of nitric oxide which can affect sympathetic nerve activity<sup>[156]</sup>. Endothelial nitric oxide synthesis is known to be defective in insulin resistant states and is a central factor to neuronal abnormalities during metabolic syndrome (increases cardiovascular risk to some extent due to sympathetic activation)<sup>[155]</sup>. Insulin also plays a key role in nitric oxide and autonomic nervous system interactions and is involved in regulation of peripheral vascular tone and arterial blood pressure. Significant evidence shows that nitric oxide is critical to the vasodilator actions of insulin<sup>[157]</sup>, sympathectomy and autonomic failure can severely limit insulin-induced vasodilatation in patients<sup>[158]</sup>. Vulnerability to lethal arrhythmias in diabetic patients with autonomic dysfunction is also elevated<sup>[159]</sup>. Cardiac autonomic dysfunction may occur more frequently when diabetes is coupled with micro albuminuria caused by microvascular damage and endothelial dysfunction<sup>[160-162]</sup>; however, it was reported in the Hoom Study that cardiovascular autonomic dysfunction and microalbuminuria were independently associated with mortality<sup>[163]</sup>. Additionally, in that study the presence of cardiovascular autonomic dysfunction doubled the 9-year mortality risk<sup>[155,164]</sup>; the ACCORD study also confirmed a significantly higher rate of mortality in patients with autonomic dysfunction<sup>[165]</sup>.

## CONCLUSION

Impaired sympathetic and parasympathetic nervous system regulation contributes to organ dysfunction and leads to significant morbidity and mortality particularly in patients with comorbidities. Early detection and management of these patients could markedly reduce adverse effects and thereby affect clinical outcomes. Prospectively, autonomic dysfunction develops because of

damage at multiple sites within organs but pathogenesis remains to be clarified. Cardiovascular autonomic dysfunction, for instance, reflects compromised interactions between vascular, neural, cardiac, inflammatory, paracrine and endocrine mechanisms. Restoration of autonomic equilibrium in animal and clinical studies using either pharmacologic or non-pharmacologic interventions is currently possible. Further investigations in neurocardiology should continue to provide important findings apropos connections between cardiac and neurohumoral control systems and thereby allow continued development of clinically relevant opportunities for neuroscience-based treatments.

### Abstract

Electrical storm (ES) is a medical emergency characterized by repetitive episodes of sustained ventricular

arrhythmias (VAs) in a limited amount of time (at least 3 within a 24-h period) leading to repeated appropriate implantable cardioverter defibrillator therapies. The occurrence of ES represents a major turning point in the natural history of patients with structural heart disease being associated with poor short- and long-term survival particularly in those with compromised left ventricular ejection fraction (LVEF) that can develop hemodynamic decompensation and multi-organ failure. Management of ES is challenging with limited available evidence coming from small retrospective series and a substantial lack of randomized-controlled trials. In general, a multidisciplinary approach including medical therapies such as anti-arrhythmic drugs, sedation, as well as interventional approaches like catheter ablation, may be required. Accurate patient risk stratification at admission for ES is pivotal and should take into account hemodynamic tolerability of VAs as well as comorbidities like low LVEF, advanced NYHA class and chronic pulmonary disease. In high risk patients, prophylactic mechanical circulatory support with left ventricular assistance devices or extracorporeal membrane oxygenation should be considered as bridge to ablation and recovery. In the present manuscript we review the available strategies for management of ES and the evidence supporting them.

**Key words:** Electrical storm; Ventricular tachycardia; Catheter ablation; Mechanical hemodynamic support; Anti-arrhythmic drugs

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Electrical storm (ES) is a life-threatening condition characterized by ongoing ventricular arrhythmias leading to appropriate implantable cardioverter defibrillator therapies. It is associated with increased mortality and requires urgent medical care. In this review, we summarize the prognostic implications for ES as well as available treatment strategies to manage ES.

## INTRODUCTION

Ventricular tachycardia (VT) electrical storm (ES) is a severe clinical condition characterized by clustering episodes of ventricular arrhythmia in a short amount of time. The current definition of ES implies at least 3 distinct episodes of sustained VT or ventricular fibrillation (VF) within the last 24-h or the occurrence of incessant VT for at least 12-h. In patients with ICD, ES is defined by  $\geq 3$  appropriate device interventions in the last 24-h (separated by at least 5-min one from the other) either with antitachycardia pacing (ATP) or direct-current shock<sup>[1]</sup>. Although ES mainly occurs in patients with structural heart disease and low left ventricular ejection fraction (LVEF), it may affect also patients with inherited arrhythmic syndromes and structurally normal heart (*i.e.*, Brugada syndrome and catecholaminergic polymorphic VT) representing a life-threatening condition requiring urgent medical care<sup>[2]</sup>. Several strategies have been proposed to manage ES with most of the data coming from small retrospective series, lacking large randomized-controlled trials. There are several substantial differences in the approach and treatment of ES in the setting of structural heart disease compared to primitive arrhythmic syndromes. In this review, we will focus on the management of ES in the setting of structural heart disease by summarizing the current therapeutic strategies in a stepwise approach based on available evidence (Figure 1).

## INITIAL CARE

Prolonged sustained VAs as well as multiple ICD shocks in the setting of ES, may contribute to worsening of systolic function and development of a low-output state leading to cardiogenic shock and multiple organ failure. In this setting, urgent ICD interrogation and reprogramming is mandatory. Documentation of appropriate ICD interventions triggered by VT/VF episodes is necessary to rule out all potentially reversible causes like electrolyte imbalances, acute ischemia, pro-arrhythmic drug effects, hyperthyroidism, infections and decompensated HF. However, reversible causes of ES account for less than 10%, and in the majority of cases no precipitating cause is identified (Table 1)<sup>[3]</sup>. Initial evaluation should include accurate patient risk stratification according to hemodynamic tolerability of the arrhythmia and presence of comorbidities (Figure 1)<sup>[4]</sup>. All patients with hemodynamic decompensation (persistent systolic blood pressure < 80-90 mmHg despite temporary resumption of sinus/paced rhythm and despite increasing doses of

vasopressors) as well as patients with hemodynamically tolerated VT but with major comorbidities (*i.e.*, LVEF  $\leq$  30%, moderate to severe chronic kidney disease and severe pulmonary obstructive disease) are considered at high risk and should be admitted to the intensive care unit in order to correct metabolic, respiratory and circulatory imbalances [mechanical ventilation and circulatory support with intra-aortic balloon pump (IABP), left ventricular assist device (LVAD), or extracorporeal membrane oxygenation (ECMO) may be required] and eventually undergo emergent CA. In both high and low-risk patients, every effort should be made to suppress VAs and avoid further ICD-shocks.

## ICD PROGRAMMING

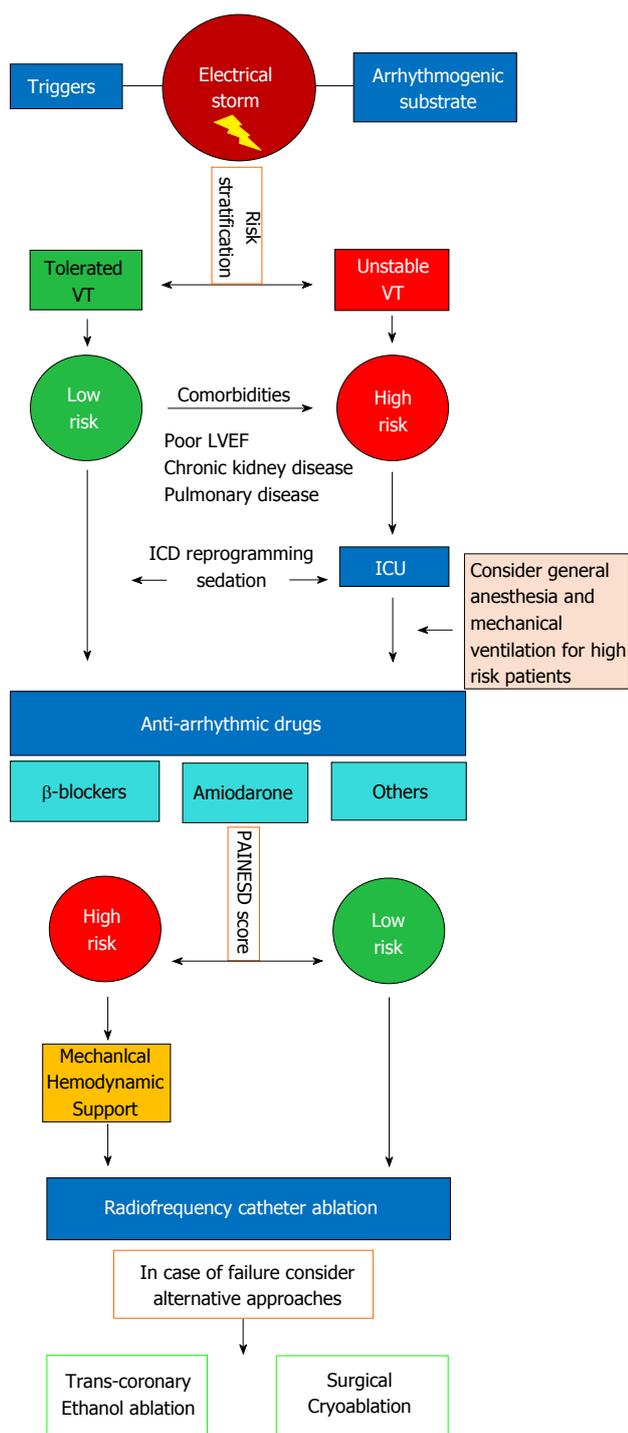

Reprogramming of ICD settings is of great importance in the initial workup of patients presenting with ES. Repeated ICD-shocks are associated with increased mortality and low quality of life<sup>[5,6]</sup>. The end-point of ICD reprogramming should be the reduction of ICD-shocks favoring interruption of VAs with ATP. In large trials, increases in both detection duration and heart rate detection threshold have been shown to reduce ICD-shocks without increasing mortality or the incidence of syncope<sup>[5,7,8]</sup>. Moreover, ATP can effectively terminate most slow VTs with a low risk of acceleration<sup>[9,10]</sup>.

## ANTIARRHYTHMIC DRUG THERAPY

Antiarrhythmic drugs (AADs) are usually required for the acute management of ES and are often used as an adjunctive therapy to prevent long-term recurrences. In a recent meta-analysis of randomized-controlled trials, we found a 1.5-fold reduction of appropriate ICD interventions with AADs compared to standard medical therapy with also a significant reduction of inappropriate ICD interventions. However, pooled analysis did not show a significant impact of AADs on all-cause mortality compared to standard medical therapy<sup>[11]</sup>. The choice of a particular drug and its dose should take into account its efficacy in controlling VA but also potential pro-arrhythmic effects as well as other side effects. Pro-arrhythmic effects have been reported in up to 7% of the patients treated with AADs for VT/VF with the higher incidence in patients with severely reduced LVEF<sup>[12]</sup>. A list of the most common AADs used in the acute and long-term management of ES as well as indications on the proper use of them and their therapeutic drug monitoring is presented in Table 2.

### **Beta-blockers**

A significant increase in the sympathetic tone is inevitably observed in patients experiencing ES, being responsible for the occurrence and maintenance of VAs. In these patients a spiral of events may occur: ICD shocks may precipitate increased sympathetic tone, resulting in further VAs and shocks, and so forth. Therefore, suppression of adrenergic tone with  $\beta$ -blockers represents

**Figure 1** Proposed algorithm for acute management of patients presenting with electrical storm. VT: Ventricular tachycardia; LVEF: Left ventricular ejection fraction; ICU: Intensive care unit.

the cornerstone of AAD therapy of ES<sup>[13]</sup>. Although most of the benefits of  $\beta$ -blockers are related to a class effect, in this setting there are some important advantages of nonselective  $\beta_1$  and  $\beta_2$  blockade. Ventricular remodeling in patients with chronic HF leads to a downregulation of  $\beta$ -receptors mostly involving  $\beta_1$ -receptors with relative sparing of  $\beta_2$ -receptors. Moreover, the lipophilic nature of some unselective  $\beta$ -blockers like propranolol, enables their penetration into the central nervous system where

**Table 1** Reversible causes of electrical storm

Acute myocardial ischemia

Infections, fever
Pro-arrhythmic drug Effects
Early postoperative period

they act by blocking presynaptic adrenergic receptors<sup>[14,15]</sup>. Propranolol has been demonstrated to be effective in suppressing VAs refractory to both metoprolol and amiodarone<sup>[16]</sup>. Short-acting intravenous drugs like esmolol can also be used, especially in patients at highest risk for hemodynamic compromise such as those with severely reduced LVEF<sup>[17]</sup>.

**Amiodarone**

Amiodarone is widely used in the acute management of ES and can generally be safely administered unless hyperthyroidism or QT prolongation are present. Amiodarone has a mixed antiarrhythmic class action with a prevalent class III action (potassium channel blocker) prolonging the ventricular refractory period when administered orally and a prevalent class I (sodium channel), class IV (L-calcium channels) and class II (sympathetic blocker) action, not prolonging ventricular refractoriness, when is administered intravenously<sup>[18]</sup>. Amiodarone has demonstrated its efficacy in several trials being able to control VAs in up to 40% of patients within 24-h from intravenous administration as well as to reduce recurrent VT over follow-up<sup>[19-22]</sup>. The combined use of both amiodarone plus  $\beta$ -blockers significantly reduces the risk of recurrent ICD-shocks compared vs  $\beta$ -blockers alone<sup>[22]</sup>. In the specific setting of ES, amiodarone has been shown to reduce the risk of ES recurrence by 50% over 5-years follow-up<sup>[23]</sup>. Patients already under amiodarone treatment may benefit from a reloading dose or a dose adjustment based upon serum levels of amiodarone even if plasma concentration monitoring has been reported of very limited benefit because the drug and its active metabolite (desethylamiodarone) accumulates in tissues at higher concentrations than in plasma<sup>[24]</sup>. Importantly, amiodarone may increase defibrillation thresholds in patients with ICDs<sup>[25]</sup> and the risks and benefits of long-term administration of amiodarone should be carefully weighed because of its several side effects including liver dysfunction (elevated AST/ALT levels in up to 30% of patients but hepatitis requiring drug discontinuation in < 3% of the cases), thyroid disorders (hypothyroidism in up to 22%, hyperthyroidism in up to 12%), pulmonary fibrosis (2%), corneal deposits (> 90%, usually of no clinical importance), optic neuropathy (< 1%) and pro-arrhythmic effect (< 1%)<sup>[26]</sup>. A recent pooled analysis of randomized controlled trials comparing CA vs AADs demonstrated an association between amiodarone and increased mortality<sup>[11]</sup>. Furthermore, among patients

**Table 2 Anti-arrhythmic medications for acute and long-term treatment of electrical storm**

		Acute management	Long-term treatment	Desired plasma concentration
β-blockers	Propranolol	Bolus: 0.15 mg/kg IV over 10 min	10-40 mg by mouth three-four times a day	NA
	Metoprolol	Bolus: 2-5 mg IV every 5 min up to 3 doses in 15 min	25 mg by mouth twice a day up to 200 mg a day	NA
	Esmolol	Bolus: 300 to 500 mg/kg IV for 1 min Infusion: 25-50 mg/kg per minute up to a maximum dose of 250 mg/kg per minute (titration every 5-10 min)	Not recommended	NA
Class III agents	Amiodarone	Bolus: 150 mg IV over 10 min, up to total 2.2 g in 24 h  Infusion: 1 mg/min for 6 h, then 0.5 mg/min for 18 h	Oral load: 800 mg by mouth twice a day until 10 g total  Maintenance dose: 200-400 mg by mouth daily	1.0-2.5 µg/mL No efficacy proven for plasma concentrations < 0.5 µg/mL Serious toxicity risk for plasma concentrations > 2.5 µg/mL
	Sotalol	Not recommended	80 mg by mouth twice a day, up to 160 mg twice a day (serious side effects > 320 mg/d)	1-3 µg/mL (not of great value, usually monitored by QT prolongation with indication to reduction/discontinuation if prolongation > 15%-20%)
Class I agents	Procainamide	Bolus: 10 mg/kg IV over 20 min Infusion: up to 2-3 g/24 h	3-6 g by mouth daily fractionated in ≥ 3 administrations	4-12 µg/mL
	Lidocaine	Bolus: 1.0 to 1.5 mg/kg IV, repeat dose of 0.5-0.75 mg/kg IV up to a total dose of 3 mg/kg  Infusion: 20 µg/kg per minute IV	Not recommended	2-6 µg/mL
	Mexiletine	Not recommended	200 mg by mouth three times a day, up to 400 mg by mouth three times a day	0.6-1.7 µg/mL

undergoing CA for VT in the setting of structural heart disease, we have recently shown that higher amiodarone dose at discharge after CA was associated with increased mortality, suggesting that discontinuation or dose reduction of amiodarone should be considered in certain patients after successful CA<sup>[27]</sup>.

### Procainamide

Procainamide is a class IC agent no longer widely used (unavailable in most countries) that may be helpful to acutely terminate VAs and prevent recurrences. It acts as fast sodium channel blocker, while its active metabolite N-acetylprocainamide blocks potassium channels and accounts for much of the antiarrhythmic effect *in vivo* as well as side effects like QT interval prolongation. Up to date there are only two small randomized controlled trials analyzing its role in the acute treatment of tolerated VT. In the study by Gorgels *et al*<sup>[28]</sup>, procainamide demonstrated its superiority to lidocaine in acute VT termination in 29 patients while in the more recent PROCAMIO trial, intravenous administration of procainamide was shown to be safe and more effective compared to amiodarone in the treatment of tolerated monomorphic VT<sup>[29,30]</sup>. The most important acute adverse reaction is hypotension (up to 30% patients) which requires drug discontinuation in 11% of cases<sup>[28-30]</sup>. Data regarding the long-term efficacy of procainamide in preventing VT are lacking, moreover chronic therapy is limited by a number of systemic side effects including lupus-like syndrome, gastrointestinal disturbances, and autoimmune blood impairments. Plasma procainamide concentrations can be useful in initial dose titration;

however, monitoring of QRS and QT interval is a valid alternative to prevent drug toxicity.

### Lidocaine and mexiletine

Lidocaine and mexiletine are both class IB AADs, acting as rapid sodium channel blockers binding to the receptor in a use-dependent fashion. The main difference between them is the bioavailability of mexiletine (80%) that allows its oral administration. The use of lidocaine in ES is more limited due to its lower efficacy in terminating scar-related VTs. During ischemic VT, the altered membrane potential as well as pH reduction increase the rate of drug binding, making lidocaine more effective in terminating VAs<sup>[31]</sup>. For this reason lidocaine is currently recommended mostly for the suppression of VAs in the setting of acute ischemia<sup>[32]</sup>. Mexiletine has shown to reduce the burden of VAs but with a trend toward increased mortality and is mostly used as an adjunctive therapy to amiodarone being able to reduce appropriate therapies in patients with ICD in case of amiodarone inefficacy<sup>[33,34]</sup>. Side effects of lidocaine and mexiletine are dose dependent and predominantly related to central nervous system accumulation (particularly in patients with HF) including tremors, seizures and hallucinations. They are generally rapidly reversible with drug reduction or discontinuation.

### Sotalol

The commercially available form of Sotalol is a racemic mix of d-isomer (acting as a class III potassium channel blocker) and l-isomer (acting as a non-selective β-blocker). Most of its antiarrhythmic (as well as pro-arrhythmic) effects result from its action on potassium channels

resulting in prolongation of repolarization and the QT interval. While sotalol has shown to reduce the frequency of ICD-shocks among patients implanted for secondary prevention, it has failed to demonstrate his superiority to  $\beta$ -blocker therapy in preventing recurrent ICD-shocks in several randomized-controlled trials<sup>[22,35,36]</sup>. Moreover, an increased rate of arrhythmic deaths has been observed among patients with LV dysfunction and previous myocardial infarction treated with sotalol d-isomer alone for primary prevention of sudden death<sup>[37]</sup>. Basing upon this data it seems appropriate to consider sotalol only for VAs irresponsive to  $\beta$ -blockers. However, in patients with chronic kidney disease and severely depressed LVEF, it still should be avoided in favor of other medications like amiodarone<sup>[22]</sup>.

## GENERAL ANESTHESIA AND MECHANICAL HEMODYNAMIC SUPPORT

Sedation should be considered in all patients presenting with ES in order to minimize pain related to ICD-shocks and reduce the sympathetic surge triggered by repeated ICD therapies. Benzodiazepines such as midazolam in addition to short-acting analgesics such as remifentanyl should be the first choice being able to suppress the sympathetic hyperactivity and provide analgesia without negative inotropic effects<sup>[38,39]</sup>. Propofol has been reported to suppress ES but must be used carefully since its negative inotropic effects can lead to cardiogenic shock<sup>[40]</sup>. Dexmedetomidine is an  $\alpha_2$ -presynaptic receptor agonist that reduces sympathetic activity by enhancing central vagal tone and inhibiting presynaptic catecholamine release. It should be used cautiously, however, since it may result in severe hypotension and bradycardia<sup>[41,42]</sup>. General anesthesia and mechanical ventilation should be preferred for patients with hemodynamic unstable VTs, because drugs used for anesthesia induction and maintenance can further depress cardiac function<sup>[43]</sup>. Patients with unstable VTs may also benefit from mechanical hemodynamic support like IABP, LVAD and ECMO. Hemodynamic support can reduce the arrhythmic burden by increasing coronary perfusion, reducing afterload and therefore myocardial wall stress and prevent multiple organ failure guarantying and adequate cardiac output<sup>[44-46]</sup>.

## NEURAXIAL MODULATION

Sympathetic hyperactivity plays a critical role in the onset and maintenance of VAs. Therefore, modulation of neuraxial efferents to the heart with epidural anesthesia or cardiac sympathetic denervation (CSD) may be a valuable option in selected patients refractory to standard medical treatment and CA<sup>[47,48]</sup>. Sympathetic denervation has been effectively used in the setting of inherited arrhythmic syndromes like long QT syndrome and catecholaminergic polymorphic VT<sup>[49,50]</sup>. However, it has been recently applied even to ES in patients with structural heart disease<sup>[47,48]</sup>. Surgical CSD is usually

performed on the left side through a video-assisted thorascopic approach and entails removal of the lower third of the stellate ganglion (to avoid Horner syndrome) and T2-T4 thoracic ganglia. It has shown to suppress/ significantly decrease the arrhythmic burden in 56% of patients refractory to AADs and CA<sup>[47]</sup>. Bilateral CSD may be considered in cases of failure of left CSD. In a small study involving 6 patients undergoing bilateral CSD after failed medical therapy, CA and epidural anesthesia, a complete response was observed in 4 (67%) of them and a partial response in another one (17%)<sup>[48]</sup>. In a recent series of 41 patients with refractory VT undergoing either left (14) or bilateral (27) CSD, a significant reduction of ICD-shocks during a mean follow-up of  $367 \pm 251$  d was observed in 90% of the patients with a significantly higher ICD-shock free survival of 48% in the bilateral CSD group compared to 30% in the left CSD group<sup>[51]</sup>.

## CATHETER ABLATION

The last decade has seen a growing role for catheter ablation (CA) in the management of VT. Even if a mortality benefit has never been demonstrated in randomized-controlled trials, CA has repeatedly shown its superiority to medical therapy in reducing the arrhythmic burden<sup>[11,52,53]</sup>. Moreover, freedom from recurrent VT after CA ablation has been associated with improved survival<sup>[54,55]</sup>. For these reasons, CA should not be considered a bailout therapy but a valuable option in all patients presenting with ES related to structural heart disease. Radiofrequency CA is effective not only in the acute management of ES, leading to a control of VAs in up to 80%-90% of the patients but also over the long-term follow-up improving either VT- and ES-free survival (Table 3)<sup>[56,57]</sup>. In the recently published VANISH trial, a trend towards a 34% relative risk reduction of ES recurrences was observed in patients treated by CA compared to escalation of AADs<sup>[52]</sup>. In a pooled meta-analysis including 471 patients with ES treated invasively by different ablation strategies (*i.e.*, CA, ethanol ablation and surgical ablation), acute elimination of all inducible VAs was reached in 72% of the cases with the clinical arrhythmia effectively suppressed in 91% of the patients and a complication rate of 2% with a procedure-related death < 1%. In terms of long-term outcomes, after a median follow-up of 1.2 years, 94% of the patients were free from ES and 72% were free from any VT. Overall mortality was 17% at 1.2-years follow-up with most of the deaths related to progressive HF (62%)<sup>[58]</sup>. Similar positive results have recently been found by our group in a large series of 267 patients undergoing CA for drug-refractory ES with an acute procedural success (non inducibility of any VT with cycle length < 250 ms at the end of the procedure) of 73%, a 54% VT-free survival and a 93% ES-free survival at 60-mo follow-up. We also observed a significant reduction of VT burden in patients experiencing VT recurrence after CA<sup>[59]</sup>. Regardless, patients with ES tend to have worse prognosis after CA compared vs patients without ES, as evidenced by the fact that those with ES have higher VT recurrence rates

VT: Ventricular tachycardia; ES: Electrical storm.

PAINESD risk score			
Variable	Score		
Pulmonary disease (chronic obstructive)	5	Low risk	≤ 8
Age > 60 yr	3		
Ischemic cardiomyopathy	6	Intermediate risk	9-14
NYHA class III or IV	6		
Ejection fraction < 25%	3	High risk	≥ 15
Storm (VT)	5		
Diabetes mellitus	3		

**Figure 2** Proposed scoring system to identify patients at high risk of hemodynamic decompensation undergoing catheter ablation that may benefit from prophylactic mechanical circulatory support. Modified from Santangeli *et al*<sup>[43]</sup>. VT: Ventricular tachycardia.

and are more likely to die or require heart transplantation or surgical LVAD over long-term follow-up after CA<sup>[60]</sup>.

As patients with chronic HF are living longer with their condition, technological advances to CA and better understanding of VT substrate has led to an increased number of procedures performed in high risk patients. Patients with advanced HF, several comorbidities as well as patients with unstable VTs are at highest risk of hemodynamic collapse during the ablation procedure and subsequent post-procedural mortality<sup>[43,61]</sup>. In a preliminary study of our group, a simple score (PAINESD score) accounting for baseline patient characteristics such as pulmonary chronic obstructive disease, age, Ischemic cardiomyopathy, NYHA class, LVEF, ES at presentation and diabetes has been demonstrated able to predict acute decompensation during VT ablation procedures and therefore has been proposed to select patients who may benefit from prophylactic mechanical support (Figure 2)<sup>[43]</sup>. Recently, the PAINESD score has been validated in a study assessing the outcomes of prophylactic vs rescue percutaneous LVAD in a cohort of 93 patients undergoing CA for VT related to structural heart disease<sup>[61]</sup>. The authors reported a higher 30-d mortality in patients who underwent rescue LVAD (58%) compared to patients who underwent prophylactic LVAD (4%) placement

and patients who were ablated without LVAD (3%). Interestingly, patients who underwent rescue LVAD had similar PAINESD scores compared to those who underwent prophylactic LVAD insertion (mean 17.8 vs 16.5) while had a significantly higher score compared to the control group (mean 13.4), highlighting the importance of prophylactic mechanical support in high risk patients in order to improve post-procedural mortality<sup>[61]</sup>. Mechanical support is helpful in that it allows for prolonged mapping and ablation of inducible unstable arrhythmias. However, we have also found it to be useful when used prophylactically in high-risk patients with large areas of VT substrate undergoing a purely substrate-based ablation approach in which the long procedural times necessarily for complete substrate ablation and the consequent fluid overload related to irrigated CA may precipitate acute decompensation<sup>[43]</sup>. Importantly, some patients with advanced HF have significant biventricular dysfunction and LVAD support may be inadequate. In these cases, devices providing biventricular support like ECMO should be considered. In a recent study involving 64 patients undergoing CA of unstable VTs, the prophylactic use of ECMO has shown to allow to safely complete the procedure in 92% of the patients reaching the endpoint of VT non inducibility in 69% of them with a 88% overall survival after a median follow-up of 21 mo<sup>[46]</sup>.

## ALTERNATIVE APPROACHES

In cases in whom radiofrequency CA has failed or is challenging (*i.e.*, presence of mitral and aortic mechanical valves), alternative approaches like trans-coronary ethanol ablation and surgical cryoablation has been described<sup>[62]</sup>. Our group has recently reported a 73% VT-free survival at 1-year follow-up in a series of 20 consecutive patients with non-ischemic cardiomyopathy and VT refractory to conventional therapy who underwent surgical cryoablation<sup>[63]</sup>. Trans-coronary ethanol ablation performed through selective coronary angiography to identify the branches

supplying the putative VT site of origin has been recently reported in a series of 46 patients with VT related to structural heart disease and refractory to CA<sup>[62]</sup>. At least partial procedural success was reached in 66% of the patients with a 74% and 82% VT recurrence rate at 6- and 12-mo follow-up, respectively and a complication rate of 32% (1 procedure related death).

## CONCLUSION

Electrical storm is a life-threatening condition with an increasing incidence related to the wider use of ICD and the improved survival of patients with advanced HF. Management of ES requires a multimodality approach including optimal ICD-reprogramming, treatment of underlying conditions, anti-arrhythmic drug therapy, sedation and CA. Radiofrequency CA appears to be the most effective treatment option, being able to control arrhythmia burden in the acute phase and improve long-term arrhythmia free survival and therefore should be considered in all patients presenting with ES. A growing evidence supports the use of prophylactic mechanical hemodynamic support as a bridge to ablation and/or recovery in high risk patients.

### Abstract

The implantable cardioverter-defibrillator (ICD) is effective to prevent sudden cardiac death (SCD) in selected patients with heart disease known to be at high risk for ventricular arrhythmia. Nevertheless, this invasive and definitive therapy is not indicated in patients with potentially transient or reversible causes of sudden death, or in patients with temporary contraindication for ICD placement. The wearable cardioverter defibrillator (WCD) is increasingly used for SCD prevention both in patients awaiting ICD implantation or with an estimated high risk of ventricular arrhythmia though to be transient. We conducted a review of current clinical uses and benefits of the WCD, and described its technical aspects, limitations and perspectives.

**Key words:** Wearable cardioverter/defibrillator; Sudden cardiac death; Secondary prevention; Primary prevention; Ventricular arrhythmias

## INTRODUCTION

Sudden cardiac death (SCD) is an unpredictable event which leads to death in the absence of immediate resuscitation maneuvers and adequate therapies. Up to 23% of SCD are attributable to ventricular arrhythmias (VA)<sup>[1]</sup>. The implantable cardioverter-defibrillator (ICD) has proved to be highly effective for SCD secondary prevention. Otherwise, it has also been demonstrated to prevent SCD in selected patients with heart disease known to be at high risk for life-threatening VA<sup>[2-4]</sup>. However, long-term ICD-related complications, cost issues, social impact and quality of life force a rigorous evaluation of patients before ICD placement. Furthermore, some situations at high risk of VA-related SCD are known to be limited in time. For example, although SCD rate was 2.3% in patients with low left ventricular ejection fraction (LVEF) during the first month following myocardial infarction (MI), ICD implantation during the first 40 d post-MI failed to reduce total mortality. This result was essentially due to a large amount of non-arrhythmic death during this period<sup>[5]</sup>. In addition, up to 40% of patients with coronary artery disease and low LVEF do not meet the current criteria for ICD implantation after complete myocardial revascularization and/or optimization of medical therapy<sup>[6]</sup>.

The wearable cardioverter defibrillator (WCD) is increasingly used for SCD prevention both in patients awaiting ICD implantation or with an estimated high risk of VA though to be transient. This external device, which has been demonstrated to effectively terminate spontaneous and induced VA by automatic defibrillation shock delivery, requires no surgical intervention and is entirely removable. We conducted a review of current clinical uses and benefits of WCD, and described its technical aspects, limitations and perspectives.

## TECHNICAL ASPECT

Currently available WCD is the LifeVest 4000® [ZOLL Lifecor Corporation (ZOLL), Pittsburgh, PA, United States]. With the LifeVest 4000®, the chest is surrounded by an elastic belt including an electrocardiographic (ECG) monitoring system with four dry, non-adhesive electrodes and the defibrillation system consisting in two posterior and one apical electrodes (Figure 1). The whole is maintained by shoulder straps forming a light washable vest and connected to a monitor unit including the battery, an LCD screen for message display and two "response buttons" for patient defibrillation shock withholding. The monitor unit is held in a holster or around the waist (Figure 2). Two batteries are delivered with the WCD; each one lasts for 24 h so that one is always in charge during the use of the other. Total device weight is about 600 g. ECG electrodes provide two left-right and front-back bipolar ECG signals (Figure 3). The ECG is continuously recorded and analyzed. Following parameters can be programmed: (1) rate intervals for ventricular fibrillation (VF) zone: 120 to 250 bpm, default 200 bpm and ventricular tachycardia (VT) zone:

120 bpm to VF zone; (2) shock delay, *i.e.*, time from arrhythmia detection to shock delivery: 60 to 180 s in VT zone and 25 to 55 s for VF zone. Further delay up to 30 s may be added at night; and (3) shock energy: 75 to 150 J.

The WCD automatically delivers, *i.e.*, without neither patient nor witness intervention, defibrillation shocks for termination of life-threatening VA. Arrhythmia detection and discrimination (for arrhythmia detected in the VT zone) occur within few seconds after the rhythm disorder onset. In case of VA detection within the programmed VT or VF zone, the device alerts the patient of the imminence of a shock starting by vibrations of the defibrillation electrodes during 5 s, followed by a low monotonal sound signal then high bitonal sound signal. Finally, a voice warning during the few lasts s precedes the shock delivery. During this period, the patient, if still conscious, can withhold shock delivery by pressing the two response buttons on the monitor unit. Without this well-done intervention, defibrillation shock is delivered, synchronized to the R-wave signal in case of monomorphic VT. In order to improve shock impedance, and to prevent skin burns, the defibrillation electrodes release a conductive gel contained in small capsules before shock delivery (Figure 4). Up to five shocks can be delivered for the same episode. ECG signal is continuously recorded and reviewable 30 s prior to the detection of arrhythmia to 15 s after the alarms stop (Figure 5). Total duration from the onset of the arrhythmia to shock delivery, (including time of fulfilling detection criteria, confirmation, alarms and capacitor charging) is about 50 s. Daily remote monitoring advises medical staff about VA occurrence and therapies, daily ECGs, as well as patient compliance (assessed by the daily wear time).

## PATIENT EDUCATION AND COMPLIANCE

Patient education by specialized healthcare givers on how to properly wear the device, change the battery and disable shock delivery is a crucial step. In our experience, 10% to 15% patients eligible for this therapy are not able to understand instructions to withhold therapies or change battery and therefore are not treated with the WCD. In order to improve patient knowledge and handle of the WCD, we systematically schedule an additional patient education session 10 to 15 d after hospital discharge.

Similarly, understanding and knowledge of his cardiac disease and potentials benefits associated with the use of the WCD is a critical part of patient care, aiming high device compliance which is the prerequisite of effective SCD protection. Lack of compliance might have dramatic consequences. Indeed, in various studies, the majority of SCD observed during follow-up were observed in patients not or not-correctly wearing the WCD<sup>[7,8]</sup>. Weight and footprint of the device were the main reasons for low compliance. On the other hand, as high as 22.5% of patients discontinued the use of WCD due to comfort or lifestyle issues in study from Feldman *et al*<sup>[8]</sup>. A 40% reduction of size and weight of the device was associated with a significant decrease in the rate of WCD therapy

**Figure 1** Wearable cardioverter defibrillator. The two defibrillator electrodes are worn on the back of the garment, when the four monitoring electrodes are placed on the elastic belt around the chest. Both systems are connected to the monitor unit.

**Figure 2** Wearable cardioverter defibrillator worn by a patient under clothes; monitor unit is worn on waist belt or in a holster.

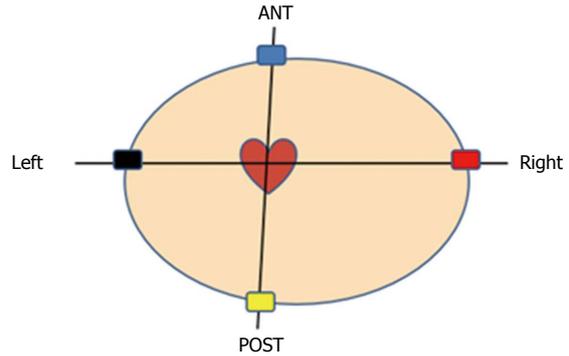

interruption (14.2%) in a more recent report<sup>[9]</sup>.

Overall, national registries showed good compliance with the actual WCD<sup>[6,10]</sup>. In United States' experience, of 3569 patients wearing WCD, > 50% of patients achieved a 90% wear time compliance<sup>[9]</sup>. In the German registry, this number grows to 72%<sup>[11]</sup>. In both studies, long period of therapy was associated with higher time of wearing. Otherwise, remote monitoring allows measurement of daily WCD wear time and medical staff is alerted in case of low patient compliance so that prompt corrective measures can be taken.

## CLINICAL STUDIES

### Efficacy

Auricchio *et al.*<sup>[12]</sup> were the firsts to report the efficacy of the first generation WCD (WCD™ device, LIFECOR, Pittsburgh, Pennsylvania) for termination of life-threatening VA. This device reliably stopped induced VT or VF by automatically delivering a 230 J defibrillation shock in 15 SCD survivors. The firsts prospective multicenter studies demonstrating clinical benefit of the WCD were the Wearable Defibrillator Investigate Trial (WEARIT) and Bridge to ICD in Patients at Risk Of Arrhythmic Death (BIROAT) studies<sup>[8]</sup>. Inclusion criteria for the WEARIT study was

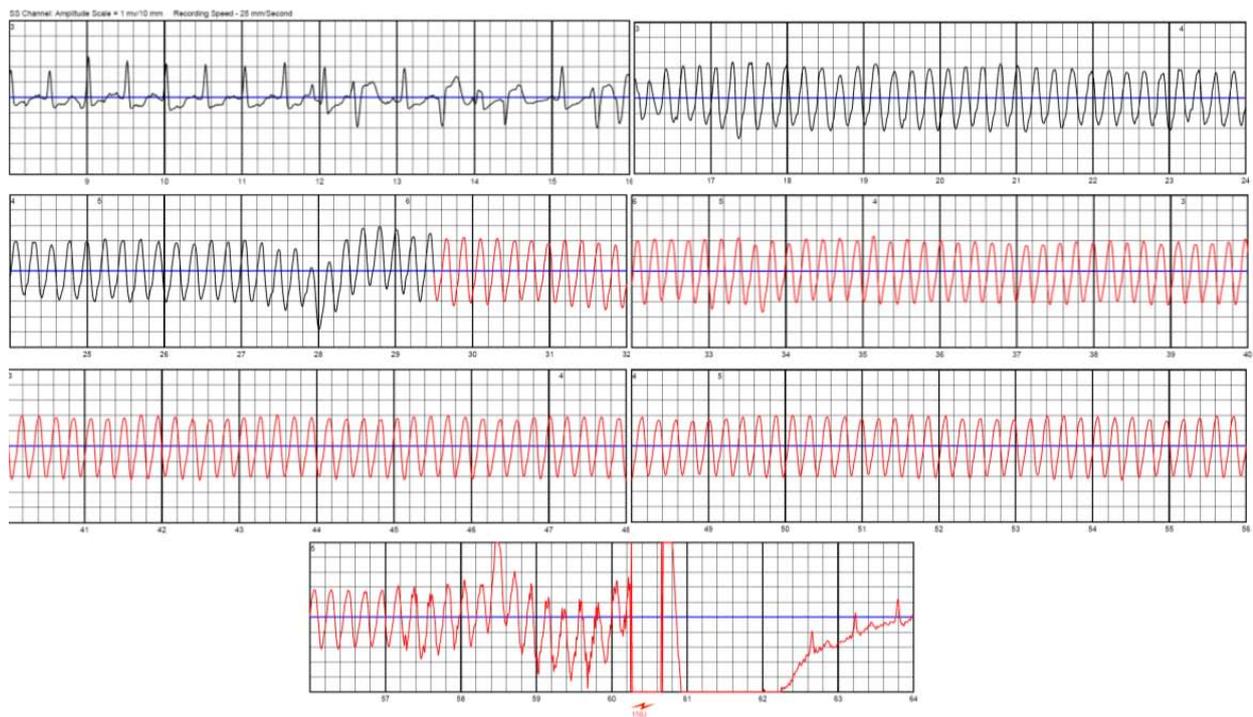

**Figure 3** Four electrocardiographic electrodes position, and two left-right and front-back bipolar electrocardiographic vectors.

**Figure 4** One defibrillator electrode with ten gel capsules inserted in, and one non-adhesive electrocardiogram electrode.

symptomatic NYHA III or IV ambulatory heart failure and LVEF < 0.30. Differently, the BIROAD study enrolled: (1) patients after a recent MI or coronary artery bypass grafting (CABG) and having complications such as VA, syncope or low LVEF < 0.30, but not receiving an ICD for up to 4 mo; and (2) patients who met criteria for an ICD but refused therapy or had to wait for at least 4 mo before implantation. A total of 289 patients were enrolled in both studies, united into one at the request of the Federal Drug Administration, and followed during a total of 901 mo of patient use. During the follow-up, 6 of 8 defibrillation attempts were successful. No patient died while correctly wearing the WCD.

Thereafter, some large studies validated the clinical benefit of this therapy and evaluated the occurrence of VA during the period of the WCD use in patients with low LVEF in the setting of ischemic heart disease. Rate of patients receiving appropriate shock within the 3 mo following percutaneous coronary intervention (PCI) or CABG varied from 1.3% to 1.7%<sup>[9,10]</sup>. Prolonging WCD wearing period to 15 mo resulted in increasing rate of appropriate WCD shock to 4.1%<sup>[13]</sup>. In the United States' experience, first shock success was of 99% for all VT/VF events, and survival after VT/VF events was 89.5%<sup>[9]</sup>. Importantly, no death could be attributed to WCD technical failure since its introduction. For note, at the end of the WCD period use, about 60% of patients were not

**Figure 5** Ventricular tachycardia correctly diagnosed and treated by wearable cardioverter defibrillator. Red line corresponds to sound signal. A 150-J defibrillation shock, automatically delivered by the device, terminated the arrhythmia.

eligible anymore for ICD implantation, mainly because of left ventricular ejection fraction improvement<sup>[6]</sup>.

**Inappropriate shock**

From 0.4% to 3% of patients experienced inappropriate WCD shock<sup>[6,9,10,14]</sup>. The WCD is an external device, which is dramatically exposed to noise detection. Inappropriate shocks are mainly related to noise artifacts or T wave oversensing<sup>[15]</sup>. Compared to conventional transvenous ICD, the rate of inappropriate shock with the WCD is low. This fact is explained by the possibility for the patient to withhold shock delivery while pressing the response buttons. Incidence of false alarms attributable to artifacts is unknown.

**Current indications**

According to current guidelines for management of patients presenting with VA and the prevention of SCD, “the WCD may be considered for adult patients with poor LV systolic function who are at risk of sudden arrhythmic death for a limited period, but are not candidates for an implantable defibrillator (e.g., bridge to transplant, bridge to transvenous implant, peripartum cardiomyopathy, active myocarditis and arrhythmias in the early post-myocardial infarction phase). In patients presenting with high risk of SCD, but non-indicated for an ICD implantation because of temporary contra-indication, in expectation of a diagnosis, or if the arrhythmic risk may evolve<sup>[16]</sup>. For the Heart Rhythm Society, the use of WCD is reasonable in patients with a clear indication of ICD placement but with temporary contra indication to the procedure (infection for example) or as a bridge therapy to heart transplantation.

Otherwise, the use of the WCD should be considered in additional clinical situations: In patients with high risk for SCD due to LV dysfunction that may resolve over time (following myocardial revascularization, myocarditis...) or with a potentially treatable cause (arrhythmia-induced or chemotherapy-induced LV dysfunction)<sup>[17]</sup>.

**Well-validated clinical situation to consider the WCD**

**After acute myocardial infarction:** Sudden cardiac death occurred in 2.3% of patients with severely depressed LVEF during the first month post-MI<sup>[18]</sup>. However, the risk of life-threatening VA significantly decreases with LVEF recovery after acute event<sup>[19]</sup>. Furthermore, in primary prevention studies, ICD benefit occurred years after implantation<sup>[3,20]</sup>. Former studies showed no impact of early implantation of ICD after AMI on overall mortality<sup>[5,21]</sup>. The DINAMIT was an open-label trial including 674 patients 6 to 40 d after an AMI, with LVEF > 0.35 and impaired cardiac autonomic function. Patients were randomized in a 1/1 fashion for medical treatment or medical treatment and ICD placement. This study did not found statistical difference in overall mortality between the 2 groups. Indeed, a smaller proportion of SCD observed in the ICD group was offset by an increase in the rate of non-arrhythmic deaths among these patients. These results are consistent with findings from the IRIS study<sup>[21]</sup>. The United States’ experience with the WCD was derived from a national database and included 8453 patients with ejection fraction < 0.35 early after acute MI<sup>[10]</sup>. One point four percent of patients were correctly treated by WCD, whose 75% in the first month of use. The median time to first WCD therapy was 9 d. The resuscitation

survival rate was of 91%. The VEST Prevention of Early Sudden Death Trial and VEST Registry (VEST) is a randomized simple blind trial currently enrolling patients with LVEF < 0.35 following AMI. This study aims to demonstrate a reduction of SCD within the first three mo following AMI. Enrollment exceeded 1700 patients in 2015, results are awaited<sup>[22]</sup>.

**After revascularization procedures:** Life-threatening VA are a frequent cause of SCD after elective revascularization CABG or PCI<sup>[23]</sup>. ICD implantation is mandated in patients with reduced LVEF < 0.35 evaluated at least 3 mo after revascularization because of possible LV systolic function recovery. In the setting of LV dysfunction <0.35 after CABG or PCI, Zishiri *et al.*<sup>[24]</sup> found a significant reduction in early mortality hazard in patients treated with the WCD (3% vs 7%,  $P < 0.05$ ). In this subset of patients, appropriate therapy rate was 1.3%.

**Terminal cardiomyopathy listed for heart transplantation:** The risk of SCD in patients awaiting heart transplantation is about 10% at one year<sup>[25]</sup>. Although ICD is largely used in this population of patients, complications, such as infection, are frequent, particularly in LV assist devices receivers<sup>[26]</sup>. The WCD was found to be a safe and efficient transitory solution to protect this population as a bridge to transplantation<sup>[27]</sup>.

**ICD infections, before re-implantation:** Cardiac implanted electronic devices infections require complete system removal, associated with antibiotic therapy for 2 to 6 wk. Period before re-implantation is long, so that patients could benefit from WCD protection without delaying hospital discharge, as the risk of SCD remains unchanged<sup>[7]</sup> during this period. Highest incidence rate of appropriate therapies remains to patients after ICD explantation for infection in expectation of reimplantation compared with other indications<sup>[14]</sup>. Therefore, the AHA guidelines sustain its use in this clinical setting with a Class II A recommendation (level of evidence C)<sup>[17]</sup>.

**Nonischemic cardiomyopathy:** Benefice of ICD in prevention of SCA in non-ischemic cardiomyopathy (NICM) patients is still a matter of debate. Low LVEF < 0.35 remains the only criterion validated to stratify the risk of SCD among these patients<sup>[4,28,29]</sup>. Plurality of etiologies, absence of criteria that define the likelihood of reversibility and potential for recovery after optimal medical therapy<sup>[30]</sup> make difficult the assessment of the long term risk of VA in this population of patients. Early ICD implantation, within the firsts mo after diagnosis failed to improve long term survival<sup>[28,31]</sup>. Therefore, LVEF assessment for SCD risk stratification is recommended at least 3 mo after optimal medical treatment<sup>[16]</sup>, and some studies tend to delay ICD placement to 9 mo<sup>[32-34]</sup>. Furthermore, in a recent large randomized study, prophylactic ICD implantation in patients with symptomatic NICM showed no impact on mortality<sup>[35]</sup>. Indeed, the

DANISH study included 556 patients with symptomatic systolic NICM and LVEF  $\leq 0.35$  who were assigned to receive an ICD, and 560 patients assigned to receive medical care, both group receiving CRT if indicated. Primary evaluation criteria was death from any cause. No difference was observed between the two groups after a median follow-up period of 67 mo. Only patients younger than 68 years of age showed a lower rate of death after ICD implantation, independent of CRT status.

Small cohorts aimed to evaluate the benefit of WCD in patients with NICM. Incidence of appropriate therapies varied from 0% to 5.5%<sup>[6,8,9,15,36]</sup>. Prospective studies are lacking in this heterogeneous population to specify real benefit.

### Unfrequent clinical presentation

**Tako-tsubo cardiomyopathy:** Tako-tsubo cardiomyopathy is a heterogeneous provider of SCD, and life-threatening VA occur during the first wk after disease onset. Prevalence of VA varies between 8% and 13.5%<sup>[37,38]</sup>. Patients with QT prolongation after stress cardiomyopathy demonstrated a higher risk of VA. This subset of patients might have substantial benefit of the WCD use<sup>[39,40]</sup>.

**Peripartum cardiomyopathy:** Peripartum cardiomyopathy patients with severely reduced LVEF have an elevated risk of VA<sup>[41,42]</sup>. Up to 38% of deaths in this population are sudden and most of them (87%) occur within the 6 mo following the diagnosis<sup>[43]</sup>. The WCD was found to correctly treat these VA during the first mo after diagnosis, until ICD implantation or systolic function recovery<sup>[44]</sup>.

Prediction of cardiomyopathy and evaluation of SCD risk after acute myocarditis is difficult. Assessment of the LVEF appears to be an insufficient criterion<sup>[45,46]</sup>. Similarly to Tako-tsubo cardiomyopathy or peripartum cardiomyopathy, myocarditis has a potentially high likelihood of cardiac recovery so that the WCD may be limited to patients in secondary prevention or with particularly high-risk features<sup>[17]</sup>.

Pharmacology-induced cardiomyopathies (alcohol, methamphetamine, trastuzumab) are associated with a great potential of recovery of LV systolic function after withdrawal of the putative agent and optimal medical therapy.

In all these various clinical settings known to result in both potentially transient LV dysfunction and high SCD risk, the WCD might be a valuable tool in both for SCD prevention and to provide additional information for subsequent SCD risk stratification.

### Clinical perspectives

**Unexplained syncope:** The diagnostic of syncope encompass various causes. First, it can be the precursor event of SCD. Then it is a major step in the rhythmic risk in patients presenting with inherited arrhythmia syndromes or structural heart diseases such as hypertrophic cardiomyopathy. During this time of evaluation, no rhythmic

protection can be offered by classical monitoring approaches, such as implantable cardiac monitors. The WCD may bridge this vulnerable period until diagnostic has been established. The Ambulatory Post-Syncope Arrhythmia Protection Feasibility Study currently enrolling patients, aims to assess utility of WCD in patients with high rhythmic risk after unexplained syncope<sup>[47]</sup>.

**End-stage renal disease:** Hemodialysed (HD) patients are known to be at high risk of SCD<sup>[48]</sup>. In a retrospective study, 75 hemodialysed patients presenting with SCD while wearing a WCD were included<sup>[49]</sup>. Seventy-eight point six percent of SCD were linked to VT/VF episodes. One-year survival after SCA was 31.4%. In comparison with historical data, the WCD therapy was associated with an improved survival ref. The ICD was associated with better survival in HD patients yet<sup>[50]</sup>, but is more exposed to complications such as device infections<sup>[51]</sup>.

### Limitations of the WCD

Although the WCD is able to automatically terminate VA, daily maintenance is necessary. A non-negligible proportion of patients are unable to correctly use and handle the device, change battery or respond to device alarms. This issue might be kept in mind before patient selection. The WCD cannot deliver antitachycardia and/or anti-bradycardia pacing. In patients with cardiac pacemakers, bipolar pacing mode should be programmed in order to avoid oversensing of pacing artifacts during VF leading to termination of the treatment algorithm<sup>[52]</sup>. In contrast, time to shock delivery, which is substantially longer compared to ICD, doesn't seem to be a limitation. As shown in the MADIT-RIT trial<sup>[53]</sup>, prolonged delays in therapy delivery were associated with reductions in inappropriate therapies and overall mortality. Finally, cost impact of this device has to be underlined. Few studies evaluated the cost-effectiveness of the WCD. After ICD removal for infection, WCD seemed to be cost-effective for SCD prevention compared to in-hospital monitoring or discharge to a skilled nursing facility before reimplantation<sup>[54]</sup>.

## CONCLUSION

The WCD is a life-saving therapy as it has been demonstrated to promptly detect and terminate VT/VF by automatically delivering defibrillation shock. This device represents a safe, easy to handle, non-invasive and reversible way to prevent SCD in patients with SCD risk though to be high for a limited period or having a transient contraindication to permanent ICD implantation. Data sustaining the use of the WCD therapy in patients with low LVEF following myocardial revascularization are strong. Similarly, current guidelines sustain the use of the WCD in patients with ICD infection requiring device removal. Further prospective and randomized studies are awaited to better guide its indications and its benefit in other clinical settings.

**Abstract****AIM**

To evaluate the long-term outcome of catheter ablation of atrial fibrillation (AF) facilitated by preprocedural three-dimensional (3-D) transesophageal echocardiography.

**METHODS**

In 50 patients, 3D transesophageal echocardiography (3D TEE) was performed immediately prior to an ablation procedure (paroxysmal AF: 30 patients, persistent AF: 20 patients). The images were available throughout the ablation procedure. Two different ablation strategies were used. In most of the patients with paroxysmal AF, the cryoablation technique was used (Arctic Front Balloon, CryoCath Technologies/Medtronic; group A2). In the other patients, a circumferential pulmonary vein ablation was performed using the CARTO system [Biosense Webster; group A1 (paroxysmal AF), group B (persistent AF)]. Success rates and complication rates were analysed at 4-year follow-up.

**RESULTS**

A 3D TEE could be performed successfully in all patients prior to the ablation procedure and all four pulmonary

vein ostia could be evaluated in 84% of patients. The image quality was excellent in the majority of patients and several variations of the pulmonary vein anatomy could be visualized precisely (*e.g.*, common pulmonary vein ostia, accessory pulmonary veins, varying diameter of the left atrial appendage and its distance to the left superior pulmonary vein). All ablation procedures could be performed as planned and almost all pulmonary veins could be isolated successfully. At 48-mo follow-up, 68.0% of all patients were free from an arrhythmia recurrence (group A1: 72.7%, group A2: 73.7%, group B: 60.0%). There were no major complications.

### CONCLUSION

3D TEE provides an excellent overview over the left atrial anatomy prior to AF ablation procedures and these procedures are associated with a favourable long-term outcome.

**Key words:** Pulmonary veins; Catheter ablation; Atrial fibrillation; Transesophageal echocardiography; Three-dimensional echocardiography

**Core tip:** Three-dimensional (3-D) transesophageal echocardiography has been shown to be a useful tool for analysing the individual left atrial morphology prior to an ablation procedure. The aim of this study was to evaluate whether favourable long-term results can be obtained by catheter ablation of atrial fibrillation after prior pulmonary vein imaging using 3-D transesophageal echocardiography. In 50 patients, 3-D transesophageal echocardiography was performed immediately prior to an ablation procedure. The image quality was excellent in the majority of patients and several variations of the pulmonary vein anatomy could be visualized precisely. At 48-mo follow-up, 68.0% of all patients were free from an arrhythmia recurrence.

Catheter ablation of atrial fibrillation facilitated by preprocedural three-dimensional transesophageal echocardiography: Long-term outcome. *World J Cardiol* 2017; 9(6): 539-546 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i6/539.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i6.539>

## INTRODUCTION

Catheter ablation is an important therapeutic option in patients with symptomatic atrial fibrillation (AF)<sup>[1-21]</sup>. However, these procedures can be quite challenging because of the variability of the individual left atrial anatomy.

Magnetic resonance imaging (MRI) or multi-detector spiral computed tomography (MDCT) are frequently used prior to an ablation procedure. These three-

dimensional (3D) imaging systems provide insights into the morphology of the left atrium (LA). Obviously, the precise knowledge of the left atrial anatomy facilitates the ablation procedures and enhances the safety of these interventions. However, these imaging techniques are associated with significant limitations [*e.g.*, radiation exposure (MDCT), impaired image quality in patients suffering from AF with fast AV-nodal conduction (especially MRI) and additional costs]. Three-dimensional transesophageal echocardiography (3D TEE) provides excellent insights into the left atrial anatomy of individual patients and is free from most of the difficulties associated with MRI or MDCT<sup>[22-26]</sup>. It has been shown to be associated with a favourable short-term outcome after catheter ablation of AF<sup>[27]</sup>.

The target of this study was to analyse the long-term outcome of AF ablation procedures facilitated by preprocedural 3D TEE with regard to success rates and complication rates.

## MATERIALS AND METHODS

### Patient population

A total of 50 patients [35 men, 15 women; mean age 60.8 years (SD ± 9.2 years)] were enrolled in this study. All of them underwent 3D transesophageal echocardiography immediately before the ablation procedure, so that a 3D TEE reconstruction of the left atrium and the pulmonary veins (PVs) could be generated.

Catheter ablation was performed for paroxysmal AF in 30 patients and for persistent AF in 20 patients. All patients were highly symptomatic and at least one failed attempt of an antiarrhythmic drug therapy was a prerequisite for being accepted for catheter ablation. Table 1 summarizes clinical characteristics of the patients enrolled in our study. For all patients, this was the first AF ablation procedure.

The ablation procedures were performed at our University Hospital Center between October 2007 and May 2011.

Inclusion criteria were: (1) documented episodes of recurrent AF ( $\geq 30$  s); (2) severe symptoms despite antiarrhythmic drug therapy (including beta-blockers) or prior attempts of electrical cardioversion; (3) ability and willingness to give informed consent; and (4) age between 18 and 85 years. Patients were not accepted for catheter ablation if one of the following conditions was present: Severe valvular heart disease or any other concomitant cardiac disease requiring surgery, severely impaired left ventricular function (left ventricular ejection fraction < 20%), left atrial diameter > 65 mm (parasternal long-axis view), left atrial thrombus, hyperthyroidism, severe renal insufficiency (creatinine  $\geq 3$  mg/dL) or another severe concomitant illness.

### Cardiac imaging

In all patients, a 3D TEE was performed immediately before the ablation procedure (X7-2t, 7 MHz/IE 33;

<sup>1</sup>Not requiring surgery. CAD: Coronary artery disease; DCM: Dilated cardiomyopathy (left ventricular ejection fraction < 40%).

Philips Healthcare, Best, the Netherlands). The images were available throughout the ablation procedures. They were displayed in a synchronised way with the geometry created with the 3D mapping system (if available).

The echocardiographic examination was performed extensively to acquire all relevant information about the left/right atrium, all cardiac valves, the left/right ventricular function and the aorta. In addition, 3D reconstructions of the left atrium and the pulmonary vein ostia were generated. The image quality was classified as: (1) good; (2) acceptable; or (3) not appropriate (for each pulmonary vein ostium). If it was not possible to visualize the right-sided or left-sided PVs at all this was noted as well. The variations of the PV anatomy are summarized in Table 2. A detailed analysis of the 3D TEE findings concerning the left atrial anatomy has been published elsewhere<sup>[27]</sup>.

No other imaging techniques (MDCT or MRI) were used before or after the ablation procedures routinely.

### Ablation procedure

The ablation strategy was depending on the type of AF.

In patients with paroxysmal AF, two strategies were used. In some patients with paroxysmal AF, a circumferential pulmonary vein ablation was performed in combination with a potential-guided segmental approach in order to achieve complete pulmonary vein isolation [group A1; CARTO system (Biosense Webster, Diamond Bar, CA, United States)]. In most of the patients with paroxysmal AF, the cryoballoon technique (Medtronic, Minneapolis, MN, United States) was used (group A2). We refrained from using the cryoballoon technique if any variations of the pulmonary veins were detected by 3D TEE (e.g., common ostium, accessory pulmonary vein). In patients with persistent AF, a circumferential pulmonary vein ablation was performed in combination with a

potential-guided segmental approach to achieve complete pulmonary vein isolation (group B). Furthermore, a linear lesion was created at the roof of the left atrium in some patients. In addition, catheter ablation of the mitral isthmus was performed in selected cases [CARTO system (Biosense Webster)]. The ablation strategies have been described in detail in previous publications<sup>[20,27]</sup>.

In addition, catheter ablation of the right atrial isthmus was performed in patients with inducible or clinically documented episodes of typical atrial flutter. The completeness of the right atrial isthmus lines was confirmed by differential pacing maneuvers in all cases.

### Follow-up

After hospital discharge, patients were seen regularly on an outpatient basis. One month after the procedure, a physical examination, a resting electrocardiogram (ECG) and a transthoracic echocardiogram were performed. The patients were questioned whether there was any evidence for an arrhythmia recurrence. In addition, a long-term ECG recording (24-h) was performed.

Three months after the ablation procedure, the patients were re-examined in the same way except for the fact that a 7-d Holter monitoring was performed and that each patient underwent a repeat 3D TEE to rule out a pulmonary vein stenosis. Then, the patients were seen at 3-mo intervals if asymptomatic. If there was an arrhythmia recurrence or other problems occurred, the further follow-up and future strategy (e.g., medical therapy, electrical cardioversion, repeat ablation procedure) were planned on an individual basis.

Twelve months, twenty-four and forty-eight months after the ablation procedure another 7-d Holter monitoring was performed (or the results of repeated 24-h recordings obtained by the referring physicians were reviewed). A blanking period of 3 mo was employed after

ablation when evaluating the follow-up results.

Oral anticoagulation was continued for at least 3 mo after the procedure in all patients and was discontinued only in patients with a CHADS2 score  $\leq 1$  thereafter. Since October 2010 the CHADS2-VASc score was used for risk assessment and oral anticoagulation was only discontinued in patients with a CHADS2-VASc score  $\leq 1$  three months after the ablation procedure (vitamin K antagonist/novel oral anticoagulants). During the first three months after catheter ablation the patients received the same antiarrhythmic medication as prior to the ablation procedure. If there was no evidence for an arrhythmia recurrence all antiarrhythmic drugs were discontinued thereafter except for beta-blockers.

### Statistical analysis

Clinical characteristics of the three study groups were compared at baseline to discover potential sources of bias. All parameters with a normal distribution are given as mean ( $\pm 1$  SD). Age, left ventricular ejection fraction, total procedure time, fluoroscopy dosage and follow-up duration were compared using an one-way ANOVA. All other parameters (underlying cardiac disease, gender) were analysed using the  $\chi^2$  test. The  $\chi^2$  test was also used for analysing the clinical endpoints (arrhythmia recurrence rate at 48-mo follow-up). Significance was accepted if the *P* value was  $\leq 0.05$ . The statistical package of JMP (Version 3.2.6, SAS Institute, Cary, NC, United States) was used for data analysis. The data evaluation was reviewed by an expert in biostatistics of our institution.

## RESULTS

The study cohort consisted of fifty patients who were enrolled between October 2007 and May 2011. They had recurrent episodes of persistent or paroxysmal AF. Catheter ablation was performed in these patients after prior 3D TEE data acquisition. In all patients, this was the first AF ablation procedure. Catheter ablation of AF could be carried out as intended in all of them.

### Ablation strategy

In some patients with paroxysmal AF a circumferential pulmonary vein ablation in combination with a potential-guided segmental approach was carried out [group A1: 11 patients; Carto system (Biosense Webster)].

In the remaining 19 patients with paroxysmal AF, the cryoballoon technique was used (group A2; Medtronic). In all of them, a 28-mm cryoballoon was chosen at the beginning of the procedure. In 4 patients, a second cryoballoon (23 mm;  $n = 1$ ; poorly accessible right inferior pulmonary vein) or a standard cryoablation catheter (Freezor Max, Medtronic;  $n = 3$ ; rather large left-sided PVs as identified by 3D TEE) had to be used to achieve complete isolation of the PVs.

In all twenty patients with persistent AF, a circumferential pulmonary vein ablation in combination with a potential-guided segmental approach was the standard strategy (group B). Moreover, linear ablation across the left atrial roof was carried out in 7 patients with persistent AF. A mitral isthmus line was created in two patients in group B.

Additionally, catheter ablation of the cavotricuspid isthmus was carried out in 5 patients in group A (A1: 4 patients, A2: 1 patient) and in 2 patients in group B.

### Procedural results

The procedural results were published elsewhere<sup>[27]</sup>. In brief, a circumferential pulmonary vein ablation was carried out in all patients in group A1. This was combined with a potential-guided segmental approach if necessary. This resulted in the complete isolation of all 4 PVs in all patients in group A1.

In group A2, all cryoablation procedures could be completed successfully using this technique (mean number of successfully isolated PVs per patient: 3.9 (SD  $\pm 0.7$  PVs)).

The circumferential ablation strategy encircling the lateral and the septal PVs could be carried out successfully in all patients in group B [sometimes in combination with a potential-guided segmental approach (12 out of 20 patients)]. This resulted in complete isolation of a mean number of 3.8 PVs/patient [(SD  $\pm 0.9$  PVs); group B]. A complete linear lesion across the left atrial roof could be created in 7 patients in group B (7/7 patients). In addition, a continuous mitral isthmus line was achieved in two patients (10%) in this group B.

Successful ablation of the cavotricuspid isthmus was carried out in a total of 7 patients (group A1: 4 patients, group A2: 1 patient, group B: 2 patients).

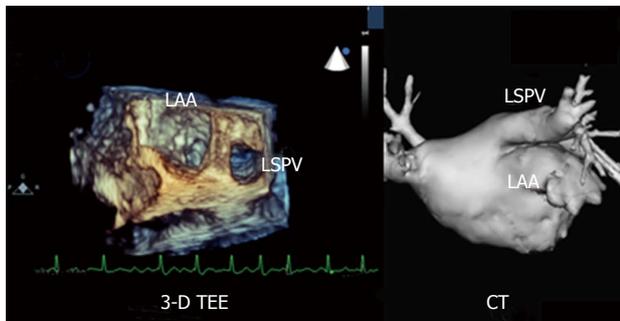

In both groups, no major complications (*e.g.*, neurologic disorders, significant pericardial effusion, PV stenosis  $\geq 70\%$ , periprocedural death) were observed during the procedure.

### Clinical outcomes

In group A, the mean follow-up duration was 1526 d (SD  $\pm 423$  d). In group B, the mean follow-up duration was 1697 d (SD  $\pm 208$  d;  $P = 0.1$ ). Thus, the mean overall

**Table 3 Long-term follow-up data**

	Group A	Group A1	Group A2	Group B	Total	P
Midterm follow-up (12 mo)	26/30	10/11	16/19	15/20	41/50	0.82
No. of patients without any arrhythmia recurrence	(86.7%)	(90.6%)	(84.2%)	(75.0%)	(82.0%)	
Long-term follow-up (4 yr)	22/30	8/11	14/19	12/20	34/50	0.62
No. of patients without any arrhythmia recurrence	(73.3%)	(72.7%)	(73.7%)	(60.0%)	(68.0%)	

**Figure 1 Three-dimensional transesophageal echocardiography-reconstruction providing an overview over the left atrial anatomy.** LSPV: Left superior pulmonary vein; LAA: Left atrial appendage; CT: Computed tomography; 3-D TEE: Three-dimensional transesophageal echocardiography.

follow-up duration was 1595 d (SD ± 360 d) (Table 3).

At 4-year follow-up, 73.3% of the study population in group A [22/30; A1: 72.7% (8/11)/A2: 73.7% (14/19)] and 60.0% of the study population in group B (12/20) were free from atrial tachyarrhythmias (*P* = 0.62). Thus, the overall rate of freedom from arrhythmia recurrences was 68.0% (no more atrial tachyarrhythmias in 34 out of 50 patients).

Four years after the procedure, 39/50 patients (78%) were clinically asymptomatic.

No major complications were observed within a follow-up period of 48 mo. Minor complications were observed in 10 patients (group: A1/A2/B: 3/2/5 patients; groin hematoma: 3 patients, pulmonary vein stenosis 30%: 1 patient, noninfectious pericarditis: 3 patients, minor pericardial effusion: 1 patient, hyperthyroidism; 1 patient, residual defect of the atrial septum; 1 patient).

In patients with recurrent atrial tachyarrhythmias, 7-d Holter monitoring demonstrated recurrent episodes of paroxysmal AF in 12 patients [group A: 9 patients (A1: 7/A2: 2); group B: 3 patients] and persistent AF in 4 patients [group A: 2 patients (A1: 1/A2: 1); group B: 2 patients]. No modification of the antiarrhythmic drug regimen and no redo procedure was necessary in 5 patients (group A1/A2/B: 1/1/3 patients) with recurrent atrial arrhythmias because they were almost free of symptoms. In 4 patients (group A1/A2/B: 1/0/3) relief of symptoms could be achieved by changing the antiarrhythmic drug regimen or an electrical cardioversion. In seven symptomatic patients a repeat ablation was necessary (group A1/A2/B: 1/4/2 patients).

**Cardiac imaging**

A 3D transesophageal echocardiography was carried out

in all 50 patients. All pulmonary veins could be visualized in 42/50 patients (84%; group A1/A2/B: 8/16/18 patients). In 8 patients (group A1/A2/B: 3/3/2), the right PVs could not be evaluated (RSPV: 0 patients; RIPV: 2 patients; RSPV+RIPV: 6 patients). The left-sided PVs could not be evaluated in 5/50 patients (group A1/A2/B: 3/0/2 patients). In all of these patients, both left-sided PVs could not be evaluated (Figures 1 and 2).

Some variations of the left atrial morphology were revealed (such as a right-sided accessory pulmonary vein or a common ostium of the left-sided or the right-sided PVs) (Table 2).

Based on the detailed knowledge of the individual left atrial anatomy the ablation strategy could be modified appropriately if necessary<sup>[27]</sup>. Thereby, major complications were avoided.

**DISCUSSION**

Catheter ablation is an important therapeutic tool in patients with recurrent symptomatic episodes of paroxysmal or persistent AF. This technique is effective in restoring and maintaining sinus rhythm even if antiarrhythmic drugs have failed or should be avoided. However, these ablation procedures are quite challenging. This is due to the fact that there are a lot of variations concerning the pulmonary vein and left atrial anatomy. 3D TEE provides detailed insights into the pulmonary vein anatomy of individual patients. In contrast to MDCT or MRI it is not associated with problems such as radiation exposure or impaired image quality if AF with rapid atrioventricular nodal conduction is present<sup>[27]</sup>.

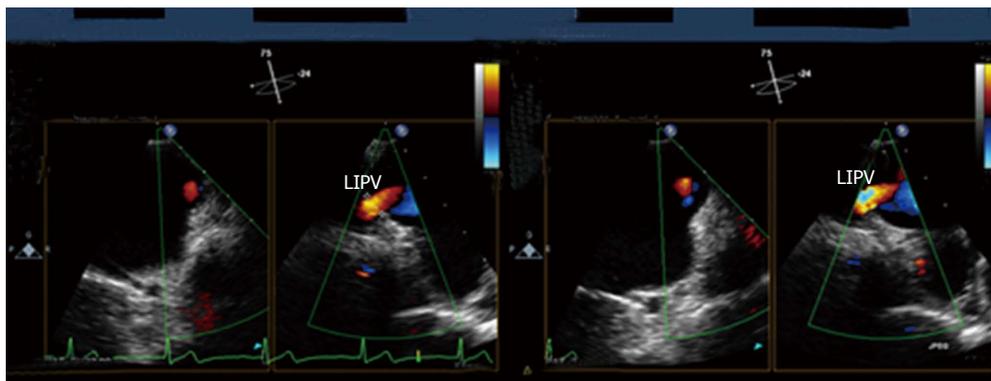

The study was performed to evaluate whether catheter ablation of atrial fibrillation facilitated by preprocedural 3D TEE is associated with a favourable long-term outcome.

**Main results**

The ablation procedures could be performed successfully in all patients in both groups after prior pulmonary vein imaging using 3D transesophageal echocardiography.

During a follow-up duration of 4 years, 73.3% of patients in group A (22/30) remained free from recurrent atrial tachyarrhythmias. In group B, 60.0% of patients (12/20, *P* = 0.62) remained free from an arrhythmia recurrence during a follow-up duration of 4 years. Thus, the overall rate of patients free from an arrhythmia recurrence was 68% at 4-year follow-up. No major complications were observed in both groups during long-term follow-up.

The data provided by our study shows that radio-

**Figure 2** Three-dimensional transesophageal echocardiography performed 3 years after catheter ablation of atrial fibrillation. Slightly increased flow velocity in the left inferior pulmonary vein (LIPV) ostium indicating a minor pulmonary vein stenosis [pulmonary vein diameter at 3-year follow-up: 2.1 mm (compared to 2.6 mm at baseline)].

frequency catheter ablation as well as cryoablation of AF can be performed effectively and safely after pre-procedural 3D TEE imaging. Pulmonary vein imaging prior to an ablation procedure using 3D TEE is associated with favourable long-term follow-up results concerning safety as well as efficacy of the procedures. Transesophageal echocardiography is recommended prior to catheter ablation of AF anyway (to rule out left atrial thrombus formation). Therefore, a 3D transesophageal echocardiography does not result in additional discomfort for the patient or additional cost. Furthermore, it is less time-consuming than performing an additional MDCT or MRI.

### Limitations

This is the long-term follow-up data of a feasibility study analysing our initial experience with AF ablation procedures facilitated by pre-procedural 3D TEE imaging. The target of our present study was to evaluate the usefulness of 3D TEE for LA visualization prior to an ablation procedure and to show that it is associated with a favourable outcome after catheter ablation of AF. The study was not designed to prove that this technique is equivalent to or superior to other imaging techniques (MDCT/MRI). Therefore, no comparison to MDCT or MRI data is provided.

Furthermore, this study was not designed to prove that pulmonary vein imaging (3D TEE, MDCT or MRI) does significantly improve the long-term outcome in comparison to patients not undergoing preprocedural PV imaging in a prospective randomized way.

Moreover, there are some technical limitations of 3D transesophageal echocardiography: First, the right pulmonary veins are sometimes difficult to visualize. Second, the 3D TEE images can only be displayed in a synchronized way during the ablation procedure and no direct image fusion with the geometry created with a 3D mapping system [Navx/Ensite (St. Jude Medical, Saint Paul, MN, United States) or CARTO (Biosense Webster)] is available so far.

In conclusion, Catheter ablation of AF can be performed with favourable results with regard to the

success rate as well as to the complication rate based on prior 3D TEE imaging. Three-dimensional TEE-models provide a good overview over the left atrial anatomy, thereby facilitating the procedure. Typical problems (such as atypical PV anatomy, variable relationship between the left atrial appendage and the left superior pulmonary vein) can be revealed. Then, the ablation strategy can be modified and complications can be avoided.

The results of our study demonstrate that pulmonary vein imaging prior to catheter ablation of AF is associated with a favourable long-term outcome with regard to a relatively high success rate and a very low complication rate. However, large randomized studies are needed to prove that this approach is superior to standard ablation procedures (either using 3D MRI-/MDCT reconstructions or no preprocedural imaging) with regard to various outcome parameters (*e.g.*, success and complication rates, procedure duration, radiation exposure).

## COMMENTS

### Background

Catheter ablation is an important therapeutic tool in patients with symptomatic atrial fibrillation (AF). However, these ablation procedures are quite challenging. This is due to the fact that there are a lot of variations concerning the pulmonary vein and left atrial anatomy. Three-dimensional transesophageal echocardiography (3D TEE) might be useful for analysing the individual left atrial morphology prior to an ablation procedure.

### Research frontiers

However, it is a matter of discussion whether the use of this technique is associated with a favourable long-term outcome with regard to the safety and efficacy of the procedures.

### Innovations and breakthroughs

A 3D TEE was performed successfully before the ablation procedure in all patients. All four pulmonary veins could be visualized in 84% of patients. The image quality was excellent in the majority of patients. Several pitfalls of the pulmonary vein morphology could be revealed (*e.g.*, accessory pulmonary veins, common pulmonary vein ostia, variable relationship between the left atrial appendage and the left superior pulmonary vein). All ablation procedures could be performed as planned. At 48-mo follow-up, 68.0% of all patients remained free from atrial tachyarrhythmias (group A1: 72.7%, group A2: 73.7%, group B: 60.0%). There was no major complications.

## Applications

The results of the study demonstrate that 3D TEE allows detailed insights into the left atrial anatomy. Catheter ablation of AF can be performed safely based on prior 3D TEE imaging.

## Terminology

Catheter ablation: Therapeutic option for the treatment of cardiac arrhythmias (catheter-based); atrial fibrillation: Atrial arrhythmia with a disorganized activation sequence.

## Peer-review

This is an interesting article. The authors have provided us with a semi-invasive method (first line or complementary) for monitoring the procedure during catheter ablation of paroxysmal and persistent AF.

**Abstract****AIM**

To describe the long-term follow-up of patients with complex congenital heart disease who underwent subcutaneous implantable cardiac defibrillator (S-ICD), focusing on local complications, appropriate and inappropriate shocks.

**METHODS**

Patients with complex congenital heart disease underwent S-ICD implant in two centers with the conventional technique. Data at follow-up were retrieved from clinical notes and institutional database.

**RESULTS**

Eight patients were implanted in two centres between 2010 and 2016. Median age at implant was 37.5 years (range 13-57). All patients who were deemed suitable for S-ICD implant passed the pre-procedural screening. Three patients were previously implanted with an anti-bradycardia device, one of whom with CRT. In one patient the device was explanted due to local infection. During

the total median follow-up of 874 d, one patient had an appropriate and one inappropriate shock triggered by fast atrial tachycardia. None of the patients had inappropriate shocks secondary to T wave oversensing or electrical interference with anti-bradycardia devices.

### CONCLUSION

S-ICD appears to be effective and safe in patients with complex congenital heart disease.

**Key words:** Subcutaneous defibrillator; Congenital heart disease; Outcomes

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Implantation of subcutaneous implantable cardiac defibrillator in patients with complex congenital heart disease appears to be effective and reliable at long term follow-up. The high proportion of grossly abnormal baseline electrocardiogram and the significant incidence of atrial arrhythmias does not seem to affect the rate of inappropriate shocks.

## INTRODUCTION

Arrhythmic complications are common in patients with congenital heart disease (CHD) requiring implantation of an anti-tachycardic device<sup>[1]</sup>. Traditional endocardial approach can be particularly challenging in these patients due to limited vascular access, intracardiac shunts or abnormal cardiac chambers<sup>[2]</sup>. Furthermore the trans venous implantable cardiac defibrillator (ICD) implant carries a risk of long term lead related complication, which have been reported in up to 20% of cases at 10 years<sup>[3]</sup>. This figure is thought to be even higher in the pediatric and CHD population. Most of the long-term event in this clinical setting are lead related<sup>[4]</sup>. Alternative implant techniques have been devised in this population, including surgical epicardial or subcutaneous coils implant. Unfortunately, these non trans-venous approaches are associated with a higher procedural risk and have a significant failure rate during follow-up<sup>[5]</sup>. The entirely subcutaneous ICD (S-ICD) proved to be effective and safe in patients fulfilling both primary and secondary prevention indication<sup>[6]</sup>. This technology is particular appealing for CHD subjects, as it does not involve the implantation of lead within the cardiac chambers. Data about the performance of S-ICD in this subset of patients are still scant, particularly as far as the long-term outcomes are concerned. A major theoretical concern of the S-ICD in

this population is related to the presence of significant ventricular hypertrophy causing profound anomalies of both depolarization and repolarization phase on the surface electrocardiogram (ECG) and the high incidence of atrial tachycardia<sup>[7]</sup>. In theory, both these issues could lead to an inappropriate shock in the long-term follow-up. Furthermore, a significant proportion of patient with CHD develop atrial-ventricular conduction impairment either as the result of their specific congenital lesion or after cardiac surgery requiring long term pacing. A recent sub analysis from a pooled analysis of the IDE and EFFORTLESS registry showed the safety of S-ICD in patients with CHD<sup>[8]</sup>. However, during the median follow-up of 567 d none of the patients had any appropriate shocks, consequently no observations about the efficacy of this technology could be performed<sup>[9]</sup>.

In this article, we report medium and long term follow-up in eight patients with complex CHD implanted with a S-ICD, reflecting the experience of two adult CHD referral centres. The details of previous surgical history, the occurrence of either appropriate or inappropriate shocks, local complications, and interference with previously implanted anti-bradycardia and CRT devices are described.

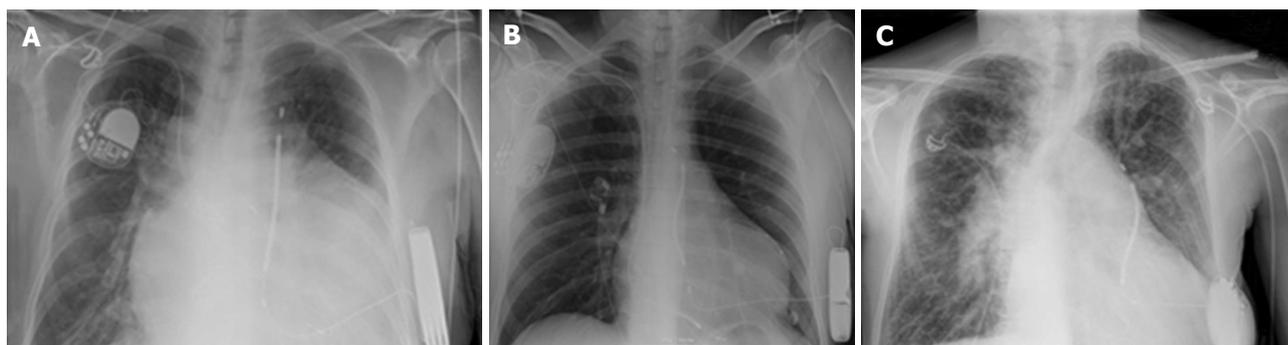

## MATERIALS AND METHODS

Patients with CHD were implanted with a S-ICD in two centres between 2010 and 2016. All patients underwent pre-implant eligibility screening. Suitability for S-ICD implantation was pre-assessed by a standardized protocol recommended by the manufacture, as previously published. This included assessment of the QRS and T wave amplitude ratio in at least two different postures (supine and standing), and during exercise on a treadmill<sup>[10]</sup>. Implant was performed under general anaesthesia with the conventional technique. Briefly, the device and lead positioning was guided by standard chest anatomical landmarks and fluoroscopy to ensure proper vector configuration across the cardiac silhouette. All devices but one were programmed from the beginning with a shock conditional zone (180-240 beats per minute, bpm) and a shock only zone above 240 bpm. All patients underwent defibrillation testing by induction of ventricular fibrillation using 50 Hz current to assess accurate detection and effective termination of the arrhythmia. Clinical and surgical details were retrieved from institutional databases. All patients implanted underwent regular follow-up at 1 and 6 mo thereafter. Data about patient clinical status, occurrence of local complication, arrhythmic burden, inappropriate and appropriate shocks were recorded.

## RESULTS

### Pre implant clinical details

Eight patients were implanted with a S-ICD device between 2010 and 2016 in two centres. Median age at implant was 37.5 years (range 13-57). Seven patients had a secondary prevention indication while one patient was implanted after one episode of syncope and documented

**Figure 1** A new transeptal endocardial lead was implanted in the left ventricle and the atrial septal defect was thereafter successfully closed with an occlude device. A: Subcutaneous implantable cardiac defibrillator and endocardial pacing system in a patient post Mustard operation; B: Patient with ASD and dilative DCM who previously underwent left ventricle lead implant; C: Patient with Eisenmenger syndrome. ASD: Atrial septal defect; DCM: Dilative cardiomyopathy.

Table 1 Pre implant clinical and anatomical characteristics							
Anatomical diagnosis	Sex	Age at implant (yr)	Pre implant ECG	Indication	Reason for SICD	Prev implant	F.U (d)
TOF	F	47	RBBB + RVH	VT	Tricuspid mech valve	No	360
VSD subaortic obstr.	M	52	LVH	Out hospital card arrest	Previous endocarditis	No	334
TGA, Mustard	M	36	RBBB + RVH	VF	SVC baffle stenosis	Yes	486
DILV TGA Eisenmenger	M	57	IVCD (aspecific)	Sustained VT	Right to left shunt	No	1139
ASD DCM	M	39	Paced LV endo	Syncope sustained VT	Previous leads implanted	Yes	1827
TGA, Mustard	M	24	Paced sub pulm vent.	Syncope NOT Sustained VT	SVC baffle occlusion	No	1890
HLVS Fontan	M	13	IVCD + RVH	Sustained VT	Extracardiac Fontan	No	1499
TGA VSD	M	23	RBBB + RVH	Sustained VT	TV repair	Yes	90

TOF: Tetralogy of Fallot; VSD: Ventricular septal defect; TGA: Transposition of great arteries; DILV: Double inlet left ventricle; ASD: Atrial septal defect; HLVS: Hypoplastic left ventricle syndrome; ECG: Electrocardiogram; RBBB: Right bundle branch block; RVH: Right ventricular hypertrophy; LVH: Left ventricular hypertrophy; IVCD: Inferior vena cava diameter; VF: Ventricular fibrillatio; LV: Left ventricular; DCM: Dilative cardiomyopathy; VT: Ventricular tachycardia; SICD: Subcutaneous implantable cardiac defibrillator; SVC: Superior vena cava; TV: Tricuspid Valve.

not-sustained ventricular tachycardia. The anatomical diagnoses were: Tetralogy of Fallot, repaired ventricular septal defect with subaortic obstruction, transposition of the great arteries that underwent Mustard repair, double inlet left ventricle with Eisenmenger physiology, atrial septal defect associated with cardiomyopathy. Three patients (37.5%) had previously undergone endocardial pacemaker implantation due to brady-tachyarrhythmic syndrome in two cases, and a CRT device in the other one (Figures 1A, B and 2). Four patients (50%) had a previous history of documented paroxysmal atrial tachyarrhythmia. The reasons for S-ICD vs conventional endocardial approach were limited or difficult access to the cardiac chambers in five patient, high infective risk in two patients and presence of right to left shunt in one patient (Table 1). In all patients, the option of conventional ICD was offered and discussed as part of the preoperative consent process.

**Pre implant ECG and screening details**

Pre implant ECG showed right bundle branch block in 3 patients (37.5 %), non specific interventricular conduction delay in two patients (28%), narrow QRS with left ventricular (LV) hypertrophy in one patient (12.5%), and paced QRS in two patients. Overall the QRS duration ranged from 110 ms to 180 ms (Table 1). All patients clinically deemed as good candidate for S-ICD passed the pre-implant screening (100% success rate). We did not

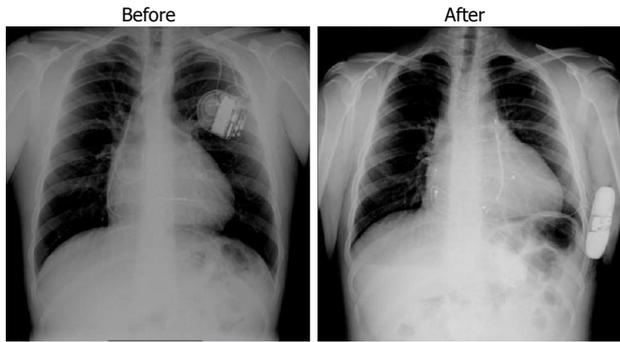

observe any difference in the QRS/T ratio between the left and right position of the electrodes.

**Operative issues**

Median procedural time was 65 min (range 58-90 min). The use of fluoroscopy was limited to check the proper position of the device and coil relative to the cardiac silhouette. In the patient with an epicardial pacing system, the coil was tunneled in the usual way without creating any mechanical interference with the previously implanted pacing lead (Figure 2). In one patient with a systemic right ventricle following Mustard operation the defibrillation test was effective only at 80 J despite repositioning of the pulse generator. None of the patients had significant bleeding during the procedure.

**Follow-up and outcomes**

Median follow-up was 812 d (range 90-1890). In four patients (50%) a follow-up longer than three years was available. Figure 3 depicts a summary of the events occurred in each individual patient according to the background anatomy. During follow-up, one patient underwent device extraction due to local infection secondary to hematoma eight months after the implant. This patient did not develop any signs of systemic infection and underwent subsequent surgical epicardial implantation. Three patients had multiple episodes of

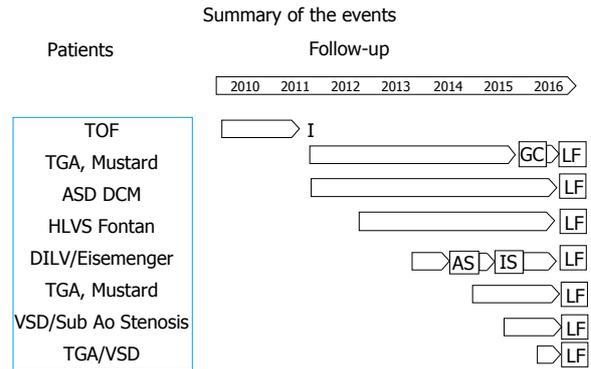

**Figure 2 Hybrid implant (subcutaneous implantable cardiac defibrillator and epicardial pacing).** The patient developed severe tricuspid regurgitation related to the endocardial lead previously implanted.

documented sustained atrial tachycardia (four clinically relevant episodes requiring admission and arrhythmia termination), triggering an inappropriate shock in one patient 18 mo after the implant (inappropriate discharge overall rate 12.5%). These patients had a history of atrial tachycardia before the implant. The same patient had an effective, appropriate shock due to fast ventricular tachycardia that occurred after eight months (appropriate discharge overall rate 12.5%). None of the patients had inappropriate shocks related to over-sensing. One patient underwent uncomplicated pulse generator replacement owing to battery depletion. One patient with large atrial septal defect associated with cardiomyopathy developed progressive LV dysfunction and underwent upgrading to biventricular stimulation. The trans-coronary sinus left LV lead was then switched off as it was causing diaphragmatic capture in the bipolar configuration and interference with the S-ICD in the unipolar one. A new transeptal endocardial lead was implanted in the left ventricle and the atrial septal defect was thereafter successfully closed with an occlude device (Figure 1). In the remaining two patients with conventional endocardial pacing system we did not observe any electrical interference during follow-up.

## DISCUSSION

Abnormal cardiac rhythm is the most common cause of hospital admission in adults with CHD. The absolute risk of sudden death and/or ventricular arrhythmias increases with prolonged follow-up, particularly in the subset of patients with reduced systemic ventricular function and evidence of extensive scar within the ventricular mass<sup>[11]</sup>. The risk of sudden death in the adult CHD population ranges from 0.1% and 0.5% per year<sup>[12,13]</sup>. However, there is no established guidance for ICD implantation in this group of patients apart from those fulfilling a secondary prevention indication. It is well recognized that ICD implantation in adult CHD might be particularly technically challenging due to vascular access issues or to the complex anatomy. Furthermore, complications at follow-up are significantly higher when compared to the general population of ICD recipients. These include

**Figure 3 Summary of the events during follow-up according to different anatomic background.** TOF: Tetralogy of Fallot; VSD: Ventricular septal defect; TGA: Transposition of great arteries; DILV: Double inlet left ventricle; ASD: Atrial septal defect; HLVS: Hypoplastic left ventricle syndrome; I: Infection; IS: Inappropriate shock; AS: Appropriate shock; GC: Generator change; LF: Last follow-up; DCM: Dilatative cardiomyopathy.

endocarditis in patient with prosthetic valve or residual native valve disease, baffle obstruction in patients who underwent atrial switch, and thromboembolism in patient with intracardiac shunts. S-ICD represents an attractive alternative for this population and may offer an effective protection against sudden death in a higher proportion of patients with reduced morbidity.

## Screening issues

Effective screening plays a pivotal role in selecting CHD subjects for the S-ICD. In congenital heart patients, a particular concern is the presence of a large percentage of T wave inversion or enlargement throughout the precordial leads, secondary to ventricular hypertrophy, right bundle branch block, or a paced QRS complex. These features, have been reported as a risk factor for ECG screening failure in the S-ICD<sup>[14,15]</sup>. Despite the fact that most of our patient had right bundle branch block and two had a paced ventricular complex, all passed the preimplant screening. Contrary to experience reported previously, all patients passed the screening with electrodes positioned on the left parasternal edge<sup>[16]</sup>. This finding should be interpreted cautiously owing to the small sample size, and might simply reflect the variability in ECG presentation in this population or the highly unpredictable vector configuration.

## Long-term outcomes

As expected, a significant proportion of patient (37%) had multiple episodes of sustained atrial tachycardia that were correctly discriminated by the device. Overall two patients had device related complications (an early local hematoma and an inappropriate shock). Only one patient had one appropriate and one inappropriate shock, accounting for a cumulative incidence of inappropriate shock over the follow-up of 1.5%. The device settings were optimized by activating the conditional shock zone. However, this percentage is consistent with the one reported in the IDE and EFFORTLESS, confirming

the reliability of the S-ICD algorithm in discriminating supraventricular from ventricular tachycardias, even in this clinical setting characterized by a high incidence of atrial arrhythmias<sup>[17]</sup>. One patient had an appropriate shock during the entire follow-up (cumulative prevalence 12.5%). Although consistent with the EFFORTLESS registry data, this percentage was lower compared with the population of patients with endocardial ICD<sup>[18]</sup>. Interestingly, a significant number of self-terminating ventricular tachycardia episodes were detected at follow-up, underscoring the appropriateness of a deliberate high cut-off rate and long time to therapy setting in this subset of patient. Furthermore, the low percentage of shocks also reflects the overall lower arrhythmic risk in patients with CHD as compared with patients with cardiomyopathies or ischaemic substrates, as already observed<sup>[12]</sup>.

### S-ICD in patients requiring anti-bradycardic pacing

A theoretical major limitation in the eligibility of CHD patient for S-ICD is the high likelihood of developing pacing dependency during follow-up. Data about the effect of a previously implanted endocardial pulse generator on the long term performance of the S-ICD are limited. In the EFFORTLESS registry, 2.8% of patients had a anti-bradycardic pacemaker implanted. In the CHD population, the experience of combined implantation of S-ICD and pacemaker did not raise concern regarding electrical interferences<sup>[19]</sup>. Although a significant proportion of patients had a pacemaker previously implanted, we did not reported clinical relevant electrical interferences in any patient but one in which the LV lead was temporarily programmed in the unipolar configuration. This finding suggest the long-term compatibility of the S-ICD with an endocardial anti-bradycardic device, provided that pacing configuration is bipolar. This safety issue, if consistently confirmed, may theoretically extend the indication to S-ICD in this particular subset of patients.

Our data suggest that S-ICD might represent a valid option for patient with complex CHD at high risk of sudden death. This technology may overcome some of the technical constrain and long-term risk related to the conventional transvenous ICD, eventually expanding the eligibility of this subset of patient for anti-tachycardic therapy.

### Limitations

A major limitation of this paper is the low number of patients, which reflect the experience of only two centres. Furthermore, we do not have a matched group of CHD patients who underwent transvenous ICD implant as control group. Systematic collection of prospective data is needed to support S-ICD as a routine alternative in this population.

## COMMENTS

### Background

Endocardial implant of devices in patients with congenital heart disease may pose a particular challenge owing to limited vascular access and complex

anatomy. Furthermore conventional endocardial pacing in this population is associated with a higher risk of lead related complications.

### Research frontiers

Subcutaneous implantable cardiac defibrillator (S-ICD) has been proved to be effective and safe in patients with a wide range of cardiomyopathies and arrhythmogenic syndromes. Limited evidences from subgroup of patients enrolled in clinical trials support the extension of the use of this technology in patients with structural heart disease.

### Innovations and breakthroughs

This paper report data relative to a uniquely long follow-up patients with congenital heart disease that underwent S-ICD implantation. Although the number of patients is low they represent a wide range of clinical settings, including single ventricle physiology.

### Applications

ICD implantation in patients with congenital heart disease is still a matter of debate, particularly concerning primary prevention indication. The development and optimization of subcutaneous technology might be a suitable tool to provide and extend the protection against sudden death in this group of patients.

### Terminology

S-ICD is a relative new technology made of a pulse generator connected with a coil. The whole system is implanted subcutaneously and is able to provide effective termination of fast rhythm by DC shock and only limited back up pacing.

### Peer-review

Very interesting and well written article. It gives an important overview of the topic in a subgroup of very complex patients.

### Abstract

#### AIM

To conduct a review of "interferon related pericarditis".

#### METHODS

We searched MEDLINE, EMBASE, Cinahl, and the Co-

chrane Database from the earliest available date through September 2016. A search strategy using the Medical Subject Headings and text keywords "interferon" and "pericarditis" were used.

#### RESULTS

Nine case reports were eligible for the present study. Six of 8 cases were women and the mean age was  $43.8 \pm 13.8$  years with chronic hepatitis C in 6 cases, malignant melanoma in 2 cases and chronic myelogenous leukemia in 1 case. The patients complained of chest pain in 6 cases, dyspnea in 5 cases and edema in 2 cases. Pericardial friction rub was heard in 3 of 9 cases. Congestive heart failure occurred in 3 of 9 cases. Two mechanisms for pericarditis were demonstrated, one is autoimmune included lupus like syndrome in 2 cases and the other is cardio toxicity in 4 cases. Treatment of interferon related pericarditis is discontinuation of Interferon treatment. Four of 9 cases were treated with prednisone and 4 with nonsteroidal anti-inflammatory drugs.

#### CONCLUSION

Interferon related pericarditis still remains uncertain. Treatment of interferon related pericarditis rests mainly on early recognition and drug discontinuation. Interferon related pericarditis was treated with steroid and/or non-steroidal anti-inflammatory drugs.

**Key words:** Chronic hepatitis C; Chronic myelogeneous leukemia; Interferon; Malignant lymphoma; Pericarditis

**Core tip:** Interferon is considered to be one of the treatments for many diseases. However, interferon therapy is associated with side effects. Recently some reports demonstrated acute pericarditis complicating interferon therapy. Two mechanisms for pericarditis were demonstrated, one is autoimmune included lupus like syndrome and the other is cardio toxicity. However, these two mechanisms are controversial. The aim of this study is to review of "interferon related pericarditis".

Nishio K, Arase T, Tada H, Tachibana H. Interferon related pericarditis: Review. *World J Cardiol* 2017; 9(6): 553-557 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i6/553.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i6.553>

## INTRODUCTION

Interferon is considered to be one of the treatments for many diseases. However, interferon therapy is associated with side effects, the most common being general symptoms such as fever, weight loss and headache. Some studies have demonstrated cardiac adverse effects of interferon for chronic hepatitis C (CHC)<sup>[1,2]</sup>. Most frequently reported are arrhythmia, congestive heart failure and sudden death. Reported with rarer frequency are polyneuropathy, paranoia and suicidal thoughts, diabetes mellitus, retinopathy, optical neuritis, diminution of hearing, seizures, loss of libido and cardio toxicity<sup>[3]</sup>. Recently some reports demonstrated acute pericarditis complicating interferon therapy<sup>[4-12]</sup>. We conducted a review of "interferon related pericarditis".

## MATERIALS AND METHODS

### Selection of case reports

We searched MEDLINE, EMBASE, Cinahl, and the Cochrane Database from the earliest available date through September 2016. A search strategy using the Medical Subject Headings and text keywords "interferon" and "pericarditis" were used. The retrieved studies were manually screened to assess their appropriateness for this study. All references cited in the studies were also reviewed to identify additional published articles not indexed in the database. The search was not restricted by language.

## RESULTS

### Patients

Nine case reports were eligible for the present study; seven were in English<sup>[4,5,7,8,10-12]</sup> and two in French<sup>[6,9]</sup>. Clinical characteristics of patients are shown in Table 1. Six of 8 cases were women and the mean age was  $43.8 \pm 13.8$  years with CHC in 6 cases, malignant melanoma in 2 cases and chronic myelogenous leukemia in 1 case. The patients complained of chest pain in 6 cases, dyspnea in 5 cases and edema in 2 cases. Pericardial friction rub was heard in 3 of 9 cases<sup>[5,8,9]</sup>. Congestive heart failure occurred in 3 of 9 cases<sup>[8-10]</sup>. Two mechanisms for pericarditis were demonstrated, one is autoimmune included lupus like syndrome (AI group) in 2 cases and the other is cardio toxicity (CT group) in 4 cases. Three of 9 articles didn't mention the mechanisms for pericarditis.

### Clinical history

Three cases had clinical history. The 28-year-old patient had allergic asthma since infancy<sup>[4]</sup>. The 24-year-old woman following therapy with interferon  $\alpha$  was diagnosed

with systemic lupus erythematosus (SLE), and she was treated with prednisone (40 mg/d)<sup>[5]</sup>. When prednisone had been stopped completely for 3 mo, a pericarditis occurred. The patient had a recurrence of SLE. The 63-year-old man was diagnosed as diffuse large B cell non-Hodgkin's lymphoma and was treated with a full course of chemotherapy consisting of cyclophosphamide, adriamycin, vincristine and dexamethasone<sup>[8]</sup>.

### Laboratory findings

The woman with SLE<sup>[5]</sup> experienced four episodes of fever and pain in the left shoulder while breathing. Antinuclear antibody and anti-ds DNA antibody tests were negative, whereas circulating immune complexes were positive at the second and the third episode. CH50 and C4 levels were decreased with slightly elevated C3d level. Laboratory results of the 63-year-old man with non-Hodgkin's lymphoma presented antinuclear antibodies (titer 1/40)<sup>[8]</sup>. The blood sample examination of the 67-year-old man with CHC showed anti-DNA antibody and anti-ds DNA IgM were positive<sup>[10]</sup>.

### Interferon daily dose and duration of treatment with interferon

Figure 1 showed a relationship between the daily dose of interferon and the duration of treatment with interferon. Autoimmune due to interferon does not dependent on the daily dose but developed within one month with interferon treatment. Cardio toxicity due to interferon does not dependent on the daily dose or the duration of treatment with interferon.

### Chest radiography

Chest radiography demonstrated abnormalities in three cases. Chest X-ray of the 63-year-old man showed an enlarged heart silhouette and bilateral pleural effusion<sup>[8]</sup>. Chest radiograph of the 53-year-old woman showed cardiomegaly<sup>[9]</sup>. Portable chest radiograph of the 67-year-old man revealed pulmonary vascular congestion without pleural effusion<sup>[10]</sup>.

### Electrocardiogram

Electrocardiogram (ECG) demonstrated abnormality in one case. ECG showed gradual ST-segment elevation in leads V1 through V6 without elevated myocardial enzyme in the 67-year-old man<sup>[10]</sup>. Coronary angiography showed that there was no significant coronary arterial stenosis in this case.

### Ultrasound cardiology

Ultrasound cardiology (UCG) demonstrated pericardial effusion in 7 of 9 cases; mild in 2 cases<sup>[6,12]</sup>, moderate in 2 cases<sup>[4,10]</sup>, severe in 1 case<sup>[9]</sup>, and no presentation in 2 cases<sup>[7,11]</sup>. The 53-year-old female was diagnosed with constructive pericarditis with pre-tamponade<sup>[9]</sup>.

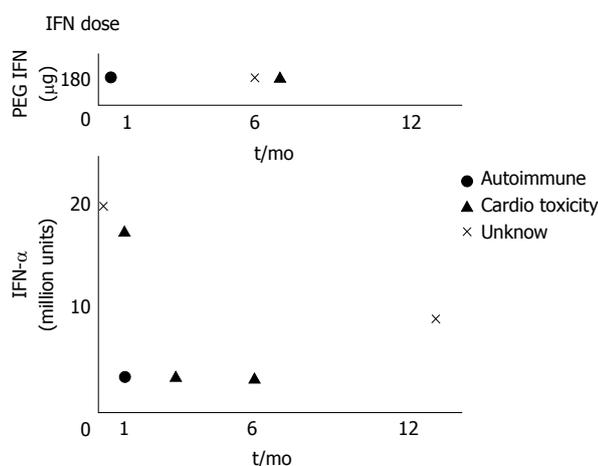

### Re-start and re-challenge test

The interferon treatment was restarted in three cases<sup>[4,6,11]</sup>. The 28-year-old patient suffered a pericarditis relapse at

**Table 1** Case reports of pericarditis associated with interferon

Ref.	Age/gender	Disease	Administered	Duration of IFN therapy	Mechanism
Fava <i>et al</i> <sup>[4]</sup>	28/NA	CML	IFN $\alpha$	13 mo	NA
Boonen <i>et al</i> <sup>[5]</sup>	24/F	CHC	IFN $\alpha$	1 mo	Autoimmune
Wisniewski <i>et al</i> <sup>[6]</sup>	42/F	CHC	IFN $\alpha$	6 h	Cardio toxicity
Gressens <i>et al</i> <sup>[7]</sup>	40/F	CHC	IFN $\alpha$ 2b	3 mo	Cardio toxicity
Benjamini <i>et al</i> <sup>[8]</sup>	63/M	MM	IFN $\alpha$ 2b	1 mo	Cardio toxicity
Hamdani <i>et al</i> <sup>[9]</sup>	53/F	CHC	PEG IFN $\alpha$ 2a	6 mo	NA

Popescu <i>et al</i> <sup>[11]</sup>	38/F	CHC	PEG IFN 2a	7 mo	Cardio toxicity
Ashraf <i>et al</i> <sup>[12]</sup>	39/F	MM	IFN $\alpha$	1 d	NA

CHC: Chronic hepatitis C; CML: Chronic myelogenous leukemia; F: Female; IFN: Interferon; M: Male; MM: Malignant melanoma; NA: Data not available; PEG IFN: Pegylated interferon.

**Figure 1** The relationship between interferon dose and duration of interferon therapy. PEG IFN: Pegylated interferon.

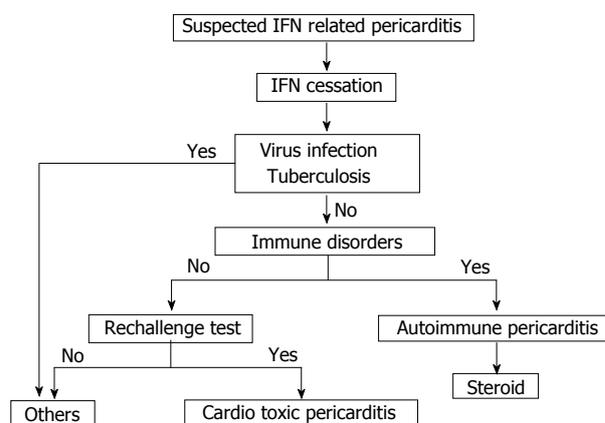

seven months after resumption of interferon  $\alpha$  therapy<sup>[4]</sup>. The 42-year-old female felt chest pain, after 7 h from administration of 1 million interferon  $\alpha$ <sup>[6]</sup>. After the first dose of interferon administration symptoms reappeared and UCG showed an increase of pericardial fluid in the 38-year-old female<sup>[11]</sup>. Re-challenge test was performed in one case<sup>[12]</sup>. Within ten hours of the re-initiation of interferon therapy, the 39-year-old woman developed chest pain identical to her previous pain.

### Complications

Two cases developed other complications. An electro-myography showed signs of polyneuropathy in the 40-year-old female<sup>[7]</sup>. The 67-year-old man developed chronic inflammatory demyelinating polyneuropathy during treatment with pegylated interferon-2a for chronic active hepatitis C viral infection<sup>[10]</sup>.

### Treatment

Treatment of drug-induced cardio toxicity rests mainly on early recognition and drug discontinuation. Interferon treatment was stopped in 7 of 9 cases. Four of 9 cases were treated with prednisone from 10 mg per day to 50 mg/d<sup>[4,5,8,10]</sup> and 4 with nonsteroidal anti-inflammatory drugs (NSAIDs)<sup>[5,7,11,12]</sup>. All of the AI group was treated with

**Figure 2** Algorithm of diagnoses and treatments for interferon related pericarditis. IFN: Interferon.

prednisone<sup>[5,10]</sup> and two of the CT group were treated with NSAIDs<sup>[7,11]</sup> and one of the CT group dexamethasone<sup>[8]</sup>. The 53-year-old female was treated with medications of anti-tuberculosis, but died because multiple organ failure<sup>[9]</sup>. Figure 2 showed an algorithm of the suspected interferon related pericarditis management.

## DISCUSSION

Cardiac adverse effects of interferon  $\alpha$  for CHC have been demonstrated<sup>[1,2]</sup>. Most frequently reported are arrhythmias, congestive heart failure and sudden death. These side effects occurred during treatment with interferon  $\alpha$ . However, pericarditis as a side effect of treatment with interferon is rare.

In 1988, the first report concerning interferon related pericarditis was presented by anonymity<sup>[13]</sup>. This report demonstrated two patients with continuous interferon therapy for chronic myelogenous leukemia had severe side effects consisting of pleural effusions and pericarditis. Montastruc *et al*<sup>[14]</sup> presented that there was an isolated pericarditis for which it was necessary to interrupt the interferon  $\alpha$  treatment. However, these two articles didn't describe in detail. Consequently, 9 articles were enrolled in the present study. Two mechanisms for pericarditis were demonstrated, one is autoimmune in 2 articles and

the other is cardio toxicity in 4 articles. Three of 9 articles didn't mention the mechanisms for pericarditis.

Prospective study reported on autoimmune phenomena in 987 patients treated with interferon for CHC. Twelve patients developed hyperthyroidism, 6 hypothyroidism, 3 interstitial pneumonia, 1 SLE, 2 rheumatoid arthritis, 2 autoimmune hepatitis and 1 autoimmune thrombocytopenic purpura<sup>[15]</sup>. In the present study, the appearance of lupus-like syndrome by the interferon treatment has been reported in 1 article and autoimmune in 1 article. The mechanism by which interferon  $\alpha$  induces autoimmune mediated complications is largely unknown. However, interferon alpha induces numerous target genes in antigen-presenting cells (APCs), such that APCs are stimulated and enhance humoral autoimmunity, promote isotype switching, and potentially activate autoreactive T cells. Moreover, interferon alpha can synergistically amplify T cell autoreactivity by directly promoting T-cell activation and keeping activated T cells alive. *Via* the latter mechanisms, interferon can trigger autoimmune diseases<sup>[16]</sup>. There is a possibility that interferon may damage endothelial cells, cause the thickening of capillary walls, and induce deposition of immune complexes. Interferon evokes the release of several cytokines, including tumor necrosis factor alpha, and interleukins 2, 6 and 1, affecting autonomic sympathetic nerve activity and vasopressor responses<sup>[17]</sup>. Interferon induces an autoimmune reaction through various mechanisms including production of gamma globulins and interleukin-6 (IL-6)<sup>[18]</sup> and inhibition of Allo-specific suppressor T lymphocytes, as well as activation of natural killer cells<sup>[19]</sup>. IL-6 was significantly increased in pericardial effusion<sup>[20]</sup>. Interferon has been associated with exacerbation or induction of a wide variety of clinical and serological immune disorders, including systemic lupus erythematosus, rheumatoid arthritis, autoimmune hepatitis, thyroid disease and diabetes mellitus. On the other hand, Orságová *et al.*<sup>[21]</sup> demonstrated that positivity of antinuclear antibodies and smooth muscle antibodies or increased rheumatoid factor and circulating immune complexes are often found in patients with chronic hepatitis B and CHC treated with interferon, but their presence does not correlate with the development of autoimmune diseases.

The cardiac toxicity of interferon alpha is also well known and uncommon. The mechanism of interferon cardio toxicity is unclear and probably multifactorial. There are no established predisposing factors for interferon cardio toxicity. The secondary effects of interferon described include arrhythmia (atrial fibrillation, sinus bradycardia, atrioventricular block), ischemic cardiomyopathy and cardiomyopathy with the dosage levels used in the treatment of hepatitis C<sup>[2]</sup>. Myocardial ischemia is mainly caused by cardio toxicity of interferon and antimetabolites<sup>[22]</sup>. Patients with previous heart disease are probably at higher risk for arrhythmia and ischemic manifestations<sup>[1]</sup>. Concerning drug toxicity, there have been reported cases of acute pericarditis after the administration of: Hydralazine, procainamide, izoniazid, phenylbutazone, dantrolene, doxorubicin, and penicillin.

These situations are extremely rare. Sonnenblick *et al.*<sup>[23]</sup> demonstrated that the cardiac effects of interferon were not related to the daily dose, cumulative total dose, or period of therapy and cardiac toxicity was reversible following the cessation of the drug therapy. Interferon inhibits cardiac cell function *in vitro*<sup>[24]</sup>.

The Naranjo adverse drug reactions (ADR) Probability Scale<sup>[25]</sup> is a validated tool used to determine the likelihood that the adverse drug reaction is caused by the implicated medication. The Naranjo algorithm requires a series of questions to be answered and scored. The total calculated score indicates the likelihood of causing an adverse drug reaction. Popescu *et al.*<sup>[11]</sup> used the Naranjo ADR Probability Scale to evaluate the correlation of pericarditis with interferon administration. This scale indicated a very probable association.

Treatment of interferon-induced cardio toxicity rests mainly on early recognition and drug discontinuation. There is a high degree of individual variation in toxicity, but most adverse events are reversible upon cessation of the drug<sup>[8]</sup>. In the present study, 4 of 9 patients were treated with prednisone and 4 with NSAIDs.

Chronic hepatitis C viral (HCV) infection and treatment with interferon are both associated with serological and clinical autoimmune manifestations<sup>[26,27]</sup>. The serological immune response to HCV infection may include the development of cryoglobulinemia, rheumatoid factor, anti-cardiolipin, antinuclear, anti-liver-kidney-microsome 1 and anti-smooth muscle antibodies. Serological autoimmune manifestations were explained by the lymphotropism of HCV and the polyclonal activation of B cells. Interferon-based treatment of HCV infection may precipitate or exacerbate the associated autoimmune disease. Classically, type II Cryoglobulinaemia, glomerulonephritis and thyroiditis are described.

Interferon related pericarditis still remains uncertain. There may be two mechanisms for pericarditis, one is autoimmune and the other is cardio toxicity. Treatment of interferon related pericarditis rests mainly on early recognition and drug discontinuation. Interferon related pericarditis was treated with steroid and/or NSAIDs.

## COMMENTS

### Background

When the authors examine a new unusual patient that the authors have never treated before, the authors need to research previous case reports. However, the case report is individual. The authors need to know what kind of examinations they need and what kind of treatments they need as soon as possible. This manuscript aimed to summarize those previous case reports concerning interferon related pericarditis.

### Research frontiers

There may be two mechanisms for interferon related pericarditis, one is autoimmune and the other is cardio toxicity. Treatment of interferon related pericarditis rests mainly on early recognition and drug discontinuation. Interferon related pericarditis was treated with steroid and/or nonsteroidal anti-inflammatory drugs.

### Innovations and breakthroughs

This is the first article that was summarized interferon related pericarditis.

## Applications

Readers will understand the previous case reports concerning interferon related pericarditis in a short time.

## Terminology

Interferon related pericarditis is one of the side effects of interferon treatment.

## Peer-review

In the current manuscript, the authors reviewed the 9 published interferon-related pericarditis cases. This interferon regimen complication is rare and this review is helpful to understand this rare complication.

### Abstract

We are reporting a case of a 80-year-old lady with effort angina who underwent coronary angiography through the right radial artery, using a dedicated radial multipurpose 5 French Optitorque Tiger catheter. The catheter was advanced into the left ventricle and a left ventriculogram was obtained, while the catheter appeared optimally placed at the centre of the ventricle and the pressure waveform was normal. A large posterior interventricular vein draining into the right atrium was opacified, presumably because the catheter's end hole inadvertently cannulated an endocardial opening of a small thebesian vein, with subsequent retrograde filling of the epicardial vein. Our case suggests that caution is needed when a dedicated radial catheter with both an end-hole and a side hole is used for a ventriculogram, as a normal left ventricular pressure waveform does not exclude malposition of the end-hole against the ventricular wall.

**Key words:** Thebesian vein; Radial access; Transradial; Cardiac phlebography

**Core tip:** Use of a dedicated radial catheter with both an end-hole and a side hole to perform a left ventriculogram, can result in inadvertent cannulation of a small Thebesian vein and subsequent opacification of a large epicardial vein. When such catheters are used for ventriculogram, a normal ventricular pressure waveform does not exclude malposition of the end-hole against the ventricular wall and extra caution is needed in order to prevent iatrogenic myocardial injury. We review current literature on myocardial injury induced by end-hole catheters used for left ventriculograms.

## INTRODUCTION

In the last years, the use of radial artery as an arterial access site for coronary procedures has gained increasing popularity, as it is considered safer compared to transfemoral procedures. Recent data from large randomized trials suggest that the radial access is associated with a reduction of major adverse events in patients with acute coronary syndrome undergoing invasive management<sup>[1]</sup>. Furthermore, there is expanding use of dedicated "multipurpose" radial catheters, which enable the operator to cannulate both coronary arteries, and also to perform chamber injection and left ventriculogram. For transradial procedures, this single-catheter approach has been shown to decrease radiation exposure, fluoroscopy time, contrast volume and total procedure time compared with standard Judkins catheters<sup>[2]</sup>. Using a single catheter also reduces the risk of spasm of the radial artery. On the other hand, those dedicated radial catheters may rarely cause myocardial injury when used for a left ventriculogram. We present a rare angiographic finding in a patient who underwent cardiac catheterization through the radial artery using a dedicated radial catheter.

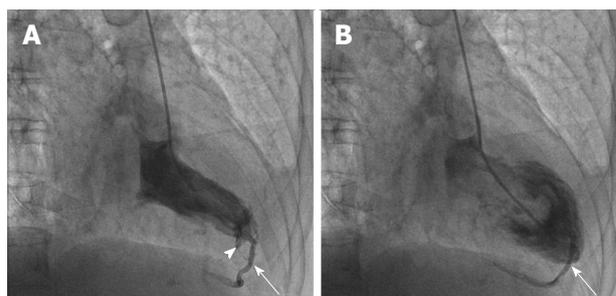

## CASE REPORT

A 80-year-old lady with effort angina underwent coronary angiography through the right radial artery, using a dedicated radial "multipurpose" 5 French Optitorque Tiger catheter (Terumo, Somerset, New Jersey). Coronary angiogram of the left and right coronary arteries demonstrated a significant stenosis in the ostium of a modest sized intermediate artery. The catheter was then advanced into the left ventricle (LV) and appeared optimally placed at the centre of the LV, while the LV pressure waveform was normal. A left ventriculogram was obtained after delivering 10 mL of contrast with a vigorous hand injection. Few ectopics were noticed at the beginning of the injection, followed by a small deflection of the catheter's tip, a minor subendocardial staining (arrowhead in panel A) and visualization of a large posterior interventricular vein, which seemed to drain directly into the right atrium (arrows in Figure 1 and supplementary Video 1).

We observed no persistent staining of the myocardium and the patient did not experience any discomfort, arrhythmia or electrocardiographic changes. The patient was monitored and was discharged few hours later.

## DISCUSSION

Dedicated radial "multipurpose" catheters such as the Tiger catheter have been specifically designed to minimise catheter exchange with ability to access both coronary ostia from the radial approach, and also provide

**Figure 1** Inadvertent phlebography of the posterior interventricular vein. Right anterior oblique image taken at time of left ventriculography. Arrows show the posterior interventricular vein in systole (A) and diastole (B). Arrowhead shows a minor subendocardial staining (A).

ability to perform chamber injection with the presence of both an end hole and a single side hole. In our case, we assume that the catheter's end hole cannulated an endocardial opening of a small Thebesian vein, with subsequent retrograde filling of the epicardial vein. Venae cordis minimae (Thebesian veins) are small valveless venous conduits that connect the coronary arteries, veins or capillaries with the cardiac chambers. Most Thebesian veins of the ventricles are connected to the cardiac venous system<sup>[3]</sup>, as was the case in our patient.

We screened the available literature and we identified a total of 7 reports with 8 cases of myocardial injury following contrast injection with end-hole catheters for left ventriculogram<sup>[4-10]</sup>. The characteristics of the patients and procedures and the type of myocardial injury and outcome are shown in Table 1. In 5 of those cases, a dedicated transradial end-hole catheter with one side hole near the tip (radial Tiger catheter) or two side holes (radial Jacky catheter) was used<sup>[4,6,7,9,10]</sup>. Traditional multipurpose (MPA) catheters with an end-hole and 2 side holes near the tip were used in 2 cases<sup>[4,5]</sup>, whereas a catheter with a single end-hole (Judkins right 4) was used from femoral access in 1 case<sup>[8]</sup>. The Thebesian venous network and/or cardiac veins were visualized in 4 cases<sup>[4,5,8,9]</sup>. A high-pressure power injection had been performed in most cases describing myocardial laceration/dissection and persistent myocardial staining<sup>[6,7,9,10]</sup>. Complete myocardial "perforation" with presence of contrast in the pericardial space was confirmed in 2 of those cases<sup>[6,10]</sup>, and emergency pericardiocentesis due to tamponade was performed in one patient<sup>[6]</sup>. No fatalities were reported (Table 1).

Even a pigtail catheter can rarely cause severe myocardial injury during ventriculography when its tip is inappropriately positioned<sup>[11]</sup>. However, apposition of the pigtail catheter's end-hole against the endocardium or cannulation of Thebesian veins is extremely unlikely, and therefore this catheter should be the preferred option for ventriculograms.

Caution is needed when a dedicated radial catheter with both an end-hole and side holes is used for a ventriculogram, as a normal left ventricular pressure waveform (likely from the side hole) does not exclude unsafe posi-

**Table 1 Patient and procedure-related characteristics and outcomes of published cases describing myocardial laceration or cannulation of Thebesian veins following left ventriculogram with end-hole catheters**

Case	Ref.	Demographics	Catheter, access	Injection characteristics	Complication	Clinical findings/outcome
1	Judkins <i>et al</i> <sup>[4]</sup>	72 yr, woman, aortic stenosis	Multipurpose-1 (right radial access)	Not provided	Opacification of Thebesian veins, coronary veins and coronary sinus	Not provided
2	Judkins <i>et al</i> <sup>[4]</sup>	77 yr, woman, chest pain	Optitorque Tiger (right radial access)	Not provided	Opacification of Thebesian veins and coronary veins	Not provided
3	Singhal <i>et al</i> <sup>[5]</sup>	46 yr, man, hypertrophic cardiomyopathy	Multipurpose-2 (femoral access)	Power injection, 25 mL of contrast, 10 mL/s	Opacification of Thebesian veins, coronary veins and coronary sinus	Ventricular tachycardia requiring cardioversion/uneventful recovery and next day discharge
4	Frizzell <i>et al</i> <sup>[6]</sup>	76 yr, woman, myocardial infarction	Optitorque Tiger (radial access)	Power injection, 30 mL of contrast over 10 s	Laceration/dissection of anterolateral myocardium and pericardial staining	Chest discomfort, pericardial effusion and cardiac tamponade/pericardiocentesis, uneventful recovery
5	Rosington <i>et al</i> <sup>[7]</sup>	71 yr, woman, angina	Optitorque Tiger (right radial access)	Power injection, 25 mL of contrast, 8 mL/s, 600 psi	Laceration/dissection of anterolateral myocardium	Chest discomfort, transient bundle branch block/uneventful course and next day discharge
6	Aqel <i>et al</i> <sup>[8]</sup>	50 yr, woman, chest pain	Judkins right 4 (femoral access)	Hand injection	Opacification of Thebesian veins, coronary veins and coronary sinus	Not provided
7	Kang <i>et al</i> <sup>[9]</sup>	66 yr, woman, angina	Optitorque Jacky radial (radial access)	Power injection, 30 mL of contrast over 2 s, 600 psi	Laceration/dissection of anterior myocardium and opacification of anterior interventricular vein and coronary sinus	Not provided
8	Basit <i>et al</i> <sup>[10]</sup>	69 yr, man, inferior wall ischemia	Optitorque Jacky radial (radial access)	Not provided	Laceration/dissection of myocardium with pericardial opacification	Chest pain, trivial pericardial effusion/uneventful recovery

tioning of the end-hole against the ventricular wall<sup>[6,7]</sup>. This malposition of the catheter may result in cannulation and injection in a Thebesian vein<sup>[4,5,8]</sup>, or injection against the endocardial layer. In our case, only a small volume of contrast was delivered in an endocardial opening of the Thebesian network with a hand injection, and this may partly explain the relatively “benign” outcome of opacifying an epicardial vein without causing any major myocardial injury. In this scenario, it seems that the injected contrast drains through the Thebesian network into the cardiac veins and therefore no significant intramyocardial shearing forces are generated. However, serious complications such as laceration/dissection of the myocardium or even catastrophic “perforation” of the ventricular wall<sup>[6,7,9,10]</sup> may occur when the contrast is injected against the endocardium, or when of a large contrast volume is injected in a Thebesian vein with high-pressure (with an automated power injector), as in this case the small Thebesian network would likely be unable to accommodate the forcefully injected large volume of contrast. Hence, we believe that our case indirectly supports the common practice of avoiding the use of radial multipurpose catheters with automated high-pressure power injectors and large volume of contrast for ventriculograms. Therefore, additional care should be taken to confirm that the catheter is optimally positioned at the centre of the left ventricular cavity and that the catheter’s tip is free before contrast injection,

and the operator should not rely only on a normal waveform of ventricular pressure. Finally, the injection of contrast must stop immediately when subendocardial or myocardial staining or opacification of an epicardial vein occurs during a ventriculogram with a dedicated radial multipurpose catheter, as this invariably indicates myocardial injury due to malposition of the catheter’s end hole against the endocardium.

## COMMENTS

### Case characteristics

This case shows that using a dedicated radial catheter with both an end-hole and a side hole for a left ventriculogram can result in inadvertent cannulation of a small Thebesian vein and subsequent opacification of an epicardial cardiac vein. This was not related to any symptoms or adverse outcomes.

### Clinical diagnosis

Minor catheter-induced endocardial staining and visualization of posterior interventricular vein.

### Differential diagnosis

Catheter-induced laceration/dissection of myocardial wall.

### Imaging diagnosis

Left ventriculogram with a dedicated radial Tiger catheter.

### Related reports

Current literature on myocardial injury induced by end-hole catheters used for

left ventriculogram is reviewed.

### Experiences and lessons

When dedicated radial end-hole catheters are used for ventriculogram, a normal ventricular pressure waveform does not exclude malposition of the end-hole against the ventricular wall and extra caution is needed in order to prevent iatrogenic myocardial injury.

### Peer-review

This is a case report about an unexpected cardiac phlebography. The manuscript is well written and describes an important aspect related to the use of multipurpose radial catheters.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Hiroki Teragawa, FACC, FAHA, MD, PhD, Director, Doctor, Department of Cardiovascular Medicine, JR Hiroshima Hospital, Hiroshima 732-0057, Japan

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

An increased cardiovascular morbidity and mortality, including the risk of sudden cardiac death (SCD), has been shown in patients with rheumatoid arthritis (RA). Abnormalities in autonomic markers such as heart rate variability and ventricular repolarization parameters, such as QTc interval and QT dispersion, have been associated with sudden death in patients with RA. The interplay between these parameters and inflammation that is known to exist with RA is of growing interest. In this article, we review the prevalence and predictors of SCD in patients with RA and describe the potential underlying mechanisms, which may contribute to this. We also review the impact of biologic agents on arrhythmic risk as well as cardiovascular morbidity and mortality.

**Key words:** Sudden death; Rheumatoid arthritis; Cardiovascular; QT; Autonomic nervous system; Arrhythmia

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Patients with rheumatoid arthritis are twice as likely to experience sudden cardiac death (SCD). This excess risk can only partially be explained by the higher rates of heart failure and ischaemic heart disease. Abnormalities of the autonomic nervous system, such as decreased heart rate variability, and abnormalities of ventricular repolarization parameters, such as QTc interval and QT dispersion, have also been implicated. In this article we review the interplay between these parameters and inflammation, exploring whether biologic agents and disease modifying anti-rheumatic drugs may have a role in reducing the burden of SCD.

death in patients with rheumatoid arthritis. *World J Cardiol* 2017; 9(7): 562-573 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i7/562.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i7.562>

## INTRODUCTION

Rheumatoid arthritis (RA) is a chronic inflammatory condition which affects 0.8% of the adult population<sup>[1]</sup>. It causes significant morbidity as a result of synovial inflammation, joint destruction, and associated disability. In addition to articular manifestations, there is substantial data demonstrating excess cardiovascular morbidity and mortality in RA<sup>[2,3]</sup>. Studies as early as the 1950s have shown that RA is associated with premature death<sup>[4]</sup>, with 50% of excess deaths being attributed to cardiovascular disease<sup>[2,5]</sup>. Sudden cardiac death (SCD) is estimated to account for 50% of cardiovascular deaths in the general population<sup>[6,7]</sup>. Patients with RA are twice as likely to experience SCD<sup>[8]</sup>, a figure comparable to patients with diabetes mellitus<sup>[9]</sup>. This review will seek to explore the risk factors that make SCD more prevalent in RA, including coronary artery disease (CAD), structural heart disease, electrophysiological abnormalities including myocardial repolarization (QTc interval, QT dispersion) and autonomic dysfunction [heart rate variability (HRV) analysis], and the interplay of inflammation on all these factors<sup>[10]</sup>. We will also review the effect that the new biologic agents may have on the incidence of cardiovascular events and SCD.

## DEFINING SCD AND ITS PREVALENCE IN RA

Sudden death is defined as "non-traumatic, unexpected fatal event occurring within 1 h of the onset of symptoms in an apparently healthy subject. If death is not witnessed, the definition applies when the victim was in good health 24 h before the event"<sup>[11]</sup>. The term SCD is used when a congenital, or acquired, potentially fatal cardiac condition was known to be present during life, or an autopsy has identified a cardiac or vascular anomaly as the probable cause of the event, or no obvious extra-cardiac causes have been identified by post-mortem examination, and therefore an arrhythmic event is a likely cause of death<sup>[11]</sup>. SCD is largely thought to result from fatal arrhythmias, in particular, ventricular tachycardia degenerating to ventricular fibrillation<sup>[12,13]</sup>. Bradyarrhythmia or electromechanical dissociation can also be associated with SCD but these tend to occur in patients with advanced cardiac disease<sup>[12,14]</sup>.

In the general population sudden death accounts for 60% of cardiovascular deaths in those with known CAD<sup>[15]</sup>, and is the first presentation of CAD in 15% of cases<sup>[16]</sup>. Over 70% of fatal arrhythmias are thought to be secondary to CAD<sup>[12]</sup>. These arrhythmias can occur

acutely secondary to direct repolarisation changes occurring during ischaemia, or remotely, typically due to initiation of re-entry circuits within areas of electrically unexcitable scar tissue or diseased myocardium in patients with established myocardial infarction (MI)<sup>[17]</sup>. Dilated and hypertrophic cardiomyopathies account for the second largest number of sudden deaths followed by valvular, congenital, infiltrative, ion-channel disorders which only account for the small remainder<sup>[12,13]</sup>.

Within the RA population, there is a wealth of data regarding the rates of cardiovascular death, however few studies have looked specifically at the epidemiology of SCD. In an inception cohort of 1010 RA patients, Goodson *et al.*<sup>[18]</sup> found an excess of cardiovascular mortality without a corresponding increase in cardiovascular admission rates as compared to controls, suggesting that cardiovascular disease has a higher case fatality in the RA population, or that it often goes unrecognized before the fatal event. Indeed, Solomon *et al.*<sup>[19]</sup> found that the rate ratio for cardiovascular death was highest in young RA adults and those with no known prior cardiovascular events. Whilst Van Doornum *et al.*<sup>[20]</sup> demonstrated that RA patients have a higher 30-d case fatality following MI as compared to controls, 17.6% vs 10.8%. In a large population cohort study of 603 RA patients followed up for 15 years, Maradit-Kremers *et al.*<sup>[5]</sup> demonstrated that RA patients were twice as likely to experience SCD (hazard ratio 1.94, 95%CI: 1.06-3.55)<sup>[8]</sup>, a figure similar to the risk of SCD amongst patients with diabetes mellitus<sup>[21]</sup>. The authors also noted a higher risk of unrecognized MIs and a lower likelihood of angina symptoms, suggesting that CAD manifests differently in RA and is more likely to manifest as cardiovascular death<sup>[8]</sup>. Similarly Mantel *et al.*<sup>[22]</sup> demonstrated that RA is associated with higher risk acute coronary syndromes, higher cumulative incidence of SCD (0.2% vs 0.13% over 3 years), and higher short term case fatality rate at 7 and 30 d. Indeed, certain RA genetic polymorphisms have been linked to premature cardiovascular disease and mortality<sup>[23-26]</sup>, although none with a strong clinical implication<sup>[27,28]</sup>.

## RISK FACTORS FOR SCD IN RA

### **Accelerated CAD, congestive cardiac failure and inflammation**

Whilst there is a higher incidence of ischaemic heart disease (IHD) in RA, several authors have shown that this increased incidence cannot be explained by traditional risk factors alone<sup>[5,29]</sup>, as such there has been growing interest in the role of inflammation as novel risk factor for atherosclerosis<sup>[30]</sup>. Indeed, in the general population, modest increases in C-reactive protein (CRP) have been associated with increased cardiovascular events<sup>[31]</sup>, and RA has been likened to diabetes as a risk factor for CAD<sup>[32]</sup>.

Studies have also suggested different patterns of CAD in RA with chronic inflammation leading to early endothelial dysfunction<sup>[33,34]</sup>, and a higher incidence of unstable plaques attributed to inflammatory cytokines<sup>[35]</sup>. Indeed tumour necrosis factor alpha (TNF- $\alpha$ ) has been implicated in all stages of atherosclerosis including endothelial dysfunction, plaque formation, rupture and promotion of the clotting cascade<sup>[36,37]</sup>. Systemic inflammation has also been associated with dyslipidaemia, impaired glucose metabolism, platelet activation and increased clotting factors<sup>[36]</sup>. However, despite the evidence linking inflammation to accelerated atherosclerosis and IHD, Maradit-Kremers *et al*<sup>[8]</sup> demonstrated that the two-fold risk of SCD seen in the RA population persisted after adjustments for history of hospitalized, or unrecognized, MI, revascularization procedures and cardiovascular risk factors. This suggests that the increased risk of SCD in RA cannot be explained by increased rates of IHD alone<sup>[10,38]</sup>.

In two studies<sup>[39,40]</sup> the excess risk of congestive cardiac failure (CCF) among RA subjects could not be explained by the increased frequency, or effect of, either cardiovascular risk factors, or IHD. In the same cohort, Gabriel *et al*<sup>[41]</sup> demonstrated that whilst 80% of CCF in the general population is attributed to classical CVD risk factors, in RA, classical risk factors only explained 40% of the incident heart failure.

Amongst RA patients experiencing new-onset heart failure, ESR levels were highest in the 6 mo immediately preceding diagnosis, suggesting that ESR may signal the onset of heart failure in patients with RA<sup>[42]</sup>. However, the relationship between SCD and severity of CCF is not as clear-cut as that seen with SCD and IHD, and less is known about RA and CCF. Data from the general population suggests that as left ventricular (LV) systolic function deteriorates, all-cause mortality and the absolute number of sudden deaths increases, but the proportion of deaths due to arrhythmias decreases<sup>[14,43]</sup>. Thus, the degree of LV systolic dysfunction lacks specificity as a predictor of death secondary to cardiac arrhythmias, because it is also powerful measure of the risk of death<sup>[12]</sup>. In line with these results, Nicola *et al*<sup>[44]</sup> found CCF contributed to the excess cardiovascular mortality in RA, primarily through the increased incidence of CCF in RA rather than increased case fatality. Studies have also shown that patients with RA have higher rates of diastolic dysfunction<sup>[45]</sup>, and heart failure with preserved ejection fraction<sup>[46]</sup>.

### **Abnormal ventricular repolarization, autonomic dysfunction and inflammation**

Inflammation, as an independent predictor of cardiovascular mortality and sudden death, has been the focus of recent research<sup>[30,47,48]</sup>. Indicators of abnormal ventricular repolarization such as QTc prolongation, QT interval dispersion, and autonomic dysfunction have

been implicated in the aetiopathogenesis of SCD. The QT interval represents the time from onset of ventricular depolarization (beginning of the Q wave) to completion of repolarization (end of T wave). The corrected QT interval (QTc) estimates the QT at a standardized heart rate of 60 bpm, while QT interval dispersion (QTd) is measure of the dispersion of ventricular repolarization (maximum QT interval - minimum QT interval). In the general population both prolongation of QTc and increased QTd are known risk factors for SCD<sup>[49,50]</sup>, and there is data linking both CRP to prolongation of QTc<sup>[51]</sup> and to SCD<sup>[47]</sup>. In animal models, prolonged QTc is associated with depolarization during phases 2 and 3 of the action potential prior to completion of repolarization<sup>[52]</sup>. These premature action potentials also known as early after depolarizations (EADs) can generate fatal ventricular arrhythmias, such as torsade de pointes, which can progress to ventricular fibrillation and SCD<sup>[12,53]</sup>.

Several studies have also shown an association between RA and prolonged QTc or increased QT dispersion variables, as well as an association between RA disease activity and QTc length<sup>[54-62]</sup> (Table 1), with the strongest evidence available for CRP as a marker of disease activity, compared with clinical scoring systems and ESR<sup>[10]</sup>. Moreover, there is growing evidence from basic science studies demonstrating that pro-inflammatory cytokines, particularly TNF- $\alpha$ , directly prolong cardiomyocyte action potential duration (APD) by regulating ion channels involved in ventricular repolarization<sup>[10]</sup>. In particular, several experimental studies have shown that TNF- $\alpha$  prolongs APD, triggering re-entrant ventricular arrhythmias<sup>[63,64]</sup>. TNF- $\alpha$  prolongs APD by inhibiting both the transient outward potassium current<sup>[65]</sup>, and the rapid delayed-rectifier potassium current<sup>[10,66]</sup>. Similarly, animal studies have shown that the pro inflammatory cytokines IL-1 and IL-6, prolong APD in ventricular myocytes *via* their effects on calcium channels<sup>[67,68]</sup>. Interestingly both levels of CRP<sup>[48]</sup> and levels of soluble TNF- $\alpha$  receptors (sTNFR) are strong and independent predictors of cardiovascular death amongst RA patients<sup>[69]</sup>.

As early as 1998, a cross-sectional study by Gödeli *et al*<sup>[54]</sup>, demonstrated a significant increase in QT dispersion variables when comparing RA patients with matched controls, as well as an increase in complex premature ventricular beats. More recently a large prospective study of 357 RA patients demonstrated that prolonged QTc was a strong predictor of death, with a 50 ms increase in QTc being associated with a doubling of the hazard for all-cause mortality<sup>[60]</sup>. The authors also showed that QTc prolongation was independently associated with CRP levels, and that the association between QTc and mortality was lost after adjustment for CRP, further supporting the role of inflammation in the increased rates SCD seen in this patient group<sup>[60]</sup>. No association was found between QTc and the presence of cardiovascular disease at baseline,

**Table 1 Studies demonstrating associations between rheumatoid arthritis and QT parameters, inflammation and mortality**

Ref.	Design	RA patients	Controls	Impact of RA and QT dispersion (QTd) and QTc	Association between QT parameter, and disease activity/duration (1), arrhythmia (2), autonomic dysfunction (3), mortality (4)
[54]	Cross-sectional	42	42	↑ QTd variables (QTd, QTcD, JTD, JTcD) <i>vs</i> controls No difference in QTc <i>vs</i> controls	(1) ESR, CRP (2) Complex premature ventricular beats
[55]	Cross-sectional	40	48	↑ QTd variables (QTd, QTcD) <i>vs</i> controls	(1) Disease duration
[56]	Cross-sectional	40	40	↑ QTd <i>vs</i> controls	(1) Extra-articular manifestations, erosive disease
[57]	Cross-sectional	58	29	↑ QT <i>vs</i> controls	(1) Secondary Sjögren's syndrome
[58]	Cross-sectional	100	100	↑ QTd <i>vs</i> controls	(1) Disease duration, DAS28, ESR, number of joints involved
[59]	Cross-sectional	25	21 controls 76 with spondylarthopathy	↑ QTc <i>vs</i> controls and those with spondyloarthopathies Infliximab therapy duration inversely correlated to QTc ( $P < 0.01$ )	(1) CRP (3) ↑ QTC associated with ↑ HR, autonomic dysfunction, particularly sympathetic dysfunction as assessed by spectral parameters of heart rate variability
[60]	Prospective cohort	357	-	↑ QTc 10% males (QTc $\geq 450$ ms) and 5.6% of females (QTc $\geq 460$ ms)	(1) CRP (4) Doubled risk of all-cause mortality per 50 ms increase in QTc, (lost after adjustment for CRP) HR = 2.17 (95%CI: 1.21-3.90)
[61]	Retrospective cohort	417	422	↑ % of RA patients with QTc prolongation (> 450 ms males, > 460 ms females) <i>vs</i> controls 20 yr after disease onset (48% <i>vs</i> 38%, $P = 0.004$ )	(1) ESR (4) Any cause QTc prolongation was associated with ↑ all-cause mortality HR = 2.99 (95%CI: 1.93-4.65)
[62]	Prospective cohort	17	-	↑ QTc (> 440 ms) in 76% of patients Tocilizumab associated with 47% ↓ in No. patients with QTc prolongation ( $P = 0.006$ )	(1) CRP and TNF- $\alpha$
[70]	Cross-sectional	117	-		(1) CRP, TNF- $\alpha$ , IL-1 $\beta$ and IL 10 ( QTc BAZ) (1) IL-1 $\beta$ and IL 10, trend towards TNF- $\alpha$ (QTc FHS)

RA: Rheumatoid arthritis; QTd: QT interval dispersion; QTc: Heart-rate corrected QT interval; QTcD: Heart-rate corrected QT interval dispersion; JTD: JT interval dispersion; JTcD: Heart-rate corrected JT interval dispersion; DAS28: Disease activity score in 28 joints; ESR: Erythrocyte sedimentation rate; CRP: C-reactive protein; ms: Milliseconds; QTc BAZ: QTc calculated using Bazett formula; QTc FHS: QTc calculated using Framingham formula.

ECG abnormalities suggestive of myocardial ischemia, LV hypertrophy, or the use of common cardiovascular medications<sup>[60]</sup>. Similarly, Chauhan *et al*<sup>[61]</sup> found a higher incidence of idiopathic QTc prolongation amongst RA patients and demonstrated that any cause QTc prolongation was significantly associated with all-cause mortality (HR = 2.99, 95%CI: 1.93-4.65) but only marginally associated with cardiovascular mortality (HR = 2.68, 95%CI: 0.84-5.6,  $P = 0.09$ ). The authors used a cut off of  $\geq 450$  ms in males and  $\geq 460$  ms in females to define QTc prolongation<sup>[61]</sup>, but interestingly, amongst the general over 55 population even a borderline increased QTc interval, defined as 451 to 470 ms in women, and 431 to 450 ms in men, was associated with a two-fold increase in the risk of SCD<sup>[53]</sup>. Following this, Lazzarini *et al*<sup>[62]</sup> showed that treating RA patients with 3 mo of the anti-IL 6-receptor

antibody, tocilizumab, was associated with a significant reduction in the QTc interval. The fact improvement was seen in such a short time frame suggests that QTc prolongation is driven by an inflammatory process rather than subclinical coronary atherosclerosis<sup>[62]</sup>.

There is also emerging data about the role of pro and anti-inflammatory cytokines in QTc prolongation amongst patients with RA. Lazzarini *et al*<sup>[62]</sup> recently demonstrated a strong association between QTc and circulating TNF- $\alpha$  levels, more so than CRP, although sample sizes were small. Adlan *et al*<sup>[70]</sup> performed a cross-sectional study of 112 patients with RA examining the relationship between QTc and cross-sectional sampling of several pro and anti-inflammatory cytokines. The authors demonstrated an association between QTc prolongation and CRP, TNF- $\alpha$ , IL-1 $\beta$  and the anti-inflammatory cytokine IL-10. A surge of IL-10

often follows the release of pro-inflammatory cytokines and its release is stimulated by adrenaline<sup>[70,71]</sup>.

Sympathetic excitation has been associated with prolongation of the QTc<sup>[72]</sup>, while cholinergic stimulation with pyridostigmine shortens QTc interval in patients with CAD<sup>[73]</sup>. RA has been associated with both reduced parasympathetic tone and increased sympathetic tone, with a recent systematic review demonstrating a 60% prevalence of autonomic dysfunction amongst patients with RA<sup>[52]</sup>. The majority of studies assessed autonomic dysfunction using clinical cardiovascular tests (CCTs) or by measuring HRV parameters<sup>[52]</sup>. CCTs include blood pressure and heart rate response to orthostasis, deep breathing and Valsalva manoeuvres, with many studies using Ewing's battery of CCTs<sup>[74]</sup>. HRV analysis attempts to assess cardiac autonomic regulation through quantification of variation in sino-atrial activity with rapid variations reflecting vagal modulation and slower variations reflecting a combination of both parasympathetic and sympathetic modulation and non-autonomic factors. HRV can be measured using time domain methods or frequency domain methods. Examples of time domain measures include; mean heart rate, AVNN (Average of all the NN intervals, with "NN" used in place of "RR" to emphasize that these are normal sinus beats), and the difference between the longest and shortest NN interval<sup>[75]</sup>. More complex statistically derived time domain measures include either those, derived from direct measurements of the NN intervals, such as SDNN (standard deviation of all NN intervals), SDANN (standard deviation of the average of NN intervals in all 5-min segments of a 24 h recording) or those derived from the differences between NN intervals such as RMSSD (square root of the mean of the squares of the differences between adjacent NN intervals) and pNN50 (percentage of differences between adjacent NN intervals that are > 50 ms)<sup>[75]</sup>. Conversely, frequency domain methods assign bands of frequency, and through fast Fourier transformation quantify the NN interval in each band<sup>[75]</sup>. The bands are typically high frequency (HF) from 0.15 to 0.4 Hz, low frequency (LF) from 0.04 to 0.15 Hz, and very low frequency from 0.0033 to 0.04 Hz. Vagal activity is the major contributor to the HF component with a combination of both sympathetic and parasympathetic activity contributing to the LF and LF/HF ratio<sup>[75]</sup>.

In the general population reduced HRV has been associated with a significantly increased risk of death post MI<sup>[76]</sup>, although as yet there are no studies demonstrating the association between autonomic dysfunction and mortality amongst RA patients. This said, there is data to show that autonomic dysfunction, namely reduced HRV is associated with prolongation of the QTc in patients with RA<sup>[59]</sup>. A study of 100 patients with chronic inflammatory arthritis (CIA) demonstrated that while CRP was independently associated with HRV, there was no association between CRP and QTc in the multivariate model, with HRV parameters and

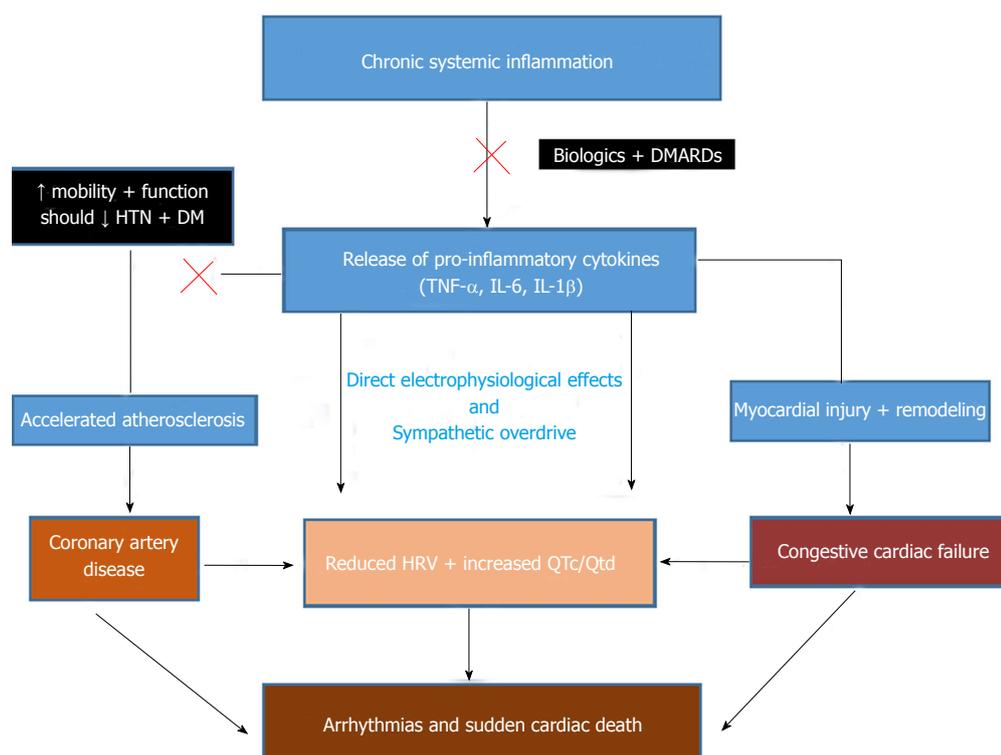

RR interval playing a predominant role in producing differences in QTc among the subjects<sup>[59]</sup>. These findings, together with the evidence that, even after sex-adjustment, QTc was correlated with heart rate and all HRV parameters suggests that the association between CRP and QTc prolongation is most likely an indirect consequence of the autonomic dysfunction and specifically increased sympathetic tone<sup>[59]</sup>. Indeed, there is growing evidence to show that the release of pro inflammatory cytokines in diseases such as RA increases sympathetic outflow activation *via* autonomic centres in brain<sup>[10]</sup>. This represents an adaptive response which dampens immuno-inflammatory activation and inhibits the release of further cytokines *via* stimulation of  $\beta$ 2-adrenoceptors in circulating lymphocytes and monocytes<sup>[77,78]</sup>. This negative feedback loop is known as the inflammatory reflex. However, sympathetic activation does not only affect the immune system, but all the systems throughout the body, and its effects may either directly<sup>[79]</sup>, or indirectly (by prolonging QT interval parameters *via* modification in calcium and/or potassium conductance) trigger the onset of arrhythmias and SCD<sup>[10]</sup>.

## IMPACT OF DISEASE-MODIFYING ANTI-RHEUMATIC DRUGS AND BIOLOGICS ON CARDIOVASCULAR OUTCOMES?

Disease-modifying anti-rheumatic drugs (DMARDs) are a category of otherwise unrelated drugs defined by their use in RA to slow down disease progression. Throughout this review the term DMARD will be used to refer to synthetic DMARDs such as methotrexate, whereas biologic DMARDs will be simply referred to as biologics.

Whilst currently there are no studies specifically evaluating the impact of synthetic DMARDs and biologics on the incidence of arrhythmias and SCD in RA, the European League Against Rheumatism advocate early aggressive treatment with these agents, for the purpose of reducing cardiovascular morbidity and mortality<sup>[3]</sup>. These agents are expected to exert their benefits *via* their direct effect on reducing inflammation, but also by improving joint inflammation and function they will potentially lead to increased levels of physical activity and reduce the incidence of other risk factors such as diabetes mellitus and hypertension<sup>[3]</sup> (Figure 1). Indeed, a prospective cohort study and concurrent literature review conducted by Meek *et al.*<sup>[80]</sup> showed a trend towards reducing cardiovascular case fatality since the advent of DMARDs and biologics. However, no comparison was made to a control population, to ensure that the findings were not just tagging the observed reduction in cardiovascular disease burden, in the general population.

In this section, we will explore whether the advent of DMARDs and particularly Biologics, has indeed reduced cardiovascular mortality and morbidity. We

**Figure 1 Proposed Mechanisms by which biologics and disease modifying anti-rheumatic drugs will reduce the risk of sudden cardiac death in patients with rheumatoid arthritis.** DMARD: Disease modifying anti-rheumatic drugs; HTN: Hypertension; DM: Diabetes; TNF: Tumour necrosis factor; IL: Interleukin; HRV: Heart rate variability; QTc: Corrected QT interval; QTd: QT interval dispersion.

will look closely at the data supporting both the anti-arrhythmic and pro-arrhythmic effects of biologics, as well as their influence on cardiac autonomic dysfunction and repolarisation parameters such as the QTc.

There is growing evidence from observational studies, including observational meta-analyses, to suggest that DMARDs in particular methotrexate<sup>[81,82]</sup> and biologics, particularly TNF inhibitors (TNFi)<sup>[37,83,84]</sup> are associated with decreased cardiovascular mortality and morbidity. To date, the largest meta-analysis has been conducted by Roubille *et al.*<sup>[84]</sup>, and included 28 observational studies, over 200000 RA patients and over 5000 cardiovascular adverse events. The authors found that TNFi were associated with a significant reduction in the risk of all cardiovascular events (CVE) (RR = 0.70,  $P = 0.005$ ), as well as MIs, strokes and major adverse cardiac events. Methotrexate was also associated with a reduction in the risk of all CVEs (RR = 0.72,  $P = 0.007$ ) and MIs. Moreover, a large observational study by Dixon *et al.*<sup>[85]</sup> suggested that patients who responded to TNFi experienced a 70% lower risk of MI than their non-responding counterparts. In addition, a recent retrospective post hoc analysis involving approximately 4000 patients with moderate to severe RA, demonstrated that during tocilizumab treatment, greater reductions in disease activity were inversely associated with future major cardiovascular events, including MIs and cardiovascular death<sup>[86]</sup>.

The lack of randomized controlled trials (RCTs)

specifically examining the impact of biologics and DMARDs on CVE is perhaps explained by the number of patients that would be required to adequately power the studies, and the duration of follow-up that would be needed to detect an effect. Some studies have examined the impact of biologics on surrogate markers of IHD such as carotid intimal thickness and brachial artery flow mediated dilatation with conflicting results<sup>[87]</sup>. A single center RCT conducted by Hsue *et al.*<sup>[88]</sup> demonstrated that depletion of B-cells with rituximab in RA patients improved both macrovascular (brachial artery flow-mediated dilation) and microvascular (reactive hyperemia) endothelial function, despite modest elevation in lipids. There is also an ongoing prospective imaging study, CADERA, bolted onto the single-center VEDERA RCT (very early vs delayed etanercept in RA, NCT 02433184), which will use cardiac MRI to explore the prevalence and change of cardiovascular abnormalities in patients receiving TNF inhibitors vs standard therapy over a 12-mo period<sup>[89]</sup>. The evidence for a link between inflammation and cardiovascular disease is so compelling that 2 RCTS, the Cardiovascular Inflammation Reduction Trial (CIRT) and the Canakinumab Anti-Inflammatory Thrombosis Outcomes Study (CANTOS), have been commenced. CIRT will investigate whether low-dose methotrexate will reduce rates of recurrent MI, stroke, and cardiovascular death among stable post MI patients with type 2 diabetes or metabolic syndrome, two conditions that are associated with an enhanced

inflammatory response (NCT01594333). CANTOS will evaluate whether interleukin-1 $\beta$  inhibition as compared to placebo can reduce rates of recurrent MI, stroke, and cardiovascular death among stable CAD patients who remain at high vascular risk due to persistent elevations of CRP (NCT01327846). In addition, tocilizumab and anakinra have been investigated as treatment for acute MIs with RCTs demonstrating an attenuation in CRP levels, CCF and cardiac remodeling following ST elevation MI<sup>[90,91]</sup>, and attenuation in CRP levels and post percutaneous intervention troponin release following non ST elevation MI<sup>[92]</sup>. There is a further ongoing trial TOCRIVA, which will assess the effects of tocilizumab on cardiovascular risk in RA patients (NCT 01752335).

The relationship between biologics and CCF is more complex and the data is conflicting. In the general population TNF- $\alpha$  levels are increased in CCF<sup>[93]</sup> and associated with severity of clinical signs and symptoms<sup>[94]</sup>. Experimental heart failure models have suggested that TNF inhibitors may improve ventricular dysfunction<sup>[95]</sup>; however, a large clinical trial assessing etanercept in the treatment of congestive heart failure showed no benefit<sup>[96]</sup>, while another one found that high-dose infliximab 10 mg/kg worsened heart failure in patients with moderate-to-severe chronic heart failure<sup>[97]</sup>. Consequently, a "black box" warning was introduced not to use these medications in patients with pre-existing heart failure<sup>[98]</sup>. The most recent data from the United States, which compared 8656 new users of synthetic DMARDs with 11587 new users of TNFi, suggested that TNFi were not associated with an increased risk of hospital admissions due to heart failure (HR = 0.85, 95%CI: 0.63 to 1.14), but identified that such a difference may well have existed prior to the introduction of the black box warning in 2002<sup>[99]</sup>. This study also noted a dose-dependent association between glucocorticoid use and heart failure. Importantly, the authors acknowledged that they were unable to adjust for potential differences in baseline disease severity between the TNFi and synthetic DMARD groups as this information was not collected<sup>[98]</sup>. The German RABBIT registry also reported similar results, with similar rates of heart failure reported in those receiving TNFi compared to those receiving combined synthetic DMARDs as well as a dose-dependent association with glucocorticoids<sup>[100]</sup>. The authors of that study suggested that the overall effect of TNFi is more beneficial than harmful, through improved control of disease activity and reduced need for glucocorticoid. Glucocorticoid use in RA patients has also been associated with a dose dependent increase in all-cause and cardiovascular mortality, at a threshold of 8 mg per day<sup>[101]</sup>. There is less data about the other biologics and CCF but a recent pilot study has shown that 12 mo of treatment with the anti-IL6 tocilizumab significantly increases LV ejection fraction and reduces LV mass index with a concomitant reduction in disease activity<sup>[102]</sup>. As aforementioned anakinra has also been associated with reduced heart

failure following ST elevation MIs<sup>[91]</sup>.

It has been suggested that by suppressing inflammation, biologics may attenuate the autonomic and electrophysiological disturbances that have been linked with SCD and arrhythmic risk amongst patients with RA. Indeed, in a small interventional study of 17 patients with active RA, 76% of which had a prolonged QTc, Lazzarini *et al.*<sup>[62]</sup> demonstrated that tocilizumab was associated with significant shortening of the QTc within a 3 to 6 mo period. This was also correlated with a decrease in both CRP and TNF- $\alpha$  levels. Similarly, Senel *et al.*<sup>[103]</sup> showed a reduction in both QTc interval, and inflammatory markers, amongst patients with Ankylosing spondylitis (AS), following 6 mo of treatment with infliximab. Amongst patient with CIA, infliximab therapy duration has also been shown to be inversely and independently associated with QTc duration<sup>[59]</sup>. Conversely, DI Franco *et al.*<sup>[104]</sup> found no significant difference in QTc interval duration amongst CIA patients treated with TNFi and rituximab. However, the authors did not report on disease activity and thus there may have been a large proportion of patients who did not achieve adequate disease control<sup>[105]</sup>. In the Diana study, 12 wk of treatment with combination synthetic DMARDs or biologics significantly improved cardiac autonomic dysfunction ( $P < 0.05$ ) in both RA and AS patients<sup>[106]</sup>. Inflammatory markers (ESR and CRP) correlated with variables of autonomic neuropathy before and after biologic treatment, suggesting that inflammatory markers may both predict the occurrence of autonomic neuropathy and response to treatment, especially with biologics<sup>[106]</sup>. Infliximab has also been associated with acute changes in HRV consistent with a decrease in sympathetic tone and shift towards relative vagal predominance<sup>[107]</sup>. Additionally, duration of treatment was also found to be correlated to increased HRV and improved cardiac autonomic function<sup>[59]</sup>.

However, the use of biologics is not without risk, and beyond the well-recognized risks of malignancy and infection, there have been reports of cardiac arrhythmias, in some cases life threatening, particularly following the use of anti-TNF monoclonal antibodies and rituximab<sup>[105]</sup>. Case reports have described ventricular arrhythmias<sup>[108,109]</sup>, supraventricular arrhythmias<sup>[110,111]</sup>, and various degrees of heart block<sup>[112-114]</sup>, associated with the use of infliximab, although in one case, the complete heart block did in fact resolve spontaneously<sup>[112]</sup>. It is thought that biologics and in particular TNF inhibiting monoclonal antibodies may be acutely unmasking the inflammation driven myocardial instability that characterizes RA, and other inflammatory conditions<sup>[105]</sup>. They could be doing this in one of three ways; firstly by worsening LV function, secondly by reducing coronary blood flow<sup>[115]</sup>, and thirdly, a mechanism which would be exclusive to monoclonal antibodies, *via* complement-mediated cytotoxic or inflammatory damage to the myocardium<sup>[105,116]</sup>. This is supported by two interesting studies in the literature.

The first, is a case report of 42-year-old AS patient who developed ventricular tachycardia requiring defibrillation following 3 doses of infliximab<sup>[117]</sup>. Despite this, the patient was retreated with infliximab given that there was no evidence of CAD on angiography and his inflammatory markers remained high. Over 2 mo a marked reduction in ventricular arrhythmias was noted with an associated attenuation of inflammatory response. The second study, a prospective, single-blind, crossover study of 75 patients with CIA, demonstrated that during acute infliximab infusion, there was 8% incidence of new-onset ventricular tachyarrhythmia vs 2.7% with placebo (OR = 3.17, 95%CI: 0.61-16.26)<sup>[107]</sup>. Although the difference was not statistically significant, the study was likely underpowered to detect this. Interestingly, those patients that experienced new onset ventricular arrhythmia showed baseline QTc and HRV values that were significantly prolonged and depressed, respectively, as compared to the patients who did not develop ventricular arrhythmia. Translating this into clinical practice, rituximab and monoclonal TNFi should be avoided in patients with significant CV risk factors, known structural heart disease or ECG abnormalities (conduction disease, QTc prolongation and HRV depression). If these drugs are still required, careful ECG monitoring should be performed in the early phases of administration, until disease activity is adequately controlled, to detect and treat any complications<sup>[105]</sup>.

## CONCLUSION

RA is a chronic inflammatory condition, which is associated with significant cardiovascular mortality and morbidity. Data suggests that RA patients are twice as likely to experience SCD compared to the general population<sup>[8]</sup>, a figure comparable to diabetics<sup>[9]</sup>. Whilst some of this excess risk can be explained by the higher rates of heart failure and IHD, thought to be partially triggered and mediated by inflammation, direct influence of inflammatory cytokines on electrophysiological parameters has been implicated in arrhythmogenesis leading to SCD in RA. Interest is growing in examining the interplay between QTc prolongation, autonomic dysfunction and the risk of SCD. Both autonomic dysfunction and QTc prolongation have been shown to be correlated to inflammation, with the best evidence in place for CRP<sup>[10]</sup>. The advent of DMARDs and biologics has improved cardiovascular morbidity and mortality<sup>[37,82]</sup>, with novel evidence demonstrating a direct normalisation effect on repolarization parameters such as QTc<sup>[62]</sup>, as well as improvement in parameters of autonomic dysfunction<sup>[106]</sup>. Randomised controlled trials assessing the impact of DMARDs and biologics on autonomic dysfunction and repolarization parameters, such as QTc or QT dispersion, are urgently required to demonstrate the potential for reduction of SCD in this patient population.

## Key messages

Patients with RA are twice as likely to experience SCD compared to the general population; This excess risk can be partially explained by the higher rates of heart failure and IHD, thought to be partially triggered and mediated by inflammation; Direct influence of inflammatory cytokines and autonomic dysfunction on electrophysiological parameters has been implicated in arrhythmogenesis in this patient group; Biologic agents and disease modifying anti-rheumatic drugs may have a role in reducing the burden of SCD by controlling inflammation.

### Abstract

Transcatheter aortic valve replacement (TAVR) is a relatively newer therapeutic modality which offers a promising alternative to surgical aortic valve replacement

for patients with prohibitive, high and intermediate surgical risk. The increasing trend to pursue TAVR in these patients has also led to growing awareness of the associated potential vascular complications. The significant impact of these complications on eventual clinical outcome and mortality makes prompt recognition and timely management a critical factor in TAVR patients. We hereby present a concise review with emphasis on diverse vascular complications associated with TAVR and their effective management to improve overall clinical outcomes.

**Key words:** Vascular; Transcatheter; Aortic valve; Concise; Review

### INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is an evolving percutaneous valve replacement procedure especially with the new improved low profile sheaths. The most widely used approach for TAVR is retrograde access through a common femoral artery (CFA). Although there is a striking decrease in all-cause morta-

**Figure 1** Schematic representation of trans catheter aortic valve replacement access approach based on common femoral artery dimensions as seen on multidetector computed tomography angiography. TAVR: Transcatheter aortic valve replacement; CFA: Common femoral artery; MDCTA: Multidetector computed tomography angiography. Republished with permission of Sage from Sardar *et al.*<sup>[39]</sup>.

lity and cardiovascular outcomes between TAVR and standard therapy at 5 years in high risk patients<sup>[1]</sup>, there is a significant component of associated major vascular complications such as annular rupture, vessel dissection, major bleeding (16.7%)<sup>[2]</sup>. Analysis of the PARTNER trial showed the rate of major and minor complications as 15.3% and 11.9% respectively which was associated with a higher rate of 30 d and 1 year mortality especially among cohort B<sup>[3]</sup>. In comparison to this historic trend, newer temporal data from the STS/ACC TVT registry has shown a significant decrease in the annual rate of vascular complications to as low as 4.2%<sup>[4]</sup>. Effective management of vascular complications to improve outcomes is of paramount importance as recent studies have shown TAVR to be non-inferior to surgical aortic valve replacement in moderate risk patients<sup>[5]</sup> and that reflects a higher potential patient pool who could benefit from this procedure.

## RISK FACTORS FOR VASCULAR ACCESS

Risk factors associated with increased risk of vascular complications in TAVR include female gender, renal failure, peripheral vascular disease with significant calcification (especially when circumferential) and concomitant peripheral vascular disease. The sheath to femoral artery diameter ratio (SFAR) greater than 1.05 also compounds risk<sup>[6]</sup>. Newer delivery systems such as Edwards SAPIEN XT and S3 decrease the risk as does operator experience and skill<sup>[7]</sup>. The subclavian approach is comparable to transfemoral TAVR<sup>[8]</sup>. Most well-known complication of caval-aortic access is caval-aortic fistula but there is paucity of data regarding vascular complications as this approach is not used commonly.

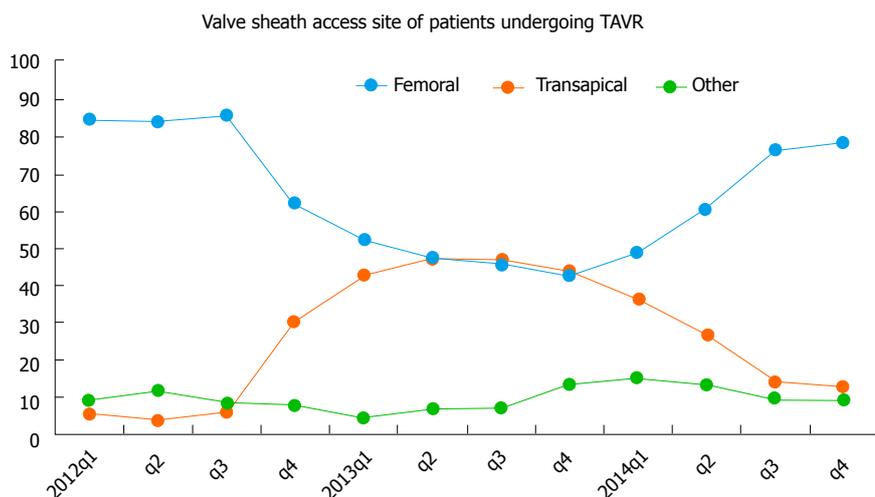

## ACCESS TECHNIQUES

### Femoral

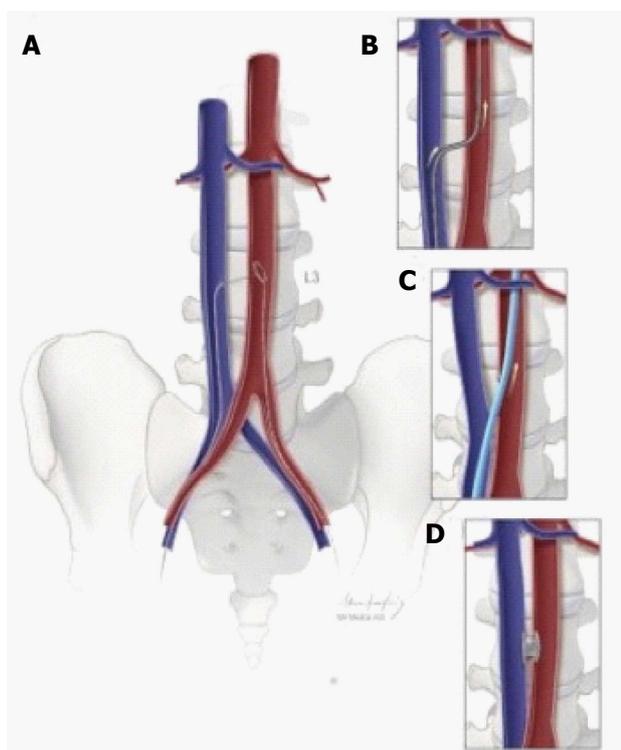

Pre-procedural multidetector computed tomography (MDCT) can help assess CFA calcification, determine the distance from skin to artery, and the vessel diameter, all of which can aid in selecting the optimal vessel entry site. A general schematic for femoral access based on MDCT is outlined in Figure 1. In recent times, there has been a significant surge in transfemoral approach as reflected by TVT registry results (Figure 2). In many centers, TF TAVR is performed using a micropuncture needle and 4 or 5 Fr sheath<sup>[9]</sup> but there is wide variability of approach dependent on an operator.

The micropuncture technique avoids potential large bore needle trauma at an unwanted CFA site (low, high or otherwise suboptimal), which may ultimately culminate in development of vascular complications. Fluoroscopy or ultrasound can be utilized to assist with identification of the appropriate site of entry, although the latter provides greater anatomic detail. A radio-opaque marker (*e.g.*, a hemostat) can be placed on the groin to mark the femoral head, facilitating guidance of needle entry under fluoroscopy. The level of sheath entry relative to the femoral head can be confirmed using fluoroscopy in an antero-posterior (AP) projection and its relation to the superficial-profunda femoral bifurcation ascertained using angiography performed from an ipsilateral oblique projection (*i.e.*, right or left anterior oblique for right- and left-sided access, respectively). B-mode ultrasound can be used as well and may result in less frequent vascular complications and higher first pass access success<sup>[10]</sup>.

Finally, needle puncture may be guided using real time digital subtraction angiography (DSA) or "road mapping" by using contralateral common femoral

**Figure 2** Transcatheter aortic valve replacement vascular access site in the transcatheter valve therapy Registry, 2012 to 2014. access and placing a cross over sheath or catheter in the common or external iliac artery on the side to be accessed. Regardless of the method employed, after confirming appropriate CFA access, the micropuncture sheath can then be exchanged over guidewire to a

larger sheath as required.

### Subclavian

Subclavian access is an alternative option with a prerequisite vessel diameter of greater than 6 mm. Increased angulation, ectasia and calcification are all adverse risk factors. With history of coronary artery bypass grafting and a left internal mammary graft, subclavian vasculature diameter should be greater than 7 mm with no significant atherosclerotic disease and no ostial stenosis to consider it feasible for TAVR access. Surgical cut-down for proper visualization and ease of access is commonly used<sup>[11]</sup>.

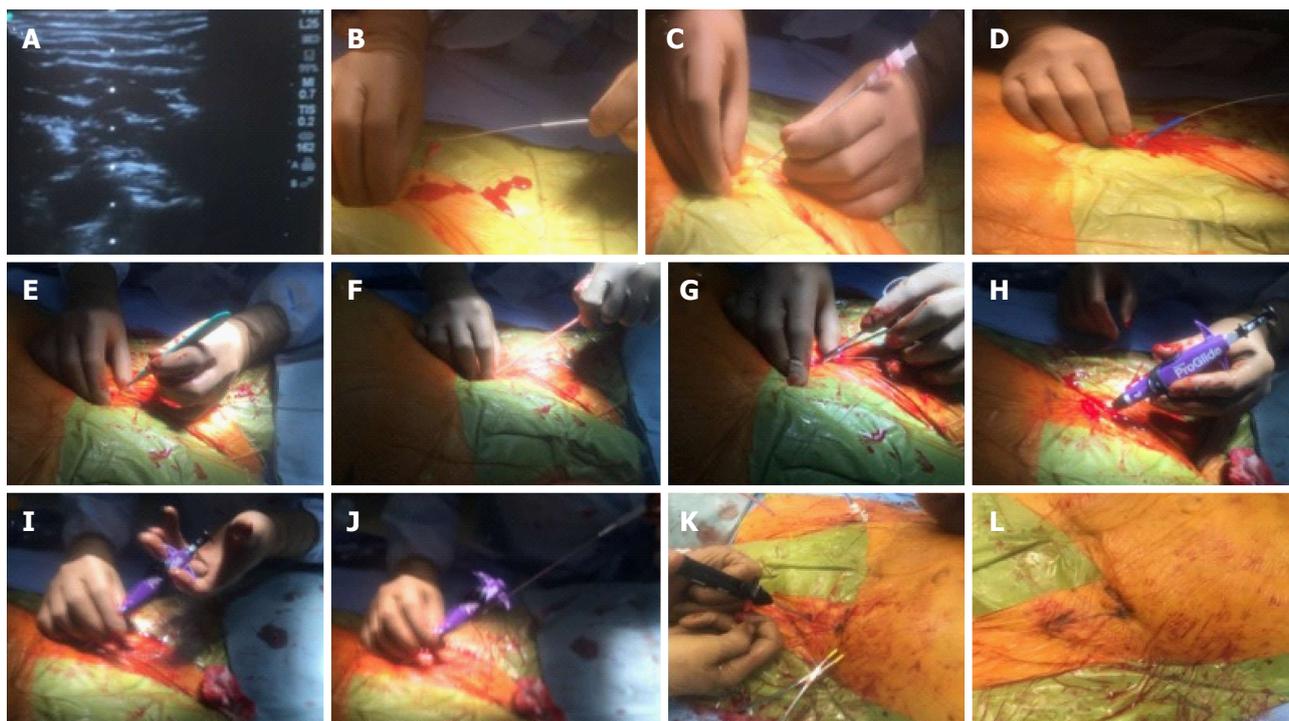

### Caval-aortic

This is an option for TAVR in patients with significant peripheral vascular disease in the femoral and iliac systems thereby limiting arterial access. The caliber and pliability of venous system provides advancement of the delivery system through the femoral vein into the inferior vena cava followed by puncture of the descending aorta and sealing the pathway with a nitinol plug on completion of the procedure<sup>[12]</sup>. A stepwise illustration is provided in Figure 3.

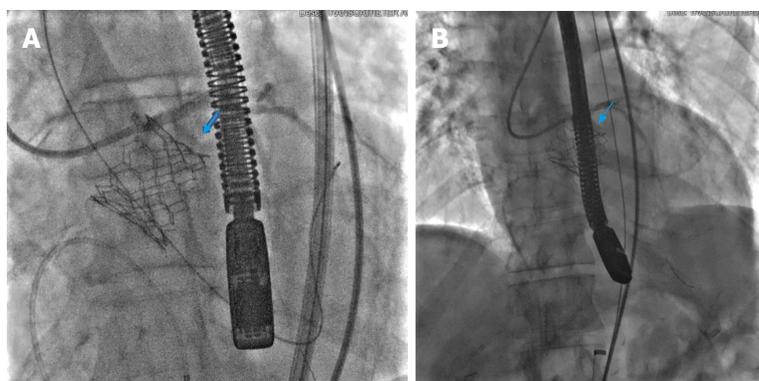

## HEMOSTASIS METHODS

Hemostasis following removal of the sheath is usually achieved with Prostar XL10F and Perclose ProGlide (Abbott Vascular Devices, Redwood City, CA, United States) in which the mechanism of action is a suture release and delivery. This method greatly decreases the incidence of access site complications<sup>[10]</sup>.

The Prostar XL and 6 Fr ProGlide are used for closure of upto 10F and 8F arteriotomies. If the devices are initially used at the time of initial access and sheath placement, hemostasis can be achieved in a more predictable and effective fashion. This is termed as the

**Figure 4** Pre-close hemostasis technique during a transcatheter aortic valve replacement procedure. A-C: A calcium-free zone is visualized using real time ultrasound and access is obtained using a micropuncture needle system; D-G: The micropuncture system is exchanged for a 180 cm 0.035 wire and the skin tract is sequentially dilated with scalpel, 7 F sheath dilator and later a forceps; H: A Proglide is advanced over the wire into the arterial lumen, and return of pulsatile blood flow confirmed; I and J: After ensuring stable Proglide position, two sequential sutures are deployed at 10 and 2 O'clock; K and L: After the removal of transcatheter aortic valve replacement sheath and guide wire, pre-close sutures are sequentially locked to ensure hemostasis.

**Figure 5** Annular rupture post transcatheter aortic valve deployment with the rupture site marked by blue arrows (A, B).

“Preclose” method and is illustrated in Figure 4. After TAVR completion, a 0.035” guidewire is always left in the artery while removing the sheath, to maintain continuous access in case an upstream perforation becomes apparent. Once sufficient hemostasis is achieved, the 0.035 wire can be removed and suture knots locked to ensure complete hemostasis. Occasionally a third Proglide or 8 Fr Angio-Seal (Abbott Vascular, Redwood City, California) can be used to adequately achieve hemostasis if required<sup>[13]</sup>.

Cross over balloon technique (COBT) is an alternative method to achieve hemostasis. COBT involves inflating a balloon above the access site prior to the

retrieval of TAVR sheath and closure of arteriotomy. COBT can be performed over 0.018” or 0.035” guidewires, and the hemostasis balloon can be inflated at low pressure to ensure safe deployment of the suture-mediated closure device<sup>[14]</sup>.

## GUIDEWIRES

There are different guidewires with varying degrees of stiffness and flexibility which can be employed during the TAVR procedure. Wires used for TAVR delivery are usually 0.035” diameter and have an inner core with a tapered distal tip that is easily shapeable to

**Table 1 Traditionally used transcatheter aortic valve replacement guidewires (permission obtained)**

Guidewire	Core material and coating	Wire guide diameter inch	Wire guide length (cm)	Taper length (cm)	Floppy tip length (cm)	Stiffness	Preshaped curve	Use
Amplatz Extra Stiff wire (Cook Medical Inc.)	PTFE-coated stainless steel	0.035	260	7	3	Least stiff	3 cm	TAVR device delivery Straightening of tortuous vessels Sheath insertion
Amplatz Super Stiff wire (Boston Scientific)	PTFE-Coated Stainless Steel	0.035	260	6	3	Stiffer than Extra stiff	1 and 3 cm	Straightening of tortuous vessels Sheath insertion
Lunderquist Extra Stiff wire (Cook Medical Inc.)	PTFE-Coated Stainless Steel	0.035	260 and 300	7.5	4	Stiffer than Amplatz extrastiff and superstiff	4 cm	Straightening of tortuous vessels Sheath insertion
Safari Guide wire (Boston Scientific)	LUBRIGREEN™ PTFE-Coated Stainless Steel	0.035	260 and 300			Stiffness equal to Amplatz extrastiff	Small curve - 16 cm distal grind and 1.7 inch/4.25 cm curve Large curve - 18 cm distal grind and 1.9 inch/4.90 cm curve	TAVR device delivery

TAVR: Transcatheter aortic valve replacement; PTFE: Polytetrafluoroethylene.

facilitate steerability. Length is usually in the range of 260 cm and some are coated to reduce resistance to minimize vessel trauma during catheter and device exchange in TAVR procedures. One should be wary of the fact that verbal description of guidewires does not co-relate with actual wire stiffness. Objective parameters such as “flexural modulus” co-relate well with wire stiffness and are more reliable as shown by Harrison et al in a retrospective analysis<sup>[15]</sup> rather than market terminology such as “super stiff” or “extra stiff”. If higher stiffness is required as in cases with significant vessel tortuosity, a pig tail curve is typically placed at the distal tip of the wire to prevent vascular or left ventricular trauma. Table 1 shows important characteristics of guidewires commonly used during TAVR.

## TAVR DEVICES

Balloon-expandable Edwards SAPIEN S3 and Edwards SAPIEN XT™ valves (Edwards Lifesciences Inc., Irvine, CA) and the self-expanding Medtronic CoreValve® Evolut™ R System valves (Medtronic, Minneapolis, MN) are United States Food and Drug Administration (FDA)-approved TAVR devices which are being used nowadays. Core Valve and Edwards Sapien S3 have a range of 23-32 mm and 20-29 mm valve size respectively with sheath size either 14 or 16 French. Currently there are two CE mark approved TAVR devices, the Lotus™ valve system (Boston Scientific Corporation,) available in 23, 25 and 27 mm sizes and the Portico Valve (St. Jude Medical, Minneapolis, Minnesota), available in 27 and 29 mm sizes<sup>[16]</sup>.

## SHEATHS

The risk of vascular trauma increases with bigger sheath sizes and has shown a downward trend with the new generation TAVR delivery systems<sup>[17]</sup>.

Older generation Edwards SAPIEN and SAPIEN XT valves required up to 24 Fr and 20 Fr sheaths, respectively, while the first Medtronic CoreValve required up to a 25 Fr sheath. Newer generation valves require 14-16 Fr sheaths.

The SoloPath sheath (Terumo Medical Corporation, Irvine, CA, United States) is a balloon expandable and re-collapsible sheath, available in various internal diameters/outer diameters of 14/17, 16/19, 18/21, 19/22, 20/23 and 21/24 Fr, in working lengths of 25 and 35 cm, and balloon expandable lengths of 20 and 30 cm respectively. The sheath is inserted into the vessel in a folded state over a balloon-expandable dilator. Once the sheath is in the desired position, the dilator is inflated, the sheath expands, and later dilator is removed. Upon completion of the procedure, balloon is deflated and sheath returns to its original OD. The safety and efficacy of the 19F SoloPath sheath was investigated for TF-TAVR in a single arm study of 90 patients. When patients were dichotomized into those with a sheath to femoral artery ratio (SFAR) of  $\leq 1.05$  vs  $> 1.05$ , the 19 F Solopath sheath appeared feasible and safe even in patients with SFAR  $> 1.05$  (a traditional indicator of increased vascular risk) and there was no difference in technical or procedural success, total vascular complications, or total bleeding rates between groups<sup>[18]</sup>. The safety of the SoloPath access sheath was confirmed in a recent multicenter

**Table 2 Internal and external diameter of large percutaneous sheaths (permission obtained)**

TAVR: Transcatheter aortic valve replacement.

study of patients with  $\leq 5.0$  mm ilio-femoral access undergoing TF-TAVR using the CoreValve device<sup>[19]</sup>. A detailed list of different access sheaths used during TAVR is given in Table 2.

## ACCESS SITE INFECTION

There are variable reports of access site infection after TF-TAVR, ranging from 1.6% to 12.1% with 90% of access site infections encountered after surgical cut down with a 10% associated mortality<sup>[20]</sup>. In many practices, all patients undergoing TAVR are pretreated with broad spectrum antibiotics and the access site skin incision is closed with a topical skin adhesive. It provides a flexible microbial barrier with wound support that may prevent infection better than traditional wound dressings<sup>[21]</sup>.

## ACCESS SITE HEMATOMA

Hematomas at point of access can occur ranging from a few minutes to days following completion of TAVR procedure. Careful attention must be paid to the access site as the ideal point is the mid femoral head above the femoral bifurcation. Prolonged hospital stay as well as increased morbidity and mortality are potential associations<sup>[22]</sup>. The occurrence has continued to decrease due to enhanced center experience, operator skill and smaller delivery systems over the last few years. Manual pressure and anti-coagulation reversal is sufficient for successful management in majority of cases. In case of compressive symptoms or profound blood loss indicated by rapid drop in hemoglobin, contralateral femoral access with balloon tamponade

is usually employed. Viabahn covered stent placement (W.L. Gore and Associates, Newark, DE) has been shown to co- relate with an efficacy of 98%<sup>[23]</sup>.

## PSEUDOANEURYSMS

Pseudoaneurysm (PSA) is a contained rupture can occur with arterial puncture below the femoral bifurcation involving superficial or deep femoral arteries or the iliac system<sup>[24]</sup>. The frequency of pseudoaneurysm ranges from 2%-6%. PSA can thrombose spontaneously in upto 90% of cases at 3 wk if the size is less than 3 cm<sup>[25]</sup>. Size greater than 2 cm along with aggressive anticoagulation are potential predisposing risk factors and can lead to persistent discomfort and act as nidus of infection to increase risk of septic embolism<sup>[26]</sup>. Rupture can occur with devastating consequences with major bleeding and hypovolemic shock and diameter greater than 3 cm potentiates the possibility<sup>[27]</sup>.

Palpation of a pulsatile mass at the access site or the auscultation of a systolic bruit are suggestive of a possible PSA. For diagnostic purposes, doppler ultrasound has a 94% sensitivity and 97% specificity for PSA<sup>[28]</sup>.

Usually a 5-7 MHz frequency probe is used and the depth should be greater than 4 cm from the skin. Color Doppler shows a turbulent flow pattern in the PSA tract and pulse Doppler shows constant flow shift towards and away from the probe which is diagnostic. Ultrasound guided compression when used has a success rate of 30%-70%. Multiple attempts are mostly needed to obtain sustained compression and thrombosis with a mean time of 33 min<sup>[29,30]</sup>. Ultrasound guided thrombin injection is an effective treatment

modality with a 97% success rate. It facilitates the conversion of fibrinogen to fibrin<sup>[31]</sup>. Injections are usually given in incremental doses of 0.2-0.4 mL till no flow is observed on the pulse Doppler.

---

## ILEO-FEMORAL DISSECTION

Ileo-femoral dissection in transfemoral TAVR has an incidence of approximately 7% even in high volume centers. External iliac artery is the most commonly involved vessel and can occur during initial advancement of the delivery system or during sheath withdrawal.

Diagnosis can be made with careful review of DSA with either retrograde or contralateral antegrade contrast injections. Significant dissections can lead to lower limb ischemia which can be critical or subcritical depending on the spread of dissection and the vessel territory involved. This can predispose to thrombus formation and vessel occlusion or compression symptoms with blood extravasation.

Computed tomographic angiography (CTA) with distal runoff can be used to identify the focus of dissection.

Contained dissections can be managed by careful monitoring as mostly they resolve on their own with course of time. In case of extensive dissections, endovascular repair can be pursued. Ballooning alone with appropriate stent placement as needed is the preferred approach. Balloon inflation can tamponade the bleeding site and in addition maintenance stents are used for vessel patency. If the dissection is unable to be sealed with this modality, surgical repair is required. Follow up imaging with CTA as indicated can be used<sup>[32]</sup>.

---

## ILEO-FEMORAL RUPTURE

Ileo-femoral rupture is another feared complication of TAVR but the occurrence has decreased significantly with the use of smaller and compact delivery systems as compared to initial TAVR procedures when the frequency was roughly 4%. As long as the sheath is in place, pelvic vascular rupture is not evident but as soon as the sheath is withdrawn, the pressure seal is taken off and huge pelvic bleed can occur with rapid clinical deterioration and death<sup>[33]</sup>.

During the sheath withdrawal, the patient's clinical status should be monitored closely. Sudden hemodynamic compromise may be evident if there is a significant defect although small tears can extend and cause clinical instability within a few hours post procedure. Angiography prior to complete sheath removal is usually performed to assess for any focal dissection or to detect any extra-luminal contrast flow.

Management includes quick sheath reintroduction to seal the site of dissection while contralateral balloon delivery and inflation can be attempted. Massive fluid repletion, quick anticoagulation reversal and

covered stent placement is required although in cases of complex dissections, surgical intervention is indicated<sup>[34]</sup>.

---

## ARTERIAL AVULSION

In cases of extensive atheromatous and calcified vessels, vessel avulsion can rarely occur during sheath withdrawal. Urgent proximal occlusive balloon placement and prompt surgical intervention needed in his scenario<sup>[35]</sup>.

---

## ARTERIAL STENOSIS, THROMBOSIS AND OCCLUSION

CFA stenosis can occur following device closure of the arteriotomy site. If there is evidence of significant flow limitation, angioplasty can be done to reduce the stenosis. In cases of arterial thrombosis and occlusion, critical limb ischemia can occur and thrombectomy is needed to restore vessel patency.

---

## AORTIC DISSECTION

Aortic dissection is an uncommon but potentially fatal complication of TAVR procedure, Incidence has been reported in the range of 0.6%-1.9%<sup>[36]</sup>.

As the access approach varies from transfemoral and transapical to transaortic, any segment can be involved including the ascending or descending aorta. In a study of 412 patients reported by Lange *et al*<sup>[37]</sup> who were treated with transapical and transfemoral approach, annular and abdominal aortic rupture occurred in four patients. Generally, continuous transesophageal monitoring is done throughout the procedure, and Type A dissections can be diagnosed promptly. If aortic dissection is suspected post procedure, aortic angiography is pursued.

The clinical manifestation of aortic dissection may manifest at any time during or after the procedure. Symptoms vary from chest pain and abdominal pain to neurological deficits depending on the extent of involvement (mesenteric, renal, carotid arteries). Clinically, hypotension and pressure difference of greater than 20 mmHg between the arms can be suggestive. Imaging modalities such as computed tomography, magnetic resonance imaging and transesophageal echocardiography (TEE) can be used depending on availability and the complexity of the clinical scenario.

The management of aortic dissection depends on initial site of dissection, extent and vascular compromise. Strict blood pressure control with systolic less than 110 mmHg by using beta blocker with alpha blocking additive effect such as Labetalol or Carvedilol is preferred. Non-dihydropyridine calcium channel blockers can be used as well. In case of hypotension, volume repletion is done to maintain mean arterial

pressure of greater than 70 mmHg. Type A dissections should be treated with prompt surgical repair while Type B dissections are medically managed and uncommonly endovascular repair is considered<sup>[38]</sup>.

## AORTIC RUPTURE

Aortic rupture is a dreaded, rare complication with extremely poor prognosis. It has an incidence of less than 1%. Commonly the presentation is acute with rapid hemodynamic instability and circulatory shock. The rupture extends quickly along tissue planes and hemorrhagic tamponade can be seen on TEE quite frequently. Infrequently, there is a subacute clinical picture as the initial aortic tear takes time to extend and manifest clinically. The mechanisms includes trauma by the device catheter if it overshoots the guidewire or forceful attempts made to manoeuvre the catheter through vessels with steep angulation and tortuosity. It can be spotted on fluoroscopy at the time of valve deployment as shown in Figure 5. There should be an extremely low threshold of suspicion in TAVR patients with even mild hemodynamic instability as prompt intervention with open surgical or endovascular approach with covered stents is needed to stabilize or repair the ruptured focus. The overall prognosis is strikingly dismal even in skilled hands as rupture extension can take place exponentially with dramatic reduction in chances of recovery.

## CONCLUSION

TAVR has certainly evolved exponentially since its initial days. Improved device profiles, equipment design and operator expertise are major factors which have significantly improved success rates by reducing possible procedure complications. Nonetheless continuing awareness, meticulous technique, timely management and availability of even better delivery systems in the future would be the key to better clinical outcomes.

### Abstract

Peripheral arterial disease (PAD) is a common disorder associated with a high risk of cardiovascular mortality and continues to be under-recognized. The major risk factors for PAD are similar to those for coronary and cerebrovascular disease. Management includes exercise program, pharmacologic therapy and revascularization including endovascular and surgical approach. The optimal revascularization strategy, endovascular or surgical intervention, is often debated due to the paucity of head to head randomized controlled studies. Despite significant advances in endovascular interventions resulting in increased utilization over surgical bypass, significant challenges still remain. Platelet activation and aggregation after percutaneous transluminal angioplasty of atherosclerotic arteries are important risk factors for re-occlusion/restenosis and life-threatening thrombosis following endovascular procedures. Antiplatelet agents are commonly prescribed to reduce the risk of myocardial infarction, stroke and death from cardiovascular causes in patients with PAD. Despite an abundance of data demonstrating efficacy of antiplatelet therapy in coronary artery disease and cerebrovascular disease, there is a paucity of clinical information, clinical guidelines and randomized controlled studies in the PAD population. Hence, data on antiplatelet therapy in coronary interventions is frequently extrapolated to peripheral interventions. The aim of this review article is to elucidate the current data on revascularization and

the role and duration of antiplatelet and anticoagulant therapy in re-vascularized lower limb PAD patients.

**Key words:** Peripheral arterial disease; Peripheral vascular disease; Antiplatelet therapy; Revascularization

**Core tip:** Peripheral arterial disease (PAD) is nearly a pandemic disorder which carries a high morbidity and mortality. Treatment includes risk factor modification, revascularization whenever feasible and medical management including antiplatelet therapy being a crucial element. Despite improvements in endovascular techniques and equipment for revascularization in PAD patients, current data regarding antiplatelet therapy in this population is limited. Our objective is to consolidate the current data on role and duration of antiplatelet and anticoagulant therapy in re-vascularized lower limb PAD patients.

## INTRODUCTION

Peripheral arterial disease (PAD) represents a major clinical problem affecting millions of people worldwide, which carries high morbidity and mortality and an increased risk of major adverse cardiovascular events including myocardial infarction (MI), stroke, premature death and impaired quality of life. The incidence of PAD is globally estimated to be between 3% and 12%<sup>[1-3]</sup>. This incidence has increased to as high as 29% in low to middle income areas, becoming one of the global problems of the 21<sup>st</sup> century<sup>[4]</sup>. Atherosclerosis in the peripheral arteries is a chronic, slowly developing disorder causing narrowing of the arteries. Depending on the degree of narrowing, clinical presentations vary from classic intermittent claudication, exercise limitations, or ischemic pain, to lower extremity ulceration or gangrene of the toes from chronic limb ischemia. Other patients found to have PAD from ankle brachial index (ABI) screening can remain asymptomatic throughout their life. Occasionally, acute events occur, frequently associated with thrombosis, embolism and/or major arterial occlusion.

Therapy for PAD includes both a pharmacologic and revascularization approach if possible. Antiplatelet therapy is the cornerstone of pharmacologic therapy in addition to risk factor reduction. The purpose of this paper is to discuss revascularization strategies and review clinical trial data for antiplatelet therapy in

patients with PAD.

## REVASCULARIZATION STRATEGY: ENDOVASCULAR THERAPY VS SURGICAL BYPASS

The optimal treatment strategy, endovascular or surgical intervention, is often debated due to the lack of head to head randomized controlled studies. Of the studies conducted, most are underpowered and lack uniform endpoint definitions making a direct comparison among studies difficult<sup>[5]</sup>.

Remarkable advancement in technology in the past decade has shifted the paradigm of revascularization strategies in PAD from an open surgical approach to percutaneous endovascular treatments including percutaneous atherectomy, percutaneous transluminal angioplasty (PTA) and stenting. Analysis conducted by Goodney *et al*<sup>[6]</sup>, provides statistical evidence based on Medicare claims between 1996 and 2006 that endovascular interventions are now performed more commonly than bypass surgery. The rate of major lower extremity amputation declined significantly more than 25% and endovascular interventions increased more than threefold [138 to 455 per 100000; relative risk (RR) = 3.30; 95%CI: 2.9-3.7], while surgery decreased by 42% (219 to 126 per 100000; RR = 0.58; 95%CI: 0.5-0.7)<sup>[6]</sup>. However, caution must be used to interpret this data as more research is warranted to determine if there is an association between lower extremity vascular procedures and improved rates of limb salvage in this population.

The BASIL trial was first published in 2005 followed by an intention-to-treat analysis published in 2010 evaluating amputation-free survival and overall survival. This was a prospective randomized controlled trial comparing the effectiveness of endovascular therapy vs open surgical approach in patients with severe limb ischemia due to infra-inguinal disease. Similar short term outcomes were found comparing both treatment modalities<sup>[7,8]</sup>. However, data also suggests that the results of angioplasty are less durable than that of surgical grafting. The primary patency rate after angioplasty is greatest for lesions in the common iliac artery and decreases distally. Additionally, the rates of patency are lower in cases with increasing lesion length, multiple and diffuse lesions, poor-quality run-off and in patients with concomitant diabetes and renal failure<sup>[9]</sup>.

The BEST-CLI trial is currently underway and designed to clarify this clinical conundrum for critical limb ischemia patients. This is a multi-center trial with a planned enrollment of 2100 patients that includes interventional cardiologists, interventional radiologists and vascular surgeons. The trial emphasizes a team based treatment approach and will compare patients eligible for both endovascular and open surgical bypass. All contemporary endovascular therapeutic modalities

**Table 1 Results of clinical trials initially designed for patients with coronary artery disease, with subgroup analysis in peripheral arterial disease**

Clinical trial	No. of patients	Patient population	Drugs studied	Primary end point	Outcomes
PEGASUS TIMI-54 subgroup analysis <sup>[40]</sup> (2016)	1143	CAD and concomitant PAD	Ticagrelor 90 mg BID + aspirin <i>vs</i> Ticagrelor 60 mg BID + aspirin <i>vs</i> Placebo + aspirin	Cardiovascular death, MI and stroke  Acute limb ischemia and peripheral revascularization for ischemia	15.2% in ticagrelor (pooled group) and 19.3% in placebo. ARR 4.1% in ticagrelor (pooled group) 60 mg dose more beneficial (ARR of 5.2%)  0.46% in ticagrelor (pooled group) and 0.71% in placebo (HR 0.65; 95%CI: 0.44-0.95; <i>P</i> = 0.026)
PLATO-subgroup analysis <sup>[32]</sup> (2015)	1144	CAD and concomitant PAD	Ticagrelor <i>vs</i> clopidogrel	Cardiovascular death, MI and stroke	18% in ticagrelor group and 20.6% in clopidogrel group (HR: 0.85; 95%CI: 0.64-1.11; <i>P</i> = 0.99)
TRA 2P-TIMI 50 <sup>[35]</sup> (2012)	26449	Previous history of MI or ischemic stroke within the previous 2 wk-12 mo or PAD	Vorapaxar <i>vs</i> placebo	Cardiovascular death, MI, and stroke	9.3% in vorapaxar group and 10.5% in placebo ( <i>P</i> < 0.001)  Subgroup analysis in PAD patients showed no difference between groups for the primary endpoint Rate of intracranial hemorrhage (1% vorapaxar <i>vs</i> 0.5% placebo; <i>P</i> < 0.001) 6.8% in clopidogrel plus aspirin group and 7.3% in aspirin group ( <i>P</i> = 0.22) Subgroup analysis in PAD patients: no benefit was derived from dual antiplatelet therapy
CHARISMA <sup>[38]</sup> (2006)	15603	Patients with either clinically documented vascular disease or risk factors for atherothrombotic disease	Aspirin plus clopidogrel <i>vs</i> aspirin monotherapy	MI, stroke or cardiovascular death	6.8% in clopidogrel plus aspirin group and 7.3% in aspirin group ( <i>P</i> = 0.22) Subgroup analysis in PAD patients: no benefit was derived from dual antiplatelet therapy
CAPRIE <sup>[15]</sup> (1996)	19185	Recent MI, recent ischemic stroke or symptomatic PAD	Aspirin <i>vs</i> clopidogrel	MI, stroke and vascular death	RRR of 8.7% clopidogrel group ( <i>P</i> = 0.043; 95%CI: 0.3-16.5) Subgroup analysis in PAD patients: 23.8% RRR in clopidogrel over aspirin ( <i>P</i> = 0.0028; 95%CI: 8.9-36.2)

MI: Myocardial infarction; PAD: Peripheral arterial disease; ARR: Absolute risk reduction; RRR: Relative risk reduction.

and surgical bypass conduits will be compared and chosen by enrollment site and physician preference. The revascularization strategy will be selected for each case in a specialized vascular center in close cooperation with an endovascular specialist and a vascular surgeon<sup>[10]</sup>.

## ANTIPLATELET THERAPY

Platelets have a fundamental role in the development of atherothrombosis<sup>[11]</sup>. Although percutaneous revascularization therapies have evolved significantly with dramatic improvement in interventional devices and techniques, the most appropriate antiplatelet therapy regimen in PAD is understudied compared to the coronary artery disease (CAD) population. Multiple antiplatelet agents have been studied in the PAD population, including aspirin, the combination of aspirin and dipyridamole, clopidogrel, ticagrelor, cilostazol and vorapaxar. Results from randomized clinical trials in patients with CAD and subgroup analysis in the PAD population and PAD alone are summarized in Tables 1 and 2 respectively. Given the number of agents studied, there is a wide discrepancy in the management of patients with PAD. Meta-analysis conducted by the Antithrombotic Trialists Collaboration Group in 2002 evaluated 287 randomized studies, and concluded that antiplatelet therapy reduced the risk of

serious vascular events (non-fatal MI, non-fatal stroke, or vascular death) by about 23%, not just among the population with unstable angina, acute MI or stroke but also among patients with CAD, PAD, and those at high risk of embolism<sup>[12]</sup>.

## ASPIRIN

Aspirin is a commonly used antiplatelet agent, which irreversibly inhibits the cyclooxygenase-1 and 2 enzymes resulting in decreased formation of thromboxane A<sub>2</sub>, thus inhibiting platelet aggregation. However, compelling evidence to support a reduction in cardiovascular events in the setting of PAD is lacking<sup>[12]</sup>. In a meta-analysis published by Berger *et al.*<sup>[13]</sup> in 2009, 18 trials comprising 5269 participants with PAD were evaluated. Cardiovascular events occurred at a rate of 8.9% (251/2823 subjects) in the aspirin or aspirin plus dipyridamole group and 11% (269/2446 subjects) in the control group (95%CI: 0.76-1.04). This finding was a 12% relative risk reduction in non-fatal MI, non-fatal stroke and cardiovascular death with aspirin, but it failed to reach statistical difference<sup>[13]</sup>. Despite these results, aspirin (dose 75-325 mg) is given a class I recommendation in the 2016 AHA/ACC PAD guidelines for management of symptomatic patients largely due to benefit of aspirin in other vascular diseases<sup>[3,14]</sup>.

**Table 2** Results of clinical trials designed for patients with peripheral arterial disease

Clinical trial	No. of patients	Patient population	Drugs studied	Primary end point	Outcomes
COMPASS <sup>[44,45]</sup> (2017)	27402	Peripheral arterial disease or coronary artery disease	Rivaroxaban plus aspirin or rivaroxaban alone <i>vs</i> aspirin alone	Myocardial infarction, stroke, CV death and the time from randomization to the first occurrence of major bleeding	Preliminary results: Trial stopped prematurely. One of rivaroxaban arms proved to be superior to aspirin alone No disclosed information on the primary bleeding endpoint or the regimen that showed superiority to aspirin alone
EUCLID <sup>[41]</sup> (2016)	13885	PAD (ABI $\leq$ 0.80 or prior (> 30 d) revascularization of the lower extremities)	Ticagrelor <i>vs</i> clopidogrel	CV death, MI, or ischemic stroke	10.8% in ticagrelor group <i>vs</i> 10.6% in clopidogrel group ( $P = 0.65$ )
MIRROR <sup>[39]</sup> (2012)	80	PAD treated with endovascular therapy	Dual antiplatelet therapy (aspirin plus clopidogrel) <i>vs</i> aspirin monotherapy	Local concentrations of platelet activation markers $\beta$ -thromboglobulin and CD40L	Reduced peri-interventional platelet activation and improved functional outcome in the dual antiplatelet therapy group
Berger <i>et al</i> <sup>[13]</sup> (Meta-analysis-2009)	5269	PAD (patients with claudication, those undergoing percutaneous intervention or bypass surgery, and asymptomatic patients with an ABI of 0.99 or less)	Aspirin or combination of aspirin plus dipyridamole <i>vs</i> placebo	Composite end point of non-fatal MI, nonfatal stroke, and CV death	8.9% in aspirin or combination of aspirin and dipyridamole, 11% in placebo (95%CI: 0.76-1.04)
WAVE <sup>[43]</sup> (2007)	2161	PAD (atherosclerosis of the arteries of lower extremities, carotid arteries or subclavian arteries)	Antiplatelet agent plus oral anticoagulant <i>vs</i> antiplatelet therapy in patients with PAD	CV death, MI and stroke	12.2% in combination therapy group and 13.3% in antiplatelet therapy alone (95%CI: 0.73 to 1.16; $P = 0.48$ )
Thompson <i>et al</i> <sup>[29]</sup> (Meta-analysis-2002)	2702	PAD (stable, moderate to severe claudication)	Cilostazol <i>vs</i> placebo	MWD, pain free walking distance	MWD: 44% and 50% (cilostazol 50 mg and 100 mg respectively) and 21.4% in placebo ( $P < 0.05$ ) Pain-free walking distance: 60% and 67% (cilostazol 50 and 100 mg respectively) and 40% in placebo group ( $P < 0.05$ )
BOA <sup>[42]</sup> (2000)	2690	Patients undergone infra-inguinal bypass surgery	Warfarin <i>vs</i> aspirin	Graft occlusion	No observed difference in warfarin compared to aspirin (HR = 0.95; 95%CI: 0.82-1.11)

ABI: Ankle brachial index; CV: Cardiovascular; HR: Hazard ratio; MI: Myocardial infarction; MWD: Mean walking distance.

## CLOPIDOGREL

Clopidogrel is a thienopyridine derivative which inhibits platelet activation by adenosine diphosphate (ADP). There is data to support the effectiveness of clopidogrel as monotherapy in PAD. The first trial to establish this benefit was the CAPRIE trial, a randomized, blinded trial which compared the relative efficacy of clopidogrel (75 mg once daily) and aspirin (325 mg once daily) in patients with high risk of ischemic events. It included 19185 subjects (recent MI, recent ischemic stroke or symptomatic PAD), followed over 1-3 years with mean follow up of 1.9 years. There was a statistically significant 8.7% relative risk reduction ( $P = 0.043$ ; 95%CI: 0.3-16.5) in the composite endpoint of MI, stroke and vascular death in the clopidogrel group. In a subgroup analysis of the PAD population from the CAPRIE trial, the average event rate per year was 3.71% in the clopidogrel arm compared to 4.86% in the

aspirin arm, resulting in a 23.8% relative risk reduction ( $P = 0.0028$ ; 95%CI: 8.9-36.2)<sup>[15]</sup>. This outcome provides support for the inclusion of clopidogrel as a class I recommended antiplatelet agent in the 2016 AHA/ACC guidelines for the management of PAD<sup>[3]</sup>.

We are currently in an era where individualized antiplatelet therapy is becoming an important concept due to the fact that significant major adverse cardiovascular events (MACE) still occur despite clopidogrel use<sup>[16]</sup>. It is possible that clopidogrel resistance due to poor metabolism may contribute to this problem<sup>[17,18]</sup>. Clopidogrel resistance has been demonstrated in populations of patients also identified to have risk factors for PAD, including diabetics<sup>[19]</sup>, smokers<sup>[20]</sup>, and chronic kidney disease patients<sup>[21]</sup>. Doubling the dose of clopidogrel in these patients has proved ineffective<sup>[22]</sup>. In these cases, a more potent P2Y<sub>12</sub> inhibitor such as prasugrel or ticagrelor should be considered as these agents have enhanced platelet inhibition<sup>[23,24]</sup>. This

concept has been validated by Spiliopoulos *et al*<sup>[25]</sup>, who measured platelet reactivity after switching from clopidogrel to ticagrelor in clopidogrel resistant patients and found a significant response in platelet inhibition.

## DIPYRIDAMOLE AND ASPIRIN

The role of dipyridamole, an inhibitor of platelet adenosine uptake, in the management of PAD is debatable. Numerous small studies have shown benefit of combining dipyridamole and aspirin compared to aspirin alone<sup>[26,27]</sup>. The ESPRIT trial published in 2006 was a large randomized controlled trial which compared the efficacy of aspirin and dipyridamole combination therapy against aspirin alone to prevent vascular events within six months after ischemic stroke or TIA. The primary outcome was the composite of death from all vascular causes, non-fatal stroke, non-fatal MI or major bleeding, which occurred at a rate of 13% in the aspirin and dipyridamole group and 16% aspirin alone group [hazard ratio (HR) = 0.80, 95%CI: 0.66-0.98; absolute risk reduction 1.0% per year, 95%CI: 0.1-1.8]<sup>[28]</sup>. However, it is uncertain if dipyridamole monotherapy would be superior to aspirin since there is no data available. Additionally, this study was not conducted in the PAD population.

## CILOSTAZOL

Cilostazol, a unique antiplatelet agent, is a phosphodiesterase III inhibitor which reversibly inhibits platelet aggregation and also possesses vasodilatory and antiproliferative properties. It has been widely studied in PAD. A meta-analysis of 8 randomized trials including 2702 PAD subjects with claudication found improvement in maximum and pain-free treadmill walking distance with cilostazol. The mean walking distance of patients taking cilostazol 50 and 100 mg twice daily increased by 44% and 50%, respectively compared to 21.4% in placebo ( $P < 0.05$ ). The pain-free walking distance increased by 60% and 67% in the cilostazol 50 and 100 mg twice daily groups respectively, compared to 40% in the placebo group ( $P < 0.05$ )<sup>[29]</sup>. Hence cilostazol has class IA recommendation to improve symptoms and walking distance in patients with claudication<sup>[3]</sup>. There are some available studies that support an additional value of cilostazol in reducing restenosis and repeat revascularization following endovascular therapy, although these studies are very small and thus hypothesis generating<sup>[30,31]</sup>.

## TICAGRELOR

Ticagrelor is a cyclopentyltriazolopyrimidine which reversibly binds to the platelet ADP P2Y<sub>12</sub> receptor, unlike the thienopyridines. Ticagrelor is metabolized by Cytochrome P450 3A4/5. Its metabolite AR-C124910XX is equally active and potent, reversibly interacting with the platelet P2Y<sub>12</sub> ADP receptor, resulting in the

inhibition of platelet aggregation. Ticagrelor has been reported to have a faster onset of action compared to clopidogrel and, like prasugrel, results in greater platelet inhibition than clopidogrel.

The PLATO trial established the benefit of ticagrelor over clopidogrel in the ACS population. In this study, 18624 ACS patients with or without ST-segment elevation were randomized to receive ticagrelor (180 mg loading dose, then 90 mg twice daily) or clopidogrel (300-600 mg loading dose, then 75 mg daily). All patients received low dose aspirin (75-100 mg daily), although 325 mg was permitted for 6 mo following PCI with stenting. There was a significant reduction in the rate of death from vascular causes, MI, or stroke with ticagrelor compared to clopidogrel (9.8% vs 11.7%,  $P < 0.001$ ), although the rate of non-CABG related major bleeding was higher (4.5% vs 3.8%,  $P = 0.03$ )<sup>[23]</sup>. An analysis of the PLATO population ( $n = 1144$ ) with concomitant PAD, found similar results to the overall trial although it did not reach statistical significance. It also showed a significantly higher rate of the primary endpoint compared to patients without PAD<sup>[32]</sup>.

The recently published EUCLID trial is a direct comparison of ticagrelor and clopidogrel in the PAD population. This is a large, multicenter, randomized, parallel blinded study that enrolled 13885 patients 50 years or older with PAD defined as ABI  $\leq 0.80$  or prior ( $> 30$  d) revascularization of the lower extremities. Patients were randomized to ticagrelor 90 mg twice daily ( $n = 6930$ ) or clopidogrel 75 mg daily ( $n = 6955$ ) and followed for 30 mo. The primary outcome of the study was the incidence of cardiovascular death, MI, or ischemic stroke, which occurred at a rate of 10.8% of the ticagrelor group and 10.6% of the clopidogrel group ( $P = 0.65$ ). There was also no noted difference in secondary outcomes including acute limb ischemia and major bleeding between the two groups. Not surprisingly, there was a higher rate of medication discontinuation in the ticagrelor group due to dyspnea. In summary, among patients with symptomatic PAD, ticagrelor was not superior to clopidogrel in preventing MACE<sup>[33]</sup>.

The THEMIS Study (Effect of Ticagrelor on Health Outcomes in Diabetes Mellitus Patients Intervention Study) is another ongoing trial which is evaluating the efficacy of ticagrelor vs placebo, in addition to standard care including aspirin, for the long-term prevention of major vascular events in patients with type 2 diabetes and coronary atherosclerosis<sup>[34]</sup>.

## VORAPAXAR

Vorapaxar is a protease activator receptor-1 (PAR-1) antagonist, inhibiting the interaction of thrombin with the PAR-1 receptor, thus inhibiting platelet aggregation. The Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic events-Thrombolysis in Myocardial Infarction 50 (TRA

2P-TIMI 50) trial published was a double blinded placebo controlled trial which evaluated vorapaxar for the secondary prevention of atherothrombosis. It included 26449 subjects with a previous history of MI or ischemic stroke within the previous 2 wk-12 mo or PAD, randomized to either vorapaxar 2.5 mg daily or placebo. Concomitant antiplatelet therapy was permitted. The primary endpoint included a composite of cardiovascular death, MI and stroke. Results revealed that the composite endpoint occurred in 9.3% of patients receiving vorapaxar vs 10.5% of patients receiving placebo (HR = 0.87; 95%CI: 0.80-0.94;  $P < 0.001$ ). Subgroup analysis in the PAD population showed no difference in the primary endpoint, however the vorapaxar group showed a significant reduction in limb ischemic events (vorapaxar 2.3% vs placebo 3.9%; HR = 0.58; 95%CI: 0.39-0.86;  $P = 0.006$ ) and the need for peripheral artery revascularization (vorapaxar 18.4% vs placebo 22.2%; HR = 0.84; 95%CI: 0.73-0.97;  $P = 0.017$ ). However, the clinical benefit offered by vorapaxar was offset by a significant increase in the rate of intracranial hemorrhage (vorapaxar 1% vs placebo 0.5%,  $P < 0.001$ )<sup>[35]</sup>.

## DUAL VS MONO ANTIPLATELET THERAPY

Data behind optimal antiplatelet therapy following peripheral endovascular treatment is limited. A recent meta-analysis reviewed dual vs mono antiplatelet therapy trials after endovascular therapy in coronary, carotid and peripheral vascular territories. The authors did not find conclusive data proving superiority of dual antiplatelet therapy over monotherapy in peripheral vascular interventions, however they did note the paucity of data in this regard<sup>[36]</sup>.

The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance trial compared the effect of combination aspirin and clopidogrel vs aspirin monotherapy in patients with either clinically documented vascular disease or risk factors for atherothrombotic disease. It included 15603 patients randomized to either clopidogrel (75 mg/d) plus low dose aspirin (75-162 mg) or placebo plus low dose aspirin for a mean follow up of 28 mo. Dual antiplatelet therapy did not significantly reduce the rate of MI, stroke or cardiovascular death (6.8% in clopidogrel plus aspirin group and 7.3% in aspirin monotherapy group,  $P = 0.22$ )<sup>[37]</sup>. In a subgroup analysis of patients with symptomatic PAD, no benefit was derived from dual antiplatelet therapy<sup>[38]</sup>.

The MIRROR study was a randomized double blinded trial, enrolling only 80 patients, which assessed the influence of dual antiplatelet therapy with aspirin and clopidogrel vs aspirin alone on local platelet activation in patients with PAD treated with endovascular therapy. Primary endpoints were local concentrations of platelet activation markers  $\beta$ -throm-

boglobulin and CD40L and the rate of clopidogrel resistance. Secondary endpoints included the clinical development of target lesion revascularization (TLR), stenosis, ABI, adverse events and days spent in hospital because of TLR, 6 mo after the intervention. The duration of therapy was 6 mo post intervention and results showed reduced peri-interventional platelet activation and improved functional outcome in the dual antiplatelet therapy group. The median peri-interventional concentration of  $\beta$ -TG was 224.5 vs 365.5 ( $P = 0.03$ ) in the clopidogrel and placebo group respectively. The concentration of CD40L was 127 in the clopidogrel group and 206.5 in the placebo group ( $P = 0.05$ )<sup>[39]</sup>.

Finally, the combination of ticagrelor and aspirin was studied against aspirin alone in the PEGASUS-TIMI 54 trial to evaluate the benefit of prolonged treatment with dual antiplatelet therapy. A total of 21162 patients with a history of myocardial infarction 1 to 3 years prior, were randomized to receive placebo or two different regimens of ticagrelor, 60 mg twice daily or 90 mg twice daily. All patients were recommended to take aspirin, with 97% taking aspirin 75-100 mg daily. The trial continued for a median of 33 mo with a primary composite endpoint of cardiovascular death, MI or stroke. The rate of the primary endpoint was 9.04% in the placebo (aspirin only) arm, 7.77% in the ticagrelor 60 mg arm and 7.85% in the ticagrelor 90 mg arm ( $P = 0.004$  ticagrelor 60 mg vs placebo;  $P = 0.008$  ticagrelor 90 mg vs placebo). This benefit was counterbalanced by a significant increase in TIMI major bleeding with both ticagrelor groups compared to placebo<sup>[40]</sup>.

The symptomatic PAD population from this trial included 1143 patients and was separately analyzed. As expected, the PAD population had a higher rate of major cardiovascular events compared to the population without PAD (19.3% vs 8.4%,  $P < 0.001$ ). Both ticagrelor groups had a lower incidence of the primary endpoint compared to placebo, but only the 60 mg arm had a statistically significant reduction. There was no difference in the rates of major bleeding between the three groups, although the numbers of patients in each group were small<sup>[41]</sup>.

## ROLE OF ANTICOAGULANT THERAPY

### Vitamin K antagonists

There is limited information describing the role of oral anticoagulation, with or without antiplatelet therapy, in patients with PAD. Warfarin and acenocoumarol, both vitamin K antagonists, have been studied in a few PAD population based studies. The Dutch Bypass Oral Anticoagulants or Aspirin (BOA) trial evaluated anticoagulation with warfarin (INR goal 3.0-4.5) compared to aspirin 80 mg daily in 2690 patients undergoing infra-inguinal bypass surgery. There was no observed difference in the patency rates with warfarin

compared to aspirin, respectively (HR = 0.95; 95%CI: 0.82-1.11). Subgroup analysis revealed that patients with vein grafts benefited from lower rates of graft occlusion (HR = 0.69; 95%CI: 0.54-0.88) in the warfarin group. However, patients with prosthetic grafts experienced higher rates of graft occlusion on warfarin (HR = 1.26; 95%CI: 0.82-1.11). As predicted, the warfarin population experienced an increased number of major bleeding episodes compared to aspirin (HR = 1.96; 95%CI: 1.42-2.71). The BOA trial reiterated that only selected patients with PAD stand to benefit from chronic warfarin therapy, particularly patients undergoing lower extremity bypass with vein grafts<sup>[42]</sup>.

The WAVE trial compared the efficacy and safety of combination therapy with an antiplatelet agent (aspirin 81-325 mg, ticlopidine or clopidogrel) and a vitamin K antagonist (warfarin or acenocoumarol) (target INR, 2.0 to 3.0) to antiplatelet therapy (aspirin, ticlopidine or clopidogrel) alone in patients with PAD. Results showed that the use of combination therapy did not prevent major cardiovascular complications to a greater extent than antiplatelet therapy alone (combination therapy group 12.2% and antiplatelet therapy alone 13.3%; 95%CI: 0.73-1.16;  $P = 0.48$ ). Instead, combination therapy was associated with a significantly higher incidence of life-threatening bleeding (4.0% vs 1.2%; 95%CI: 1.84-6.35;  $P < 0.001$ ) and moderate bleeding (2.9% vs 1.0%; 95%CI: 1.43-5.58;  $P = 0.002$ )<sup>[43]</sup>. Due to lack of evidence to support any benefit of the addition of warfarin to antiplatelet therapy in the reduction of thrombotic events in patients with PAD, oral anticoagulant therapy is highlighted as a class III (no benefit and possible harm) recommendation in the most recent AHA/ACC guidelines<sup>[3]</sup>.

## DIRECT ACTING ORAL ANTICOAGULANT AGENTS

Studies are currently ongoing to investigate the potential role of direct acting oral anticoagulant agents (DOAC) (dabigatran, rivaroxaban, apixaban and edoxaban) therapy in the PAD population. Apixaban, edoxaban and rivaroxaban are all factor Xa inhibitors, while dabigatran is a direct thrombin inhibitor. Preliminary results from the Cardiovascular Outcomes for People using Anticoagulation Strategies trial have recently been released, following early termination due to clinical benefit. In this study, 27402 patients with documented atherosclerosis (coronary and/or peripheral) were randomized to either 2.5 mg of rivaroxaban twice-daily plus aspirin 100 mg daily, 5 mg rivaroxaban twice-daily monotherapy or aspirin 100 mg once daily monotherapy. Primary endpoints were defined as the time from randomization to the first occurrence of either myocardial infarction, stroke or cardiovascular death and the time from randomization to the first occurrence of major bleeding. The primary efficacy outcome data was not released, but the

company stated that the trial reached its prespecified criteria for superiority in at least one of the rivaroxaban-based arms compared to aspirin alone. Bleeding information was not disclosed, although the company release mentioned "confirmation of the existing safety profile"<sup>[44,45]</sup>. In a similar trial, edoxaban, a once-daily factor Xa inhibitor is being evaluated in a randomized multicenter study in patients with PAD to assess the efficacy of its addition to aspirin compared to a clopidogrel plus aspirin regimen in preventing stenosis or occlusion in patients undergoing femoro-popliteal endovascular intervention<sup>[46]</sup>.

## ANTIPLATELET THERAPY AND PATENCY POST PERIPHERAL ENDOVASCULAR TREATMENT

Restenosis after percutaneous transluminal angioplasty is a major limitation for favorable outcomes, and is influenced by a number of factors such as vascular inflammation, platelet activation and aggregation. Data on post endovascular intervention duration of treatment with antiplatelet therapy is insufficient. There is high rate of re-occlusion and target lesion stenosis post angioplasty. Patency rate after PTA is impacted by variables; such as length of diseased segments, severity of the disease in run-off arteries, the number of lesions treated and presence of cardiovascular risk factors<sup>[1,47]</sup>.

The ideal antiplatelet regimen and appropriate duration of treatment has not been well validated in clinical trials. The combination of aspirin and dipyridamole trended toward a superior impact on patency after femoro-popliteal angioplasty compared with vitamin K antagonists at 3, 6, and 12 mo. Aspirin 50 to 300 mg, with or without dipyridamole, given before femoro-popliteal endovascular treatment, reduced the incidence of re-occlusion at 6 and 12 mo without any safety concerns when compared with no therapy or vitamin K antagonists<sup>[48]</sup>. The Clopidogrel and Aspirin in the Management of Peripheral Endovascular Revascularization study which was designed to assess the efficacy and safety of this regimen after femoro-popliteal PTA was stopped prematurely because of insufficient randomization numbers. Off-label use of dual antiplatelet therapy in many patients led to its failure. The combination of clopidogrel and aspirin showed higher inhibition of platelets before and after angioplasty in patients undergoing endovascular intervention for claudication<sup>[49]</sup>. As mentioned previously, in the MIRROR study, treatment with clopidogrel and aspirin reduced target lesion revascularization improving the patency of treated lesions and decrease the need for revascularization<sup>[39]</sup>.

Lower extremity bypass is another important treatment for patients with symptomatic PAD when less-invasive endovascular procedures are not an

**Table 3** Current available guidelines addressing antiplatelet therapy for peripheral arterial disease

Class of recommendation	Guidelines
Class Ia	Aspirin in daily doses of 75 to 325 mg or clopidogrel 75 mg/d is recommended to reduce the risk of MI, stroke, or vascular death in individuals with symptomatic atherosclerotic lower extremity PAD
Class IIa	Antiplatelet therapy is reasonable to manage asymptomatic individuals with an ABI less than or equal to 0.90 to reduce the risk of MI, stroke, or vascular death
Class IIb	Dual-antiplatelet therapy (aspirin and clopidogrel) may be reasonable to reduce the risk of limb-related events in patients with symptomatic PAD after lower extremity revascularization

PAD: Peripheral arterial disease; MI: Myocardial infarction.

option because of anatomic or technical considerations. Graft failure is related to multiple factors including type of graft material, site of anastomosis, rate of stenosis, type of antiplatelet used post procedure and duration of medical treatment post intervention. Prosthetic grafts with anastomosis to the tibial arteries seem to have highest rate of failures. Most grafts fail in the first two years, mainly attributed to graft stenosis<sup>[50]</sup>.

Antiplatelet therapy with aspirin improves grafts patency and limb salvage. Patients receiving a prosthetic graft were more likely to benefit from administration of antiplatelet agents than those treated with a venous graft<sup>[51]</sup>. Risk of graft occlusion while on single antiplatelet therapy; typically aspirin, still remains high. Incidence reported to be 15% per year when a vein is used and 20% with synthetic material (polytetrafluoroethylene) rising to 45% and 75%, respectively, for below-knee grafts<sup>[52,53]</sup>. In the CASPAR trial, combination of aspirin and clopidogrel showed statistically significant decrease in prosthetic graft failure with decreasing rate of occlusion and amputation to levels similar to those seen with venous grafts<sup>[54]</sup>.

## DISCUSSION

### Current practice

Dual antiplatelet therapy is often used in patients undergoing infra-inguinal angioplasty and stenting as mentioned in a survey by Allemang *et al*<sup>[55]</sup> from the vascular surgery community itself, which revealed that the most common antiplatelet therapy after lower extremity endo-luminal therapy was a combination of aspirin and clopidogrel. Duration of therapy also varied, with 1 to 3 mo as the most common time frame. Therapy use increased with distal endovascular treatment and with the placement of stents and there was no consensus over the duration of therapy<sup>[55]</sup>. However, there is no robust data to support such practice. Rationale for shorter duration of antiplatelet therapy post endovascular interventions in patients with PAD is primarily drawn from the fact that there is endothelial damage from balloon angioplasty and stenting is generally reserved as a last resort for treating flow limiting localized complications. However, in the current era, peripheral vascular intervention invariably involves atherectomy and significantly longer length of lesions

compared to those seen in the coronary realm. This translates to more extensive endothelial damage and subsequent re-endothelialization which would make longer duration of dual antiplatelet therapy appear intuitive.

### Current guidelines

The recently updated AHA/ACC guidelines for the management of patients with PAD, recommend either aspirin in daily doses of 75 to 325 mg or clopidogrel 75 mg per day as safe and effective antiplatelet therapy to reduce the risk of MI, stroke, or vascular death in individuals with symptomatic atherosclerotic lower extremity PAD (class IA). A Class IIa recommendation is given for considering antiplatelet therapy to manage asymptomatic individuals with an ABI less than or equal to 0.90. Dual antiplatelet therapy with aspirin and clopidogrel may be reasonable after lower extremity revascularization (class IIb), due to the lack of well designed, large clinical trials<sup>[3]</sup>. A summary of the current AHA/ACC Guideline recommendations for antiplatelet therapy in PAD is provided in Table 3.

## CONCLUSION

There have been significant advances in open surgical and endovascular modalities for the treatment of peripheral vascular disease. Long term patency rates for either modality continue to improve, however, randomized controlled trial data comparing the two options head to head are lacking. There appears to be a consensus emerging that endovascular therapy when feasible should be attempted first, although robust randomized data is still needed to support this approach. With contemporary atherectomy techniques, drug coated balloons and stents, a bigger armamentarium is available for immediate and long term success of endovascular therapy. Similarly there is lack of data regarding post intervention medical therapy. Although dual antiplatelet therapy with aspirin and clopidogrel is commonly used, the duration of such therapy is highly variable without a strong recommendation in practice guidelines. Practice patterns for dual antiplatelet therapy are influenced and extrapolated from data available for PCI. It is apparent that there is paucity of clinical trial data for the treatment of peripheral vascular disease

and subsequent care. Additional data is warranted from large scale multicenter randomized controlled trials and observational studies to assess the optimal medical treatment and duration of medical therapy across the spectrum of PAD.

### Abstract

The main stay pharmacotherapy for heart failure (HF) is targeted towards rennin-angiotensin-aldosterone (RAAS) and neprilysin pathways (NP). Both therapeutic strategies decreases morbidity and mortality but also

carry considerable adverse effects. This review of the literature highlights the new generation of HF drug, sacubitril-valsartan (SV), trade name Entresto (researched as LCZ696, Novartis) which simultaneously blocks RAAS and NP. This dual action of angiotensin receptors blocker and neprilysin inhibitor (NPI) has improved HF prognosis and it is an evolution in the management of HF. Although the initial follow-up of patients treated with SV has yielded promising results, there are concerns regarding potential side effects especially an increase in the risk of Alzheimer's disease (AD) and young onset of AD. NPI interferes with the breakdown and clearing of beta-amyloid peptides, the plaques seen in AD, raising concern for AD in SV patients. On the other hand, hypertension and cardiovascular diseases are established risk factors for AD which can be decreased by SV therapy. It is therefore essential that SV treated patients are followed up over an extended period of time to detect any adverse cognitive changes.

**Key words:** Heart failure; Sacubitril-valsartan; Entresto; LCZ696; Neprilysin inhibitor; Alzheimer's disease

**Core tip:** We are discussing an innovative and exciting new treatment for heart failure (HF). This advance in pharmacotherapy has shown promising results and is rapidly incorporating into standard medical therapy for HF. There is, however, a theoretical concern for cognitive dysfunction and early onset Alzheimer's disease particularly in the young. This review informs clinicians of the mechanism and potential for cognitive dysfunction, thereby increasing awareness and promoting informed prescribing.

## INTRODUCTION

Heart failure (HF) is typified by the reduced ability of the heart to deliver an adequate supply of blood and oxygen to the tissues. Its causes are numerous including ischemic heart disease, diabetes, hypertension, cigarette smoking, obesity and valvular heart disease<sup>[1]</sup>. Over 5 million individuals worldwide suffer from HF and its incidence is rising with 550000 new diagnoses annually<sup>[1,2]</sup>. With a steadily aging population, HF incidence is projected to increase to 46% by the year 2030<sup>[1,2]</sup>. HF is associated with increased morbidity, mortality and cost<sup>[1,3]</sup>.

HF occurring due to depressed left ventricular function [ejection fraction (EF)  $\leq$  40%] is known as HF with reduced EF (HFrEF)<sup>[4]</sup>. Pharmacological intervention for HF largely depended on angiotensin inhibitors such as angiotensin receptor blockers (ARBs) and angiotensin converter enzyme inhibitors (ACEi). Recently, a new strategy using a Neprilysin inhibition (NIs) and recombinant natriuretic peptides was proven as a therapeutic option to target HF pathophysiology<sup>[5]</sup>. The new generation of HF pharmacotherapy entails the simultaneous inhibition of both the angiotensin and Neprilysin pathways, the latest version of which is Entresto<sup>®</sup> - the combination of sacubitril and valsartan (SV) (researched as LCZ696)<sup>[6,7]</sup>. In this concise review, we highlight the mechanisms of SV activity, the results of the successful clinical trial and the potential adverse effects, highlighting those on cognitive function.

## METHODS

The search for the relevant articles was conducted on Medline. The following terms "Entresto", "neprilysin inhibitors", "angiotensin inhibitors", "dementia" and "Alzheimer's Disease" "cognitive impairment" were searched in different combinations. The search was limited to articles in English language but no search filters were used for timeline and subjects.

## INCLUSION CRITERIA

Articles that met our following inclusion criteria were included in this review: (1) discussed pathophysiology of HF and target pharmacotherapy mechanism; (2) discussed pathophysiology of development of AD; (3) ongoing trials of Entresto; (4) reported link between neprilysin inhibitors and development of AD; and (5) articles that were published full and in English language.

## PATHOPHYSIOLOGY OF HF

The pathophysiology of HFrEF results mainly from the activation of the renin-angiotensin-aldosterone (RAAS) neuro-hormonal compensatory mechanism. Although the peripheral vasoconstriction initiated by the RAAS mechanism maintains blood pressure and cardiac output for a short time, sustained activation of

RAAS leads to ventricular hypertrophy, hypertension and angioedema, ultimately worsening myocardial dysfunction<sup>[8,9]</sup>. A second compensatory mechanism, the natriuretic peptide (NP) system, counteracts the vasoconstrictive and sodium/water retentive effects of the RAAS system<sup>[10]</sup>.

## GOALS OF PHARMACOTHERAPY

The initial HF pharmacotherapy targeted the RAAS circuit using ARBs<sup>[11]</sup>, ACEi<sup>[12]</sup>, beta-blockers<sup>[13]</sup>, diuretics<sup>[14]</sup> and aldosterone inhibitors<sup>[15]</sup>. All of these drugs have proven to be effective in lowering the morbidity and mortality in HFrEF. The NP system consists of four related peptides (Atrial, Brain, C-Type, and Dendroaspis NP) and a membrane bound peptidase called Neprilysin that degrades these vasoactive peptides<sup>[16]</sup>. NP system targeting drugs have included a recombinant form of BNP (Nesiritide)<sup>[17]</sup> as well as NIs, *e.g.*, candoxatril, recedodotril, *etc*<sup>[18,19]</sup>. HF pharmacotherapy targeting the NP system and the respective clinical trials are summarized in Table 1<sup>[20-32]</sup>. Although strategies blocking either of these two pathways have reduced mortality and morbidity in HF<sup>[12,28,32]</sup>, the prognosis still remains poor due to long term ineffectiveness of the drugs as well as adverse physiological effects<sup>[5]</sup>.

The newest strategy in HFrEF pharmaco-intervention is the combination of ARB and NI (ARNI) that causes a dual inhibition of the RAAS pathway and Neprilysin: The prototype drug was LCZ696<sup>[6,7]</sup> which is made up of 1:1 ratio of the ARB valsartan<sup>[33]</sup> and the NI sacubitril (AHU 377)<sup>[34]</sup>. The action of SV is multimodal. Sacubitril is a pro-drug which is activated to Sacubitrilat (LBQ657), the active metabolite that inhibits NP while valsartan simultaneously blocks the angiotensin receptor. The dual action of Sacubitril and valsartan augment the beneficial actions of the NPs and inhibits the deleterious effects of the RAAS system<sup>[7]</sup>. The PARADIGM-HF trial was conducted by McMurray *et al*<sup>[31]</sup> to determine the efficacy of SV compared to the ACE inhibitor Enalapril<sup>[35,36]</sup>, which improves mortality and morbidity. The median follow-up duration was 27 mo and SV reduced HF related symptoms and overall survival by 20%<sup>[31]</sup>. Additionally, the ARNI approach avoids the common side-effects of ACEi such as cough and angioedema that result from impaired degradation and elevated levels of bradykinin<sup>[37]</sup>. In the ONTARGET trial, ARBs were documented to result in a lower rate of cough and angioedema compared to ACEi: Therefore, combination therapy prefers ARBs over ACEi<sup>[38]</sup>.

The United States Food and Drug Administration had approved SV for clinical use and at present it is produced under the name of Entresto<sup>®</sup> by Novartis<sup>[39]</sup>. The recommended dose of Entresto is 49 mg sacubitril/51 mg valsartan twice daily increased to 97 mg sacubitril/103 mg valsartan after 2-4 wk. It is contraindicated in patients with history of angioedema, hypotension, hyperkalemia or renal dysfunction and in pregnant women due to fetal toxicity<sup>[40]</sup>. In the

**Table 1** Overview of drugs targeting the neprilysin pathways and its pathways

Drug	Mechanism	Clinical trials and year	Results on HF symptoms
Nestiride	Increasing natriuretic peptide activity	VMAC, 2000 <sup>[20]</sup> PRECEDENT, 2002 <sup>[21]</sup> ASCENT-HF, 2009 <sup>[22]</sup>	Improved BP and dyspnea Less cardiac arrhythmias More hypotension
Candoxatril	NPi	Single-centered investigation with only a limited number of patients <sup>[23-25]</sup>	More exercise tolerance Increase in vascular resistance
Omapatrilat	NPi	IMPRESS, 2000 <sup>[26]</sup> OVERTURE, 2002 <sup>[27]</sup> OCTAVE, 2004 <sup>[28]</sup>	More exercise tolerance Increase in angioedema Reduction in BP Lower mortality
LCZ696	NPi	PARAMOUNT, 2012 <sup>[29]</sup> PARADIGM, 2014 <sup>[30,31]</sup> PARAGON, ongoing <sup>[32]</sup>	Reduction in BP Improved ejection fraction Lower mortality No change in angioedema

BP: Blood pressure; HF: Heart failure; NPi: Neprilysin inhibitors.

PARADIGM-HF trial, 10.7% of the patients reported at least one of the following adverse effects hypotension, renal failure, hyperkalemia, fatigue and dizziness<sup>[31]</sup>.

In clinical practice, approximately 50% of the HF patients have a preserved left ventricular ejection fraction (HFpEF) and present with similar morbidity and mortality as seen in patients with HFrEF<sup>[2-4]</sup>. Sacubitril/valsartan is validated in HFrEF but is being evaluated for HFpEF in the PARAMOUNT-HF (The Prospective comparison of ARNI with ARB on Management of Heart Failure with Preserved Ejection Fraction) trial. Patients who treated with sacubitril/valsartan showed a reduction in NYHA class and left atrial volumes<sup>[29]</sup>. At present, the PARAGON-HF trial is ongoing comparing the effects of sacubitril/valsartan versus valsartan in the HFpEF patients<sup>[32]</sup>.

## NEPRILYSIN INHIBITORS AND ALZHEIMER'S DISEASE

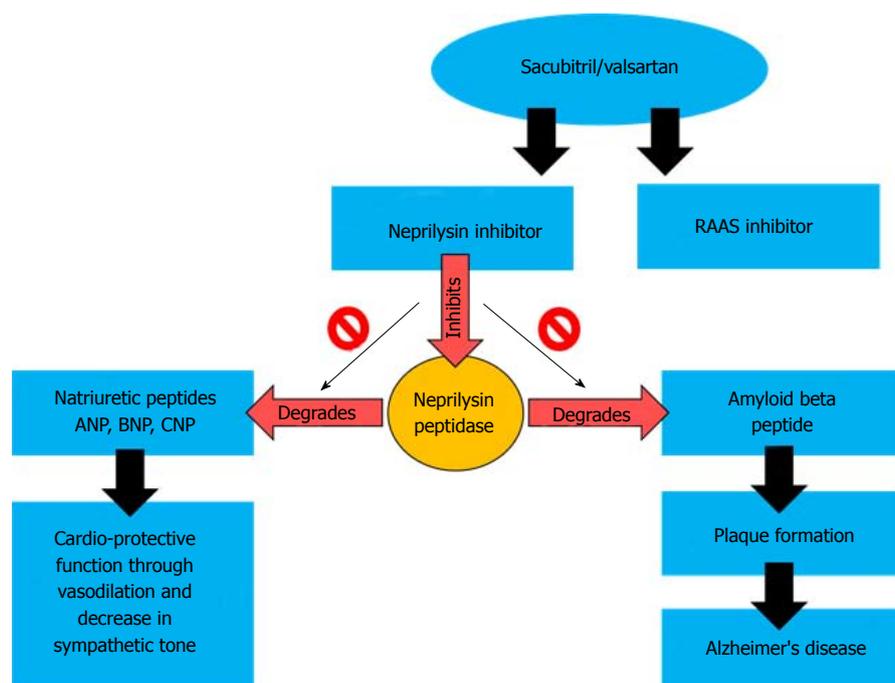

An interesting facet of the use of NIs in the treatment of cardiovascular diseases is their potential role in the development or progression of Alzheimer's disease (AD), as there is considerable overlap between the populations suffering from HF and AD<sup>[41]</sup>. The hallmark of AD is the accumulation of beta amyloid ( $\beta$ A) peptide in the brain causing neurotoxic plaques that are supposedly responsible for the pathology of AD<sup>[42]</sup>. Under normal physiological conditions, the  $\beta$ A peptide is degraded by proteases such as ACE, NP and insulin degrading enzyme<sup>[43]</sup>. NP has a broad range of substrates apart from the NPs such as bradykinin, enkephalins as well as the  $\beta$ A peptide<sup>[44]</sup>. Additionally, patients with AD have lower expression of NP compared to healthy subjects<sup>[45]</sup>, and NP deficient mice develop the murine form of AD<sup>[46]</sup>. This possible correlation was further highlighted when intracerebral infusion of NPi lead to the development of AD-like lesions in rabbits<sup>[47]</sup>. Lastly, certain polymorphisms in the NP gene (NEP) were associated with a higher propensity

for AD in a Finnish cohort<sup>[48]</sup>. Therefore, NP is as much a pharmaceutical target for the treatment of AD as for HF, except that the strategies are opposite for both pathologies (Figure 1). Indeed, NP centered therapies have been developed independently for AD and tested at the pre-clinical levels. CNS targeted recombinant human NP was able to reduce  $\beta$ A peptide toxicity in the mouse model of AD<sup>[49,50]</sup>.

## ENTRESTO® AND ALZHEIMER'S DISEASE

Clinicians should be aware of the possible inhibitory action of SV in the clearing of  $\beta$ A peptide while considering it for HF treatment. In patients who are at the risk of developing AD, whether due to age or genetic predisposition, the chronic exposure to SV may accelerate the clinical onset of the disease. Critical to this hypothesis is the ability of SV to cross the blood brain barrier (BBB) in order to block brain NP. There is evidence that certain NIs like S-acetyltiorphan can cross the BBB<sup>[51]</sup> while some like candoxatril cannot<sup>[52]</sup>. Both Sacubitril and its active metabolite LBQ657<sup>[7]</sup> are under the threshold size of 400 kD which makes them fit to cross the BBB<sup>[53,54]</sup>. It is noteworthy that the PARADIGM-HF trial<sup>[31]</sup> had excluded patients with AD and did not include any cognitive function tests to evaluate drug safety. McMurray *et al.*<sup>[55]</sup> have confirmed some correlation between EN treatment and  $\beta$ A peptide levels in a recent review article. While cynomolgus monkeys treated with SV had increased levels of  $\beta$ A peptide in the CSF, the healthy volunteers treated with EN for two weeks had no change in  $\beta$ A peptide levels. McMurray *et al.*<sup>[31]</sup> showed that the dementia and cognitive defects were not increased in the EN treated patients during the trial. However, it should be noted that the earliest symptoms of AD can take as long as 8-10 years to manifest<sup>[56]</sup>. If there is a correlation between EN therapy and AD, one would predict an earlier onset of symptoms.

It is therefore imperative that patients on SV are followed up for cognitive abilities and potentially

**Figure 1** Schematic representation of the contradictory effects of angiotensin receptor and neprilysin inhibitors on cerebrovascular disease and Alzheimer's disease. ANP: Atrial natriuretic peptide; BNP: Brain natriuretic peptide; CNP: C-type natriuretic peptide.

evaluated for AD. One can consider cerebrospinal fluid (CSF) analysis for  $\beta$ A peptide levels and amyloid plaques through PET scans if early signs of dementia ensue<sup>[57]</sup>. In the ongoing PARAGON-HF<sup>[32]</sup> trial, AD patients have not been excluded and serial cognitive tests have also been included as part of initial follow-up.

Another concern is that the proportion of HF patients younger than 40 years old is increasing<sup>[58]</sup>. Younger patients receiving SV have the potential for a longer term exposure and the consequent potential for increased risk of young onset Alzheimer's disease (YOAD) is noteworthy. YOAD is described in subjects less than 65 years of age and has a more rapid progression than the typical late onset Alzheimer's<sup>[59]</sup>.

Interestingly, one can also describe SV as having protective effect against AD since hypertension and cardiovascular diseases are established risk factors for AD<sup>[60]</sup>, is decreased by SV therapy. ACEi or ARBs have also been shown to decrease in dementia and other symptoms of AD through reducing hypertension and cardiovascular disease<sup>[61]</sup>. It will be interesting to follow the neuro-cognitive outcomes from PARAGON-HF trial.

## CONCLUSION

Clinicians should be aware of the potential adverse effects of SV and make informed decisions in prescribing SV, particularly to patients with existing neuro-degenerative diseases or the very young. As there are no definitive answers yet about the long term effects of SV, we await the results from PARAGON-HF and reports to follow with interest. Patients who are currently

receiving SV treatment should be well monitored for potential adverse events with particular attention to dementia. A low threshold for testing for AD if/when dementia symptoms occur seems warranted. More study on the implications for young HF patients is warranted.

### Abstract

Cardiac and pericardial masses may be neoplastic, benign and malignant, non-neoplastic such as thrombus or simple pericardial cysts, or normal variants cardiac

structure can also be a diagnostic challenge. Currently, there are several imaging modalities for diagnosis of cardiac masses; each technique has its inherent advantages and disadvantages. Echocardiography, is typically the initial test utilizes in such cases, Echocardiography is considered the test of choice for evaluation and detection of cardiac mass, it is widely available, portable, with no ionizing radiation and provides comprehensive evaluation of cardiac function and valves, however, echocardiography is not very helpful in many cases such as evaluation of extracardiac extension of mass, poor tissue characterization, and it is non diagnostic in some cases. Cross sectional imaging with cardiac computed tomography provides a three dimensional data set with excellent spatial resolution but utilizes ionizing radiation, intravenous iodinated contrast and relatively limited functional evaluation of the heart. Cardiac magnetic resonance imaging (CMR) has excellent contrast resolution that allows superior soft tissue characterization. CMR offers comprehensive evaluation of morphology, function, tissue characterization. The great benefits of CMR make CMR a highly useful tool in the assessment of cardiac masses. (Fluorine 18) fluorodeoxyglucose (FDG) positron emission tomography (PET) has become a corner stone in several oncological application such as tumor staging, restaging, treatment efficiency, FDG is a very useful imaging modality in evaluation of cardiac masses. A recent advance in the imaging technology has been the development of integrated PET-MRI system that utilizes the advantages of PET and MRI in a single examination. FDG PET-MRI provides complementary information on evaluation of cardiac masses. The purpose of this review is to provide several clinical scenarios on the incremental value of PET and MRI in the evaluation of cardiac masses.

**Key words:** Cardiac; Pericardial tumors; Echocardiography

## INTRODUCTION

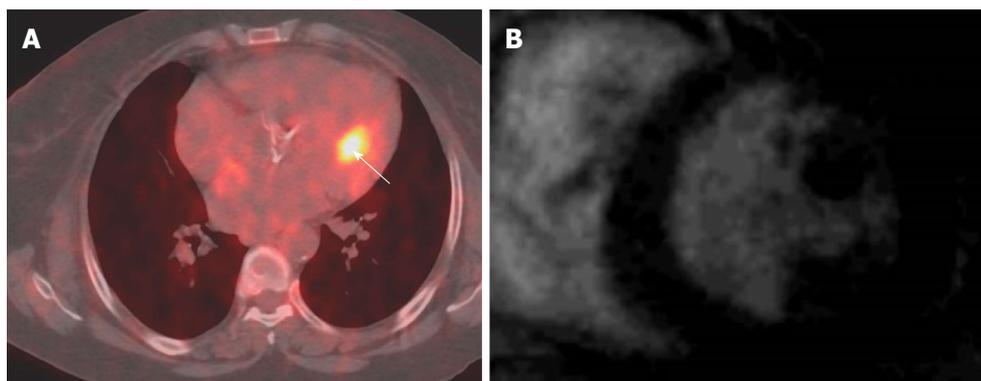

Primary cardiac tumors, Benign and Malignant, are rare with an estimated prevalence of 0.002%-0.3% at autopsy<sup>[1]</sup>. The primary benign cardiac tumors are common and include myxomas, fibromas, rhabdomyomas, lipoma, fibroelastomas, hemangioma, and paragangliomas. The primary malignant cardiac neoplasm is generally sarcomas, mesotheliomas, or lymphoma. Cardiac metastases involving the heart and pericardium (secondary cardiac tumors) from direct invasion or hematological spread are 20%-40% more common than primary cardiac tumors and usually associated with poor prognosis primary related to advanced stage of primary malignancy<sup>[2]</sup>. However, the most common type of cardiac mass is in fact pseudotumors or tumors like structures such as intracardiac thrombus, pericardial cyst, valvular vegetation, perivalvular abscess, or normal cardiac variant such as crista terminalis.

Patients with primary cardiac tumors may present with a range of symptoms that can simulate cardiac disease. The clinical presentation is determined mostly by location, size, and texture, the rate of growth and invasiveness of the tumor. For example, patients with mechanical obstruction related to cardiac mass in outflow tract may present with heart failure or valvular disease, systolic dysfunction or diastolic dysfunction related to impaired contractility. Pericardial disease may present as pericardial effusion, pericardial tamponade, or pericardial thickening and nodularities.

Several imaging modalities are used in the evaluation of cardiac and Pericardial tumors with their inherent advantages and disadvantages. Transthoracic

echocardiography is widely available and is considered the procedure of choice for diagnosis of intracardiac tumors. It provides information on the size, mobility, shape and location of the cardiac mass but limited information on mass tissue characterization. In certain patients, such as obese patients or patients with chronic obstructive lung disease trans esophageal echocardiography offers a diagnostic alternative<sup>[3]</sup>. Cardiac computed tomography (CT) is a noninvasive technique which offers a high spatial resolution and sufficient temporal resolution. Both cardiac and intracardiac mass can be very clearly depicted as well as their degree of myocardial and pericardial involvement; however, radiation and iodinated contrast injection are some of CT imaging<sup>[4]</sup>. Cardiac magnetic resonance (CMR) has several advantages in the diagnosis of patients with cardiac tumors. The greatest advantages of CMR over various imaging modalities, is that CMR have a unique ability to characterize tissue composition based on the inherent T1 and T2 relaxation of different tissue; in addition CMR provides excellent temporal and spatial resolution, multiplanar 3D imaging capabilities, large field of view, evaluating adjacent vascular structures, lymph nodes involvement and mediastinum<sup>[5,6]</sup>. Positron emissions tomography (PET) offers an accurate evaluation of the metabolic activity of the tumors *via* utilizing (fluorine 18) fluorodeoxyglucose (FDG). FDG PET is very helpful for staging malignancies, optimizing biopsy location, radiation therapy planning and detection of tumors recurrence and response to therapy. In cases of cardiac metastases FDG pet can detect both primary lesions such as lung cancer and cardiac metastases. The extent of FDG uptake by tumors is useful for differentiation between benign and malignant tumors<sup>[7]</sup>.

Positron emission tomography-magnetic resonance imaging (PET-MRI) hybrid scanners are a newly developed type of clinical imaging system. PET-MRI benefits from the advantages of both PET and MRI. MRI provides tumors tissue characterization with T1 and T2, and different pulse sequence with and without gadolinium injection, extent of the tumors invasion and local metastasis, in addition, CMR offers a comprehensive examination of the heart and any complication related to the tumors such as pericardial effusion or valvular dysfunction. PET assesses the metabolic evaluation of the tumors, and evaluation of the primary extracardiac tumors or other distant metastases. Integrated PET-MRI systems provide improved spatial and temporal alignment, CMR image based motion correction is also improved, artefacts such as motion and partial volume effect in PET scanning. Integrated PET-MRI system significantly reduces time of imaging acquisition compared to performing two separate examinations, improve throughput and also reduce patient's discomfort<sup>[8,9]</sup>. In this review, we will discuss several clinical scenarios in which CMR and PET provides additive information, these illustrated cases performed as sequential examinations, not

**Figure 1** Localization of abnormal fluorodeoxyglucose activity in the heart. A: Axial fused PET-CT image shows focal intense FDG uptake in the heart (arrow) in patient with melanoma that thought represents cardiac metastases; B: Selected delayed enhancement short axis image of the same patient with other images (not shown) shows no abnormal enhancement or tissue infiltration, the FDG uptake was corresponding to hypertrophic papillary muscle, follow PET-CT was normal. PET: Positron emission tomography; CT: Computed tomography; FDG: Fluorodeoxyglucose.

on integrated PET-MRI scan, these includes: (1) characterization and Localization of abnormal FDG uptake in the heart; (2) characterization and Localization of abnormal FDG uptake adjacent to the heart; (3) differentiation between tumoral thrombus from bland thrombus; (4) distant Metastasis (M staging); (5) evaluation of aggressiveness of the lesion and assessment of cardiac involvement; and (6) other potential indications.

### CHARACTERIZATION AND LOCALIZATION OF ABNORMAL FDG UPTAKE IN THE HEART

The patterns and distribution of FDG in the normal myocardium may be classified into three types; no to faint uptake, regional uptake, and diffuse uptake. There is no specific pattern myocardial FDG uptake<sup>[10]</sup>. Furthermore, myocardial FDG uptake in the same individual is neither stable nor reproducible unless under the same fasting condition. The PM has a characteristic location on axial and coronal images. PM uptake can occasionally be seen without myocardial uptake, this appearance can mimic an intraventricular thrombus or tumor<sup>[11]</sup>. Focal intense FDG uptake is frequently observed in the basal septal region in patients with active cardiac sarcoidosis<sup>[12]</sup>. Several reports describing FDG patterns in cardiac tumors have been published<sup>[13,14]</sup>. However, the usefulness of FDG in the differentiation between benign (including thrombus) and malignant tumors.

Different imaging modalities are often necessary for approaching final diagnosis of primary or metastatic cardiac tumors. The differential diagnosis can be narrowed down by clinical history, signs and symptoms of the clinical presentation, history of primary neoplasm. Normal cardiac variants and variable myocardial uptake of FDG may raise the suspicion of cardiac metastasis in some PET-CT studies in patients with cancer. In such clinical circumstances, CMR is very

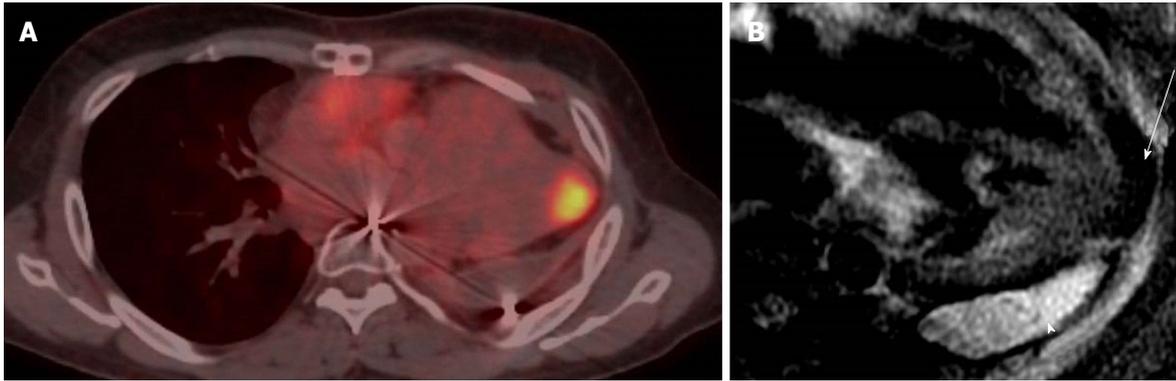

useful (Figures 1 and 2).

### CHARACTERIZATION AND LOCALIZATION OF ABNORMAL FDG UPTAKE ADJACENT TO THE HEART

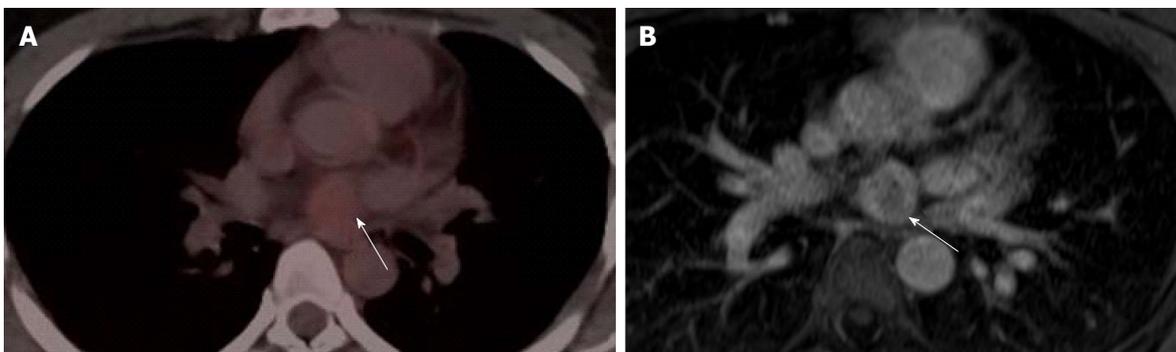

One of the most and frequent artefact in PET-CT is due to respiratory motion during scanning. It typically creates mismatch between a specific stage of breath cycle during the CT and average of many breath cycles of the PET images. The diaphragm that is visualized in a single position during fast CT acquisition is different from mean position of PET images or in case of respiratory motion. misregistration of CT and PET images disrupts images fusion of normal organ and may cause erroneous localization of FDG avid lesion in the liver, upper abdomen, base of the lung, or adjacent to the heart. The best way to correct for respiratory motion between CT and PET images would be acquired gated images to discriminate different interval for a breath cycle<sup>[15]</sup>. There are some techniques in integrated PET-MRI that correct for motion artifact, motion can be derived from MR data without the need for navigators, an approach called self-navigation, and these techniques require that K-space be sampled in a motion sensitive scanner<sup>[16]</sup>. The motion control and gating approaches will continue to be used in integrated PET-MRI scanner, the field will likely move towards data-derived approaches<sup>[17]</sup>. Oncologic PET-CT scans may reveal abnormal focus of hypermetabolism in the chest, either in or adjacent to the heart. It is often not possible to accurately localize this lesion using PET or the corresponding low-dose CT scan. In such situations, MRI can provide additional information in localizing and characterizing these masses (Figures 3 and 4).

### DIFFERENTIATION BETWEEN TUMORAL THROMBUS FROM BLAND THROMBUS

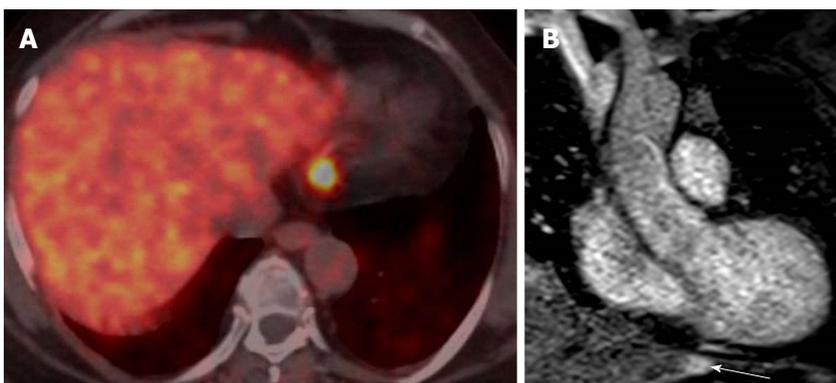

Tumor thrombosis is often clinically asymptomatic,

**Figure 2** Localization and characterization of abnormal fluorodeoxyglucose activity in the heart. A: Axial PET-CT images in patient with history of invasive thymoma underwent surgical resection shows intense FDG focal uptake in the cardiac apex highly suspicious for cardiac metastases, review CT component of PET-CT shows area of and soft tissue; B: Four-chamber DE image with triple inversion recovery shows complete fat suppression of the apical activity in keeping with brown fat (arrow), with high signal fluid intensity consistent with post-operative lobulated fluid collection (arrowhead). PET: Positron emission tomography; CT: Computed tomography; FDG: Fluorodeoxyglucose.

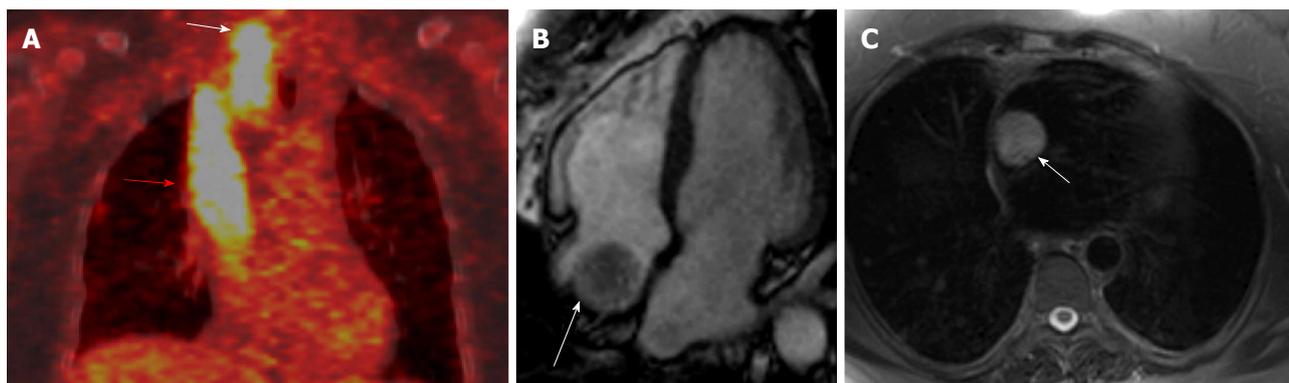

**Figure 3** Localization and characterization of abnormal fluorodeoxyglucose activity adjacent to the heart. A: Localization and characterization of abnormal FDG activity adjacent to the heart. Axial PET-CT image of the heart shows a non-FDG avid nodule near the base of the heart (arrow), PET-CT was performed for incidentally discovered nodule mass on Echocardiography. The study was otherwise unremarkable; B: Axial first pass perfusion image shows highly vascular intrapericardial tumors with no evidence of tissue invasion (arrow); this lesion was surgically removed and pathologically proven schwannoma. PET: Positron emission tomography; CT: Computed tomography; FDG: Fluorodeoxyglucose.

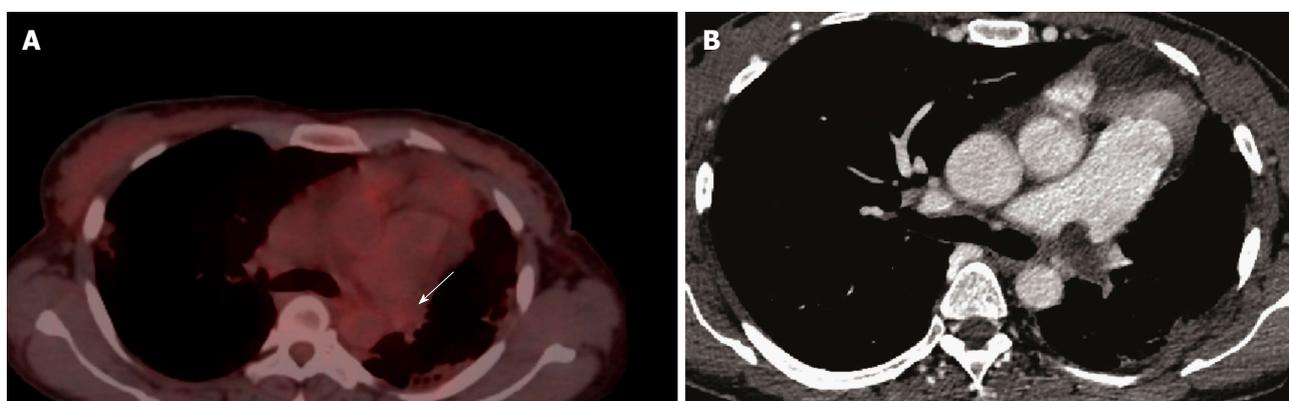

**Figure 4** Localization and characterization of abnormal fluorodeoxyglucose activity adjacent to the heart. A: Axial Ga-68 DOTATATE PET/CT shows a focal intense radiotracer uptake adjacent to the heart with difficulty to accurately localize; patient is known to have history of ileocecal area carcinoid and underwent surgery; B: Coronal first pass perfusion images show highly vascular lesion in the tip of the left lobe of the liver corresponding to abnormal radiotracer uptake, this location is very common for PET-CT misregistration and there was no focal lesion identified in CT component of PET-CT. PET: Positron emission tomography; CT: Computed tomography; FDG: Fluorodeoxyglucose.

the diagnosis of tumoral thrombus is usually made incidentally, discrimination between benign, and tumor thrombus can have significant implications in patient's management. In general, tumor thrombus

is a rare complication of solid cancers, with occult inferior vena cava tumor thrombosis having a reported incidence of 0.11%. Few case reports have described the diagnosis of tumor thrombus by PET-CT in

**Figure 5** Differentiation between tumoral thrombus from bland thrombus. A: Differentiation between tumoral thrombus from bland thrombus in patient with history of thyroid cancer treated with total thyroidectomy presented with neck mass. Coronal fused FDG-PET image shows intense linear FDG uptake from in the thyroid bed (white arrow) and spreading through SCV to the right atrium (red arrow); B: Four chamber cine image shows irregularly defined mass in the right atrium (arrow), the rest of cardiac examination was unremarkable; C: Axial HASTE at the junction of superior vena cava and right atrium shows a high signal intensity mass (arrow). PET: Positron emission tomography; CT: Computed tomography; FDG: Fluorodeoxyglucose.

**Figure 6** Differentiation between tumoral thrombus from bland thrombus. A: Differentiation between tumoral thrombus from bland thrombus in female patient with history ovarian cancer, patient was known to have chronic pulmonary embolism, there was a bland thrombus almost occluding the left pulmonary artery was no FDG uptake (arrow); B: Axial CT image shows a left pulmonary artery thrombus. CT: Computed tomography; FDG: Fluorodeoxyglucose.

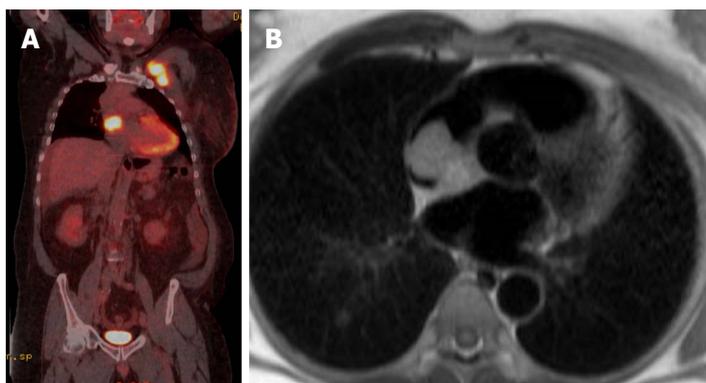

various cancer including pancreatic, colon, renal cell cancer and adrenocortical cancer. In contrast, venous thromboembolism (VTE) is relatively common than tumor thrombosis in patients with cancer. Cancer has been associated with 18% of all cases of incidental VTE. Across all patients with cancer, the risk for VTE has elevated seven folds, in certain malignances the risk for VTE may increase up to 28-folds<sup>[18]</sup>.

Tumor thrombosis is composed mainly of viable tumor cells and usually has high metabolic neoplastic activity<sup>[19]</sup> with subsequent high FDG uptake. FDG uptake in malignant cells is mediated through glucose transporters receptors. In contrast, benign thrombus is composed of activated of platelets, macrophages and fibrin. Therefore, benign thrombus is none metabolically active, simple, non-infected thrombus called bland thrombus. On PET-CT images, bland thrombus appear as intravascular filling defect without FDG uptake and can be found in veins of any size and location.

Distinguishing between benign thrombus and tumor thrombus on basis of presence or absence of FDG uptake may be difficult, it is quite reasonable for

inflammatory or infectious thrombus to demonstrate some degree of FDG uptake. It is reported that inflammatory cells cause significant increase in FDG uptake in presence of platelet-aggregation factors and cytokines including growth factors<sup>[20]</sup>. In addition, expression of the glucose transporter is also increased in activated granulocytes and macrophages<sup>[21]</sup>. The differential diagnosis can be narrowed down by correlating clinical presentation, distinctive clinical features, demographics, and relevant laboratory findings in association with imaging characterization of the thrombus.

Different imaging modalities are available for distinguishing between benign and malignant thrombus. PET-CT offers comprehensive anatomical and metabolic evaluation of the thrombus, particularly, if CT component performed with IV iodinated contrast. On MRI, the signal intensity of the thrombus may vary depending on the age of the thrombus. Gadolinium contrast is useful for differentiating thrombus from tumor, Thrombus typically does not enhance but tumors usually enhance on delayed imaging<sup>[22]</sup>. One

**Figure 7 M staging.** A: M staging: Coronal PET-CT image of patient with lymphoma with unexpected cardiac involvement; B: Axial T1-weighted image at the level of interatrial septum shows well defined mass attached to the atrial septum and nearly fills the right atrium and was proved to be lymphoma. PET: Positron emission tomography; CT: Computed tomography.

study reported, diffusion weighted (DW) imaging enables differentiation between portal vein tumoral thrombus from bland thrombus in patients with hepatocellular carcinoma (HCC), when apparent diffusion coefficient (ADC) of the thrombus to ADC of HCC is less than 2 and when the thrombus showed signal intensity similar to HCC, DW imaging may be very helpful in certain patients, such as patients with contraindication for contrast material injection and/or history of previous reaction to contrast media<sup>[23]</sup> (Figures 5 and 6).

## M STAGING

CMR is a very helpful imaging technique for diagnosis of cardiac tumors which enables evaluation of anatomy, function, tissue type, and vascularity and relationship to adjacent structures. It also allows searching for primary tumors in case of cardiac metastases and detection for metastases in the thorax and liver/abdomen. However, CMR is not adequate for M staging, PET-CT is useful technique for M staging of wide varieties of cancers, several studies reported that PET-CT is more accurate than other conventional imaging staging in several cancer such as several types of lymphoma, solid cancer such as breast, lung, ovary, and head and neck cancers. The newer MRI technique, whole body diffusion weighted imaging is used for tumors detection, characterization, therapy monitoring. In certain with low FDG, uptakes such as neuroendocrine tumors, thyroid cancer and several low malignancy lymphomas, whole body DW is additive for PET-CT for tumors detection, staging, and assessment for response for therapy<sup>[24,25]</sup> (Figure 7).

## EVALUATION OF AGGRESSIVENESS OF THE LESION AND ASSESSMENT OF CARDIAC INVOLVEMENT

FDG PET uptake reflects the metabolic glycolysis in tumors and supplies additional information to mor-

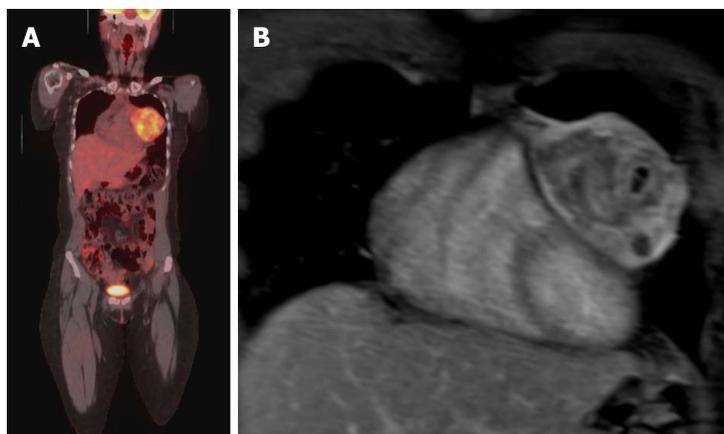

phological imaging. Generally, there is correlation between glucose accumulation in tumors tissue and degree of malignancy, with some exceptions<sup>[26,27]</sup>. However, PET has not yet systematically evaluated for characterization of cardiac tumors, furthermore, PET imaging can assess the local extent of the tumors and tumor infiltration to adjacent tissue. In addition, it is not often possible to accurately localize the lesion using low dose CT component of PET-CT. Contrast-enhanced CT visualizes several morphological features of cardiac tumors and helps to discriminate between benign and malignant tumors. CT high sensitive markers for malignancy includes location of the tumors outside the heart, tissue inhomogeneity and contrast enhancement. The presence of pericardial effusion is a high specific feature for malignancy, but tumors size is neither specific nor sensitive for malignancy<sup>[28]</sup>. A well-defined tumor without infiltration to adjacent structures is highly suggestive for benignity. CMR may have benefit over CT in the assessment of local tumor extension because MRI provides high soft tissue contrast<sup>[29,30]</sup>. Therefore PET-MRI can have role in the detection of T-stage and assessment of local invasion and infiltration (Figures 8 and 9).

## OTHER POTENTIAL INTEGRATED PET-MRI APPLICATIONS RELATED TO CARDIAC TUMORS

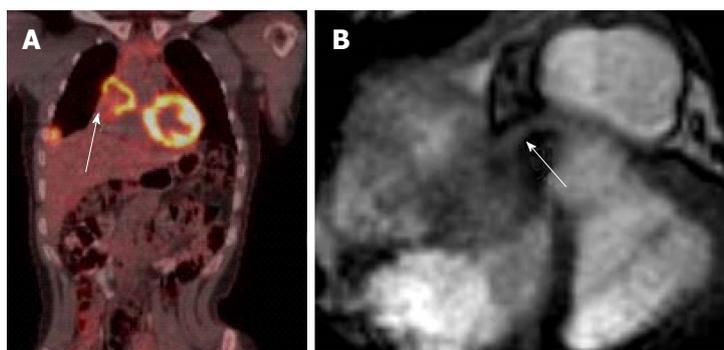

PET-MRI with optimal coregistration is essential to differentiate between residual scar tissue and tumors relapse, integrated PET-MRI imaging obviously combines the advantage of both methods in a single examination. FDG PET- and MRI-imaging yielded 100% sensitivity and 92% specificity in detecting tumors malignancy, but combined PET-MR yielded 100% sensitivity and specificity in one small study, one of the limitations of this study was small ample size<sup>[31]</sup>. In addition, in integrated PET-MRI, MRI component can assess the cardiac function, volume, morphology, and metabolism, and accurately assess tumors infiltration to

**Figure 8** Evaluation of the aggressiveness of the lesion and assessment of cardiac involvement. A: Evaluation of the aggressiveness of the lesion and assessment of cardiac involvement; whole body PET-CT image of patient with extensive Ewing sarcoma of the left hemithorax, PET-CT images are not sufficient to evaluate local extension of the tumor to the heart; B: Axial delayed enhancement image shows large necrotic mass occupying the left hemithorax with direct left ventricle (upper arrow) the arrow without circle and left atrial invasion (lower arrow). PET: Positron emission tomography; CT: Computed tomography.

**Figure 9** Evaluation of the aggressiveness of the lesion and assessment of cardiac involvement. A: Evaluation of the aggressiveness of the lesion and assessment of cardiac involvement; Coronal PET-CT image in a patient with Ewing sarcoma of the left chest wall with direct compression of the left side of the heart; B: Coronal Post contrast T1-weighted image of the heart shows no evidence of cardiac invasion with clear separation of the mass from the heart, the mass was surgically removed and there was no evidence of cardiac invasion. PET: Positron emission tomography; CT: Computed tomography.

**Figure 10** Evaluation of coronary artery involvement by the tumor. A: Coronal PET-CT image in a female patient with history of breast cancer with mediastinal and lung metastasis and recurrent chest pain; B: Axial cine image at the base of the heart shows metastatic lesion invading the heart causing mechanical obstruction of the right coronary artery (arrow). PET: Positron emission tomography; CT: Computed tomography.

various cardiac struts such as valves, papillary muscle, or coronary artery (Figure 10).

## CONCLUSION

With the commercial availability of PET-MRI true

simultaneous PET and MRI in a single study is real. Several studies have demonstrated the feasibility and incremental value of combined PET and MRI in many clinical applications. A combination of PET and MRI can provide incremental information in many cardiovascular scenarios. Evaluation of cardiac tumors may be most

straightforward application for PET-MRI because it offers a unique opportunity to evaluate the tumor morphology, characterization, infiltration to adjacent structures, local and M staging and comprehensive cardiac evaluation in a single study.

### Abstract

#### AIM

To synthesize the available literature on hand dysfunction after transradial catheterization.

#### METHODS

We searched MEDLINE and EMBASE. The search results were reviewed by two independent judicators for studies that met the inclusion criteria and relevant reviews. We included studies that evaluated any transradial procedure and evaluated hand function outcomes post transradial procedure. There were no restrictions based on sample size. There was no restriction on method of assessing hand function which included disability, nerve damage, motor or sensory loss. There was no restriction based on language of study. Data was extracted, these results were narratively synthesized.

#### RESULTS

Out of 555 total studies 13 studies were finally included in review. A total of 3815 participants with mean age of 62.5 years were included in this review. A variety of methods were used to assess sensory and motor dysfunction of hand. Out of 13 studies included, only 3 studies reported nerve damage with a combined incidence of 0.16%, 5 studies reported sensory loss, tingling and numbness with a pooled incidence of 1.52%. Pain after transradial access was the most common form of hand dysfunction (6.67%) reported in 3 studies. The incidence of hand dysfunction defined as disability, grip strength change, power loss or any other hand complication was incredibly low at 0.26%. Although radial artery occlusion was not our primary end point for

this review, it was observed in 2.41% of the participants in total of five studies included.

### CONCLUSION

Hand dysfunction may occur post transradial catheterisation and majority of symptoms resolve without any clinical sequel.

**Key words:** Transradial access; Transfemoral access; Hand dysfunction

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Transradial access (TRA) is default access site in many countries to perform coronary procedures. Hand function may occur post TRA, however our review shows that its incidence is exceedingly low and most symptoms resolve without any clinical sequel.

Hand dysfunction after transradial artery catheterization for coronary procedures. *World J Cardiol* 2017; 9(7): 609-619 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i7/609.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i7.609>

## INTRODUCTION

Coronary angiography is the current gold standard in providing anatomical information regarding the extent and severity of coronary artery disease<sup>[1,2]</sup>. Access site practice has changed in a number of European and Asian countries from mainly being transfemoral (TFA) to transradial (TRA)<sup>[3,4]</sup> in view of less access site related bleeding complications, mortality and shorter hospital stay associated with TRA<sup>[5-11]</sup>. For instance, in the United Kingdom use of radial access has increased from 14% to 80% between 2005 and 2014 in patients undergoing percutaneous coronary intervention (PCI) and it is estimated that this practice change has saved an estimated 450 lives nationally<sup>[12]</sup>. In the most recent European Society of Cardiology guidelines for management of non-ST elevation myocardial infarction (NSTEMI), TRA received class 1A indication for invasive management of NSTEMI with PCI<sup>[2]</sup>. Furthermore national bodies have formulated recommendations to prevent and minimize procedure related complications of TRA such as reducing the risk of radial artery occlusion (RAO), minimizing patient and operator radiation exposure and transitioning to TRA for primary PCI<sup>[13,14]</sup>.

Nevertheless, despite of its clear advantages over TFA, TRA is not without limitations and is associated with longer operator learning curve<sup>[15,16]</sup>, increased radiation exposure in individual operators at the start of their learning curves<sup>[17,18]</sup> and higher case radial proportion to translate the better results of randomized trials into clinical practice<sup>[11,19,20]</sup>. Moreover, vas-

cular complications such as RAO<sup>[21]</sup> and radial artery spasm<sup>[22]</sup> are not uncommon and very recently concerns have been raised that patients undergoing TRA PCI may encounter hand dysfunction<sup>[23]</sup>.

Whether access site related complications can lead to hand dysfunction is unclear and studies have reported inconsistency results. A study by van Leeuwen *et al*<sup>[24]</sup> investigated the impact of TRA on limb function at long term follow up, reported 9% and 11% of the patients develop temporary or permanent hand dysfunction respectively. Whereas Zwaan *et al*<sup>[25]</sup> reported a pooled incidence of 0.32% in 14 studies evaluating hand dysfunction post TRA.

Considering that the TRA is the predominant access site for cardiac catheterization procedures in many countries, there is little data around hand dysfunction post procedure. In view of the limited published data we conducted a systematic review to evaluate the hand dysfunction post TRA.

## MATERIALS AND METHODS

We searched MEDLINE and EMBASE on 23 August 2016 using the search terms: [(radial or transradial or radial artery) AND (catheterisation or catheterization or angiography or angiogram or angioplasty or percutaneous coronary intervention or PCI)] AND (hand function or grip strength or disability or dysfunction or sensation or paraesthesia or paralysis). The search results were reviewed by two independent adjudicators (MAU, CWW) for studies that met the inclusion criteria and relevant reviews. The bibliographies of included studies and relevant reviewers were screened for additional studies.

We included studies with patients undergoing transradial procedure and evaluated hand function outcomes post procedure. No control group was required so studies could be single arm. There were no restrictions based on language, sample size or method of assessing hand function which included disability, nerve damage, motor or sensory loss. These results were then narratively synthesized.

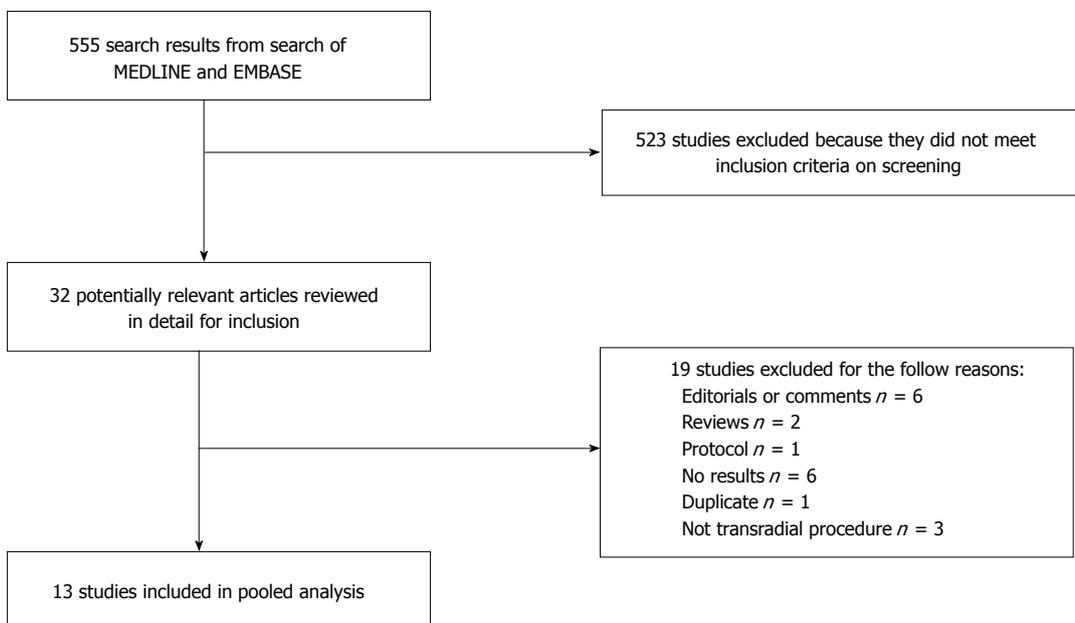

## RESULTS

Our search yielded 555 related studies out of which after screening and reviewing the full manuscripts, 13<sup>[24,26-38]</sup> studies were included in the final review. Detail process of inclusion and exclusion is illustrated in Figure 1.

Table 1 provides the description of studies, year of study, percentage of males and number of participants. A total of 3815 participants with mean age of 62.5 years were included in the studies. Table 2 describes the various methods of assessment employed to assess hand dysfunction, follow up time and results. We observed significant heterogeneity in the methods of assessment hand function and follow

Wu <i>et al</i> <sup>[37]</sup>	Cohort study; United States; 1996-1998	40	65	88%	Participants underwent 6-Fr and 8-Fr transradial procedure
Zankl <i>et al</i> <sup>[34]</sup>	Prospective cohort study; Germany; 2010	488	Unclear	Unclear	Participants had transradial coronary angiography and angioplasty with 5- and 6-Fr introducer, 4-, 5- and 6-Fr catheters

**Figure 1 Flow diagram of study inclusion/ exclusion.**

up time. For instance, the follow up of assessment varied from anytime between the day procedure was undertaken up to a year post TRA. Similarly, an array

of methods were employed to assess the sensory and motor component of hand function such as questionnaire based surveys in the form of Disabilities

**Table 2 Results of studies**

Ref.	Measure of hand function and vascular complications	Follow up post procedure	Results
Benit <i>et al</i> <sup>[26]</sup>	Local complications assessed in clinic by history and EMG	1 mo	Nerve damage documented by EMG: 0/50 Local pain: 0/50
Campeau <i>et al</i> <sup>[27]</sup>	Patients were re-examined or questioned over telephone about local complications	1 to 3 mo	No nerve injury: 0/100
Chatelain <i>et al</i> <sup>[28]</sup>	Physicians assessed for any clinical events	Assessment prior to discharge	Paraesthesia of right thumb during exercise: 1/159
De Belder <i>et al</i> <sup>[29]</sup>	Clinical evaluation	4-6 wk	Haematoma and paraesthesia post procedure: 1/75 Hand sensation and function at 4-6 wk: 0/75
Kiemeneij <i>et al</i> <sup>[30]</sup>	Examination and ultrasound study performed if radial artery pulsations or flow were absent	1 to 3 mo	Functional disability of the hand: 0/100
Lotan <i>et al</i> <sup>[31]</sup>	Assessment methods unclear	1 mo follow up	Small hematoma in wrist: 3/100 Small pseudoaneurysm: 2/100 Numbness of the thumb and index finger: 1/100 No flow on Doppler: 2/100
Prull <i>et al</i> <sup>[32]</sup>	Clinical evaluation with ultrasound	Post-procedure assessment	Vascular complication: 9/93 Motor skills, coordination or force reduction of hand after procedure: 0/93
Sciahbasi <i>et al</i> <sup>[33]</sup>	Radial artery occlusion by ultrasound test. Handgrip strength by Jamar Plus dynamometer. Thumb and forefinger pinch test by Jamar Plus electronic pinch gauge	Day of procedure and at least 30 d follow up	No pseudoaneurysm: 0/93 Radial artery occlusion: 9/99 Hand grip strength change at follow up: 0/99 Thumb and forefinger pinch test change at follow up: 0/99
Tharmaratnam <i>et al</i> <sup>[35]</sup>	Questionnaire posted to address and clinical notes for significant clinical events	Unclear	Problem with radial access site: 166/1283 (12.9%) Pain at puncture site: 95/1283 (7.4%) Swelling: 46/1283 (3.6%) Bruising: 30/1283 (2.3%) Non-specific sensory abnormalities either pain or paraesthesia in hand: 22/1283 (1.71%)
Valgimigli <i>et al</i> <sup>[39]</sup>	Radial artery occlusion by duplex echocardiographic examination. Hand grip strength test with dynamometer	Just after procedure, 1 d, 30 d and 1 yr	Radial artery occlusions at day 1: 5/942 Radial artery occlusions at 1 year: 3/942 Change in handgrip strength test: 0/942
Van Leeuwen <i>et al</i> <sup>[24]</sup>	Quick DASH questionnaire and CISS questionnaire. Patients were asked to describe any procedure-related extremity complaints or loss of function at 1 mo	Pre, 30 d and 1 yr post procedure	Ischemic vascular or bleeding complications: 0/942 Temporary upper limb complaint (< 30 d): 26/286 (9%) Persisting upper limb complaint (> 30 d): 31/286 (11%) Pain: 13/286 Numbness: 2/286 Tingling: 3/286 Stiffness: 2/286 Less power: 2/286
Wu <i>et al</i> <sup>[37]</sup>	Ultrasound assessment for radial artery occlusion, aneurysm or dissection. Grip strength based on dynamometer results. Palmar pinch, key pinch and tip pinch strength tests were assessed by dynamic endurance test	Late follow up 315 d	Upper limb function by QuickDASH at 30 d: No change over time, baseline 4.55 (IQR 0-13.64), follow up 2.27 (IQR 0-9.32) Upper limb function by CISS at 30 d: No change over time Upper limb function by QuickDASH at 1 yr: no change over time, baseline 2.39 (IQR 0-13.64), follow up 0 (0-11.02) Cold intolerance was not associated with access route at 1 yr Hand complication in hospital: 0/40 Radial occlusion: 1/40 Late radial occlusions: 5/34 Radial artery aneurysm: 0/40 Radial artery dissection 0/40 Grip strength: Baseline 68 ± 34, post-catheterization 69 ± 35 Palmar pinch: Baseline 18 ± 10, post-catheterization 17 ± 6 Key pinch: Baseline 19 ± 7, post-catheterization 19 ± 6 Tip pinch: Baseline 14 ± 6, post-catheterization 14 ± 4 Endurance: Median for 6 Fr and 8 Fr is 78 (IQR 53, 108) and 58 (IQR 32, 68) respectively, post-catheterization 58 (IQR 47, 84) and 56 (IQR 38, 80), respectively
Zankl <i>et al</i> <sup>[34]</sup>	Assessment with ultrasound	4 wk follow up	Radial artery occlusion at 1 d: 51/488 Persistent radial artery occlusion at 4 wk: 21/488 Radial nerve paralysis: 1/488

CISS: Cold intolerance symptom severity; EMG: Electromyography.

**Table 3 Summary of pooled results for hand dysfunction or vascular complications post transradial procedure**

Hand dysfunction or vascular complication	No. of studies	No of events	No of participants	Percentage of events
Nerve damage	3 <sup>[26,27,34]</sup>	1	638	0.16%
Sensory loss, tingling and numbness	5 <sup>[24,28,29,31,35]</sup>	29	1903	1.52%
Pain	3 <sup>[24,26,35]</sup>	108	1619	6.67%
Hand function, disability, grip strength change, stiffness, power loss and hand complications	6 <sup>[24,30,32,33,37,39]</sup>	4	1560	0.26%
Vascular complications including occlusions, hematoma, pseudoaneurysm and dissection	6 <sup>[29,31,32,35,37,39]</sup>	54	1762	3.06%
Radial artery occlusion	5 <sup>[31,33,34,37,39]</sup>	40	1663	2.41%

**Table 4 Disabilities of Arm, Shoulder and Hand (QuickDASH) Questionnaire**

	No difficulty	Mild difficulty	Moderate difficulty	Severe difficulty	Unable
1 Open a tight or new jar	1	2	3	4	5
2 Do heavy house hold chores eg. Wash walls, floors	1	2	3	4	5
3 Carry a shopping bag or briefcase	1	2	3	4	5

of Arm, Shoulder and Hand (Quick DASH) or Cold Intolerance and Symptom Severity (CISS) or postal surveys, electromyography (EMG), dynamometer and forefinger pinch grip tests.

Table 3 presents pooled results of various form of limb dysfunction described by the studies. Out of 13 studies included, only 3 studies reported nerve damage<sup>[26,27,34]</sup> with a combined incidence of 0.16%, 5 studies reported sensory loss, tingling and numbness<sup>[24,28,29,31,35]</sup> with a pooled incidence of 1.52%. Pain after TRA was the most common form of hand dysfunction (6.67%) reported in 3 studies<sup>[24,26,35]</sup>. The incidence of hand dysfunction defined as disability, grip strength change, power loss or any other hand complication was incredibly low at 0.26%<sup>[24,30,32,33,37,39]</sup>. Although RAO was not our primary end point for this review, it was observed in 2.41% of the participants in total of five studies included<sup>[31,33,34,37,39]</sup>.

In one the very early studies from pre-stent era, Campeau *et al.*<sup>[27]</sup> assessed the neurological damage to hand following TRA using 5 Fr, 6 Fr or 7 Fr sheath. Patients were assessed at 1 and 3 mo either clinically or *via* telephone reported no nerve injury. It is not clear how the nerve damage was assessed in patients reviewed by telephone. Another study employing a more subjective assessment of nerve function using EMG in 150 patients receiving TRA using a 6

Fr sheath reported no damage to the median nerve at 1 mo follow up. In a large retrospective analysis of 1283 patients undergoing TRA using hydrophilic sheaths, 13.2% patients reported non-specific sensory symptoms post procedure<sup>[35]</sup>. However, the results were dependent on a questionnaire based postal survey and no objective method was used to assess for the sensory loss. Similarly two other studies<sup>[28,29]</sup> assessing the neurological dysfunction post TRA, reported only 1 case of paraesthesia of right thumb and 1 case of forearm haematoma resulting in some sensory disturbance of hand but no loss of function. More importantly, both cases made full recovery without any clinical sequel.

In a prospective study of 203 patients after TRA, Valgimigli *et al.*<sup>[39]</sup> assessed the motor component of hand function by performing handgrip strength tests using a dynamometer at 30 d and 1 year, maximal isometric strength on handgrip test did not change over time. Van Leeuwen *et al.*<sup>[24]</sup> conducted a randomised study of 338 patients to evaluate motor component of upper limb function using self-reported shortened version of Disabilities of Arm, Shoulder and Hand (Quick DASH, Table 4) and sensory component using Cold Intolerance and Symptom Severity (CISS, Table 5) questionnaires at baseline and 30 d. There was no statistically significant change in Quick DASH score at baseline to follow up in patients undergoing

**Table 5 Cold Intolerance symptoms severity Questionnaire**

Questions	Score
Which of the following symptoms of cold intolerance do you experience in your injured limb on exposure to cold? Pain, numbness, stiffness, weakness, aching, skin colour change (white/bluish white/blue)	
How often do you experience these symptoms? (Please tick)	
Continuously/all the time	
Several times a day	
Once a day	
Once a week	
Once a month or less	
Never	
When you develop cold induced symptoms, on your return to a warm environment are the symptoms relieved? (Please tick)	
Not applicably	
Within a few minutes	
Within 30 min	
After more than 30 min	
What do you do to ease or prevent your symptoms occurring? (Please tick)	
Take no special action	
Keep hand in pocket	
Wear gloves in cold weather	
Wear gloves all the time	
Avoid cold weather/stay indoors	
Other (please specify)	
How much does cold bother your injured hand in the following situations? (Please score 0-10)	
Holding a glass of ice water	
Holding a frozen package from the freezer	
Washing in cold water	
When you get out of a hot bath/shower with air room temperature	
During cold wintry weather	
Please state how each of the following activities have been affected as a consequence of cold induced symptoms in your injured hand and score each (please score 0-4)	
Domestic chores	
Hobbies and interests	
Dressing and undressing	
Tying your	

TRA (baseline 4.55; IQR: 0.00 to 13.64; follow-up 2.27 IQR: 0.00 to 9.32,  $P = 0.06$ ). Similarly there was no change in the CISS score over time. An important feature of the study was they included patients undergoing TFA to make a comparison between the two access sites. More recently, HANGAR (HAND Grip test After tRansradial percutaneous coronary procedures) study investigated 108 patients with stable angina undergoing PCI using 6Fr sheath with a primary endpoint of variation in hand grip strength measured with the Jamar Plus dynamometer after the procedure<sup>[33]</sup>. The secondary endpoints of interest were thumb and forefinger pinch measured using key pinch and electronic pinch gauge respectively. Out of 99 patients, 9 patients developed radial artery occlusion after the procedure, the patients were then divided in two groups according to the radial patency (group 1) or occlusion (group 2) The hand grip test values were significantly reduced compared with baseline values ( $40 \pm 11$  kg in group 1,  $P < 0.0001$  and  $37 \pm 17$  kg in group 2,  $P = 0.007$ ) after the procedure but returned back to baseline at follow up. Interestingly thumb and finger pinch function was unaffected at baseline, after the procedure and follow up. Finally ARCUS (Effects of transradial percutaneous coronary intervention on upper extremity function) is an ongoing trial assessing

the effects of TRA on hand function by taking various measurement such as Echo Doppler for radial artery occlusion, Questionnaires testing including Quick DASH (Table 4), Boston Carpal Tunnel Questionnaire (BCTQ, Table 6) and Visual Analogue Scale (VAS), volumetry of hand and forearm, sensibility of fingertips, key and palmar grips and isometric strength of wrist and elbow<sup>[40]</sup>. The interim results were published recently suggesting that 143 of 191 (74.9%) patients had some form of upper limb dysfunction defined as a compiled binary score of various measurements taken<sup>[38]</sup>. Furthermore, RAO was 9.8% in upper limb dysfunction group as compared to 0% RAO in non-upper limb dysfunction group.

## DISCUSSION

In the current review, we synthesize the evidence on the incidence and clinical impact of hand dysfunction after TRA. We observe a very low incidence of hand dysfunction in limited literature and importantly, we observe significant heterogeneity in the definition and method of assessment of hand dysfunction amongst the studies, with no internationally accepted measure of hand dysfunction that can be used as the gold standard for such studies. Many of these studies are

**Table 6 Boston Carpal Tunnel Syndrome Questionnaire**

	1	2	3	4	5
A: Symptom severity scale (11 items)					
1 How severe is the hand or wrist pain that you have at night?	Normal	Slight	Medium	Serious	Very serious
2 How often did hand or wrist pain wake you up during a typical night in the past two weeks?	Normal	Once	2-3	4-5	> 5
3 Do you typically have pain in your hand or wrist during the daytime?	No Pain	Slight	Medium	Serious	Very Serious
4 How often do you have hand or wrist pain during daytime?	Normal	1-2 times/d	1 times/d	> 5 times/d	Continued
5 How long on average does an episode of pain last during the daytime?	Normal	< 10 min	10-60 continued	> 60 min	Continued
6 Do you have numbness (loss of sensation) in your hand?	Normal	Slight	Medium	Severe	Very Serious
7 Do you have weakness in your hand or wrist?	Normal	Slight	Medium	Severe	Very Serious
8 Do you have tingling sensations in your hand?	Normal	Slight	Medium	Severe	Very Serious
9 How severe is numbness (loss of sensation) or tingling at night?	Normal	Slight	Medium	Severe	Very Serious
10 How often did hand numbness or tingling wake you up during a typical night during the past two weeks?	Normal	Once	2-3 times	4-5 times	> 5
11 Do you have difficulty with the grasping and use of small objects such as keys or pens?	Without difficulty	Little difficulty	Moderate difficulty	Very difficulty	Very difficult

Writing					
Buttoning of cloths					
Holding a book while reading					
Gripping of a telephone handle					
Opening of jars					
House hold chores					
Carrying of grocery basket					
Bathing and dressing					

poorly conducted and subjective reports of sensory/hand dysfunction with only few studies quantifying any changes in a robust manner. Finally, we find no evidence of widespread clinically significant hand dysfunction post TRA and the potential benefits of TRA in reducing major bleeding, access site related complications and mortality outweigh such rare events.

The majority of studies that reported cases of neurological deficits following TRA were underpowered<sup>[26,29,37]</sup>. In most circumstances, studies relied on subjective reporting of symptoms by patients, rather than quantifying the neurologic deficit with proper neurophysiological or other robust objective testing<sup>[24,27-31,34,35]</sup>. Benit *et al*<sup>[26]</sup> assessed nerve damage clinically and quantified this using EMG. Valgimigli *et al*<sup>[39]</sup> and Sciahbasi *et al*<sup>[33]</sup> used dynamometer to assess hand grip function whereas only Sciahbasi *et al*<sup>[33]</sup> used electronic pinch gauge to check for thumb and finger pinch tests. Van Leeuwen *et al*<sup>[24]</sup> used QuickDASH questionnaire and Cold Intolerance Symptom Severity (CISS) questionnaire based assessment of hand function post TRA.

The clinical significance of neurological and motor injuries leading to hand dysfunction must be con-

sidered. Many neurological injuries are known to be transient and resolve over time. For instance, van Leeuwen *et al*<sup>[24]</sup> reported that almost 20% patients developed subjective neurological complications in the form of numbness, tingling, stiffness and less power, more importantly nearly 50% resolved by 30 d at follow up. Similarly, pain is commonly reported by patients regardless of the access site practice but long term sequel of such symptoms is unclear. In addition, there is no consensus on the optimal method of assessing hand function and studies so far have used various methods such VAS, BCTQ, Disabilities of Arm, Shoulder and Hand (QuickDASH) and CISS (Tables 4-6).

Visual analogue scale is measure of pain intensity on a continuous scale anchored by pain descriptor ranging from "no pain (0 score)" to worst pain (score 10)<sup>[41]</sup>. BCTQ questionnaire comprises of a symptom severity scale and a functional status scale (Table 6). The symptom severity scale has 11 questions scored from 1 point (mildest) to 5 points (most severe). Likewise, functional status scale has eight questions scored from 1 point (no difficulty with activity) to 5 points (cannot perform the activity at all)<sup>[42]</sup>. Similarly,

CISS score is usually employed to detect cold intolerance. It consists of 6 questions and based on response, patient with a score of 30 or higher is said to have pathological CISS score<sup>[43,44]</sup>. There is a need of internationally agreed, sensitive method of assessing hand function amongst the radial community to evaluate and monitor for such complications.

The mechanisms that may underlie hand dysfunction after TRA remains unclear though there are several possible explanations. For instance, Flexor Carpi Radialis, Flexor Pollicis Longus tendons and Median nerve lies next to radial artery at wrist from lateral to medial respectively. Neurological deficits may occur from direct damage to these structures during cannulation of the radial artery. There also may be indirect extrinsic compression of these structures due to haematomas which may result in motor or sensory deficit of the hand. Endothelial dysfunction, intimal hyperplasia and medial dissections resulting in radial artery stenosis and occlusion are well known complications associated with TRA<sup>[45,46]</sup>. Haematoma or pseudoaneurysm is another relatively rare complications encountered after TRA. There is a possibility that such vascular complications may lead to transient or permanent ischemia of the nervous supply of hand leading to sensory deficit or directly cause motor dysfunction of small muscles of hand. Additionally, there are anatomic variations of neurovascular bundles of hand<sup>[47]</sup> which might be injured during the puncture leading to hand dysfunction such as sensory or motor symptoms. There are isolated case reports that describe this mechanism of nerve damage<sup>[48-50]</sup>. RAO may occur post TRA<sup>[21]</sup>, however it is usually asymptomatic and rarely causes ischemia due to the excellent collateral supply of hand from ulnar and intermediate artery<sup>[45,51]</sup>. Notably, recent results of ACRUS trial suggested that hand dysfunction was very common in patients developing RAO compared to the ones with a patent radial artery post procedure<sup>[38]</sup>. However, in the study conducted by Valgimigli *et al.*<sup>[39]</sup> across whole spectrum of Allen test, there were no differences in serial lactate measurement after the procedure suggesting that it is unlikely such mechanism can lead to clinically significant hand dysfunction.

It is unclear what factors are associated with hand dysfunction after TRA. It could very well be that certain patient factors, such as baseline hand muscle strength, history of musculoskeletal disorders, gender, atypical anatomy may be a risk factor but no studies have evaluated such predictors. Another important point how minor changes in hand function may impact on a patient's life. For example individuals that require very fine manual dexterity for their profession such as watchmakers, pianists, and surgeons may notice very minor changes in hand function whilst in other patient groups this may be less relevant. Finally, the way in which complications are managed may also affect hand function such as how quickly a haematoma

is identified and compressed. Future studies should be focused in assessing both patient and procedure related factors which may lead to development of hand dysfunction with clinically relevant end points. Finally, current literature does not provide an insight around the prevalence and significance of lower limb function in patients undergoing transfemoral access. Adequately powered randomized trial with a control group is required to better understand the incidence and mechanisms involved in the development of hand dysfunction post TRA.

In conclusion, hand dysfunction is an exceedingly rare complication post TRA. There is significant heterogeneity in the methodology and reporting of the studies investigating hand function after TRA. Patients may develop non-specific sensory symptoms or muscle weakness but majority of these symptoms resolve over time. Future studies should be focused around assessing such complications using robust methodology and more importantly reporting on the clinical relevance of hand function. Given the reductions in mortality, MACE and major bleeding complications associated with use of TRA in high risk groups undergoing PCI, TRA should remain the default access site for PCI in such high risk groups of patients at risk of bleeding complications, in line with international guidelines and consensus statements.

## COMMENTS

### Background

The uptake of transradial access (TRA) for cardiac procedures is growing with both observational and randomized controlled trial data showing decreases in mortality and access site related bleeding complications across the whole spectrum of acute coronary syndromes compared to procedures undertaken through the femoral approach.

### Research frontiers

Recently, concerns have been raised around hand dysfunction following transradial procedures.

### Innovations and breakthroughs

The review of the literature suggests that hand dysfunction after TRA has been reported in several studies and case reports. The quality of the evidence describing these complications is poor as many studies are underpowered and do not report any events. These complications appear to be rare and of uncertain clinical impact in most cases. Isolated case reports have reported rare complications such as compartment syndrome requiring emergency surgery or complex regional pain syndrome which can be disabling due to chronic pain.

### Applications

The current literature is limited as there is no standardized method of assessment of hand function with very few studies that provide mechanistic insight. Higher quality studies with clinically relevant endpoints are needed to better understand the incidence and clinical significance of the hand dysfunction following TRA.

### Terminology

TRA: Transradial access; TFA: Transfemoral access; PCI: Percutaneous coronary intervention; UED: Upper Extremity dysfunction.

**Peer-review**

It is an excellent review.

### Abstract

#### AIM

To summarize the current evidence on psychological issues in thoracic aortic disease (TAD) and infective endocarditis (IE) setting.

#### METHODS

We performed a narrative review about psychological issues in adults with IE and TAD. Through the electronic databases, PubMed and PsycINFO, we searched full manuscripts in English and published until September 1, 2014.

#### RESULTS

We found sixteen studies exploring psychological issues in patients with IE (six studies) and in TAD (ten papers). Psychological issues assessed were quality of life, depression, anxiety and posttraumatic stress disorder. Quality of life was explored in IE (four papers) and in TAD (eight papers). Depression and anxiety were analyzed in TAD only (five papers). Post-traumatic stress disorder was assessed in IE (one study). Quality of life was found impaired in three of four studies about IE and in three of eight studies about TAD. Posttraumatic stress disorder was present in 11% and was associated with lower levels of quality of life in IE patients. In TAD patients, anxiety and depression levels after different invasive interventions did not differ.

#### CONCLUSION

Sixteen studies report about psychological issues in IE and TAD. Most of them explore quality of life and to a less extent anxiety and depression.

**Key words:** Infective endocarditis; Thoracic aortic disease; Psychology; Depression; Anxiety; Quality of life; Posttraumatic stress disorder

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Some papers and guidelines have recently reported that psychosocial factors such as depression, anxiety and other mental disorders like personality disorders and post-traumatic stress disorder are related to morbidity and mortality due to cardiovascular diseases. Chronic heart failure, arrhythmias, and acute myocardial infarction are one of the most studied pathologies. However, other cardiovascular diseases are poorly or not yet studied from a psychological point of view, including infective endocarditis and thoracic aortic disease. The study of psychological issues in these severe diseases could bring us information about specific needs to cover with psychological interventions and to design specialized care training and practice.

## INTRODUCTION

Infective endocarditis (IE) is an inflammatory disease of the heart, an infection of the endocardium that usually involves valves and adjacent structures. The incidence of IE ranges from one country to another within 3-10 episodes/100000 person-years. It is higher in patients with underlying valvular heart diseases, prosthesis and those with intravenous drug abuse. IE with positive blood cultures represents 85% of all IE. Causative microorganisms are most often staphylococci, streptococci, and enterococci<sup>[1-7]</sup>. This disorder presents in a variety of clinical forms according to the initial clinical manifestation, underlying cardiac disease, microorganism involved, prosthesis presence, and development of complications. It may present as an acute and rapidly progressive infection or as sub-acute with low-grade fever and non-specific symptoms. With a modern combination of antimicrobial therapy and heart valve surgery, the in-hospital mortality rate of patients with or chronic disease IE varies from 9.6 to more than 26% (1-8)<sup>[1-8]</sup>. Psychological factors such as depression, anxiety and some personality traits could negative influence IE development and prognosis.

On the other hand, thoracic aortic diseases (TAD) include a wide spectrum of degenerative, structural, acquired, genetic-based, and traumatic disease states and presentations. The overall global death rate from aortic aneurysms and aortic dissection increased from 2.49 per 100000, to 2.79 per 100000 inhabitants between 1990 and 2010. TAD may be diagnosed after a long period of subclinical development or after an acute presentation such as acute aortic syndromes. Acute aortic syndromes are often the first sign of the disease, requiring rapid diagnosis and decision-making to improve prognosis. Medical therapy aims to reduce

shear stress on the diseased segment of the aorta by reducing blood pressure and cardiac contractibility. Further management options include endovascular therapy and surgery<sup>[9,10]</sup>. Psychological factors such as anxiety, depression and personality, could promote subclinical development and could negatively influence medical outcome after surgery and endovascular therapy, as well.

The aim of this review is to summarize the current evidence on psychological issues in TAD and IE setting. Thus, we performed a narrative review about psychological issues in adults with both TAD and IE.

## MATERIALS AND METHODS

Through the electronic databases PubMed and PsycINFO we searched all full manuscripts published in English until September 1, 2014.

The main data search terms were: Infective endocarditis + psychology, infective endocarditis + psychiatry, infective endocarditis + depression, infective endocarditis + anxiety, infective endocarditis + quality of life, infective endocarditis + personality, infective endocarditis + illness perception, infective endocarditis + therapeutic adherence, infective endocarditis + coping, thoracic aortic disease + psychology, thoracic aortic disease + psychiatry, thoracic aortic disease + depression, thoracic aortic disease + anxiety, thoracic aortic disease + personality, thoracic aortic disease + quality of life, thoracic aortic disease + therapeutic adherence, thoracic aortic disease + illness perception, thoracic aortic disease + coping.

## RESULTS

We found sixteen studies exploring psychological issues in patients with IE and TAD: Six about IE and ten about TAD. Main results are summarized in Tables 1 (IE) and 2 (TAD). Psychological issues assessed were mainly quality of life, depression, anxiety and post-traumatic stress disorder.

Quality of life was reviewed in 4 papers for IE and for TAD in 8 papers using Short Form 36 Health Survey questionnaire (SF-36) or EuroQol five dimensions questionnaire (EQ-5D).

Post-traumatic stress disorder was assessed in IE (one study) using the Post-traumatic stress disorder questionnaire. Depression and anxiety were analyzed in TAD (five papers) using Hospital Anxiety and Depression Scale (HADS).

### IE

We included six manuscripts about psychological issues in IE, all published in the last 5 years. Two papers used a qualitative method and four studies used a quantitative prospective design.

**Quantitative studies:** Quantitative studies assessed quality of life using standardized questionnaires.

Table 1 Scheme of main findings about infective endocarditis

Ref.	Methods and materials	Main results
Verhagen <i>et al</i> <sup>[11]</sup> , 2009	Prospective, 67 treated for left-sided native valve endocarditis complete Short Form 36 Health Survey questionnaire and Posttraumatic Stress Disorder questionnaire	Quality of life was significantly impaired in IE patients, compared with an age- and sex-matched population. Posttraumatic stress disorder 11%
Perrotta <i>et al</i> <sup>[12]</sup> , 2010	Prospective, 40 infective prosthetic valve endocarditis or native endocarditis with abscess operated with homograft replacement. Short Form 36 Health Survey questionnaire	Statistically significant differences in quality of life were found between IE patients and an age-matched and gender-matched general population
Berg <i>et al</i> <sup>[15]</sup> , 2010	Qualitative, 10 patients. Semi-structured interview	Patients explain that a sudden unexpected physical change occurred that is difficult to understand and interpret. During the hospital admission, time is spent thinking about choices and lost possibilities before admission. They talk about investing their energy and attention on getting well
Yeates <i>et al</i> <sup>[13]</sup> , 2010	Prospective, 9 active native left sided valve endocarditis and cerebrovascular complications. EuroQol five dimensions questionnaire	6 reported some problems with mobility, 5 reported some problems with usual activities and 5 pain or discomfort
Nayak <i>et al</i> <sup>[14]</sup> , 2011	Prospective, 85 active endocarditis, native valve endocarditis or prosthetic valve endocarditis. EuroQol five dimensions questionnaire	Quality of life was not impaired
Rasmussen <i>et al</i> <sup>[16]</sup> , 2014	Qualitative, 11 patients. Semi-structured interview	Patients felt physically weak and mentally imbalanced to a varying degree. Uncertainty of recovery trajectory and future capacity was considered stressful

Three of four studies reported quality of life impaired in IE patients. One study reported the presence of a posttraumatic stress disorder in 11% of the cases.

In 2009, a prospective and multicenter follow-up study was performed aiming to assess quality of life and posttraumatic stress disorder of adults treated because a left-sided native valve endocarditis. Twelve months after the end of the antimicrobial treatment 67 adults completed both the SF-36 and the Posttraumatic stress disorder questionnaires. The quality of life was significantly impaired in IE patients, compared with an age- and sex-matched population. A posttraumatic stress disorder was present in 11% of the cases. The type of infecting microorganism, the length of hospitalization, type of cardiac surgery, and infective complications did not affect the result of the quality of life scores<sup>[11]</sup>.

In 2010, another study reported the outcomes and quality of life after homograft replacement for IE. After a mean follow-up of 37 ± 11 mo, the quality of life was assessed using a SF-36 form. Forty five patients completed a specific questionnaire.

Statistically significant differences between patients operated with homograft and an age-matched and gender-matched general population were depicted in four subscales: Role-physical, general health, vitality, mental health<sup>[12]</sup>.

In the same year, Yeates *et al*<sup>[13]</sup> assessed the quality of life of IE patients who suffered cerebrovascular complications using the EQ-5D questionnaire. After a mean follow-up of 37.2 mo, 9 adults responded EQ-5D questionnaire by telephone: 7 reported no problems with self-care, 6 reported some problems with mobility, 5 reported some problems with usual

activities and 5 pain or discomfort.

In 2011, another study evaluated the early and mid-term outcomes, mortality and morbidity and quality of life of patients operated for IE. After a mean follow-up time of 37.2 mo, 85 patients answered a EQ-5D questionnaire. In that study, the patient's quality of life was not impaired<sup>[14]</sup>.

**Qualitative studies:** Qualitative studies review patient's experiences after IE diagnoses. Berg *et al*<sup>[15]</sup> described in 2010 IE experiences before and during hospital admission, including experience of physical symptoms and expectations for future health. Ten patients were included just before or after discharge, after a mean of 51.5 d of hospital admission. IE was perceived as an "intermezzo in life": Presage and appearance of IE, reaction to IE, living through IE, the little life with IE, body change and loved ones at distance.

The patients explained that perceived a sudden unexpected physical change, difficult to understand and interpret. This happens after a very long hospital admission, far different from one's normal way of life. During the hospital admission, they spent some time thinking about choices and lost possibilities before admission. They mentioned the idea of investing their energy and attention on getting well. Patients felt like not being able to interpret their body's signals, or that they did not receive clear signals whatsoever from the body that there is something wrong. Symptoms of IE are similar to and are often misinterpreted as a common infection or virus, such as a lung infection or influenza. Another important idea reported was that the disease does not only affect the patients, but can

Table 2 Scheme of main findings about thoracic aortic disease

Ref.	Methods and materials	Main results
Immer <i>et al</i> <sup>[22]</sup> , 2004	Prospective, 363 patients. 176 acute type A dissections, 187 aortic aneurysms. Antegrade cerebral perfusion 41 cases. Short Form 36 Health Survey questionnaire	Averaged quality life score was higher with the use of antegrade cerebral perfusion, independently of the duration of deep hypothermic circulatory arrest
Stalder <i>et al</i> <sup>[23]</sup> , 2007	Prospective, 244 patients. 76 isolated replacement of the ascending aorta, 42 separate aortic valve replacement and supracoronary replacement of the ascending aorta, 86 mechanical composite graft, 40 biologic composite graft. Short Form 36 Health Survey questionnaire	No difference in quality of life between groups was found
Dick <i>et al</i> <sup>[17]</sup> , 2008	Post hoc analysis, 122 patients. 52 thoracic endovascular aortic repair, 70 open aortic repair. Short Form 36 Health Survey questionnaire and Hospital Anxiety and Depression Scale	Anxiety and depression scores were not significantly different between group
Immer <i>et al</i> <sup>[26]</sup> , 2008	Prospective, 567 patients. 387 deep hypothermic circulatory arrest with pharmacologic protection with pentothal only, 91 selective antegrade cerebral perfusion and pentothal, 89 continuous cerebral perfusion through the right subclavian artery and pentothal. Short Form 36 Health Survey questionnaire	No statistical differences in quality life scores Average quality of life after an arrest time between 30 and 50 min with continuous cerebral perfusion through the right subclavian artery was significantly better than selective antegrade cerebral perfusion
Krähenbühl <i>et al</i> <sup>[24]</sup> , 2008	Prospective, 907 patients. 219 acute aortic dissection type A, 617 aortic aneurysm. Transient neurological dysfunction 89 cases. Short Form 36 Health Survey questionnaire	Patients with transient neurological dysfunction showed a significantly impaired quality of life
Dick <i>et al</i> <sup>[18]</sup> , 2009	Post hoc analysis, 52 patients. 27 treated electively, 25 emergency indications. Short Form 36 Health Survey questionnaire and Hospital Anxiety and Depression Scale	Anxiety and depression scores were in normal range and not increased after emergency situations No statistical differences between groups in quality of life were found
Lohse <i>et al</i> <sup>[25]</sup> , 2009	Prospective, 124 patients. 45 supracoronary replacement of the ascending aorta, 59 Wheat procedure, 15 David procedure, 12 Bentall-De Bono procedure, 3 Cabrol procedure. Short Form 36 Health Survey questionnaire	Different surgical techniques had no statistically significant influence on postoperative quality of life
Aicher <i>et al</i> <sup>[19]</sup> , 2011	Prospective, 166 patients. 86 aortic valve repair, 41 valve replacement with mechanical prosthesis, 39 valve replacement with pulmonary autograft. Short Form 36 Health Survey questionnaire and Hospital Anxiety and Depression Scale	No differences were found in anxiety or depression scores between groups Patients after aortic valve repair <i>vs</i> replacement with pulmonary autograft revealed similar quality of life scores
Lehr <i>et al</i> <sup>[20]</sup> , 2011	Prospective, 144 patients. 51 mechanical conduit, 93 biological valve conduit. Hospital Anxiety and Depression Scale	No significant differences were found between groups for either anxiety and depression
Okamoto <i>et al</i> <sup>[21]</sup> , 2013	Prospective, 128 patients. 49 aortic surgery, 79 coronary artery bypass. Hospital Anxiety and Depression Scale	No statistical differences were found in depression or anxiety scores

also have a great impact on the life of their families<sup>[15]</sup>.

In 2014, a qualitative study described patient experiences during recovery after IE. Eleven patients were interviewed 3 to 6 mo after discharge. Patients talked of IE as an unpredictable disease. They described a phase of adaptation to a new life situation, which some perceived as manageable and temporary, whereas others found it extremely distressing and prolonged. Most of them experienced a persisting weakness and felt frustrated about the prolonged recovery phase. Patients felt physically weak and mentally imbalanced to a varying degree. They described a time of emotional instability and different psychological reactions, ranging from mild mood swings to severe anxiety. Uncertainty of recovery trajectory and future capacity was considered stressful. They worried about sources of infections; open wounds and they recognized that even a hemorrhoid could become a cause for concern. Most of them described how significant the support from family and friends had been during hospital admission and recovery. Some also described feeling concerned and guilty; being the cause of the stress and strain their loved ones had been through<sup>[16]</sup>.

### TAD

We found ten suitable manuscripts that studied psychological issues using standardized questionnaires in TAD patients, after surgery or endovascular therapy and a variable follow up period.

**Depression and anxiety:** Five papers studied depression and anxiety in patients treated with surgery or endovascular therapy. No statistical differences were found in anxiety and depression scores after aortic valve repair using mechanical replacement *vs* after aortic valve repair using pulmonary autograft; after underwent thoracic aortic surgery *vs* after coronary artery bypass grafting; after thoracic endovascular aortic repair *vs* after open aortic repair or after thoracic endovascular aortic repair which indication was done electively *vs* emergency.

In 2008, a study assessed anxiety and depression on diseases of descending thoracic aorta, in patients treated either by thoracic endovascular aortic repair or open aortic repair. After mean follow-up of  $34 \pm 18$  mo, 75 adults fulfilled a HADS form. Although depression and anxiety scores tended to be more elevated in patients that underwent thoracic endovascular aortic

repair than in patients that underwent open aortic repair patients, statistical significances were not found<sup>[17]</sup>.

In 2009, Dick *et al*<sup>[18]</sup> studied the impact of urgency procedures on quality of life in patients with descending thoracic aorta disease. Twenty seven patients completed the HADS after mean follow-up of  $29 \pm 16$  mo. Anxiety and depression scores were in normal range and did not increase after emergency situations.

In 2011, a study was conducted to assess and compare anxiety and depression after aortic valve repair using two replacement alternatives: Mechanical valve and pulmonary autograft. After a follow up interval that ranged between 3 and 7 years, 166 subjects responded the HADS questionnaire. No differences were found regarding anxiety or depression scores between groups<sup>[19]</sup>.

In the same year, anxiety and depression over a group of patients who underwent aortic root replacement with mechanical and biological conduits were assessed and compared by Lehr *et al*<sup>[20]</sup>. Seventy four patients completed a HADS form after a median follow-up of 40 mo. Anxiety and depression scores were not significantly different between groups.

In 2013, other study compared anxiety and depression in patients undergoing thoracic aortic surgery with another cohort of patients undergoing coronary artery bypass grafting. Hospital anxiety and depression scale was complete at 1-5 years postoperatively by 98 patients. Twenty-eight percent of thoracic aortic surgery patients had depression and 14% anxiety. Twenty percent of coronary bypass patients had depression and 16% anxiety. No statistical differences were found in depression or anxiety scores either in this study<sup>[21]</sup>.

**Quality of life:** Over ten, eight studies analyzed the impact of different surgical procedures and endovascular therapy on the quality of life of patients with diseases of aortic root and aortic valve, ascending aorta, aortic arch, and descending aorta.

One study assessed the quality of life after aortic valve replacement comparing two replacement alternatives: Mechanical and pulmonary autograft. Over a follow-up interval between 3 and 7 years, 166 subjects completed a SF-36 questionnaire. Patients who had undergone aortic valve repair and replacement with pulmonary autograft depicted similar quality of life scores, but this matter was better in patients after replacement with mechanical prosthesis regarding physical functioning, general health, and mental health<sup>[19]</sup>.

**Ascending aorta:** Four papers studied the quality of life of patients with diseases of ascending aorta.

In 2004 a study analyzed the impact of the duration of the deep hypothermic circulatory arrest and the potential effects of antegrade cerebral perfusion

on quality of life in patients undergoing surgery of the thoracic aorta. Two hundred and ninety adults completed the SF-36 questionnaire after mean follow up of  $2.4 \pm 1.2$  years. Averaged quality life score was significantly better with the use of antegrade cerebral perfusion, independently of the duration of deep hypothermic circulatory arrest<sup>[22]</sup>.

In 2007 another manuscript analyzed the impact of different surgical procedures on quality of life in patients with ascending aorta diseases. Patients were divided according to the operative procedure: Isolated replacement of the ascending aorta, separate aortic valve replacement and supracoronary replacement of the ascending aorta, mechanical composite graft, and biologic composite graft. After mean follow-up of  $26.6 \pm 8.8$  mo, 176 patients completed a SF-36 questionnaire. No difference in quality of life between groups was found<sup>[23]</sup>.

Krähenbühl *et al*<sup>[24]</sup>, in 2008, assessed the influence of transient neurological dysfunction (defined as a Glasgow coma scale value  $< 13$ ) on the quality of life of patients undergoing surgery of ascending aorta and proximal aortic arch. Over a mean follow-up interval of  $27 \pm 14$  mo, 79 subjects completed a SF-36 questionnaire. Patients with transient neurological dysfunction showed a significantly impaired quality of life except for bodily pain.

In 2009, a study assessed the quality of life among patients who underwent replacement of a dilated ascending aorta. Patients were divided according to the operative procedure. Operative procedures consisted of supracoronary replacement of the ascending aorta, the Wheat procedure, the David procedure, the Bentall-De Bono procedure, and the Cabrol procedure. One hundred and twenty two patients completed a SF-36 questionnaire after mean follow-up of  $36.4 \pm 15.5$  mo. Different surgical techniques had no statistically significant influence on postoperative quality of life. However, many subscales of SF-36 were below the norm when compared with a standard population, in particular physical pain and physical function<sup>[25]</sup>.

**Aortic arch:** Two studies assessed quality of life of patients with diseases of aortic arch.

Immer *et al*<sup>[26]</sup> published (2008) a study assessing the impact of continuous cerebral perfusion through the right subclavian artery on quality of life. With a mean follow-up of  $2.4 \pm 1.2$  years, 453 adults respond SF-36 questionnaire. Interestingly, the average quality of life after an arrest time between 30 and 50 min with continuous cerebral perfusion through the right subclavian artery was significantly better than when selective antegrade cerebral perfusion was used.

As we mentioned previously, in 2008, Krähenbühl *et al*<sup>[24]</sup> assessed the influence of transient neurological dysfunction on quality of life of patients undergoing surgery of proximal aortic arch and ascending aorta, showing that patients with transient neurological

dysfunction showed a significantly impaired quality of life later.

**Descending aorta:** Two studies explored quality of life of patients with diseases of descending aorta. Dick *et al.*<sup>[17]</sup>, in 2008 analyzed quality of life in patients treated either by thoracic endovascular aortic repair or by open aortic repair for diseases of the descending thoracic aorta. Seventy-five adults completed the SF-36 questionnaire after a mean follow-up of  $34 \pm 18$  mo. Quality of life scores of open aortic repair in the patients included in this study ranged from 63 to 110; the median was 93. Quality of life scores of thoracic endovascular aortic repair ranged from 60 to 112, with a median of 83. Thus, the authors concluded that after thoracic aortic repair the quality of life was reduced.

One year later, Dick *et al.*<sup>[18]</sup>, published another paper regarding the impact of urgency procedures on quality of life in patients with descending thoracic aorta disease. After a mean follow-up of  $29 \pm 16$  mo, 27 adults responded the SF-36 questionnaire. Quality of life scores after emergency range between 58 and 124, with a median of 72. Quality of life scores after elective endovascular aortic repair range between 61 and 105, median: 85. No statistical differences between groups in quality of life were found.

## DISCUSSION

We summarize the results of a small number of studies dealing with psychological issues in IE and TAD. Despite the high impact that psychological conditions might cause in these severe diseases, we could verify that there is not much information available on these matters. Thus, we aimed to review the available evidence on this context.

Some papers<sup>[27-29]</sup> and guidelines<sup>[30-33]</sup> previously reported that psychosocial factors such as depression, anxiety and other mental disorders such as personality disorders and post-traumatic stress disorders are related to morbidity and mortality due to cardiovascular diseases. Chronic heart failure, arrhythmias, and acute myocardial infarction are one of the most studied pathologies in that setting. Otherwise, other cardiovascular diseases are poorly or not studied from a psychological point of view, such as IE and TAD. We found four studies comparing anxiety and depression scores in patients with TAD after treatment and only one paper assessing post-traumatic stress disorder after IE treatment.

When specialists choose a specific type of invasive intervention, psychological aspects are usually ignored. The identification of interventions that increase anxiety and/or depression could be of interest from a medical point of view because anxiety and/or depression might negatively influence patient recuperation after the intervention. In TAD patients, anxiety and depression levels after different invasive interventions did not differ. No statistical differences were found in anxiety

and depression scores: After aortic valve repair using mechanical replacement vs after aortic valve repair using pulmonary autograft; after underwent thoracic aortic surgery vs after coronary artery bypass grafting; after thoracic endovascular aortic repair vs after open aortic repair, after thoracic endovascular aortic repair which indication was done electively vs emergency. Moreover, baseline anxiety and depression scores had not been reported. Depression or/and anxiety before invasive intervention, might negatively influence coping and recuperation after intervention.

A posttraumatic stress disorder was present in 11% and was associated with lower levels of quality of life in IE patients. IE patients with posttraumatic stress disorder reported feeling nervousness and depressive, having problems with work or other daily activities and having frequent interference with social activities due to physical or emotional problems. Although the percentage of posttraumatic stress disorder in IE might be considered low, IE patients with posttraumatic stress disorder need specialized mental health care and interventions to improve their quality of life.

Most of the studies assessed IE and TAD quality of life after treatment. Quality of life was reported to be impaired in three of four studies about infectious endocarditis and in three of eight studies about TAD. However, recent clinical guidelines about infectious endocarditis did not mention quality of life and recent guidelines about TAD did not make the slightest reference to quality of life either.

Most of quantitative studies about IE reported that after 12 or 37 mo after IE diagnosis, quality of life was clearly impaired. Only one study explored the possible influence of the causal microorganism, length of hospitalization, type of cardiac surgery, and infective complications in quality of life scores. The authors concluded that those issues did not clearly affect quality of life scores. In two studies, the patients evaluated their personal health as poor mentioning that it was likely to get worse. In one study, patients reported feeling tired, worn out all, nervousness and depressive. Since depression was not assessed, we can not know if those IE patients had depression, although this is a possibility. Moreover, elevated pro-inflammatory cytokines in IE could promote psychological alterations such as depression, especially in vulnerable patients, and this might compromise prognosis and the ability to cope the disease.

The cerebral perfusion technique used in invasive intervention of TAD patients might have neurological consequences and could influence the perceived quality of life as well. After a surgery of thoracic aorta, patients might postoperatively develop confusion, agitation and delirium, also named "temporary neurological dysfunction". Although resolution of these symptoms usually occur before hospital discharge, patients with temporary neurological dysfunction had lower scores in quality of life than patients without temporary neurological dysfunction. Patients with temporary

neurological dysfunction evaluate their personal health as poor and believe that it is likely to get worse. This way, they reported feeling nervousness, depressive, and having problems with work or other daily activities. The incidence of neurological complications might be decreased using selective antegrade cerebral perfusion. A study reported that the average quality of life after an arrest time between 30 and 50 min with continuous cerebral perfusion through the right subclavian artery was significantly better than selective antegrade cerebral perfusion. One important limitation was that all the studies revised did not include assessment before treatment or a proper control group. In addition, detailed medical records about patients that answered these mentioned questionnaires used to assess psychological issues are frequently not available.

Sixteen studies have been published about psychological issues in IE and TAD. Most of them explored quality of life and to a less extent anxiety and depression. Papers reviewed were heterogeneous in patients and procedures; they included few participants, they did not include control groups and they did not evaluate patients before treatment. Thus, we feel that more studies are needed, especially with a prospective design. The study of psychological issues is relevant and could bring us information about specific needs to be covered by psychological interventions and to design specialized care training and practice.

## COMMENTS

### Background

Some papers and guidelines reported that psychosocial factors such as depression, anxiety and other mental disorders such as personality disorders and post-traumatic stress disorder are related to morbidity and mortality due to cardiovascular diseases. Chronic heart failure, arrhythmias, and acute myocardial infarction are one of the most studied pathologies. Otherwise, other cardiovascular diseases are poorly or not yet studied from a psychological point of view, such as infective endocarditis (IE) and thoracic aortic disease (TAD). The study of psychological issues in these severe diseases could bring people valuable information about specific needs to cover with psychological interventions and to design specialized care training and practice. The aim of this review is to summarize the current evidence on psychological issues in TAD and IE setting. The authors performed a narrative review about psychological issues in adults with both TAD and IE.

### Research frontiers

From the health-psychology standpoint, both IE and TAD are almost forgotten research subjects. Patients with medical disorders usually require specialized medical attention and psychological care. It might be expected that patients with severe cardiovascular diseases will not be the exception, especially in the cases of IE and TAD, which generally require several invasive interventions. This area of interest is pretty new. All the papers revised in this research were published in the present century. Nevertheless, precise data on the psychological disorders that could be associated with IE and TAD is still lacking.

### Innovations and breakthroughs

Sixteen studies have been published about psychological issues in IE (six studies) and TAD (ten papers). Psychological issues assessed were quality of life, depression, anxiety and posttraumatic stress disorder. Quality of life was reported impaired in three of four studies about infectious endocarditis and in three of eight studies about TAD. However, recent clinical guidelines about infectious endocarditis did not mention quality of life and recent guidelines

about TAD made slightest reference to quality of life. Depression and anxiety were analyzed in TAD only (five papers). Anxiety and depression levels after different invasive interventions did not differ. No statistical differences were found in anxiety and depression scores: After aortic valve repair using mechanical replacement vs after aortic valve repair using pulmonary autograft; after underwent thoracic aortic surgery vs after coronary artery bypass grafting; after thoracic endovascular aortic repair vs after open aortic repair, after thoracic endovascular aortic repair which indication was done electively vs emergency. Moreover, baseline anxiety and depression scores had not been reported. Depression or/and anxiety before invasive intervention, might negatively influence patient recuperation after intervention. Regarding to IE, since depression was not properly assessed in the published manuscripts we do not have precise data. However, elevated pro-inflammatory cytokines in IE could promote psychological alterations such as depression, especially, in vulnerable patients, and this might compromise prognosis and coping disease. Post-traumatic stress disorder was assessed in IE (one study). It was present in 11% and was associated with lower levels of quality of life in IE patients. Although percentage of posttraumatic stress disorder in IE might be considered low, IE patients with posttraumatic stress disorder need specialized mental health care and interventions to improve quality of life.

### Applications

Despite the high impact that psychological conditions might cause in these severe diseases, the authors could verify that there is not much information available. It would be desirable that future studies used prospective designs, included control group and completed psychological assessment before and after treatments/interventions.

### Terminology

Psychological aspects revised in this paper include depression, anxiety, personality, coping, therapeutic adherence, illness perception and quality of life.

### Peer-review

The focus on IE is very timely and important, and the author presents the data in a very meaningful and useful manner.

### Abstract

Open surgery is the elective treatment for mycotic aneurysms of the aorta. This surgery consists of resection of the aneurysm, debridement and revascularization with an *in situ* or extra-anatomic bypass. Even when surgery has been successful, the morbidity is raised and the endovascular treatment has become an alternative for specific patients. When mycotic aneurysms involved the visceral arteries, more complex techniques are necessary such as fenestrated endovascular aortic repair or chimney endovascular aortic repair and the most frequent complications of this are endoleaks and occlusion the visceral arteries. We present a case of a patient with a paravisceral abdominal mycotic aneurysms that was result with 2 chimney technique (in the right renal and superior mesenteric arteries) and a single Nellix EVAS (Endologix, Irvine, Calif) of 12 cm long without evidence of endoleaks in the follow-up.

## INTRODUCTION

Open surgery is the elective treatment for mycotic aneurysms of the aorta. This surgery consists of resection of the aneurysm, debridement and revascularization with an *in situ* or extra-anatomic bypass<sup>[1]</sup>. Even when surgery has been successful, the morbi-mortality is raised and the endovascular treatment has become an alternative for specific patients<sup>[2]</sup>.

The main problem of this kind of pseudoaneurysms is the location. When the mycotic aneurysm is in the descending aorta or infrarenal aorta without compromising the supra-aortic trunks or the visceral arteries, endovascular treatment is possible with a successful outcome<sup>[2]</sup>. Nevertheless, it has not been well described in the literature this type of procedure for paravisceral abdominal aortic aneurysm.

When mycotic aneurysms involved the visceral arteries, more complex techniques are necessary such as Fenestrated endovascular aortic repair (f-EVAR) or chimney endovascular aortic repair (Ch-EVAR) and the most frequent complications of this are endoleaks and occlusion the visceral arteries<sup>[3,4]</sup>.

We present a case of a patient with a paravisceral abdominal mycotic aneurysms with absolute contraindication for open surgery with two unsuccessful endovascular treatments, that was result with chimney technique and Nellix (Endologix, Irvine, Calif) chimney endovascular sealing (Ch-EVAS).

## CASE REPORT

A 72-year-old woman was admitted in the emergency department presented with acute abdominal pain. She had a medical history of former smoker, multiple coronary by-pass with dehiscence of the chest wound, pulmonary embolism treated with anticoagulants and respiratory failure (SpO<sub>2</sub> 82%).

To the physical examination, the patient was presenting an acute abdominal pain with rigidity, guarding and peritoneal irritation so an AngioCT scan was performed and showed gastrointestinal perforation and a 4.9 cm paravisceral abdominal aneurysms with intraluminal thrombus (Figure 1A). Small bowel resection and jejunostomy was done.

Anatomopathology showed miliary tuberculosis with intestinal involvement and peritoneal implants.

With this result and the presence of the aortic aneurysms we made the diagnosis of tuberculous mycotic aneurysm with compromise of the four visceral branches. Although, the endovascular treatment was decided because of the clinical situation of the patient, the endovascular options have not been simple because of the location of the aneurysms. The options were a f-EVAR, which was impossible for the time confection or a Ch-EVAR with the risk of endoleaks in the pseudoaneurysms that needs 4 chimney.

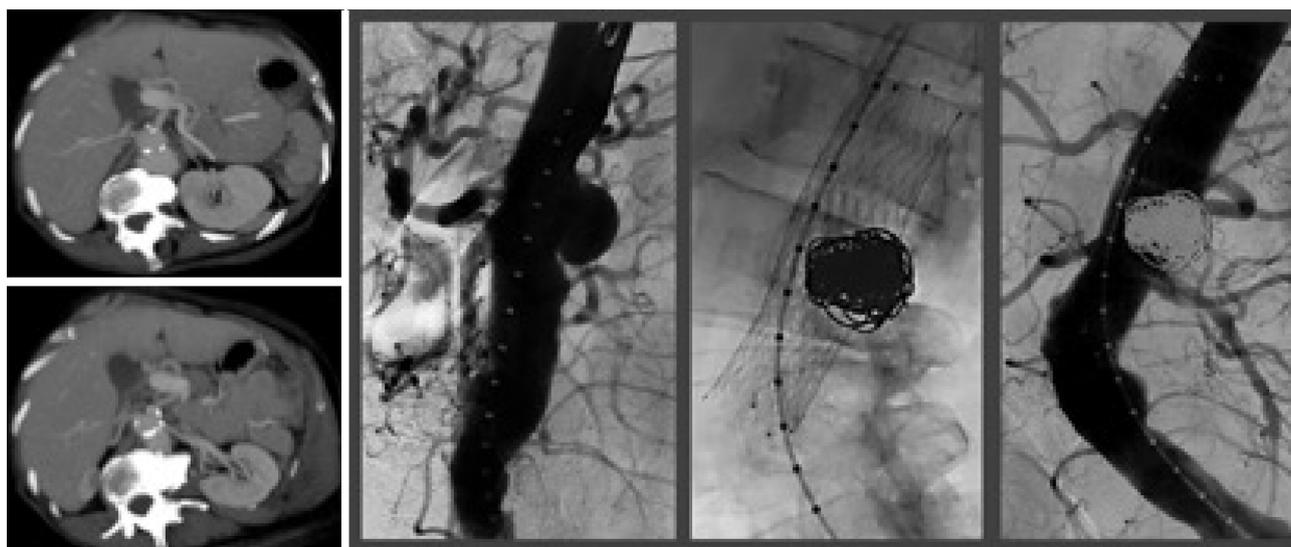

Another therapeutic option was Ch-EVAS which was not available in our country. Base on the foregoing, and knowing that it was not a definitive treatment, the decision was to perform stent assisted coil embolization technique of the aneurysms.

In the procedure, for a femoral access a Sinus XL stent (OptiMed, Ettlingen, Germany) was placed in the aortic visceral topography and across it embolization of the pseudoaneurysm with coils was performed with a successful initial first result (Figure 1B and D) and without complications. The patient was discharged 48 h later with parenteral nutrition, aspirin 100 mg/d and antibiotics therapy for tuberculosis.

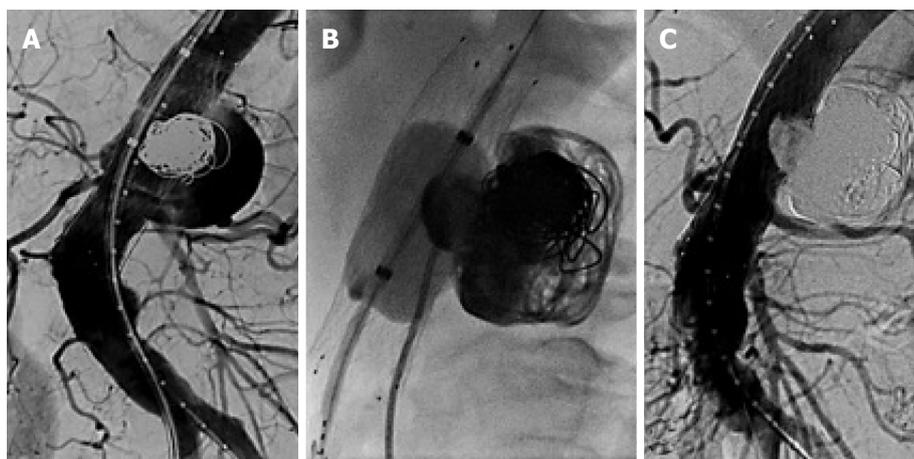

Four month later, an AngioCT scan revealed that the mycotic aneurysm had grown and a for a percutaneous femoral access a balloon-assisted coils and n-butyl 2-cyanoacrylate embolization was performed with good angiographic outcomes (Figure 2). The patient was still undergoing treatment for her infection disease and was discharged 24 h later without complications. Bowel transit and abdominal wall reconstruction was made a month later. Two month after surgery, the patient was admitted with low back pain and the CT angiogram showed an endoleak with aneurysm sac enlargement and extravasation of the embolic agents used previously that indicated rupture, so an endovascular treatment with Ch-EVAS was decided, because it was already available in our country.

Under general anesthesia a percutaneous femoral access was done for the introduction of a single Nellix EVAS of 12 cm long (the aortic diameter was normal and it was not necessary to spread up to the iliac arteries) and a open left subclavian access to place the chimneys for the right renal and superior mesenteric arteries. Both chimneys were performed with a Viabahn covered stent (Gore and Associates, Flagstaff, AZ) of 7 mm × 100 mm for the right renal artery and 8 mm × 100 mm for the superior mesenteric artery. Inside the chimneys a nitinol self-expanding stent was placed to give them a greater radial force strength and to avoid the chimney collapse by the polymer (Figure 3).

The left renal artery was catheterized but it was not possible to advance a catheter across the strut of the Sinus stent, so an angioplasty with a 6-mm low-profile coronary balloon was performed. Despite these, it was not possible to introduce a 4 Fr diagnostic catheter

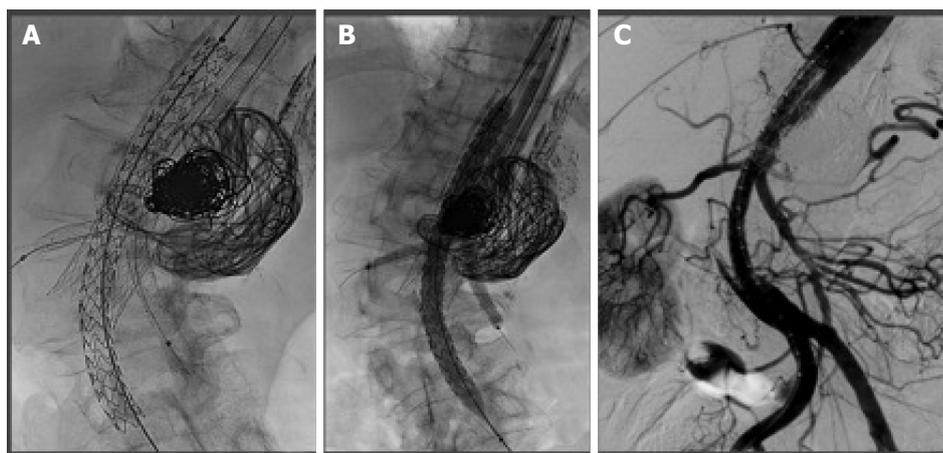

**Figure 1** AngioCT scan and digital subtraction angiography. Mycotic aneurysm and the relation with the visceral branches, stent assisted coil embolization of aneurysms with a Sinus XL stent and complete embolization of the mycotic aneurysms without evidence of flow inside the sac.

**Figure 2** Digital subtraction angiography (A-C). Flow in the mycotic aneurysms an increased de diameter of the sac. Coils and n-butyl 2-cyanoacrylate embolization performed with the balloon-assisted technique and final angiographic control shows absence of flow in the interior of the aneurysms.

**Figure 3** Digital subtraction angiography. Rechanneling of the pseudoaneurysms. Renals and superior mesenteric arteries catheterization (the left renal artery with a coronary balloon angioplasty) and the presence of n-butyl 2-cyanoacrylate out of the pseudoaneurysms. Chimney in the right renal artery and superior mesenteric artery.

**Figure 4** Single Nellix endovascular sealing and the chimneys (A-C). Fluoroscopy of the balloons inflated during the filling of the bag of the Nellix EVAS with the polymer. Permeability of the endograft, both chimneys and the celiac trunk without evidence of endoleaks.

so it was decided to abandon the left renal artery. It was decided not to be catheterized the celtrunk for the idea that it would be compensated for the superior mesenteric artery, as it happened.

The final angiographic control showed the exclusion of the mycotic aneurysms with permeability of the right renal artery and superior mesenteric artery which supply the celiac trunk and its branches (Figure 4). After the procedure, the patient was discharged 5 d later without complications, normal renal function, clopidogrel 75 mg, aspirin 100 mg a day and antibiotic therapy. AngioCT scan follow-up at 3 mo, showed absence of endoleaks and permeability of the right renal artery, superior mesenteric artery and the celiac trunk.

## DISCUSSION

Open surgery is the elective treatment for mycotic aneurysms of the aorta, however in patient with absolute contraindication for surgery, the endovascular treatment become an important alternative for this patients that have been well described in the multicentric European study which concluded that endovascular treatment it is a feasible and lasting option in most patients<sup>[2]</sup>. Nevertheless, in this study of all treated aneurysms only in the 7% of them it was used f-EVAR techniques, not having specific comments about the follow-up in these patients. Another endovascular option for the treatment of paravisceral abdominal mycotic aneurysms is the Ch-EVAR. However, the rate of endoleaks with this technique in a review by Patel *et al*<sup>[4]</sup> was estimated at 5% to 37.5%.

In a recent review by Li *et al*<sup>[5]</sup> the rate of endoleaks type IA was 11.8% with a permeability of the branches of 96.6% at 6 mo. Because of these, in our case we this alternative was scorned in view of the high percentage of endoleaks (4 or 3 chimneys were necessary) and the consequent risk of rupture. In this location, the f-EVAR is a good choice to treat this

aneurysm. The only problem is the time of confection that limits the use in pseudoaneurysms that need an early resolution. In the last 2 years, it has been reported some cases of paravisceral aneurysms treated with Ch-EVAS technique that show promising result<sup>[6-8]</sup>. Torella *et al*<sup>[7]</sup> presented 2 cases of juxtarenal aortic aneurysms treated with Ch-EVAS with 2 chimneys in each case and without evidence of endoleaks type IA. Youssef *et al*<sup>[6]</sup> published recently a series of 7 patients treated with Ch-EVAS with four chimneys for patient in which they reported no early endoleaks with a permeability of 96% of the branches to 6 mo of follow-up.

The Ch-EVAS turns out to be an interesting concept since the polymer realizes a copy of the aortic anatomy occupying the space of the gutters that they originate with the conventional Ch-EVAR technique reducing the risk of endoleaks. The case that we presented it would be the first case treated with Ch-EVAS that has been reported since in the bibliographical review that we made we do not find cases of paravisceral abdominal mycotic aneurysms treated with this technology. While so far, the reports on Ch-EVAS are only clinical case reports, they represent encouraging results as a future alternative of first choice for the treatment of paravisceral aortic aneurysms.

## COMMENTS

### Case characteristics

A 72-year-old woman with a medical history of military tuberculosis with abdominal involvement that was treated in two opportunities for a mycotic aortic aneurysm with compromise of the four visceral branches with endovascular technique was admitted at the emergency department with low back pain two months after the second treatment.

### Imaging diagnosis

Computed tomography angiogram showed an endoleak with mycotic aneurysm enlargement.

### Treatment

Endovascular treatment performed with Chimney endovascular aneurysm

sealing (Ch-EVAS) with good result with exclusion and absent of endoleaks in the final angiography control. In the follow up the patient continuous asymptomatic with no evidence of endoleaks or another complication.

### Experiences and lessons

A mycotic aneurysm of the aorta with involvement of the visceral arteries is a dreadful condition and repair it can be quite challenging. The endovascular treatment has become an important alternative. The Ch-EVAS turns out to be an interesting concept because it solves the endoleak problems with the conventional chimney endovascular aneurysm repair. In the authors' bibliographical review, the authors did not find cases of paravisceral abdominal mycotic aneurysms treated with this technology.

### Peer-review

This is an interesting case report about the endovascular treatment of paravisceral mycotic aneurysm.

### Abstract

We present a case report about percutaneous closure of a congenital Gerbode defect using Nit-Occlud® Lê VSD coil. The patient was referred to our hospital with a diagnosis of ventricular septal defect (VSD) and severe pulmonary arterial hypertension. But transthoracic echocardiography revealed a communication between the left ventricle (LV) and the right atrial (RA), called Gerbode defect. Catheterization confirmed the shunt from the LV to the RA. We successfully closed the defect with a VSD coil. After uneventful 6 mo follow-up, the patient was out of dyspnea, the symptom urged him to have medical attention. This case report is to discuss the diagnosis and percutaneous treatment approach for this rare congenital heart disease.

**Key words:** Congenital Gerbode defect; Nit-Occlud® Lê VSD coil; Congenital heart disease; Transcatheter device closure; Device embolization

**Core tip:** Congenital Gerbode defect is rare, only accounts for about 0.08% among congenital heart diseases. The diagnosis is easily misinterpreted with others condition on clinical examination and echocardiography. The treatment of this disease is also lack of recommendation. There are several approaches can be applied for this kind of defect such as conservation, cardiac surgery, intravascular intervention or intra-operative device closure. There are several devices can be used for transcatheter closure such as ventricular septal occluder, atrial septal occluder, ADO I or ADO II. This is the first report using Nit-Occlud® Lê VSD coil to close Gerbode defect successfully.

## INTRODUCTION

The left ventricular to right atrial (LV-RA) communication was first described by Frank Gerbode in 1958<sup>[1]</sup>. This defect can be either congenital or acquired. While congenital LV-RA shunt is very rare, acquired LV-RA shunt is reported more common, can be induced by endocarditis, trauma, valve replacement, myocardial infarction, *etc*<sup>[2]</sup>. There are several varieties of Gerbode defect<sup>[1]</sup>: Supravalvular (direct) type, subvalvular (indirect) type and a combination of these two lesions.

The diagnosis of congenital Gerbode defects is quite challenging: While the clinical symptoms may mimic ventricular septal defect (VSD), it can be misinterpreted on TTE with tricuspid regurgitation and pulmonary arterial hypertension. Further investigation by transesophageal echocardiography (TEE), magnetic resonance imaging (MRI), computed tomographic angiography (CTA), ... may help to determine the right diagnosis.

## CASE REPORT

A 31-year-old male who had dyspnea on exertion 3 mo before hospitalization, was referred to our hospital with a diagnosis of heart failure in patient with VSD and severe pulmonary hypertension. He had healthy active lifestyle, normal physical and mental development. The clinical examination showed a loud harsh holosystolic murmur (4/6 Levine scale) at 4<sup>th</sup> intercostal spaces along left sternal border, radiated downward and a systolic thrill could be palpated. His blood pressure was 125/85 mmHg. The ECG showed sinus rhythm. The BNP was slightly increased. Chest X-ray, ionogram, creatinine, glucose, blood count and clotting times were in normal range. The TTE revealed a shunt between the LV and the RA. The jet went into the RA looked similar to the tricuspid valve regurgitation flow with high velocity, about 4.8 m/s. The other findings included slight dilation of the right heart chambers, mild RV systolic dysfunction and Qp:Qs was 1.6.

Cardiac catheterization was performed. LV contrast injection illustrated quite large shunt from the LV to the RA. The defect was in long conical figuration with diameters of 9.5 mm at the biggest LV ampulla, 4.0 mm at the narrowest position and 8.5 mm length. It was quite far from the aortic valve and coronaries. The pulmonary arterial pressure was 56/22/35 mmHg.

After getting across the defect with a Terumo wire from LV and snaring the wire at the superior vena cava for making the arteriovenous loop, an 8F deli-

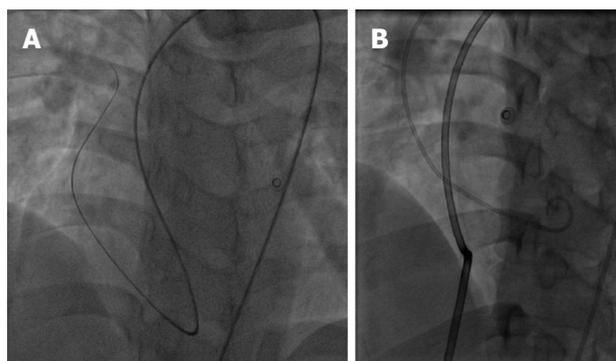

Figure 1 Through the defect, the Terumo wire was introduced to the right atrial and superior vena cava from left ventricular (A) and the 8F delivery catheter went from inferior vena cava and right atrial to the left atrial and aorta (B).

Figure 2 The Nit-Occlud® Lê VSD coil.

very catheter was introduced to LV and aorta from RA through the defect (Figure 1). Then, a 12 mm × 6 mm Nit-Occlud® Lê VSD coil (Figure 2) was deployed to close the defect with aortic approach (Figure 3). The procedure was quite similar to perimembranous VSD occlusion with likely satisfied result (Figure 4). There was only small residual shunt from LV to RA on LV contrast injections and echocardiography, no aortic regurgitation, no cardiac arrhythmia on ECG and the hemodynamic was stable.

But while the patient was kept following on cathlab table for complications, mostly concerning bradycardia and heart block, we detected some free bizarre movement of device distal part (Video 1). The device was going to drift out of the defect at 15 minutes after coil release. We quickly retrieved the coil with multi-snare and 10F catheter from the RA through inferior vena cava (Figure 5). Another attempt to close the defect with a bigger 14 mm × 8 mm Nit-Occlud® Lê VSD coil was performed (Figure 6). The final result looked fine with mild residual LV-RA shunt, no aortic regurgitation, no arrhythmia. Six hours after the procedure, there was still a grade 2/6 murmur can be found on auscultation and mild shunt from LV to RA on echocardiography. After 24 h, both the murmur and residual shunt flow were gone. After 5 d of close

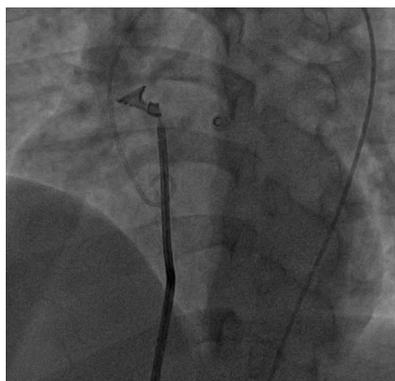

Figure 3 The 12 mm × 6 mm Nit-Occlud® Lê VSD coil was deployed with aortic approach.

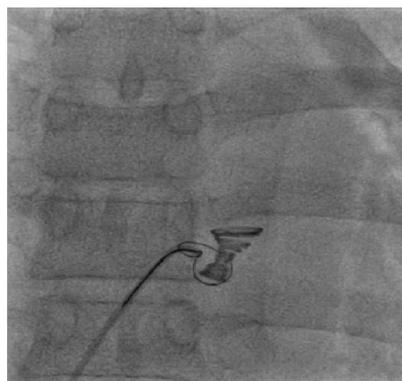

Figure 5 The drifting coil was retrieved with a multi-snare from the atrial side.

Figure 4 The 12 mm × 6 mm Nit-Occlud® Lê VSD coil immediately after release.

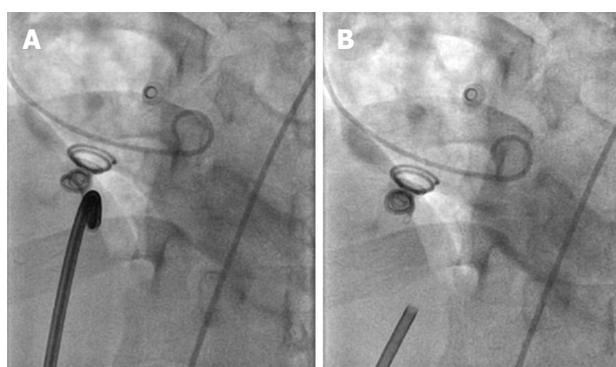

Figure 6 The bigger 14 mm × 8 mm Nit-Occlud® Lê VSD coil before (A) and immediately after release (B).

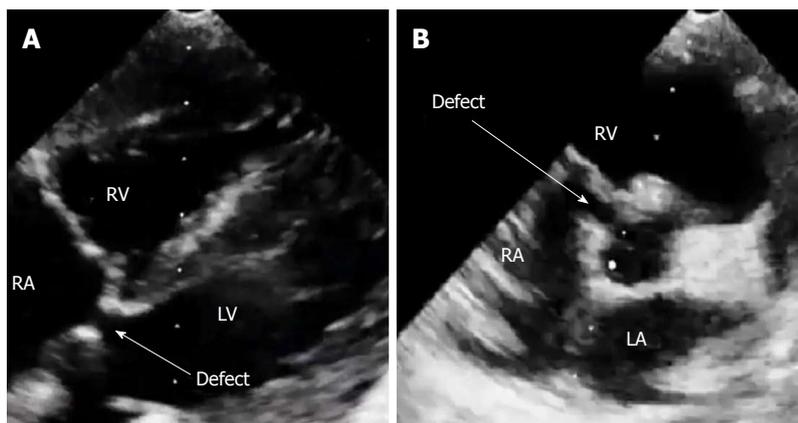

following up uneventful, the patient was discharged in good physical and mental condition. We have been checking the patient at 1 mo, 3 mo and 6 mo after the procedure. Till now, the patient has no symptom on exertion, the device is in good position without any shunt on echocardiography and there is no murmur on heart auscultation.

## DISCUSSION

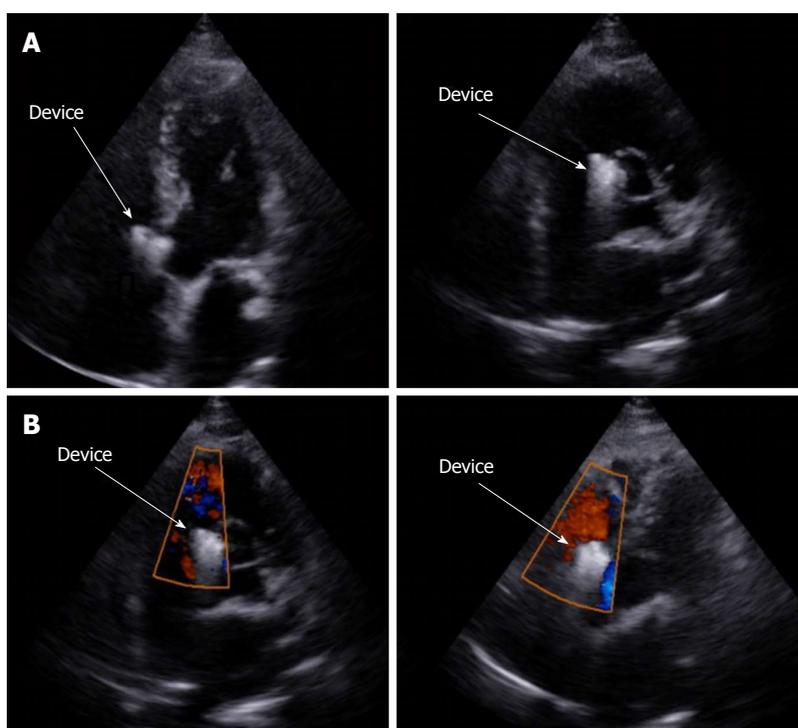

Congenital Gerbode defect is rare, only accounts for about 0.08% among congenital heart diseases<sup>[1]</sup>. Patients may have symptoms or not depends on the defect size and the shunt from LV to RA. Heart auscultation can detect a systolic murmur with position and intensity similar to the VSD but slightly lower and radiating downward.

TTE is useful for diagnosis of Gerbode defect. In 2D mode, the LV-RA shunt may be detected in some views, such as parasternal short axis, four and five chambers or subcostal views (Figure 7). The image quality was better in subcostal view as there was no bone or lung tissue to obstruct the view. Pulsed wave Doppler was helpful in detecting the shunt by the high turbulent audio signal. Continuous wave Doppler helped detect and measure peak systolic velocities across the shunt. Color flow imaging was useful in

localizing defect position and shunt flow. However, in Gerbode defect, the shunt flow, affected by the septal leaflet of the tricuspid valve, may change direction unexpectedly. So, it can mimic the direction of tricuspid regurgitation flow and made sonographers misrecognize as tricuspid regurgitation in the setting of severe pulmonary artery hypertension<sup>[3]</sup>. In this case, at first, the clinical physician thought about VSD and sent the patient to the sonographer for more detail. The conclusion they received was VSD with very high systolic pulmonary arterial pressure, about 115 mmHg. Both the clinical physician and sonographer were cheated by the shunt flow. So quick clinical examination and echocardiography in this kind of defect may easily lead to a misdiagnosis. The sonographer should meticulously look for Gerbode defect if physical examination suspects VSD but echocardiography can not detect any high velocity flow or aliasing in the right ventricle. The presence of normal diastolic pulmonary arterial pressure using pulmonic regurgitation jet is also very useful to distinguish the true pulmonary arterial hypertension from high velocity jet in the RA caused by Gerbode defect<sup>[4,5]</sup>. Actually, only about 2/3 of the LV-RA shunts of either congenital or acquired origin can be well diagnosed with TTE<sup>[6]</sup>. The 1/3 of others have to rely on other means like contrast echo, TEE, MRI, CTA or catheterization for accurate diagnosis.

**Figure 7** The Gerbode defect were best seen on echocardiography at subcostal five chamber view (A) or parasternal short axis view (B).

**Figure 8** Six months following up showed steady result with good device position and no shunt on echocardiography. A: Transthoracic echocardiography performed 6 mo after the procedure showed good device position at apical five chamber view (left) and parasternal short axis view (right); B: Colour doppler showed no residual shunt at apical five chamber view (left) and parasternal short axis view (right) 6 mo after device deployment.

Till now, there has been no clear official guidance for optimal treatment of Gerbode defect. Physicians may personally choose suitable therapy among conservation, cardiac surgery, intravascular intervention or intraoperative device closure. Patients without symptom and right ventricular volume overload, due to a small LV-RA shunt, may not need the treatment<sup>[7]</sup>. But if left untreated, the significant LV-RA shunt may lead to progressive congestive heart failure<sup>[8]</sup> and up to 8.7% of patients with LV-RA shunt developed infectious endocarditis in long-term follow-up<sup>[9]</sup>. So, some authors<sup>[10-14]</sup> suggested that correction of this type of defect with significant LV-RA shunt is necessary.

Even though the surgical closure is accepted as a treatment of choice<sup>[12]</sup>, some successful transcatheter closures for Gerbode defect have been reported. There is a paucity of information in the existing literature on transcatheter therapy for this type of defect. Indications of intervention may be same as those in the left to

right shunt lesion<sup>[14]</sup>. The devices used for occlusion this kind of defect varies from centers to centers. The first device reported used to close of an acquired Gerbode defect following VSD surgical correction was Amplatzer ventricular septal occluder<sup>[11]</sup>. Another device, amplatzer septal occluder (ASO) commonly used for atrial septal defect closure, also being used to close Gerbode defect complicated from mitral valve surgery with marked improvement in exercise tolerance<sup>[13]</sup>. The smallest patient reported, a 3-mo old baby with an acquired Gerbode shunt after VSD patch closure, was treated using an amplatzer duct occluder (ADO) with complete closure achieved 2 wk after device deployment and good long term follow-up<sup>[12]</sup>. Recently, a report of 12 Gerbode defect patients that were transcatheterly closed with ADO II showed satisfactory outcomes<sup>[14]</sup>. Until now, there is no specific device purposely manufactured for Gerbode defects closure. The devices used to occlude this kind of defects are borrowed from

products created for other defect types such as atrial septal defect, VSD, patent ductus arteriosus, etc. In this case, giving the size and shape of the defect, a suitable device could be chosen for transcatheter occlusion among ADO, ADO II, membranous or muscular VSD occluder, VSD Coil or ASO. With a quite big and long defect like that, heart block and injuring adjacent structures could likely happen when using ADO, VSD occluder or ASO. A good device might be ADO II, but it was not available in our center at that time. So, we finally decided to use the Nit-Occlud® Lê VSD coil (PFM Medical, Germany), which are commonly used for VSD closure. This device is made of Nitinol coils with securely attached polyester fibers and a cone-in-cone configuration (Figure 2). The bigger proximal cone is more flexible and will be partially deployed on the left ventricular side of the defect. The smaller distal cone will be deployed on the other side of the defect and its diameter should be at least twice the defect smallest diameter. The first device chosen might be undersized purposely, for minimizing surrounding structures injury. That could explain for device embolization after deployment. The second bigger device was appropriate for the defect with firmly sitting in the correct position. So, choosing a suitable device with correct size is very important to prevent device embolization in transcatheter Gerbode defect closure.

After device successfully released, there was rising concern of hemolysis and hematuria because the contrast ejection and echocardiography showed small residual shunt. But after 24 h, the murmur on heart auscultation and residual shunt on echocardiography was completely gone. Six months following up also showed steady result with no heart murmur, good device position, no shunt on echocardiography (Figure 8) and the patient achieved almost normal life.

In conclusion, the diagnosis of congenital Gerbode defect is quite challenging, can be easily misinterpreted. Percutaneous device occlusion offers a feasible, safe and effective therapy for this type of defect. Among devices used for transcatheter closure of Gerbode defects, the Nit-Occlud® Lê VSD coil may be a good candidate.

## COMMENTS

### Case characteristics

A 31-year-old male who had normal physical and mental development presented with dyspnea on exertion and a loud harsh holosystolic murmur at 4<sup>th</sup> intercostal spaces along the left sternal border with a systolic thrill could be palpated.

### Clinical diagnosis

Ventricular septal defect.

### Differential diagnosis

Tricuspid regurgitation, mitral regurgitation, pulmonic stenosis, patent ductus arteriosus.

### Laboratory diagnosis

The BNP was slightly increased. Other labs were within normal limits.

### Imaging diagnosis

Echocardiography showed a shunt from left ventricle to the right atrium.

### Pathological diagnosis

Communication between the left ventricle and right atrium (congenital Gerbode defect).

### Treatment

The defect was transcatheterly closed using a Nit-Occlud® Lê VSD coil with no residual shunt at 6 mo follow-up.

### Related reports

Congenital Gerbode defect is a rare congenital heart disease and can be easily misinterpreted. Percutaneous device occlusion offers a feasible, safe and effective therapy for this disease.

### Experiences and lessons

In congenital Gerbode defect, careful review of echocardiography is an important key to avoid misdiagnosis and the transcatheter closure with an appropriate device is a crucial factor to ensure the procedural success.

### Peer-review

The reported case is well described and interesting.

# World Journal of *Cardiology*

*World J Cardiol* 2017 August 26; 9(8): 640-714

## Editorial Board

2014-2017

The *World Journal of Cardiology* Editorial Board consists of 416 members, representing a team of worldwide experts in cardiology. They are from 46 countries, including Argentina (3), Australia (7), Austria (6), Belgium (2), Brazil (8), Canada (11), China (37), Croatia (1), Cuba (1), Cyprus (1), Czech Republic (2), Denmark (3), Egypt (1), Finland (3), France (3), Germany (32), Greece (10), Hungary (5), India (4), Iran (2), Ireland (1), Israel (5), Italy (63), Japan (32), Kosovo (1), Malaysia (1), Mexico (1), Morocco (1), Netherlands (9), New Zealand (1), Nigeria (2), Norway (2), Poland (8), Portugal (2), Saudi Arabia (2), Singapore (3), Slovenia (1), South Korea (9), Spain (14), Switzerland (3), Thailand (3), Turkey (13), United Arab Emirates (1), United Kingdom (20), United States (73), Uruguay (2), and Venezuela (1).

### REVIEW

- 640 Diagnosis and management challenges of in-stent restenosis in coronary arteries

*Alraies MC, Darmoch F, Tummala R, Waksman R*

- 652 Cardiovascular involvement in celiac disease

*Ciaccio EJ, Lewis SK, Biviano AB, Iyer V, Garan H, Green PH*

### MINIREVIEWS

- 667 Is there evidence for statins in the treatment of aortic valve stenosis?

*Akin I, Nienaber CA*

### ORIGINAL ARTICLE

#### Basic Study

- 673 Interleukin-19 is cardioprotective in dominant negative cyclic adenosine monophosphate response-element binding protein-mediated heart failure in a sex-specific manner

*Bruns DR, Ghincea AR, Ghincea CV, Azuma YT, Watson PA, Autieri MV, Walker LA*

#### Case Control Study

- 685 Effects of hypertonic saline solution on body weight and serum creatinine in patients with acute decompensated heart failure

*Lafrenière G, Béliveau P, Bégin JY, Simonyan D, Côté S, Gaudreault V, Israeli Z, Lavi S, Bagur R*

#### Observational Study

- 693 Estimating pressure gradients by auscultation: How technology (echocardiography) can help improve clinical skills

*Kadle RL, Phoon CKL*

- 702 Coronary angiography findings in cardiac arrest patients with non-diagnostic post-resuscitation electrocardiogram: A comparison of shockable and non-shockable initial rhythms

*Martínez-Losas P, Salinas P, Ferrera C, Nogales-Romo MT, Noriega F, Del Trigo M, Núñez-Gil JJ, Nombela-Franco L, Gonzalo N, Jiménez-Quevedo P, Escaned J, Fernández-Ortiz A, Macaya C, Viana-Tejedor A*

### CASE REPORT

- 710 Very late bioresorbable scaffold thrombosis and reoccurrence of dissection two years later chronic total occlusion recanalization of the left anterior descending artery

*Di Serafino L, Cirillo P, Niglio T, Borgia F, Trimarco B, Esposito G, Stabile E*

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Bahri Akdeniz, MD, Professor, Department of Cardiology, Dokuz Eylul University, 35340 Izmir, Turkey

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

### Abstract

Over the course of the 3 decades, percutaneous coronary intervention (PCI) with stent implantation transformed the practice of cardiology. PCI with stenting is currently the most widely performed procedure for the treatment of symptomatic coronary disease. In large trials, drug-eluting stents (DES) have led to a significant reduction in in-stent restenosis (ISR) rates, one of the major limitations of bare-metal stents. Due to these favorable findings, DES was rapidly and widely adopted enabling more complex coronary interventions. Nevertheless, ISR remains a serious concern as late stent complications. ISR mainly results from aggressive neointimal proliferation and neoatherosclerosis. DES-ISR treatment continues to be challenging complications for interventional cardiologists.

**Key words:** Stent; In-stent; Restenosis; Percutaneous coronary intervention

## INTRODUCTION

Percutaneous coronary intervention (PCI) with stenting is currently the most widely performed procedure for the treatment of symptomatic coronary disease<sup>[1]</sup>. Over the course of the 3 decades, PCI with stent implantation transformed the practice of cardiology. In large trials, drug-eluting stents (DES) have led to a significant reduction in in-stent restenosis (ISR) rates, one of the major limitations of bare-metal stents (BMS)<sup>[2]</sup>. Due to these favorable findings, DES was rapidly and widely adopted enabling more complex coronary interventions. Nevertheless, ISR remains a serious concern as late stent complications.

## DEFINITION

ISR is defined as the gradual re-narrowing of a stented coronary artery lesion due to arterial damage with subsequent neointimal tissue proliferation<sup>[3,4]</sup>. Angiographically IRS is a binary event defined as recurrent diameter stenosis at the stent segment more than 50% of the vessel diameter as determined by coronary angiography<sup>[4]</sup>. The angiographic definition remains the main definition since it allows determination of ISR severity and morphological pattern. The clinical definition of ISR requires the presence of greater than 50% diameter in-stent stenosis and one of the following: Clinical symptoms of recurrent angina, objective signs of ischemia (EKG changes), positive coronary hemodynamic assessment with fractional flow reserve (FFR) less than 0.80, intravascular ultrasonography (IVUS) minimum cross-sectional area less than 4 mm<sup>2</sup> (6 mm<sup>2</sup> for left main), or restenosis with  $\geq 70\%$  reduction in lumen diameter even in the absence of clinical symptoms or signs.

## CLASSIFICATION

Multiple classification systems have been identified to address the severity of ISR. Mehran system<sup>[5]</sup> is a morphologic classification of ISR lesions in to four patterns. Pattern I (focal) is ISR ( $\leq 10$  mm in length) lesion within the stent, pattern II (diffuse) is ISR greater than 10 mm within the stent, pattern III (proliferative) is ISR greater than 10 mm extending outside the stent, and pattern IV (occlusion) is totally occluded ISR. This classification system predicts the need for repeat revascularization after intervention (19%, 35%, 50%, and 98%, respectively)<sup>[5]</sup>. American College of Cardiology/American Heart Association lesion

classification has been also validated in patients with ISR<sup>[6]</sup>. Type A lesions had a probability of success of more than 85% and a low risk of acute occlusion. Type B lesions had a probability of success of between 60% and 85% and a moderate risk of abrupt occlusion. Finally, type C lesions had a probability of success of less than 60% and a high risk of abrupt occlusion following the procedure (Table 1). Lesions B2 and C have been reported to be frequently associated with suboptimal acute results with a higher restenosis rate and poorer long-term clinical outcomes<sup>[7]</sup>.

## INCIDENCE

In general, rates of ISR range from 3% to 20% with drug-eluting stents and 16% and 44% with BMS. This occurs mostly between 3 to 20 mo after stent placement<sup>[3,8]</sup>. The incidence of ISR depends on the definition, stent type, location, patient comorbidities and lesion complexity (*i.e.*, lesion length, vessel size, and bifurcation lesions). The introduction of DES has significantly reduced the occurrence of neointimal proliferation, which is considered the main mechanism for ISR. The decrease in ISR was translated into decreased clinical need for subsequent repeat revascularization<sup>[9-11]</sup>. A meta-analysis of 38 randomized controlled trials with more than 18000 patients showed significant reduction in TLR with both sirolimus-eluting stent (SES) and paclitaxel-eluting stents (PES) compared with BMS<sup>[10]</sup>. However, due to the complexity of ISR beyond device and stent design, the rates of ISR in both BMS and DES are still relatively high<sup>[12]</sup>. Routine angiographic surveillance 6 to 8 mo after stent implantation was done in one study that revealed ISR rates of 30.1%, 14.6%, and 12.2% for BMS, first-generation DES, and second-generation DES, respectively<sup>[13]</sup>.

### **Bare-metal stents ISR**

Despite relatively high restenosis rates, bare-metal stents are still frequently used in clinical practice during PCI<sup>[14]</sup>. This is related to unaffordable prices of DES and more importantly, lower risk of bleeding due to shorter duration of dual antiplatelet therapy (DAPT) that is required after BMS compared with DES. BMS-ISR causes a significant therapeutic burden in current clinical practice. One pooled analysis reported a one-year TLR and TVR rates after BMS of 12% and 14.1% respectively<sup>[15,16]</sup>. Clinical restenosis was evident within 6-12 wk after BMS implantation<sup>[16]</sup>. Beyond 1 year, rate of BMS restenosis is negligible and most stenting events are related to disease progression in vessel segments other than the stented lesion<sup>[16]</sup>.

### **Drug-eluting stents ISR**

Restenosis rate of DES increased in the recent years due to expanded use to include high-risk patients with complex coronary lesions. The DES-ISR rate has been reported in 3%-20% depending on DES type, the duration of follow-up, and the complexity of the lesions

**Table 1 ACC/AHA lesion-specific classification of the primary target stenosis**

Lesion type		Lesion characteristic according to AHA/ACC classification				
Type A lesions	Discrete (< 10 mm length)	Concentric	Readily accessible	Non angulated segment < 45°	Smooth contour	Little or no calcification
	Less than totally occlusive	Not ostial in location	No major branch involvement	Absence of thrombus		
Type B1 lesions	Tubular (10-20 mm length)	Eccentric	Moderate tortuosity of proximal segment	Moderately angulated segment, 45°-90°	Irregular contour	Moderate to heavy calcification
	Total occlusion < 3-mo-old	Ostial in location	Bifurcation lesions requiring double Guidewires	Some thrombus present		
Type B2 lesions	Two or more "B" characteristics					
Type C lesions	Diffuse (> 2 cm length)	Total occlusion > 3-mo-old	Excessive tortuosity of proximal segment	Extremely angulated segments, > 90°	Inability to protect major side branches	Degenerated vein grafts with friable lesions

in which the stents were placed<sup>[3]</sup>. When compared with BMS, DES is associated with lower ISR. At one-year follow up, SES markedly reduced the incidence TLR from 16.6% to 4.1% when compared with BMS<sup>[17]</sup>. For first-generation DES, j-Cypher registry of 12812 patients who received SES, the TLR rate was 7.3% at 1 year, and 15.9% at 5 years<sup>[18]</sup>. Ischemia-driven TLR was also the same in patients randomly assigned to SES or PES (13.1% vs 15.1%) in the SIRTAX LATE study<sup>[19]</sup>. Second generation stents have been associated with lower death and myocardial infarction compared with first-generation DES. However, zotarolimus-eluting stent (ZES) found to be noninferior to PES for TVR at 1 and 5 years<sup>[20]</sup>. In a pooled analysis of multiple studies comparing everolimus-eluting with ZES, the rates of TVR at up to five years of follow-up were 6.3% and 5.0%, respectively<sup>[21]</sup>.

## PREDICTORS OF IN-STENT RESTENOSIS

Patient comorbidities, lesion characteristic, and procedural characteristics are the main predictors of ISR.

### Patient characteristics

Patient characteristics and comorbidities that are associated with higher rate of ISR include; metal allergy, local hypersensitivity reactions with immunologic and inflammatory response to the drug or the polymer, age, female gender, diabetes mellitus, chronic kidney disease (including hemodialysis), and multivessel coronary artery disease<sup>[3,22,23]</sup>.

### Lesion characteristics

Lesion characteristics associated with ISR include; lesion length, smaller reference artery diameter, ostial lesion, initial plaque burden and residual plaque after implantation. In contrast with BMS, DES tends to have a more focal pattern of ISR, except in diabetics, where the ISR tends to be more confined to the stent edges<sup>[24,25]</sup>. Focal ISR (Mehran pattern I) has been associated with a lower rate of ISR recurrence than nonfocal (Mehran pattern > I) ISR<sup>[25]</sup>.

### Procedural characteristics

Operator and technique dependent characteristics include stent undersizing, incomplete lesion coverage, stent under expansion, and malapposition. Mechanical properties of stents that may lead to recoil because of loss of radial force, stent fractures, and altering increase in shear stress are all associated with higher rates of ISR. For every 10 mm of excess stent length beyond lesion has been independently associated with increased post-procedural percent diameter stenosis by 4% and increased TLR at 9 mo (OR = 1.12, 95%CI: 1.02-1.24)<sup>[26-29]</sup>. Stent fracture, on the other hand, can trigger focal ISR or thrombosis<sup>[30-32]</sup> which can result in a reduction in drug delivery at the breakage point of the stent. Stent fracture occurs more frequently in the right coronary artery, overlapping stents, longer stents, SESs (because of the ridged closed cell structure), and excessively tortuous angulated vessels<sup>[33]</sup>. Malapposition, also known as incomplete stent apposition (ISA), is defined as the absence of contact between stent struts and the vessel wall not overlying a side branch. Malapposition seems to be related to procedural technique due to under-sizing the stent, use of low deployment pressures, and severely calcified lesions, which do not allow for homogenous stent expansion<sup>[34]</sup>. Oversized stents can also lead to extensive trauma to the vessel wall and increased proliferative reaction<sup>[35]</sup>. Geographic miss occurs when the stent does not fully cover the injured or diseased segment of the artery (axial miss) or the ratio of balloon to artery size is less than 0.9 or greater than 1.3 (longitudinal miss). Geographic miss is associated with increased risk of TLR and MI at 1 year<sup>[36]</sup>. DESs decrease neointimal growth. As a result, geographic miss or strut fracture may be larger factors of ISR in DESs compared with BMSs<sup>[12]</sup>.

## PATHOGENESIS

The main mechanism of ISR following stent implantation is neointimal tissue proliferation because of arterial wall damage<sup>[21,22]</sup>. Neointimal tissue proliferation could be focal or distributed uniformly along the

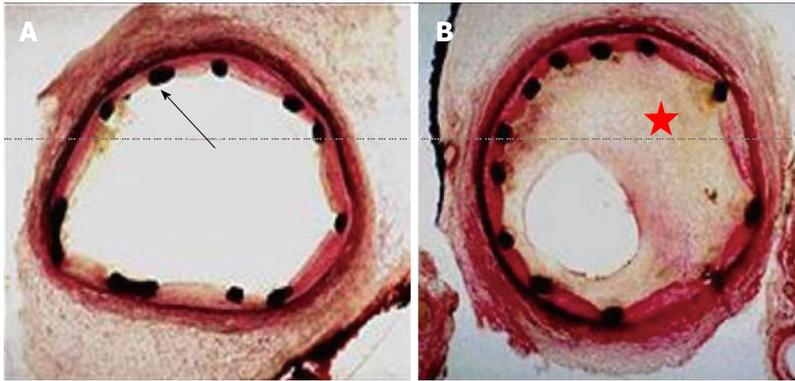

Figure 1 The figure showing cross-section of coronary artery immediately after implantation of a bare metal stent black dots represent the stent struts (red arrow) (A); the figure showing significant in-stent restenosis with neointimal hyperplasia (red star) 6 mo after the implantation of a bare metal stent (B).

length of the stent (Figure 1). ISR, which happens early within days of stent deployment, is due to elastic recoil and relocation of axially transmitted plaque. The causes of late (weeks to months) ISR commonly are reorganization of thrombus, neointima formation and remodeling<sup>[37]</sup>.

Neoatherosclerosis yet is another contributing factor to ISR. The stimulation of neointima formation happens due to injury to the vessel during the PCI and stent deployment. A cascade of events are triggered by the intimal and medial damage, leading to proliferation and migration of vascular smooth muscle cells, extracellular matrix formation which ultimately activates the coagulation-fibrinolysis system<sup>[38]</sup>. The local inflammation can lead to the development of neoatherosclerosis characterized by accumulation of lipid-laden foamy macrophages within the neointima with or without a necrotic core formation and calcification, which can occur years after stent placement<sup>[39]</sup>. Neoatherosclerosis is associated with a higher proportion of in-stent atherosclerotic plaque, which could explain unstable symptoms and myocardial infarction presentation of patients with ISR years after PCI. The incidence of neoatherosclerosis was significantly greater in DES compared with BMS (31% vs 16%,  $P < 0.001$ )<sup>[40]</sup>. Younger age, longer implant durations, SES usage, PES usage and underlying unstable plaques, are independent risk factors for neoatherosclerosis<sup>[14,40]</sup>.

## CLINICAL PRESENTATION

Due to the gradual and slow progression of ISR compared with stent thrombosis, majority of ISR presents as progressive recurrent angina<sup>[40]</sup>. The time for symptoms to develop due to DES-ISR is 3 to 12 mo after stent placement<sup>[41]</sup>. BMS stent on the other hand develop ISR symptoms sooner with reported average period of 6 mo post-PCI<sup>[42]</sup>. BMS-ISR presented as MI in 3.5%-20% of patients<sup>[43]</sup>. DES-ISR is similar to that of BMS with approximately 16%-66% of patients presenting with unstable angina and 1%-20% with MI<sup>[44,45]</sup>.

## ANATOMIC ASSESSMENT

### Routine surveillance

Routine angiographic surveillance is not recommended

because it has been shown to increase the rates of oculostenotic revascularization.

### Intravascular ultrasonography

IVUS is considered a fundamental intracoronary imaging modality to assess ISR. The stent and procedures characteristics can be readily assessed as contributing mechanism of ISR using IVUS<sup>[35]</sup>. IVUS delineate external elastic lamina behind the stent struts very well, which provides valuable insights on vessel sizing for optimization of stent expansion (Figure 2F and G). IVUS does help detect the presence of neointimal hyperplasia obstructing the stent, stent underexpansion, stent fracture, or edge restenosis. In addition, it can provide insights into optimal vessel sizing for choosing the appropriate stent size (Figure 2K and L). However, IVUS has limited axial resolution (150  $\mu\text{m}$ ), which makes neointimal interface hard to define<sup>[12]</sup>.

### Optical coherence tomography

Optical coherence tomography (OCT) provides better axial resolution (15  $\mu\text{m}$ ), allowing better resolution of the vessel lumen, neointimal tissue, and stent struts distribution. The morphology of ISR can be identified using OCT which could show macrophage infiltration, necrotic core, in-stent calcification and neoatherosclerotic plaque rupture<sup>[46,47]</sup>. The weakness of the OCT resides in the poor tissue penetration, which cause poor visualization of the residual plaque that is beyond the stent<sup>[12]</sup>.

## HEMODYNAMIC ASSESSMENT

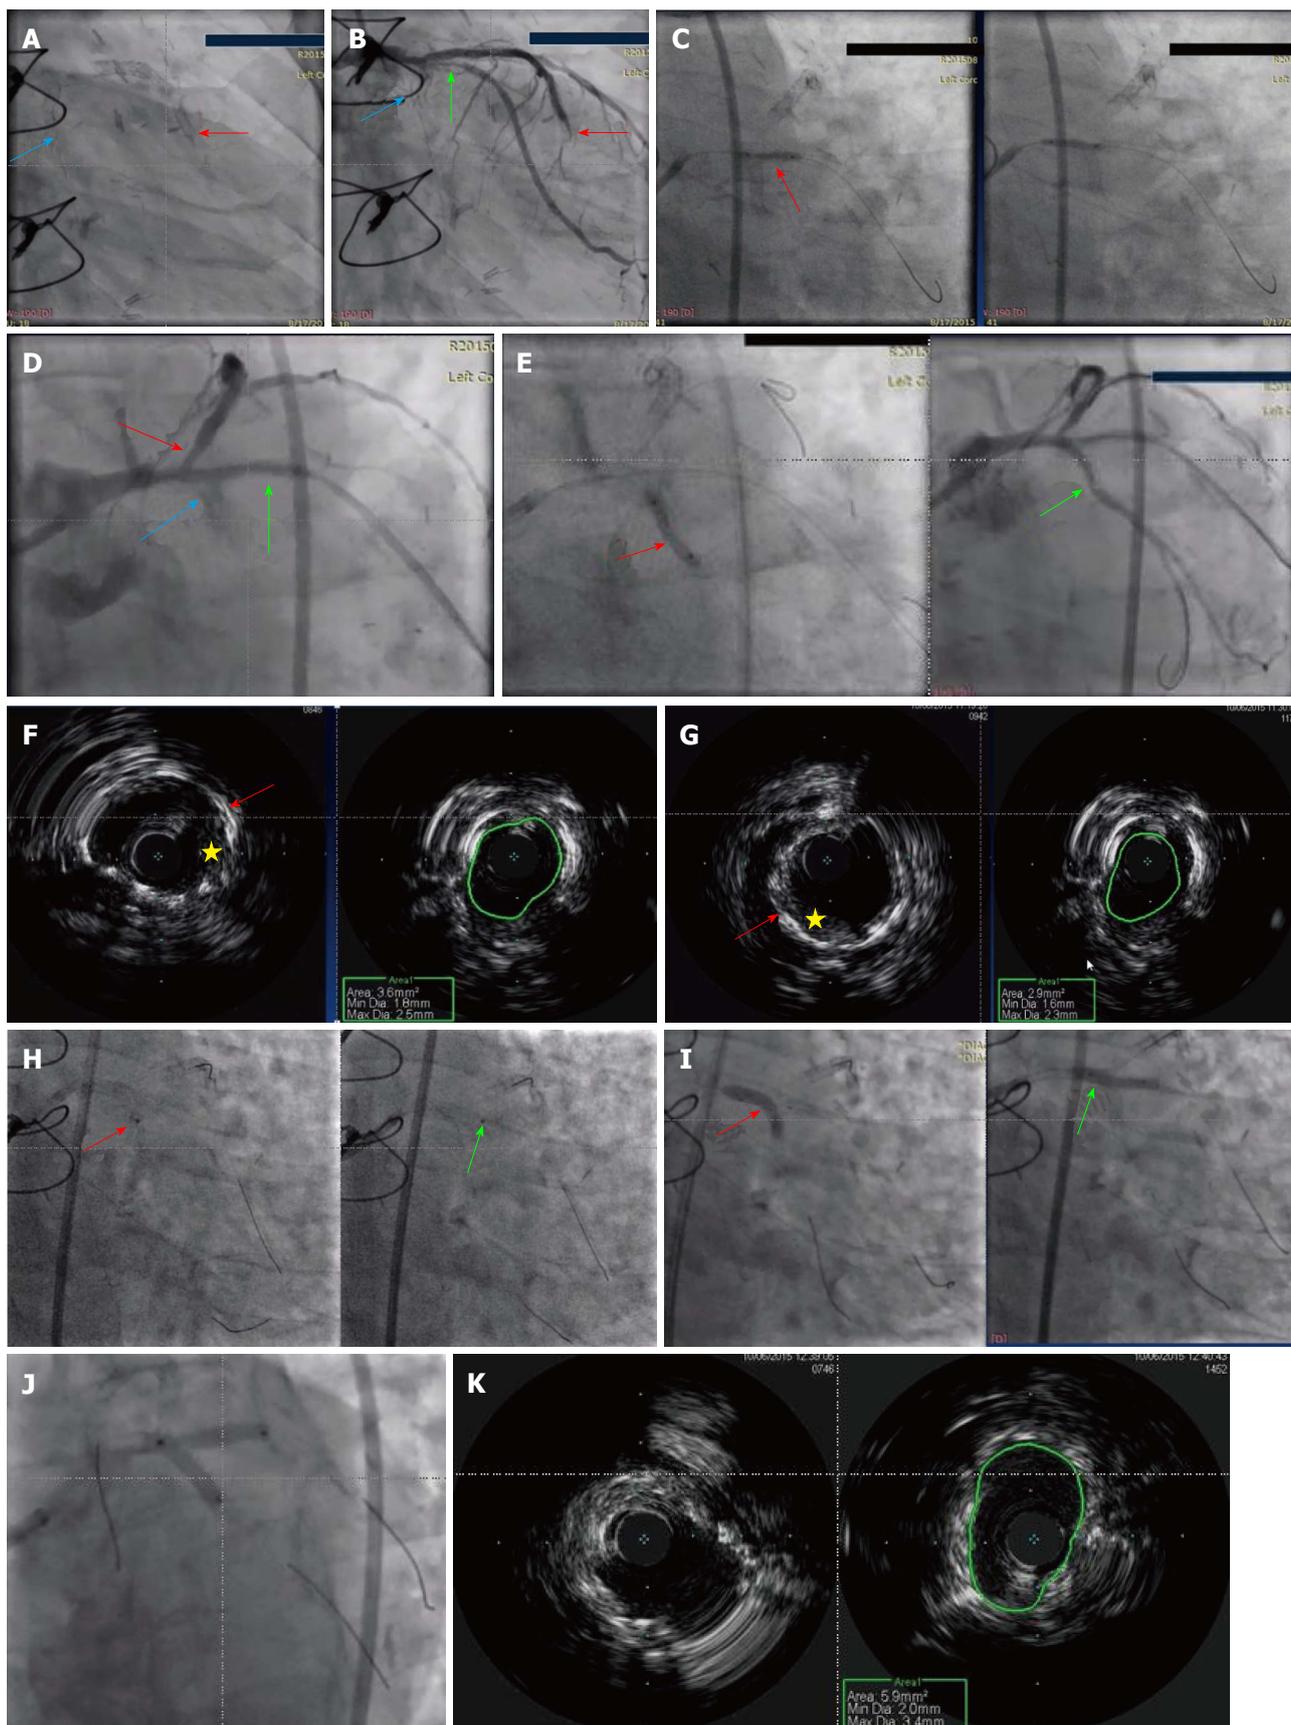

### Fractional flow reserve

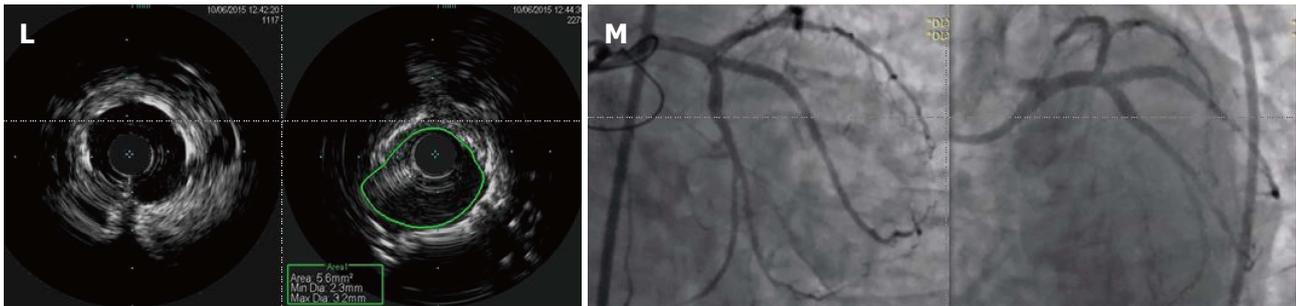

FFR has been validated for clinical decision making in patients with ISR. The clinical outcome of patients with ISR with deferred interventions based on a FFR > 0.75 is excellent<sup>[48]</sup>. This diagnostic strategy is useful in controversial cases with angiographically moderate or inconclusive ISR.

## TREATMENT

### Balloon angioplasty

Balloon angioplasty (BA) is one of the earliest interventions that were used to treat ISR by displacing in-

**Figure 2** Sixty-seven-year-old man presented with increasing chest pain at rest. He has past medical history significant for coronary artery disease with PCI and coronary artery bypass grafting. He had PCI with (3.0 mm × 12 mm) DES to LCx, (2.5 mm × 16 mm) DES to RI and (2.5 mm × 16 mm) DES to obtuse marginal a year prior to his presentation. The left internal mammary artery to LAD is patent, however, he is known to have occluded SVG to RI and SVG to first diagonal (D1). Given his increasing chest pain, coronary angiogram was done. A: Coronary stents before contrast injection in LAD (red arrow), LCx (blue arrow); B: Coronary angiogram of the same patient showing severe proximal LCx ISR (blue arrow) with no flow, severe proximal RI ISR (green arrow) with slow flow, and mid LAD severe ISR (red arrow); C: Dilation of the RI coronary artery with 2.5 mm × 22 mm NC balloon with 22 atm inflation pressures was done; D: Coronary angiogram showing the proximal RI ISR (green arrow) post balloon dilation. Red arrow shows severe proximal LAD stenosis with poor flow. LCx has completely occluded ISR (blue arrow); E: The left circumflex ISR lesion (red arrow) was wired and with balloon dilation the flow was restored in the LCx (green arrow); F: IVUS imaging of the underexpanded stent in the proximal LCx lesion. Left panel shows stent struts (red arrow) with evidence of neointimal hyperplasia (yellow star). The right panel shows small stent CSA of only 3.6 mm<sup>2</sup> which is below the target 5 mm<sup>2</sup> in Asians and 6 mm<sup>2</sup> in non-Asians; G: IVUS imaging of the underexpanded stent in the proximal ramus coronary artery. Left panel shows severely under-expanded stent (red arrow) with evidence of neointimal hyperplasia (yellow star). The right panel shows small stent CSA of only 2.9 mm<sup>2</sup>; H: Excimer Laser Coronary Angioplasty treatment of LCx (left panel - red arrow) and ramus artery (right panel - green arrow) using 0.9 mm coronary laser and the heparinized flush technique. Laser catheter was advanced slowly at 0.2-0.5 m/s during laser emission with careful monitoring of heart rate and blood pressure. Vessel injury such as perforation, dissections and acute closure are the main side effects; I: Post laser balloon dilation with (3.5 mm × 20 mm) NC balloon of both LCx (red arrow) and ramus (green arrow) arteries; J: Sequential kissing stenting technique in the proximal LCx and ramus arteries with DES 3.5 mm × 18 mm in Ramus and 3.5 mm × 15 mm in LCx; K: IVUS imaging of the stent in the proximal LCx coronary artery that shows good expansion of the stent with great increase in CSA to 5.9 mm<sup>2</sup>; L: IVUS imaging of the stent in the proximal ramus coronary artery that shows good expansion of the stent with great increase in CSA to 5.6 mm<sup>2</sup>; M: TIMI III flow was achieved in the LCx and Ramus coronary arteries without any compromise of LAD. PCI: Percutaneous coronary intervention; DES: Drug-eluting stents; LCx: Left circumflex; RI: Ramus intermedius; LAD: Left anterior descending artery; SVG: Saphenous vein graft; ISR: In-stent restenosis; NC: Non-compliant; IVUS: Intravascular ultrasound; CSA: Cross-sectional area.

stent tissue from the lumen in axial and longitudinal direction to the outer portion of the vessel wall as well as further expanding the stent<sup>[49]</sup> (Figure 2). This intervention could be useful in focal ISR. The outcome of BA for focal ISR. However, during balloon inflation, slippage or watermelon seeding can occur, leading to edge-related complications. Cutting or scoring balloons can help minimize this, but also have limitations in delivery through stented regions or distal areas<sup>[50]</sup>. Lateral blades or atherotomes anchor the balloon in the lesion and minimize slippage<sup>[51]</sup>. Progressive balloon dilations and small/short balloons can also prevent side effects from balloon slippage<sup>[52]</sup>. One of the limitations of BA is that subacute tissue re-intrusion back to the lumen tends to occur within minutes after the last balloon inflation. This explains the early lumen loss phenomenon detected in BA studies in this setting, a finding also associated with subsequent recurrent restenosis.

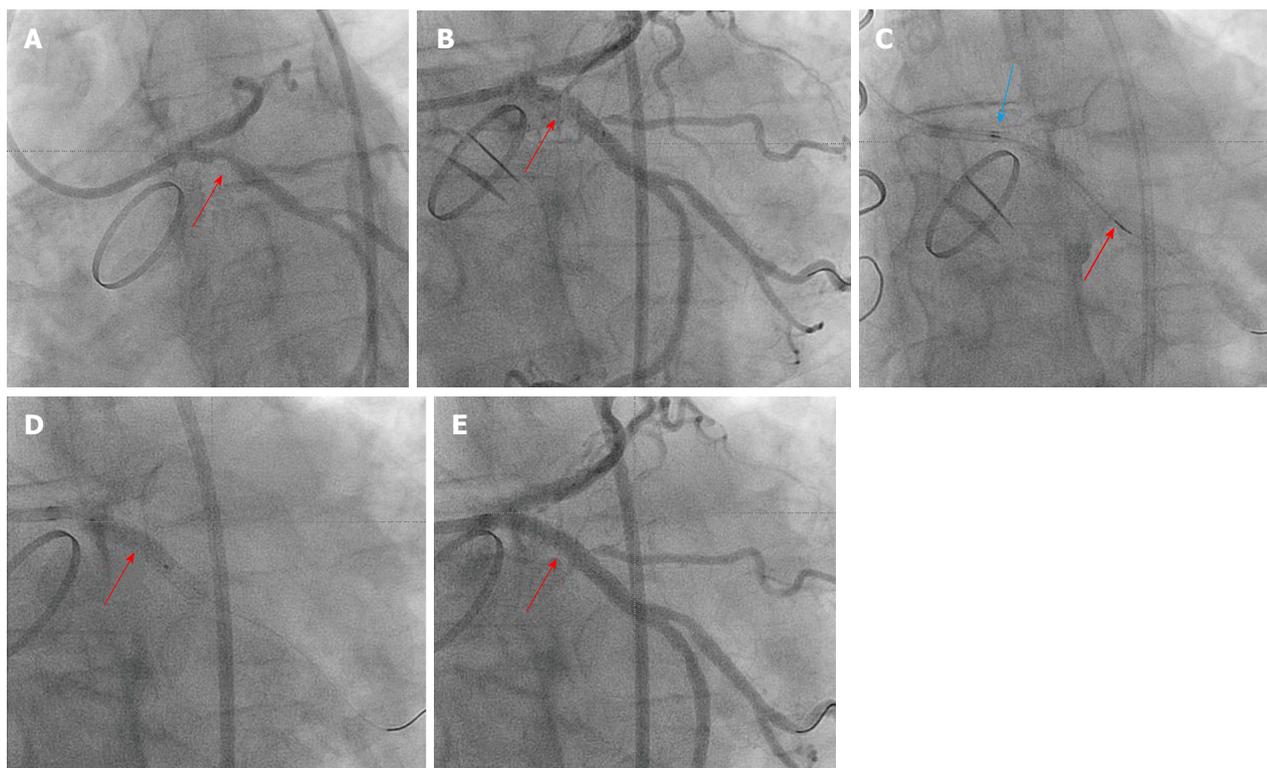

### Vascular brachytherapy

Brachytherapy inhibits neointimal formation within the stent, but not the stent edges, by delivering radiation to the areas of ISR. Brachytherapy effectively suppressed the proliferative response and significantly reduced clinical and angiographic restenosis rates (Figure 3C). Both beta and gamma radiation sources could achieve major reductions in the angiographic restenosis rates<sup>[53]</sup>. Gamma emitters had profound tissue penetration, whereas beta emitters had less tissue penetration

(Figure 3E). Randomized clinical trials in patients with ISR demonstrated the superiority of brachytherapy compared with conventional BA or atheroablative techniques<sup>[53-55]</sup>. Adding an extra layer of metal to treat DES or BMS-ISR is not ideal and will continue to place patients at future risk for ISR. Therefore, DEB and vascular brachytherapy are better options compared with DES. Vascular brachytherapy is available in few centers in the United States and is used primarily for recurrence of DES-ISR, but logistic issues and lack of radiation oncology support impede its uses. Therefore, restenting with second-generation DES became the default therapy for DES-ISR.

### Excimer laser angioplasty

Excimer laser angioplasty (ELA) produces monochromatic light energy, which generates heat and shock waves that disrupt plaque (Figure 2H). Mehran *et al.*<sup>[56]</sup> compared results of ELA vs rotational atherectomy (RA), both followed by percutaneous transluminal coronary angioplasty (PTCA). 119 patients with 158 ISR lesions were treated with ELA plus PTCA and 130 patients with 161 ISR lesions were treated with RA plus PTCA. Volumetric IVUS analysis showed a greater reduction in intimal hyperplasia volume after RA than after ELA (43 mm<sup>3</sup> vs 19 mm<sup>3</sup>,  $P < 0.001$ ). However, the 1-year TLR rates were similar: 26% with ELA plus PTCA vs 28% with RA plus PTCA ( $P =$  nonsignificant). ELA is not currently a well-accepted treatment for ISR, but the ultimate role of this therapy

**Figure 3** Fifty-five-years-old caucasian male with mantle cell radiation for Hodgkin's lymphoma complicated with radiation heart valve disease with severe aortic valve stenosis status post mehanical aortic valve replacement surgery. Few years later he presented with chest pain and had PCI to the proximal LAD and LCx with DES. However, both few months later he developed ISR and underwent another PCI with DES to the proximal LAD and LCx. Patient was referred for vascular brachytherapy for the treatment of ISR of the LCx due to increased chest pain at rest and recurrent ISR of proximal LCx. A: Coronary angiogram showing 90% focal proximal LCx ISR (red arrow); B: Balloon angioplasty of the proximal LCx lesion (red arrow) to prepare the lesion before brachytherapy delivery; C: Coronary angiogram showing the Novoste Beta-Cath™ System that was used to deliver a source train that contains 12 individual radioactive seeds blue arrow to red arrow). Once properly positioned, 23 Gy from the center of the source center was prescribed. The patient was monitored during the dwell time which required 4 min and 49 s; D: Another balloon angioplasty was done after the radioactive seeds are pulled from LCx; E: Final TIMI-III flow in the LCx. PCI: Percutaneous coronary intervention; LAD: Left anterior descending artery; LCx: Left circumflex; DES: Drug-eluting stents; ISR: In-stent restenosis.

is still unclear.

### **Drug-eluting balloon angioplasty**

It was proposed that repeat stenting for ISR raises concerns for creating multiple stent layers. Therefore, the use of DEB angioplasty should minimize the metal layer and eventually decrease future ISR. For that purpose, multiple randomized studies have been done to evaluate the efficacy and durability of DEB compared with DES in treating BMS or DES-ISR. Few studies have shown that DEB is non-inferior to DES for BMS and DES-ISR<sup>[52-61]</sup>. However, none of these studies have been powered for clinical endpoints. DEB is currently not available for use in the United States. In addition, their use has been associated with issues that may limit their use mostly related to the use of paclitaxel and potential of particulates showering to the distal vessel bed, as well as the high profile of the device. Comparison of DEB with DES for treatment of ISR will be discussed in the following section.

### **Drug-eluting stents**

Balloon angioplasty alone carries a high risk of recurrent stenosis, especially in diffuse and/or severe ISR<sup>[44,62,63]</sup>.

The randomized trials Paclitaxel-eluting Stents vs Brachytherapy for In-stent Restenosis (TAXUS V ISR) and Sirolimus-eluting Stents vs Vascular brachytherapy (SISR) trial showed better outcomes for DES compared with brachytherapy<sup>[64,65]</sup>. Two major randomized trials compared DES with DEB for patients with ISR. The ISAR-DESIRE 3 trial randomized 402 patients with ISR in DES to paclitaxel-eluting balloon (PEB) vs first generation DES (PES) vs balloon angioplasty<sup>[52]</sup>. At a median follow-up of 3 years, the risk of TLR was similar with PEB vs PES (HR = 1.46, 95%CI: 0.91-2.33,  $P = 0.11$ ) and lower with PEB vs balloon angioplasty (HR = 0.51, 95%CI: 0.34-0.74,  $P < 0.001$ ). The risk of death/MI was lower, but not statistically significant, with PEB vs PES (HR = 0.55, 95%CI: 0.28-1.07,  $P = 0.08$ ). This finding was driven by a lower risk of death (HR = 0.38, 95%CI: 0.17-0.87,  $P = 0.02$ ). The risk of death/MI was similar with PEB vs balloon angioplasty (HR = 0.96, 95%CI: 0.46-2.0,  $P = 0.91$ ). Using the second generation DES, Restenosis Intra-Stent of Drug-Eluting Stents: Drug-Eluting Balloon vs Everolimus-Eluting Stent (RIBS IV) trial, evaluated the comparative efficacy of DEB and EES in patients presenting with DES-ISR<sup>[66,67]</sup>. A total of 309 patients with DES-ISR

were randomly allocated to DEB, or second generation DES (EES) patients in the EES arm had a significantly larger minimal lumen diameter ( $2.03 \pm 0.7$  mm vs  $1.80 \pm 0.6$  mm,  $P < 0.01$ ) net lumen gain ( $1.28 \pm 0.7$  mm vs  $1.01 \pm 0.7$  mm,  $P < 0.01$ ), and lower percent diameter stenosis ( $23\% \pm 22\%$  vs  $30\% \pm 22\%$ ,  $P < 0.01$ ) and binary restenosis rate ( $11\%$  vs  $19\%$ ,  $P = 0.06$ ), compared with patients in the DEB arm. At the 1-year clinical follow-up (100% of patients), the main clinical outcome measure (composite of cardiac death, myocardial infarction, and target vessel revascularization) was significantly reduced in the EES arm ( $10\%$  vs  $18\%$ ,  $P = 0.04$ , HR = 0.58, 95%CI: 0.35-0.98), mainly driven by a lower need for target vessel revascularization ( $8\%$  vs  $16\%$ ,  $P = 0.035$ ).

A meta-analysis looked into treatment of ISR comparing DEB, DES, and BA reported that treatment with DEB had a trend toward better outcomes than with DES<sup>[68-72]</sup>. The risk of TLR was lower in patients treated with DEB (OR = 0.22, 95%CI: 0.10-0.42) or DES (OR = 0.24, 95%CI: 0.11-0.47) than in those treated with BA. In a comparison of DEB and DES, the risk of TLR (OR = 0.92, 95%CI: 0.43-1.90) was similar. The risk of major adverse cardiac events, which was mainly driven by TLR, was also significantly lower in the DEB and DES groups (OR = 0.28, 95%CI: 0.14-0.53) than in the BA group, but it was similar between the DEB and DES groups (OR = 0.84, 95%CI: 0.45-1.50). For TLR, the probability of being ranked as the best treatment was 59.9% (DEB), 40.1% (DES), and 0.1% (BA).

There is no clear evidence on which type of DES should be used to treat ISR of a DES. Some experts argue that using a different type of DES helps to overcome drug resistance, but no strong data support this practice. A recently published network meta-analysis addressed the question of which strategy is preferred for the treatment of ISR, with the primary outcome defined as the percent diameter stenosis at angiographic follow-up<sup>[73]</sup>. This analysis suggested that PCI with second-generation DES (EES) was the most effective treatment, whereas percutaneous coronary intervention with DEB was ranked as the second most effective treatment but without significant differences from first-generation DES. Two additional similar design meta-analyses have reported similar findings suggesting second generation DES as treatment of choice for BMS and DES-ISR<sup>[74,75]</sup>. As a result, the 2009 update of the American College of Cardiology/American Heart Association/Society for Cardiovascular Angiography and Interventions guideline update for PCI and the 2005 European Society of Cardiology Task Force recommend DES for ISR whether the initial stent was BMS or DES<sup>[76-78]</sup>.

A recently published pooled analysis of the RIBS V and RIBS IV compared the efficacy of EES in patients with BMS-ISR and DES-ISR<sup>[79-82]</sup>. The study detected clinical and morphological differences of ISR in BMS vs DES, including for the later more focal ISR pattern and delayed onset of presentation. Nevertheless, the

outcome of the patients with DES restenosis was less favorable with regard to the angiographic indices, including lumen diameter post procedure and at follow-up. DES-ISR group treated with EES had both increased mortality and need for target vessel revascularization as compared with BMS-ISR group at one year follow up. The authors conclude that EES provides favorable outcomes in patients with ISR and that the results of EES are less satisfactory in patients with DES-ISR than in those with BMS-ISR.

## CONCLUSION

In-stent restenosis remains a prevailing clinical problem. The substrate of ISR includes a pathological spectrum ranging from smooth muscle cell proliferation to neoatherosclerosis. Optimal stent deployment, utilization of imaging-guided implantation by IVUS or OCT, adequate coverage of the lesion, verifying stent expansion and apposition to the vessel wall and minimal use of BMS are considered the main strategies to decrease ISR. Based on the currently available literature, the use of BMS should be minimal in clinical practice and replaced with second generation DES. For patients presenting with first ISR, vascular brachytherapy should be considered in patients with focal ISR, or high bleeding risk or requiring DAPT interruption. 2<sup>nd</sup> generation DES should be a second line therapy to avoid adding an extra layer of metal to treat DES. For patients presenting with recurrent ISR, second generation DES have better long-term outcomes specially if combined with DEB. DEB should be used as first line therapy for bifurcation restenosis to prevent excess metal at the carina.

### Abstract

Celiac disease (CD) is an autoimmune response to

ingestion of gluten protein, which is found in wheat, rye, and barley grains, and results in both small intestinal manifestations, including villous atrophy, as well as systemic manifestations. The main treatment for the disease is a gluten-free diet (GFD), which typically results in the restoration of the small intestinal villi, and restoration of other affected organ systems, to their normal functioning. In an increasing number of recently published studies, there has been great interest in the occurrence of alterations in the cardiovascular system in untreated CD. Herein, published studies in which CD and cardiovascular terms appear in the title of the study were reviewed. The publications were categorized into one of several types: (1) articles (including cohort and case-control studies); (2) reviews and meta-analyses; (3) case studies (one to three patient reports); (4) letters; (5) editorials; and (6) abstracts (used when no full-length work had been published). The studies were subdivided as either heart or vascular studies, and were further characterized by the particular condition that was evident in conjunction with CD. Publication information was determined using the Google Scholar search tool. For each publication, its type and year of publication were tabulated. Salient information from each article was then compiled. It was determined that there has been a sharp increase in the number of CD - cardiovascular studies since 2000. Most of the publications are either of the type "article" or "case study". The largest number of documents published concerned CD in conjunction with cardiomyopathy (33 studies), and there have also been substantial numbers of studies published on CD and thrombosis (27), cardiovascular risk (17), atherosclerosis (13), stroke (12), arterial function (11), and ischemic heart disease (11). Based on the published research, it can be concluded that many types of cardiovascular issues can occur in untreated CD patients, but that most tend to resolve on a GFD, often in conjunction with the healing of small intestinal villous atrophy. However, in some cases the alterations are irreversible, underscoring the need for CD screening and treatment when cardiovascular issues arise of unknown etiology.

**Key words:** Cardiovascular; Celiac disease; Gluten;

Heart; Vascular

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Celiac disease (CD) is a public health concern suffered by about 1% of the population worldwide. It often goes undetected even in developed countries, owing to the varied and occult presentation which can make diagnosis difficult. Untreated, systemic manifestations including cardiovascular ailments can occur. In this review, information concerning the cardiovascular involvement in CD patients is described and discussed. Treatment of CD patients with a gluten free diet can reverse some, but not all of the cardiovascular involvement. Thus the need for prompt diagnosis and treatment.

Ciaccio EJ, Lewis SK, Biviano AB, Iyer V, Garan H, Green PH. Cardiovascular involvement in celiac disease. *World J Cardiol* 2017; 9(8): 652-666 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i8/652.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i8.652>

## INTRODUCTION

Celiac disease (CD) is characterized by an immunologic response to gluten, which often results in diffuse inflammatory damage to the small intestinal mucosa, and malabsorption of nutrients<sup>[1]</sup>. CD is of special interest among chronic diseases due to several factors: (1) it is associated with specific comorbidities; (2) it involves a compromised absorption of nutrients; and (3) a gluten-free diet (GFD) is currently the main long-term treatment<sup>[2]</sup>. Studies have shown that certain cardiovascular maladies, including cardiomyopathy, myocarditis, arrhythmias, and premature atherosclerosis, are more prevalent in individuals with CD as compared to individuals without the disease<sup>[3,4]</sup>. In this article, published works concerning the effects of CD on the cardiovascular system, and the risk of cardiovascular disease, are reviewed. The method of some previous analyses is followed to quantitatively characterize the published articles<sup>[5-7]</sup>, and to then compile the most salient information for review.

## RESEARCH

The Google Scholar search tool was used to find associations between CD and the heart and vascular systems. Keywords pertaining to the heart and vascular system, tabulated in Table 1, were used for search in conjunction with "celiac disease", "coeliac disease", or "gluten". The searches were limited to the co-detection of these terms in the publication title, which is suggestive of the importance of the keywords. The cardiovascular keywords used for

search were derived from encyclopedic descriptions of the heart, vascular, and cardiovascular systems. Under these headings, all relevant terms were extracted as keywords. They were categorized as heart terms and vascular terms. The format used for search in Google Scholar was, for example: (1) allintitle: "celiac disease" "myocardial"; (2) allintitle: "coeliac disease" "myocardial"; and (3) allintitle: "gluten" "myocardial", where the results for the three forms of expression pertaining to CD were then combined. Heart and vascular keywords, tabulated in Table 1, were then combined to form summary topics for analysis. The number of CD/cardiovascular publications per year was then graphed for all of the summary topics.

The type of published document was also recorded for each keyword entry. Each citation used was categorized by type of published documentation as shown in Table 2. There are six possible publication types according to the list. All published documents were categorized as one of the types noted in Table 2. Graphical displays were utilized to separately show the number of CD/cardiovascular documents of each type noted in Table 2 that were published per year. Then for each of the summary topics, the total number of publications of each type in Table 2 were compiled. Also for each of the summary topics, the total number of studies and the mean publication year of the studies for the journals the studies were published in were tabulated. The essential points in each study were then condensed and described in review form, in separate sections, for each of the summary topics.

## PUBLICATION SUMMARY STATISTICS

In Figure 1 is presented a graph of the number of publications per year in which CD and cardiovascular terms appeared. The earliest studies in which CD was investigated for cardiovascular function were published in 1970. However until the year 1998, only a handful of such studies were published, after which there began a substantial increase in the publishing of CD/cardiovascular studies. Although there were fluctuations in the number of studies in the 2000s and 2010s, the overall trend was a sharp upward swing in published studies. The data for 2017 only includes the first few weeks of the year.

The number of studies for selected types that was published per year is shown in bar graph form in Figure 2. The results are shown for articles (cohort), case studies, abstracts, and letters, and review and editorial publications. Many of the CD/cardiovascular published studies were either articles or case studies. As for graphs of the total studies published that were shown in Figure 1, the graphs of individual published document types in Figure 2 begin to exhibit substantial increases about the year 2000. There were also a number of abstracts and case reports published in the late 1980s and 1990s, as is notable in the case reports

**Table 1 Cardiovascular terms used for search in the study**

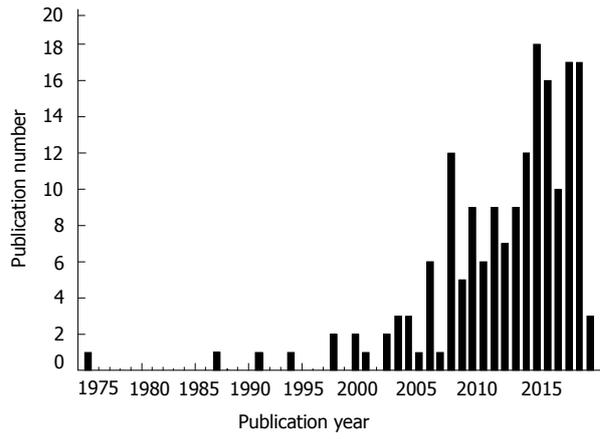

Heart terms	Vascular terms
Afterload, preload	Angiogenesis
Arrhythmia, rhythm	Aorta, aortic
Atrial, atrium	Arterial, arteries, artery
Atrioventricular	Arteriosclerosis, atherosclerosis
Bachmann's	Atherogenesis, atherogenic
Cardiac, cardio	Blood pressure
Cardiologist	Cardiovascular
Cardiomyopathies, cardiomyopathy	Circulatory
Congenital	Circumflex
Contractility	Coronary
Depolarization	Embolism
Effusion	Haemoptysis, hemoptysis
Ejection	Hemorrhage
Electromechanical	Haemodynamics, Hemodynamics
Endocardium, epicardium	Haemosiderosis, hemosiderosis
Fibrillation	Stroke
Foramen ovale	Thrombosis, thromboembolism
Frank-Starling	Vascular
Heart	Vein, veins
Infarction	Vena cava
Ischaemic, ischemic	Venous
Mitral	Venule, venules
Myocardial, myocardium	
Myocarditis	
Myocyte	
Pericardial, pericardium	
Purkinje	
QT	
Septum	
Sinoatrial	
Stenosis	

**Table 2 Categories of published documents**

Type	Description
Articles	Includes research articles, cohort studies and case control studies
Reviews	These included reviews of the literature and meta-analyses
Case studies	Limited to $n = 1-3$ patients in the study
Letters	These could include comments on other articles as well as case reports in letter form
Abstracts	When no full paper had been published, abstracts were included in the references
Editorials	These were typically comments on papers published in the same journal issue

graph in Figure 2. There are only a few review and editorial publications to date, but they are recent.

Based on all of this data, in Table 3 are provided, for each document type, the number of published studies for each topic, with the totals for all articles shown in the last row. Most of the published works are either articles (74) or case studies (62). There are also substantial numbers of letters (23) and abstracts (20). The totals for each term are given to the right in the table. The sum total, 190, is greater than the number of cited articles in this review, 180, because a particular citation could be used in more than one review topics

**Figure 1 Overall published studies on celiac disease/cardiovascular by year.**

section. Furthermore, several citations used in the Introduction were not cardiovascular studies and were not included in Table 3. A number of topics were particularly of interest for CD/cardiovascular publishing. These include papers on CD and cardiomyopathy (33 studies), thrombosis (27), cardiovascular risk (17), atherosclerosis (13), stroke (12), and arterial function and ischemic heart disease (11 each). In Table 4 are shown keyword terms and total number of studies, and median (range) study year of the journal. The median year for all of the studies is 2004 or later, except for the term "haemodynamics" (1998). Thus the possible connection between CD and "haemodynamics" tended to be investigated at earlier dates, as compared with other cardiovascular conditions.

**Compilation of the celiac disease - cardiovascular literature**

In this section, the study results for each keyword of Table 1 are combined into summary topics, to show the general consensus and trends for CD/cardiovascular publications. Thus the most pertinent information from all studies belonging to a particular cardiovascular term was collated by topic. The total number of studies (#) and median and range in years (median year) are shown for published studies concerning each topic. The terms are separated and noted as belonging to vascular or heart categories, followed by cardiovascular risk assessment.

**Vascular - arterial function [# = 11, median year = 2014 (2011-2016)]**

Arterial function is of great concern in CD. Measurements to quantify alterations are made using echocardiography and pulse wave velocity<sup>[8,9]</sup>. In untreated CD, aortic function can deteriorate, and this deterioration is predictive of subclinical atherosclerosis and future cardiovascular events<sup>[8]</sup>. Aortic strain and distensibility tend to be significantly lower, and the aortic stiffness index significantly higher, in untreated CD patients vs controls<sup>[8,10]</sup>. CD patients are at increased risk for

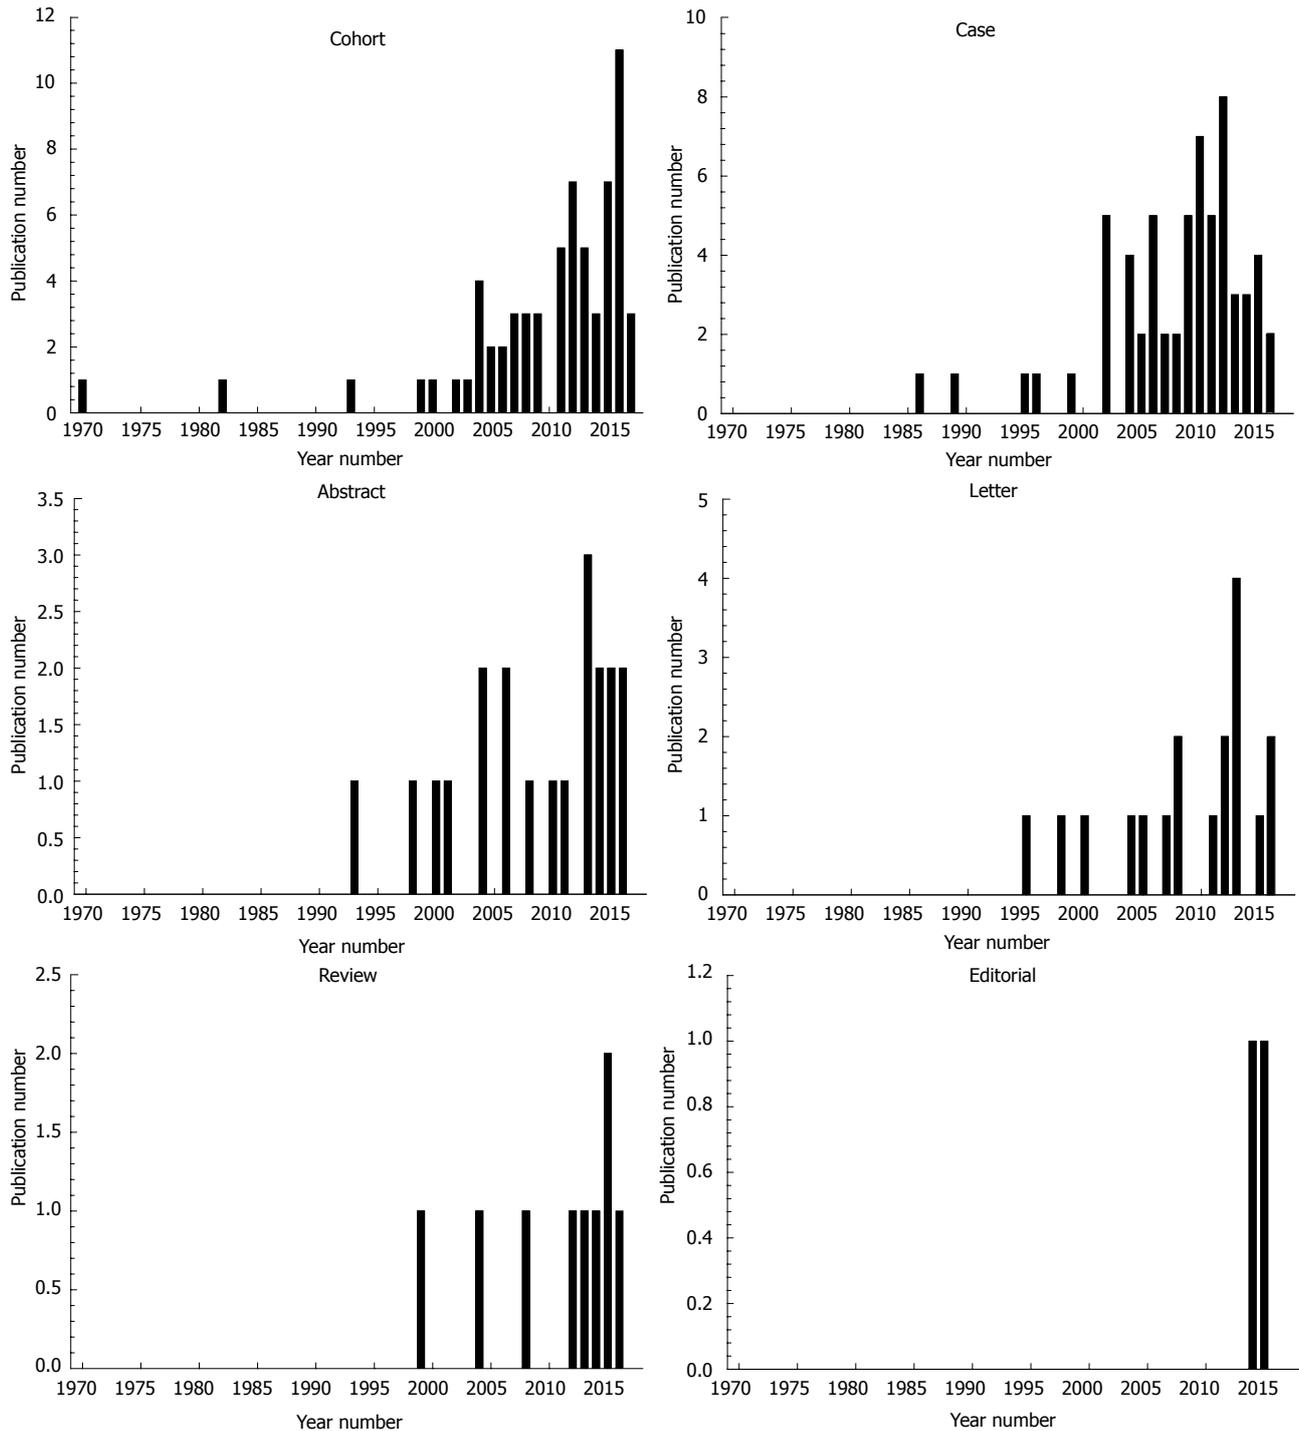

Figure 2 Published studies per year according to document type.

coronary artery disease<sup>[9]</sup>, which may have a genetic association<sup>[11]</sup>. Occlusion of the brachiocephalic trunk and right and left common carotid artery has been noted in CD<sup>[12]</sup>. In adult CD patients lacking cardiovascular risk factors, abnormal homocysteine, erythrocyte sedimentation rate, C-reactive protein, and insulin levels may, along with inflammation, be contributive to arterial stiffening<sup>[9]</sup>. Spontaneous coronary artery dissections have been observed as a cause of acute myocardial infarction in CD patients<sup>[3]</sup>. There is also some support

for an association between CD and cerebrovascular disease<sup>[13]</sup>. Correlation has been shown between restoration of the small intestinal villous atrophy and normalization of vascular parameters in gluten-abstinent CD patients<sup>[14]</sup>. Yet after onset of the GFD, the lack of a significant reduction in aortic elastic properties suggests that some risk of cardiovascular disease may persist<sup>[10]</sup>. Type 1 diabetic patients with early presence of micro- or macrovascular complications should always be screened for CD<sup>[15]</sup>. Type I diabetes mellitus and CD can coexist,

<sup>1</sup>Studies: Total number of studies published on the topic. Studies could be used as references for more than one topic.

and there is evidence that microvascular complications are more severe in patients with both conditions<sup>[16,17]</sup>.

**Vascular - atherosclerosis [# = 13, median year = 2013 (2008-2016)]**

Atherosclerosis has been linked to myocardial infarction and ischemic stroke, with chronic inflammation being a likely pathogenic factor<sup>[18]</sup>. Untreated adults with CD are at increased risk of early atherosclerosis, as suggested by the presence of chronic inflammation, vascular impairment, unfavorable biochemical patterns<sup>[19-21]</sup>,

and relative lack of the classical risk factors. Carotid intima-media thickness values are significantly higher in patients with coexisting diabetes and CD as compared to those patients with diabetes or CD alone<sup>[16,22]</sup>. CD youth have also been associated with increased risk of developing early atherosclerosis<sup>[19]</sup>. They are also more likely to have greater mean low density lipoprotein (LDL) cholesterol and thicker carotid intima media as compared with controls, and their endothelium-dependent dilatation is decreased, all of which negatively affect vascular function<sup>[23,24]</sup>. The GFD enables a reduction in inflammatory parameters, oxidative stress, and insulin resistance, factors that when unchecked can lead to atherosclerosis<sup>[10,25]</sup>. Gluten avoidance followed by restoration of the intestinal villi to normal function is likely to revert cardiovascular dysfunction in less than 1 years' time<sup>[2,20,21,23,24]</sup>. Areas with improved markers on a GFD include the common carotid arteries for intima media thickness, and the humeral artery for endothelium-dependent dilatation<sup>[26]</sup>. However, patients on the GFD often show weight gain and increase in triglyceride blood levels, which suggests a risk to atherogenicity<sup>[27]</sup>, although alterations of other risk factors do not necessarily support this supposition<sup>[28]</sup>. CD patients should always be encouraged to choose a healthy GFD<sup>[27]</sup>.

**Vascular - angiogenesis [# = 7, median year = 2009 (1970-2013)]**

In untreated CD, the overall architecture of the small-bowel mucosal vasculature may be altered, leading to inhibition of angiogenesis<sup>[29]</sup>. On the GFD, the vasculature normalizes as compared to healthy subjects, in parallel to mucosal recovery, and mucosal autoantibody deposits diminish in the small intestine<sup>[29,30]</sup>. Autoantibody production in CD mainly targets against transglutaminase 2 (TG2)<sup>[29]</sup>. These autoantibodies are found in untreated

CD patients' serum<sup>[31]</sup>, but also bound to extracellular TG2 below the epithelial basement membrane and around capillaries in the small intestinal mucosa, as well as in extra-intestinal organs. The autoantibodies can interfere with angiogenesis, including changes in transendothelial migration of lymphocytes<sup>[29,32,33]</sup>, which is probably influenced by common genetic variants in angiogenesis-related genes<sup>[34]</sup>. *In vitro*, CD autoantibodies reduce endothelial branching, increase endothelial permeability to macromolecules and lymphocytes, and enhance lymphocyte adhesion to the endothelium<sup>[29,35]</sup>. Ultrastructural alterations of the small blood vessels embedded in the subepithelial connective tissue of the jejunal mucosa are most severe in CD patients not on the GFD. Similar changes occur when gluten is administered to pediatric CD patients previously on a GFD, and are one of the earliest pathological changes seen in the biopsy material<sup>[35]</sup>.

#### **Vascular - thrombosis [# = 27, median year = 2007 (1995-2016)]**

Thrombotic events are increased in CD<sup>[36]</sup>, can be recurrent<sup>[37]</sup>, and may be present at multiple locations<sup>[38]</sup> which are observable *via* Doppler ultrasonographic examination<sup>[39]</sup>. Thrombophilia may result from hyperhomocysteinemia and deficiencies in protein S, folate, and vitamin B2<sup>[40-42]</sup>. The thrombotic events in CD may also result from dehydration due to diarrhea<sup>[43]</sup>. Cerebral venous sinus thrombosis can occur in CD patients<sup>[40,44-46]</sup>, even in absence of gastrointestinal symptoms<sup>[45]</sup>, but can resolve with symptomatic treatment<sup>[40]</sup>. Venous thrombosis can be a sequela of undetected CD<sup>[42,47-54]</sup>, and may result in thromboembolic events<sup>[48,55]</sup>. CD may be accompanied by portal vein thrombosis<sup>[56,57]</sup>, and mesenteric<sup>[58]</sup> or splenic<sup>[59]</sup> vein thrombosis may present in occult or subclinical celiac disease<sup>[58]</sup>. There is an increased risk of developing venous thromboembolism from chronic inflammation and vitamin deficiency in CD<sup>[44,60,61]</sup>. On a GFD, there is favorable evolution of young CD patients with thrombosis<sup>[62]</sup>. CD should be considered in young patients with thrombosis, especially if the event occurs in an unusual location<sup>[62]</sup>.

#### **Vascular - stroke [# = 12, median year = 2008 (2001-2017)]**

Patients with CD have been found to be at an increased risk for stroke, which can persist after onset of the GFD<sup>[63,64]</sup>. Stroke events can be recurrent<sup>[65]</sup>. Cerebral infarction and transient hemiplegia may also present in untreated asymptomatic CD patients<sup>[66]</sup>. CD should be considered as a possible etiology for stroke cases of unknown cause, particularly in youth, whether gastrointestinal manifestations are evident or not<sup>[67]</sup>. The pathogenesis of stroke in CD youth may involve vitamin B12 deficiency<sup>[68]</sup> and possibly hyperhomocysteinemia, which may be secondary to folic acid deficiency<sup>[69]</sup>, cerebral arterial vasculopathy, and antiphospholipid

syndrome, a secondary autoimmune disorder<sup>[70-72]</sup>. Children with recurrent acute ischemic stroke should be screened for CD<sup>[73]</sup>. Because CD is a potentially treatable cause of cerebral vasculopathy and stroke<sup>[74]</sup>, serology-specifically anti TTG antibodies should be included in the evaluation for cryptogenic stroke in childhood, even in the absence of typical gastrointestinal symptoms<sup>[72]</sup>.

#### **Vascular - hemorrhage [# = 10, median year = 2007 (1997-2012)]**

When unresponsive CD is treated with corticosteroids and immunosuppression therapy, it can be complicated by the presence of small intestinal lymphoma, and result in hemorrhage<sup>[75,76]</sup>. During hemorrhage, coagulopathy can occur, which is attributable to vitamin K deficiency associated with malabsorption of multiple fat soluble vitamins in these patients<sup>[75]</sup>. The immune response to CD, triggered by gluten, can lead to deposition of circulating immune complexes on the membrane of alveolar capillaries, resulting in pulmonary hemosiderosis<sup>[77]</sup>. Lane-Hamilton syndrome refers to the co-occurrence of idiopathic pulmonary hemosiderosis and CD<sup>[78]</sup>. Idiopathic pulmonary hemosiderosis is severe and potentially fatal, and is characterized by recurrent episodes of alveolar hemorrhage, hemoptysis, and anemia, and can share a common immune pathway with CD<sup>[79]</sup>. Left untreated, it can lead to poor prognosis, with progression to pulmonary fibrosis and chronic respiratory limitation<sup>[80]</sup>. In patients with diffuse alveolar hemorrhage, even in the absence of gastrointestinal symptoms, screening for CD should be done using anti-transglutaminase antibodies<sup>[79,81]</sup>. If CD is found, the GFD helps control symptoms, enables a reduction of immunosuppressive treatment, and improves clinical course<sup>[79]</sup>. Improvement of the co-occurrence of CD and pulmonary hemosiderosis over a period of months is found when patients are placed on the GFD<sup>[82,83]</sup>. Thus patients with pulmonary hemosiderosis should always be screened for CD<sup>[80,82]</sup>. Patients with hereditary hemorrhagic telangiectasia with unexplained iron malabsorption should also be screened for CD<sup>[84]</sup>.

#### **Vascular - haemodynamics [# = 4, median year = 1998 (1993-2005)]**

Alteration of blood flow is an important issue. The pathophysiological changes in the small bowel mucosa during the active phase of CD can induce haemodynamic changes<sup>[85]</sup> including an abnormal splanchnic circulation<sup>[86]</sup>, and splenic vein obstruction may be present<sup>[47]</sup>. The postprandial mesenteric blood flow can be significantly increased and delayed in time<sup>[86]</sup>. A hyperdynamic mesenteric circulation and higher peak systolic velocity of the superior mesenteric artery is often manifested in untreated CD patients as compared with healthy controls and treated celiac patients<sup>[85,87]</sup>. Treatment with the GFD can improve haemodynamics<sup>[85,87]</sup>.

**Vascular - other [# = 5, median year = 2004 (1993-2013)]**

Several other vascular maladies have been noted to occur in conjunction with CD. The combination of CD, epilepsy, and cerebral calcification is a rare condition known as CEC syndrome<sup>[88]</sup>. Folate malabsorption is a suggested mechanism, because cerebral calcification can be seen in other conditions related to folate deficiency<sup>[88]</sup>. Membranous obstruction of the inferior vena cava can also occur<sup>[89]</sup>. In patients with hyperhomocysteinaemia and sub-clinical CD, endothelial dysfunction is associated with increased systemic vascular resistance that can lead to a reversible form of hypertension<sup>[90]</sup>. CD adults tend to have a lower prevalence of hypertension and hypercholesterolaemia as compared with the general population<sup>[91]</sup>. However in patients with hypertension, CD, and hyperhomocysteinaemia (*via* malabsorption of essential cofactors), CD treatment can improve blood pressure control<sup>[90]</sup>. Covert hemoptysis may be responsible for disproportionately severe anemia in CD patients<sup>[92]</sup>.

**Heart - pericardial effusion [# = 4, median year = 2008 (2000-2014)]**

The heart itself can be greatly affected in CD patients. Echocardiography has been used to show that there is a higher incidence of pericardial effusion in CD<sup>[93]</sup>. In adults, this phenomenon can be asymptomatic<sup>[94]</sup>. The predisposing factors for pericardial effusion include vessel dysfunction in the presence of high antibody titer, selenium deficiency, and viral infection due to reduced immunological competence, in conjunction with a diminished ability to eliminate toxic free radicals<sup>[93,95]</sup>. After onset of the GFD and with iron supplement, pericardial effusion, along with peripheral edema and fatigue, decreases<sup>[94,96]</sup>. Presence of left ventricle dilation, suggesting an initial phase of heart damage, is reversible on the GFD<sup>[96]</sup>. CD children may also have pericardial fluid, and show no difference compared to those lacking effusion with respect to ECG, chest X-ray, blood cell count, serum enzymes, serum protein, and iron levels<sup>[95]</sup>. Pericardial effusion is reversible in children when they are treated with a GFD<sup>[95,96]</sup>. Thus pediatric cardiologists should be alerted to the possibility that mild left ventricular enlargement can be caused by CD<sup>[96]</sup>.

**Heart - Myocarditis [# = 6, median year = 2004 (2002-2012)]**

Autoimmune myocarditis may be a complication of CD<sup>[97]</sup>. Biopsy-proven granulocytic myocarditis of unknown etiology can be found in the setting of silent CD<sup>[98]</sup>. Progressive heart failure may accompany viral myocarditis in untreated CD; patient condition can improve following standard heart failure treatment and GFD<sup>[99]</sup>. A strong fluorescence around heart muscle fibers has been noted in untreated CD patients but not in patients on the diet or in controls<sup>[100]</sup>. This suggests that an autoimmune process toward antigenic components of the myocardium can occur in untreated

CD, and lead to cardiac tissue injury, resulting in myocarditis<sup>[101]</sup>. In these patients, immunosuppression and GFD are often effective therapeutic options<sup>[101]</sup>. It is thus highly important to screen for CD in patients with these conditions to avoid progression and clinical deterioration<sup>[102]</sup>. It has been found that the CD prevalence in children with myocarditis is greater than in children without myocarditis<sup>[102]</sup>, who should therefore also receive CD screening.

**Heart - cardiomyopathy [# = 33, median year = 2010 (1986-2016)]**

Cardiomyopathy associated with CD is a serious and potentially lethal condition which requires a multi-disciplinary approach involving both a gastroenterologist and a cardiologist<sup>[103-106]</sup>. There is a higher prevalence of CD in patients with dilated cardiomyopathy<sup>[107-109]</sup>, idiopathic cardiomyopathy<sup>[110-113]</sup> and ischaemic or valvular cardiomyopathy<sup>[110]</sup>. There is also a higher prevalence of CD in the relatives of patients with sporadic and inherited dilated cardiomyopathy<sup>[114]</sup>. Severely dilated left ventricle, concomitant left ventricular dysfunction, very low ejection fraction, pulmonary hemosiderosis, heart block, and/or heart failure have been reported in cardiomyopathy patients with CD<sup>[112,115-120]</sup>. Severe progressive dilated cardiomyopathy, requiring heart transplantation, can occur<sup>[121]</sup>. Dilated cardiomyopathy in CD may be accompanied by congestive heart failure and is also becoming increasingly recognized in the pediatric population<sup>[122,123]</sup>. These children may also present with acute onset congestive heart failure, as well as severe left ventricular systolic dysfunction<sup>[123]</sup>. Upper limb venous thrombosis and recurrent haemoptysis secondary to pulmonary haemosiderosis may be present<sup>[123]</sup>. Cirrhotic cardiomyopathy without gastrointestinal symptoms has also been found in pediatric patients<sup>[124]</sup>.

Although a serious condition, the precise cause-and-effect relationship between CD and cardiomyopathy when they occur in tandem is currently unknown<sup>[125]</sup>. Dilated cardiomyopathy may evolve due to carnitine deficiency<sup>[126,127]</sup>, which is related to CD, but may also develop after onset of the GFD, particularly in patients lacking carnitine supplementation<sup>[126]</sup>. Idiopathic dilated cardiomyopathy may have an autoimmune mechanism<sup>[110,128]</sup>. The tTG-positive serology in relatives with echocardiographic abnormalities suggests that immune-mediated mechanisms are at work in subsets of these patients and their families<sup>[106]</sup>. In individuals with idiopathic congestive cardiomyopathy and CD, ultrastructural and electrophoretic examination of myocardial samples shows a selective loss of actin, and electron microscopy reveals characteristic alterations of enterocyte microvilli<sup>[129]</sup>. Hence there can be an involvement of the microfilament system in both the myocardial sarcomeres and the enterocytes of these patients<sup>[129]</sup>. Ischemic cardiomyopathy can occur due to an accelerated atherosclerosis when chronic inflammation is present in CD<sup>[130]</sup>.

Compliance with a GFD is mandatory if patients are

to avoid progression of their cardiomyopathy<sup>[105,131]</sup>. The GFD has been shown to have a beneficial effect on cardiac performance in CD patients with dilated cardiomyopathy<sup>[132]</sup>. After start of the GFD, abnormal left ventricular dimensions, and diminished cardiac function, including decreased ejection fraction, can improve markedly and may even be completely reversible<sup>[103,108,118,128,133]</sup>. After two years on a GFD, patients presenting with dilated cardiomyopathy associated with CD show progressive increase in mean serum carnitine levels as compared to values observed prior to the diet<sup>[127]</sup>. Children with CD and dilated cardiomyopathy also have improved cardiac function once adherent to the GFD<sup>[109]</sup>. In CD patients on the GFD, there is no association with later onset of myocarditis, cardiomyopathy or pericarditis<sup>[134]</sup>.

Screening for CD in patients with dilated cardiomyopathy, pulmonary haemosiderosis, and iron deficiency anemia in the absence of known etiology is advisable regardless of the intestinal symptoms<sup>[105,108,116,123,133]</sup>. Serologic tests for IgA-EmA and tissue transglutaminase antibodies should be used to screen for CD<sup>[106]</sup>. Comorbidities including iron-deficiency anemia in patients with dilated cardiomyopathy should arouse suspicion of CD<sup>[117]</sup>. All patients diagnosed with cardiomyopathy and CD should be offered an endomyocardial biopsy for better histological and diagnostic definition<sup>[128]</sup>. It is beneficial to assess CD in children with dilated cardiomyopathy in the absence of known etiologies<sup>[104,135]</sup>.

#### **Heart - infarction [# = 5, median year = 2009 (2008-2015)]**

Acute myocardial infarction with ST-elevation and spontaneous coronary artery dissection can occur in young patients with CD<sup>[3,136]</sup>. However, chronic hypocalcemia in untreated CD patients due to poor absorption of minerals can result in electrocardiographic changes that mimic acute myocardial infarction<sup>[120]</sup>. In CD, there is a higher all-cause mortality one year post-myocardial infarction as compared with the general population<sup>[20]</sup>. Mesenteric infarction has also occurred as a consequence of CD, and clinicians should be aware of this possibility<sup>[137]</sup>.

#### **Heart - electromechanical functioning [# = 7, median year = 2014 (2008-2016)]**

Measurement of electromechanical parameters is beneficial to determine the degree of cardiac involvement in CD<sup>[138]</sup>. Atrial conduction delays are significantly higher in untreated CD as compared with healthy individuals, and may lead to atrial fibrillation<sup>[139]</sup>. Measurement of atrial electromechanical delay parameters might therefore be useful to predict atrial fibrillation risk<sup>[139]</sup>. Statistically significant differences in left ventricular function as assessed by echocardiography imaging are found in CD patients vs controls<sup>[140]</sup>. Patients with CD can have impaired diastolic and systolic function as measured by tissue Doppler echocardiography<sup>[141]</sup>. Mitral valve prolapse<sup>[142]</sup> and subclinical myocardial dysfunction of

both ventricles<sup>[143]</sup> can be present in both the pediatric and adult CD population. In children, significantly lower contractility indices and higher left ventricular dimensions are evident as compared with controls<sup>[144]</sup>. On the GFD, valve regurgitations resolve, and echocardiographic parameters significantly improve<sup>[144]</sup>.

#### **Heart - ischemic heart disease [# = 11, median year = 2014 (2004-2016)]**

There is an increased risk of ischemic heart disease and higher cardiovascular mortality in CD<sup>[145,146]</sup> despite the lack of traditional risk factors<sup>[26,147]</sup> including blood pressure, body mass index, serum cholesterol, lipids, exercise, and smoking<sup>[4,148]</sup>. First-degree relatives of CD patients are also at an increased risk of ischemic heart disease, but the excess risk is slight<sup>[149]</sup>. CD and ischemic heart disease may share a common underlying link, rather than a cause-and-effect relationship<sup>[18,150]</sup>. The underlying association between CD and ischemic heart disease may be chronic inflammation, a major risk factor in the general population; however, potential confounders may also be involved<sup>[18,146,148]</sup>. After onset of the GFD, persistent villous atrophy detected during follow-up biopsy was not associated with increased risk of ischemic heart disease<sup>[151,152]</sup>.

#### **Rhythm disturbances [# = 8, median year = 2014 (1989-2016)]**

Compared to controls, untreated CD patients have increased P-wave dispersion and higher interatrial, intra-left atrial, and intra-right atrial conduction delay<sup>[153]</sup>. Tp-e interval, Tp-e/QT and Tp-e/QTc ratios are also increased in CD<sup>[154]</sup>. There is a higher prevalence of atrial fibrillation among CD patients<sup>[153,155]</sup>. Atrial fibrillation, when it occurs, is associated with an increased risk of ischaemic stroke and heart failure<sup>[156]</sup>. The chronic inflammation that can occur in untreated CD is a recognized risk factor for atrial fibrillation<sup>[155,156]</sup>. CD patients have slower atrial electrical conduction, which may also increase the risk of atrial fibrillation<sup>[153]</sup>. However, persistent villous atrophy on follow-up biopsy was not associated with any increased risk of atrial fibrillation<sup>[151,152]</sup>. It has been reported that CD patients with pulmonary hemosiderosis can develop infranodal heart block, necessitating implantation of a pacemaker<sup>[77,157]</sup>. These patients may lack digestive manifestations but have iron deficiency and vitamin deficiency anemia<sup>[77]</sup>. Rhythm alterations in CD can thus result from other pathogenic mechanisms including electrolyte disturbances caused by malabsorption, which can normalize on the GFD<sup>[77]</sup>. Patients with rhythm disturbances and chronic anemia of unclear origin should therefore be tested for CD<sup>[77]</sup>.

#### **Heart - congenital heart defect [# = 4, median year = 2014 (1982-2016)]**

CD patients are likely to more commonly have atrial septal defect as compared to controls<sup>[158]</sup>. Screening

for CD in children with congenital heart defect is recommended, since serum TTG IgA levels are significantly higher in patients with congenital heart defect vs control children<sup>[159]</sup>. Down syndrome patients with congenital heart defect have higher CD prevalence as compared to patients without congenital heart defect, and CD prevalence in Down syndrome patients is higher than in controls<sup>[160]</sup>. In children with congenital heart disease and CD, growth improves on a GFD<sup>[161]</sup>.

#### **Heart - other [# = 6, median year = 2012 (2004-2016)]**

Chronic hypocalcemia, which may occur in untreated CD due to malabsorption, has been associated with reversible cardiac dysfunction<sup>[120]</sup>. Untreated CD children tend to show an imbalance of cardiac sympathetic and parasympathetic activity due to enhanced sympathetic tone<sup>[162]</sup>. This imbalance is still detected after a six months period of GFD<sup>[162]</sup>. This suggests the presence of a subclinical autonomic nervous system dysfunction<sup>[162]</sup>. There is a higher prevalence of CD in patients with Postural Orthostatic Tachycardia Syndrome (POTS)<sup>[163]</sup>, thus these patients should also be screened for CD<sup>[164]</sup>. Left ventricular hypertrabeculation/noncompaction may be associated with CD<sup>[165]</sup>. Subclinical systolic dysfunction of the left ventricle may be present in CD children<sup>[166]</sup>.

#### **Cardiovascular disease risk factors [# = 17, median year = 2013 (2007-2017)]**

Cardiovascular disease (CVD) as a whole has many etiologies and is the leading cause of death in developed countries<sup>[167,168]</sup>. There is a modestly increased risk of CVD in CD patients<sup>[63]</sup>. Both male and female CD patients may have higher estimated risk for CVD as compared to controls<sup>[169,170]</sup>. However, CVD risk factors conferred by CD have not been well-defined<sup>[171]</sup>. This has led to conflicting evidence as to whether CD patients actually have increased baseline risk<sup>[172]</sup>. CD patients are susceptible to increased platelet activation and increased mean platelet volume and RDW values, factors that contribute to increased risk<sup>[173,174]</sup>. Using the Framingham Heart Study (FRS) 10-year general CVD risk score, lower values were found among CD patients as compared with controls, which may be due to a lesser body mass index and reduced tobacco use among CD patients<sup>[171]</sup>. Risk factors other than those measured by the FRS may be observed as increased risk of CVD in CD patients<sup>[171]</sup>. There can also be a positive association between CD and CVD risk due to ascertainment bias<sup>[175]</sup>. In CD children, risk factors can be frequently observed as compared with healthy subjects<sup>[18]</sup>. Overall, certain CVD risk factors have been found to be higher in CD youth as compared with the general population, although neither blood pressure nor overweight and obesity rates were increased<sup>[176]</sup>. Youth with type 1 diabetes and CD had lower high density lipoprotein (HDL) cholesterol, increasing CVD risk, as compared with non CD patients<sup>[177]</sup>.

The lack of a uniform set of risk factors can influence whether CVD risk is affected by a GFD<sup>[172]</sup>. In actuality, both risk and protective factors for CVD are likely to be present in CD, at baseline and also on a GFD<sup>[172]</sup>. Modifiable risk factors for CVD can include body mass index and cholesterol, which have been shown to increase on the GFD<sup>[168]</sup>. In CD individuals with type 1 diabetes on a GFD, improvement in HDL-cholesterol, and a lower resting heart rate, has been demonstrated as compared with those CD patients without diabetes<sup>[178]</sup>. On a GFD, the lipid profile of CD patients can also improve<sup>[17]</sup>. At one year on a GFD, waist circumference may increase, but without significant rise in total or LDL cholesterol<sup>[173,174]</sup>. The GFD should therefore ideally go beyond gluten exclusion and include body weight control and high quality nutrients<sup>[172]</sup>. A relatively high proportion of CD children on the GFD had one or more CVD risk factors<sup>[179]</sup>. The most common CVD risk factors are high fasting triglycerides, elevated blood pressure, and high LDL cholesterol concentrations<sup>[179]</sup>. Insulin resistance is also found, underscoring the need for CVD screening and dietary counseling targeting the pediatric CD population<sup>[179]</sup>. Screening for CD and monitoring of HDL cholesterol is recommended in youth with type 1 diabetes<sup>[177]</sup>. CVD risk factors also include metabolic disorders caused by malabsorption in pediatric CD patients<sup>[180]</sup>. Hence timely correction of water and electrolyte imbalance, and administration of cardiometabolic therapy, is necessary<sup>[180]</sup>.

## **CONCLUSION**

Published studies pertaining to the connection between cardiovascular conditions and CD began in the late 1960's, consisting of a few studies each year, and was followed by a substantial increase beginning about the year 2000. Many of the published studies are either articles (including cohort and case control studies) or case studies consisting of one to three patients. Often, as might be expected, a number of case studies appeared in the literature prior to the cohort studies. Based on the evidence presented in these papers, it is apparent that cardiovascular involvement in CD is a real phenomenon and that there are many manifestations, owing to the multifaceted, systemic physiological changes that can occur in CD. A number of the cardiovascular issues that can occur in untreated CD patients, will resolve on a GFD, often in conjunction with healing of the small intestinal villi. Cardiomyopathy is the most frequently documented cardiovascular condition observed in conjunction with CD, and seems to mostly or completely resolve with appropriate treatment, including a GFD. However, if CD is left unrecognized until a late stage, damage done to the heart may not be entirely reversible. Similarly, to the present time there has been substantial documentation of a number of other cardiovascular conditions found in conjunction with untreated CD including

thrombosis and thromboembolism, ischemic heart disease, stroke, and arrhythmia. There has also been significant investigation of CD and risk of cardiovascular disease. On this topic, a current problem is that there is no uniform set of cardiovascular risk factors used for analysis. Future studies should settle the question of how to best treat these co-occurring conditions, and to determine if other cardiovascular manifestations of CD are common phenomena.

### Abstract

Research revealed that the pathogenesis of aortic stenosis (AS) not merely comprises of a mechanical wear and tear process yet that active biological processes, similar to

those of coronary artery disease are involved, a promising role for statins in disease-modifying therapy was suggested. However, recently, many prospective studies could not observe decreased progression nor regression of the disease. Here, we review the current knowledge on the pathomechanisms of AS and its similarities and differences with atherosclerosis. Moreover, we discuss whether there is still a place for statins in the treatment of particular AS patient subgroups.

**Key words:** Aortic stenosis; Statins; HMG-CoA enzyme inhibitor; Coronary artery stenosis; Aortic valve surgery

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Aortic stenosis is a age-dependent and growing disease. As there are several similarities with atherosclerotic disease of other regions there are growing research on underlying pathophysiology. The treatment benefit of classic atherosclerosis treatment is evaluated in case of aortic valve stenosis.

### INTRODUCTION

Aortic stenosis (AS) is the most common heart valve disease in Western countries. It affects 12.4% of the population over the age of 75 years<sup>[1]</sup> with a male predominance of 80% in symptomatic AS<sup>[2]</sup>. AS is usually characterized by an asymptomatic latent period of several years or even decades before patients suffer from discomforts. However, once patients with severe AS display symptoms (typically

syncope, angina and/or dyspnoea), the prognosis is poor with a 2-year and 5-year survival rate of 50% and 20%, respectively; hence valve replacement surgery is usually mandated<sup>[3]</sup>. Since the elderly population in Western countries is expected to double by 2050, it is imperative to define early diagnostic and treatment strategies. Even though AS or the fibrous thickening and calcification of the valves is a widespread disease, its underlying molecular mechanisms are still unknown<sup>[4]</sup>. Traditionally, it was accepted that AS is caused by the progression of calcium deposition continued to aortic valvular leaflets. However, research demonstrating the involvement of active cellular processes over the past 15 years<sup>[5]</sup>. Genetic polymorphism seems to influence the degree of aortic valve sclerosis<sup>[6]</sup>, with a focus on chronic inflammatory processes. Moreover, it has become clear that the development of AS shows many similarities with atherosclerosis including infiltration and retention of lipoproteins, lipids, T-lymphocyte and other inflammatory cells, as well as osteoblastic activation<sup>[7-9]</sup>. Accordingly, numerous studies demonstrated a strong association to coronary artery disease (CAD) and many of its risk factors, including hypercholesterolemia<sup>[10,11]</sup>. This opened the field to develop effective disease-modifying strategies, which would halt or even regress the disease, thus avoiding the need of surgical or interventional replacement. At first, statins seem to be the most obvious medical treatment choice since its use is well-established for the primary and secondary prevention of CAD<sup>[12]</sup>. Moreover, statins have been shown to exert pleiotropic effects beyond their cholesterol-lowering effect, such as anti-oxidation, plaques stabilization and reduction of vascular inflammatory processes<sup>[13,14]</sup>. Numerous retrospective observational studies showed a delay in AS progression when statins were administered concomitantly which encouraged the use of statins for treatment of AS<sup>[15-19]</sup>. However, 3 recent large-scale prospective randomized clinical trials investigating the effects of intense lipid-lowering therapy with statins showed no effect on neither progression, nor regression of AS. Meanwhile, new insights are emerging, demonstrating distinct differences in (molecular) pathology between CAD and AS. Here, we review what is known today about the pathogenesis of AS and the potential influence of statin therapy in AS patients, with a distinction between degenerative or calcific AS, congenital AS, AS with coronary heart disease as comorbidity, and, treatment before and after aortic valve surgery.

## PATHOMECHANISMS OF DEGENERATIVE OR CALCIFIC AS AND CAD: SIMILARITIES AND DIFFERENCES

Since it became clear that AS is not merely the result of mechanical stress and ageing, but rather an active biological processes involving inflammatory contributing

to the disease; pharmacological treatment possibilities were completely opposed to valve replacement surgery inevitable at the time when AS has reached a severe symptomatic status. What has been revealed of the current knowledge of the pathogenesis of AS so far, revealed many similarities with CAD. Hence, it was obvious to turn to statins for the treatment of AS since they have proven efficacy for the primary and secondary prevention of CAD. Nevertheless, it is shown that, besides lipid-lowering, statins display pleiotropic effects such as anti-inflammatory and antioxidant effects as well as plaque-stabilization and improvement of endothelium dysfunction<sup>[20]</sup> (Figure 1). The potential use of statins was initially encouraged by positive results from numerous retrospective studies. Yet recently, three prospective randomized studies showed neither regression, nor reduction in progression of AS: SEAS (Simvastatin and Ezetimibe in Aortic Stenosis), SALTIRE (Scottish Aortic Stenosis and Lipid Lowering Trial, Impact on Regression) and ASTRONOMER (Aortic Stenosis Progression Observation: Measuring Effects of Rosuvastatin)<sup>[21-23]</sup>. All three trials demonstrated that extensive lipid-lowering induced by statins failed to correlate with neither improvement of aortic-jet velocity of the valve, nor with regression of valvular calcification. Such disappointing results were surprising because of the many well recognized similarities between CAD and AS in terms of pathogenesis. Moreover, statin use has become an established principle for CAD. Furthermore, similar risk factors have been identified for both diseases such as age, sex (male gender), dyslipidaemia, hypertension, smoking, diabetes and renal dysfunction<sup>[24,25]</sup>. Aortic valve stenosis can be characterized an 'early lesion', which are similar to those of atherosclerotic plaques in vessels<sup>[8]</sup> and both CAD and AS are characterized by infiltration and accumulation of (oxidized) low-density lipoproteins (LDL) and T-lymphocytes, thus filling tissue inflammation and the release of pro-inflammatory cytokines such as tumour necrosis factor (TNF)- $\alpha$  and interleukin (IL)-1 $\alpha$  which in turn induce cell proliferation<sup>[7,9,26]</sup>. Calcification and osteogenesis, mediated by inflammation and processes involving metalloproteinases, have been identified as players in the pathogenesis of AS<sup>[27-29]</sup>. Finally, neo-angiogenesis contributes to AS development<sup>[30,31]</sup> and is responsible for reduced concentrations of the anti-angiogenesis protein chondromodulin-1 in damaged aortic valve tissue<sup>[32]</sup>. The resulting cell apoptosis, extracellular matrix formation and consequent thickening and calcification of the cusps, decreases aortic valve mobility and orifice areas, ultimately leading to an increased pressure gradient<sup>[33]</sup>. Nevertheless, there are some fundamental differences in the underlying molecular mechanisms with an early inflammation affecting fibroblasts in AS as opposed to late onset of inflammation in smooth muscle cells in CAD. Yet, plaque instability is not the leading clinical problem with AS; however clearly the main cause of symptoms with CAD<sup>[34]</sup>. It is important to note that

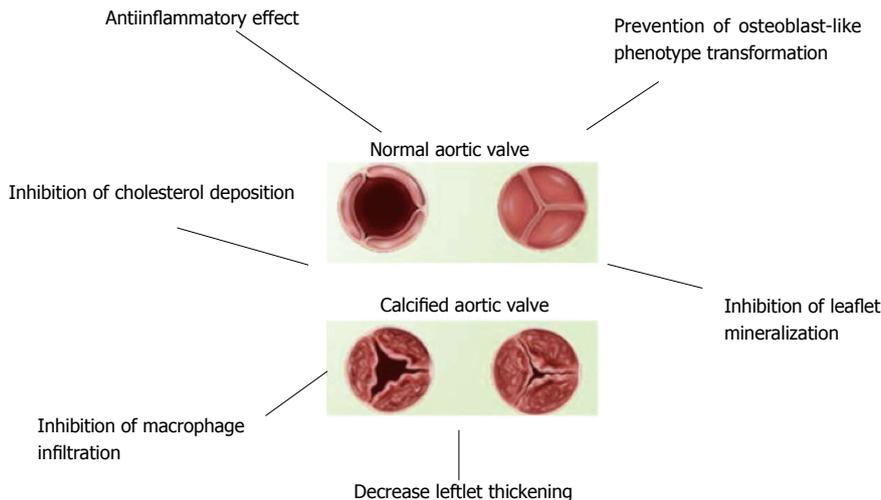

Figure 1 Schematic overview of statin effects on aortic valve calcification.

those retrospective studies on the effect of statins in AS included patients already exposed to statins prescribed for primary or secondary prevention of CAD. Moreover, study patients had only mild to moderate AS as severe AS was excluded. Based on sub-analyses of the 3 RCT's, several research groups support the lipid hypothesis as a common denominator of both diseases, with similarities between atherosclerosis and AS seen in initial stages of AS. Later on, disease progression is mostly determined by plasticity and structure of the leaflets, and by mechanical stress<sup>[35,36]</sup>. Yet, results of a recent meta-analysis challenged suggested role of statins to prevent the onset of AS in non-symptomatic patients<sup>[37]</sup>. They pooled high risk patients without known AS from 3 large scale RCT's who evaluated the effect of high (80 mg) and normal (10 mg) daily doses of atorvastatin and found no significant differences between placebo, low or high atorvastatin with regards to the onset of AS. Furthermore, across the board any subtle correlation between hyperlipidaemia and AS progression<sup>[15,17]</sup> turned out to be inconsistent<sup>[18,19]</sup>.

#### Effect of statins on AS in patients with CAD

As much as 40% of patients undergoing aortic valve replacement surgery suffers from atherosclerosis as well. Moreover, AS progresses faster in older patients with CAD<sup>[2]</sup>. There is evidence of beneficial effects of statins in presence of CAD<sup>[38]</sup>. Dyslipidaemia is an independent predictor of AS progression and adequate lipid-lowering by statin use in patients with CAD has beneficial effects on valve integrity<sup>[39]</sup>. Yet, a quantitative relationship between lipid-lowering and changes in AS progression has not been found. It is worth mentioning that most studies investigated patients with intermediate or advanced AS which appears difficult to modify by drugs; however, a potential effect in early AS could still be debated<sup>[40]</sup>. Another point to address is patient selection bias, especially in the SEAS trial that excluded patients

with diabetes or CAD. Even though no correlation between statin use and beneficial effects on AS have been shown, it is highly likely that patients with AS and relevant comorbidities such as atherosclerosis, which is a common clinical scenario, may be positively affected<sup>[41,42]</sup>. Indeed, statins would mitigate AS progression only when hyperlipidaemia is present<sup>[43]</sup> but more profound research is needed. Current guidelines suggest offering patients with comorbidities such as CAD, diabetes or hyperlipidaemia statins. Conversely, untreated metabolic syndrome in patients with AS is related to faster stenosis progression and worse prognosis<sup>[44]</sup>. These observations were more pronounced in younger patients (< 57 years of age). Interestingly, however, statins in younger patients with metabolic syndrome and AS turned out to be disadvantageous with AS progression and lower insulin resistance supporting the notion that lipophilic statins may actually induce diabetes type II<sup>[45,46]</sup>; this effect is even more pronounced when patients suffer from metabolic syndrome as well<sup>[47]</sup>. This effect was not seen in older patients, suggesting that the pathophysiological mechanisms of AS progression may be related to the patient's age<sup>[44]</sup>.

## CONGENITAL AORTIC STENOSIS

Congenital defects resulting in AS include partially fused leaflets, thickened leaflets, narrowing of the supra- or subvalvular area, and, most frequently, bicuspidity. A bicuspid aortic valve is the result of the fusion of two of the three leaflets during the developmental phase and is with an incidence of almost 2% the most common congenital cardiac malformation<sup>[48]</sup>. The abnormal structure of the bicuspid aortic valve results in excess stress onto leaflets, resulting in valvular thickening, calcification, and increased rigidity and restricted aortic orifice. For that reason, AS is the most frequent complication of bicuspid aortic valve. While randomized prospective

trials mainly included older AS patients, the PROCAS (Progression of Stenosis in Adult Patients with Congenital Aortic Stenosis) trial was designed to evaluate the effect of statins on the progression of stenosis in young asymptomatic adults (aged between 18 and 45) with congenital AS. Not surprising, the investigators did not find any benefit from extensive lipid-lowering by 10 mg rosuvastatin, independent of the degree of valve calcification<sup>[49]</sup>. These findings are in line with those of the bicuspid valve patients subgroup of the ASTRONOMER trial<sup>[23]</sup>.

## STATIN THERAPY AND AORTIC VALVE SURGERY

Because of their anti-ischemic and anti-inflammatory effects and protection of the endothelium statins have been suggested to reduce atrial fibrillation after aortic valve surgery, yet with conflicting<sup>[50,51]</sup>. Some beneficial effects of perioperative statin therapy on mortality, stroke, renal insufficiency, length of ICU and hospital stay were found<sup>[52,53]</sup> however leading to the conclusion that preoperative statin use is justified in case of coronary artery bypass grafting (CABG). Indeed, advantageous effects on the above-mentioned endpoints have been demonstrated in only CABG patients and not in others<sup>[54-56]</sup>. Conversely, just to add to the confusion statin were also reported to delay restenosis after balloon aortic valvuloplasty or bioprosthetic valve replacement<sup>[57-59]</sup>, but findings were not<sup>[60]</sup>. With pre- and postoperative statin therapy in patients undergoing aortic valve replacement an increased long-term survival was found with biological valve replacement but not with mitral valve repair or mechanical valve replacement<sup>[61]</sup>. Finally, a retrospective study of bicuspid aortic valve patients undergoing surgery showed a significant decrease in ascending aortic dilatation when exposed to statins preoperatively<sup>[62]</sup>. Clearly, more clinical data are required to justify perioperative use of statin therapy.

## FUTURE CONSIDERATIONS

Future research in this context needs to focus both, elucidating the molecular pathways involved in the pathogenesis of AS and developing potential pharmacological treatment strategies. In that regard, it is of interest to determine both vascular and valvular aspects and when they occur during the evolution of AS. As such, different treatment approaches might apply for distinct stages of the disease. In addition, defining predisposing genetic deviations may help define preventative and curative approaches to slow disease progression. Additionally, in the quest for new pharmacological agents to treat AS, low-cost accurate animal model are missing; only ageing swine can develop AS<sup>[34]</sup>. At present, there is no evidence that statins halt the progression or induce the

regression of AS. The notion that their administration is harmless and devoid any side effects is untrue as we know adverse effects of statins in asymptomatic AS patients without concomitant diseases may in fact induce new risk factors (diabetes mellitus, aortic valve calcification)<sup>[44,63]</sup>. In conclusion, the general consensus to date is that treatment with statins is not recommended in patients with valvular aortic stenosis and in absence of standard indications to lipid-lowering treatment.

### Abstract

#### AIM

To investigate the role of interleukin-19 (IL-19) in a murine model of female-dominant heart failure (HF).

## METHODS

Expression of one copy of a phosphorylation-deficient cyclic adenosine monophosphate response-element binding protein (dnCREB) causes HF, with accelerated morbidity and mortality in female mice compared to males. We assessed expression of IL-19, its receptor isoforms IL-20R  $\alpha/\beta$ , and downstream IL-19 signaling in this model of female-dominant HF. To test the hypothesis that IL-19 is cardioprotective in dnCREB-mediated HF, we generated a novel double transgenic (DTG) mouse of dnCREB and IL-19 knockout and assessed cardiac morbidity by echocardiography and survival of male and female mice.

## RESULTS

IL-19 is expressed in the murine heart with decreased expression in dnCREB female compared to male mice. Further, the relative expression of the two IL-19 receptor isoforms manifests differently in the heart by sex and by disease. Male DTG mice had accelerated mortality and cardiac morbidity compared to dnCREB males, while female DTG mice showed no additional detriment, supporting the hypothesis that IL-19 is cardioprotective in this model.

## CONCLUSION

Together, these data suggest IL-19 is an important cytokine mediating sex-specific cardiac (dys) function. Ongoing investigations will elucidate the mechanism(s) of sex-specific IL-19 mediated cardiac remodeling.

**Key words:** Cardiac dysfunction; Sex differences; Heart failure; Interleukin-19

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Heart failure (HF) is a sexually dimorphic disease. In a female-dominant model of HF, the dominant negative cyclic AMP response-element binding protein (dnCREB) mouse, female mice show accelerated cardiac morbidity and mortality alongside downregulated interleukin-19 (IL-19) expression, while male mice maintain IL-19 expression and are protected against cardiac dysfunction. We generated a novel double transgenic mouse with dnCREB and IL-19 knockout to test the hypothesis that IL-19 is cardioprotective. We show accelerated cardiac morbidity only in male mice, supporting the hypothesis that IL-19 is a sex-specific cardioprotective cytokine.

## INTRODUCTION

Heart failure (HF) is the leading cause of mortality within the United States, affecting more than 5 million Americans<sup>[1]</sup>. HF is frequently perceived as a disease with poorer prognosis in male patients, perhaps since women are protected against cardiovascular disease premenopausally. However, many large-scale epidemiological studies do not support this conclusion. Sexually divergent manifestation of HF is observed regarding etiological factors, in response to a variety of HF therapies, and in presentation of HF and its comorbidities. Although the prevalence of HF is lower in women compared to men, treatment and survival outcomes for female patients are poorer with females having disproportionately higher morbidity and mortality<sup>[1]</sup>. Women are more likely to be symptomatic and functionally limited<sup>[2]</sup>, experience less improvement following hospitalization<sup>[3]</sup>, and show higher level of disability at similar levels of left ventricular (LV) dysfunction with worse quality of life<sup>[4]</sup> than male counter-parts. Together, the sex differences in HF highlight the necessity to understand female disease to close the gap in treatment and prognosis.

The deleterious effects of inflammatory cytokines in the context of HF are well documented as elevated circulating levels of cytokines predict adverse outcomes in patients with HF<sup>[5]</sup>. Inflammatory cytokines directly affect cardiomyocyte contractility<sup>[6]</sup>, as well as influence LV remodeling and hypertrophy. Few studies, however, have examined sex-specific differences in cytokine expression, though sparse data indicate inflammatory profiles may be sexually dimorphic<sup>[7]</sup>. Interleukin-19 (IL-19) is a member of the IL-10 subfamily of interleukins. IL-19 signals through an IL-20 receptor heterodimer IL-20R $\alpha$  and  $\beta$  to activate cytoplasmic tyrosine kinases of the Janus family signal transducer activator of transcription (JAK-STAT)<sup>[8]</sup>. Differential relative expression of IL-20R subunits has been reported in different tissue types<sup>[9]</sup> and is suggested as a potential mechanism of differential downstream IL-19 signaling, though this hypothesis has not yet been tested in the heart. While initially thought to be restricted to immune cells, IL-19 expression has since been observed in a wide variety of tissue types. IL-19 exerts both pro-inflammatory and anti-inflammatory properties, depending on tissue and disease specific factors<sup>[10]</sup>. Previous work has demonstrated anti-inflammatory properties of IL-19 in endothelial and vascular smooth muscle cells<sup>[8]</sup>, but its role in the heart remains unknown.

Here, we investigated the expression of IL-19 and its receptor complex in a female dominant model of HF. Cardiac-specific expression of a dominant negative cyclic AMP response element-binding protein (dnCREB) results in dilated cardiomyopathy with accelerated mortality in female mice<sup>[11]</sup>. In this model, the transcription factor CREB is rendered phosphorylation inactive *via* mutation of a critical Ser residue located

in the kinase-inducible domain the protein<sup>[12]</sup>. In the unphosphorylated state, CREB can bind to DNA but cannot activate transcription, thus rendering the transcription factor inactive. This single nucleotide mutation results in significant cardiac dysfunction and accelerated morbidity and mortality in female mice compared to males. In comparison to male dnCREB mice, female dnCREB have significantly worse LV systolic function, higher heart rate, and diminished cardiac output, resulting in overall greater cardiac morbidity compared to male mice with the same genetic mutation<sup>[11]</sup>. This exaggerated pathology in female dnCREB is particularly interesting, as the majority of HF models involving genetically manipulated mice demonstrate more profound morbidity in the male sex<sup>[13]</sup>. In addition to this novel sexual divergence, the role of CREB in cardiac dysfunction is important, as CREB is functionally lost in rodent models of HF<sup>[14]</sup> and loss of CREB-regulated genes is observed early in the failing human heart<sup>[15]</sup>. Here, we show for the first time that IL-19 is expressed in the rodent heart, and is expressed in a sexually dimorphic manner in HF. Further, we demonstrate dysregulated downstream IL-19 signaling in female-dominant HF and suggest that IL-19 is cardioprotective in this model.

## MATERIALS AND METHODS

### Animals

The mouse model used in this study was a heterozygous, phosphorylation-deficient (Ser<sup>133</sup> to Ala<sup>133</sup>) mutant CREB (dnCREB) transgenic mouse<sup>[16]</sup> and non-transgenic (control, Con) littermates. dnCREB mice begin showing signs of contractile dysfunction at eight weeks of age. By 12 wk, female mice display significant mortality compared to males<sup>[11]</sup>. Homozygous IL-19 knockout (IL-19 KO) mice were generated as previously described<sup>[17]</sup> and show no overt signs of cardiac dysfunction or early morbidity and mortality. To have dnCREB and IL-19 KO mice on the same background, dnCREB mice were back-bred onto the C57 background for a minimum of 6 lineage passages. Male dnCREB mice were then crossed with female IL-19 KO to create heterozygous IL-19 KO. Male dnCREB IL-19 heterozygous mice from this F1 generation were then crossed with IL-19 KO female mice to create homozygous IL-19 KO and heterozygous dnCREB double transgenic male and female mice (DTG). Mice were housed at 4 per cage after weaning. Cages were inspected daily, and date of death noted for those mice found dead. Experiments were conducted in accordance with the National Institutes of Health "Guide for the Care and Use of Laboratory Animals", and were approved by the Institutional Animal Care and Use Committee at the University of Colorado-Denver.

### Echocardiography

Cardiac function was assessed by two-dimensional transthoracic echocardiography using a VisualSonics

Vevo 770 high-resolution ultrasound imager equipped with a 35-MHz transducer. Mice were lightly sedated with isoflurane and body temperature was maintained at 37 °C. Parasternal long- and short-axis B-mode videos and M-modes images (at the level of the midpapillary short axis) were routinely acquired. LV wall thicknesses and inner dimensions at diastole and systole were measured from the parasternal short-axis M-mode images.

### Isolation of primary ventricular cardiac myocytes and fibroblasts

Cardiomyocytes were isolated from C57BL/6 male and female mice (approximately 14 wk of age) by enzymatic dissociation of the whole heart on a Langendorff apparatus as previously described<sup>[18]</sup>. Briefly, hearts were rapidly removed and rinsed in a control buffer (133.5 mmol/L NaCl, 4mmol/L KCl, 1.2 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 10 mmol/L HEPES, 1.2 mmol/L MgSO<sub>4</sub>, and 1% bovine serum albumin) to remove blood, weighed and mounted on a Langendorff apparatus. The isolated heart was then perfused at 37 °C for 3 min with control buffer before switching to enzyme solution (control solution containing collagenase type II (2.4 mg/mL) and 25 μmol/L CaCl<sub>2</sub>). After perfusion, ventricles were removed, minced in control solution and incubated at 37 °C for an additional 3 min with titration. Dissociated cells were then filtered through a nylon mesh to remove big pieces of undigested tissues. Isolated cells were rinsed in control solution and allowed to settle by gravity to remove debris and non-cardiomyocytes. Calcium was added to the myocytes in step-wise fashion by settling/resuspension in 4 steps. Purified myocytes were resuspended in Medium 199 supplemented with 110 mg/L sodium pyruvate, 0.1 mmol/L β-mercaptoethanol, 100 U/mL penicillin, 100 μg/mL streptomycin, and 10% fetal calf serum and cultured on laminin-coated culture plates at a density of approximately 6000 cells/cm<sup>2</sup> at 37 °C for 2 h before washing to remove dead and non-adherent cells. Cells were maintained overnight in serum-containing medium before experimentation. Ventricular fibroblasts were isolated following the first low-speed spin to sediment myocytes. Fibroblasts were plated in Dulbecco's modified eagle medium (DMEM) plus 10% fetal calf serum and 1% penicillin/streptomycin and allowed to culture until confluence. Upon reaching confluence, the media was changed to serum-free DMEM for one hour. Cells were then washed one time with PBS and harvested for subsequent experimentation.

### Western blot analysis

The LV was carefully dissected away from the right ventricle and atria, and flash-frozen in liquid nitrogen. LV were homogenized in isoelectric focusing buffer (8 mol/L urea, 2.5 mol/L thiourea, 4% Chaps, 2 mmol/L EDTA) containing 2 mmol/L tributylphosphine, 10 mmol/L DTT and protease inhibitors. The homogenate was centrifuged at 14000 g for 5 min, and the super-

natant saved for protein analyses. Protein concentration was determined using a modified protein assay (Bio-Rad) and prepared in Laemmli sample buffer (Bio-Rad). Proteins were resolved on 7.5% SDS-PAGE gels and transferred to PVDF. Following blocking in 5% bovine serum albumin for one hour at room temperature, membranes were incubated with primary antibody overnight at 4 °C. The following primary antibodies were used: Phospho-Stat3 (Tyr705) (Cell Signaling 9131; 1:1000), Stat3 (Cell Signaling 9139; 1:1000). Membranes were washed and incubated with secondary antibody for one hour at room temperature. Protein bands were visualized using a chemiluminescent substrate and autoradiography. Membranes were probed first with phospho signal transducer and activator of transcription 3 (STAT3), stripped, and then re-probed for total STAT3. Equal loading of proteins was verified by Ponceau-S staining.

### Real-time RT-PCR

RNA was extracted from LV and isolated cells using standard TRIzol protocol (Thermo Fisher) and reverse transcribed using iScript cDNA synthesis kit (BioRad). For detection of murine IL-19 and IL-20R, real-time RT-PCR was performed with the iCycler My iQ using iQ SYBR Green Supermix (BioRad), normalized to the housekeeping gene 18S ribosomal RNA (18S). Primer sequences were as follows. IL-19 forward: 5'-GGCTAAAAGTATGTTTCAGTTCTCC-3', IL-19 reverse: 5'-AAATCTCTGGAGCGATGTCAG-3', IL-20R $\alpha$  forward: 5'-AACTGGCAGGCTGTGTATCC-3', IL-20R $\alpha$  reverse: 5'-TTGTCAGGTGCCTGGTTCTC-3', IL-20R $\beta$  forward: 5'-CGAGGAGGGACGGAAGAATG-3', IL-20R $\beta$  reverse: 5'-TACGGCCTCTCTCGATGTCA-3', 18S forward: 5'-GCCGCTAGAGGTGAAATTCTTG-3', 18S reverse: 5'-CTTTCGCTCTGGTCCGTCTT-3'. Myosin heavy chain  $\beta$  (MYHC $\beta$ ), atrial natriuretic factor (ANF), brain natriuretic peptide (BNP), myosin heavy chain  $\alpha$  (MYHC $\alpha$ ), and sarcoplasmic reticulum Ca<sup>2+</sup> ATPase (SERCA) oligonucleotide sequences were used as previously published<sup>[19]</sup>.  $\Delta$ Ct were calculated relative to the housekeeping gene 18S to allow comparisons across all groups (genotype and sex). As such, a lower  $\Delta$ Ct indicates higher expression.

### Statistical analysis

Significance was set a priori at  $P < 0.05$ . Data were analyzed by Students t-test using GraphPad and 2-way ANOVA (genotype by sex) using IBM SPSS Statistics Version 24. Data with unequal variance were log-transformed to meet assumptions for homoscedasticity. Data are expressed as means  $\pm$  SE of the mean. Where statistical analyses trend towards significance ( $P < 0.1$ ), values are also noted above figures. Kaplan-Maier survival curves were generated for survival data, and differences in survival were assessed with log rank test. The statistical methods of this study were reviewed by David Kao, MD from the University of Colorado-Denver.

## RESULTS

### IL-19 signaling in the female dominant dnCREB model of HF

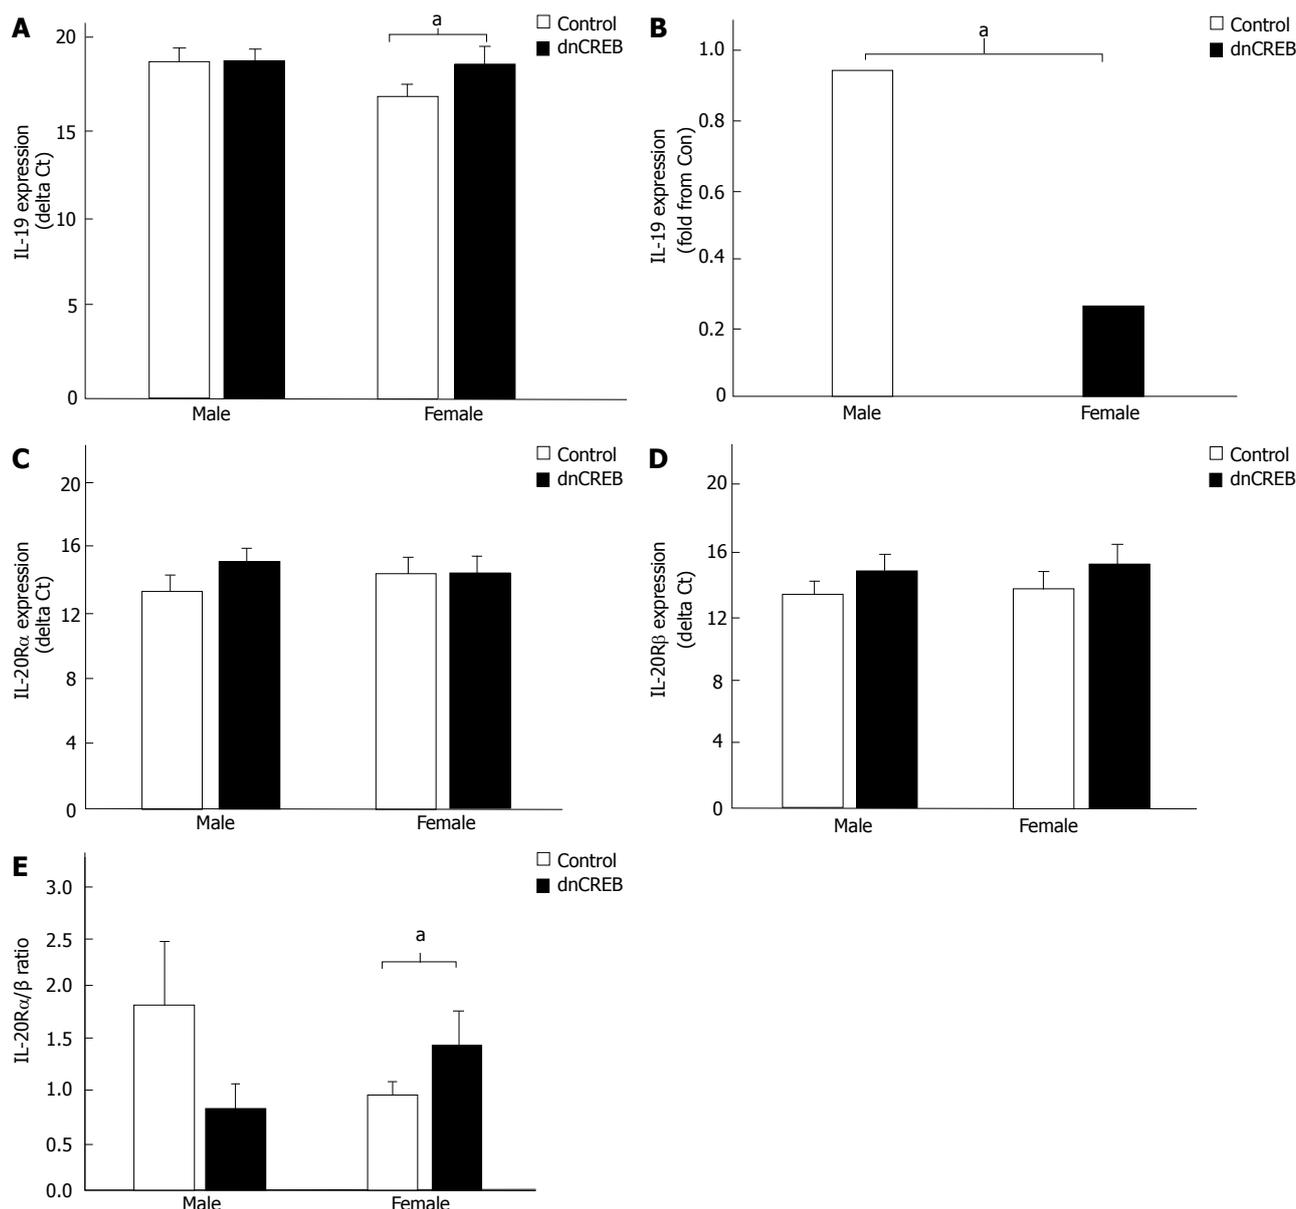

To begin to delineate the role of IL-19 in dnCREB-mediated HF, we assessed the expression of IL-19 and its receptor subunits in the LV from dnCREB mice compared to controls. Male dnCREB mice showed no change in IL-19 expression (Figure 1A); however, female dnCREB mice demonstrate significantly downregulated IL-19 expression (Figure 1A) with disease, a statistically different outcome in male and female mice (Figure 1B). Neither male nor female mice showed significant changes in expression of IL-20R $\alpha$  or  $\beta$  with disease (Figure 1C and D). However, the ratio of  $\alpha/\beta$  was significantly upregulated only in female dnCREB (Figure 1E). We then assessed activation of STAT3 as a downstream mediator of IL-19 signaling. Both male and female dnCREB mice showed downregulated STAT3 activation compared to control mice (Figure 2); however female dnCREB mice STAT3 activation was suppressed to 40% of control, while male dnCREB mice were suppressed to 70% of control.

### Survival of IL-19 KO and dnCREB double transgenic mice

The sexual dimorphic regulation of IL-19 and its receptor subunits in dnCREB-mediated suggests that IL-19 is cardioprotective in the setting of dnCREB, since female mice in this model suffer premature morbidity and mortality compared to males and express significantly attenuated IL-19. To test this hypothesis, we generated a novel double transgenic model (DTG) of IL-19 knockout in dnCREB-mediated HF. Survival analyses show that DTG males died from HF earlier in the development of disease than dnCREB male mice; with nearly identical survival curves to dnCREB females and female DTG (Figure 3). During this time, there was no morbidity in the Con or IL-19 KO mice (data not shown). Thus, knockout of IL-19 in this model accelerates mortality only in male mice, with no additional effect in females.

### Assessment of cardiac function in DTG mice

To confirm that accelerated mortality in DTG mice is due to cardiac dysfunction, we examined contractile function in male and female DTG mice at 10 wk of age by echocardiography. Representative M-mode echocardiographs are shown in Figure 4, and quantification (no hyphen) of echocardiography is reported in Table 1. Previous reports of the dnCREB model of female-dominant HF reported diminished fractional shortening (19.4% and 8.79%) and cardiac output (17.4 and 14.6 mL/min) in male and female mice respectively, with a significant difference between sexes<sup>[11]</sup>. Consistent with the dnCREB model, our DTG mice showed evidence of significant cardiac contractile dysfunction, with low fractional shortening (14% and 12%), stroke volume (24 and 23  $\mu$ L), and cardiac output (13.59 and 14.35 mL/

**Figure 1** Expression of interleukin-19 and interleukin-20R in the dominant negative cyclic AMP response-element binding protein model of female-dominant heart failure. A: Female male significantly downregulated IL-19 expression in the setting of dnCREB-mediated heart failure compared to male mice which maintained IL-19 expression; B: A significant difference between sexes; C: IL-20R $\alpha$  and IL-20R $\beta$  (D) expression were unchanged in either sex; D: However, the ratio between IL-20R $\alpha$ / $\beta$  was significantly upregulated in female dnCREB mice. Expression of IL-19 and IL-20R was assessed by qRT-PCR, and  $\Delta$ Ct calculated relative to 18S. The ratio of IL-20R $\alpha$ / $\beta$  was calculated as a fold change of  $\alpha$ - $\beta$  within each sex. Data are expressed as mean  $\pm$  SEM. <sup>a</sup>*P* < 0.05, *n* = 5-9 mice per group. dnCREB: Do-minant negative cyclic AMP response-element binding protein.

min) in male and female mice, respectively. However, genetic ablation of IL-19 completely abrogated the previously reported sex difference in the dnCREB model. That is, male DTG mice display similar levels of cardiac morbidity as female DTG, suggesting that IL-19 is cardioprotective in the dnCREB model of HF.

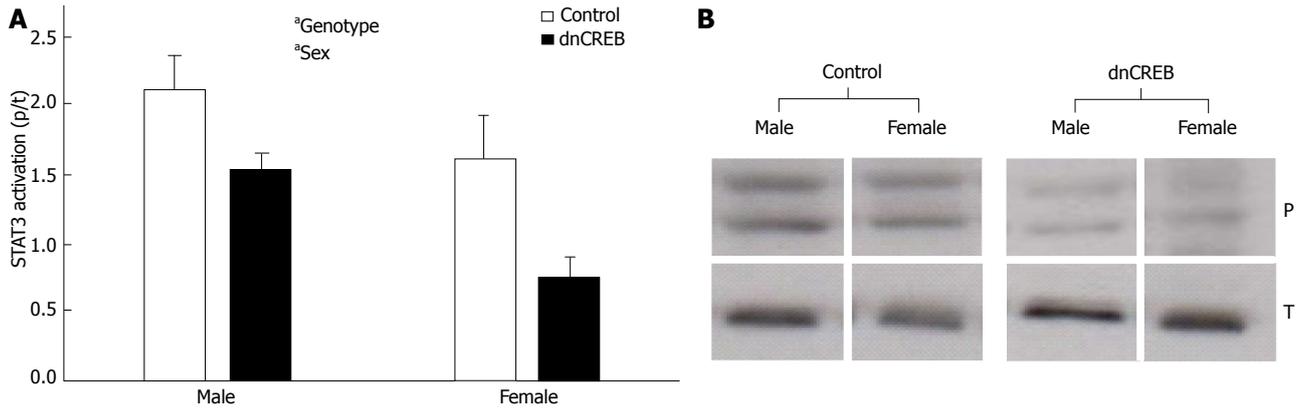

**IL-20R expression and STAT3 activation in DTG mice**

We assessed the relative expression of IL-20R $\alpha$  and  $\beta$  subunits in DTG male and female mice. We found male and female DTG mice to express similar levels of both subunits, with no difference in the ratio of the receptor subunits (Figure 5A and B). In addition, we assessed activation of STAT3 in male and female DTG mice and

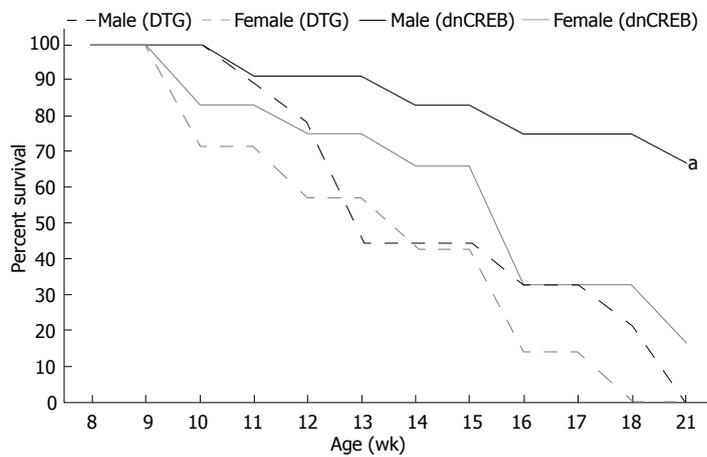

found STAT3 activation to be similar between sexes (Figure 5C and D). Expression of IL-20R and STAT3 activation in DTG male and female mice contrast with dnCREB mice, where downstream IL-19 signaling was significantly different between sexes.

**Biochemical responses to dnCREB-mediated HF**

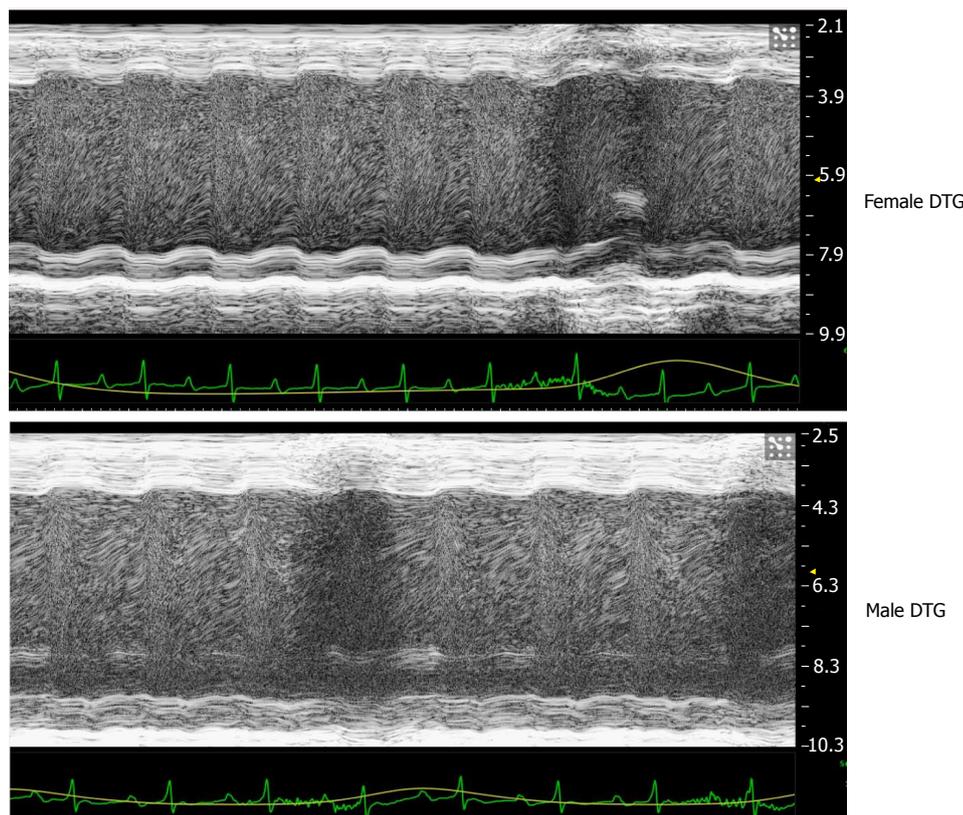

We assessed the expression of five genes in the hypertrophic gene program. These genes, components of the fetal gene program, are differentially expressed in established pathologic cardiac hypertrophy. While myosin heavy chain  $\alpha$  (MYHC $\alpha$ ) expression was unchanged by either sex or genotype (Figure 6A), myosin heavy chain  $\beta$  (MYHC $\beta$ ), atrial natriuretic factor (ANF) and

brain natriuretic peptide (BNP) were all significantly upregulated in dnCREB and DTG mice (Figure 6B-D), while sarcoplasmic reticulum Ca<sup>2+</sup> ATPase (SERCA) expression was significantly downregulated (Figure 6E). Surprisingly, we observed no overall effect of sex on fetal gene program expression; however, BNP expression was more robustly induced in female dnCREB mice compared to male dnCREB (4.8 fold vs 2.6 fold, *P* < 0.05, data not shown).

**Expression of IL-19 and IL-20R in isolated cardiac myocytes and fibroblasts**

IL-19 signaling is uncharacterized in the heart. It is

imperative we understand IL-19 signaling in the male and female heart to understand the dysregulation that occurs with disease. Therefore, we isolated primary cardiac myocytes and fibroblasts from male and female mice to assess IL-19 signaling in these two cell types. Both fibroblasts (Cfib) and myocytes (CM) expressed IL-19, with no differences between sexes in either cell type (Figure 7A). Both cell types also express IL-20R $\alpha$ , with higher expression in CM than Cfib, and a trend towards lower expression in female myocytes than males (Figure 7B). Fibroblasts and myocytes similarly express IL-20R $\beta$ , with no difference between sexes (Figure 7C), however the ratio of IL-20R $\alpha/\beta$

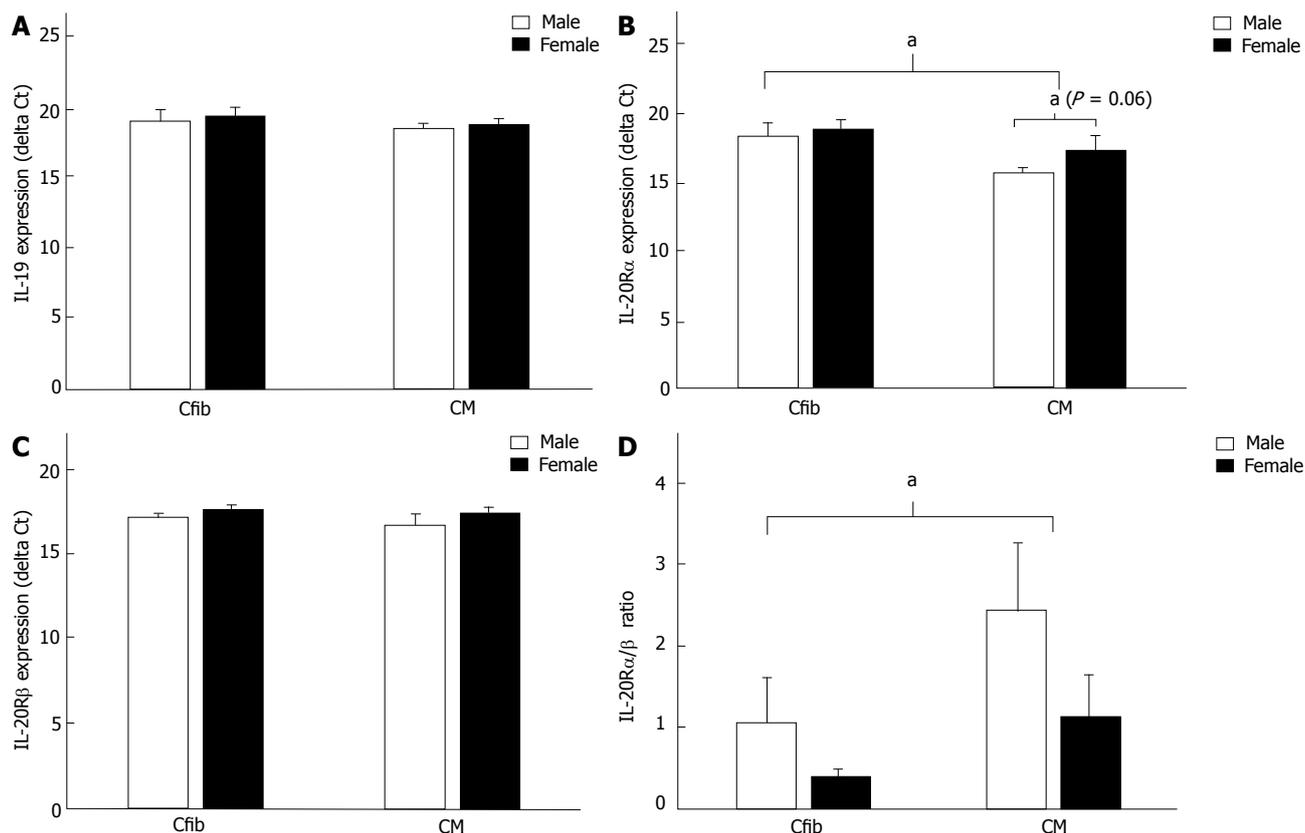

**Figure 6** Activation of the fetal hypertrophic gene program in dominant negative cyclic AMP response-element binding protein and double transgenic mice. A: Myosin heavy chain  $\alpha$  (MYHC $\alpha$ ) expression was unchanged by either sex or genotype; B: Myosin heavy chain  $\beta$  (MYHC $\beta$ ); C: Atrial natriuretic factor (ANF); D: Brain natriuretic peptide (BNP) were all significantly upregulated in both male and female dnCREB and DTG mice; E: Sarcoplasmic reticulum Ca<sup>2+</sup> ATPase (SERCA) expression was significantly downregulated in both sexes with disease. Expression of fetal hypertrophic genes was assessed by qRT-PCR, relative to the housekeeping gene 18S. Data are expressed as mean  $\pm$  SEM and assessed by 2-way ANOVA. <sup>a</sup>*P* < 0.05 vs Control; *n* = 4-7 mice per group. a: Significant effect of genotype. dnCREB: Do-minant negative cyclic AMP response-element binding protein; DTG: Double transgenic.

was significantly higher in CM than Cfib (Figure 7D), suggesting the potential for cell-type specific responses to IL-19 signaling in the heart.

## DISCUSSION

HF is a sexually dimorphic disease, adversely affecting female patients regarding morbidity and mortality. The maladaptive role of cytokines in HF is well documented; however, only a few studies have considered sex differences in cytokine expression or signaling. We show for the first time that IL-19, a previously

undescribed cytokine in the heart, is expressed in rodent cardiac tissue and two previously unexamined cardiac cell types: Cardiac myocytes and fibroblasts. Further, we report dysregulation of IL-19 signaling in a female-dominant model of HF, suggesting a cardioprotective role of IL-19 in the heart. We propose the following model, as summarized in Figure 8, where IL-19 signaling through IL-20R $\alpha/\beta$  activates STAT3 and canonical downstream cardioprotective mechanisms. This pathway is significantly downregulated in female dnCREB mice, resulting in attenuated STAT3 activation, LV remodeling, cardiac dysfunction, and premature

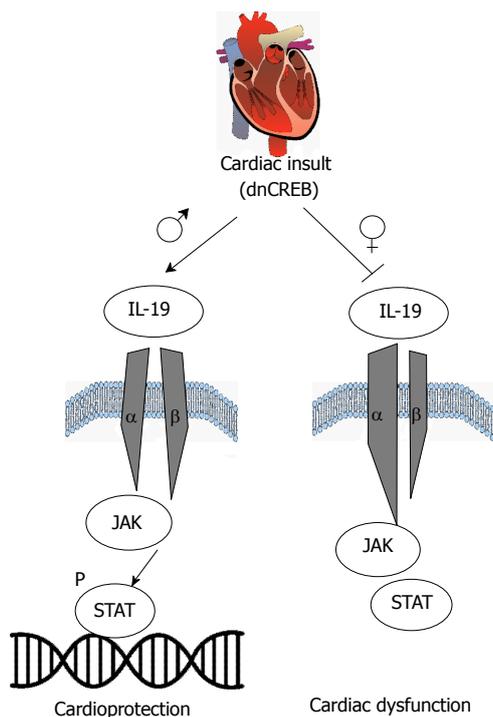

**Figure 7 Interleukin-19 and interleukin-20R expression in male and female cardiac fibroblasts and myocytes.** A: Both male and female Cfib and CM express IL-19, with no differences between sexes or cell types; B: Both Cfib and CM express IL-20R $\alpha$ , with higher expression in CM than Cfib, as evident by the lower delta Ct. Male CM tended to express higher IL-20R $\alpha$  than female CM ( $P = 0.06$ ); C: Both Cfib and CM express IL-20R $\beta$ , with no differences between cell types or sex; D: The ratio of IL-20R $\alpha$ / $\beta$  was significantly higher in CM than Cfib. IL-19 and IL-20R expression were assessed by qRT-PCR and normalized to the housekeeping gene 18S. Data are expressed as mean  $\pm$  SEM and assessed by 2-way ANOVA;  $n = 7-8$  mice per group. Cfib: Cardiac fibroblasts; CM: Cardiac myocytes.

mortality. However, male dnCREB mice maintain IL-19 expression with disease, resulting in heightened cardioprotection and significantly less morbidity and mortality compared to female mice. Ongoing investigations will elucidate further mechanistic insight into sexually divergent downstream IL-19 mediated cardiac signaling and whether this novel cytokine represents a new therapeutic target for the treatment of women's heart disease.

IL-19 was first discovered over a decade ago and classified as a member of the IL-10 family based on structure and location of the IL-19 gene and the use of similar receptor complexes<sup>[20]</sup>. Since its discovery, however, the function of IL-19 has remained unclear. In a number of disease states including asthma<sup>[21]</sup>, sepsis<sup>[22]</sup>, and acute kidney injury<sup>[23]</sup> IL-19 acts as a pro-inflammatory factor. Conversely, in inflammatory bowel disease<sup>[17]</sup> and vascular disease<sup>[24]</sup>, IL-19 appears to be anti-inflammatory and protect against disease progression. These data imply that IL-19 may function as either pro- or anti-inflammatory depending on the tissue and disease context. Further, it suggests that downstream IL-19 signaling including receptor subunit expression may be implicated in the disparate biological outcomes. A study examining IL-20R expression in 24 different human tissues reports significant differential  $\alpha$ /

$\beta$  subunit expression between tissue types<sup>[9]</sup> suggesting differential relative expression of these two subunits may be implicated in the varying biological outcomes of IL-19 signaling. Various groups have attempted to define the binding kinetics and receptor requirements for IL-19 signaling. While most report a requirement for the IL-20R heterodimer and the rapid formation of a stable 1:1:1 complex in the presence of a ligand, other evidence also supports less stable homodimer formation<sup>[25]</sup>. In support of homodimer IL-20R signaling, IL-19 has clear effects on lymphocytes derived from IL-20R $\beta$  knockout mice<sup>[26]</sup>. Thus the specific requirement for receptor dimerization remains controversial, as does the effect of subunit expression on IL-19 downstream function. We assessed IL-20R subunit expression in isolated primary cardiac myocytes and fibroblasts and found differential expression of the receptor subunits, suggesting that IL-19 may modulate IL-20R in a cell-type specific manner. These data are consistent with previous reports of IL-19 signaling in the vasculature which demonstrate that IL-19 stimulation of vascular smooth muscle cells induces expression of IL-20R $\beta$  with no effect on endothelial cells<sup>[27]</sup>. Further, receptor subunit expression may be regulated in a sex-specific manner during disease progression as evidenced by differential IL-20R $\alpha$ / $\beta$  ratios in male and female dnCREB

**Figure 8 Working model of interleukin-19 in sex-specific heart failure.** Cardiac insult (inactivation of cyclic AMP response-element binding protein) results in maintained interleukin-19 (IL-19) expression in male mice, with maintained expression of IL-20 receptor subunits. Activation of downstream JAK-STAT signaling in male hearts is cardioprotective. However, cardiac insult in female mice results in attenuated IL-19 signaling, dysregulated expression of IL-20R subunits, and cardiac dysfunction. Ongoing investigations will delineate the downstream mediators implicated in IL-19 cardioprotection in a sex-specific manner.

mice. Together, these data suggest that cell and context-specific regulation of IL-20 receptor isoforms may be important in disease, and may do so in a sexually dimorphic manner. Elucidation of the effects of IL-19 on specific cardiac cell populations (including inflammatory cells, endothelial, and vascular smooth muscle unexamined here) from male and female models warrants future investigation.

IL-19 treatment of IL-20R $\alpha/\beta$  expressing cells leads to tyrosine phosphorylation of STAT3<sup>[28]</sup>. STAT3 is universally cardioprotective in response to a number of cardiac insults including ischemia-reperfusion injury<sup>[29]</sup> and hypertrophy<sup>[30]</sup>. Myocyte-specific STAT3 knockout mice develop cardiac fibrosis and myocardial dysfunction even in the absence of stress<sup>[31]</sup>. These mice are also more susceptible to inflammation-induced cardiac damage and greater contractile dysfunction<sup>[32]</sup>, and ultimately lack of myocyte STAT3 leads to age-related HF<sup>[31,32]</sup>. Furthermore, human failing hearts exhibit reduced STAT3 levels and activity compared to healthy controls<sup>[33]</sup>. Thus, STAT3 is crucial for cardiac resistance to inflammation and other acute injuries. We show attenuated STAT3 activation in the LV from dnCREB male and female mice. Further, this effect is more robust in female dnCREB mice, correlating with the female-dominance of the dnCREB model and the early mortality of female mice. The mechanisms

of STAT3-mediated cardiac protection in our model are not yet characterized; though canonical (Tyr705) STAT3 activation has proposed anti-oxidant, anti-apoptotic, and pro-angiogenic target genes (Reviewed in<sup>[34]</sup>). In addition, STAT3 also enhances mitochondrial respiration and acts on complex I to inhibit reactive oxygen species formation; mechanisms which are augmented by non-canonical phosphorylation of STAT3 at Ser727<sup>[35]</sup>. The action of STAT3 on mitochondrial function is particularly interesting and warrants future investigation, as dnCREB female mice have increased oxidant production, attenuated antioxidant defenses, and disrupted mitochondrial structure and function compared to male dnCREB<sup>[11]</sup>.

In summary, we show for the first time that IL-19 demonstrates clear sexually dimorphic expression in the female-dominant dnCREB model of HF. Ablation of IL-19 in this model accelerates male mortality and causes severe cardiac morbidity, suggesting a cardioprotective role for IL-19 in the heart. Elucidation of IL-19 signaling in this model and in other models of female-dominant HF will facilitate the identification of novel therapeutics for women’s heart disease.

## COMMENTS

### Background

Heart failure (HF) is a sexually dimorphic disease, with worse morbidity and mortality in female patients compared to males. Inflammation is hypothesized to play a detrimental role in HF development, though whether it is regulated in a sexually dimorphic manner remains unknown. Interleukin-19 (IL-19) is an inflammatory cytokine with an unknown function in the healthy heart or in HF. Therefore, the authors set out to assess the role of IL-19 in female dominant HF.

### Research frontiers

HF is characterized by inflammatory signaling, though how this may be regulated in a sex-specific manner is unknown. Since HF is a sexually dimorphic disease, it is imperative that understand molecular mechanisms which contribute to disease in a sex-specific approach.

### Innovations and breakthroughs

Although IL-19 has been studied in the vasculature, few reports exist regarding cardiac signaling. The authors show for the first time that IL-19 demonstrates clear sexually dimorphic expression in a model of female-dominant HF. Genetic ablation of IL-19 in this model accelerates male mortality, suggesting IL-19 is cardioprotective.

### Applications

Development of sex-specific therapies will improve HF outcomes, and is a primary goal of personalized medicine. To develop sex-specific therapies, the authors must understand mechanisms which underlie HF in both males and females. Although the impact of IL-19 in the human heart remains unknown, the data identify sex-specific mediators of cardiac function, and suggest that therapies for the failing human heart be explored in both sexes.

### Peer-review

This is a very interesting topic. The paper is well written, clear and interesting. The results provide adequate grounds for the conclusion.

**Abstract****AIM**

To test the safety and effectiveness of hypertonic saline solution (HSS + F) as a strategy for weight loss and

prevention of further deterioration of renal function.

### METHODS

Patients admitted with acute decompensated heart failure (ADHF) who received HSS + F were included in the study. After a period of a standard ADHF treatment, our patients received an intravenous infusion of furosemide (250 mg) combined with HSS (150 mL of 3% NaCl) twice a day for a mean duration of 2.3 d. Our primary outcomes were weight loss and a change in serum creatinine per day of treatment. The parameters of the period prior to treatment with HSS + F were compared with those of the period with HSS + F.

### RESULTS

A total of 47 patients were included. The mean creatinine on admission was  $155 \mu\text{mol/L} \pm 65 \mu\text{mol/L}$ , the ejection fraction was  $40\% \pm 17\%$ . The experimental treatment (HSS + F) resulted in greater weight loss per day of treatment than the standard treatment ( $-1.4 \text{ kg/d} \pm 1.4 \text{ kg/d}$  vs  $-0.4 \text{ kg/d} \pm 1.0 \text{ kg/d}$ ,  $P = 0.0168$ ). Importantly, the change in creatinine was not significantly different.

### CONCLUSION

This study supports the effectiveness of HSS + F on weight loss in patients with ADHF. The safety profile, particularly with regard to renal function, leads us to believe that HSS + F may be a valuable option for those patients presenting with ADHF who do not respond to conventional treatment with intravenous furosemide alone.

**Key words:** Heart failure; Decompensated; Hypertonic saline; Renal failure; Fluid overload

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hypertonic saline solution (HSS) has been proposed in recent years as a potential therapy to facilitate diuresis in patients with decompensated heart failure and to overcome diuretic resistance. This study supports the effectiveness of HSS + F on weight loss in patients with acute decompensated heart failure and a high burden of comorbidities, despite a proportion of patients having preserved ejection fraction, right heart failure and advanced renal failure. The administration of small intravenous boluses of HSS in conjunction with intravenous furosemide can be a feasible and inexpensive therapeutic option which can prevent the use of costlier and more invasive treatments such as ultrafiltration, hemodialysis and inotropic infusion.

Effects of hypertonic saline solution on body weight and serum creatinine in patients with acute decompensated heart failure. *World J Cardiol* 2017; 9(8): 685-692 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i8/685.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i8.685>

## INTRODUCTION

Heart failure (HF) is a well-recognized major public health problem affecting about 26 million people worldwide<sup>[1]</sup>. Its impact in terms of mortality, morbidity, quality of life and cost is considerable. Acute decompensated heart failure (ADHF) is a leading cause of hospitalization and a common issue in emergency departments. Loop diuretics have long been recognized as the key for the treatment of ADHF<sup>[2]</sup>, however, high doses can cause adverse effects, including electrolyte abnormalities and deterioration of renal function. In addition, patients can develop resistance to diuretics and congestive symptoms can persist despite treatment with high doses<sup>[3]</sup>. Currently available treatment options include higher doses or a continuous infusion of intravenous diuretics<sup>[4,5]</sup>, a combination of different classes of diuretics for their synergistic effects<sup>[6,7]</sup>, and in severe/advanced cases, parenteral inotropes<sup>[8-10]</sup> and ultrafiltration<sup>[11,12]</sup>. The last two options are not associated with a better prognosis, and in fact, can cause deleterious effects and their use is limited by the cost and availability<sup>[11-14]</sup>.

The hypertonic saline solution (HSS) has been proposed in recent years as an adjunctive therapy for intravenous loop diuretics to improve or restore their initial pharmacological efficacy<sup>[3]</sup>. Among the proposed mechanisms to explain the benefits of HSS, it has been reported that it would prevent intravascular depletion due to diuretics<sup>[15,16]</sup> and thus would maintain renal flow and the glomerular filtration rate (GFR) during intensive treatment of intravenous furosemide<sup>[17]</sup>.

Compared to the administration of high doses of intravenous furosemide alone, concomitant use of HSS (HSS + F) has shown, in patients with ADHF, a more rapid and complete resolution of the signs and symptoms of congestion by increasing urine volume and by potentiating weight loss<sup>[16,18,19]</sup>, the potential to protect against deterioration of renal function during intensive diuretic therapy<sup>[15,20]</sup>, an improvement of cardiac biomarkers and echocardiographic parameters<sup>[19,21,22]</sup>, a reduced length of hospital stay and frequency of re-hospitalizations<sup>[23]</sup> and a good safety profile<sup>[24]</sup>.

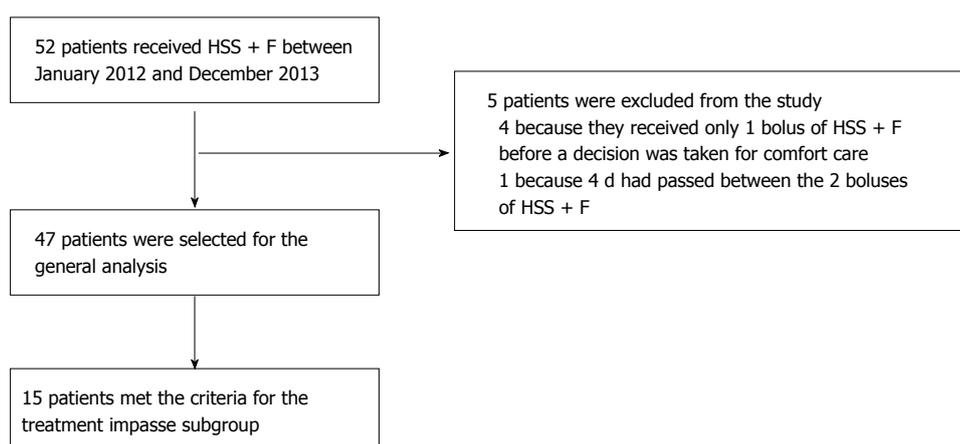

Therefore, the aim of the present report was to test the safety and effectiveness of HSS + F as a strategy for weight loss and prevention of further deterioration of renal function compared to the usual intensive treatment with intravenous furosemide alone.

## MATERIALS AND METHODS

Patients admitted with ADHF and who received HSS + F between January 2012 and December 2013 at the Quebec University Hospital Centre were included for the analysis. The decision to prescribe HSS + F following the standard treatment for a given patient was left to the discretion of the treating cardiologist,

who had received at the beginning of the study a list of the suggested inclusion and exclusion criteria (Figure 1). All clinical, echocardiographic and laboratory data were prospectively collected in a dedicated database. Institutional review board approval and patient consent were not required because of the nature of this study.

### Intervention

On admission for ADHF, most patients were on fluid restriction of 1.5 L/d, received an intravenous furosemide dose that was adjusted according to the clinical response and the conventional HF treatment that was considered appropriate by the treating physician based on current recommendations<sup>[25,26]</sup>. When patients were considered to be refractory to this treatment, based on a poor response to standard therapy (weight, creatinine, clinical judgment), intravenous furosemide was replaced by an intravenous infusion of HSS + F (150 mL of 3% NaCl + 250 mg of furosemide) administered

over one hour twice a day for a suggested period of 48 h that could be extended or shortened depending on the clinical response. Patients underwent the usual daily medical examination for the evaluation of the signs and symptoms of HF. Vital signs and weight were recorded daily; serum creatinine, sodium (Na) and potassium (K) levels were closely monitored during treatment. Moreover, the clinician's impression concerning the treatment effectiveness was recorded in the medical notes. Patients were all compared to themselves with a before and after study design. The effects of treatment with intravenous furosemide alone (standard treatment) were compared to the treatment with intravenous furosemide plus HSS (HSS + F) (experimental treatment) administered following the standard treatment. The results available from days one to four prior to the initiation of saline treatment were analyzed and compared to the experimental treatment d (Figure 2).

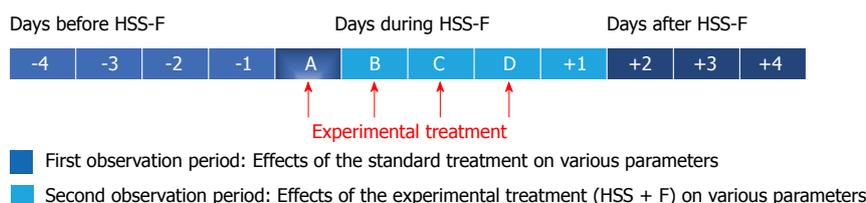

Figure 3 Flow diagram of participants in the study. HSS: Hypertonic saline solution.

### Outcomes

Our primary outcomes were the decrease in weight and the change of creatinine per day of treatment. Secondary outcomes were the effect of the experimental treatment on the serum Na and K levels and its safety profile regarding neurological events.

### Subgroup analysis

The effects of HSS + F on weight and creatinine were studied in the “treatment impasse” subgroup defined as all patients with increased weight and creatinine per day of treatment despite standard therapy.

### Statistical analysis

Continuous data are presented as mean  $\pm$  SD or median [interquartile range (IQR)] depending on variable distribution, and categorical data are presented as frequencies (percentage). Differences between the weight reduction in the experimental treatment and the standard treatment periods were assessed by Wilcoxon Signed Rank test for paired samples. The same approach was used for all other analyses as the change of creatinine per day of treatment between these two periods and analyses in the “treatment impasse” subgroup. The level of statistical significance was set as  $P < 0.05$ . Data were analyzed using the SAS statistical software, version 9.3.

## RESULTS

A total of 52 patients received HSS + F for ADHF. Five patients were excluded from the study; four because they received one bolus of HSS + F before the decision of giving end-of-life comfort care only, and one patient was not selected because four d had elapsed between the two boluses of HSS + F, making interpretation difficult.

Hence, a total of 47 patients (32 men, 68%), mean age of  $77.6 \pm 9.5$  years, were included in the study (Figure 3). Thirty-two (68%) patients had chronic kidney disease based on an estimated GFR (eGFR)  $\leq 60$  mL/min per  $1.73 \text{ m}^2$ . Moreover, the mean creatinine was  $155 \pm 65 \mu\text{mol/L}$ , leading to an eGFR of  $42 \pm 22$  mL/min per  $1.73 \text{ m}^2$  on admission. Of note, 12 (25.5%) presented with a serum Na  $< 135$  mmol/L. The left ventricle ejection fraction (LVEF) was  $40\% \pm 17\%$  and half of the patients had  $\leq 40\%$  (Table 1). In addition, 31 patients had pleural effusion, 11 had ascites, 11 presented with arterial hypotension and/or orthostatic

hypotension and 13 had acute kidney injury defined as a 1.5-fold increase in serum creatinine or absolute increase in serum creatinine of  $\geq 26.4 \mu\text{mol/L}$  from their baseline value<sup>[27,28]</sup>.

Before receiving HSS + F, six (12.8%) patients required non-invasive ventilation and three (6.4%) patients were intubated for respiratory failure, but no form of mechanical ventilation was initiated during treatment with HSS + F. In addition, eight (17%) patients had a thoracentesis during hospitalization (two during the HSS + F treatment period and six outside of the observation period) and four (8.5%) patients had a paracentesis (two during the standard treatment and none during the HSS + F treatment). Moreover, eight (17%) patients received an infusion of inotropes, but only three during the observation period (one during the experimental treatment, one throughout the two treatments studied and the remaining during the standard treatment only). Six (12.8%) patients underwent coronary angiography during hospitalization, but only two patients had it during the observation period (one during the standard treatment and the other had two coronary angiograms: One before and another during treatment with HSS + F).

### Intervention

Patients received a mean of  $5.1 \pm 2.0$  doses of HSS + F for a mean duration of  $2.3 \pm 1.0$  d. During the treatment period with HSS + F, patients lost  $3.9 \pm 3.8$  kg. Interestingly, the treating physician reported a significant improvement in signs and symptoms of congestion with this experimental treatment on 38 (81%) patients. In addition, weight loss per day of treatment was significantly greater with HSS + F treatment than with the standard treatment ( $-1.4 \pm 1.4$  kg/d vs  $-0.4 \pm 1.0$  kg/d, mean difference of  $0.8 \pm 1.8$  kg/d,  $P = 0.0168$ ) (Table 2). The change in creatinine per day of treatment was not statistically different between treatments (Table 2). The mean serum Na increased by 2.4 mmol/L (95%CI: 1.6-3.1,  $P < 0.0001$ ) and the mean serum K decreased by 0.2 mmol/L (95%CI: -0.4 to -0.1,  $P = 0.0001$ ) with the experimental treatment compared to the standard treatment. The mean daily dose of intravenous furosemide given during the standard treatment period was  $106 \pm 67$  mg. Four patients received an additional continuous infusion of furosemide for a mean duration of 2.3 d. Nine patients received mainly oral furosemide, with a correspondingly larger mean daily

<sup>1</sup>Average of the five most recent creatinine values before hospitalization. Values are expressed as mean ± SD or *n* (%). NYHA: New York Heart Association; COPD: Chronic obstructive pulmonary disease; eGFR: Estimated glomerular filtration rate; MDRD: Modification of Diet in Renal Disease equation; LVEF: Left ventricle ejection fraction; ACEI: Angiotensin-converting-enzyme inhibitor; ARBs: Angiotensin II receptor blockers.

dose of 196 ± 165 mg. Seven doses of metolazone were given during the standard treatment and 7 doses during the experimental treatment.

The administration of HSS + F was well tolerated by all patients and no major adverse events were observed. It is noteworthy to be highlighted that there was no pulmonary congestion or neurological consequences due to HSS + F strategy. However, the HSS + F treatment was discontinued in 2 (4.3%) patients due to an excessive increase in serum Na (*i.e.*, from 120 mmol/L to 128 mmol/L) in 1 patient and a significant decrease in blood pressure for the other.

A total of 7 (15%) patients died during the hospital stay. The median time between death and the end

**Table 2** Weight loss and creatinine change per day of treatment (*n* = 47)

Variable	mean ± SD	95%CI	<i>P</i> value
Weight loss (kg/d)			
Standard treatment	-0.39 ± 1.02	(-0.77, -0.03)	
Experimental treatment	-1.43 ± 1.43	(-1.86, -1.02)	
Standard-experimental difference	0.80 ± 1.77	(0.15, 1.44)	0.0168
Change in creatinine (μmol/L per day)			
Standard treatment	3.48 ± 9.89	(0.51, 6.68)	
Experimental treatment	-0.69 ± 9.62	(-3.51, 2.00)	
Standard-experimental difference	4.20 ± 14.25	(-0.49, 8.88)	0.331

of treatment with HSS + F was 3 (IQR: 1-33) d. However, two of these deaths were attributed to a shift to end-of-life palliative care requested by the family (treatment with HSS + F originally scheduled for 48 h was discontinued). The average hospital stay was 20 ± 12 d with a median of 16 (IQR: 11-24) d.

Notably, in the impasse treatment subgroup (*n* = 15), consisting of patients selected because of their negative response to the standard treatment, in addition to a significant weight loss achieved with the experimental treatment (-1.2 kg/d ± 1.3 kg/d vs -0.3 kg/d ± 0.6 kg/d with the standard treatment, mean difference of 1.5 kg/d ± 1.7 kg/d, *P* = 0.0026), there was an increase in creatinine level with the standard therapy that was not seen with the experimental therapy; indeed, the mean creatinine difference was also statistically significant (11 ± 13 μmol/L per day, *P* = 0.008) (Table 3).

## DISCUSSION

In a population of patients admitted with ADHF, the administration of HSS + F led to a greater weight loss per day of treatment compared to the standard intravenous furosemide strategy; even if a considerable proportion of them presented HF with preserved LVEF and/or advanced renal failure.

The difference in weight loss achieved through treatment with HSS + F is comparable to that demonstrated in previous studies<sup>[16,18,19,21-23,29,30]</sup>. Among these studies, the difference between the average in weight loss in the group treated with HSS + F compared to the group treated with intravenous furosemide alone ranged from 0.3-5.6 kg<sup>[21,30]</sup>. Because patients generally had some weight loss with the treatment with intravenous furosemide alone before starting treatment with HSS + F, it is possible that we have underestimated the weight loss due to HSS + F that could have been achieved without the prior use of intravenous furosemide alone.

We were unable to demonstrate a statistically significant difference in terms of creatinine, although it tended to decrease with the experimental treatment while the trend was reversed with the standard treatment. It has been previously shown an increase in

**Table 3** Weight loss and creatinine change per day of treatment in the impasse subgroup (*n* = 15)

Variable	mean ± SD	95%CI	P value
Weight loss (kg/d)			
Standard treatment	0.25 ± 0.64	(-0.04, 0.58)	
Experimental treatment	-1.20 ± 1.30	(-1.89, -0.57)	
Standard-experimental difference	1.45 ± 1.65	(0.54, 2.36)	0.0026
Change in creatinine (μmol/L per day)			
Standard treatment	7.33 ± 8.65	(3.01, 11.70)	
Experimental treatment	-3.79 ± 11.34	(-10.41, 1.63)	
Standard-experimental difference	11.13 ± 13.29	(3.77, 18.49)	0.008

creatinine among those treated with intravenous furosemide alone, while there is either a decrease in creatinine in patients treated with HSS + F<sup>[16,18,22,23]</sup> or a mild increase that is less than furosemide alone<sup>[19,21,30]</sup>. It is noteworthy to be outlined that the lack of statistical significant in creatinine levels may be explained in part by the inclusion of patients with advanced renal failure. Indeed, Engelmeier *et al.*<sup>[29]</sup> recruited patients with advanced renal failure (eGFR < 40 mL/min) and did not demonstrate a significant advantage of using HSS for the prevention of worsening renal function. Moreover, another study showed that HSS affords a protective role in the deterioration of renal function induced by loop diuretics, but does not exert a substantial protective effect in patients with ADHF who have pre-existing advanced renal failure and exhibiting a mean creatinine  $\geq 194$  μmol/L<sup>[15]</sup>. However, in our study, the renal function of many patients worsened during treatment with intravenous furosemide alone, so the change in creatinine during treatment with HSS + F could be a reflection of the previous treatment.

Treatment with HSS + F was well tolerated and its safety profile was reassuring as demonstrated in previous studies<sup>[18,24]</sup>. Of note, although we did not adjust the Na concentration in the HSS depending on the patient's serum Na as done in most studies, there were no severe electrolyte disturbances, except in one patient who had an increase in serum Na of 8 mmol/L within 24 h, but without any neurological symptoms or further consequences. Our results indicate that serum Na levels should be monitored, but adjusting the tonicity of the HSS based on the serum Na level may not be necessary. This facilitates the administration of HSS and reduces the risk of errors.

The result for the impasse subgroup, with few available treatment options, is of particular interest. Those patients, who increased their weight and creatinine while treated with intravenous furosemide alone, had benefited from the therapy in terms of weight loss and renal function.

The use of parenteral inotropes in a number of patients hospitalized for HF is potentially deleterious and requires tighter monitoring<sup>[31]</sup>. Moreover, the treatment of advanced ADHF by ultrafiltration or intravenous inotropes is not associated with a better prognosis and is limited

by the cost and availability<sup>[11-14]</sup>. Therefore, according to some studies<sup>[19,30]</sup>, simultaneous administration of appropriate doses of HSS during treatment with intravenous diuretics reduce diuretic resistance, which in fact, is the phenomenon of a decrease in the natriuretic response and thus, requires the use of further increasing doses of diuretics that often results in the deterioration of renal function<sup>[3]</sup>. Hence, the administration of small intravenous boluses of HSS associated with intravenous furosemide is a valid and inexpensive therapeutic option.

### Limitations

The main limitation of this study lies with the fact of a small sample size and even prospective, the non-randomized nature of the study. Therefore, the fact that certain clinical variables that appeared to account more frequently in some group but finally did not reach statistical significance were related to the small sample size. Patients were compared to themselves under the standard and experimental treatments, and the latter being influenced by the previous one. In addition, since the standard treatment was at the discretion of the clinician, the doses of furosemide, the doses of other drugs and the use of thoracentesis or paracentesis were not the same for both treatments. Thus, confirming these results in a larger series of randomized patients might have a high impact on patient selection and clinical decision-making in this high-risk group of patients.

In conclusion, the results of this study support the effectiveness of HSS + F on weight loss. The safety profile, particularly with regard to renal function, leads us to believe that HSS + F may be a valuable option for those patients presenting with ADHF who do not respond to conventional treatment with intravenous furosemide alone.

## COMMENTS

### Background

Compared to the administration of high doses of furosemide monotherapy, the concomitant use of hypertonic saline solution (HSS + F) has shown, in some single-centre studies, clinical benefits and a good safety profile in patients with acute decompensated heart failure (ADHF).

### Research frontiers

Patients can develop resistance to diuretics and congestive symptoms may persist despite treatment with high doses of furosemide.

### Innovations and breakthroughs

This study supports the effectiveness of HSS + F on weight loss in patients with ADHF.

### Applications

The safety profile, particularly regarding renal function, leads us to believe that HSS + F may be a valuable option for those patients presenting with ADHF who do not respond to conventional treatment with intravenous furosemide alone.

### Terminology

This study aims to test the safety and effectiveness of HSS + F as a strategy for

weight loss and prevention of further deterioration of renal function.

### Peer-review

This is a well-written manuscript about the treatment of severe acute heart failure.

## Abstract

### AIM

To extend our previously-published experience in estimating pressure gradients (PG) *via* physical examination in a large patient cohort.

### METHODS

From January 1, 1997 through December 31, 2009, an attending pediatric cardiologist compared clinical examination (EXAM) with Doppler-echo (ECHO), in 1193 patients with pulmonic stenosis (PS, including tetralogy of Fallot), aortic stenosis (AS), and ventricular septal defect (VSD). EXAM PG estimates were based primarily on a murmur's pitch, grade, and length. ECHO peak instantaneous PG was derived from the modified Bernoulli equation. Patients were 0-38.4 years old (median 4.8).

### RESULTS

For all patients, EXAM correlated highly with ECHO: ECHO = 0.99 (EXAM) + 3.2 mmHg;  $r = +0.89$ ;  $P < 0.0001$ . Agreement was excellent (mean difference =  $-2.9 \pm 16.1$  mmHg). In 78% of all patients, agreement between EXAM and ECHO was within 15 mmHg and within 5 mmHg in 45%. Clinical estimates of PS PG were more accurate than of AS and VSD. A palpable precordial thrill and increasing loudness of the murmur predicted higher

gradients ( $P < 0.0001$ ). Weight did not influence accuracy. A learning curve was evident, such that the most recent quartile of patients showed  $ECHO = 1.01 (EXAM) + 1.9$ ,  $r = +0.92$ ,  $P < 0.0001$ ; during this time, the attending pediatric cardiologist had been  $> 10$  years in practice.

### CONCLUSION

Clinical examination can accurately estimate PG in PS, AS, or VSD. Continual correlation of clinical findings with echocardiography can lead to highly accurate diagnostic skills.

**Core tip:** Knowing pressure gradients across valves, arteries, and ventricular septal defects is important to clinical management of patients. In a large cohort of patients, we have determined the high degree of accuracy of the physical examination against the benchmark Doppler echocardiography. We discuss this clinical approach in the context of clinical practice, technology, and healthcare costs.

Kadle RL, Phoon CKL. Estimating pressure gradients by auscultation: How technology (echocardiography) can help improve clinical skills. *World J Cardiol* 2017; 9(8): 693-701 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i8/693.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i8.693>

## INTRODUCTION

Strong clinical skills, including history-taking and physical diagnostic skills, remain an important part of patient evaluation - central to the practice of medicine. The clinical skills required for auscultation are especially important in childhood, when more than 50% of children have heart murmurs, most of which are benign<sup>[1,2]</sup>. In recent years however, there have been a decline in clinical examination skills and an increasing reliance on diagnostic testing<sup>[3-7]</sup>.

The gradual loss of emphasis on physical exam skills has several implications<sup>[8-11]</sup>. The physical exam is an integral part of the doctor-patient relationship, and can also garner otherwise unattainable observations and findings. Additionally, the information obtained from the physical exam can help delineate the need for further testing. Although there have been several initiatives to minimize wasteful testing by focus on clinical examination<sup>[12-14]</sup>, few groups have described specific and learnable techniques to do so.

In this follow-up to a small pilot study<sup>[15]</sup>, our objectives of this study were several-fold. We hoped

to further validate our technique of estimating peak pressure gradients through auscultation with a much larger cohort of patients. We also hoped to debunk the idea that the physical exam has a dwindling role in medicine; we believe its use in conjunction with technology can allow for a more accurate clinical assessment. We also hoped to determine the specific situations and characteristics associated with a more accurate physical exam, allowing others to learn this technique as well.

## MATERIALS AND METHODS

The methods are essentially as detailed in our previous report<sup>[15]</sup>. This study was approved by the Institutional Review Boards at NYU Langone Medical Center and Bellevue Hospital Center (both located in New York, NY, United States). Including our initial cohort of 151 patients<sup>[15]</sup>, a total of 1193 consecutive patients with pulmonary stenosis (PS,  $n = 563$ ), aortic stenosis (AS,  $n = 234$ ), or ventricular septal defect (VSD,  $n = 396$ ) were studied by both auscultation and Doppler echocardiography over a 13-year period between February 1997 and December 2009. Not all patients were diagnosed with these lesions at the visits; some were "first" visits, but the physical examination was characteristic for valvar stenosis or VSD, and therefore a clinical estimate of the pressure gradient could be made even before a diagnosis was established by echocardiography. All levels of PS (including tetralogy of Fallot) and AS, all types of VSDs, and residual lesions after surgical or transcatheter interventions were included. In our patient population, the AS seen was congenital, rheumatic, or postoperative, not the fibrocalcific AS seen in older patients. "Complex" AS or PS (as opposed to valvar AS or PS) denotes non-valvar stenosis, or multi-level stenosis; examples include the PS in patients with tetralogy of Fallot, subvalvular AS and supra-valvular AS. It has been standard clinical practice in our pediatric echocardiography laboratory for the author (CKLP), an attending echocardiographer, to examine every patient briefly as time permits; it is felt by at least some echocardiographers, including the author, that this preliminary examination (which may include palpation and auscultation, especially of the heart sounds and murmurs) improves the reliability of the echocardiographic study. This physical examination helps to assess the degree of clinical suspicion and to focus the requested echocardiogram. For lesions with pressure gradients, the author routinely estimates a pressure gradient (see below) before the echocardiographic study. It should be noted this study was started (1997) only 1.5 years following the completion of clinical fellowship training by CKLP; therefore, at the completion of data acquisition (2009), 13.5 years had elapsed since completion of training.

The auscultatory pressure gradient was estimated by an "auscultatory scale" based predominantly on

**Table 1 Summary table of key findings for pulmonary stenosis, aortic stenosis, and ventricular septal defect**

Lesion	<i>n</i>	Mean gradient (mmHg)	Agreement to: ≤ 15 mmHg	≤ 10 mmHg	≤ 5 mmHg	<i>r</i>
Pulmonary stenosis						
PS (all)	563	42 ± 28	82%	70%	49%	0.85
Valvar PS	313	36 ± 22	89%	77%	56%	0.85
Complex PS	250	49 ± 32	72%	61%	40%	0.84
PVR	81	48 ± 25	84%	65%	42%	0.86
Aortic stenosis						
AS (all)	234	38 ± 24	81%	71%	49%	0.8
Valvar AS	112	42 ± 24	77%	68%	46%	0.76
Complex AS	122	34 ± 23	85%	75%	52%	0.85
AVR	34	46 ± 22	71%	65%	38%	0.71
Ventricular septal defect						
VSD	396	83 ± 31	70%	60%	36%	0.82

“Complex” AS or PS denotes non-valvar stenosis or multi-level stenosis, such as the PS observed in patients with tetralogy of Fallot. AS: Aortic stenosis; AVR: Aortic valve replacement; CHD: Congenital heart defects; PS: Pulmonary stenosis; PVR: Pulmonary valve replacement; VSD: Ventricular septal defect.

a murmur’s perceived predominant frequencies and frequency spread<sup>[15,16]</sup>. A stethoscope is inched around the chest until the highest frequencies of a murmur are heard. These frequencies are then used to estimate the pressure gradient. As the examiner continued to gain clinical experience, other components of auscultation were incorporated into the clinical estimate of the pressure gradients, including murmur loudness and length. Short murmurs generally comprised < 50% of systole, medium-length 50% to < 100% of systole with a crescendo-decrescendo quality, and long/holosystolic 100% of systole. Gradients were estimated in 5 mmHg range increments (for example, 5-10 mmHg or 25-30 mmHg) and then recorded as a midpoint value [5-10 (= 8 mmHg), 25-30 (= 28 mmHg), etc.]. In the remainder of this article, the terms “auscultation” and “auscultatory gradient” will refer to this technique of assessing the frequency composition of a murmur unless otherwise specified.

To avoid bias, the auscultatory gradient was recorded before Doppler echocardiography, and the Doppler examination was performed by a pediatric cardiac sonographer who was unaware of the auscultatory estimate. Echocardiograms performed solely by the author were excluded. In standard fashion, the Doppler beam was aligned as parallel as possible with the blood flow jet, without angle correction, interrogating for the maximal flow velocity from multiple views. The peak instantaneous Doppler pressure gradient was calculated with the modified Bernoulli equation. Any perceived inconsistencies between the auscultatory gradient and the echocardiographic results were resolved with further imaging.

Ideally, patients should be in a calm resting state for both the auscultatory examination and the echocardiogram because changes in activity level will change the cardiac output and therefore flow characteristics, including gradients. Because we do not routinely use conscious sedation, we examined patients in as calm a state as possible, recognizing that

variability in the resting state will introduce variability into our assessments.

Age, weight, diagnoses, and history of interventions were obtained from the patient reports.

The relationship between the auscultatory and Doppler pressure gradients was assessed by simple linear regression. Agreement was assessed by Bland-Altman analysis<sup>[17]</sup>. Results are expressed as mean ± SD. Differences were analyzed with a 2-tailed Student *t* test. Comparison of categorical variables was performed with chi-square analysis or Fisher’s exact test. Statistical significance was set at *P* < 0.05.

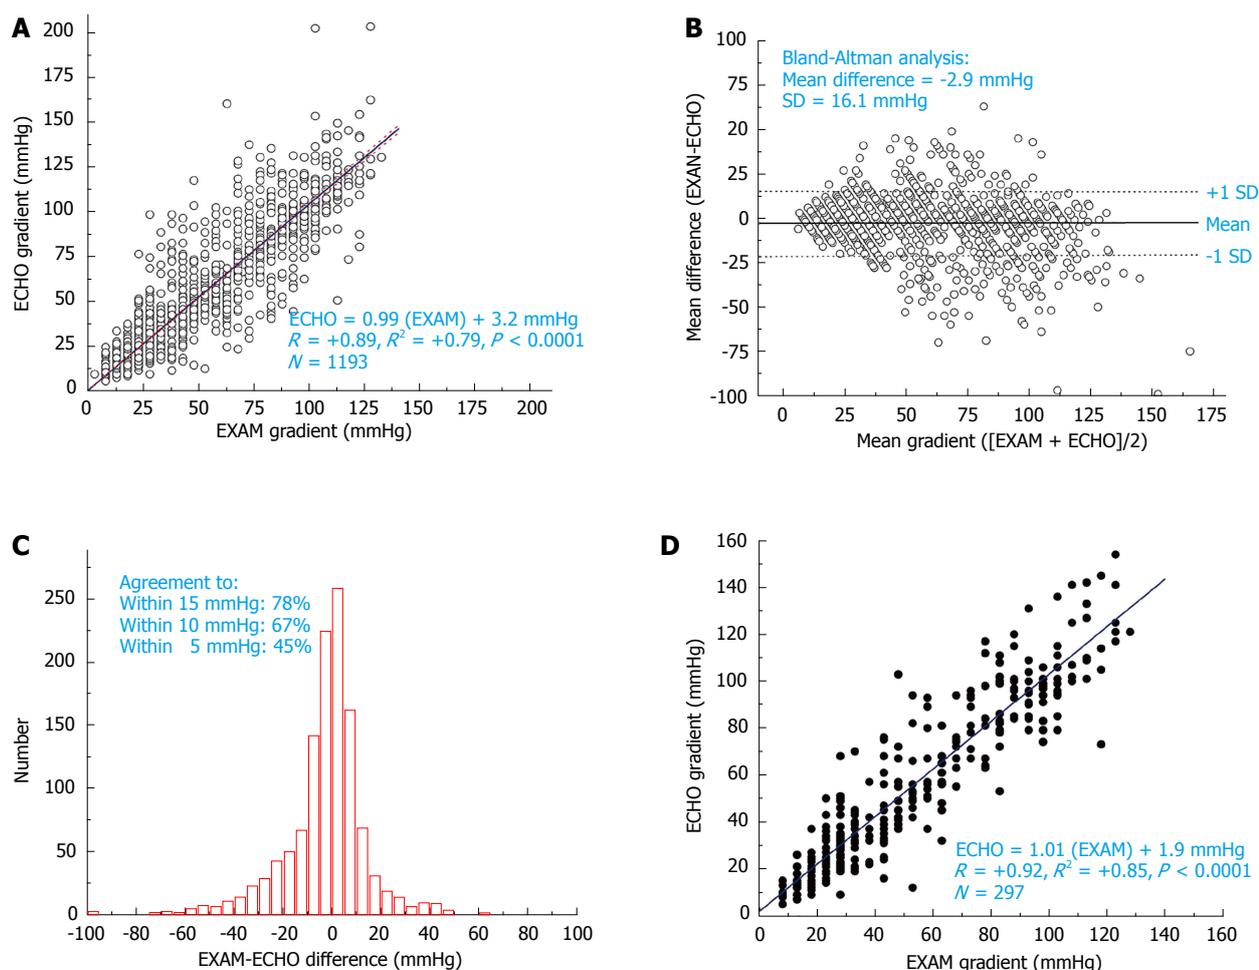

## RESULTS

### Patient demographics

Patients were 0-38.4 years old (mean 6.8 years, median 4.8), weighing 0.83-129 kg (mean 26.8 kg, median 18.2). There were 339 patients between 0-1 years of age (infants); 270 patients > 1 year-5 years (toddlers and young children); 311 patients between > 5 years-12 years (school-age children); 200 patients between 12-18 years (adolescents); and 73 patients older than 18 years (adults).

### Accuracy and correlations of various congenital cardiac conditions

For all patients, auscultation correlated highly with echocardiography: ECHO= 0.99 (AUSC) + 3.2 mmHg; *r* = +0.89 (*r*<sup>2</sup> = +0.79); *P* < 0.0001 (Figure 1A). Agreement was excellent [mean difference between clinical exam and echo = -2.9 ± 16.1 mmHg (SD), also as seen in the Bland-Altman analysis, Figure 1B]. In 78% of all patients, agreement between auscultation and echocardiography was within 15 mm Hg; in 67%, within 10 mmHg; and in 45%, within 5 mmHg (Figure 1C). Clinical estimates of PS pressure gradients were more accurate than of AS and VSD (Table 1). Valvar PS appeared to be more accurately estimated than other lesions, and VSD showed the worst agreement overall.

**Figure 1 Accuracy and correlations of various congenital cardiac conditions.** A: Regression plot of all patients; B: Bland-Altman plot; C: Histogram displaying spread between the Doppler and physical examination gradients, and the agreement between Doppler and physical examination to within 15, 10, and 5 mmHg; D: Regression plot of most recent quartile of patients.

A learning curve was evident. Overall agreement and correlation in the original published cohort of 151 patients [ $ECHO = 0.99 (AUSC) + 7.12$ ,  $r = +0.84$  ( $r^2 = +0.71$ )] were worse (Phoon 2001); the most recent quartile of patients showed  $ECHO = 1.01 (AUSC) + 1.9$ ,  $r = +0.92$  ( $r^2 = +0.85$ ),  $P < 0.0001$  ( $n = 297$ ) (Figure 1D). The initial cohort<sup>[15]</sup> corresponded to a time period from early 1997 through mid-1998, while the most recent quartile of data corresponded to a time period from mid-2007 through end of 2009; thus, there was a 10-year difference in clinical experience.

**Correlates with patient factors affecting accuracy**

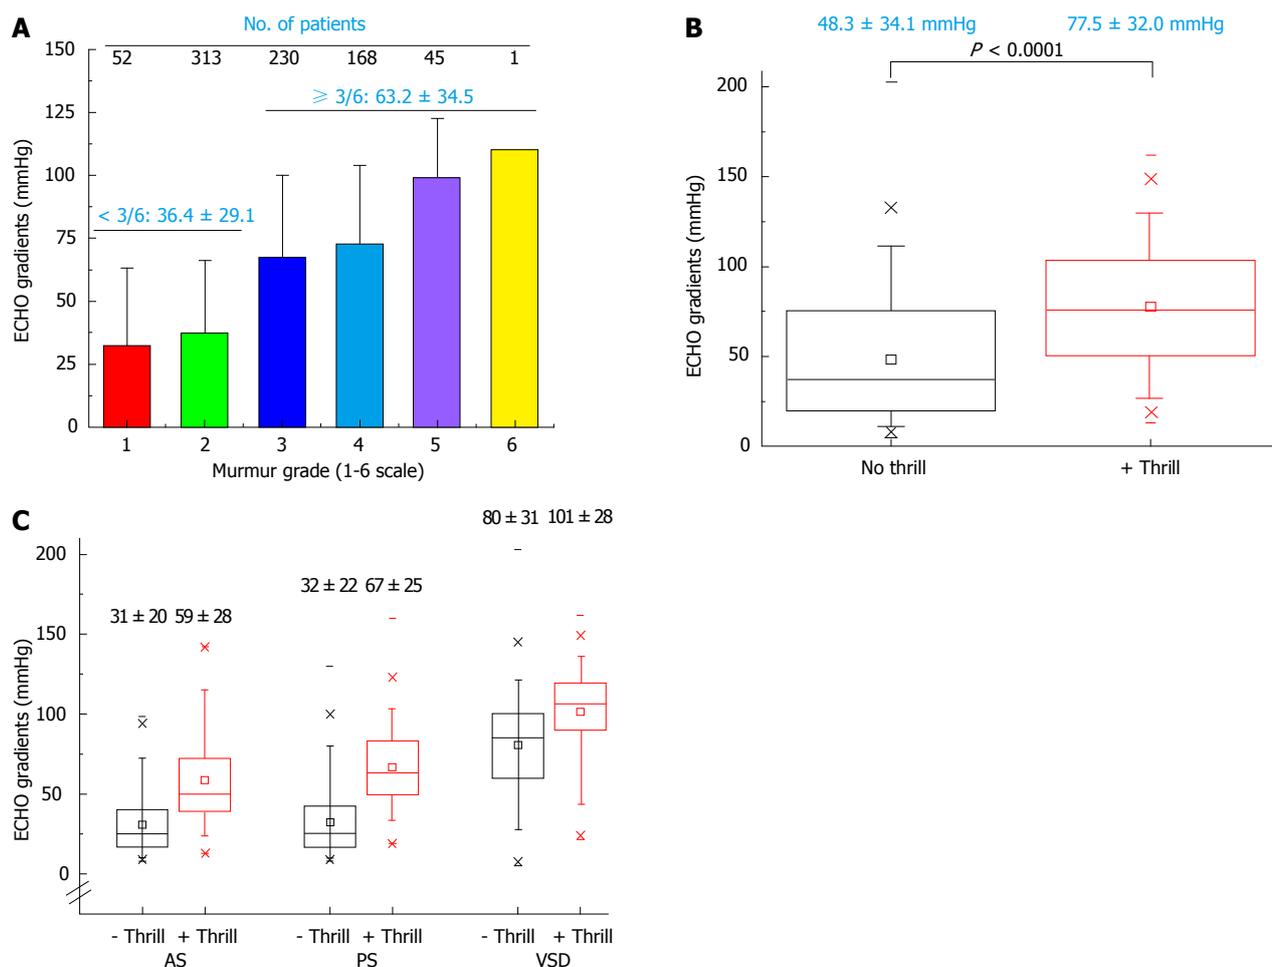

Increasing loudness of the murmur (standard 1-6 grade scale) predicted higher gradients ( $r = +0.54$ ,  $P < 0.0001$ ), with the largest gap occurring between grades 2 (mean PG:  $36 \pm 29$  mmHg) and 3 (mean PG:  $63 \pm 35$  mmHg) (Figure 2A). Similarly and as expected, a palpable precordial thrill predicted significantly higher gradients [all  $P < 0.0001$ : PS:  $32 \pm 22$  mmHg (no thrill) vs  $67 \pm 25$  (+thrill); AS:  $31 \pm 20$  vs  $59 \pm 29$ ; VSD:  $80 \pm 31$  vs  $101 \pm 28$ ] (Figure 2B, C). Despite the highly significant differences in patients

with and without a palpable precordial thrill, there was considerable overlap in the pressure gradients. Possible influencing factors are shown in Table 2. Heavier weight and prior surgery did not appear to influence accuracy. Infants and young toddlers appeared to be less accurately assessed. Although a previous echocardiogram (and therefore possibly knowledge of the previous gradient) exhibited a better correlation, the correlation coefficient even during a “first” visit was very high (Table 2).

In several cases, the physical examination “trumped” the echocardiogram, although this represented a small percentage of all patients. Nearly all were VSD’s, for which Doppler echocardiography underestimated the predicted peak gradient due to a suboptimal Doppler incident angle (Table 3). In such cases, the VSD gradient alone would have predicted the presence of pulmonary hypertension.

**DISCUSSION**

This large dataset extends our previous observations and confirms that physical examination, relying mainly

**Figure 2** Correlates with patient factors affecting accuracy. A: Loudness of heart murmur (standard grade system, 1-6) plotted against peak Doppler (“ECHO”) gradient; B: Box-and-whiskers plot of Doppler peak gradients in the absence and presence of a palpable thrill, all patients; C: Box-and-whiskers plots of specific congenital lesions (aortic stenosis, pulmonic stenosis, ventricular septal defect), thrill absent vs thrill present.

on auscultation, can be very accurate in determining pressure gradients. We emphasize that our purpose was not to diagnose specific conditions *de novo*, but to evaluate pressure gradients clinically. Other studies have previously demonstrated that the cardiac physical exam, specifically auscultation, can accurately distinguish benign from pathologic murmurs<sup>[15,18-24]</sup>. Although these studies look at auscultation in general, they do not specifically analyze pressure gradients. We have now in more detail analyzed some of those aspects of clinical auscultation, as well as patient characteristics, which impact the accuracy of the physical examination. A key finding in this study is how technology - in this case, echocardiography - can help improve clinical skills, presumably by providing feedback to the examiner.

#### Comparison of different lesions: PS, AS, VSD

Pressure gradients have been examined in dogs, and have been found to both correlate with echocardiographic findings<sup>[25-28]</sup> and be associated with severity of disease<sup>[29]</sup>. These studies corroborate the validity of our findings, and we further show its applicability to human subjects. Several groups have

shown that examination can diagnose both AS and PS successfully<sup>[30-36]</sup>. Diagnosis of VSDs by clinical exam is also accurate but can be imperfect for major VSDs<sup>[37]</sup>. Our study takes these analyses further by laying out a specific auscultatory technique to assess heart murmurs, and by continually correlating clinical findings with echocardiographic data to improve accuracy. We demonstrate that auscultation has the greatest accuracy in predicting pressure gradients in PS, and is still accurate but less so in VSD. We speculate that the murmur of PS is consistently directed in a similar direction in nearly all patients, whereas VSD jets would exhibit far more variability that may change their auscultatory characteristics. We additionally experienced several cases in which echocardiography underestimated the severity of the murmur, or missed the etiology of a murmur completely, demonstrating the significance of auscultation in a clinical exam.

#### When to be careful: Accuracy is affected by certain patient variables

Several auscultatory characteristics have been identified to predict pathologic disease, such as holosystolic timing, harshness, grade 3 or more, or palpable

**Table 2 Summary table of variables that might affect accuracy of clinical estimates of gradients**

Variable	n	Mean gradient (mmHg)	Agreement to: ≤ 15 mmHg	≤ 10 mmHg	≤ 5 mmHg	r
Weight						
≤ 10 kg	367	61 ± 32	71%	61%	42%	+0.81
> 10 to 20 kg	270	57 ± 36	79%	69%	46%	+0.92
> 20 to 40 kg	236	53 ± 38	81%	71%	48%	+0.91
> 40 to 70 kg	237	49 ± 34	81%	67%	42%	+0.91
> 70 kg	82	45 ± 35	85%	74%	48%	+0.88
Age						
< 2 yr	414	60 ± 32	71%	62%	42%	+0.83
≥ 2 yr	779	52 ± 36	81%	70%	46%	+0.91
Prior echo?						
No prior	321	61 ± 36	72%	64%	43%	+0.85
+Prior	872	53 ± 35	79%	68%	45%	+0.90
Operative status (all CHD)						
No operative	688	65 ± 37	74%	64%	43%	+0.89
Post-operative	505	42 ± 27	82%	70%	46%	+0.87

CHD: Congenital heart defects.

**Table 3 Examples of cases when physical examination “trumped” echocardiography or echocardiography presented misleading data**

Case	Age (yr)	Lesion	Clinical Gradient	DOPP Gradient	Comment
1	6.7	Supravalvar PS s/p repair of TOF with homograft from RV to PA	63	24	Homograft poorly visualized; tricuspid regurgitation jet predicted a systolic RV pressure of 66 mmHg plus the right atrial v-wave, so the PS gradient was significantly underestimated by DOPP
2	6.9	VSD, s/p repair of TOF	70	66	Prior echocardiograms did not visualize VSD; exam led to finding of a tiny residual VSD
3	10.8	VSD	88	63	Poor DOPP incident angle predicted pulmonary hypertension
4	0.005	VSD	68	NA	VSD was so tiny and anterior, a jet could not be obtained for a DOPP gradient
5	4.3	VSD	73	61	BP 104/50; poor DOPP incident angle predicted pulmonary hypertension
6	0.01	VSD	88	48	Technician obtained initial VSD DOPP gradient of 28 mmHg; exam prompted a search for a better DOPP angle
7	2.8	VSD	83	55	Poor DOPP incident angle predicted pulmonary hypertension; tricuspid regurgitation jet predicted normal PA pressures
8	5.5	VSD, s/p repair	98	62	Poor DOPP incident angle predicted pulmonary hypertension; tricuspid and pulmonary regurgitation jets predicted normal PA pressures
9	3.8	VSD	73	53	Poor DOPP incident angle predicted pulmonary hypertension; tricuspid regurgitation jet predicted normal PA pressures
10	15.4	VSD, Shone’s complex with minimal LV outflow tract obstruction	93	63	Poor DOPP incident angle predicted pulmonary hypertension
11	15.7	VSD	118	73	Poor DOPP incident angle predicted pulmonary hypertension, even though the VSD was 2.8 mm in diameter; tricuspid and pulmonary regurgitation jets predicted normal PA pressures

BP: Blood pressure; DOPP: Doppler echocardiography; LV: Left ventricular; PA: Pulmonary artery; PS: Pulmonary stenosis; RV: Right ventricular; TOF: Tetralogy of Fallot; VSD: Ventricular septal defect.

precordial thrill<sup>[24,38]</sup>. We confirmed such factors can be used to estimate pressure gradients clinically, specifically the loudness of the murmur and the presence of a palpable thrill. Somewhat surprisingly, neither heavier weight nor prior surgery worsened clinical accuracy, even though we had wondered if adipose or scar tissue would impact the auscultated frequency spectrum of heart murmurs.

We believe several teaching points can be made from our data. Although the data exhibit much overlap, the presence of a precordial thrill may help differentiate higher gradients in PS and AS, although this appears to be much less useful with VSD’s. For both PS and AS,

the presence of a thrill is likely to indicate a pressure gradient of > 40-45 mmHg. Infants and toddlers also are more difficult to assess clinically.

**Philosophical and practical issues**

Our study raises the question of whether clinical skills such as these are important in the current era of medical practice. It is debatable or even unlikely a study such as this will impact use of technology or healthcare costs significantly. Nevertheless, it is our impression that: (1) some cases were diagnosed based primarily on clinical findings, and echocardiography played a limited or initially misleading role; and (2)

our data exposes some strengths and weaknesses of the cardiac physical examination with regards to estimating pressure gradients. We and others continue to believe the gradual loss of emphasis on physical exam skills has several implications.

The physical exam is a central part of the doctor-patient relationship. The intimate contact of a physical exam not only gives the patient a sense of comfort and confidence in their physician, but can itself help the patient heal<sup>[10,11,39,40]</sup>. Besides the desired dynamic bedside skills help to create, there is also a great deal of information obtained through the physical exam that might otherwise be lost<sup>[11,41]</sup>. Many clinical signs and symptoms cannot be classified by technology alone, and can only be appreciated with a thorough physical exam. Fred discussed the implications of over-reliance on CT scans in the diagnosis of patients, including delays in treatment by waiting for a CT scan to confirm a diagnosis that can be made by physical examination alone<sup>[9]</sup>. McGee described several instances where the physical exam bested technological testing, including reactive arthritis and pericarditis<sup>[42]</sup>.

However, as Verghese *et al.*<sup>[39]</sup> argue, it is not a fight of physical exam skills vs technology, but the attempt to merge these two to produce the optimal comprehensive exam. Ippisch *et al.*<sup>[43]</sup> demonstrated this with regards to cardiology specifically. Neither the physical exam nor a hand-carried echocardiography machine were as accurate as the two used together<sup>[6]</sup>. We conclude that technology does not erode physical exam skills but in fact improves both bedside skills and clinical judgment. Technology and clinical examination can and should go hand-in-hand for optimal patient care. "It has to make sense"<sup>[16]</sup>.

### **Balancing exam with technology**

Recently, several groups have discussed the development of technologies that can assist physicians in analyzing heart murmurs, including computer-assisted auscultation and artificial neural networks<sup>[44,45]</sup>. Heart murmurs are complex sounds that can nevertheless be analyzed by a simple frequency analysis, which can be done either with advanced technologies or with a trained ear and a stethoscope.

It has been shown that physicians listening to recorded heart sounds can accurately distinguish innocent from pathologic murmurs<sup>[46-48]</sup>. Therefore, telecardiology (tele-auscultation) may find potential use in areas where access to echocardiography is limited. Many rural areas, both in the United States and around the world, do not have either an echocardiography machine or a trained echocardiographer. Doctors trained to auscultate for peak pressures could feasibly receive digital heart sounds from remote areas, and improve remote diagnostic capabilities.

### **Cost considerations**

As physicians move away from their stethoscopes,

they increasingly rely on diagnostic testing that may be unnecessary and is often uninformed, and certainly costly. Unfortunately in our study, it is impossible to know how many patients could have avoided an echocardiogram, based purely on auscultatory estimation of a pressure gradient; other clinical questions may also prompt an echocardiogram. Nevertheless, in response to the increasing impact of echocardiography on health care costs, the ACCF and the ASE prepared a 2011 revision on appropriate use criteria (AUC) for echocardiography<sup>[14]</sup>. More recently AUC has also been described for pediatric echocardiography, specifically to determine the need for TTE as an initial diagnostic tool in the outpatient setting<sup>[13]</sup>. The AUC are not absolute, but should be applied to clinical exams to determine when an echocardiogram is appropriate. We believe that an increased focus on auscultation would aid in this.

### **Limitations**

This technique has been proven rigorously for one cardiologist only. The study period corresponded to this cardiologist's early and middle career. Of note, in our original study, we validated the auscultatory scale using a senior pediatric cardiology fellow. In our anecdotal experience, several other individuals have mastered this technique to some degree. Similar to our findings, others have shown that attention to clinical examination skills can allow residents and students to improve their physical exam skills and diagnoses<sup>[1]</sup>. Moreover, similar findings in animal studies as cited above further validate our approach<sup>[25-29]</sup>.

This study was performed primarily in children but included heavier children as well as some adults. Still, this data may not be applicable to adults with calcific valve disease or other pathologies not addressed in this study. In addition, pressure gradients depend on flow, and the true severity of a valvar or arterial obstruction may not be reliably assessed when there is myocardial failure. For instance, severe AS in adults may present with only a short, unimpressive midsystolic murmur or even no murmur at all. Finally, we did not test this technique for diastolic gradients.

### **Conclusions and future directions**

Physical examination can accurately estimate pressure gradients in most patients with PS, AS, or VSD. An accurate physical examination may provide data that may be missed by technology, contribute to the patient-doctor relationship, and has a role for the cost-conscious physician. And it may prove useful in areas with limited access to technological resources. We do not propose that the physical exam should replace echocardiography, but believe that the use of the two in conjunction allows for the optimal patient assessment. Contrary to the belief that technology erodes clinical skills, continual correlation of clinical findings with a technological "gold standard" such as echocardiography can lead to highly accurate

diagnostic skills and improved clinical judgment, thereby enhancing clinical skills training and further substantiating the value of clinical examination.

## COMMENTS

### Background

Strong clinical skills, including physical examination skills, remain central to the practice of medicine. In recent years, there has been a much-decried decline in clinical examination skills. The authors had performed a small pilot study over 15 years ago with 151 patients that indicated that physical examination can be very accurate in determining pressure gradients across stenosis or septal defects.

### Research frontiers

Very little research is being performed to help clinicians improve clinical skills, or to determine the strengths and/or weaknesses of clinical examination. Moreover, very little is known about how technology such as imaging can help clinicians improve their physical examination skills.

### Innovations and breakthroughs

In pediatric cardiology, physical examination is felt to be very accurate in determining normal from abnormal heart murmurs. What is not known, however, is whether the physical examination can accurately predict pressure gradients in aortic stenosis, pulmonary stenosis, and ventricular septal defect. Knowledge of such pressure gradients helps guide clinical management. Almost no work has been done on this area.

### Applications

Honing physical examination skills such as being able to predict pressure gradients has two potential benefits: (1) The clinician may rely less on technology and therefore may reduce the use of expensive testing (imaging); and (2) The clinician may use the physical examination findings in conjunction with testing (imaging) to come to a better overall evaluation of the patient.

### Terminology

Aortic stenosis (AS): Anatomical obstruction to blood flow at any level, including subaortic stenosis, valvar aortic stenosis, supra-aortic stenosis (narrowing of the ascending aorta). In this project, aortic stenosis did not include coarctation of the aorta; Pulmonary stenosis (PS): Anatomical obstruction to blood flow at any level, including subpulmonary or infundibular stenosis, valvar stenosis, and supra-aortic stenosis (narrowing of the main pulmonary artery). For the purposes of this project, the authors did not include stenoses of the peripheral branch pulmonary arteries; Ventricular septal defect (VSD): the authors included VSD's at any site, including perimembranous, muscular, and supracristal (subpulmonary) VSD's; Doppler echocardiography, peak instantaneous pressure gradient: For aortic or pulmonary stenosis, there will be a higher-pressure site (proximal to the obstruction) and a lower-pressure site (distal to the obstruction). For ventricular septal defects, the higher-pressure site is generally the left ventricle, while the lower-pressure site is the right ventricle. The difference in pressures ( $\Delta P$ ) between the two sites in the heart or arteries can be estimated using the Doppler principle on echocardiography systems; most commonly, one uses the modified Bernoulli equation,  $\Delta P = 4V^2$ , where V is the maximal velocity across the region of interest (stenosis or VSD) as acquired from the Doppler ultrasound transducer.

### Peer-review

This is a well-written and interesting paper demonstrating how clinical auscultation in expert hands may approximate echo results. The results are important in an era of considerable expenses in technology and of looking down on clinical examination.

**Abstract****AIM**

To investigate the impact of coronary artery disease in a cohort of patients resuscitated from cardiac arrest with non-diagnostic electrocardiogram.

**METHODS**

From March 2004 to February 2016, 203 consecutive patients resuscitated from in or out-of-hospital sudden cardiac arrest and non-diagnostic post-resuscitation electrocardiogram (defined as ST segment elevation or pre-sumably new left bundle branch block) who

underwent invasive coronary angiogram during hospitalization were included. For purpose of analysis and comparison, patients were classified in two groups: Initial shockable rhythm (ventricular tachycardia or ventricular fibrillation;  $n = 148$ , 72.9%) and initial non-shockable rhythm ( $n = 55$ , 27.1%). Baseline characteristics, coronary angiogram findings including Syntax Score and long-term survival rates were compared.

## RESULTS

Sudden cardiac arrest was witnessed in 95.2% of cases, 66.7% were out-of-hospital patients and 72.4% were male. There were no significant differences in baseline characteristics between groups except for higher mean age (68.1 years vs 61 years,  $P = 0.001$ ) in the non-shockable rhythm group. Overall 5-year mortality of the resuscitated patients was 37.4%. Patients with non-shockable rhythms had higher mortality (60% vs 29.1%,  $P < 0.001$ ) and a worst neurological status at hospital discharge based on cerebral performance category score (CPC 1-2: 32.7% vs 53.4%,  $P = 0.02$ ). Although there were no significant differences in global burden of coronary artery disease defined by Syntax Score (mean Syntax Score: 10.2 vs 10.3,  $P = 0.96$ ) there was a trend towards a higher incidence of acute coronary lesions in patients with shockable rhythm (29.7% vs 16.4%,  $P = 0.054$ ). There was also a higher need for *ad-hoc* percutaneous coronary intervention in this group (21.9% vs 9.1%,  $P = 0.03$ ).

## CONCLUSION

Initial shockable group of patients had a trend towards higher incidence of acute coronary lesions and higher need of *ad-hoc* percutaneous intervention vs non-shockable group.

**Key words:** Sudden cardiac arrest; Electrocardiogram; Invasive coronary angiography; Percutaneous coronary intervention; Syntax score; Coronary artery disease

**Core tip:** Coronary artery disease represents the most common cause of sudden cardiac arrest. Current resuscitation guidelines recommend emergency coronary angiography in patients with cardiac arrest and ST elevation or new left bundle branch block on post-resuscitation electrocardiogram. However, electrocardiogram findings may be a poor predictor of an acute coronary lesion in this context and nowadays, the benefit of early coronary angiography is still under debate in patients without ST elevation. In this study, we analyzed our single-center data of patients with cardiac arrest and non-diagnostic electrocardiogram to describe the burden of coronary artery disease and their prognosis depending on initial rhythm.

Coronary angiography findings in cardiac arrest patients with non-diagnostic post-resuscitation electrocardiogram: A comparison of shockable and non-shockable initial rhythms. *World J Cardiol* 2017; 9(8): 702-709 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i8/702.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i8.702>

## INTRODUCTION

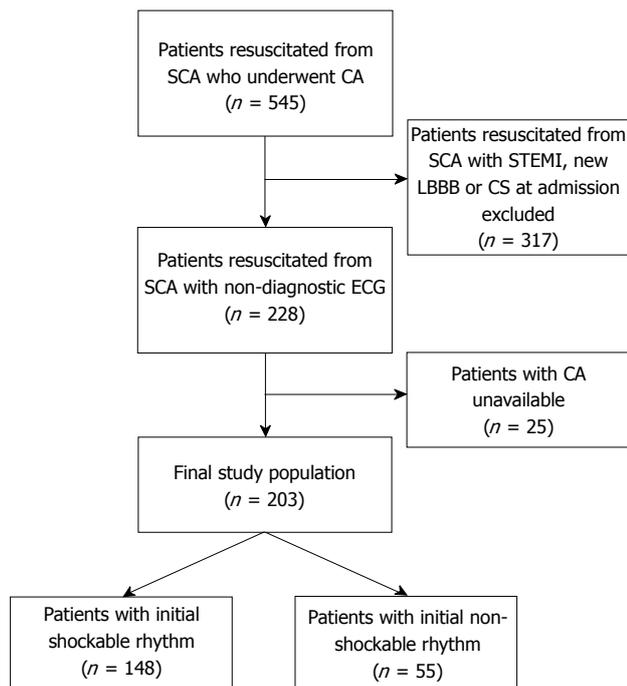

Sudden cardiac arrest (SCA) is one of the most common causes of death in the developed world, affecting nearly 560000 people annually in the United States. Although a majority of deaths occur during the initial resuscitation, a substantial proportion of cardiac arrest deaths occur in patients who have been initially successfully resuscitated after first medical contact. Despite the important advances in emergency medical services and post cardiac arrest syndrome care over the last decades, survival free from neurological deficit is still low<sup>[1]</sup>.

Coronary artery disease (CAD) represents the most common cause of SCA and current resuscitation guidelines recommend the performance of an emergency coronary angiography (CA) and appropriate percutaneous coronary interventions (PCI) in patients with SCA and ST segment elevation or presumably new left bundle branch block (LBBB) on post-resuscitation electrocardiogram (ECG). In patients without ST elevation after SCA but with suspected or with a high risk of cardiac origin, emergency CA is reasonable in selected situations (for example, electrically or hemodynamically unstable patients)<sup>[2,3]</sup>. Such "suspicion of cardiac origin" is not well defined and therefore the recommendation remains somewhat ambiguous.

Regarding the likelihood of a cardiac origin of the SCA, the ECG may be a poor predictor of acute coronary occlusion in resuscitated patients<sup>[4-7]</sup>. Also, a recent meta-analysis showed a high prevalence of significant CAD ranging from 59% to 71% in patients resuscitated from SCA without an obvious non-cardiac etiology<sup>[8]</sup>. Furthermore, pre-arrest symptoms reported in this setting are unreliable and dependent on the presence of by-standers. In summary, the suspicion of cardiac origin is largely subjective or uncertain for most patients. For these reasons, and without available randomized data, the justification for use of an early invasive strategy in survivors of SCA without an obvious non-cardiac cause of arrest is based on observational data<sup>[9-11]</sup>.

From a single-center registry of patients resuscitated from SCA undergoing CA, we present in this paper the results of a sub-analysis comparing patients with shockable and non-shockable initial rhythms<sup>[12]</sup>. The aim of this sub-analysis was to investigate the impact of CAD in a cohort of SCA patients with non-diagnostic

ECG depending on initial rhythm.

## MATERIALS AND METHODS

### Study population

All patients recovered from in or out-of-hospital SCA and admitted to a tertiary care center with 24/7 emergent PCI availability that underwent invasive CA were extracted from a multipurpose database including data from interventional procedures, critical care unit and hospital admission.

From March 2004 to February 2016, 545 consecutive SCA patients were identified. For this study, we focused on patients without emergent indication for CA. Therefore, patients with ST segment elevation or presumably new LBBB on post-resuscitation ECG, or cardiogenic shock at admission were excluded ( $n = 317$ ). Of the remaining 228 patients, 25 had unavailable or incomplete CA films. Thus, our final study population was 203 patients. For the purpose of this sub-analysis, patients were classified into two groups depending on initial ECG: Shockable [ventricular tachycardia or ventricular fibrillation ( $n = 148$ , 72.9%)] and non-shockable rhythm ( $n = 55$ , 27.1%) (Figure 1).

Clinical and outcome data were collected from clinical record, patient's charts or telephone contact with patients or their relatives. Follow-up was completed up to 5-year after index admission.

### Cardiac catheterization

The indication and timing of CA in our study population was individualized for each patient based on treating

physician's criterion. CA was classified as early when performed  $< 24$  h after hospital admission or late when performed  $\geq 24$  h after admission. Two interventional cardiologist reviewed all CA blinded to original reports. The percentage diameter stenosis (DS%) was visually estimated for each lesion. Quantitative CA was used if discordances  $> 10\%$  were found between both investigators. Significant stenosis was defined as  $\geq 50$  DS%, severe stenosis when DS% was  $\geq 70\%$  and non-obstructive CAD when DS% was  $< 50\%$ . A normal coronary angiogram was defined as 0 DS% in all arteries with no other pathological findings. Culprit lesion was defined as the presence of an acute arterial occlusion (plaque rupture with occlusive thrombus) or an incomplete coronary artery occlusion in presence of complex lesion morphology as previously defined<sup>[13]</sup>. Chronic total occlusion (CTO) was defined as a Thrombolysis In Myocardial Infarction (TIMI) grade 0 flow for at least 3 mo of estimated duration. Estimation of occlusion duration was based on at least one of the following: Prior history of myocardial infarction in the target vessel territory, comparison with a previous angiogram, or the presence of collateral circulation or bridging collaterals. Critical stenosis was considered when DS% was  $\geq 90\%$  but  $< 100\%$  and there were no CTO features. Acute coronary lesion was defined as critical or culprit lesion for the purpose of this investigation. *Ad-hoc* PCI was defined if performed at the moment of the index CA at the operator's discretion. Procedural success was defined as complete restoration of antegrade blood flow (TIMI 3) and  $< 30\%$  residual diameter stenosis by visual assessment.

Burden of CAD was measured using the Synergy Between Percutaneous Coronary Intervention With Taxus And Cardiac Surgery (SYNTAX) Score and number of vessels with significant and/or severe stenosis. We calculated the Syntax Score for each patient, as previously reported<sup>[14,15]</sup>. If the patient had previous PCI we used residual Syntax score (rSS) defined as the SYNTAX score remaining after PCI. If the patient had previous coronary artery bypass graft (CABG) surgery we calculated the CABG-SYNTAX score proposed by Farooq *et al*<sup>[16]</sup>. Both rSS and CABG-SYNTAX score reflect the current burden of CAD (successfully revascularized segments are equalized to segments with CAD  $< 50\%$ , thus not incrementing SYNTAX score).

### Statistical analysis

Statistical analysis was performed using SPSS 21 (SPSS Inc, Illinois, Chicago, United States). Continuous variables are presented as mean and standard deviation. Categorical variables are expressed as frequency and percentage. In quantitative variables, the groups were compared using a two-tailed Student's *t*-test for independent samples. Categorical variables were compared with the  $\chi^2$  test. The Kaplan-Meier method was used to estimate the cumulative patient survival rates and log-rank test for comparison. All test were two

sided and  $P < 0.05$  was considered significant.

## RESULTS

### Baseline characteristics

Of 203 consecutive patients resuscitated from SCA with non-diagnostic ECG, 148 had initial shockable rhythm and 55 had non-shockable rhythm. Table 1 shows the baseline characteristics of the study cohort. There were no statistical differences between groups in baseline characteristics except for higher mean age in the initial non-shockable group (68.1 years vs 61 years,  $P = 0.001$ ).

### CA findings

Early CA was performed in 115 patients (56.9%). The most relevant angiography findings are reproduced in Table 2. Overall, mean value of Syntax Score

calculated was 10.30 with no statistical differences between groups (10.33 vs 10.23,  $P = 0.95$ ). There were also no differences ( $P = 0.71$ ) in the percentage of vessels with significant stenosis (0, 1, 2 or 3 vessels with  $\geq 50$  DS%). However, patients with initial shockable rhythm showed a trend towards a higher incidence of acute coronary lesions (29.7% vs 16.4%,  $P = 0.054$ ) and higher rate of *ad-hoc* PCI (21.9% vs 9.1%,  $P = 0.03$ ), mainly for left anterior descending artery lesions (45.9%).

The prognostic value of acute coronary lesions as defined by this study was assessed through a stratified Kaplan Meier analysis. Figure 2 shows Kaplan Meier curves for all cause 5-year survival depending on the finding of an acute coronary lesion. Patients with shockable rhythm and with acute coronary lesions had a non-significant increased mortality, whereas no significant differences or trends were found in the

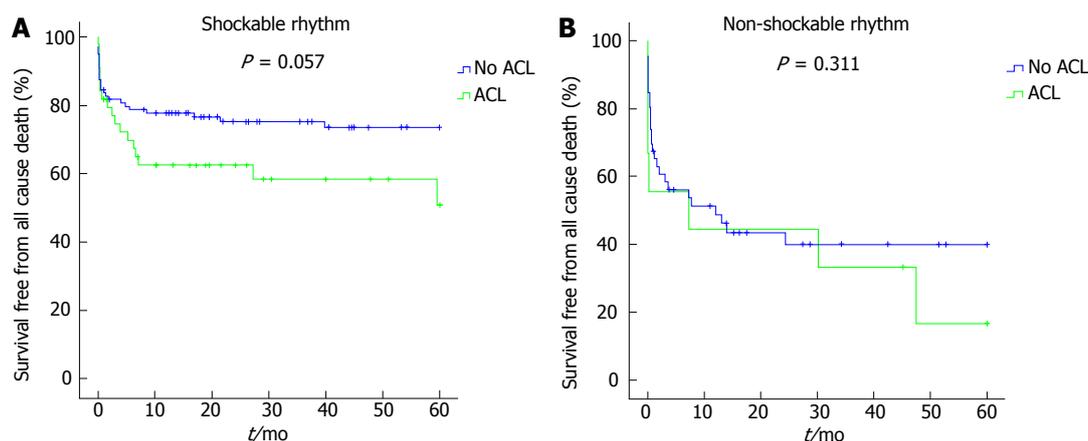

Figure 2 Kaplan Meier curves for all cause 5-year survival depending on the finding of an acute coronary lesion. ACL: Acute coronary lesion.

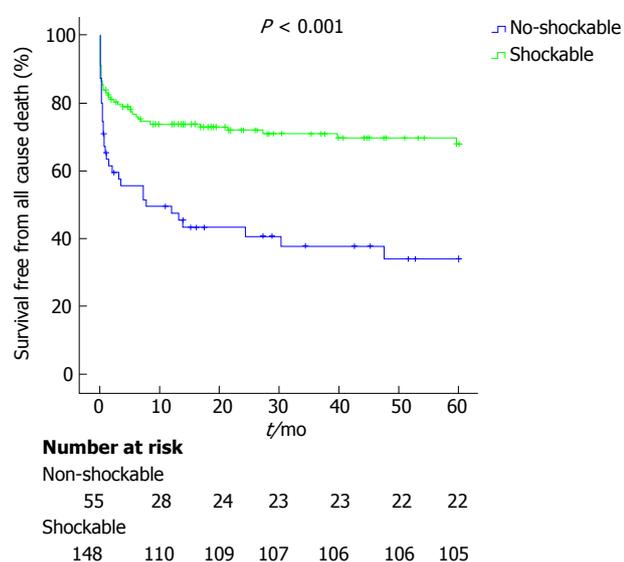

Figure 3 Kaplan-Meier curves for 5 years survival.

non-shockable group. Interestingly, in patients with shockable rhythm, those who underwent *ad hoc* PCI of the acute coronary lesions had a trend towards improved survival compared to patients with untreated acute coronary lesions (mean all-cause survival  $41.3 \pm 5.4$  mo vs  $29.7 \pm 6.9$  mo,  $P = 0.147$ ). However, in patients with initial non-shockable rhythm, *ad hoc* PCI did not improve survival rates ( $P = 0.948$ ).

### In-hospital and long-term survival

Overall, 151 (74.4%) patients survived until hospital discharge and 97 (64.2%) survived with a favorable neurological outcome based on cerebral performance category score (CPC). Patients with initial shockable rhythm had a better prognosis, with higher survival rates to discharge compared with those with non-shockable rhythm (56.4% vs 81.1%,  $P < 0.001$ ). Patients with shockable rhythm also had a better neurological status at discharge (CPC 1-2: 32.7% vs 53.4%,  $P = 0.02$ ). Five-years mortality was 37.4% in the global cohort. Patients with non-shockable rhythm

had a higher five-year mortality (60% vs 29.1%,  $P < 0.001$ , Figure 3).

## DISCUSSION

This study is a sub-analysis of a large single-center registry of selected SCA patients with CA and non-diagnostic post resuscitation ECG<sup>[12]</sup>. The present study compares shockable vs non-shockable rhythms and reveals a similar high burden of CAD in both groups. Although these findings are consistent with previous observational studies<sup>[8]</sup>, our study is novel because it is the first to explore differences between shockable and non-shockable rhythms in this setting. Since the publication in 1997 of a seminal study by Spaulding *et al*<sup>[17]</sup>, many studies with important methodological limitations have reported the possible survival impact of an early invasive approach in this context<sup>[9,18-21]</sup>. However, other studies did not find any benefit from such an invasive strategy and proposed to restrict its use to highly selected patients<sup>[10,11,22]</sup>. Besides, in contrast to the usual presentation of acute coronary syndromes, the standard tools to evaluate coronary ischemia in post cardiac arrest patients are less accurate. The sensitivity and specificity of the usual clinical data, ECG or biomarkers to predict an acute coronary artery occlusion are unclear<sup>[4-6,23]</sup>. For these reasons, there is still an ongoing debate on the use of an early invasive strategy in all survivors of SCA without an obvious non-cardiac cause. We conducted this sub-analysis in order to assess if the initial rhythm after resuscitation could be a predictor of CAD burden and acute coronary lesions.

Given the high probability of CAD (measured as mean Syntax Score), our data supports a low threshold for CA regardless of initial rhythm. According to current resuscitation guidelines, it is reasonable to discuss and consider emergent cardiac catheterization in patients with a high risk of a coronary cause for their cardiac arrest<sup>[3]</sup>. However, definitive data will come with the results of several ongoing randomized trials designed to determine whether early CA improves outcomes in

out-of-hospital cardiac arrest, in patients without ST elevation [one of those (COUPE trial) conducted by our group]<sup>[24-27]</sup>.

Some differences in acute coronary lesions were found between the two groups. Those patients with initial shockable rhythm had a higher incidence of acute coronary lesions (29.7% vs 16.4%,  $P = 0.054$ ) and consequently a greater requirement of *ad-hoc* PCI (21.9% vs 9.1%,  $P = 0.03$ ). These acute coronary lesions might also have a potential impact on prognosis (Figure 2). Unfortunately, our study was underpowered to show the effect of revascularization on these lesions, but this should be considered a relevant research target for future studies. These findings are in accordance with the observed trend that reveals that CA and PCI after ventricular tachycardia or ventricular fibrillation has substantially increased over the last years, regardless of the presence of ST elevation<sup>[28]</sup>.

Regarding the prognosis of initial ECG rhythm analysis, SCA patients are usually divided into non-shockable rhythms (pulseless electrical activity and asystole) or shockable rhythms (ventricular tachycardia and ventricular fibrillation). Non-shockable rhythms are the most prevalent first recorder rhythm and survival rates of this group are worst compared with initial shockable rhythm<sup>[1]</sup>. Studies have shown that increased age, female gender, and prolonged ROSC are associated with a non-shockable rhythm while public location and witnessed arrest are associated with a shockable rhythm<sup>[29]</sup>. In our study, survival rates were also higher in patients with initial shockable rhythms (60% vs 29.1%,  $P < 0.001$ ), as previously reported<sup>[1]</sup>. However, there were no statistical differences in baseline characteristic except for higher mean age (68.1 years vs 61 years,  $P = 0.001$ ) in the non-shockable rhythm group, probably due to the study design and patients selection.

The present study should be interpreted within the context of several limitations of a single-center observational study and relatively small size of the study population. The cohort included in this study was selected from consecutive patients who survived to in or out-of-hospital SCA and were subsequently selected for CA by clinicians upon admission. Patients with an explicit non-cardiac etiology of SCA would not be selected for CA and the final decision to proceed with CA was based on the clinical judgment of individual physicians. It is likely that CA was selectively more frequently offered to patients with a better likelihood of neurological recovery.

In conclusion, in our cohort of patients with SCA and non-diagnostic ECG, initial shockable rhythm group of patients had a similar burden of CAD compared to those with non-shockable rhythms. Patients with initial shockable rhythm had a trend towards a higher incidence of acute coronary lesions and a higher need of *ad-hoc* percutaneous coronary intervention. A low threshold for early CA should be considered in this subgroup of resuscitated SCA patients.

## COMMENTS

### Background

Acute coronary syndromes are a common cause of sudden cardiac arrest (SCA). Based on observational studies, current resuscitation guidelines recommend emergency coronary angiography (CA) in patients with SCA and ST segment elevation on post-resuscitation electrocardiogram (Class I, level B). However, because of fewer data available, in patients without ST segment elevation, emergency CA is reasonable in selected patients with suspected cardiac origin (Class II a, level C), regardless of initial rhythm.

### Research frontiers

Electrocardiogram findings may be a poor predictor of an acute coronary lesion in patients after a SCA. Without randomized data, the benefit of early CA in patients without ST elevation remains controversial.

### Innovations and breakthroughs

In patients with SCA and non-diagnostic post-resuscitation electrocardiogram, initial shockable rhythms show a trend towards a higher incidence of acute coronary lesions and higher need of *ad-hoc* percutaneous coronary intervention.

### Applications

The results of the study suggest that a low threshold for early CA should be considered in this subgroup of resuscitated SCA patients.

### Terminology

Shockable rhythms include ventricular tachycardia and ventricular fibrillation in opposition to non-shockable rhythm that include asystole and pulseless electrical activity.

### Peer-review

The manuscript is well-written, the statistical analysis is appropriate, and the data support the conclusions. This work will be of interest to the readership, and is potentially impactful regarding acute treatment of initially resuscitated, hospitalized cardiac arrest patients.

### Abstract

We describe the case of a patient presenting with ST-segment elevation myocardial infarction due to very late scaffold thrombosis. The patient was already admitted for an elective percutaneous recanalization of a chronically occluded left anterior descending artery (LAD). The procedure was performed according the sub-intimal tracking and re-entry (STAR) technique with 4 bioresorbable vascular scaffolds implantation. However, even though the coronary flow was preserved at the end of the procedure, the dissected segment was only partially sealed at the distal segment of the LAD. After 18 mo of regular assumption, dual antiplatelet therapy was discontinued for 10 mo before his presentation at the emergency room. This is the first reported case of a very late scaffold thrombosis after coronary chronic total occlusion (CTO) recanalization performed according to the STAR technique. This case raises concerns about the risk of very late scaffold thrombosis after complex CTO revascularization.

**Key words:** Bioresorbable vascular scaffolds; Scaffold dismantling; Scaffold thrombosis

**Core tip:** We describe a case of a 53-year-old male patient who was admitted with anterior ST-elevation myocardial infarction 28 mo after elective percutaneous revascularization of a chronically occluded left anterior descending (LAD) threatened with 4 bioresorbable vascular scaffolds (BVS) in order to seal a long flow limiting dissection after sub-intimal tracking and re-entry technique. Coronary angiography showed a large thrombus at the proximal segment of the proximal BVS and a long dissection was evident from mid to distal LAD. In this case, the progressive reduction of both scaffolds radial strength and structure dismantling might have been responsible for both intraluminal thrombosis and reoccurrence of vessel dissection.

Very late bioresorbable scaffold thrombosis and reoccurrence of dissection two years later chronic total occlusion recanalization of the left anterior descending artery. *World J Cardiol* 2017; 9(8): 710-714 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i8/710.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i8.710>

## INTRODUCTION

Bioresorbable vascular scaffolds (BVS) represents the latest revolution in the field of interventional cardiology. Providing temporary scaffolding and disappearing few years later, BVS results particularly appealing for the treatment of long segments of coronary arteries such as it usually occurs for percutaneous revascularization (PCI) of chronic total occlusions (CTO). However, limited data are available about the long-term efficacy of BVS in this particular setting. Herein we report a case of a very late scaffold thrombosis after CTO revascularization.

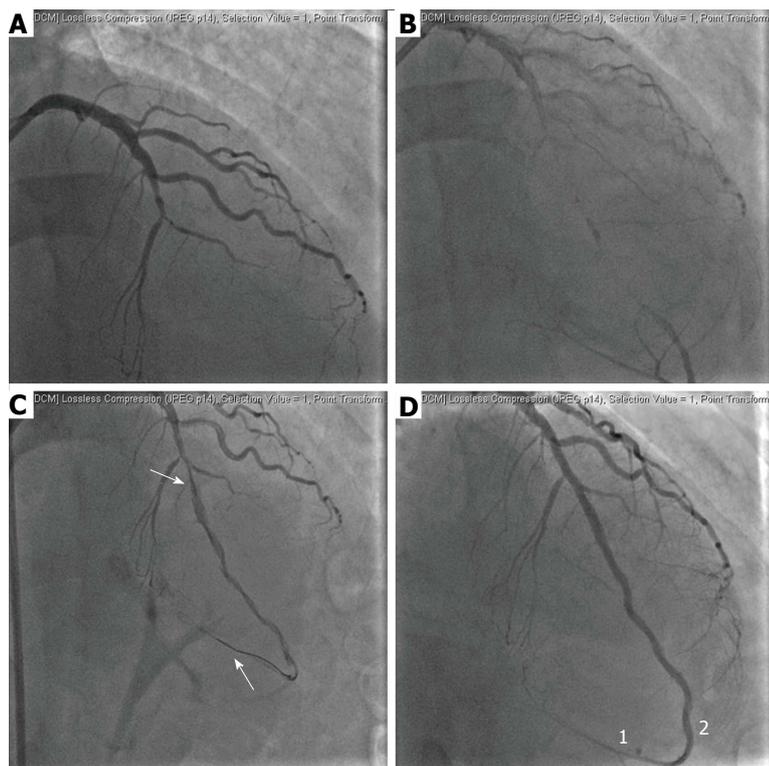

## CASE REPORT

A 53-year-old male patient, with hypertension and dyslipidemia, presented with anterior ST-elevation myocardial infarction, 28 mo after elective percutaneous coronary intervention (PCI) of the chronically occluded left anterior descending artery (LAD), with implantation of 4 marker-to-marker bioresorbable vascular scaffolds (BVS, Absorb Abbott Vascular, Abbott Park, Illinois), performed in another cath-lab. BVS implantation followed chronic total occlusion (CTO) recanalization unintentionally performed according the subintimal tracking and re-entry (STAR) technique. The dissected segment was only partially sealed up to the distal segment of the LAD (Figure 1). The patient completed 18 mo of dual antiplatelet therapy (DAPT) 10 mo before his presentation at the emergency room. The

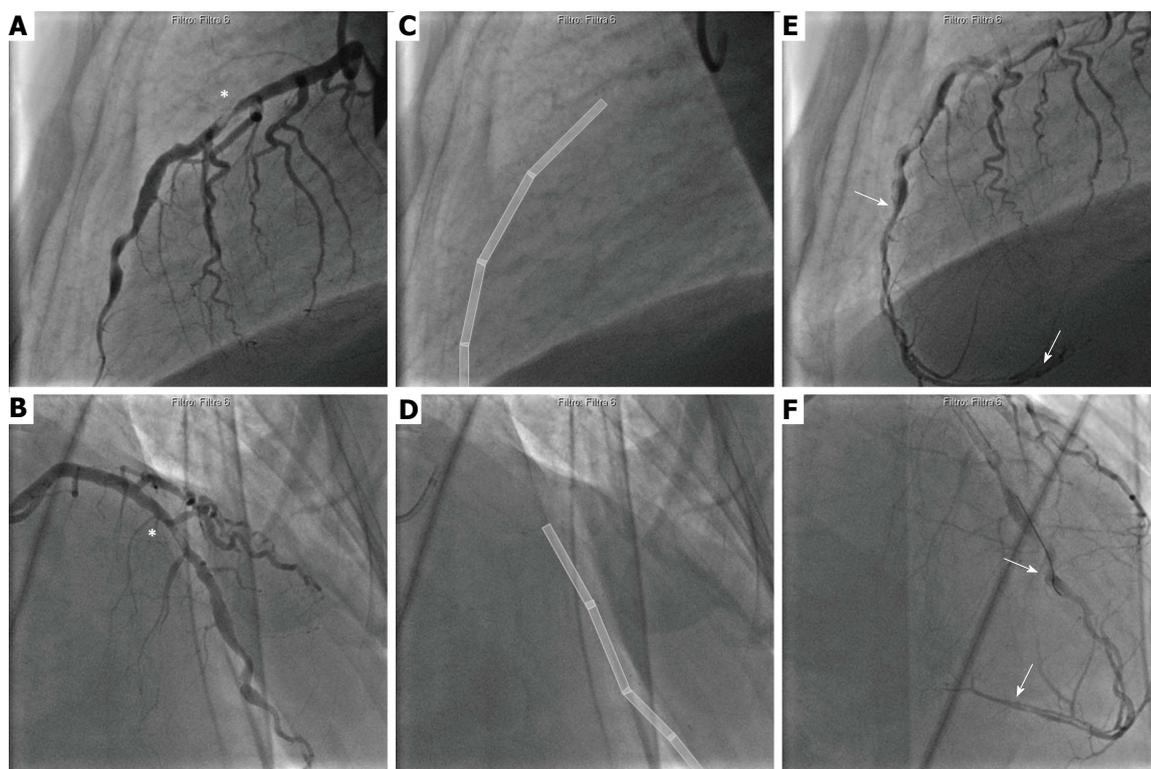

index coronary angiography showed a large thrombus at the proximal segment of the proximal BVS followed by a long dissection up to the very distal LAD segment (Figure 2). Thrombus aspiration and proximal drug eluting stent (DES) implantation was performed, while medical treatment was suggested for the distal chronic dissection (Figure 3). DAPT with ASA and Ticagrelor was finally resumed and clinical follow up planned.

## DISCUSSION

To the best of our knowledge, this is the first clinical case reporting on a very late scaffold thrombosis and reoccurrence of coronary dissection after PCI of a chronic coronary total occlusion. Since neither optical coherence tomography (OCT) nor intravascular ultrasound (IVUS) were available at the time of both baseline and index procedures, the mechanism subtending the BVS failure in this particular case remains unknown. However, we might speculate that intraluminal scaffold dismantling together with scaffold discontinuity and restenosis during the resorption process, might have been responsible of thrombus formation at the mid-LAD, as previously described<sup>[1-3]</sup>. In addition, the gradual scaffold resorption process, together with the incomplete scaffold coverage of the dissected segment at the time of the CTO PCI, might have been responsible of incomplete dissection healing, with progressive expansion of the subintimal hematoma, resulting in a "dual lumen" coronary artery<sup>[4,5]</sup>. CTOs are the most challenging coronary lesions for PCI, mainly because of two reasons: (1) Procedure related: CTO remains technically challenging, in fact PCI failure is reported in up to 35% of CTOs and > 40% of CTOs are not attempted and treated either with medical therapy or with CABG; (2) Patient related: Identification of those patients for whom PCI of CTO does not bring any significant clinical benefit, despite successful revascularization, is still debatable<sup>[6]</sup>. By the way, the use of BVS for CTO revascularization is particularly appealing mainly because PCI normally involves long coronary segments, thereby limiting future surgical interventions and increasing the risk of late malapposition after Drug Eluting Stents (DES) implantation<sup>[7,8]</sup>. However, limited data are available about the use of BVS for PCI of CTOs. In fact, most of the randomized controlled trials conducted so far compared BVS and DES in simple or intermediate coronary artery stenosis, thereby the long-term efficacy of such new devices for percutaneous revascularization of complex stenosis, such as CTOs is still not clear. Recently, a propensity score adjusted analysis of 537 patients undergoing to PCI of a CTO showed a trend toward a higher adjusted risk of ischemia-driven target lesion revascularization for patients undergoing to BVS implantation as compared with DES<sup>[9]</sup>. However, larger randomized studies are warrant in order to better define the role of BVS in CTO-PCI.

**Figure 1** Baseline chronic total occlusion-percutaneous revascularization of the left anterior descending. A and B: Mid-LAD occlusion with omolateral reperfusion of the distal segment; C: Dissected segment after CTO recanalization and balloon dilation (white arrows); D: Final result after four BVS implantation and (2) contrast staining at the distal LAD suggesting the presence of subintimal hematoma with the occlusion of the distal apical branch (1). BVS: Bioresorbable vascular scaffolds; LAD: Left anterior descending; CTO: Chronic total occlusion.

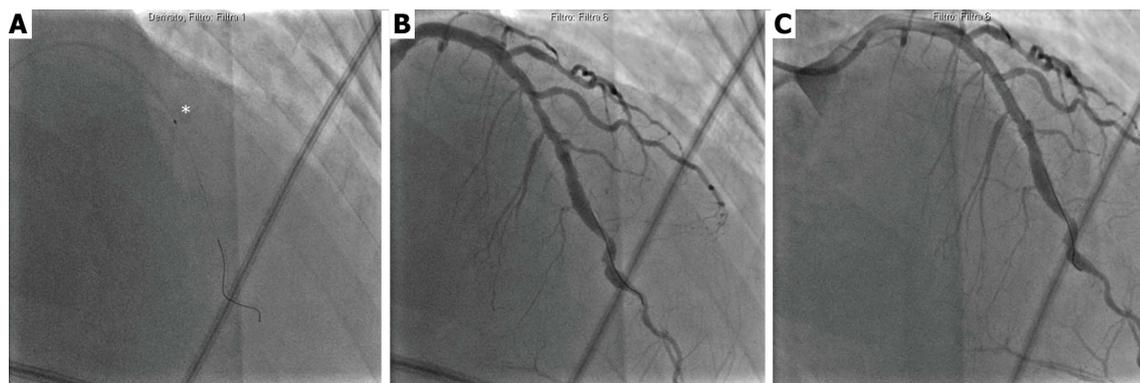

**Figure 2** Coronary angiography of the left anterior descending at 28 mo after chronic total occlusion recanalization. A and B: Large in-scaffold thrombus at the proximal edge of the previously implanted BVS (C, D, white boxes), at the mid LAD (\*); E and F: Dissected segment (white arrows) from the mid-LAD up to the distal segment, with a resulting image of a “dual lumen” LAD. LAD: Left anterior descending; BVS: Bioresorbable vascular scaffolds.

**Conclusion**

This case raises concerns about the risk of very late scaffold thrombosis and the use of BVS in complex CTO-PCI, particularly when “full polymer jacket” is not

warranted for the entire dissected coronary segment. A prolonged DAPT should be encouraged while a complete sealing of the dissected segment should be considered<sup>[10]</sup>.

**Figure 3** Percutaneous revascularization of the left anterior descending. A and B: After coronary wire crossing, thrombus aspiration was successfully performed (\*) and a drug eluting stent was finally implanted with good final result (C).

## COMMENTS

### Case characteristics

A 53-year-old male patient presenting with chest pain for an anterior ST-elevation myocardial infarction.

### Clinical diagnosis

Anterior ST-elevation myocardial infarction due to very late scaffold thrombosis.

### Differential diagnosis

Clinical characteristic, patient's medical history and echocardiography were useful for differential diagnosis between pericarditis and aortic dissection.

### Laboratory diagnosis

High sensitive Troponin-I increased together with myoglobin and creatine kinase-MB.

### Imaging diagnosis

Definite diagnosis was possible with invasive coronary angiography which showed a large thrombus at the proximal segment of the proximal bioresorbable vascular scaffolds (BVS) followed by a long dissection up to the very distal left anterior descending segment.

### Pathological diagnosis

In the acute setting of the coronary syndrome, no thrombus was kept for pathological analysis.

### Treatment

Thrombus aspiration and proximal drug eluting stent implantation was performed, while medical treatment was suggested for the distal chronic dissection.

### Related reports

To our knowledge, there are only few case reports about very late scaffold thrombosis.

### Experiences and lessons

This case raises concerns about the use of BVS in complex chronic total occlusion percutaneous revascularization (PCI), thereby suggesting a prolonged dual-antiplatelet therapy tailored according to both patients' clinical characteristics and PCI procedures.

### Peer-review

This case report of late thrombosis after chronic total occlusion recanalization with bioabsorbable scaffold is well organized.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Paul Erne, Professor, Department of Cardiology, University Hospital, Zurich CH-8091, Switzerland

**AIM AND SCOPE**

*World Journal of Cardiology* (*World J Cardiol*, *WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Use of X-ray contrast allows us to differentiate between two or more adjacent structures on radiographic studies. The X-ray contrast agent can be the one with increase X-ray absorption, like iodine and a barium X-ray contrast agent or the one with decrease X-ray absorption like air and carbon dioxide contrast agent. Each contrast agent possesses different risks and benefits in various ways. Carbon dioxide as an intravascular contrast agent can be used as an alternative intravascular contrast agent and has superior results in some cases. In patients with renal dysfunction or iodinated contrast allergy, the use of Iodinated Contrast Agent poses the risk of considerable morbidity. Similarly, use of Gadolinium is discouraged in subject with severe renal dysfunction. Use of carbon dioxide (CO<sub>2</sub>) as an intravascular contrast, offers an alternative in such patients for certain procedures, as it is not nephrotoxic and it does not incite allergic reactions. It is inexpensive, readily available and due to its unique physical properties, it can be used to image a wide variety of vascular beds and chambers. The aim of this paper is to systemically review the current literature to describe the indications, contraindications, adverse effects, instruments, precautions, latest methodologies and data supporting for the use of CO<sub>2</sub> as a contrast agent.

**Key words:** Iodinated; Carbon dioxide; Contrast; Vascular; Gadolinium

**Core tip:** In patients with renal dysfunction or iodinated contrast allergy, use of iodinated contrast agent poses the risk of considerable morbidity. Similarly, use of gadolinium is discouraged in subject with severe renal dysfunction. Use of carbon dioxide (CO<sub>2</sub>) as an intravascular contrast offers an alternative in such patients for certain procedures, as it is not nephrotoxic and it does not incite

allergic reactions. It is inexpensive, readily available and due to its unique physical properties it can be used to image a wide variety of vascular beds and chambers. This article describes the indications, contraindications, adverse effects, instruments, precautions, latest methodologies and data supporting for the use of CO<sub>2</sub> as a contrast agent.

Ali F, Mangi MA, Rehman H, Kaluski E. Use of carbon dioxide as an intravascular contrast agent: A review of current literature. *World J Cardiol* 2017; 9(9): 715-722 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i9/715.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i9.715>

## INTRODUCTION

In medical parlance, contrast is a mean which allows us to differentiate between two or more adjacent elements on a radiographic study. There are essentially two prototypes of X-ray contrast agents: (1) Positive agents (which increase X-ray absorption: Iodine or barium based); and (2) negative agents [decrease X-ray absorption: Air, carbon dioxide (CO<sub>2</sub>)]<sup>[1]</sup>. In animal experiments (1940s) and later in human studies (1950s), CO<sub>2</sub> enabled investigators to delineate both right and left heart structures. With the introduction of digital subtraction angiography (DSA) in 1980s, the image quality improved significantly<sup>[1]</sup>. Conditions where use of iodinated contrast agent (ICA) are precluded such as impaired kidney functions, dye allergy, CO<sub>2</sub> may be used as an alternate contrast agent with comparable results and in some cases superior results<sup>[2-4]</sup>.

### Physical properties

Understanding of physical properties of CO<sub>2</sub> is central for its use. Administration of CO<sub>2</sub> needs extreme care. It is a colorless, odorless and significantly compressible gas. CO<sub>2</sub> has low molecular weight as compared to ICA, is less viscous than blood and ICA and due to this property it can be used to image small collateral vessels. It displaces the blood in the vessels and acts as a negative contrast agent. This property creates a significant gradient between the radiographic density of the vessel wall and the lumen. DSA technique uses this difference in the densities to provide a contrast image. CO<sub>2</sub> is more soluble than oxygen (O<sub>2</sub>) and dissolves in the blood within 2-3 min after injection. When mixed with water it creates carbonic acid (H<sub>2</sub>CO<sub>3</sub>) which dissociates into bicarbonate (HCO<sub>3</sub><sup>-</sup>) and hydrogen (H<sup>+</sup>) ions carried by blood flow to the lungs. Reverse reaction happens in the lungs where the breakdown product of H<sub>2</sub>CO<sub>3</sub>, CO<sub>2</sub> is then exhaled. These chemical reactions are facilitated by enzymes called carbonic anhydrases.

During its use, monitoring of vital signs is required. Capnography if available would be useful in monitoring the ventilation.

### Administration

There are 3 commonly used methods of administering CO<sub>2</sub>. Preferred method is *via* automated injectors (automated CO<sub>2</sub> mmanders). Hand held syringes have been used in the past but are not commonly used now due to increased risk of complications such as air contamination and explosive over dosage<sup>[5,6]</sup>.

**Automated CO<sub>2</sub> mmanders:** Have the utility of being handy, portable, safe and easy to use but their high cost (approximately 3000 USD)<sup>[7]</sup> make them an unpopular choice.

**The modified plastic bag system with O-ring:** Is a preferred method by some experts. Kit packs consisting of bag, tube and valves are available commercially (custom waste management kit by Merit Medical, South Jordan, UT; or Angio-Dynamics Queensbury, NY)<sup>[8,9]</sup>. The usual source of CO<sub>2</sub> is an Aluminum or steel cylinder of medical grade CO<sub>2</sub> which is about 99.99% pure, fitted in a series circuit with a valve, a gauge, a regulator, a diaphragm and an antibacterial filter. A 1500 mL plastic bag with a single port connected with a low pressure tube and a 2-way stopcock at the distal end of the tube is then connected to the CO<sub>2</sub> cylinder. It is then filled and manually purged at least 3 times. The filled bag is then connected at its 2-way stopcock end with an O-ring connector which on the other end is connected with the delivery syringe (20-60 mL). There is a 1-way valve between the O-ring and the syringe. The syringe is then connected with another 1-way valve and then with a 100 cm connecting tube. The distal end of this tube has one more 1-way valve which is then connected with a 3-way valve. This 3-way valve can then be connected with the angiographic catheter. On the other port an additional syringe for back-bleeding or eliminating the air from the system can be attached (Figure 1). To fill the delivery syringe the plunger is simply retracted. The 1-way valves will allow the CO<sub>2</sub> in the plastic bag to move into the syringe. The plunger can then be advanced at the desired rate and amount. The 1-way valves will allow the gas to move towards the 3-way valve which can then be adjusted depending on the ports required to be used. The angiographic catheter is at times filled with blood which can be cleared by using the additional syringe attached at the 3-way valve. Forceful boluses of 3-5 mL CO<sub>2</sub> can be used to clear the catheter from any remaining fluid. The catheter can then be flushed with 1-3 mL of CO<sub>2</sub> every 2-3 min. All the connections of the circuit need to be air tight to avoid any air aspiration or embolism. The plastic bag should be filled enough to remain flaccid as tightly filled bag may pose risk of overdose due to gas compression<sup>[9]</sup>.

**Underwater seal:** This is a relatively simple, inexpensive and easier method but there may be a slight risk of air contamination and or inadvertent explosive

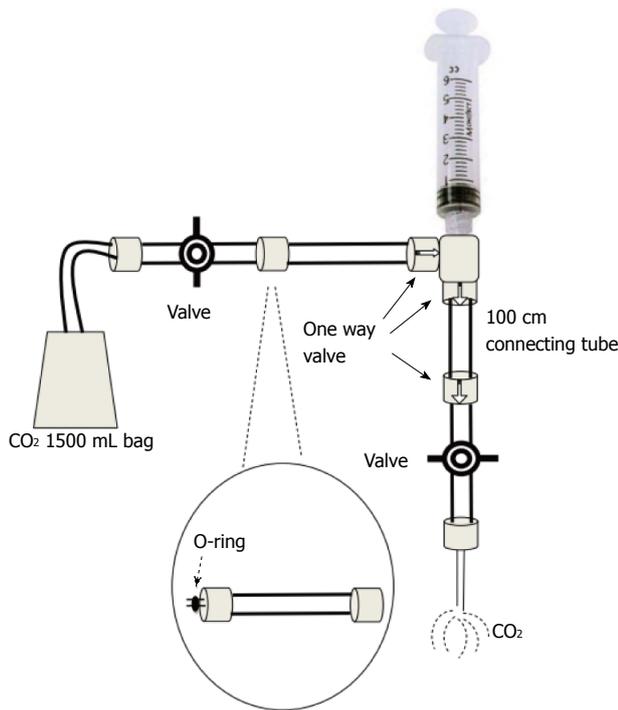

Figure 1 The modified plastic bag system with O-ring.

administration of CO<sub>2</sub> into the patient<sup>[10]</sup>. In this system, the CO<sub>2</sub> source is connected to a regulator, a particle filter and a 3-way tap by connecting tubes. One end of 3-way valve has a sliding 2-way valve connected to a 60 cc syringe. The other end of 3-way valve has a tube serving as a simple under water seal by having the other end of the tube dipped in a bowl of saline. When the CO<sub>2</sub> source is turned on and the 3-way valve is on to the syringe, the syringe will get filled without pulling the plunger, by the positive pressure of the CO<sub>2</sub> coming from the source. Once the syringe is filled the 2-way valve is turned off and 3-way valve is turned to the under-water seal. Bubbles of CO<sub>2</sub> would be seen in the bowl of saline coming out of the tube's end. The CO<sub>2</sub> source is then turned off and the 3-way valve is then turned on to the syringe and the water seal. The CO<sub>2</sub> can then be purged through the water seal. This process of filling and purging can be repeated at least 3 times to make sure that there is only CO<sub>2</sub> and no air in the tubing and syringe system. Then the filled syringe along with a 2-way valve turned off, can then be disconnected and attached to the angiography catheter. Right before it is connected to the angiography catheter, the 2-way valve is turned on to release the positive pressure in the syringe to come down to atmospheric pressure. This will avoid explosive administration and or over dosing of pressurized CO<sub>2</sub> in the syringe but at the same time this may create a very small risk of air contamination. Only fully filled syringes should be used while using this method as half-filled syringes when opened to atmospheric pressure will certainly lead to higher risk of air contamination. The innovators of this system also described their experience of 5 years in

over 250 patients and no directly related complications were noticed<sup>[10]</sup>.

### Dosage

Typically 30-40 mL of CO<sub>2</sub> is injected for abdominal aortography or IVC visualization. Twenty to thirty milliliter is used for lower extremity vessels and other aortic branches like celiac, superior mesenteric or renal arteries. The left renal artery which is more posteriorly located can be filled even with 10 mL if injected with patient lying on the right side. Injections can be repeated at approximately 3 min intervals. Thirty to fifty milliliter may be used for runoff studies by injecting at low rate of 10 mL/s.

### Potential uses of CO<sub>2</sub>-based angiography (Figure 2)

The diagnostic accuracy is acceptable in comparison to contemporary ICA and in some conditions such as TIPS, CO<sub>2</sub> is even rendered superior to the ICA.

**Aortic aneurysm repairs:** CO<sub>2</sub> has been used in endovascular repairs of aortic aneurysms<sup>[11-14]</sup>. A recent prospective study of 72 patients with abdominal aortic aneurysm (AAA) endovascular repair demonstrated that CO<sub>2</sub> has overall sensitivity of 84% and specificity of 72% as compared to ICA as the standard criterion for detection of endoleaks and in patients who are at risk of nephrotoxicity from ICA, CO<sub>2</sub> can be used as an acceptable alternative to ICA<sup>[15]</sup>. Another study describes the outcomes of CO<sub>2</sub>-guided procedures are similar to those which are ICA-guided<sup>[14]</sup>. Additional benefit of CO<sub>2</sub> use in endovascular repair of AAA is that an accessory catheter which is otherwise required for ICA may not be required for CO<sub>2</sub> injection as it can be administered through the endograft sheath or femoral access sheath<sup>[13]</sup>.

**Aortography:** CO<sub>2</sub> may be used for aortography and for runoff studies in most patients<sup>[16]</sup>. If needed supplemental ICA imaging may be used in order to obtain additional information. To get the retrograde aortogram, CO<sub>2</sub> may be injected retrograde through the femoral artery by percutaneous catheterization with a 4-Fr end-hold catheter (Cobra-shaped or shepherd hook catheter) or catheters with side-holes (Omni-flush, pigtail, Racquet, multipurpose). Contra-lateral superficial femoral arterial views can also be taken through the same port by moving the catheter into the contralateral superficial femoral artery. For antegrade views micro-catheters of 3-Fr may be used for popliteal, tibial and peroneal arteries. Use of intra-arterial nitroglycerine and or leg elevation may be done for better visualization of smaller vessels such as tibial and plantar branches.

**Renal artery angiography (Figure 3):** CO<sub>2</sub> can be used in the assessment of renal artery stenosis, aneurysms, AV (arterio-venous) malformations, AV fistulas, renal artery stenting, invading tumors in renal

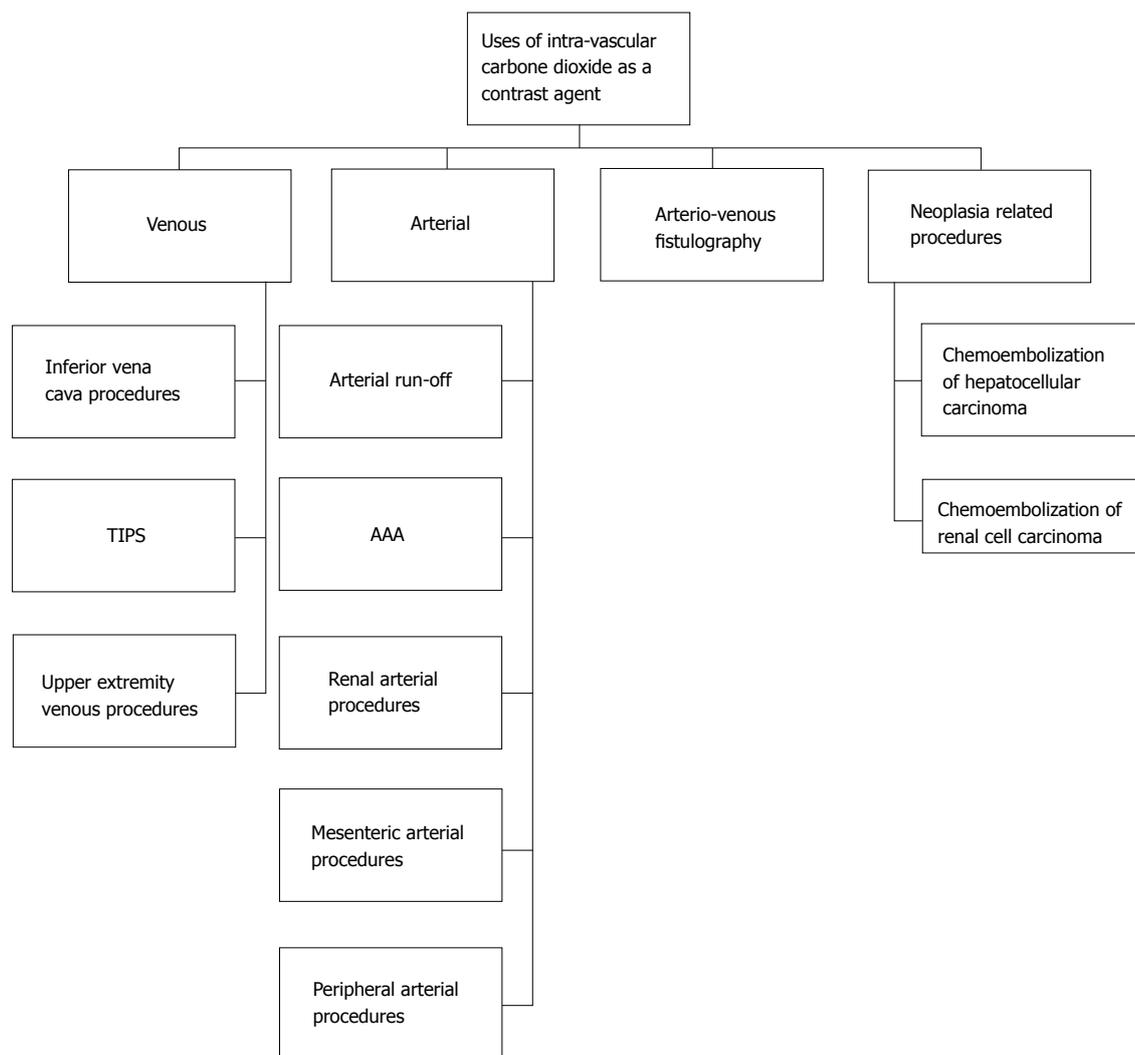

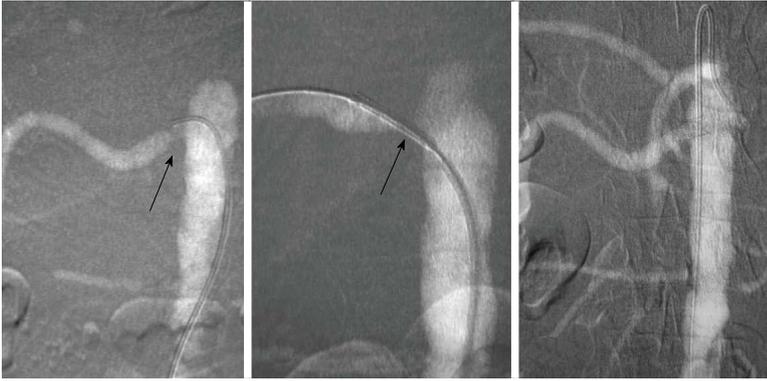

Figure 2 Potential uses of carbon dioxide angiography. AAA: Abdominal aortic aneurysm.

veins or arteries, renal cell carcinomas, evaluation of transplanted kidney vascular stenosis and for its angioplasty and/or stenting, anastomotic stenosis, diffuse arterial disease related to chronic rejection and AV fistulas after renal transplant biopsy (in which case it may be superior to ICA)<sup>[17,18]</sup>. In such cases CO<sub>2</sub> may be used as initial imaging modality to get an overview and then small dose ICA may be used for confirmation of the findings<sup>[11]</sup>. CO<sub>2</sub> does not adequately fill the distal portion of renal artery very well in a supine patient, as it is located posterior to the aorta. In this situation, the patient may be turned on the side to bring the renal arteries superior with respect to the aorta. Recent studies have also demonstrated the use of CO<sub>2</sub> in combination with intravascular ultrasound for successful vascular stenting. In a study of 18 patients, 27 successful renal artery stenting procedures were done using CO<sub>2</sub> and intravascular ultrasound with good outcomes<sup>[19,20]</sup>.

**Inferior venae cava imaging:** CO<sub>2</sub> can be used for the placement of inferior venae cava (IVC) filters, IVC venous

anomalies and thrombus visualization, recanalization of occlusion and estimation of IVC diameters (accuracy of about 97%). In a study of 50 patients, CO<sub>2</sub> was used for IVC filter placement at the bedside in ICU setting. Only 2 of these patients required additional ICA for better visualization. The study concluded with positive results and favored the use of CO<sub>2</sub> as first line contrast agent in ICU patients requiring IVC filter<sup>[21]</sup>.

**Portal vein imaging (portography):** A very important utility of CO<sub>2</sub> is in the delineation of the portal vein anatomy (wedged hepatic venography) during TIPS procedure (Figure 4). CO<sub>2</sub> is found to be superior to ICA for this use and can be used as first line contrast agent for portography<sup>[22]</sup>. The reason is buoyancy and low viscosity of CO<sub>2</sub> making it travelling through the sinusoids easily and deeply. In liver transplants, anastomosis can also be visualized using CO<sub>2</sub>. In a study of 16 patients, the utility of CO<sub>2</sub> was compared with ICA for balloon-occluded retrograde trans-venous venography (BRTV) and obliteration (BRTO) for gastric varices and it was found that varices were visualized

**Figure 3** A carbon dioxide renal arteriogram showing renal artery orifice stenosis with subsequent stent placement and resolution of the stenosis with good flow. The carbon dioxide contrast is injected through the sheath. Adapted with permission from Dr. Kyung Cho.

**Figure 4** Carbon dioxide wedged hepatic protogram showing portal vein stenosis (arrow). Adapted with permission from Dr. Kyung Cho.

better with CO<sub>2</sub> than with ICA and even in cases where ICA could not reach the varices, CO<sub>2</sub> successfully delineated these varices (in 7 out of 16 patients), leading to successful obliteration of the varices<sup>[23]</sup>. According to some estimates, success rate of portal vein visualization with CO<sub>2</sub> wedged hepatic venography is approximately 90%. A diagnostic catheter of 5-Fr can be used for wedged hepatic venography. Using the femoral or jugular vein approach, catheter can be advanced into a peripheral hepatic vein for wedging. It is also being used for multi-detector CT cholangiopancreatography. In a study of 73 patients, the feasibility of CO<sub>2</sub> enhanced CT cholangiopancreatography was assessed and found to be very useful for interventional procedures<sup>[24]</sup>.

**Splenoportography:** Can also be done by using CO<sub>2</sub> in selected patients<sup>[25]</sup> such as a patient in which portal vein imaging study for patency is inconclusive<sup>[26]</sup>. Twenty-two to twenty-five gauge needle can be used to inject CO<sub>2</sub> into the parenchyma of spleen. This is useful in pediatric patients as it obviates the catheterization of femoral artery for arterial portography. Endoscopic ultrasound guided direct portal venography with CO<sub>2</sub> by using a small FNA needle has also been used in animal studies with favorable results<sup>[27]</sup>.

**Tumor embolization procedures:** CO<sub>2</sub> can be used

for the following oncological embolization procedures: Embolization of renal cell carcinoma and its metastatic lesions in the bone, hepatocellular carcinoma<sup>[28,29]</sup>, radiofrequency ablation and transcatheter arterial chemo-embolization of hepatocellular carcinoma (by using intra-arterial CO<sub>2</sub> for enhancement for ultrasonography guidance)<sup>[30]</sup>, uterine artery embolization in uterine leiomyoma<sup>[31]</sup>. These procedures can be optimized by using super-selective angiographic techniques with help of micro-catheters of 3 Fr.

**Upper extremity venography:** Can be performed using the CO<sub>2</sub><sup>[32]</sup>. It can be useful for AV-fistula formation<sup>[33]</sup>, insertions of trans-venous pacer wires<sup>[34]</sup>, central venous catheters and for the delineation of any atypical vascular anatomy. The preferable site of injection is antecubital vein and a 21 gauge catheter may be used. In a series of 146 AV fistulography procedures using CO<sub>2</sub> as the first line contrast agent, 141 cases required AV fistula intervention and in 115 of these cases intervention was performed successfully using CO<sub>2</sub> alone. Rest of the cases required ICA for various reasons in addition to CO<sub>2</sub> for intervention<sup>[35]</sup>. For AV fistula assessment, one needs to be careful of not letting CO<sub>2</sub> reflux into arterial system due to potential risk of neurologic sequelae including infarction. Also there is a potential of overestimation of fistula stenosis.

**Gastrointestinal bleeding:** Due to increased compressibility and low viscosity it may be useful in detecting the site of occult bleeding or ongoing blood loss such as the gastrointestinal tract, with higher sensitivity than ICA. CO<sub>2</sub> can also be used in selected angiographies for chronic mesenteric ischemia<sup>[36]</sup>.

**Contrast ultrasonography:** CO<sub>2</sub> can be used to enhance sonography by employing CO<sub>2</sub> microbubbles. In a study where conventional sonography was compared with CO<sub>2</sub> micro-bubble enhanced sonography; the former detected only 6 tumors however with CO<sub>2</sub>-microbubble enhanced sonography 14 tumors were detected and then treated successfully with radiofrequency ablation

**Table 1 Summary of the characteristics of carbon dioxide and against iodinated contrast agents**

Characteristics	Carbon dioxide	Iodinated contrast agents
Overall sensitivity	Less	Higher
Overall specificity	Less	Higher
Nephrotoxicity	No	Yes
Allergenic	No	Yes
Cost	Low	High
Ease of administration	Cumbersome	Easier
Limitations	Visibility and air contamination	Dose related toxicity and allergy
Delivery <i>via</i> small caliber catheters	Possible	Difficult
Radiation exposure	Increased if digital subtraction angiography used	Standard
Dose	Rate related toxicity	Volume related nephrotoxicity
Contraindications	Pulmonary-systemic communications; not for use in heart, brain or spinal vasculature	Allergy, nephrotoxicity
Hepatotoxicity	Rare	Rare
Quality of image	Good	Better
Procedure duration	Increased	Standard

using CO<sub>2</sub>-microbubbles enhanced sonography<sup>[37]</sup>.

## LIMITATIONS

Overall CO<sub>2</sub> is a relatively safe agent<sup>[38]</sup>. In a study of 800 subjects, only one complication of transient colonic ischemia was reported. In another study of 1200 subjects only 7 subjects developed some kind complication. Livedo reticularis, bowel ischemia and renal dysfunction have been described after in 1 patient with CREST syndrome<sup>[38]</sup> (Table 1).

The adverse effects are primarily either dose related or buoyancy related. Majority of the adverse effects are due to "vapor-lock phenomenon" which result when large amounts of CO<sub>2</sub> are injected or a small amount is injected too frequently with very short intervals causing trapping of CO<sub>2</sub> gas column in the vessel and consequently obstructing the vessel. This may lead to ischemia of the tissues. Cases with transient mesenteric ischemia and ischemic colitis secondary to "vapor lock phenomenon" have been described in the literature. Similar mechanism may potentially precipitate right sided heart failure. Sometimes CO<sub>2</sub> bubbles may accumulate in an aortic aneurysm and may cause blood flow obstruction, leading to tissue ischemia. Even a transient occlusion of inferior mesenteric artery may result in mesenteric ischemia. Typically, this happens with the use of excessive dose of CO<sub>2</sub>. Similarly a vapor lock may happen in the pulmonary artery and this may lead to significant hypotension. Air contamination may also cause vapor-lock phenomenon that is typically worse and more persistent. Usually CO<sub>2</sub> bubbles in the pulmonary artery dissolve within 30 s. If they persist beyond 30 s then either air contamination or CO<sub>2</sub> over-dosage should be suspected and the tubing system should be checked for any air leak. For hypotension secondary to vapor lock phenomenon, patient should be placed in Trendelenburg position or lateral decubitus positions. Aspirating the air using a catheter from the pulmonary artery should also be considered.

Due to its buoyancy the visualization of a dependent

(inferior or caudal positioned) vessels may be sub-optimal (such as visualization of renal arteries in supine position). This problem can be circumvented by putting the patient in lateral decubitus position. CO<sub>2</sub> may get trapped in organs which are non-dependant and cause decreased blood flow or ischemia such as in transplanted kidneys or mesenteric vessels. If we place the patient in lateral decubitus position, the CO<sub>2</sub> may remain trapped in right atrium instead of moving into pulmonary arteries. Changing the body position may help clearance in these situations. Similarly using low volumes of CO<sub>2</sub> with adequate time intervals may help avoiding these adverse effects. Although 100 mL is the recommended maximum volume for arterial use and 50 mL for venous use, by using above mentioned precautions, larger total volume may be used. Vessels which are more anterior such as superior mesenteric artery (SMA), CO<sub>2</sub> is useful in their evaluation, particularly for proximal mesenteric stenosis. For more distal assessment ICA probably provides superior imaging.

Due to its dissolution in blood soon after injection vessels with slower flow may not have adequate visualization and this may lead to overestimation of stenosis. Similarly due to the expansive nature of CO<sub>2</sub> and elasticity of vessels, CO<sub>2</sub> may lead to overestimation of the vessel diameter. This may cause errors in estimation of balloon or stent size during intervention procedures.

The use of CO<sub>2</sub> for cerebral, spinal and or cardiac procedures should be avoided as there is a potential risk of ischemia to vital organs<sup>[39]</sup>. In animal models neurotoxicity has been reported after cerebral use. For the same reasons, before the use of CO<sub>2</sub> presence of atrial or ventricular septal defects or pulmonary arterio-venous malformation should be ruled out to avoid the risk of paradoxical embolism to CNS and or coronary embolization. CO<sub>2</sub> may also aggravate or worsen pulmonary arterial pressure therefore the use of this agent should be avoided in pulmonary hypertension. There are some relative contraindications for the use of CO<sub>2</sub> for upper extremity which are similar for other uses

as well and these are the presence of cardiac septal defects, pulmonary AV malformations, pulmonary hypertension and severe emphysema. In a series of 146 arteriovenous fistulography procedures, in 3 cases when manual injection of CO<sub>2</sub> into the brachial artery was performed, a reflux of the gas into the thoracic aorta occurred precipitating transient loss of consciousness<sup>[35]</sup>.

Typically, CO<sub>2</sub> angiography does not cause any significant changes in the serum osmolality or blood gas values<sup>[40]</sup> unless excessive quantities of CO<sub>2</sub> are used or significant derangements of pulmonary function happen. Caution is required in cases where pulmonary functions are compromised such as in chronic obstructive pulmonary disease, as clearance of CO<sub>2</sub> may be decreased. Doses of CO<sub>2</sub> for diagnostic purposes are typically between 20–40 cc and it has no effect on vital signs. Any change in vital signs should prompt the considerations for air contamination or air trapping.

Peristaltic and breathing movements sometime may decrease the image quality of mesenteric CO<sub>2</sub> angiography. This problem may be avoided by selective or superselective CO<sub>2</sub> injection into the mesenteric arterial branch, getting additional mask images or using intravenous glucagon to suppress the peristalsis. While using CO<sub>2</sub>, sedation should be avoided or minimized as any of the side effects of CO<sub>2</sub> overdosing or air contamination may be missed in the presence of heavy sedation. During the procedure patients vital signs (pulse-oxymetry, blood pressure, heart rate, respiratory rate, ECG, and if possible capnography) need to be monitored closely. Any change in these parameters should raise the suspicion of CO<sub>2</sub> over dosage or air contamination.

The utility of CO<sub>2</sub> as contrast agent for CT angiography for abdominal aorta and peripheral vessels is also currently being evaluated<sup>[41,42]</sup>. In an animal study the use of CO<sub>2</sub> micro-bubbles mixed in saline was compared with conventional CO<sub>2</sub> gas and ICA and demonstrated that vessels can be depicted using X-ray angiography and CO<sub>2</sub> micro-bubbles as enhancement<sup>[43]</sup>. CO<sub>2</sub> bubbles sometimes may provide better visualization than plain CO<sub>2</sub> gas with additional benefit of low dose requirement<sup>[44]</sup>.

## CONCLUSION

CO<sub>2</sub> is useful in cases where ICA cannot be used due to allergy or impaired kidney functions. CO<sub>2</sub> may be superior to ICA in certain procedures such as in TIPS.

### Abstract

Takotsubo cardiomyopathy (TC) is characterized by reversible ventricular dysfunction, not limited to the distribution of an epicardial coronary artery. A disease

primarily afflicting post-menopausal women, it is frequently mistaken for acute anterior wall myocardial infarction. Alternatively called Stress Cardiomyopathy, physical or emotional triggers are identified in only three fourths of TC patients. Long considered a benign condition, recent findings suggest poor short term prognosis similar to acute coronary syndrome (ACS). Despite the widely recognized pathophysiological role of catecholamine excess, its diagnostic role is uncertain. TC is suspected based on typical wall motion abnormalities in ventriculogram or echocardiogram. Several additional electrocardiographic, laboratory and imaging parameters have been studied with the goal of clinical diagnosis of TC. While several clinical clues differentiate it from ACS, a clinical diagnosis is often elusive leading to avoidable cardiac catheterizations. Natriuretic peptides (NPs), a family of peptide hormones released primarily in response to myocardial stretch, play a significant role in pathophysiology, diagnosis as well as treatment of congestive heart failure. TC with its prominent ventricular dysfunction is associated with a significant elevation of NPs. NPs are elevated in ACS as well but the degree of elevation is typically lesser than in TC. Markers of myocardial injury such as troponin are usually elevated to a higher degree in ACS than in TC. This differential elevation of NPs and markers of myocardial injury may play a role in early clinical recognition of TC.

**Key words:** Takotsubo cardiomyopathy; Natriuretic peptide; Brain natriuretic peptide; N-terminal-pro brain natriuretic peptide; Troponin; Cardiac biomarkers; Acute myocardial infarction

**Core tip:** Takotsubo cardiomyopathy (TC) characterized by reversible ventricular dysfunction is frequently mistaken for acute anterior wall myocardial infarction often leading to avoidable cardiac catheterizations. While several clinical clues differentiate TC and acute coronary syndrome

(ACS), a clinical diagnosis still remains elusive. We review the pathophysiology and diagnosis of TC with a focus on role of cardiac biomarkers [natriuretic peptides - brain natriuretic peptide (BNP) and NT-proBNP and cardiac myonecrosis markers - Troponin, CKMB and Myoglobin]. We have done a review of several studies looking at diagnostic utility of cardiac biomarkers in differentiating TC and ACS.

## INTRODUCTION

Takotsubo cardiomyopathy (TC), originally described by Sato *et al*<sup>[1]</sup> in 1990, is variably known as stress cardiomyopathy, broken heart syndrome, and apical ballooning syndrome. A disease process primarily affecting post-menopausal women, it is characterized by transient left ventricular (LV) dysfunction, not limited to distribution of an epicardial coronary artery. Clinical presentation of TC most often has a significant overlap with acute coronary syndrome (ACS) with symptoms, cardiac biomarker profiles and EKG changes suggesting myocardial ischemia or infarction. TC is estimated to occur in 1%-2% of patients presenting as ACS. With prevalence in 2008 reported as 0.02% of hospitalizations in United States<sup>[2]</sup>, TC incidence has increased with a 3-fold increase in TC hospitalization in United States between 2007 and 2012<sup>[3]</sup>. The inability to confidently diagnose TC based on clinical presentation leads to almost universal use of cardiac catheterization in these patients. Several indicators including cardiac biomarker elevation have been studied with the goal of making a clinical diagnosis of TC (Table 1).

## EPIDEMIOLOGY

Women have a 9-fold higher risk of TC compared to men<sup>[4]</sup>. Women > 55 years have about 5-fold higher risk than women < 55 years<sup>[4]</sup>. While a physical or emotional trigger is often identified, no specific triggers have been reported in little over a fourth of TC patients<sup>[4]</sup>. Reported stressors include surgery, critical illness, death of dear ones, dobutamine or ergonovine stress test, lightning strike, prolonged immobilization and thyrotoxicosis. TC recurrence has been reported in greater than 10% of the patients in the first four years<sup>[5]</sup>. Initially thought to have a benign course, recent data show short term prognosis for TC is similar to ACS. In the InterTAK registry, severe in-hospital complications, such as shock and death were similar in TC and ACS<sup>[4]</sup>. According to the SWEDEHEART study, prognosis of takotsubo syndrome is poor, with early and late mortality similar

to STEMI and NSTEMI<sup>[6]</sup>.

## PATHOPHYSIOLOGY

### Clinical findings

Four different morphotypes of TC have been described: (1) Classical - apical ballooning with basal hyperkinesis; (2) Mid-ventricular - basal hyperkinesis, mid-ventricular hypokinesis and normal or hyperkinetic apex; (3) Basal (inverted) - basal and mid-ventricular hypokinesis with apical hyperkinesis; and (4) Focal - hypokinesis of a focal myocardial segment<sup>[4]</sup>. TC predominantly affects the left ventricle but right ventricular (RV) involvement with a more malignant course has been described as well<sup>[7]</sup>. The classic type characterized by basal hyperkinesis is often associated with left ventricular outflow tract (LVOT) obstruction and shock<sup>[8]</sup>. Significant reversible mitral regurgitation (MR) and higher brain natriuretic peptide (BNP) levels related to the ventricular dilation have been described in the classic form. The inverted (basal) form seems to have higher levels of troponin and lower levels of BNP as well as lower incidence of LVOT obstruction and MR<sup>[8]</sup>.

### Mechanisms

Several etiologies have been proposed including catecholamine excess, derangement of myocardial glucose and fatty acid metabolism, microcirculatory dysfunction, coronary vasospasm, estrogen deficiency *etc.* Norepinephrine may trigger  $\alpha$ 1-mediated coronary vasospasm and  $\beta$ 1-mediated hyperdynamic basal contraction, as basal myocardium has higher density of sympathetic nerve endings and higher content of norepinephrine. The biased agonism of epinephrine and apical-basal gradient of  $\beta$ 2-adrenergic receptor ( $\beta$ 2AR) may explain the apical stunning. High level of epinephrine could trigger signal switching of  $\beta$ 2AR from stimulatory G-protein to inhibitory G-protein. Apical myocardium with higher concentrations of  $\beta$ 2AR may be more susceptible, compared to basal myocardium leading to apical stunning<sup>[9]</sup>. The histological changes of TC mirror catecholamine toxicity seen in pheochromocytoma. Loss of cardioprotective action of estrogen against catecholamine excess may explain higher incidence of TC in postmenopausal women. Positron emission tomography (PET) studies have suggested disturbances in glucose and fatty acid metabolism in TC patients<sup>[10]</sup>. Findings suggestive of coronary vasospasm as well as microcirculatory dysfunction have been described in coronary angiograms of TC patients.

## DIFFERENTIAL DIAGNOSIS

ACS is the primary differential diagnosis as both disease states have significant overlap in their clinical presentation. TC is often mistook for acute anterior wall ST elevation myocardial infarction (occlusion of proximal left anterior descending artery). Other differential diagnoses include myocarditis, endogenous catecholamine excess

**Table 1** Diagnostic clues for differentiating takotsubo cardiomyopathy and acute coronary syndrome

History	Stressful stimulus Female sex Age > 55 yr Neuropsychiatric conditions	
EKG findings	Absence or paucity of reciprocal ST depression Widespread T wave inversion QTc prolongation	
Laboratory findings	Catecholamine levels Natriuretic peptides Myonecrosis markers Others	Metanephrine, Normetanephrine BNP, NT-proBNP Myoglobin, CK-MB, Troponin I, Troponin T Copeptin, sST2, soluble lectin like oxidized LDL receptor-1 (sLOX-1), IMA
Imaging	Echocardiogram  Coronary angiogram  SPECT  PET CMR	Reversible wall motion abnormalities > distribution of a epicardial coronary artery Reversible mitral regurgitation, Left ventricular outflow tract obstruction Absence of ruptured plaque Diminished flow Coronary vasospasm Reduced Thallium uptake Reduced fatty acid metabolism in BMIPP imaging Reduced myocardial MIBG uptake Reverse metabolism perfusion mismatch T2 hyperintensity; lack of first pass hypoperfusion; LGE (may be seen if MRI done early)

sST2: Soluble suppression of tumorigenicity-2; sLOX-1: Soluble lectin like oxidized LDL receptor-1; IMA: Ischemic modified albumin; SPECT: Single photon emission computed tomography; BMIPP:  $\beta$ -Methyliodophenyl-pentadecanoic acid; MIBG: Metaiodobenzylguanidine; PET: Positron emission computed tomography; CMR: Cardiac Magnetic resonance imaging; LGE: Late gadolinium enhancement; MRI: Magnetic resonance imaging; LDL: Low-density lipoprotein; BNP: Brain natriuretic peptide.

(pheochromocytoma), exogenous catecholamine excess (Cocaine, Amphetamine), peripartum cardiomyopathy and cerebrovascular disease (Japanese guidelines have cerebrovascular disease as exclusionary criteria unlike the commonly used Mayo criteria). Other differential diagnosis for chest pain such as aortic dissection, pulmonary embolism should be considered as well.

## DIAGNOSIS

Several diagnostic criteria including the Modified Mayo<sup>[11]</sup> and Japanese<sup>[12]</sup> criteria have been proposed underlining the difficulty in diagnosis of TC. As per the widely used Modified Mayo criteria, all of the following 4 criteria must be met for diagnosing TC: (1) transient hypokinesia, akinesia, or dyskinesia of the LV mid segments with or without apical involvement; the regional wall motion abnormalities extend beyond a single epicardial vascular distribution; a stressful trigger is often, but not always present; (2) absence of obstructive coronary disease or angiographic evidence of acute plaque rupture; (3) new electrocardiographic abnormalities (either ST-segment elevation and/or T-wave inversion) or modest elevation in cardiac troponin; and (4) absence of pheochromocytoma and myocarditis. Several approaches have been proposed to facilitate differentiating TC from ACS. They include use of laboratory findings [catecholamine levels, cardiac biomarkers, lipid levels and investigational markers such as soluble lectin like oxidized LDL receptor-1 (sLOX-1), Copeptin, ischemic modified albumin (IMA), sST2 (soluble suppression of tumorigenicity-2), etc.], imaging

modalities [echocardiography, computed tomography (CT) coronary angiogram, invasive coronary angiogram, cardiac magnetic resonance imaging (CMR), single photon emission computed tomography (SPECT) and PET], EKG findings and risk scores.

## LABORATORY FINDINGS

More studies have focused on laboratory findings due to their universal availability at the time of presentation as well as availability of repeat measurements. Several markers including Copeptin<sup>[13]</sup>, lipid profile<sup>[14]</sup>, sLOX-1<sup>[15]</sup>, IMA<sup>[16]</sup>, sST-2<sup>[17]</sup> have been proposed for differentiating TC from ACS. High HDL-C and lower levels of LDL and triglycerides have been reported in TC compared to MI<sup>[14]</sup>. Forty percent of TC pts had hyperalphalipoproteinemia or hypotriglyceridemia. sLOX-1 elevation has been found comparable to troponin rise in ACS and is lower in non-ACS patients including TC<sup>[15]</sup>. Changes in level of sST2 have additional predictive value for TC in patients with normal Troponin I<sup>[17]</sup>. The most studied laboratory findings though are natriuretic peptides (NP), markers of cardiomyonecrosis (troponin I and T, creatine kinase and myoglobin) and catecholamines.

### NP

NP belong to a family of peptide hormones with natriuretic and vasodilatory properties in addition to other pleiotropic effects<sup>[18]</sup>. Atrial natriuretic peptide (ANP), BNP and C-type natriuretic peptide (CNP) constitute the natriuretic peptide family. Under normal conditions

ANP is primarily released from atria, BNP from both atria and ventricles (ventricles more than atria) and CNP from nervous tissue and vascular endothelium<sup>[19,20]</sup>. The NPs act *via* the natriuretic peptide receptors (NPR) NPR-A, NPR-B and NPR-C<sup>[18]</sup>. ANP and BNP act primarily through NPR-A leading to natriuresis, vasodilation, inhibition of aldosterone synthesis, thirst suppression, sympatholysis and inhibition of release of vasopressin and adrenocorticotrophic hormone<sup>[18,20]</sup>. Additional effects on pulmonary vasculature and airway smooth muscle cells have been described<sup>[20]</sup>. CNP which has less potent natriuretic effect, acts primarily *via* NPR-B and modulates vascular tone, cardiac remodeling and proliferation of vascular smooth muscle cells. Primary mechanism of NP clearance is by NPR-C mediated internalization and lysosomal degradation<sup>[21]</sup>. While ANP was discovered earlier in the 1980s, BNP and amino terminal proBNP (NT-proBNP) - an inactive by-product of BNP formation, have been more widely studied for their role in pathophysiology, diagnosis as well as treatment of heart failure.

### BNP

BNP is initially produced in the form of preproBNP a 134 amino acid (AA) peptide. Cleavage of the 26 AA signal peptide forms the proBNP which is further cleaved by enzyme Corin into active 32 AA BNP and inactive 76 AA amino terminal proBNP (NT-proBNP). BNP has a short half-life (about 20 min) and is cleared by neutral endopeptidase (Nepilysin) and by NPR-C mediated clearance. NT-proBNP has a longer half-life (120 min) and is cleared renally<sup>[22]</sup>. Use of neprilysin inhibitor (sacubitril) increases BNP levels by inhibiting its clearance but does not affect clearance of NT-proBNP<sup>[23]</sup>. Upper limit of normal in the non-acute setting is 35 pg/mL for BNP and 125 pg/mL for NT-proBNP<sup>[24]</sup>. In acute setting, higher cut-off values are recommended (BNP < 100 pg/mL and NT-proBNP < 300 pg/mL)<sup>[24]</sup>. In the Breathing Not Properly trial, BNP < 100 pg/mL had a high diagnostic accuracy of 83.4% to distinguish other causes of dyspnea from heart failure<sup>[25]</sup>. The PRIDE (ProBNP Investigation of Dyspnea) study proposed an age based cut-off for NT-proBNP (> 450 pg/mL for age < 50, > 900 pg/mL for age > 50) for diagnosing HF and < 300 pg/mL for ruling out CHF<sup>[26]</sup>. International Collaborative of NT-proBNP (ICON) study, a pooled analysis recommended a cut off of > 1800 pg/mL for age > 75<sup>[27]</sup>. Asians and african americans have higher levels compared to caucasians and hispanics<sup>[28]</sup>. Obese patients tend to have lower levels and heart failure with preserved ejection fraction (HfPEF) patients have levels lower than heart failure with reduced ejection fraction (HfrEF) patients<sup>[29,30]</sup>. Causes of BNP and NT-proBNP elevation include cardiac causes such as heart failure, ACS, valvular heart disease, pericardial diseases, atrial fibrillation, myocarditis, and cardioversion and non-cardiac causes such as advancing age, anemia, renal failure, pulmonary diseases, critical illness, sepsis,

burns, etc<sup>[24]</sup>.

### NP in TC

Reversible LV dysfunction without significant myocardial ischemia and or necrosis is the hallmark of TC, leading to significant elevation of NP. Among TC patients, the classic form of TC with basal hyperkinesis and apical ballooning appears to have higher degree of NP elevation compared to the basal (inverted) variant<sup>[8]</sup>. BNP has been correlated with the degree of basal hyperkinesis, measured by  $\delta$ Base (difference between end systolic and end diastolic dimension of the LV base measured 10 mm below aortic valve)<sup>[31]</sup>. NT-proBNP levels rise within first 24 h after the onset of symptoms with slow and incomplete resolution during the 3 mo thereafter<sup>[32]</sup>. NT-proBNP levels have been shown to correlate with plasma catecholamine levels and the severity of LV dysfunction, as measured by the wall motion score index and LV ejection fraction<sup>[32]</sup>.

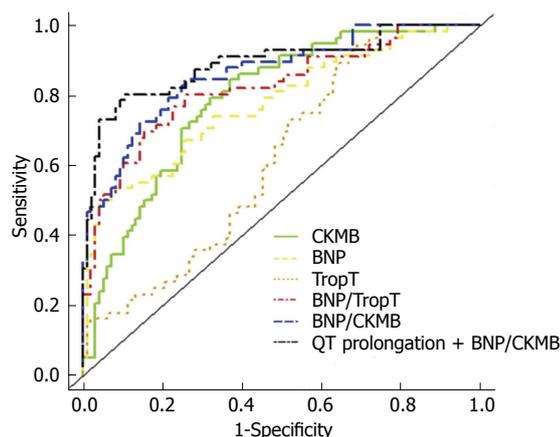

### Myonecrosis markers in TC

With lack of significant myonecrosis, TC patients usually have lesser degree of elevation of cardiac myonecrosis markers such as myoglobin, creatine kinase and troponin when compared to ACS patients. Studies comparing TC with anterior ST elevation myocardial infarction (STEMI) showed significantly lower mean peak troponin T levels in TC patients<sup>[33]</sup>. Some studies suggested threshold values for troponin to rule out TC while other studies contradicted it. Ramaraj *et al.*<sup>[34]</sup> found troponin T > 6 ng/mL or troponin I > 15 ng/mL were unlikely in TC but Song *et al.*<sup>[8]</sup> found about 20% of patients included in their study of TC patients had troponin I > 15 ng/mL. Among TC patients, inverted (basal) type TC patients tend to have higher elevation of myonecrosis markers<sup>[8]</sup>.

### Relative elevation of NP and Myonecrosis markers in TC

Comparing TC to STEMI, Madhavan *et al.*<sup>[35]</sup> found lower troponin (0.62 ng/mL vs 3.8 ng/mL), higher BNP (944 pg/mL vs 206 pg/mL) but no significant differences in plasma normetanephrine, metanephrine, cortisol or hs-CRP levels. Fröhlich *et al.*<sup>[36]</sup> found NT-proBNP (ng/L)/myoglobin ( $\mu$ g/L) ratio of 3.8, distinguished TC from STEMI, while a NT-proBNP (ng/L)/myoglobin ( $\mu$ g/L) ratio of 14, distinguished TC from NSTEMI. NT-proBNP (ng/L)/TnT ( $\mu$ g/L) ratio of 2889, distinguished TC from STEMI, while a NT-proBNP (ng/L)/TnT ( $\mu$ g/L) ratio of 5000 distinguished TC from NSTEMI. NT-proBNP levels usually peaked 22 to 26 h after a cardiac event, whereas TnT levels peaked 8 to 13 h after the first manifestation of chest pain. In a study of 52 patients with TC, Lahoti *et al.*<sup>[37]</sup> found higher NT-proBNP/troponin T in TC than in ACS patients (5154 vs 183). Peak BNP/peak troponin ratio > 2500 yielded a 90% sensitivity and specificity for TC.

Randhawa *et al.*<sup>[38]</sup> compared 58 patients and 97 acute myocardial infarction patients and found early

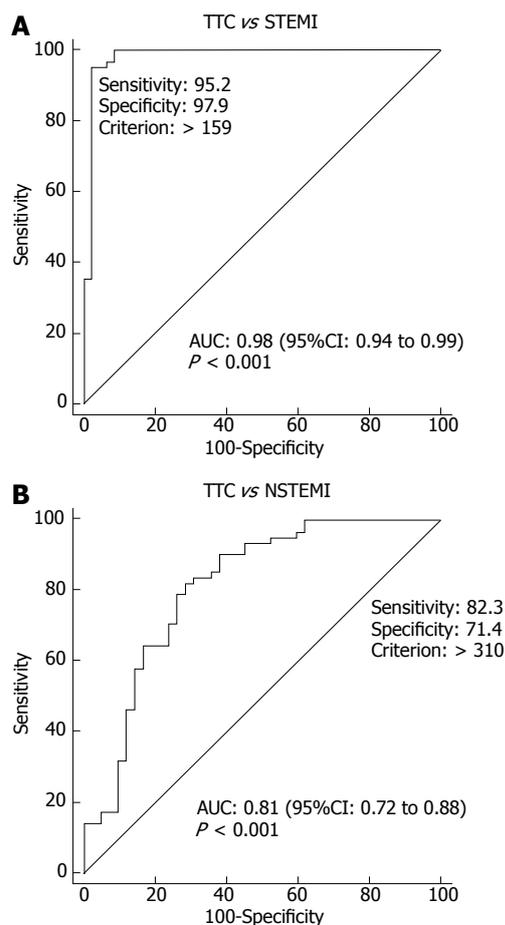

**Figure 1** Receiver operator characteristic analysis to distinguish acute myocardial infarction and takotsubo cardiomyopathy (Reproduced from Randhawa *et al.*<sup>[39]</sup>; Permission requested). BNP: Brain natriuretic peptide; CKMB: Creatine kinase - MB fraction.

BNP/TnT and BNP/CKMB ratios help to differentiate TC from AMI with greater accuracy than BNP alone. Median BNP/TnT and BNP/CKMB ratios were, respectively, 1292 and 28.44 in the TC group and 226.9 and 3.63 in the AMI group. TC was distinguished from AMI with 95% specificity with the use of BNP/TnT ratio of  $\geq 1272$  (sensitivity 52%) with area under the curve (AUC) of 0.822 and BNP/CKMB ratio  $\geq 29.9$  (sensitivity 50%) with AUC of 0.862. When QT prolongation was combined with BNP/CKMB, the AUC was even higher (Figure 1). Doyen *et al.*<sup>[39]</sup> found TnI elevations in TC comparable to anterior NSTEMI but lower than anterior STEMI, earlier peaking of troponin in TC than ACS (6 h vs 12 h) and higher BNP/TnI ratio (642) than anterior NSTEMI (184.5) or anterior STEMI (7.5). BNP/TnI ratio showed high area under the curve (AUC) in receiver operating characteristic (ROC) analysis. The AUC for TC vs STEMI was 0.98 (0.94 to 0.99) and TC vs NSTEMI was 0.81 (0.72 to 0.88) (Figure 2). The InterTAK registry study group<sup>[40]</sup> compared matched cohorts of 455 TC (out of 1750 TC patients in InterTAK registry) and 455 ACS patients. Median troponin levels in TC were not significantly different from ACS but CK and BNP levels were significantly different.

### InterTAK Diagnostic Score

InterTAK Diagnostic Score<sup>[39]</sup> was developed using a derivation cohort with TC patients recruited from the International Takotsubo Registry and ACS patients from a Zurich hospital (TC,  $n = 218$ ; ACS,  $n = 436$ ). The score has seven variables each with an assigned score value: Female sex 25, emotional trigger 24, physical trigger 13, absence of ST-segment depression (except in lead aVR) 12, psychiatric disorders 11, neurologic disorders 9, and QTc prolongation 6 points. A cut-off value of 40 score points yielded a sensitivity of 89% and specificity 91%. With a score of  $\geq 50$ , nearly 95% of TC patients were correctly diagnosed and with a score  $\leq 31$ , approximately 95% of ACS patients were diagnosed

**Figure 2** Receiver operating characteristic analysis for brain natriuretic peptide/ troponin I ratio to differentiate takotsubo cardiomyopathy from acute coronary syndrome in patients with (A) ST-segment elevation and (B) without ST-segment elevation (Reproduced from Doyen *et al.*<sup>[39]</sup>; Permission requested).

correctly<sup>[39]</sup>. The score was subsequently validated in an independent validation cohort (TTS,  $n = 173$ ; ACS,  $n = 226$ )<sup>[39]</sup>.

While several studies have reported higher levels of NPs in TC and higher troponin in ACS, utilizing ratio of NP to troponin, CKMB or myoglobin to differentiate TC from ACS in clinical practice is more complicated. As discussed earlier the cut off values used in different studies varied widely (Table 2). In general the ratio is higher for TC than ACS and among ACS the ratio is higher for NSTEMI compared to STEMI. The use of different markers for myonecrosis - troponin I and T, CKMB or myoglobin as well as ventricular stretch - BNP or NT-proBNP in different studies affects the wider applicability. Also, most of the studies used peak troponin and or NP levels instead of levels at presentation, which limits the utility of this ratio in avoiding cardiac catheterizations in acute settings. In addition, all these studies were retrospective. The InterTAK score derived from a large cohort study did not include cardiac biomarkers. In the derivation cohort, while the CK was higher in ACS patients and BNP higher in TC patients, the troponin levels were surprisingly higher in TC patients ( $6.67 \times$  ULN) compared to ACS

patients (3.75).

### Catecholamines

With catecholamine excess thought to underlie the pathogenesis of TC, several studies have looked at catecholamine measurements with mixed results. Nguyen *et al*<sup>[32]</sup> reported correlation of peak NT-proBNP levels in TC patients with simultaneous plasma normetanephrine levels as well as LV ejection fraction. On the contrary Madhavan *et al*<sup>[35]</sup> found significantly higher elevation of BNP in TC patients compared to STEMI patients but similar plasma normetanephrine, metanephrine and cortisol levels. In their study majority of TC patients had normal 24-h urine metanephrines, catecholamines and cortisol.

### IMAGING

Echocardiographic findings in TC include reversible wall motion abnormalities extending beyond distribution of an epicardial coronary artery, basal hyperkinesis, LVOT obstruction, reversible MR and RV dysfunction. Reverse McConnell's sign with RV basal hyperkinesis and hypokinesis of RV apex has been described in TC<sup>[41]</sup>. Common coronary angiogram findings include absence of ruptured plaque or obstructive coronary artery disease. Coronary vasospasm with provocative maneuvers as well as delayed filling has been reported in TC patients. Ventriculogram often demonstrates the typical takotsubo-like shape. Microcirculatory dysfunction has been demonstrated in TC using index of microvascular resistance<sup>[42]</sup>. CMR findings include enhancement in T2-weighted images representing myocardial edema in the hypocontractile segments during acute phase and absence of first-pass perfusion hypoenhancement<sup>[43]</sup>. Evidence on late gadolinium enhancement (LGE) findings in TC are conflicting. Some studies suggest absence of LGE differentiates TC from ACS and myocarditis while other studies have reported reversible LGE in TC, if CMR is done in acute phase (< 72 h)<sup>[44,45]</sup>. Reduction of fatty acid metabolism during acute phase has been reported using <sup>123</sup>I-β-methyliodophenylpentadecanoic acid (BMIPP) imaging<sup>[46]</sup>. Reduced intramyocardial uptake

during <sup>123</sup>I-metaiodobenzylguanidine (MIBG) imaging suggests sympathetic denervation<sup>[46]</sup>. A reverse perfusion metabolism mismatch in PET with normal perfusion and reduced <sup>18</sup>F-fluoro deoxyglucose (FDG) uptake has been described in TC patients<sup>[43]</sup>.

### ELECTROCARDIOGRAM

Several EKG criteria have been proposed to help differentiate TC from ACS. These include lack or rarity of reciprocal ST depression, widespread T wave inversion, low QRS voltage on presentation, attenuation of QRS voltage in serial EKGs, QTc prolongation, frontal plane ST vector, ST segment elevation (STE) in aVR without STE in V1, lower rate of Q-waves, more frequent STE in the inferior leads, higher ratio of the sums of STEs in leads V4-V6 to the sums of STEs in leads in V1-V3, lower amplitude of STE (< 1.5 mm) and a summated amplitude of the S-wave in V1 plus the R-wave in V6 < 1.5 mV<sup>[47,48]</sup>. While these EKG findings could have additive value in diagnosis of TC, their diagnostic accuracy for TC diagnosis have been found wanting in some studies<sup>[49,50]</sup>.

### CONCLUSION

TC presents a diagnostic challenge by virtue of its similarity in clinical presentation with anterior wall STEMI. The different pathophysiology underlying these two processes leads to a differential degree of elevation in NP and troponin with NP relatively higher in TC and troponin relatively higher in STEMI. While conceptually sound, the use of various assays (BNP vs NT-proBNP, Troponin I vs Troponin T) and wide range in elevation of NPs and Troponin with significant overlap in these two conditions, limits the diagnostic utility of ratio of NPs and troponin. Use of uniform assays for NP and myonecrosis markers and larger trials could pave the way for wider use of NP/troponin ratio in clinical decision making in future.

### Abstract

There is strong relationship between obesity and cardiovascular disease including coronary artery disease (CAD). However, the literature has shown better outcomes in higher obese patients who undergo percutaneous cardiovascular interventions for CAD, a phenomenon known as the obesity paradox (OX). In this review, we performed extensive search for OX in patients undergoing percutaneous coronary intervention. We also discussed possible mechanism OX and disparities in different race and sex.

**Key words:** Obesity paradox; Coronary artery disease; Obesity; Percutaneous coronary intervention; Racial disparities

**Core tip:** Literatures have shown strong association between obesity and coronary artery disease (CAD). However, a phenomenon known as obesity paradox (OX) exist which means that obese patients who undergo percutaneous coronary intervention for CAD, they have better outcome compared to normal and underweight patients. New studies also suggest racial and sexual disparities in OX. Multiple mechanisms and patho-physiology have been implicated for OX. In this review, we performed literature search of OX undergoing percutaneous intervention, propose mechanism of OX and racial and sexual disparities.

## INTRODUCTION

Obesity is a condition in which the body mass index (BMI) is above 30.0 kg/m<sup>2</sup><sup>[1]</sup>. According to the Centers for Disease Control and Prevention (CDC), more than one-third of United States adults, which account for 78.6 million people, are obese<sup>[1]</sup>. It is one of the leading health problems in the United States<sup>[2]</sup> and is strongly associated with a higher risk of developing cardiovascular diseases such as hypertension, coronary artery disease (CAD), heart failure (HF), and arrhythmias like atrial fibrillation<sup>[3]</sup>.

Obese individuals generally have increased total blood volume which is associated with hypertension, high stroke volume, and increased cardiac output as the heart has to pump blood against high pressure<sup>[4]</sup>. Increased cardiovascular workloads typically lead to left ventricular hypertrophy and dilation which can further contribute to dyslipidemia and diabetes mellitus - syndromes typically associated with obesity. In addition, obesity is also an independent risk factor for CAD, a condition which arises when blood flow through the arteries becomes constricted following a steady buildup of atherosclerotic plaques along the arterial walls. CAD also increases the cardiovascular workload and leads to the pathologies discussed above. A common strategy of treating CAD is through percutaneous coronary intervention (PCI), a non-surgical approach that involves catheterization of the coronary arteries. Interestingly, research has shown that obese people have better outcomes and fewer complications following a PCI, despite the high health risk of CAD, a phenomenon that has been termed as the obesity paradox<sup>[5]</sup>.

Since most studies suggest a significant relationship between obesity and cardiovascular risks, it is imperative to review the information available in case studies and controlled trials. Thus, the aim of the study is to present a better understanding of how obesity relates to specific medical conditions and their associated outcomes.

## RESEARCH METHODS

We searched PubMed, Ovid, and Google Scholar for English language articles using terms obesity, paradox, PCI, CAD in various combinations. The abstracts were reviewed and articles related to OX and PCI were examined in detail.

## OBESITY AND PCI

Obese individuals are at a higher risk of developing (CVD)<sup>[6]</sup> and obesity is a poor prognostic factor for cardiovascular mortality<sup>[7]</sup>. Nevertheless, a growing body of evidence suggest better outcome and prognosis

in this very population following some forms of intervention<sup>[5,8-13]</sup>. This obesity paradox basically refers to the observation that while the risk of developing coronary heart disease is greater in obese individuals, the clinical outcomes - including cardiovascular mortality, myocardial infarction (MI), and related complications - are less common in these individuals after a PCI (Table 1).

A systemic review by Gurm *et al*<sup>[14]</sup> of four different randomized controlled trials of platelet glycoprotein II b/III a inhibition showed that the 30-d and one-year post-PCI complications were worse in patients with low (below 18.4 kg/m<sup>2</sup>), normal (18.5-24.9 kg/m<sup>2</sup>), overweight (25-29.9 kg/m<sup>2</sup>), and excessive (above 40 kg/m<sup>2</sup>) BMI compared to the obese individuals (BMI 30-39.9 kg/m<sup>2</sup>). They analyzed the Prevention of Ischemic Complication (EPIC) trial, the Long-term Outcome with Abciximab GP II b/III a blockade (EPILOB) trial, the Integrilin to Minimise Platelet Aggregation and Coronary Thrombosis- II (IMPACT- II) trial and The Evaluation of Platelet II b/III A Inhibitor for Stenting (EPISTENT) trial. They analyzed 11300 patients for 30-d morbidity and mortality and 7290 patients for a 12-mo follow-up. They also observed a paradoxical effect in the obese group compared to the low, normal and overweight BMI patients after PCI. The 30-d mortality was statistically significantly lower and similar results were detected in the long-term follow-up.

In a cohort study, Angerås *et al*<sup>[15]</sup> analyzed 64436 patients from the Swedish Coronary Angiography and Angioplasty Registry. They divided the patients into two groups based on the significance of CAD and the treatment options (PCI, coronary artery bypass, or medical treatment). These patients were followed for up to 3 years for overall mortality. Their analysis showed a U-shaped mortality curve, with the least mortality in obese and overweight patients compared with normal, underweight, and morbidly obese patients. Hence, this study provides additional evidence of an obesity paradox.

In the Using the Rapamycin-Eluting Stent Evaluated at Rotterdam Cardiology Hospital (RESEARCH) registry, Younge *et al*<sup>[16]</sup> analyzed 1019 patients who underwent PCI and followed them for 7 years for all-cause mortality to determine the association between health status, BMI, and mortality. They found that the overall mortality was decreased in overweight compared with obese and normal weight patients.

Lazzeri *et al*<sup>[17]</sup> conducted a retrospective analysis to study the relationship between age and obesity in the outcome of ST-elevation MI (STEMI) in patients treated with primary PCI therapy. The study included 1268 patients who were divided based on their BMI and age. The study had 2.9% patients with a lean BMI, 31.8% with normal, 51.7% with overweight, and 13.6% with an obese BMI, out of which 68.1% were less than 75 years of age and 31.9% were above 75 years of age. All-cause mortality was measured during in-hospital stay and at 1-year follow-up. They

**Table 1** Summary of association between percutaneous coronary intervention and obesity

Ref.	Study population	Study design	Outcome measures	Relationship with obesity
Akin <i>et al</i> <sup>[2]</sup>	1436 normal weight, 2839 overweight, and 1531 obese patients	Retrospective Cohort Study	Primary endpoints were the rate of major adverse cardiac and cerebrovascular events and target vessel revascularization	Baseline clinical parameters were more severe in overweight and obese patients
Angerås <i>et al</i> <sup>[13]</sup>	64436 patients going under angiography. Patients were divided into 9 groups based upon BMI	Cohort Study	To investigate the relationship between BMI and mortality in patients with ACSs	Obese and overweight patients have least mortality compared with normal, underweight, and morbidly obese patients
Gurm <i>et al</i> <sup>[14]</sup>	4 randomized, controlled trials	Systematic Review	To study the impact of BMI on outcome patients undergoing PCI	Increased BMI is associated with reduced risk of complications after PCI
Kaneko <i>et al</i> <sup>[11]</sup>	1205 patients: 92 lean, 640 normal-weight; 417 overweight, and 56 obese	Retrospective Cohort Study	Impact of obesity on Japanese patients who undergo primary PCI	Over-weight and obese patients were independently associated with favorable long-term clinical outcomes after PCI
Lazzeri <i>et al</i> <sup>[17]</sup>	1268 patients: 37 lean, 403 normal, 656 overweight, 172 obese patients	Case Series	Impact of age on the prognostic value of BMI	In patients < 75 yr, overweight patients showed increased in-hospital mortality rate and a poorer long-term survival rate
Kosuge <i>et al</i> <sup>[20]</sup>	3076 patients undergoing PCI	Case Control Study	In-hospital mortality	BMI itself had no impact on in-hospital mortality in patients undergoing primary PCI
Sharma <i>et al</i> <sup>[19]</sup>	36 studies (12 CABG; 26 PCI)	Meta-Analysis	Total mortality, CV mortality, and myocardial infarction	The risk of total mortality, CV mortality, and MI was highest among underweight patients as defined by low BMI and CV mortality was lowest among overweight patients
Stähli <i>et al</i> <sup>[9]</sup>	1993 patients: 461 (23.1%) were of normal weight, 985 (49.4%) overweight, 396 (19.9%) obese, and 144 (7.2%) very obese	Retrospective Cohort Study	All-cause mortality	Overweight and obese patients had lower all-cause mortality
Lancefield <i>et al</i> <sup>[10]</sup>	4762 patients undergoing PCI	Meta-Analysis	In-hospital and 12-mo MACE and mortality rates after PCI	Overweight and obese patients had lower in-hospital and 12-mo MACE and mortality rates after PCI
Uretsky <i>et al</i> <sup>[5]</sup>	22576 hypertensive patients with coronary artery disease	Randomized Control Trial	Primary outcomes include first occurrence of death, nonfatal myocardial infarction, or nonfatal stroke	Obese patients had a decreased risk of primary outcomes
Kang <i>et al</i> <sup>[12]</sup>	3824 STEMI patients: 129 underweight, 1253 normal weight, 1959 overweight, 483 obese	Retrospective Cohort Study	In-hospital mortality, revascularization in 1 yr, mortality in 1 yr, and overall mortality	Obese patients had significantly lower in-hospital and overall mortalities
Numasawa <i>et al</i> <sup>[13]</sup>	10142 patients: 462 underweight, 5945 normal, 3100 overweight and 635 obese	Retrospective Cohort Study	In-hospital outcomes	Obese patients are at a lower risk for in-hospital complications during and after PCI
Younge <i>et al</i> <sup>[16]</sup>	1019 patients: 354 normal, 468 overweight, and 197 obese	Prospective Cohort Study	All-cause mortality	Overweight, but not obesity, was associated with a lower risk for 7-yr mortality in PCI patients
Wang <i>et al</i> <sup>[21]</sup>	6083 patients (normal: 1592; overweight: 3026; obese: 1465)	Retrospective Cohort Study	Clinical-driven repeat revascularization, including TLR and non-TLR	Obesity was not associated with TLR, but was associated with a higher risk of non-TLR

ACS: Acute coronary syndrome; BMI: Body mass index; CV: Cardiovascular; CABG: Coronary artery bypass grafting; MACE: Major adverse cardiac event; PCI: Percutaneous coronary intervention; STEMI: ST-segment elevation myocardial infarction; TLR: Target lesion revascularization.

concluded that patients with a lean BMI had the highest mortality across all age subgroups at short and long-term follow-ups, and younger obese patients (age < 75 years) showed the lowest mortality only at short-term follow-up. Their findings indicate that obese populations develop cardiovascular heart disease at a younger age compared with the lean population and therefore, have less all-cause mortality at short-term. They also concluded that the obesity paradox is age-related because most of the obese individuals included in the study were in the younger age groups and their current medical condition was based on their consistent weight in the obese range. Therefore, with intervention

and appropriate weight loss regimen, a majority of the health problems could potentially dissipate with the decrease in the patients' weights. The lowest mortality at short-term observed in the younger obese patients is an expected result because the medical intervention helped them to recover from their medical conditions. Therefore, based on the above findings, it can be inferred that the obesity paradox is related to age in some instances.

A study by Akin *et al*<sup>[2]</sup> analyzed the relationship between BMIs after PCI with drug-eluting stent (DES). The investigators followed patients who underwent PCI with DES to determine if they had major cardiac,

cerebrovascular events (MACCE), such as death, MI, or cerebrovascular accident, and target vessel revascularization (TVR) during their in-hospital stay and at 1-year follow-up. A total of 5806 patients were enrolled in this study, out of which 24.7% had normal BMI, 48.9% were overweight, and 26.4% obese. No difference was observed in overall in-hospital MACCE rate in relation to BMI. However, in-hospital death was noted to be significantly higher in patients with normal BMI compared with overweight and obese patients. At one-year follow-up, there was no significant difference in MACCE-free and TVR-free survival in relation to BMI. It can be concluded that no "obesity paradox" was observed in patients after PCI with DES.

Sharma *et al*<sup>[19]</sup> conducted a meta-analysis of 36 studies [12 coronary artery bypass graft (CABG) and 26 PCI] to investigate the relationship of BMI with total mortality, cardiovascular mortality, and MI post-PCI and CABG. They reported that the relative risk of total mortality, cardiovascular mortality, and MI was the highest among patients with low BMI and lowest among overweight patients<sup>[19]</sup>.

In another analysis limited to post-PCI patients, Sharma *et al*<sup>[19]</sup> noted that the total mortality, CV mortality, and MI were the highest among patients with low BMI at the end of a mean follow-up period of 1.6 years. The CV mortality was the lowest among overweight patients. The investigators explained that better outcomes in overweight and obese patients could have been influenced by age, as the severely obese patients in the study were younger than the normal-weight patients on average by 7 years for PCI and 4 years for CABG. Because their study was not a randomized trial, patients could have had unmeasured CVD risk factors that affected outcomes. They also reported that in the CABG subgroup, CV mortality was highest among severely obese patients; therefore, they stated that prospective studies were needed to determine associations between weight and outcomes and to explore any underlying mechanisms.

Stähli *et al*<sup>[9]</sup> assessed long-term mortality of 1993 patients undergoing chronic total occlusion (CTO) PCI at a tertiary care center. They studied patients according to different BMI categories: 23.1% were of normal weight, 49.4% were overweight, 19.9% were obese, and 7.2% were very obese. They found that compared with normal weight BMI patients (16.3%), overweight patients had a lower all-cause mortality (10.2%, log-rank  $P = 0.001$ ), while obese (11.1%, log-rank  $P = 0.08$ ) and severely obese (13.2%, log-rank  $P = 0.39$ ) patients had similar mortality rates. Being overweight was significantly associated with lower all-cause mortality. They concluded that overweight is associated with an improved survival in patients undergoing PCI for CTO, particularly in men.

Kosuge *et al*<sup>[20]</sup> studied 3076 patients to determine the impact of BMI on outcomes after PCI for acute myocardial infarction (AMI). They reported that obese patients had a higher frequency of diabetes mellitus,

hyperlipidemia, hypertension and smoking.

Wang *et al*<sup>[21]</sup> examined 6083 patients who were divided into three groups according to BMI: Normal ( $n = 1592$ ), overweight ( $n = 3026$ ), and obese ( $n = 1465$ ). The follow-up focused on clinical-driven repeat revascularization, including target lesion revascularization (TLR) and non-TLR. There was no significant difference in the incidence of TLR among normal, overweight, and obese patients (6.3% vs 6.1% vs 7.1%,  $P = 0.423$ ). In contrast, the incidence of non-TLR was significantly higher in obese patients compared with normal and overweight (8.4% vs 6.0% vs 5.8%,  $P = 0.003$ ). They concluded that, among patients undergoing PCI with DES, obesity was not associated with TLR but was associated with a higher risk of non-TLR.

## MECHANISM OF OBESITY PARADOX

Various possible mechanisms have been proposed for the observed obesity paradox in coronary heart disease. As BMI increases the size of coronary artery proportionally increase as well and small coronary artery are associated with worse outcome after PCI and CABG<sup>[22]</sup>. Another possible explanation could be that the obese patients are protected against malnutrition and wastage of energy, therefore cardiac remodeling after MI would be greater in obese compared to underweight patients. Obese patients have a high calorie reserve which is beneficial in case CAD induces cachexia, a known adverse prognostic factor in HF. The resulting weight loss also improves disease prognosis; in non-obese individuals however, any non-purposeful weight loss due to cachexia will have a detrimental effect on the patients' overall health<sup>[23]</sup>. In addition, the obese patients with heart disease are likely to make lifestyle changes that include better diet, caloric restrictions, daily exercise which can positively shift the disease prognosis. Obese patients also have an altered cytokine and hormonal profile which can be cardio-protective and to neutralize the harmful effects of other biological factors that are upregulated in acute and chronic heart disease. The high levels of the inflammatory TNF- $\alpha$  can be quenched by the high density of TNF- $\alpha$  receptors on the adipose tissues<sup>[24]</sup>. In addition, obese individuals have been shown to have significantly lower levels of circulating natriuretic peptides, which are associated with HF pathophysiology<sup>[25]</sup>. The higher levels of free lipoproteins in the obese also help block LPS and other inflammatory cytokines<sup>[26]</sup>.

## GENDER AND RACIAL DISPARITY IN OBESITY PARADOX

A recent cohort study by Vest *et al*<sup>[27]</sup> showed that overweight females with HF had a survival advantage compared to overweight males. They reviewed 3811 HF patients and determined the impact of BMI on mortality. When the data was adjusted for potential confounders,

the overweight and obese males did not show any significant survival advantage; in the females however, the mortality associated with HF was higher in normal weight group compared to the obese even after the confounding factors were adjusted.

An association between race and obesity paradox has also been explored. A retrospective study by Kokkinos *et al.*<sup>[28]</sup> correlated BMI with mortality in 2013 African-American and 2000 Caucasian males with a mean age 60 years. A correlation was observed between BMI and mortality in the entire cohort, the healthy weight participants had a significantly higher risk, a hazard ratio (HR) of 1.7, compared to the obese subjects. This association was stronger in the African-American group (HR 1.95) compared to the Caucasian group (HR 1.53). However, the study was not focused on the obesity paradox specifically among CVD patients as presence of a cardiovascular disease was not considered as an inclusion or an exclusion factor for the participants.

## LIMITATIONS

The hypothesis of obesity paradox is controversial as the respective studies are limited by various biases and limitations. Most studies on the obesity paradox are retrospective in nature and therefore do not present any evidence of a direct link between obesity and better CAD treatment prognosis. Obese patients with CAD usually present earlier to the clinicians compare to their leaner counterparts. Therefore, the prolonged survival seen in the obese may simply be an earlier detection. There is evidence that the higher blood pressures seen in obese individuals makes them tolerate and respond better to CAD medications<sup>[29]</sup>. This may be easily confused with an inherent cardio-protective mechanism in the obese. Smoking is a common risk factor for CAD onset and poor prognosis and is most correlated with individuals with leaner BMIs: This could be another reason for a perceived better prognosis in the obese<sup>[30]</sup>. CAD prognosis is often confounded by the presence of other patho-physiological conditions like cancer<sup>[30]</sup>. The obesity paradox has been negated in one study that used X-ray absorptiometry to directly assess body fat levels instead of using the BMI index<sup>[31]</sup>.

## CONCLUSION

There is an obesity epidemic and obese patients have higher prevalence of co-morbid conditions such as arrhythmia, hypertension, hyperlipidemia, diabetes mellitus, which then increase the risk for CAD. Studies have shown favorable outcome after coronary intervention in obese patients proving phenomenon OX. There is an also strong disparity between different sex and race for OX and further studies are needed to investigate these disparities.

syncope of presumed arrhythmic origin. Familial sudden cardiac death (f-SCD) is not a recognized independent risk factor. Finally, positive electrophysiologic study (+EPS) has a controversial prognostic value. Current ESC guidelines recommend implantable cardioverter defibrillator (ICD) implantation in patients with a Brugada type 1 ECG pattern if they have suffered a previous resuscitated cardiac arrest (class I recommendation) or if they have syncope of presumed cardiac origin (class IIa recommendation). In clinical practice, however, many other patients undergo ICD implantation despite the suggestions of the guidelines. In a 2014 cumulative analysis of the largest available studies (including over 2000 patients), we found that 1/3 of patients received an ICD in primary prevention. Interestingly, 55% of these latter were asymptomatic, while 80% had a + EPS. This means that over 30% of subjects with a Brugada type 1 ECG pattern were considered at high risk of SCD mainly on the basis of EPS, to which a class II b indication for ICD is assigned by the current ESC guidelines. Follow-up data confirm that in clinical practice single, and often frail, risk factors overestimate the real risk in subjects with the Brugada type 1 ECG pattern. We can argue that, in clinical practice, many cardiology centers adopt an aggressive treatment in subjects with a Brugada type 1 ECG pattern who are not at high risk. As a result, many healthy persons may be treated in order to save a few patients with a true Brugada Syndrome. Better risk stratification is needed. A multi-parametric approach that considers the contemporary presence of multiple risk factors is a promising one.

**Key words:** Brugada syndrome; Brugada type 1 electrocardiogram; Sudden cardiac death

### Abstract

Patients with a Brugada type 1 electrocardiogram (ECG) pattern may suffer sudden cardiac death (SCD). Recognized risk factors are spontaneous type 1 ECG and

**Core tip:** On the basis of frail risk factors, many cardiology centers adopt an aggressive treatment in subjects with a Brugada type 1 electrocardiogram pattern who are not at high risk. As a result, many healthy persons may

be treated in order to save a few patients with a true Brugada Syndrome. Better risk stratification is needed, for example the adoption of a multiparametric approach.

Delise P, Allocca G, Sitta N. Brugada type 1 electrocardiogram: Should we treat the electrocardiogram or the patient? *World J Cardiol* 2017; 9(9): 737-741 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i9/737.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i9.737>

## INTRODUCTION

Brugada syndrome was first described by the Brugada brothers in 1992<sup>[1]</sup> as a distinct heritable clinical entity characterized by malignant arrhythmias in patients without organic heart disease and by a peculiar electrocardiogram (ECG) pattern consisting of coved-type ST elevation  $\geq 2$  mm in one or more leads from V1 to V3 (Brugada type 1 ECG pattern).

During the last 25 years, both in scientific papers and in current practice, the terms "Brugada type 1 ECG pattern" and "Brugada Syndrome" have frequently been used synonymously. Even the recent ESC guidelines on the prevention of sudden cardiac death (SCD)<sup>[2]</sup> equate the Brugada type 1 ECG pattern with Brugada Syndrome, basing the diagnosis of Brugada syndrome only on ECG criteria. This is, to say the least, curious, as the definition of any syndrome includes symptoms and various clinical and instrumental signs.

This semantic error has the deleterious consequence that any subject with a Brugada type 1 ECG pattern is considered to be at risk of SCD, both in the presence and in the absence of symptomatic or asymptomatic arrhythmias.

In medicine, similar mistakes have been made many times in the past when an ECG sign has been equated to a disease. For example, more than 60 years ago, negative T waves were defined by the Mexican School<sup>[3]</sup> as "ischemia", and this ECG anomaly was identified with coronary artery disease. This error was corrected only after many years, when it was demonstrated that negative T waves were not always a manifestation of myocardial ischemia; rather, they may be a nonspecific finding or may be due to various heart diseases (hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, pulmonary embolism, *etc.*).

Likewise, a so-called Brugada type 1 ECG pattern, in addition to indicating a Brugada syndrome, may be a nonspecific, benign finding or the consequence of a right ventricular cardiomyopathy<sup>[4]</sup>, pulmonary embolism, *etc.* (Brugada phenocopies)<sup>[5]</sup>.

It follows that "Brugada type 1 ECG pattern" and "Brugada syndrome" should not be used as synonyms, even though, in the presence of a Brugada type 1 ECG, a Brugada syndrome in its asymptomatic phase may be suspected.

## CURRENT INDICATIONS FOR IMPLANTABLE CARDIOVERTER DEFIBRILLATOR IN PRIMARY PREVENTION IN SUBJECTS WITH BRUGADA TYPE 1 ECG PATTERN

Current ESC guidelines<sup>[2]</sup> recommend implantable cardioverter defibrillator (ICD) implantation in patients with a Brugada type 1 ECG pattern if they have suffered a previous resuscitated cardiac arrest (class I recommendation) or if they have syncope of presumed cardiac origin (class II a recommendation). In clinical practice, however, many other patients undergo ICD implantation despite the suggestions of the guidelines.

In 2014, Delise *et al.*<sup>[6]</sup> performed a cumulative analysis of the largest available studies<sup>[7-16]</sup>, which included a total of 2176 patients with a Brugada type 1 ECG pattern who had no history of cardiac arrest. In this study, we found that 1/3 of patients received an ICD in primary prevention.

In addition, our cumulative data<sup>[6]</sup> (Table 1) show that, frequently in clinical practice, indications for ICD implantation not only do not completely follow current guidelines, but also do not fully consider the weight of the various potential risk factors. Indeed, recognized risk factors are spontaneous type 1 ECG and syncope of presumed arrhythmic origin. In contrast, a drug-induced type 1 ECG pattern and the absence of symptoms identify a low risk<sup>[12-21]</sup>. Familial SCD is not a recognized independent risk factor<sup>[16,17,20]</sup>. Finally, +EPS has a controversial prognostic value<sup>[11,12,17,19,20]</sup>.

Interestingly, in our cumulative analysis<sup>[6]</sup>, of 566 patients who received an ICD in primary prevention, only 45% were symptomatic for syncope. In addition 65% had a spontaneous Brugada type 1 ECG pattern, while 35% had a drug-induced Brugada type 1 ECG. In contrast, 80% had a positive EPS (Table 1). In other words, ICD indication was mainly guided by EPS, to which a class IIb indication for ICD is assigned by the current ESC guidelines<sup>[2]</sup>.

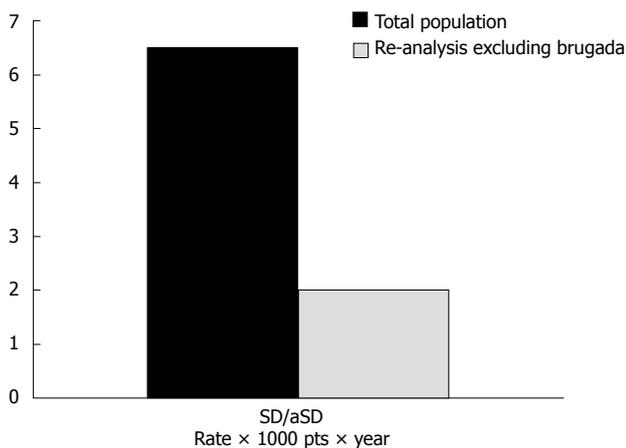

Further data come from a recent paper by Conte *et al.*<sup>[17]</sup>, of the Group of Pedro Brugada, who published their 20-year single-center experience of ICD implantation in patients with Brugada ECG pattern/syndrome. In this population, 151 patients received an ICD in primary prevention, 30% of whom were asymptomatic. In these 30 asymptomatic patients, the indication for ICD was mainly guided by a family history of Brugada syndrome (59%), f-SCD (59%) and +EPS (61%). Of note, the vast majority (76%) had a drug-induced type 1 ECG.

The main reason why many cardiologists do not follow guidelines and overestimate the risk of subjects with a Brugada type 1 ECG pattern stems from the frail scientific basis of currently used risk factors. Indeed, all prospective studies (ours included) which have

<sup>1</sup>From Delise *et al*<sup>[6]</sup>, modified. Spont.: Spontaneous; Drug-I: Drug-induced; Fam. SD: Familial sudden death; Asympt.: Asymptomatic; EPS: Electrophysiologic study; NA: Not available.

**Figure 1** Incidence of sudden cardiac death/aborted sudden cardiac death × 1000 patients × year in subjects with type 1 Brugada type 1 electrocardiogram pattern without implantable cardioverter defibrillator. Cumulative analysis of 1366 patients including and excluding the paper of Brugada *et al*<sup>[7]</sup> from Delise *et al*<sup>[6]</sup> modified. SD: Sudden death.

evaluated risk factors have been based on population registries<sup>[6]</sup>. Furthermore, all these studies have evaluated a combined end-point constituted by fast ventricular arrhythmias (FVA) recorded by ICD, and by SCD in subjects without ICD<sup>[6]</sup>. However, ICD-recorded FVA are only a surrogate of SCD<sup>[22,23]</sup>, as FVA are frequently self-terminating and do not necessarily lead to SCD. It follows that, in all these studies, any single risk factor probably overestimates the real risk of SCD.

In addition, all recognized and possible risk factors (spontaneous type 1 ECG, syncope, familial SD, +EPS), when tested singly against recorded FVA in patients with ICD, show an unsatisfactory performance: Variable sensitivity (ranging from 39% to 86%), low specificity (21%-61%) and low positive predictive value (ranging from 9% to 15%)<sup>[6]</sup>.

## CLINICAL OUTCOME OF SUBJECTS WITH BRUGADA TYPE 1 ECG

As all prospective studies have evaluated a combined end-point constituted by fast ventricular arrhythmias (FVA) recorded by ICD, and sudden death (SD) in subjects without ICD<sup>[6]</sup>, it is impossible to say what the

outcome of patients would be if they did not undergo ICD implantation. Indeed, no randomized studies have been performed that are able to establish the real risk of SCD and the ability of ICD to prevent it.

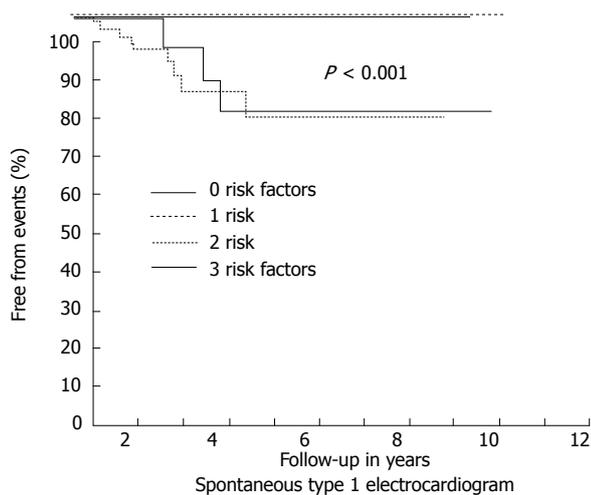

Despite these limitations, most prospective studies have shown that, in general, the risk of arrhythmias is low in asymptomatic patients, in those with drug-induced type 1 ECG and in those with negative EPS<sup>[6-17]</sup>. For example, in the study by Conte *et al*<sup>[17]</sup>, asymptomatic patients with ICD in primary prevention had an incidence of appropriate shocks of only 0.16 per year.

No prospective study has focused on the risk of SCD in patients without ICD. However, in our cumulative analysis<sup>[6]</sup>, we also analyzed 1366 patients without ICD separately. These patients were generally asymptomatic (84%) and did not have familial SCD (82%); about half (54%) had a spontaneous and about half (46%) a drug-induced type 1 ECG. EPS was positive in only 22%. In other words, most of them were correctly classified as being at low risk according to the guidelines. In these patients, SCD occurred in 6.5 per 1000 patients per year.

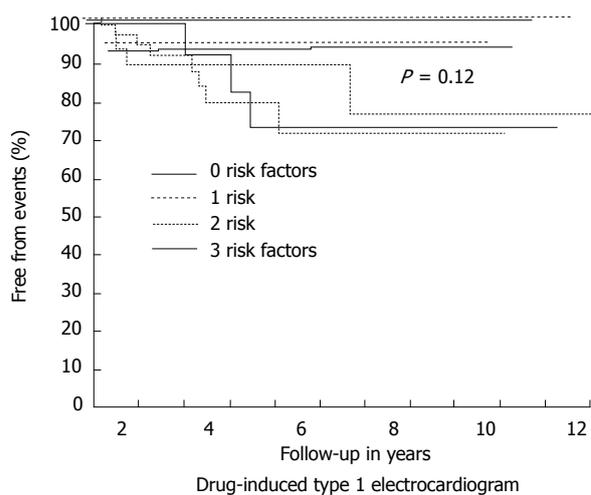

In a subsequent re-analysis of this population<sup>[24]</sup>, we excluded the 2003 paper by Brugada, because his population had a much higher risk than those of the remaining authors (high prevalence of familial SD, multiple risk factors, three-fold higher incidence of SCD). In this re-analysis, the incidence of SCD fell to 2 per 1000 patients per year (Figure 1). We can argue that patients classified as being at low risk according to the guidelines generally have a benign outcome.

## USEFULNESS OF A MULTIPARAMETRIC APPROACH FOR RISK STRATIFICATION

In 2011, our group<sup>[11]</sup> suggested that selecting patients on the basis of the presence of single or multiple risk factors could better stratify the risk of events. Specifically, on considering f-SCD, syncope and +EPS as risk factors, we found that, during follow-up, no events occurred in patients with either 0 or 1 risk factor, while events occurred only in patients with 2 or 3 risk factors. This was observed whether the patients had a spontaneous or a drug-induced Brugada type 1 ECG

**Figure 2** Incidence of events (appropriate implantable cardioverter defibrillator shocks + sudden cardiac death) in patients without implantable cardioverter defibrillator) in subjects with spontaneous Brugada type 1 electrocardiogram (from Delise *et al*<sup>[11]</sup> modified).

**Figure 3** Incidence of events (appropriate implantable cardioverter defibrillator shocks + sudden cardiac death) in patients without implantable cardioverter defibrillator) in subjects with drug-induced Brugada type 1 electrocardiogram (from Delise *et al*<sup>[11]</sup> modified).

(Figures 2 and 3). Similar results were reported by Okamura *et al*<sup>[25]</sup> in 2015.

Recently, Sieira *et al*<sup>[26]</sup>, from Pedro Brugada’s group, proposed a score model to predict the risk of events in patients with Brugada Syndrome. The model includes several risk factors: Spontaneous type 1 ECG (1 point), early f-SCD (1 point), +EPS (2 points), syncope (2 points), sinus node dysfunction (3 points) and previous aborted SCD (4 points). Interestingly, in line with our data, a significantly increased risk was observed in subjects with more than 2 points.

## CONCLUSION

In current clinical practice, many cardiology centers adopt an aggressive treatment in subjects with a Brugada type 1 ECG pattern who are not at high risk. Thus, these subjects undergo ICD implantation or experimental therapies such as ablation of the right ventricular outflow tract<sup>[27,28]</sup>. As a result, many healthy persons may be treated in order to save a few patients with a true Brugada Syndrome. The consequences of such a policy are deleterious in terms of the psychological impact on the subjects treated, the procedural risks involved and the costs accruing to the community.

The solution to this problem is not easy. However, it is reasonable to restrict indications only to high-risk patients, as indicated by the guidelines. Moreover, in addition to the indications provided in the guidelines, ICD implantation might be reasonable in subjects with multiple risk factors<sup>[11,25,26]</sup>. Finally, in controversial cases and/or in cases at low risk, it is a good rule to discuss indications, contraindications and complications with patients and their families, so that they are aware that there is still a risk, even though it is small.

In the future, only new scientific data will help us to better identify the risk of SCD in subjects with a

Brugada type 1 ECG pattern, a possibly misleading ECG sign.

**Abstract****AIM**

To identify predictors of need for repeat procedures after initial atrial fibrillation (AF) ablation.

**METHODS**

We identified a cohort undergoing first time AF ablation at our institution from January 2004 to February 2014 who had cardiac magnetic resonance (CMR) imaging performed prior to ablation. Clinical variables and anatomic characteristics (determined from CMR) were assessed as predictors of need for repeat ablation. The decision regarding need for and timing of repeat ablation was at the discretion of the treating physician.

**RESULTS**

From a cohort of 331 patients, 142 patients (43%) underwent repeat ablation at a mean of  $13.6 \pm 18.4$  mo after

the index procedure. Both male gender (81% vs 71%,  $P = 0.05$ ) and lower ejection fraction ( $57.4\% \pm 10.3\%$  vs  $59.8\% \pm 9.4\%$ ,  $P = 0.04$ ) were associated with need for repeat ablation. On pre-ablation CMR, mean pulmonary vein (PV) diameters were significantly larger in all four PVs among patients requiring repeat procedures. In multivariate analysis, increased right superior PV diameter significantly predicted need for repeat ablation (odds ratio 1.08 per millimeter increase in diameter, 95%CI: 1.00-1.16,  $P = 0.05$ ). There were also trends toward significance for increased left and right inferior PV sizes among those requiring repeat procedures.

### CONCLUSION

Increased PV size predicts the need for repeat AF ablation, with each millimeter increase in PV diameter associated with an approximately 5%-10% increased risk of requiring repeat procedures.

**Key words:** Atrial fibrillation ablation; Repeat ablation; Cardiac magnetic resonance imaging; Pulmonary veins; Imaging

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Among patients undergoing initial atrial fibrillation ablation, those with larger pulmonary vein (PV) size determined by pre-procedure cardiac magnetic resonance imaging had an increased likelihood of needing repeat ablation procedures. Each millimeter increase in PV diameter was associated with an approximately 5%-10% increased risk of requiring repeat procedures.

Clinical and anatomic predictors of need for repeat atrial fibrillation ablation. *World J Cardiol* 2017; 9(9): 742-748 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i9/742.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i9.742>

### INTRODUCTION

Although catheter ablation can be an effective treatment strategy for atrial fibrillation (AF), approximately 1 in 6 patients will undergo repeat ablation within 1 year of their initial ablation procedure<sup>[1]</sup>. This has motivated the search for clinical and demographic parameters that might predict an increased likelihood of AF recurrence and need for repeat ablation.

Although many studies have assessed predictors of AF recurrence after ablation, it is unclear whether there are additional relevant predictors of need for repeat ablation. Among clinical variables, the pattern of AF (paroxysmal vs persistent), congestive heart failure, hypertension, tobacco use and gender have all been associated with risk of AF recurrence<sup>[2-4]</sup>, as have serum biomarkers such as C-reactive protein (CRP)<sup>[5]</sup>. Anatomic

characteristics identified on cardiac imaging have also been evaluated as predictors of AF recurrence. Prior studies have suggested that larger left atrial (LA) size and lower left ventricle ejection fraction (LVEF) are associated with increased AF recurrence after ablation, although a meta-analysis demonstrated significant heterogeneity across studies in the predictive capacity of these parameters<sup>[6]</sup>. Although the pulmonary veins (PVs) are known to play an important role in the pathophysiology of AF and prior studies have assessed differences in PV anatomy and geometry between patients with and without AF, the role of PV anatomic features as predictors of AF recurrence and need for repeat ablation have not been well characterized.

In this analysis, we sought to identify predictors of the need for repeat ablation in a cohort of patients undergoing initial AF ablation.

### MATERIALS AND METHODS

The Emory University institutional review board approved the study protocol. Patients at Emory University Hospital Midtown undergoing initial catheter ablation for AF between January 2004 and February 2014 who had pre-procedure cardiac magnetic resonance (CMR) imaging performed were included in this analysis. Baseline demographic data, clinical covariates, and procedural details were ascertained by review of electronic medical records. The decision to perform AF ablation along with specific details of the ablation strategy and peri-procedural management was performed at the discretion of the treating physician. PV isolation was the primary goal of all procedures, with additional substrate modification performed at operator discretion. The decision regarding need for and timing of repeat ablation was also left to the discretion of each operator.

All patients included in this analysis underwent pre-procedure gadolinium-enhanced CMR to delineate LA and PV anatomy. CMR was performed on a 1.5 Tesla Philips Intera® magnetic resonance imaging (MRI) scanner (Amsterdam, The Netherlands) using a five-element phased-array cardiac coil. PV anatomy was defined using turbo spin echo and gradient echo imaging in axial and double oblique planes following administration of gadopentetate dimeglumine (Magnevist®) or gadobenate dimeglumine (MultiHance®) at a dose of 0.075-0.10 mmol/kg. Orthogonal projections of angiographic images were used to measure PV and LA dimensions<sup>[7]</sup>.

### Statistical analysis

Continuous variables are presented as mean  $\pm$  SD, and categorical data are summarized as frequencies and percentages. Comparisons across groups were performed using the Student's *t* test or  $\chi^2$  test, as appropriate. A binomial logistic regression of variables with univariate  $P$ -value  $\leq 0.1$  was used for the multivariate analysis. For all comparisons, a two-tailed  $P < 0.05$  was considered to be statistically significant. Analysis was performed using MATLAB software (Mathworks, Inc., Natick, MA, United

**Table 1 Clinical predictors of need for repeat ablation *n* (%)**

Parameter	Single ablation ( <i>n</i> = 189)	Repeat ablation ( <i>n</i> = 142)	<i>P</i> value

States).

## RESULTS

A cohort of 331 patients underwent first time AF ablation with pre-ablation CMR scans. Of the entire cohort, 142 (43%) underwent repeat ablation at a mean of 13.6 ± 18.4 mo after the initial procedure. Among repeat procedures, 61% were performed primarily for recurrent AF and the remaining were performed primarily for organized atrial tachycardias. Touch-up lesions were performed on at least one PV for 69% of patients upon repeat ablation.

Across the entire cohort at the initial procedure, mean age was 58.4 ± 10.3 years and 24% had persistent AF, without significant differences between those undergoing a single *vs* repeat procedures. During the index ablation, 91% of patients had radiofrequency (RF) ablation and the remaining had Cryoballoon ablation, again without significant differences in the single *vs* repeat procedure groups. In addition to PV isolation, 101 (31%) patients underwent additional substrate modification during the initial procedure, including 79 patients who underwent linear lesions (either mitral annulus or LA roof) and 55 patients who

**Table 2 Anatomic predictors of need for repeat ablation**

Pre-ablation size parameters	Single ablation ( <i>n</i> = 189)	Repeat ablation ( <i>n</i> = 142)	<i>P</i> value
Right atrial area (cm <sup>2</sup> ) <sup>1</sup>	23.0 ± 5.8	24.4 ± 5.4	0.08
Left atrial area (cm <sup>2</sup> ) <sup>1</sup>	28.0 ± 5.3	29.3 ± 6.2	0.13

Right superior vein	19.4 ± 4.0	21.5 ± 4.3	< 0.01
Right inferior vein	18.0 ± 3.5	19.6 ± 5.8	< 0.01
Left superior vein	17.7 ± 3.4	18.7 ± 3.0	< 0.01
Left inferior vein	17.0 ± 2.7	18.6 ± 5.0	< 0.01

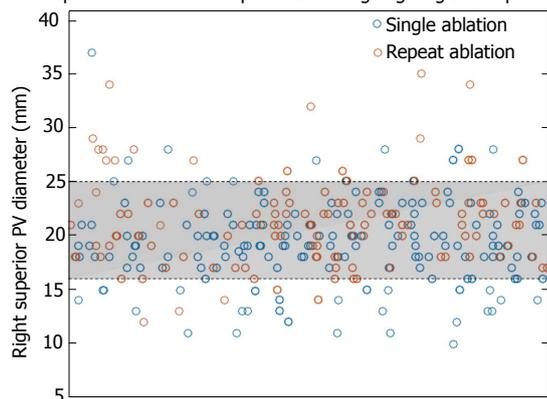

Data presented as mean ± SD. <sup>1</sup>Data reported for 123 patients in single ablation group and 81 patients in repeat group. Comparison of cardiac magnetic resonance parameters stratified by patients who received single ablation procedure *vs* repeat ablation during study period.

had LA complex fractionated atrial electrograms (CFAEs) ablated. Duration of the first ablation procedure, defined as the elapsed time between initial and final ablation lesions, was longer in patients who required repeat procedures, although the difference was not significant (148.4 ± 53.5 min *vs* 138.3 ± 55.2 min, *P* = 0.11).

Baseline clinical characteristics, stratified by patients with and without repeat ablation are shown in Table 1. Males were more likely to undergo repeat ablation (81% *vs* 71%, *P* = 0.05). Left ventricular ejection fraction was lower in patients undergoing repeat ablation, although the absolute difference between groups was small (57.4% ± 10.3% *vs* 59.8% ± 9.4%, *P* = 0.04). Other clinical parameters, including the prevalence of hypertension, coronary artery disease, diabetes mellitus and obstructive sleep apnea were similar between groups. Medications at the time of initial ablation were also similar.

Anatomic predictors of need for repeat ablation identified by CMR are presented in Table 2. Mean left and right PV ostial diameters were significantly larger in patients undergoing repeat ablation: Right superior PV, 21.5 mm ± 4.3 mm *vs* 19.4 mm ± 4.0 mm (*P* < 0.01); right inferior PV, 19.6 mm ± 5.8 mm *vs* 18.0 mm ± 3.5 mm (*P* < 0.01); left superior PV, 18.7 mm ± 3.0 mm *vs* 17.7 mm ± 3.4 mm (*P* < 0.01); left inferior PV, 18.6 mm ± 5.0 mm *vs* 17.0 mm ± 2.7 mm (*P* < 0.01). Although on average patients requiring repeat procedures had larger PVs, there was significant overlap in the distributions, making it difficult to identify clinically meaningful thresholds to predict an increased risk of need for repeat ablation. For example, in the distribution of right superior PV diameter, only 5% of patients with a single ablation had diameters > 25 mm, and among patients requiring repeat procedures, only 4% had right superior PV diameters < 16 mm (Figure 1). However, 80% of the measurements fell between 16 and 25 mm with significant overlap between those undergoing a single *vs* repeat procedures (Figure 1). Cumulative PV diameter was also significantly larger in patients who required repeat ablation: 78.5 ± 11.2 mm *vs* 71.6 ± 9.5 mm (*P* < 0.01), although there was

Overlap between PV size in patients undergoing single vs repeat ablation

**Figure 1** Distribution of right superior pulmonary vein ostial diameter measurements. There was significant overlap in the distributions of patients with single and repeat procedure, with 80% of all measurements falling between 16 and 25 mm. PV: Pulmonary vein.

still significant overlap in size compared with those who did not undergo repeat procedures. Of the 142 patients in the repeat ablation group, 96 (68%) required PV touch-up lesions during the second ablation. Patients who required touch-up lesions were more likely to have larger left inferior PV diameter on MRI before initial ablation:  $19.1 \pm 5.7$  mm vs  $17.5 \pm 3.0$  mm ( $P = 0.045$ ). Sizes of the other PVs were not significantly different between those who did and did not require PV touch-up at the second procedure.

Mean right ( $24.4 \pm 5.4$  cm<sup>2</sup> vs  $23.0 \pm 5.8$  cm<sup>2</sup>,  $P = 0.08$ ) and left ( $29.3 \pm 6.2$  cm<sup>2</sup> vs  $28.0 \pm 5.3$  cm<sup>2</sup>,  $P = 0.13$ ) atrial areas assessed by CMR were numerically larger in patients with repeat ablation, although the differences were not significant. Of note, due to evolution in the protocol for measuring atrial volumes by CMR at our institution, right and LA area data were only available for 204 out of 331 patients. There was a statistically significant but modest direct correlation between PV size and LA area for all but the left inferior PV (Figure 2). A multivariate linear regression of all 4 PVs with LA area was also significant ( $R^2 = 0.11$ ,  $P < 0.01$ ), demonstrating a direct relationship between PV and LA size. Male gender was also associated with larger PV size, although the results were only significant for the right superior PV [odds ratio (OR) = 1.10, 95%CI: 1.03-1.18,  $P < 0.01$ ] and left superior PV (OR = 1.19, 95%CI: 1.09-1.31,  $P < 0.01$ ).

Results of an analysis to identify multivariate clinical and anatomic predictors of need for repeat ablation are presented in Table 3. The only multivariate predictor of need for repeat ablation was larger right superior PV diameter (OR = 1.08 per millimeter increase in diameter, 95%CI: 1.00-1.16,  $P = 0.05$ ). There were also trends toward significance in multivariate analysis for increased left and right inferior PV dimensions as predictors of need for repeat ablation. Clinical variables including male gender and LVEF were no longer significant predictors of need for repeat ablation after

**Table 3** Multivariate analysis of anatomic and clinical predictors

Variable	Odds ratio (95%CI)	P value
Clinical parameters		
Male gender	1.53 (0.77-3.05)	0.23
LVEF	0.98 (0.95-1.01)	0.25
Warfarin	1.04 (0.43-2.51)	0.92
Direct OAC	0.59 (0.24-1.46)	0.25
Anatomic parameters		
Right superior PV diameter	1.08 (1.00-1.16)	0.05
Right inferior PV diameter	1.07 (0.99-1.15)	0.09
Left superior PV diameter	1.05 (0.95-1.16)	0.36
Left inferior PV diameter	1.10 (0.99-1.22)	0.07

Multivariate binomial logistic regression of clinical and anatomic variables with univariate  $P$  values  $\leq 0.1$ . LVEF: Left ventricle ejection fraction; PV: Pulmonary vein.

multivariate adjustment. It should be noted that despite a univariate  $P < 0.1$  ( $P = 0.08$ ), we excluded RA area from the multivariate analysis because only a small percentage of patients had data available.

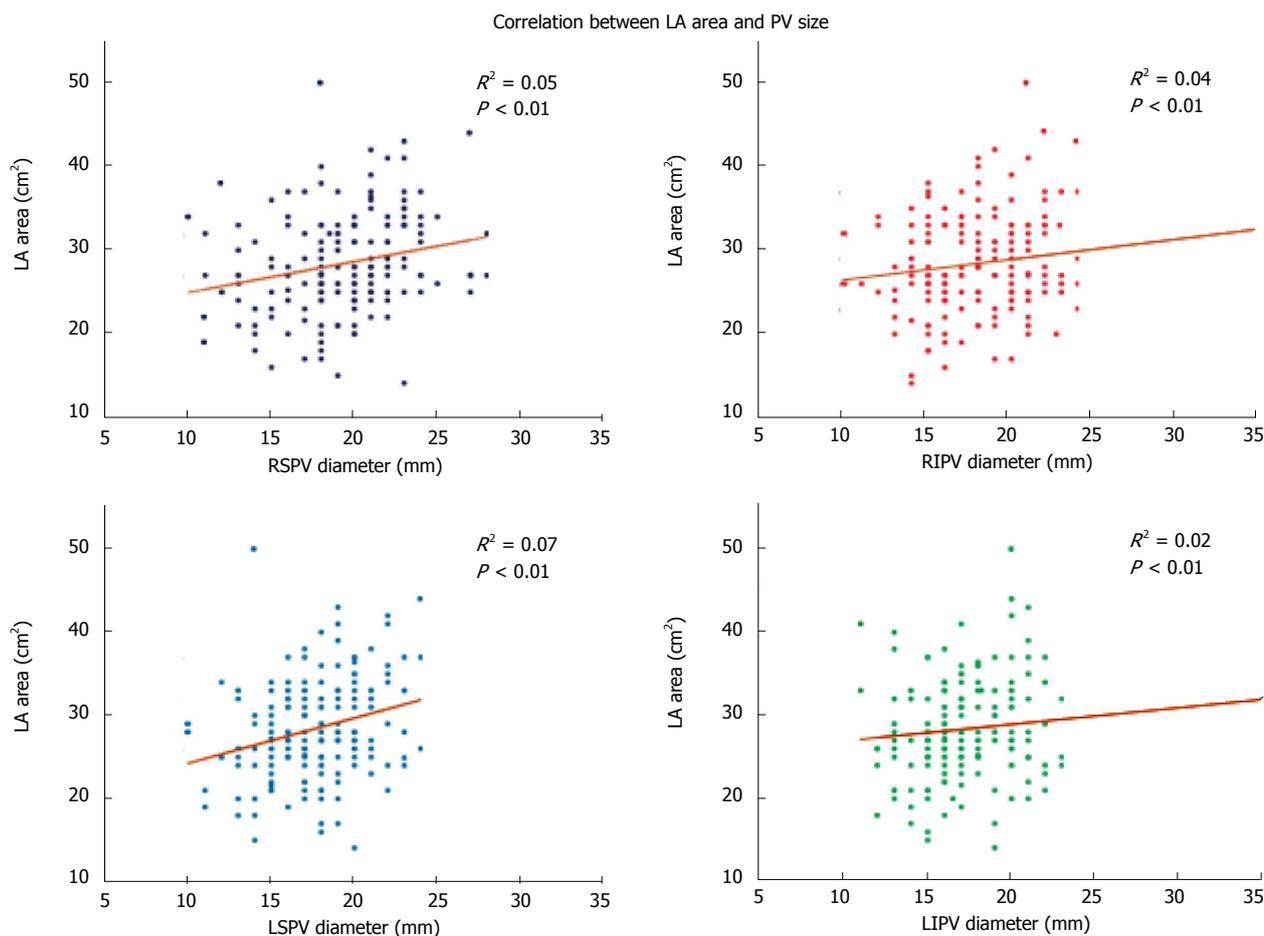

## DISCUSSION

In this cohort of 331 patients undergoing first time AF ablation, both clinical parameters including male gender and LVEF and anatomic characteristics assessed by CMR, most notably increased PV size, were associated with need for repeat ablation. However, in multivariate analysis, only increased PV size remained a significant predictor, suggesting that clinical factors may have limited utility in predicting the likelihood of repeat ablation. These findings also highlight the possibility that pre-procedure imaging may be useful in counseling patients undergoing initial AF ablation on the likelihood of needing repeat procedures and may facilitate more informed decision-making.

### Clinical predictors of need for repeat ablation

In our cohort, male gender was more prevalent among those requiring repeat ablation. Our findings regarding male gender are consistent with the results from the STOP-AF trial, in which the only clinical parameter predictive of early recurrence was male sex<sup>[4]</sup>. Interestingly, in our analysis, male gender was correlated with PV diameter, so it is conceivable that male gender is a marker for larger PV size and was thus no longer significant in multivariate analysis once PV size was taken into account.

Left ventricular ejection fraction was lower in patients undergoing repeat ablation, which is also consistent with previous findings looking at predictors of AF recurrence<sup>[8]</sup>. It should be noted, however, that in our analysis mean ejection fractions were in the normal range in both groups (single and repeat ablations) and the absolute difference in LVEF, although significant, was small. Such small differences in LVEF within the normal range are unlikely to have any clinically meaningful impact in helping to risk stratify patients likely to need

**Figure 2** Correlation between pulmonary vein size and left atrial area among all patients in the cohort. All but the left inferior pulmonary vein (PV) were significantly correlated with left atrial (LA) area, although the correlation coefficients were small. RSPV: Right superior pulmonary vein; RIPV: Right inferior pulmonary vein; LSPV: Left superior pulmonary vein; LIPV: Left inferior pulmonary vein.

multiple procedures.

None of the other clinical parameters in our study were significantly different between the cohorts who had a single ablation vs those who required repeat procedures. This corroborates the recent findings of Al-Hijji *et al*<sup>[9]</sup>, who studied predictors of repeat catheter ablation in a large study of over 8600 patients, and found no association between congestive heart failure, hypertension and diabetes and need for repeat ablation. Other studies have implicated obstructive sleep apnea in the pathophysiology of AF<sup>[10]</sup>, and, indeed, the total prevalence within our study population was 19%-greater than typical estimates of between 3%-7% in the general population<sup>[11]</sup>. However, the proportion of patients with OSA was not significantly different among patients requiring repeat ablation in our cohort. Broadly speaking, our data along with others suggest that clinical variables likely have limited utility in identifying those patients most likely to require repeat ablation procedures.

#### **Anatomic predictors of need for repeat ablation**

In contrast to clinical variables, several anatomic predictors assessed by pre-ablation CMR were signi-

ficantly different between those undergoing single vs. repeat ablations in our cohort. Previous studies have assessed anatomic predictors of AF recurrence after ablation. Two studies which used pre-ablation CT to characterize PV and LA anatomy found that anomalous PV anatomy (*e.g.*, presence of left common PV trunk or presence of middle accessory PVs) was not correlated with procedure outcome<sup>[12,13]</sup>. To our knowledge, only one other study investigated the effect of PV size. Our findings corroborate the results of Hauser *et al*<sup>[14]</sup> who reported that patients with at least one PV ostial area larger than 461 mm<sup>2</sup> were more likely to have early recurrence of AF and those with at least one PV area larger than 371 mm<sup>2</sup> were more likely to have late recurrence. The results of our multivariate analysis suggest that an increase in PV diameter of one millimeter is associated with a roughly 5%-10% increased likelihood of requiring a repeat ablation.

Although the pathophysiology of AF is not fully understood, it is known that the myocardial sleeves extending around the PVs are sites of enhanced automaticity and anisotropic conduction which may facilitate re-entry and provide some of the triggers and substrate necessary for AF<sup>[15]</sup>. Several hypotheses may explain why

larger PVs are associated with an increased likelihood of need for repeat ablation. Since the majority of patients in our study had point-by-point RF ablation, it is conceivable that with larger veins, permanent and transmural isolation is more difficult to achieve due to the need for larger/wider circumferential lesions resulting in a higher likelihood of gaps or recovery of conduction. Patients who required repeat ablation had numerically (although not statistically significant) longer initial ablation times, which may reflect a wider area requiring ablation around larger PVs. In contrast, rather than a purely anatomic explanation, it is also conceivable that larger PV size may be associated with larger LA size and reflect a more advanced atrial substrate or a higher prevalence of risk factors which may contribute to recurrence after ablation and need for repeat procedures.

Previous studies have shown that LA size is larger in patients with AF, and that larger LA size is an independent predictor of AF recurrence after ablation<sup>[16]</sup>. However, the association between LA size and PV size is inconsistent and not all studies have demonstrated a direct relationship<sup>[17]</sup>. In our cohort, LA size was weakly correlated with PV diameter. LA size was numerically larger in patients requiring repeat ablation, but the difference was not statistically significant. However, due to an evolution in the technique for measurement and reporting of atrial volumes at our institution during the course of this study, we were only able to report LA area in 204 of the 331 patients (61%), which raises the possibility that we were underpowered to detect a significant difference in LA size.

### Limitations

We used repeat ablation, as opposed to AF recurrence, as the primary endpoint for this study. Whereas AF recurrence is an objective measure and much has been reported about predictors of AF recurrence after ablation, need for repeat ablation is a more subjective endpoint and has been less well validated. Although thresholds for performing repeat ablation may vary between providers and across different patient circumstances, the need for repeat procedures has an important impact on resource utilization and is an important metric when counseling patients on expected outcomes after an initial procedure. We chose not to report data on AF recurrence in this cohort. During the time course covered by this analysis, many institutions, including ours, have evolved to more rigorous monitoring for recurrent arrhythmias after ablation, as reflected in the most recent HRS/EHRA/ECAS consensus statement on AF ablation<sup>[18]</sup>. Given this evolution, along with increasing numbers of patients with implantable devices capable of detecting AF, it is likely that our ability to detect clinically silent recurrent AF has improved significantly which would confound the results of any analysis looking at AF recurrence as an endpoint.

As an additional limitation, we cannot rule out the possibility that some patients underwent repeat procedures at another facility after having an initial ablation performed at our institution and therefore, would not

have been captured as needing repeat procedures for the purpose of this analysis.

Due to evolution in the technique for measuring and reporting atrial volumes on CMR at our institution, we were only able to report right and LA volumes on a subset of patients in the cohort and therefore, may have been underpowered for analyses involving atrial volumes. Lastly, we did not have data available to assess other anatomic parameters that may affect ablation outcomes, such as mitral valve pathology and PV anatomic variants.

### Conclusion

Our data demonstrate that increased PV size is an important predictor of outcomes after AF ablation, with each millimeter increase in PV diameter associated with a roughly 5%-10% increased risk of needing a repeat procedure. These findings suggest that results of pre-procedure cross-sectional imaging may be useful in counseling patients undergoing initial AF ablation on the likelihood of needing repeat procedures and may facilitate more informed decision-making. Additional study will be needed to determine whether ablation strategies can be altered at the time of initial ablation in patients with large PVs to mitigate the increased risk of needing repeat procedures.

## COMMENTS

### Background

Although many studies have assessed predictors of atrial fibrillation (AF) recurrence after ablation, it is unclear whether there are additional relevant predictors of need for repeat ablation. In this study, the authors analyzed clinical and anatomic predictors of need for repeat AF ablation.

### Research frontiers

A significant percentage of patients require repeat procedures after initial AF ablation and tools to identify those at highest risk of needing repeat procedures would be useful.

### Innovations and breakthroughs

Larger pulmonary vein (PV) size determined by pre-procedure cardiac magnetic resonance imaging had an increased likelihood of needing repeat ablation procedures. Each millimeter increase in PV diameter was associated with an approximately 5%-10% increased risk of requiring repeat procedures.

### Applications

The data suggest that pre-procedure magnetic resonance imaging may be useful in identifying individuals at highest risk for needing repeat AF ablation procedures.

### Peer-review

The manuscript is well written and highlights a popular topic with AF recurrence after pulmonary vein isolation.

**Abstract****AIM**

To assess utility and correlation of known anticoagulation parameters in the management of pediatric ventricular assist device (VAD).

**METHODS**

Retrospective study of pediatric patients supported with a Berlin EXCOR VAD at a single pediatric tertiary care center during a single year.

**RESULTS**

We demonstrated associations between activated thromboplastin time (aPTT) and R-thromboelastography (R-TEG) values ( $r_s = 0.65$ ,  $P < 0.001$ ) and between anti-Xa assay and R-TEG values ( $r_s = 0.54$ ,  $P < 0.001$ ). The strongest correlation was seen between aPTT and anti-

Xa assays ( $r_s = 0.71$ ,  $P < 0.001$ ). There was also a statistically significant correlation between platelet counts and the maximum amplitude of TEG ( $r_s = 0.71$ ,  $P < 0.001$ ). Importantly, there was no association between dose of unfractionated heparin and either measure of anticoagulation (aPTT, anti-Xa or R-TEG value).

### CONCLUSION

This study suggests that while there is strong correlation between aPTT, anti-Xa assay and R-TEG values for patients requiring VAD support, there is a lack of relevant correlation between heparin dose and degree of effect. This raises concern as various guidelines continue to recommend using these parameters to titrate heparin therapy.

Utility and correlation of known anticoagulation parameters in the management of pediatric ventricular assist devices. *World J Cardiol* 2017; 9(9): 749-756 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i9/749.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i9.749>

## INTRODUCTION

Appropriate anticoagulation continues to be a significant challenge in pediatric patients supported with ventricular assist devices (VADs). VAD implantation leads to dysregulation of hemostasis through contact of blood with foreign materials and introduction of shear forces that activate vascular endothelium, platelets, leukocytes and the coagulation cascade. This constellation of events increases the generation of thrombin and thus greatly increases the risk of thrombosis. Clinicians attempt to address the resultant imbalance between the pro- and anti-thrombotic states through the administration of anticoagulation and antiplatelet therapy. However, appropriate titration of these therapies in the pediatric population is challenging and resulting in various complications related to either a pro-thrombotic state leading to embolic complications or an overly anti-

thrombotic state presenting as post-operative bleeding, gastrointestinal bleeding or hemorrhagic stroke.

Despite technological advances in VAD design and development of new methods of anticoagulation, complication rates remain significant. Adults on VAD support have bleeding rate of 15%-50% while the risk of stroke has been reported at 5%<sup>[1,2]</sup>. Unfortunately the overall incidence of these complications in children with VAD appears to be higher<sup>[3-5]</sup>. While the VAD technology and anticoagulation agents are the same as those for adult patients, there are marked differences in dosing of medications, device performance characteristics in children and intrinsic differences in the maturity of the hemostatic system in children as they develop<sup>[6-9]</sup>. One retrospective study of 28 pediatric patients with various types of VAD demonstrated major bleeding in 29% and stroke in 25%. Given that there are several types of VAD that can be used in the pediatric population, and technology is constantly evolving, interpretation of older studies is challenging. The Berlin Heart EXCOR Pediatric VAD, a pulsatile extracorporeal device, is currently the most commonly used in pediatrics as it can accommodate a wide range of patient sizes and can support both the right and left heart as necessary. A prospective study comparing the Berlin Heart Pediatric EXCOR device to extracorporeal membrane oxygenation (ECMO) as bridge-to-transplantation demonstrated bleeding in 50% of patients and stroke in 29%<sup>[3]</sup> in the setting of a prescribed anticoagulation protocol with high degree of adherence.

The major obstacle to achieving adequate anticoagulation while minimizing the risk of hemorrhagic complications revolves around ineffective monitoring strategies and the lack of evidence-based pediatric guidelines to assist clinicians in modifying therapy. Various laboratory tests exist that measure specific components of the hemostatic system, including anti-Xa, activated thromboplastin time (aPTT), prothrombin time (PT), and international normalized ratio (INR), but none of these gives a complete picture of hemostasis<sup>[7,10-12]</sup>. Thromboelastography (TEG) has been proposed to more accurately demonstrate the *in vivo* state of hemostasis<sup>[13,14]</sup>. Specifically the R-value is thought to reflect the anticoagulant effect of heparin. Current VAD anticoagulation guidelines, including those adopted for clinical trials, lack standardization to guide heparin therapy<sup>[15]</sup>. In addition, there is very limited data on coagulation parameters in pediatric patients supported on VADs. This disconnect may explain why, in many cases, using target lab values to indicate degree of anticoagulation does not prevent poor clinical outcomes. This study attempts to assess the utility and correlation between various measures of anti-coagulation, including the value of TEG, in a cohort of patients who received the Berlin Heart Pediatric EXCOR VAD.

## MATERIALS AND METHODS

Anticoagulation parameters from four patients su-

Table 1 Patient demographics

	Patient 1 K	Patient 2 S	Patient 3 P	Patient 4 N

Days on VAD	141	69	13	54
Outcome	OHT	OHT	OHT	OHT

Relevant clinical data from the four patients studied including diagnosis prior to receiving VAD, type of ventricular support (LVAD), absolute number of days on VAD support and eventual patient outcome. All patients received Berlin EXCOR devices as bridge to successful transplantation. DCM: Dilated cardiomyopathy; CHB: Congenital heart block; OHT: Orthotopic heart transplantation; LVAD: Left ventricular assist device.

supported with a Berlin Heart EXCOR VAD at a single center during 2013 were studied retrospectively. The study was approved by the institutional review board. Standard anticoagulation therapy was initiated for all of these patients after the implantation of the Berlin EXCOR VAD in accordance with the published guidelines<sup>[15]</sup>. All management decisions for anticoagulation and anti-platelet therapy were made by the VAD team, again with target levels for various parameters consistent with the published protocol. Briefly, our standard regimen included unfractionated heparin initiated typically about 12 h post-operative, followed by initiation of anti-platelet therapy with aspirin and dipyridamole typically, 48 h post-operative in the setting of good surgical hemostasis. This was followed by dose adjustments as needed based on monitoring parameters. Patients were monitored closely by assessing various anticoagulation parameters such as PT, aPTT, anti-Xa assay, complete blood count, fibrinogen level daily. TEG was performed using a TEG<sup>®</sup> 5000 Thrombelastograph<sup>®</sup> Hemostasis Analyzer system (Haemonetics Corporation, MA, United States). Kaolin TEG as well as heparinase TEG were both performed as part of a standard approach to assess whole blood anticoagulation related to heparin as well as the health of coagulation system without the heparin effect. Additionally, TEG was also used to perform platelet-mapping studies using the platelet agonists arachidonic acid (AA) and adenosine diphosphate (ADP) to study platelet inhibition achieved by aspirin and dipyridamole. We tabulated all laboratory tests that were ordered to both assess their coagulation system and to direct their anticoagulation therapy. Additionally, we tabulated incidental heparin dose at time of laboratory collection, as well as clinical data reflecting outcomes, adverse events, morbidities and mortality. Statistical analysis was performed using SPSS 21 software (SPSS Inc., Chicago, IL, United States). Continuous data are reported as mean  $\pm$  SD, categorical data are reported as frequency (%). Continuous data was compared using student *t*-test while  $\chi^2$  test was used for categorical

Table 2 Distribution of values for various measures of coagulation status

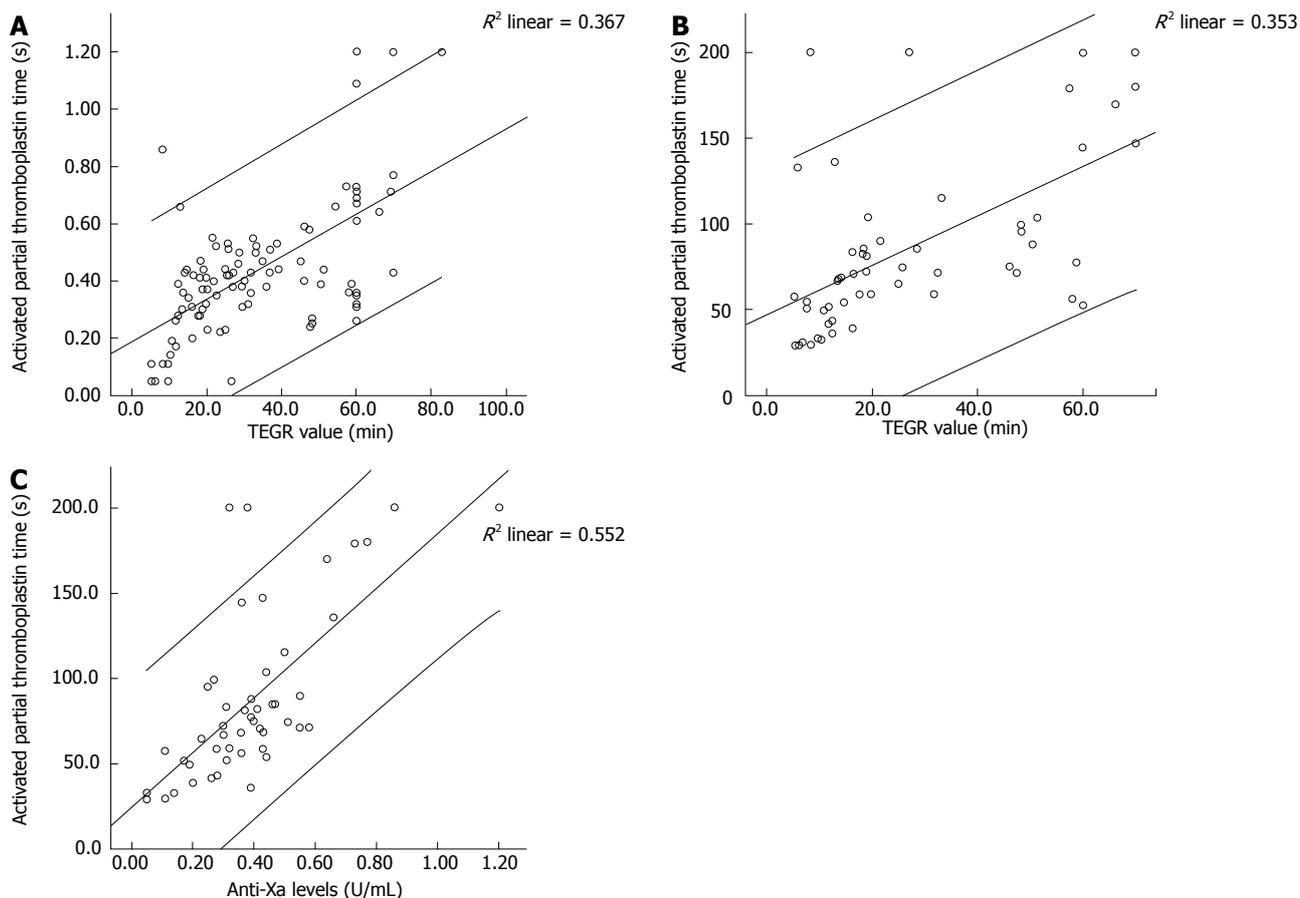

Test	<i>n</i>	Minimum	Maximum	mean	SD
Prothrombin time	97	12.5	30.8	14.542	2.34

Heparin dose (units/kg per hour)	131	15	46	33.66	7.15

Summary of data are presented as number of individual data points (*n*) with value ranges, mean value and standard deviation given. TEG values without heparinase are represented by R (reaction time), ANGLE (alpha-angle), MA (mean amplitude). TEG values with heparinase are noted as RHEP, KHEP (K = coagulation time), ANGLEHEP, MAHEP and GAHEP (GA = overall clot strength). Percent of platelet inhibition *via* the AA and ADP pathways are shown. The range of administered heparin dose at the time of laboratory value collection is also presented. AA: Arachidonic acid; ADP: Adenosine phosphate; PT: Prothrombin time; aPTT: Activated thromboplastin time; INR: International normalized ratio.

variables. Spearman's Correlation was used to assess correlation between various tests. Statistical significance was defined as  $P < 0.05$ .

## RESULTS

Chart review of anticoagulation parameters from a total of four patients who were supported with the Berlin EXCOR Pediatric VAD during a single year yielded nearly 100 data points for every test. Three of the four patients had the primary diagnosis of dilated cardiomyopathy while the fourth patient carried a diagnosis of congenital heart block and developed pacemaker induced cardiomyopathy (Table 1). No other significant comorbidities, genetic syndrome or coagulation disorders noted prior to the implants. Indications for VAD placement were heart failure non-responsive to standard inotropic therapy with milrinone and need for a second agent (dobutamine), along with evidence of end-organ injury. The later was extremely poor tolerance of enteral feeds in 3 patients while it was increased need for respiratory support (including intubation) in one patient. Berlin EXCOR VAD implantation was performed in the standard fashion

**Figure 1** Scatterplots demonstrating correlation between standard measures of anticoagulation for patients on left ventricular assist device support. The estimated linear regression line (line of best fit) is shown along with 95%CI for individual value predictions for (A) anti-Xa and TEG-R levels, (B) aPTT and TEG-R levels, and (C) aPTT and anti-Xa levels. The  $R^2$  values are shown alongside each panel (all  $P < 0.001$ ). aPTT: Activated thromboplastin time; TEG: Thromboelastogram.

	aPTT correlation coefficient	<i>P</i>	Anti-Xa correlation coefficient	<i>P</i>	R-TEG correlation coefficient	<i>P</i>
aPTT	1		0.71	< 0.001	0.65	< 0.001
Anti Xa	0.71	< 0.001	1		0.54	< 0.001
R-TEG	0.65	< 0.001	0.54	< 0.001	1	

Spearman correlation analyses were used to determine the degree of correlation between aPTT, anti-Xa and R values (R-TEG). aPTT: Activated thromboplastin time; TEG: Thromboelastogram.

per manufacturer’s detailed instructions. There were no intraoperative complications.

**Measures of anticoagulation and correlations**

The results for the various tests are shown in Table 2. As noted, there was wide variation in the degree of anticoagulation achieved. We performed Spearman correlation testing to assess the relationship between individual tests measuring degree of anticoagulation, namely, aPTT, anti-Xa assay and R value on TEG. There was a strong and statistically significant correlation between all of these three parameters, with the strongest

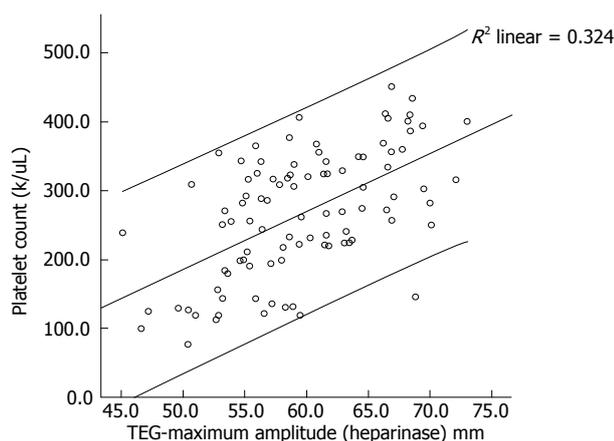

correlation existing between the aPTT value and anti-Xa assays ( $R^2 = 0.55$ , Spearman correlation coefficient of 0.71,  $P < 0.001$ ). R-TEG had correlation coefficients of 0.54 and 0.65 with anti-Xa and aPTT, respectively. These correlations are summarized in Table 3 and demonstrated in Figure 1.

**Role of platelets**

We also assessed the correlation between platelet count (PLT) and the maximum amplitude (MA) on TEG with heparinase added to nullify the heparin effect. We demonstrated that there was a strong and statistically significant correlation between the two values (Spearman correlation coefficient of 0.71,  $P < 0.001$ ) (Figure 2).

**Heparin dose and effect**

Similar to previous studies, we found no clinically relevant association between heparin dose and the degree of anticoagulation measured by the tests. There was no relationship between aPTT and Heparin dose (Figure 3A) giving a Spearman’s rho correlation coefficient of 0.152 and a  $P$  value of 0.168. Similarly, there was no correlation between the heparin dose and

**Figure 2 Correlation between platelet count and maximum amplitude after treatment with heparinase.** The estimated linear regression line (line of best fit along with 95%CI) is shown for platelet counts and TEG-MA (heparinase). Correlation coefficient of 0.541 ( $P < 0.001$ ). TEG: Thromboelastogram.

anti-Xa levels (Spearman's rho of  $-0.004$ ,  $P = 0.971$ ). There was weak correlation between heparin dose and TEG-R values (Spearman's rho of  $0.24$ ,  $P = 0.015$ ). To account for patient variation in response to heparin as well as inherent differences in the coagulation system in pediatric patients, we also performed a correlation analyses by patient. In this case, there was a large variation in correlation between heparin dosing and aPTT or anti-Xa levels for a given patient. The  $R^2$  value ranged from  $0.0318$  to  $0.108$  with a  $P$  value between  $0.01$  to  $0.18$  giving a statistically unstable model.

### VAD associated coagulopathy

It has been widely hypothesized that the circulatory support devices themselves induce a coagulopathic state beyond that induced by anti-coagulant therapy<sup>[7,16]</sup>. The degree and nature of coagulopathy was assessed using heparinase-TEG to neutralize the heparin effect. Figure 4 shows dot-density plots of the distribution of individual values for individual parameters such as R, K, Angle, Maximum Amplitude value obtained on heparinase TEG. As demonstrated in the panel, we found a wide variation in the health of the underlying coagulation system with variable demonstration of factor deficiencies as well as clot strength. Four point nine to 13.72% of all values for individual parameters were out of the normal range (represented by solid grey circles in the plots) suggesting significant coagulopathy or factor deficiencies. These findings were used to guide therapy for correcting the coagulopathy by administering appropriate factors in the form of cryoprecipitate or fresh frozen plasma.

### Outcomes

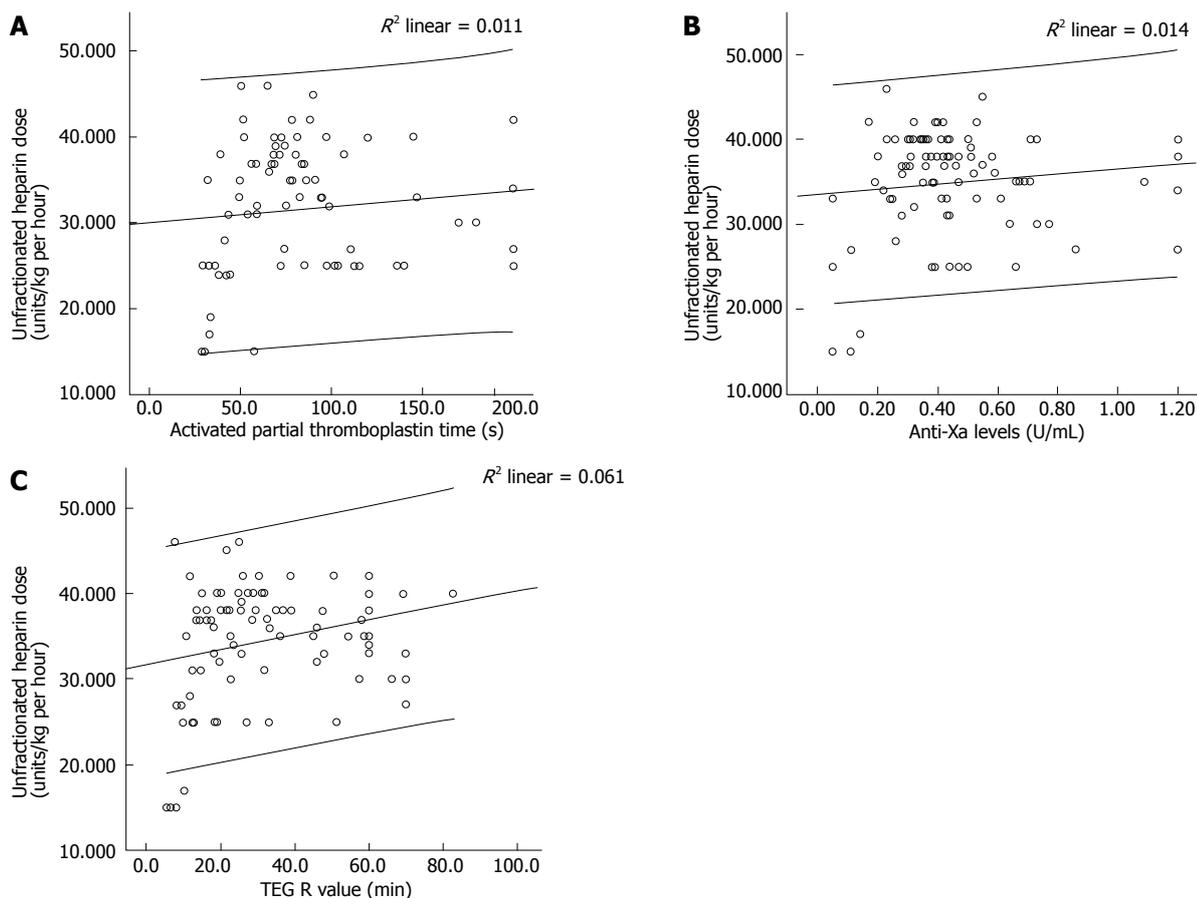

The mean duration of VAD support was 69.25 d (range 13 to 141 d). Two patients suffered stroke. One patient suffered an ischemic stroke with hemorrhagic conversion, a second patient suffered an ischemic stroke diagnosed by computed tomography (CT). Although the

exact timing of the strokes could not be ascertained, the degree of anticoagulation was within prescribed ranges for the 12 h before the CT scan and or clinical detection of the event. Both these patients made complete clinical recovery. A secondary endpoint was need for VAD pump change-out. A total of 8 pump exchanges were performed. The indications for pump change were made by the VAD team based on rate of clot growth, visualization of a dark clot measuring greater than 4 mm and subjective mobility of the clots. White clots and fibrin deposits in the blood chamber did not initiate pump exchanges, per manufacturer guidelines. Pump exchanges were well tolerated and did not result in any procedural complication. We were unable to identify predictors, such as degree of anticoagulation, fibrinogen levels, heparin dosing and the occurrence of either stroke or need for pump change. There were no mortalities in the cohort. All four patients underwent successful heart transplantation and at follow-up are alive and well.

## DISCUSSION

Managing anticoagulation in the pediatric VAD patient remains a challenging task. Failure to provide adequate anticoagulation results in thromboembolic events. Unfortunately, if the balance is tipped too far, devastating hemorrhagic complications may ensue. Clinicians are further stymied by the lack of evidence-based guidelines to direct therapy based on available laboratory data. The current study provides a direct comparison of these laboratory tests to determine their degree of correlation with one another as well as with anticoagulant effect. In a robust comparison sample of greater than 100 individual data points from four patients, our study showed very strong correlations between aPTT, anti-Xa assay and R-TEG (Figure 1). This is not unexpected, but demonstrates that these tests segregate together and may be substituted for one another, especially in the clinically relevant ranges.

The role of TEG in routine monitoring remains controversial<sup>[17]</sup>. While TEG has limitations, including difficulty with reproducibility, the utilization of TEG may be beneficial when employed routinely by experienced practitioners within a single center. Interestingly, we found a significant and clinically important correlation between platelet count and MA-TEG (Figure 2). This supports the importance of maintaining a normal platelet count and need for increased anti-platelet agents in the setting of thrombocytosis to manage the strength of clot formation. Additionally, TEG with- and without heparinase is important for diagnosing coagulopathy on VAD and guiding therapy. Furthermore, the presence of a wide range of values suggests a significant underlying coagulopathy that would otherwise be under-appreciated. This may be secondary to multiple factor deficiencies, prothrombotic microparticles or activation of coagulation factors. TEG may enable clinicians to monitor underlying VAD-induced coagulopathy and thereby explain how

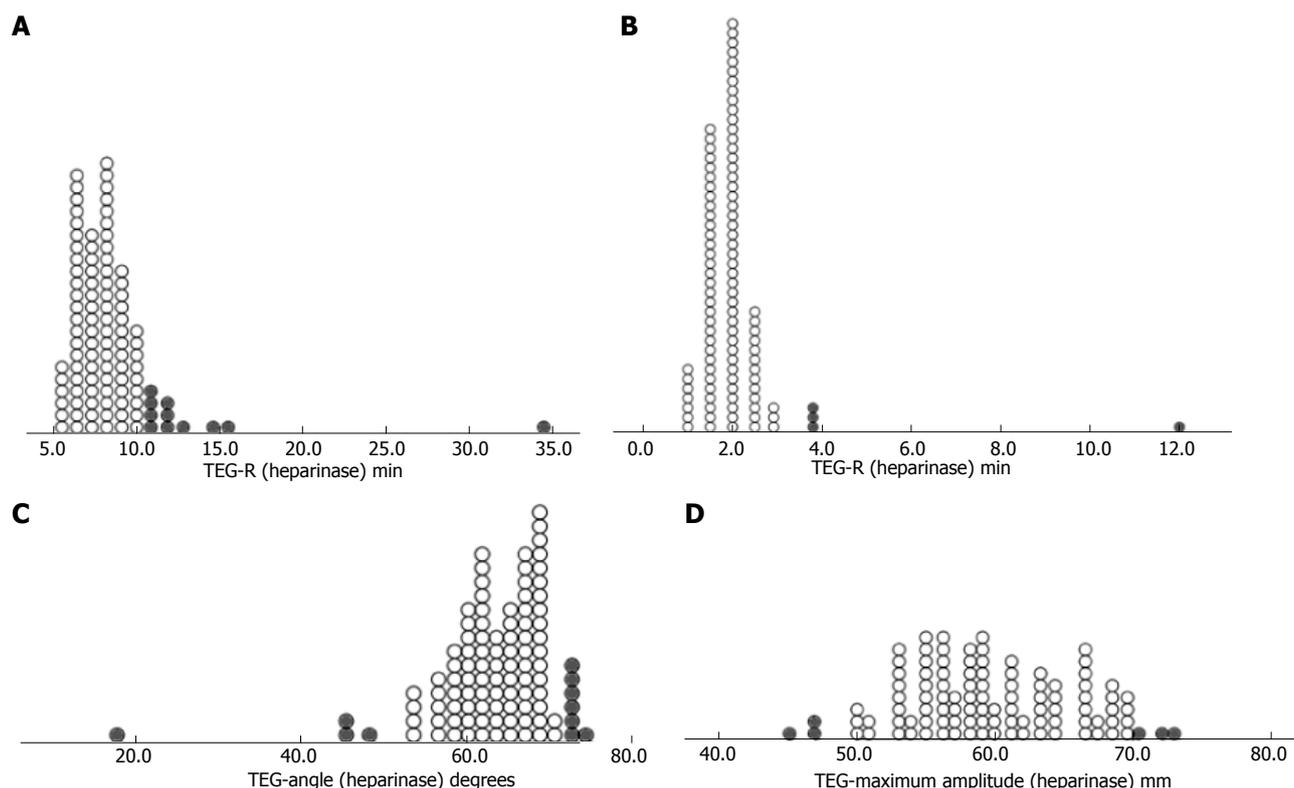

**Figure 3** Scatterplots demonstrating correlation between unfractionated heparin dose and (A) activated thromboplastin time (B) Anti-Xa levels and (C) thromboelastogram-R value. The estimated linear regression line (line of best fit) is shown along with 95%CI for individual value predictions. aPTT: Activated thromboplastin time; TEG: Thromboelastogram.

complications of anticoagulation therapy arise despite achievement of target levels for other coagulation parameters. We are currently validating this hypothesis using a larger cohort of patients that includes those dependent upon mechanical circulatory support devices as well as those requiring extracorporeal membrane oxygenation support.

One important observation from our investigation is the lack of relevant correlation between unfractionated heparin (UNFH) dose and degree of effect as measured by aPTT, anti-Xa or R value (Figure 3). This potentially reflects a significant variation in response to heparin by patient as well as by the coagulation milieu at any given time. These results differ somewhat from data that suggests good correlation between aPTT and UNFH levels in adults on extracorporeal life support (ECLS)<sup>[18]</sup> as well as a recent study in a small cohort of pediatric patients on ECLS<sup>[19]</sup>. These discrepancies may reflect variations in heparin response amongst patients due to developmental differences in hemostasis and genetic variability<sup>[20,21]</sup>. Lastly, none of these tests are specific in their assessment of the effect of unfractionated heparin *in vivo*. A lack of correlation between heparin dose and PTT or anti-Xa assay has also been noted in other settings, including a cohort of critically ill children<sup>[10]</sup>.

This is extremely relevant as various guidelines continue to recommend use of these monitoring parameters to titrate heparin therapy.

We also noted timing and significance of thrombotic or hemorrhagic events in our patient cohort. Three patients experienced significant morbidities. Two had an ischemic stroke and one had a hemorrhagic stroke. The older patient had an uneventful course. All patients eventually underwent successful bridge to transplantation and were discharged to home. At follow-up, all of them are alive. The patients with ischemic strokes have made a complete functional recovery, albeit after extensive rehabilitation. The patient who had hemorrhagic stroke still has speech delay and motor delay, but no deficits. Unfortunately, due to a small number of events, predictive modeling could not be performed to analyze further risk factors. Correlation of TEG and anticoagulation values with thromboembolic or hemorrhagic events in a larger patient cohort will provide valuable data as to the predictive ability of these tests. This study was also limited only to a single type of VAD. Future studies will include non-pulsatile and implantable devices such as Heartmate II or HeartWare HVAD in an effort to not only provide device-specific information, but also to determine if standards can be

**Figure 4** Dot-density plots of thromboelastogram (heparinase) parameters R (panel A), K (panel B), angle (panel C) and maximum amplitude (panel D) showing distribution of individual values. Abnormal values are represented by solid grey circles. TEG: Thromboelastogram.

applied across all devices.

This study provides valuable data regarding the utility of common laboratories to monitor the state of hemostasis in VAD patients, as suggested by existing guidelines. It also highlights the imprecise nature of current means of monitoring and demonstrates that multiple targets in the hemostatic pathway need to be targeted in order to achieve the desired balance between prevention of device thrombosis and hemorrhagic consequences.

## COMMENTS

### Background

Appropriate anticoagulation continues to be a significant challenge in pediatric patients supported with ventricular assist devices (VADs) resulting in high rate of complications related to bleeding or clotting related complications. Clinicians attempt to address the imbalance between the pro- and anti-thrombotic states through the administration of anticoagulation and antiplatelet therapy. However, the data regarding monitoring parameters is largely an extension of adult experience with very little data to support any pediatric monitoring strategies.

### Research frontiers

There is therefore an immediate need for improving our understanding of coagulation and anticoagulation parameters in pediatric patients on VAD as well as for studies that validated anticoagulation strategies.

### Innovations and breakthroughs

The current study provides a direct comparison of various laboratory tests to determine their degree of correlation with one another as well as with anticoagulant effect. In a robust comparison sample, this study showed very

strong correlations between activated thromboplastin time (aPTT), anti-Xa assay and R-thromboelastography (R-TEG). Additionally, the authors show that the dose-response relationship between heparin and these monitoring parameters is very weak, underscoring the authors' presumption that current guidelines for dose-titration based on anti-Xa levels may not be appropriate. Lastly, for the first time, the authors show the degree of underlying coagulopathy that can be assessed using TEG and underline the utility of the same.

### Applications

The study underscores the need for continued research in pediatric coagulation system especially within hitherto unexplored world of pediatric VAD and hopefully improves understanding of monitoring and management parameters to improve the morbidity and mortality associated with VADs.

### Terminology

VAD: Ventricular assist device, mechanical support as a circulatory assist; TEG: Thromboelastogram - a whole blood test for assessing the coagulation system in real time.

### Peer-review

This is an interesting manuscript about the utility and correlation of anticoagulation parameters such as aPTT, anti-Xa, and R-TEG in the management of pediatric VADs.

**Abstract****AIM**

To apply real time three-dimensional transesophageal echocardiography (RT3D TEE) for quantitative and qualitative assessment of the mitral valve annulus (MVA) and tricuspid valve annulus (TVA) in the same patient.

**METHODS**

Our retrospective cohort study examined the MVA and TVA in 49 patients by RT3D TEE. MVA and TVA shape were examined by TEE. The MVA and TVA volume data set images were acquired in the mid esophageal 4-chamber view. The MVA and TVA were acquired separately, with optimization of each for the highest frame rate and image quality. The 3D shape of the annuli was reconstructed using the Philips® Q lab, MVQ ver. 6.0 MVA model software. The end-systolic frame was used. The parameters measured and compared were annular area, circumference, high-low distances (height), anterolateral-posterolateral (ALPM), and anteroposterior (AP) axes.

**RESULTS**

A total of 49 patients (mean age 61 ± 14 years, 45%

males) were studied. The ALPM and the AP axes of the MVA and TVA are not significantly different. The ALPM axis of the MVA was  $37.9 \pm 6.4$  mm and  $38.0 \pm 5.6$  mm for the TVA ( $P = 0.70$ ). The AP axis of the MVA was  $34.8 \pm 5.7$  mm and  $34.9 \pm 6.2$  mm for the TVA ( $P = 0.90$ ). The MVA and the TVA had similar circumference and area. The circumference of the MVA was  $127.9 \pm 16.8$  mm and  $125.92 \pm 16.12$  mm for the TVA ( $P = 0.23$ ). The area of the MVA was  $1103.7 \pm 307.8$  mm<sup>2</sup> and  $1131.7 \pm 302.0$  mm<sup>2</sup> for the TVA ( $P = 0.41$ ). The MVA and TVA are similar oval structures, but with significantly different heights. The ALPM/AP ratio for the MVA was  $1.08 \pm 0.33$  and  $1.09 \pm 0.28$  for the TVA ( $P < 0.001$ ). The height for the MVA and TVA was  $9.23 \pm 2.11$  mm and  $4.37 \pm 1.48$  mm, respectively ( $P < 0.0001$ ).

### CONCLUSION

RT3D TEE plays an unprecedented role in the management of valvular heart disease. The specific and exclusive shape of the MVA and TVA was revealed in our study of patients studied. Moreover, the intricate codependence of the MVA and the TVA depends on their distinctive shapes. This realization seen from our study will allow us to better understand the role valvular disease plays in disease states such as hypertrophic cardiomyopathy and pulmonary hypertension.

## INTRODUCTION

The mitral valve annulus (MVA) and the tricuspid

valve annulus (TVA) are multi-component complex structures<sup>[1]</sup>. The anatomy and geometry of the MVA has been previously described in many studies that utilized advanced imaging techniques<sup>[2-5]</sup>. This allowed for a better comprehension of valve dysfunction and provided significant implications for surgical repair<sup>[5]</sup>. Similarly, the geometry of the TVA has been previously assessed in numerous studies utilizing real time three-dimensional transesophageal echocardiography (RT3D TEE) to allow for complete visualization of the cusps of this complex structure<sup>[1]</sup>. Furthermore, RT3D TEE can visualize atrio-ventricular valves from both the atrial and ventricular side in great detail<sup>[1]</sup>. Measurements of the MVA and TVA, both researched and documented in the literature, have not been routinely measured and compared in the same person. This study aimed to apply RT3D TEE for quantitative and qualitative assessment and comparison of the MVA and TVA in the same patients. Gaining an understanding of the similarities and differences between these two valves will likely provide a better understanding of cardiac physiology and pathophysiology and lead to improvements in clinical practice.

## MATERIALS AND METHODS

### Study population

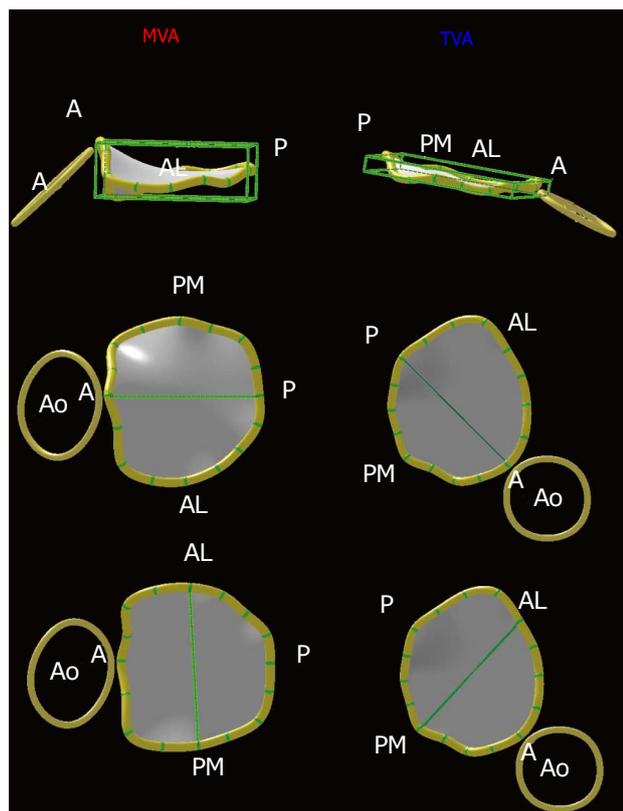

In this retrospective cohort study, the MVA and TVA were examined in forty-nine patients by RT3D TEE after institutional review board approval was obtained. The study population included all patients that were referred to the North Shore University Hospital Echocardiography lab for standard TEE during a three month period. The TEE performing physician was capable of performing RT3D TEE. All patients had sinus rhythm, no prosthetic rings, no mechanical/bioprosthetic valves, no  $> 2+$  MR or  $> 2+$  TR, no more than moderate MS/AS, no more than moderate chamber dilation, and no regional wall abnormalities. Only patients with optimal studies were included.

### Data acquisition and analysis

MVA and TVA shape were examined by TEE. The MVA and TVA volume data set images were acquired in the mid esophageal 4-chamber view. The MVA and TVA were acquired separately, with optimization of each for the highest frame rate and image quality. The MVA and TVA were never acquired in the same image because the frame rate was too low. The 3D shape of the annuli was reconstructed using the MVA model software (Figure 1, Philips® Q lab, MVQ ver. 6.0). The end-systolic frame was used. The parameters measured and compared were annular area, circumference, high-low distances (height), anterolateral-posterolateral (ALPM), and anteroposterior (AP) axes.

## RESULTS

A total of 49 patients (mean age  $61 \pm 14$  years, 45% males) were studied. Among the 49 patients 59% had hypertension, 18% had diabetes mellitus, 31% had

**Figure 1** Comparison of the mitral valve annulus to the tricuspid valve annulus using three-dimensional analysis software to provide detailed measurements of three-dimensional structure. MVA: Mitral valve annulus; TVA: Tricuspid valve annulus; AL: Anterolateral; PM: Posterolateral.

coronary artery disease, and 57% had dyslipidemia. Furthermore, 51% were on a beta blocker, 24% were on a calcium channel blocker, 39% were on an angiotensin converting enzyme inhibitor or angiotensin receptor blocker, and 57% were on a statin. The ALPM and the AP axes of the MVA and TVA are not significantly different. The ALPM axis of the MVA was  $37.9 \pm 6.4$  mm and  $38.0 \pm 5.6$  mm for the TVA ( $P = 0.70$ ). The AP axis of the MVA was  $34.8 \pm 5.7$  mm and  $34.9 \pm 6.2$  mm for the TVA ( $P = 0.90$ ). Similarly, the MVA and the TVA had similar circumference and area. The circumference of the MVA was  $127.9 \pm 16.8$  mm and  $125.92 \pm 16.12$  mm for the TVA ( $P = 0.23$ ). The area of the MVA was  $1103.7 \pm 307.8$  mm<sup>2</sup> and  $1131.7 \pm 302.0$  mm<sup>2</sup> for the TVA ( $P = 0.41$ ). The MVA and TVA are similar oval structures, but with significantly different heights. The ALPM/AP ratio for the MVA was  $1.08 \pm 0.33$  and  $1.09 \pm 0.28$  for the TVA ( $P < 0.001$ ). The height for the MVA and TVA was  $9.23 \pm 2.11$  mm and  $4.37 \pm 1.48$  mm, respectively ( $P < 0.0001$ ; Table 1).

## DISCUSSION

Two-dimensional echocardiography (2DE) has been utilized in previous studies and proved to be a valuable imaging modality for the functional assessment of the MVA and TVA<sup>[3-7]</sup>. However, 2DE did not provide detailed anatomical information of the MVA or TVA. Previous

case studies exploited the advanced imaging technique of RT3D TEE in visualizing the MVA and TVA in different patients<sup>[1]</sup>. This present study demonstrates that RT3D TEE allows for the comprehensive analysis and exact characterization of the anatomy of the MVA and TVA in the same patient.

One of the salient findings in our study was that, although the MVA and TVA had similar annular areas, circumference, ALPM axes, and AP axes, they both have a bimodal pattern with significantly different heights. The MVA is more elevated, circular and saddle shaped. This property allows for a secure anchoring of the leaflets that may minimize leaflet stress<sup>[8,9]</sup>. This unique shape of the MVA may also be due to the common location of the anterior mitral leaflet and the right coronary aortic leaflet which are united by a fibrous region. On the other hand, the posterior part of the MVA appears to be more flexible from the muscular fiber received from the proximal aspect of the posterior leaflet<sup>[8]</sup>. These unique assets contribute to the dynamic nature of the MVA for its proper functioning. RT3D TEE allows us to understand the anatomy which is necessary for reconstructive surgery of the MVA in mitral valve (MV) disease. The aim is such to restore the normal MVA shape and dynamics to enhance repair durability.

The MVA has more of an elliptical-saddle shape that is planar and ovoid. The shape of the TVA stems from its bicuspid embryology<sup>[9,10]</sup>. The TVA has two high points and two low points oriented to the right atrium and the right ventricular apex, respectively. The elliptical shape contributes to the competency of the tricuspid valve (TV) throughout the cardiac cycle. The preservation of the unique shape of the TVA also depends on the normal and unique shape of the MVA during the cardiac cycle. RT3D TEE demonstrates that anatomically the TVA and MVA form a figure eight across the ventricular septum. The shape of the TVA is requisite during ventricular systole when the high pressure of the left ventricle bends the interventricular septum and mitral annulus towards the right ventricle. RT3D TEE allows for better dynamic imaging to help in surgical planning in TV stenosis and regurgitation<sup>[8-10]</sup>.

RT3D TEE plays an unprecedented role in the management of valvular heart disease. It allows for superior characterization of specific components of the valvular apparatus. Several studies have utilized RT3D TEE to

evaluate the MVA and TVA in different patients. The aim of this study was to evaluate the native MVA and TVA using RT3D TEE in the same patients. The specific and exclusive shape of the MVA and TVA was revealed in the patients studied. Moreover, the intricate codependence of the MVA and the TVA depends on their distinctive shapes. This realization seen from our study will allow us to better understand the role valvular disease plays in disease states such as hypertrophic cardiomyopathy and pulmonary hypertension.

## COMMENTS

### Background

Three dimensional (3D) imaging of the heart has allowed for improved understanding and delineation of cardiac structure and function. Real time three-dimensional transesophageal echocardiography (RT3D TEE) has been on the forefront of allowing this 3D imaging to be used in mainstream cardiac practice for many years. The mitral valve annulus (MVA) and the tricuspid valve annulus (TVA) are multi-component complex structures and 3D imaging has allowed better understanding of their structure.

### Research frontiers

Measurements of the MVA and TVA, both researched and documented in the literature, have not been routinely measured and compared in the same person.

### Innovations and breakthroughs

The study aims to apply RT3D TEE for quantitative and qualitative assessment and comparison of the MVA and TVA in the same patient. Measurements in the same patient with comparison of the MVA and TVA have not been routinely performed and documented. The authors used an innovative comparison of these two valve areas in the same patient.

### Applications

Gaining an understanding of the similarities and differences between these two valves will provide a better understanding of cardiac physiology and pathophysiology and thereby hopefully lead to improvements in clinical practice.

### Terminology

MVA: This is the fibrous ring that comprises the structural skeleton of the two mitral valve leaflets. The mitral annulus is generally saddle-shaped and its shape is dynamic throughout the cardiac cycle; TVA: This is the fibrous ring that comprises the structural skeleton of the three tricuspid valve leaflets. The tricuspid annulus is generally saddle-shaped and its shape is dynamic throughout the cardiac cycle; RT3D TEE: Three-dimensional visual tool employing echocardiography to achieve a better understanding and assessment of normal and pathological cardiac function and anatomy and the spatial relationships of the structures identified.

## Peer-review

This is an interesting manuscript.

### Abstract

#### AIM

To review the early and more recent studies of Bivalirudin,

to assess the safety, effectiveness, and cost benefits of this drug.

#### METHODS

Literature search of MEDLINE and PubMed databases from 1990 to 2017 using keywords as "bivalirubin" and "angiomax", combined with the words "safety", "effectiveness", "efficiency", "side effects", "toxicity", "adverse effect", and "adverse drug reaction".

#### RESULTS

A total of 66 publications were reviewed. The changes in clinical practice and differences in clinical protocols make it difficult to do direct comparisons of studies among each other. However, most trials showed decreased bleeding complications with bivalirudin, although ischemic complications and mortality were mostly comparable, with some favor towards bivalirudin.

#### CONCLUSION

Bivalirudin and heparin are both acceptable options according to current ACA/AHA guidelines. Authors conclude however, that due to bivalirudin safer bleeding profile, it should be the preferred medication for anticoagulation.

**Key words:** Efficiency; Cost effectiveness; Bivalirudin; Safety

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Bivalirudin is a direct thrombin inhibitor used in clinical practice since 1990's. It was initially introduced as an alternative medication to heparin during percutaneous coronary intervention. Early studies showed advantages of bivalirudin over heparin. We did a systematic review of the literature since 1990 and summarized all relevant trials. The majority showed better outcomes with bivalirudin. However, some trials are difficult to compare directly as protocols and patient populations differ. Bivalirudin and heparin are both acceptable options according to current

ACA/AHA guidelines. Authors conclude however, that due to bivalirudin safer bleeding profile, it should be the preferred medication for anticoagulation.

Mehrzhad M, Tuktamyshov R, Mehrzhad R. Safety, efficiency and cost effectiveness of Bivalirudin: A systematic review. *World J Cardiol* 2017; 9(9): 761-772 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i9/761.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i9.761>

## INTRODUCTION

To prevent peri-procedural thrombotic complications, anticoagulation is required during percutaneous coronary intervention (PCI) and other percutaneous transluminal coronary angioplasty. The most common anticoagulant regimens are unfractionated heparin (UFH) and low molecular weight heparins (LMWHs)<sup>[1]</sup>. Bivalirudin (Angiomax) is a specific and reversible direct thrombin inhibitor, used for anticoagulant in patients with unstable angina undergoing percutaneous transluminal coronary angioplasty, patients undergoing PCI, or in patients with, or at risk of heparin-induced thrombocytopenia (HIT), undergoing PCI<sup>[2]</sup>. Evidence from early trials has pointed unique advantages with this drug with predictable pharmacokinetics, avoidance of HIT, and perhaps most importantly, a reduction in bleeding complications. The purpose of this study is to review the early and more recent studies of Bivalirudin, to assess the safety, effectiveness, and cost benefits of this drug.

## MATERIALS AND METHODS

A literature search was performed of the MEDLINE and PubMed database from 1990-2017, using keywords as "Bivalirudin" or "angiomax", combined with the words "safety", "effectiveness", "efficiency", "side effects", "toxicity", "adverse effect", and "adverse drug reaction".

## RESULTS

### Drug information

Drug information was showed in Table 1.

### Early trials comparing bivalirudin to other anticoagulant drugs

In 1993, bivalirudin was introduced in a multicenter dose escalation study to overcome the theoretical limitations of heparin. The appropriate dose was set to 1.8-2.2 mg/kg per hour, and was suggested as a feasible sole anticoagulant drug in patients with stable or unstable patients undergoing elective coronary angioplasty. They documented that it was associated with rapid onset of action, dose dependent anticoagulant effect and minimal bleeding complications<sup>[3]</sup>.

In 1995, Bittl *et al*<sup>[4]</sup> performed a randomized, double

blind, multicenter study comparing bivalirudin with high dose [UFH (initial bolus of 175 U/kg)] in patients undergoing urgent coronary angioplasty for unstable angina, or post-infarction (< 2 wk after myocardial infarction) angina. The results showed that the overall safety profile of bivalirudin was found to be superior<sup>[5]</sup>. This study was also reproduced in 2001, with an intention to treat principle, using contemporary and more clinically accepted endpoints and reducing the proportion of the missing data. The results of this re-analysis showed, again, that bivalirudin reduced ischemic complications, defined as death, myocardial infarction (MI) or repeat revascularization, at 7 d (6.2% vs 7.9%,  $P = 0.039$ ), 90 d (17.5% vs 24.3%,  $P < 0.001$ ) and 180 d (24.5% vs 30.3%,  $P < 0.001$ ) follow-ups. This benefit was more apparent and persistent in the post-infarction angina patient group at 7 d (4.9% vs 9.9%,  $P < 0.009$ ), 90 d (13.3% vs 27.2%,  $P < 0.001$ ) and 180 d (20.3% vs 32.0%,  $P < 0.001$ ) follow-ups. This reanalysis also documented significantly lesser major hemorrhagic events with bivalirudin at 7-d, 90-d and 180-d follow-ups (3.5% vs 3.7% vs 9.3%,  $P < 0.001$ ). Thus, this study determined bivalirudin's unique and unexpected uncoupling of outcomes for an anticoagulant, *i.e.*, lesser ischemic events as well as lesser bleeding complications<sup>[6]</sup>. However, this study used a high dose UFH that might have exaggerated the benefits seen in major bleeding rates with bivalirudin.

The results of a double-blind, randomized HERO study in 1997 showed that bivalirudin can be used as an adjunct to improve the early patency achieved with streptokinase in STEMI patients presenting within 12 h. This effect of bivalirudin was found to be more effective than using UFH as an adjunct, and was achieved at a lower aPTT levels. Furthermore, it was not associated with increased bleeding risk<sup>[7]</sup>. The bolus dose of UFH in this study was 5000 U, which is approximately 71 U/kg in a 70 kg patient.

A meta-analysis was done, analyzing 11 studies with a total number of 35970 patients, comparing different direct thrombin inhibitors with UFH in patients with acute coronary syndrome (ACS) (including patients who underwent PCI). In this analysis, it was found that bivalirudin reduced the composite of death and MI and also reduced the major bleeding events<sup>[8]</sup>. But none of these eleven studies used glycoprotein II b/IIIa inhibitor.

Before Thienopyridine introduction, in 2001, Kleiman *et al*<sup>[9]</sup> performed a study on 42 patients who underwent elective PCI and they found that combining bivalirudin with eptifibatid is a feasible drug combination of choice. There were no major bleeding events, and only a single non-Q-wave MI occurred in a patient treated with bivalirudin. The CACHET study in 2001 was an open label, randomized trial performed on patients who underwent PCI for elective coronary balloon angioplasty or stenting. Patients with acute MI (< 12 h) were excluded. It showed that bivalirudin with planned or provisional abciximab was at least as

**Table 1 Dose information**

Dose	0.75 mg/kg IV bolus then 1.75 mg/kg per hour if no prior antithrombotic therapy is administered
Half life	For patients who have received UFH, wait 30 min, then give 0.75 mg/kg IV bolus, then 1.75 mg/kg per hour IV infusion Healthy patients: 25 min. The half-life is increased in patients with CKD, and is estimated to 3.5 h in dialysis-dependent patients
Mechanism of action	Reversible direct thrombin inhibitor. Thus, inhibits thrombin by directly binding to it
Theoretical advantages over heparin-	Directly inhibits thrombin Binds to clot-bound thrombin also Lab monitoring of efficacy is not required Does not cause HIT Short half life Almost nil thrombin induced platelet aggregation
Antidote and toxicity	No known antidote Should be discontinued 3 h before CABG In cases of toxicity, hemodialysis should be considered
CKD	Dose is reduced in patients with renal failure
Recommendations from the American College of Cardiology/ American Heart Association and European Society of Cardiology for the use of bivalirudin in patients undergoing PCI	Class of recommendation - I, level of Evidence-B For patients undergoing PCI: Bivalirudin is useful as an anticoagulant with or without prior treatment with UFH Class of recommendation - I, level of Evidence-C With HIT: It is recommended that bivalirudin or argatroban be used to replace UFH Class of recommendation - I, level of Evidence-B Either discontinue bivalirudin or continue at 0.25 mg/kg per hour for up to 72 h at the physician's discretion if given before diagnostic angiography and no PCI or CABG

PCI: Percutaneous coronary intervention; CKD: Chronic kidney disease; HIT: Heparin-induced thrombocytopenia; UFH: Unfractionated heparin.

safe and effective as UFH (initial bolus of 70 U/kg), plus planned abciximab in reducing the composite clinical endpoint of death, MI, repeat revascularization or major bleeding. However, this was a pilot study with a small sample size of only 268 patients<sup>[10]</sup>. The REPLACE-2 trial from 2003 was a randomized, double blind, active-controlled trial conducted among 6010 patients undergoing urgent or elective PCI. Patients presenting with acute MI were excluded. Study patients received either bivalirudin or UFH (65 U/kg initial bolus) plus glycoprotein II b/IIIa inhibitors (GPI). GPI were used provisionally in the bivalirudin group. This study showed that bivalirudin was not inferior to UFH plus GPI in reducing the incidence of ischemic events (death, MI and repeat revascularization) at 30-d (7.6% vs 7.1%,  $P = 0.40$ ) and 6 mo (18.8% vs 17.5%,  $P = 0.21$ ) follow-ups. The mortality in the bivalirudin group at 30-d (0.2% vs 0.4%,  $P = 0.26$ ), 6 mo (1.0% vs 1.4%,  $P = 0.15$ ) and 1 year (1.89% vs 2.46%,  $P = 0.16$ ) follow-ups is non-inferior to UFH plus GPI. However, the results were not statistically significant. The 30-d major bleeding episodes were statistically significantly lower in bivalirudin group (2.4% vs 4.1%,  $P < 0.001$ )<sup>[11]</sup>.

The, PROTECT-TIMI 30 from 2005, evaluated glycoprotein II b/IIIa inhibition role with eptifibatide when administered with indirect thrombin inhibition as compared with monotherapy with bivalirudin among patients with non-ST-segment elevation. 857 moderate to high risk patients with at least one or more of the following risk factors: Diabetes, a positive cardiac biomarker either CK-MB or troponin T/I, ST-segment deviation  $> 0.5$  mm,

or TIMI risk score  $\geq 3$ , was evaluated when presenting with chest pain or an anginal equivalent symptom at rest  $\geq 10$  min in the setting of a non ST elevation acute coronary syndrome, which were anticipated to undergo PCI of a native coronary artery. This study compared the combination of eptifibatide and heparin (UFH/enoxaparin) with bivalirudin. Results showed that the primary end point of post-PCI coronary flow reserve was significantly higher with bivalirudin (1.43 vs 1.33,  $P = 0.036$ ). The myocardial perfusion (post-PCI TMPG) was found to be better in eptifibatide group (57.9% vs 50.9%,  $P = 0.048$ ) and the 48 h post-PCI composite of death and MI was lower in eptifibatide group (8.8% vs 6.6%,  $P = 0.246$ ). Duration of post-PCI ischemia was also lower in eptifibatide group (36 min vs 169 min,  $P = 0.013$ ). In the UFH plus eptifibatide group, there were increased bleeding episodes, more notably TIMI minor bleeding episodes, (2.5% vs 0.4%,  $P = 0.027$ ) and bleeding episodes that required transfusion (4.4% vs 0.4%,  $P < 0.001$ ). This study showed that, moderate- to high-risk patients with ACS undergoing PCI, bivalirudin therapy lowers bleeding and the need for blood transfusion and is thus safer than heparin plus eptifibatide therapy<sup>[12]</sup>.

The ACUITY trial evaluated the role of bivalirudin in patients with moderate or high-risk ACS patients. Patients with acute ST elevation or shock were the important exclusion criteria in this study. The anti-thrombotic regimens used in this study were heparin (UFH or enoxaparin) plus GPI, bivalirudin plus GPI, and bivalirudin monotherapy. This trial was a 13819 patient, open label study in which the patients were randomized

to receive one of the above three antithrombotic regimens. Bivalirudin had comparable clinical outcomes in patients with moderate and high-risk acute coronary syndromes treated with glycoprotein II b/IIIa inhibitors in whom percutaneous coronary intervention is done as unfractionated heparin or enoxaparin. Moreover, anticoagulation with bivalirudin alone suppressed adverse ischemic events to a similar extent as does glycoprotein II b/IIIa inhibitors plus heparin, while also significantly lowering the risk of major hemorrhagic complications<sup>[13]</sup>.

The ARMYDA-7 BIVALVE study compared bivalirudin with UFH in 401 high-risk patients undergoing PCI. The inclusion criteria in this study was the following: Age > 75 years, diabetes mellitus (definitions according to the American Diabetes Association criteria), chronic renal failure (CrCl between 30 and 60 mL/min). Clopidogrel 600 mg was preloaded in all patients in this study. At 30-d follow-up, it was found that bivalirudin caused similar rates of MACE, *i.e.*, cardiac death, MI, stent thrombosis, or target vessel revascularization (11.1% vs 8.9%  $P = 0.56$ ) with significantly lower rates of bleeding (1.5% vs 9.9%,  $P = 0.0001$ )<sup>[14]</sup>. One of the important exclusion criteria was to exclude patients who were undergoing primary PCI for acute MI.

The HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) was, open-label, randomized trial done on 3602 patients who were undergoing primary PCI for STEMI (presentation from onset of symptoms < 12 h). Patients were randomized to receive bivalirudin or UFH (initial bolus of 60 U/kg) plus GPI (control). Patients then underwent randomization to bare metal or paclitaxel-eluting stents. Ninety-two point seven percent of patients underwent primary PCI and the rest were treated either medically or by primary CABG. A very small portion of patients were deferred PCI (0.2%). Ninety-four point five percent of patients received GPI in patients who were assigned to UFH plus GPI. Seven point two percent of patients in the patients assigned to bivalirudin group required GPI (mainly because of absence of reflow or giant thrombus after PCI). At 30 d, the MACE rates were significantly lower in bivalirudin group (9.2% vs 12.1%,  $P = 0.005$ ). Bivalirudin group patients also had lower rates of non-CABG-related major bleeding (NCRMB 4.9% vs 8.3%,  $P < 0.005$ ) and all-cause mortality (2.1% vs 3.1%,  $P = 0.047$ ). The significant benefit in the NACE rates was mainly due to the lower major bleeding rates in the bivalirudin group<sup>[15]</sup>. At one year, reductions in MACE (15.6% vs 18.3%,  $P = 0.022$ ), NCRMB (5.8% vs 9.2%,  $P < 0.0001$ ) and all-cause mortality (3.5% vs 4.8%,  $P = 0.037$ ) rates were noted with bivalirudin. MACE rates were similar between the two groups (11.9% vs 11.9%,  $P = 0.98$ )<sup>[16]</sup>. Reduction in one-year mortality (8.4% vs 15.9%,  $P = 0.01$ ) and MI recurrence (3.6% vs 7.9%,  $P = 0.042$ ) was also found in high risk patients<sup>[17]</sup>. In patients with diabetes mellitus, significant benefit was seen in terms of reduction in cardiac death at 30 d with bivalirudin compared with the control group

(2.1% vs 5.5%,  $P = 0.01$ ). At one year, similar benefit in reduction of cardiac death was noted which was more evident in insulin dependent-DM patients (1.4% vs 9.4%,  $P = 0.04$ ). However, no benefit was seen in NCRMB rates (8.7% vs 10.7%,  $P = 0.42$ )<sup>[18]</sup>.

### **Studies on bleeding profile and other outcomes**

A subanalysis of the REPLACE-2 study showed that pretreatment with antithrombin therapy before randomization did not affect the bleeding outcomes in patients treated with bivalirudin<sup>[19]</sup>. Even in the subanalysis of patients with renal impairment (creatinine clearance < 60 mL/min), lower bleeding incidence and efficacy that was non-inferior to UFH plus GPI, showed in another subanalysis of the REPLACE-2 trial<sup>[20]</sup>. However, it should be noted that none of the individual subgroup in this trial was sufficiently powered to support definitive conclusions. This study documented that using bivalirudin with provisional GPI was easy to administer, as well as simple because only 7.2% ( $P = 0.001$ ) patients in this group required provisional GPI inhibitors compared with 5.2% ( $P = 0.001$ ) of provisional use and 96.5% ( $P$  value not significant) of planned use of GPI inhibitors in patients of the UFH group<sup>[11]</sup>. However, this study did not include patients with acute MI or unstable ischemic syndromes who often require empiric GPI. This study determined with certainty that using bivalirudin with provisional GPI is appropriate in the subgroup of patients with low to moderate risk characteristics for periprocedural or long-term ischemic complications of PCI, especially if these patients have more risk factors for bleeding. This approach was cost effective with savings from \$375 to \$400 per patient in the 4651 United States patients studied<sup>[21]</sup>. Since almost one fourth of the patients undergoing PCI are diabetic patients, a post hoc analysis of REPLACE-2 was done only on patients with diabetes mellitus and found that no difference in both short and long term ischemic events in the bivalirudin and UFH plus GPI groups<sup>[22]</sup>. Moreover, in patients with diabetes mellitus who underwent PCI, bivalirudin as a monotherapy resulted in similar 30 d composite ischemia (8.5% vs 9.7%,  $P = 0.63-1.22$ ) and lower major bleeding rates (4.6% vs 8.5%,  $P = 0.36-0.81$ ) when compared with heparin plus GPI group<sup>[23]</sup>. Furthermore, a study analyzed the outcomes in NSTEMI patients of this trial who were pretreated with heparin and then switched to bivalirudin. Though the composite ischemia was similar in these patients when compared with patients on consistent heparin plus GPI (9.0% vs 8.2%,  $P = 0.47$ ), these patients had lesser rates of 30 d major bleeding episodes (3.5% vs 6.7%,  $P < 0.01$ )<sup>[24]</sup>.

The NAPLES trial from 2009 was done on 355 diabetic patients undergoing elective PCI for asymptomatic/stable/unstable angina. It compared bivalirudin monotherapy with the combination of UFH and tirofiban in these patients. After 30-d follow up, the composite endpoint (death, MI, revascularization and all bleeding) was found to be lower in the bivalirudin group (18.0% vs 31.5%,  $P = 0.004$ )<sup>[25]</sup>. At that time, evidence was

increasing that pretreatment with 300 mg or 600 mg clopidogrel improves outcomes<sup>[13,15,26-28]</sup>. The ISAR-REACT 3 and 4 trials, studied the efficacy and safety of bivalirudin compared with that of UFH in patients with stable or unstable angina (cardiac biomarker negative), pretreated with 600 mg clopidogrel, undergoing PCI. Overall, the rates of major bleeding were significantly lower with bivalirudin (3.1% vs 4.6%,  $P = 0.008$ ).

The 30-d primary outcome (composite of death, MI, urgent target-vessel revascularization and major bleeding) with bivalirudin was similar to that of UFH (8.3% vs 8.7%,  $P = 0.57$ ), showed in a study with 4570 enrolled patients with stable or unstable angina. The rates of major bleeding were significantly lower with bivalirudin (3.1% vs 4.6%,  $P = 0.008$ )<sup>[29]</sup>. No significant differences in the primary outcome was found between the two groups even after one year of follow up (17.1% vs 17.5%,  $P = 0.816$ )<sup>[30]</sup>. In the subgroup of unstable angina patients (836 patients) of this study, the 30-d primary outcome with bivalirudin was similar to that of UFH (10.0% vs 10.8%,  $P = 0.88$ )<sup>[29]</sup>. No significant differences in the primary outcome was found in this subgroup of patients between the two groups even after one year of follow up (21.5% vs 20.1%,  $P = 0.458$ )<sup>[30]</sup>. In this study the dose of heparin was high (140U/kg initial bolus). This might have made the benefit with bivalirudin in reducing major bleeding rates more apparent. ISAR-REACT 3A study compared the reduced dose of UFH (initial bolus of 100 U/kg) with bivalirudin in 2505 stable (cardiac biomarker negative) patients undergoing PCI. UFH at 100 U/kg showed net clinical benefit in these patients when compared with bivalirudin<sup>[31]</sup>.

ISAR-REACT 4, a randomized, double blind study done in 2011, on 1721 patients compared the combination of abciximab plus UFH (70 U/kg initial bolus) with bivalirudin in patients with NSTEMI undergoing PCI. All patients received pretreatment with 600 mg clopidogrel. The primary end point of net clinical outcome (death, large recurrent MI, urgent target-vessel revascularization and major bleeding) was similar in both the groups at 30 d (10.9% vs 11.0%,  $P = 0.94$ ). The relative risk of major bleeding was lower with bivalirudin (approximately 0.55)<sup>[32]</sup>.

ISAR-REACT 3 and 4 trials showed that bivalirudin was non-inferior in reducing ischemic complications, and safer than UFH in clopidogrel pretreated patients. A pooled analysis from the ACUITY and ISAR-REACT 4 NSTEMI patients who underwent PCI after clopidogrel pretreatment found that bivalirudin monotherapy was as efficient as heparin (UFH/enoxaparin) plus GPI in reducing net adverse clinical events (13.4% vs 14.7%,  $P = 0.21$ ) and superior to heparin plus GPI in reducing major bleeding events (3.4% vs 6.3%,  $P = 0.21$ )<sup>[31]</sup>. However, a recent meta-analysis did not support that pretreatment with clopidogrel, improved outcomes<sup>[33]</sup>.

The Naples III was a double blind, randomized trial that included 837 patients with increased risk of to receive either bivalirudin or heparin infusion for

transfemoral elective coronary stenting. Patients had to be cardiac biomarkers negative without any EKG changes, suggesting ongoing acute or recent MI. The primary endpoint was the rate of in-hospital major bleed, which occurred in 2.6% (11 patients) in the heparin group vs 3.3% (14 patients) in the bivalirudin group. The authors concluded that there was no difference between these two groups in the rate of major bleeding<sup>[34]</sup>.

### Safety with combination drug use

The REPLACE-1 study was done to evaluate whether bivalirudin in combination with planned GPI was an effective and safe approach or not. The patients were randomized in an open-label fashion to receive bivalirudin or UFH during the procedure. Seventy-six percent of patients received GPI blockade in this study in which 71.7% of patients received it in a planned fashion (almost identical percentage of patients in bivalirudin and UFH groups). Overall, the composite efficacy endpoint of death, MI and revascularization occurred in 5.6% of patients in the bivalirudin group compared with 6.9% of patients in the UFH group. The major bleeding rates with bivalirudin were non-inferior to that of UFH (2.1% vs 2.7%,  $P = 0.52$ ). In patients who received GPI, 7.2% of patients in the bivalirudin group experienced the composite of death, MI and revascularization compared with 6.1% of patients in the UFH group and the major bleeding episodes were the same (2.9% vs 2.9%) in both the groups. Thus, this study showed that, regardless of whether patients received GPI or not, bivalirudin reduces the ischemic events. Furthermore, this trial represented the largest prospective dataset of bivalirudin administered concomitantly with planned GP II b/III a blockade and provided evidence of the safety and efficacy of this combined antithrombotic approach<sup>[35]</sup>. These end points were recorded during the hospital stay or within 48 h, whichever came first, which was different from a set time duration used in CACHET trial (7 d). Also, this was a blinded study unlike CACHET trial. REPLACE-2 supported the findings in CACHET trial.

The PROTECT-TIMI 30 trial was a randomized, open label, parallel group study on 857 moderate to high risk patients (having at least one or more of these risk features, *i.e.*, diabetes, a positive cardiac biomarker either CK-MB or troponin T/I, ST-segment deviation > 0.5 mm, or TIMI risk score  $\geq 3$ ) with non ST elevation acute coronary syndromes presenting with chest discomfort or an anginal equivalent at rest  $\geq 10$  min and were anticipated to undergo PCI of a native coronary artery. This study compared the combination of eptifibatide and heparin (UFH/enoxaparin) with bivalirudin. Results showed that the primary end point of post-PCI coronary flow reserve was significantly higher with bivalirudin (1.43 vs 1.33,  $P = 0.036$ ). The myocardial perfusion (post-PCI TMPG) was found to be better in eptifibatide group (57.9% vs 50.9%,  $P = 0.048$ ) and the 48 h post-PCI composite of death and MI was lower in eptifibatide

group (8.8% vs 6.6%,  $P = 0.246$ ). Duration of post-PCI ischemia was also lower in eptifibatide group (36 min vs 169 min,  $P = 0.013$ ). In the UFH plus eptifibatide group, there were increased bleeding episodes more notably TIMI minor bleeding episodes (2.5% vs 0.4%,  $P = 0.027$ ) and bleeding episodes that required transfusion (4.4% vs 0.4%,  $P < 0.001$ ). This study showed that bivalirudin therapy lowers bleeding and the need for blood transfusion and thus safer than heparin plus eptifibatide therapy<sup>[12]</sup>.

### Mortality rates

When bivalirudin plus GPI was compared with heparin plus GPI in the ACUTY trial in a subgroup analysis of 7780 patients undergoing urgent PCI that there were no significant difference in 30 d rates of composite ischemia, *i.e.*, death, MI or revascularization (9% vs 8%,  $P = 0.16$ ) and major bleeding (8% vs 7%,  $P = 0.32$ ). In this subgroup analysis, when bivalirudin monotherapy group was compared with heparin plus GPI, the proportion of individuals with composite ischemia was found to be very much the same (8.8% vs 8.2%,  $P = 0.45$ ) but the major bleeding events were significantly lower in the bivalirudin monotherapy patients (4.5% vs 7.8%  $P < 0.0001$ )<sup>[13]</sup>. In naive patients who were administered heparin plus GPI ( $n = 1462$ ), similar rates of composite ischemia (5.5% vs 6.2%,  $P = 0.47$ ) and more major bleeding rates (4.9% vs 2.5%,  $P = 0.28$  to 0.75), were noted at 30 d when compared with patients naive to antithrombin therapy who were administered bivalirudin monotherapy ( $n = 1427$ ). The one-year follow up of PCI subgroup patients showed similar rates of composite ischemia and mortality in all the 3 regimen groups<sup>[24]</sup>. In a major review, although the study demonstrated that using bivalirudin had several advantages such as being more cost effective, and lesser major bleeding events, it received criticism from researchers due to the open-label design, not including patients with acute STEMI, stating that using such definitions of bleeding endpoints made comparison between studies tough, considering hematoma > 5 cm at the puncture site as a major bleeding event among other factors<sup>[36]</sup>. Dangas *et al*<sup>[37]</sup> showed that patients who received UFH as early treatment and were switched to bivalirudin, 30 d (7.6% vs 12.3%,  $P = 0.0001$ ) and 2 years (8.4% vs 13.0%,  $P = 0.0003$ ), major bleeding rates were found to be lower than that of the control group. These patients also had lower 30-d (1.6% vs 2.9%,  $P = 0.04$ ) and 2 year (2.3% vs 3.8%,  $P = 0.04$ ) rates of cardiac mortality. MI recurrence rate (4.0% vs 7.1%,  $P = 0.0002$ ) was also found to be lower at 2-year follow-up<sup>[37]</sup>. At 3 years, lower rates of all-cause mortality (5.9% vs 7.7%,  $P = 0.03$ ) and NCRMB (6.9% vs 10.5%,  $P = 0.0001$ ) were found with bivalirudin. For every 1000 patients treated with bivalirudin, 18 lives were saved. MACE (21.9% vs 21.8%,  $P = 0.95$ ) and NACE (25.5% vs 27.6%) rates were similar between the two groups<sup>[38]</sup>. A pooled analysis of the patients who underwent PCI in

REPLACE-2, ACUTY and HORIZONS-AMI trials showed that there is a strong positive association between NCRMB within 30 d and the 1 year mortality risk, post PCI<sup>[2]</sup>. This study supported the conclusions derived by the researchers in other similar analysis<sup>[39]</sup>. In the integer based risk score for NCRMB (TIMI) developed by this pooled analysis researchers, bivalirudin monotherapy was the only variable that received a negative score (-6) among all the 28 variables<sup>[2]</sup>.

### Timing studies

A *post-hoc* analysis was done to assess whether the timing of clopidogrel administration had any influence on safety and efficacy. They found that, in patients who received clopidogrel before or within 30 min after PCI, treatment with bivalirudin monotherapy resulted in significantly less bleeding rates (3.5% vs 6.6%,  $P < 0.0001$ ) and similar 30-d composite ischemia (8.2% vs 8.3%, risk ratio: 0.98, 95% confidence interval: 0.81 to 1.20) when compared with heparin plus GPI treatment. They also found that, in the patients who receive clopidogrel > 30 min or not at all after PCI, bivalirudin monotherapy might be associated with worst ischemic outcomes (14.1% vs 8.5%, risk ratio: 1.66, 95%CI: 1.05 to 2.63)<sup>[40]</sup>. This might have been due to the short half-life of bivalirudin. A subset of high risk patients undergoing PCI of the left anterior descending artery (LAD), was studied separately. Among 1445 patients who underwent PCI to the LAD, in the HORIZONS-AMI trial, the use of bivalirudin was associated with significantly lower rates of cardiac death (3.8% vs 6.8%,  $P = 0.01$ ), reinfarction (5.3% vs 9.5%,  $P < 0.004$ ), and major bleeding events (7.3% vs 11.8%,  $P = 0.004$ ) compared to UFH plus GPI<sup>[41]</sup>.

Ideally, the treatment for STEMI should be started when patients are on their way to the hospital. The EUROMAX study addressed this question by comparing the use of bivalirudin vs heparin plus optional GPI (control group) during emergency transport to the hospital for primary PCI. A total 2218 patients were enrolled. The primary outcome of death and non-CABG major bleeding occurred in 5.1% in bivalirudin group vs 8.5% in control group ( $P = 0.001$ ). The study specified that bivalirudin had to be continued for at least 4 h after PCI. One of the limitations of the study was that GPI administration was not randomized and 11.5% of patients in bivalirudin group received it comparing to 69.1% in heparin group<sup>[42]</sup>.

In contrast, the HEAT-PPCI study showed that bivalirudin was not beneficial over heparin in PCI. This was an open-label, single center, randomized trial where 1829 patients were randomized to either receive bivalirudin or heparin. The primary outcome of MACE occurred in 8.7% of patients in bivalirudin group and 5.7% in heparin group (95%CI: 1.09-2.13,  $P = 0.01$ ). The superiority of heparin was primarily due to decreased rate of reinfarction. Both groups were given GPIs at same rate. Patients were given a bolus of bivalirudin at the end of the procedure if activated clotting time was less than

225 s but the drip was not continued after procedure<sup>[43]</sup>.

The Bright trial was conducted at 82 centers in China. In this trial, 2194 patients with MI, both STEMI and NSTEMI, were randomized into three groups: The first group received bivalirudin alone, the second group heparin alone and the third group received heparin plus tirofiban infusion. In the bivalirudin group the medication had to be given for at least 30 min and no more than 4 h post PCI, and reduced dose of infusion (0.2 mg/kg per hour comparing to mandatory rate 1.75 mg/kg per hour right after PCI) could be administered for up to 20 h post PCI at physician discretion (15.6% patients of bivalirudin group). In the third group tirofiban infusion was given for 18 to 36 h total. The primary outcome of the study was net clinical adverse events (NACE) at 30 d consisting of major adverse cardiac or cerebral events (all-cause death, reinfarction, ischemia-driven target vessel revascularization, or stroke) and bleeding. NACE occurred in 65 patients (8.8%) in bivalirudin group compared to 96 patients (13.2%) in heparin alone group ( $P = 0.008$ ). The 30-d bleeding rate was also less frequent in bivalirudin group at 4.1% comparing to 7.5% in heparin alone group and 12.3% in bivalirudin plus tirofiban group ( $P < 0.001$ )<sup>[44]</sup>.

The Matrix trial studied patients with ACS undergoing PCI and compared heparin infusion to bivalirudin with or without post-PCI continuation of bivalirudin. The primary outcomes of the study were MACE and NACE. There was no significant difference in MACE in bivalirudin group and heparin group (10.3% vs 10.9%,  $P = 0.44$ ), or in NACE (11.2% vs 12.4%, respectively,  $P = 0.12$ ). Bivalirudin was associated with a lower rate of death from any cause than was heparin (1.7% vs 2.3%,  $P = 0.04$ ), as well as lower rate of death from cardiac causes (1.5% vs 2.2%,  $P = 0.03$ ). Post-PCI infusion of bivalirudin did not significantly change the outcome in comparison to stopping the infusion after completing procedure. In this study the use of transfusion without overt bleeding did not satisfy the criteria for major bleeding<sup>[45]</sup>.

Bivalirudin was compared to heparin not only during PCI but also during transcatheter valve replacement (TAVR). In this Bravo-3 trial, 802 patients with aortic stenosis were randomized to receive bivalirudin or UFH during the procedure. Although bivalirudin group showed slightly better results in the number of major bleedings at 48 h (6.9% vs 9.0%,  $P = 0.27$ ) and net adverse cardiovascular events at 30 d (14.4% vs 16.1%,  $P = 0.35$ ), these results were not statistically significant. Authors concluded that UFH should be used during the procedure because of the lower cost<sup>[46]</sup>.

### Stent thrombosis comparison trials

Within the first 24 h post-PCI stent thrombosis rates were more in patients assigned to bivalirudin compared with the control group (1.4% vs 0.3%,  $P < 0.001$ ). The stent thrombosis rates after 24 h were more in the control group than with bivalirudin (4.4% vs 2.8%;  $P$

= 0.02). Stent thrombosis occurred at a higher rate in patients who received higher loading dose (600 mg) of clopidogrel<sup>[47]</sup>. Stent thrombosis rates were similar in both the groups at 30 d, one year and 3-year follow ups. When compared to bare metal stents, stent thrombosis rates were lesser with paclitaxel-eluting stents at 3 years (9.4% vs 15.1%,  $P < 0.0001$ )<sup>[38]</sup>.

### Bivalirudin in fondaparinux pre-treated patients undergoing PCI

Fondaparinux is a factor Xa inhibitor, given subcutaneously. Today, this drug is approved in patients undergoing orthopedic surgery and as initial therapy for venous thromboembolisms. The clinical value of fondaparinux in patients with ACS has also been investigated<sup>[48]</sup>. The PENTUA (Pentasaccharide in Unstable Angina) study on NSTEMI patients compared different doses of fondaparinux against enoxaparin in patients with non-ST elevation ACS. In PCI patients, there were no significant differences between the groups in the primary endpoint of death, MI, or recurrent ischemia at the end of 9 d<sup>[49]</sup>. A study done on 20078 patients with ACS were randomly assigned to receive either Fondaparinux (2.5 mg daily) or enoxaparin (1 mg per kilogram of body weight twice daily) for a mean of six days and evaluated death, myocardial infarction, or refractory ischemia at nine days (the primary outcome); major bleeding; and their combination. Patients were followed for up to 6 mo. Fondaparinux was found to be similar to enoxaparin in reducing the risk of ischemic events at nine days, but it substantially reduced major bleeding complications and improved long term mortality and morbidity<sup>[50]</sup>.

The OASIS-5 study compared 2.5 mg daily fondaparinux with enoxaparin 1 mg/kg twice daily for a mean of 6 d in over 20000 patients with ACS. The primary endpoint of death, MI, or refractory ischemia at 9 d was similar between the groups and there was a non-significant trend toward lower event rates with fondaparinux at 30 d. Furthermore, Fondaparinux markedly lowered the rates of bleeding (2.2 % vs 4.1%). The mortality rates with fondaparinux were lower at both 30 and 180 d follow-up<sup>[51]</sup>. However, OASIS-6 (Sixth Organization to Assess Strategies in Acute Ischemic Syndromes) was a randomized, double-blind study performed on STEMI patients. Two point five milligram dose fondaparinux was compared to UFH. It showed that the patients in the fondaparinux group had excess PCI complications and catheter thrombosis rates. In this study, no benefit was seen in death and reinfarction rates with fondaparinux in patients undergoing primary PCI<sup>[52]</sup>.

SWITCH III was an open-label, randomized, multi-center pilot study done on 100 patients with non-ST-segment elevation ACS initially treated with fondaparinux and undergoing early invasive strategy. It compared treatment with bivalirudin vs UFH in these patients. Results in this study suggest that bivalirudin when compared to standard-dose UFH, had a similar safety profile in terms of thrombotic events and peri-PCI

**Table 2 Major studies comparing bivalirudin and heparin**

Trial name	Type of trial	Number of patients	Bleeding risk	Thrombosis risk	Mortality benefit	Comments
REPLACE-2	Randomized, double blind	6010	Favors bivalirudin	Bivalirudin noninferior	Bivalirudin noninferior	
ACUTY	Randomized, open-label	13819	Favors bivalirudin	Comparable	Comparable	
ARMYDA-7	Randomized, open-label	401	Favors bivalirudin	Comparable	Comparable	Primarily decrease in access site bleeding in bivalirudin group
BIVALVE						
HORIZONS-AMI	Randomized, open-label, multicenter	3602	Favors bivalirudin	Comparable	Favors bivalirudin	Heparin group was given glycoprotein II b/IIIa inhibitors
NAPLES	Randomized, open-label	355	Favors bivalirudin	Comparable	No deaths in study period	All patients with diabetes mellitus. Heparin group was given tirofiban
ISAR-REACT 4	Randomized, double-blind	1721	Favors bivalirudin	Comparable	Comparable	Heparin group was given abciximab
NAPLES III	Randomized, double-blind	837	Comparable	Not studied	Not studied	Femoral approach access in PCI
EUROMAX	Randomized, open-label	2218	Favors bivalirudin	Favors heparin	Comparable	GP II b/IIIa inhibitor was optional in heparin group
HEAT-PPCI	Randomized, open-label	1829	Comparable	Favors heparin	Favors heparin	Use of GP II b/IIIa was option in both groups
BRIGHT	Randomized, open-label	2194	Favors bivalirudin	Comparable	Comparable	
MATRIX	Randomized, open-label	7213	Favors bivalirudin	Favors heparin	Favors bivalirudin	Post-PCI infusion of bivalirudin didn't affect the outcome

PCI: Percutaneous coronary intervention.

bleeding. Thus, in NSTEMI patients initially treated with upstream fondaparinux who undergo PCI, bivalirudin can be used<sup>[53]</sup>.

**Trials on newer antiplatelet drugs with bivalirudin**

Prasugrel and ticagrelor are the novel antiplatelet drugs. In patients undergoing PCI for ACS, dual antiplatelet therapy with aspirin and prasugrel reduced the ischemic events in TRITON-TIMI 38 study<sup>[54]</sup>. Another study showed that prasugrel was found to be as safe and effective as clopidogrel in ACS patients undergoing PCI with bivalirudin anticoagulation<sup>[55]</sup>. The benefit of reduction in ischemic events was more in STEMI patients. BRAVE-4 trial on patients undergoing urgent PCI for STEMI demonstrated a more pronounced inhibition of platelet aggregation as well as platelet adhesion and aggregate formation to collagen under flow in prasugrel plus bivalirudin treated patients<sup>[56]</sup>.

**DISCUSSION**

In conclusion, bivalirudin is now the most commonly used anticoagulant for transradial PCI in the United States, while weight adjusted unfractionated heparin remains the most common choice outside the United States<sup>[57]</sup>. Table 2 outlines the biggest studies comparing bivalirudin to heparin. Bivalirudin reduced both ischemic and bleeding events in femoral-treated patients, even though no such clinical benefit was observed in the radial-treated patients<sup>[58]</sup>. Except in stable (cardiac biomarker negative) patients where heparin could be used, bivalirudin should

be considered for anticoagulation in patients undergoing PCI especially if a patient has increased risk of bleeding. Switching from UFH or enoxaparin or fondaparinux to bivalirudin is also an option. Furthermore bivalirudin is safe to use in patients with HIT. The combination of newer antiplatelet drugs with bivalirudin in PCI patients has shown promising results. The cost of bivalirudin is high. However, this therapy reduces the overall costs since it lowers complications, hospital stays, and all over mortality<sup>[59,60]</sup>. Moreover, the combination of bivalirudin and drug eluting stents has resulted in better outcomes. Peri-procedural PCI bleeding avoidance strategies have become paramount to optimize the clinical benefit, and the interaction between bivalirudin and radial approach deserves additional investigations. There are numerous studies comparing heparin against bivalirudin. Unfortunately, many of them are difficult to compare because of difference in protocols and definitions. Some of the studies, like HORIZONS AMI, were conducted in the era when administration of GPIs was routine and newer P2Y12 inhibitors like ticagrelor and prasugrel were not yet available. The HEAT-PPCI trial showed the heparin to be superior over bivalirudin in preventing major adverse ischemic events. Heparin's longer half-life may partially explain the decreased rate of ischemic events in HEAT-PPCI trial. Many trials defined the requirement for the transfusion as a major bleeding but this was not the case in MATRIX trial unless there was overt bleeding. Recent ACC/AHA guidelines do not specify the preference of one medication over another during PCI for NSTEMI or STEMI, and both heparin and bivalirudin are acceptable

options in these guidelines. Each individual patient's ischemic and bleeding risks should be taken into account. However, in spite of some minor conflicting data, we conclude that bivalirudin should be used as preferred method of anticoagulation during PCI for ACS as the majority of randomized trials showed more superior long-term advantages over heparin, including safety, efficiency and cost-effectiveness. This will likely bring higher value to patients, defined as better outcomes for less cost, which is the ultimate goal in healthcare.

## COMMENTS

### Background

Anticoagulation is required during (PCI) and other percutaneous transluminal coronary angioplasty. Historically, heparin was used for this purpose until 1990's when bivalirudin was introduced to clinical practice. There is still ongoing debate about the drug of choice for peri-PCI anticoagulation.

### Research frontiers

Bivalirudin is a direct thrombin inhibitor with a short half-life and this quality may decrease bleeding complications during PCI. There is extensive amount of literature comparing bivalirudin to heparin.

### Innovations and breakthroughs

In this article the authors reviewed the literature comparing bivalirudin to heparin.

### Applications

The article will help to understand the literature comparing bivalirudin to heparin and to make conscious and medical decision making between these medication.

### Terminology

Bivalirudin is a direct thrombin inhibitor widely used to prevent thrombotic complication during PCI.

### Peer-review

This is an excellent review about the safety, effectiveness, and cost benefits of bivalirudin. This manuscript is nicely structured and well written.

# World Journal of *Cardiology*

*World J Cardiol* 2017 October 26; 9(10): 773-795

## Editorial Board

2014-2017

The *World Journal of Cardiology* Editorial Board consists of 416 members, representing a team of worldwide experts in cardiology. They are from 46 countries, including Argentina (3), Australia (7), Austria (6), Belgium (2), Brazil (8), Canada (11), China (37), Croatia (1), Cuba (1), Cyprus (1), Czech Republic (2), Denmark (3), Egypt (1), Finland (3), France (3), Germany (32), Greece (10), Hungary (5), India (4), Iran (2), Ireland (1), Israel (5), Italy (63), Japan (32), Kosovo (1), Malaysia (1), Mexico (1), Morocco (1), Netherlands (9), New Zealand (1), Nigeria (2), Norway (2), Poland (8), Portugal (2), Saudi Arabia (2), Singapore (3), Slovenia (1), South Korea (9), Spain (14), Switzerland (3), Thailand (3), Turkey (13), United Arab Emirates (1), United Kingdom (20), United States (73), Uruguay (2), and Venezuela (1).

### EDITORS-IN-CHIEF

Jian-Jun Li, *Beijing*  
Giuseppe De Luca, *Novara*  
Nathan D Wong, *Irvine*

### ASSOCIATE EDITOR

Fabio Barili, *Cuneo*  
Raffaele Bugiardini, *Bologna*  
Olaf Walter Franzen, *Zürich*  
Philipp Kahlert, *Essen*  
Giora Landesberg, *Jerusalem*  
Elsayed Z Soliman, *Winston Salem*

### GUEST EDITORIAL BOARD

#### MEMBERS

Editorial Board Member of *World Journal of Cardiology*, Peter E Ong, MD, Senior Scientist, Department of Cardiology, Robert Bosch Krankenhaus, Stuttgart 70376, Germany

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Cardiac magnetic resonance (CMR) is a non-invasive, non-ionizing, diagnostic technique that uses magnetic fields,

radio waves and field gradients to generate images with high spatial and temporal resolution. After administration of contrast media (*e.g.*, gadolinium chelate), it is also possible to acquire late images, which make possible the identification and quantification of myocardial areas with scar/fibrosis (late gadolinium enhancement, LGE). CMR is currently a useful instrument in clinical cardiovascular practice for the assessment of several pathological conditions, including ischemic and non-ischemic cardiomyopathies and congenital heart disease. In recent years, its field of application has also extended to arrhythmology, both in diagnostic and prognostic evaluation of arrhythmic risk and in therapeutic decision-making. In this review, we discuss the possible useful applications of CMR for the arrhythmologist. It is possible to identify three main fields of application of CMR in this context: (1) arrhythmic and sudden cardiac death risk stratification in different heart diseases; (2) decision-making in cardiac resynchronization therapy device implantation, presence and extent of myocardial fibrosis for left ventricular lead placement and cardiac venous anatomy; and (3) substrate identification for guiding ablation of complex arrhythmias (atrial fibrillation and ventricular tachycardias).

**Key words:** Cardiac magnetic resonance; Ablation; Sudden cardiac death; Cardiac resynchronization therapy; Arrhythmic risk stratification

Cardiac magnetic resonance imaging: Which information is useful for the arrhythmologist? *World J Cardiol* 2017; 9(10): 773-786 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i10/773.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i10.773>

## INTRODUCTION

Cardiac magnetic resonance (CMR) is a non-invasive, non-ionizing, diagnostic technique that uses magnetic fields, radio waves and field gradients to generate images with high spatial and temporal resolution and without limitations due to the acoustic window, compared to other imaging techniques<sup>[1,2]</sup>. It provides a very precise "in vivo" tissue characterization through the different quantity of protons in different chemical environments, identifying the presence of fat, water (oedema), blood, fibrosis and scar<sup>[1,2]</sup>. In particular, after the administration of contrast media (*e.g.*, gadolinium chelate), it is possible to acquire late images which make possible the identification and quantification of myocardial areas with scar/fibrosis (late gadolinium enhancement, LGE)<sup>[1]</sup>. First used as a research tool, CMR has become a daily instrument in clinical cardiovascular practice for the assessment of several pathological conditions, including ischemic and non-ischemic cardiomyopathies and congenital heart disease<sup>[1]</sup>.

In recent years, its field of application has also extended to arrhythmology, both in diagnostic and prognostic evaluation of arrhythmic risk and in therapeutic decision-making. It is possible to identify three main fields of application of CMR in arrhythmology: (1) arrhythmic and sudden cardiac death (SCD) risk stratification in different heart diseases; (2) decision-making in cardiac resynchronization therapy (CRT) device implantation [cardiac vein anatomy, scar burden and left ventricular (LV) lead placement]; and (3) substrate identification for guiding ablation of complex arrhythmias [atrial fibrillation and ventricular tachycardias (VTs)].

In this review, we discuss the possible useful applications of CMR that can help the arrhythmologist in the management of patients with this broad spectrum of arrhythmological conditions.

## ARRHYTHMIC AND SCD RISK STRATIFICATION

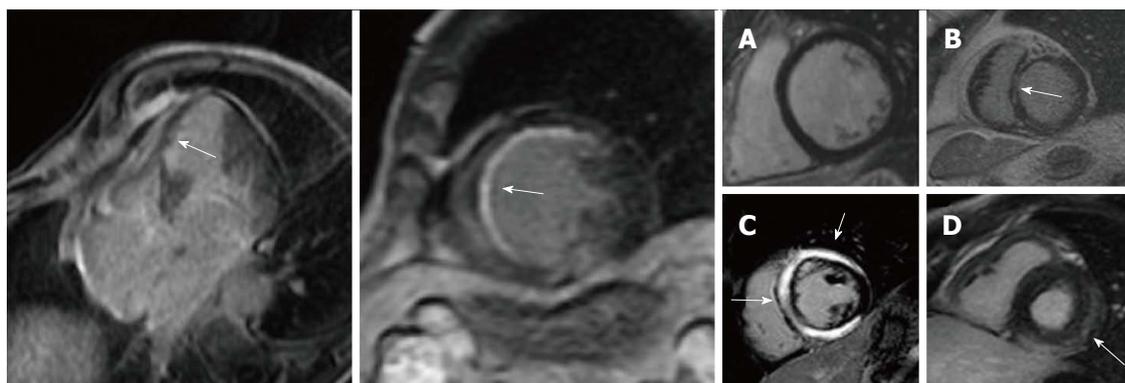

SCD is responsible for 25% of 17 million cardiovascular

deaths every year in the world. The great majority of these deaths (> 90%) have an arrhythmic origin, namely, VT degenerating into ventricular fibrillation (VF), primary VF or torsade de pointes<sup>[3]</sup>.

The underlying causes vary in different age groups, with channelopathies and cardiomyopathies prevailing in young people, while degenerative diseases are more common in older people. In general, the main causes are: Acute and chronic coronary heart disease (75%-80%); cardiomyopathies (10%-15%); valvular, inflammatory and infiltrative diseases (5%-10%); and molecular/genetic conditions (< 5%)<sup>[3]</sup>. Prevention can be made with pharmacological or device therapy. This latter consists in ICD (implantable cardioverter defibrillator) implantation that is recommended in different groups of high risk patients with ischemic or non-ischemic heart diseases. However, risk stratification is sometimes very challenging, especially in primary prevention. Current approaches have limited sensitivity and specificity in many clinical settings, identifying only a very small portion of future cardiac arrests with sufficient precision to justify ICD therapy<sup>[3,4]</sup>. Moreover, ICD implantation is not without complications and many patients will not benefit even if implanted according to guidelines<sup>[3,4]</sup>. Lately, scientific interest is pointing to a polyparametric approach, using a combination of different risk markers to better dichotomize high and low risk patients<sup>[4,5]</sup>. In this context, CMR can give its contribution, especially through the identification and quantification of myocardial areas with scar and fibrosis. Ventricular fibrosis is an important substrate for the genesis of ventricular arrhythmias (VA): Within fibrotic tissue the slow and heterogeneous conduction favors re-entrant circuits, increasing vulnerability to VT and VF<sup>[6-8]</sup>.

### **Dilated ischemic and non-ischemic cardiomyopathies**

A left ventricular ejection fraction (LVEF) of 35% or less is the major determinant of ICD implantation for SCD primary prevention in patients with ischemic or nonischemic LV dysfunction<sup>[3]</sup>. Even in the recent European Society of Cardiology (ESC) guidelines<sup>[3]</sup>, the only suggested markers of arrhythmic risk to guide ICD implant are LVEF and NYHA functional class (Table 1). However, it is now well-known that ejection fraction alone has limited sensitivity and specificity as a risk marker for SCD, because it is not able to distinguish the risk of sudden death from death caused by heart failure or other non-cardiac diseases. Subsequently, many patients implanted for primary prevention according to current guidelines will have little benefit from their ICD, with a low rate of appropriate ICD therapy (2%-4%/year)<sup>[9]</sup>, while they can suffer from side effects (even > 10%/year overall), in particular inappropriate shocks, lead failure and infections<sup>[10,11]</sup>. On the other side, many patients who are at risk of SCD are missed when using only LVEF, because the largest part of sudden arrhythmic death patients have only mildly depressed ejection fraction<sup>[9,12,13]</sup>. Anyway, the substrates of SCD are particularly complex, so it is unlikely for a single test to achieve significantly better predictive accuracy than LVEF. To overcome this

**Figure 1** Late gadolinium-enhanced cardiac magnetic resonance images of ischemic (left panel) and non-ischemic (right panel) dilated cardiomyopathy. In ischemic cardiomyopathy LGE has a subendocardial or transmural distribution in myocardial segments following a coronary artery. In non-ischemic etiology, it shows a “midwall” pattern (panel B, C) or subepicardial distribution (panel D). LGE: Late gadolinium enhancement.

**Table 1** Current European Society of Cardiology recommendations for implantable cardioverter defibrillator implantation for primary prevention in patients with ischemic and non-ischemic left ventricular dysfunction

Recommendations
Class I: ICD therapy is recommended to reduce SCD in patients with symptomatic HF (NYHA class II–III) and LVEF $\leq$ 35% after $\geq$ 3 mo of optimal medical therapy who are expected to survive for at least 1 yr with good functional status
Level of evidence A: Ischemic etiology (at least 6 wk after myocardial infarction)
Level of evidence B: Non-ischemic etiology

From ref. [3]. ICD: Implantable cardioverter defibrillator; SCD: Sudden cardiac death; LVEF: Left ventricular ejection fraction; HF: Heart failure; NYHA: New York Heart Association.

limitation, a combination of markers has been proposed<sup>[9]</sup>, for example, combining ejection fraction with different tests that investigate different arrhythmic mechanisms (LGE-CMR, T-wave alternans, programmed ventricular stimulation, evaluation of autonomic tone, etc.).

The pathophysiology of VA in structural heart diseases is due - in most cases - to re-entrant circuits. Electrophysiological studies and anatomic mapping have highlighted, in these cases, the presence of extensive areas where the electrical potentials are absent (indicating the absence of viable myocardium, scar and fibrosis) and areas with low-amplitude, fragmented, late potentials compared to healthy myocardium (conduction with high anisotropy and low speed)<sup>[6-8]</sup>. The classic arrhythmogenic substrate of re-entry arrhythmias is represented by a mix of these areas, with inflammation often acting as a trigger. Thanks to its ability to identify both areas of myocardial scar/fibrosis and inflammation, CMR can provide essential information in this context<sup>[8,9]</sup>.

Myocardial fibrosis can be evaluated with the LGE imaging technique. Gadolinium-based contrast agents are washed out by viable myocytes and accumulate in extracellular spaces, such as areas of fibrotic tissue, where cardiomyocytes have been replaced by collagen, or in areas of acutely damaged myocardium<sup>[7,8]</sup>. The LGE imaging techniques have been validated by histology in several studies with animal models<sup>[14]</sup>. To date, due to the high spatial resolution (approximately 2 mm), it is the most accurate method to detect myocardial fibrosis and to precisely identify its location and extension, distinguishing

in particular endocardial, epicardial or transmural involvement. The pattern of LGE distribution is particularly useful in the differential diagnosis between ischemic and non-ischemic fibrosis<sup>[15-17]</sup>. Virtually all patients with ischemic cardiomyopathy have LGE, presenting with a subendocardial or transmural distribution in myocardial segments following a coronary artery territory<sup>[16]</sup>; the most common pattern consists of core dense fibrosis within a heterogeneous peri-infarct (gray) zone, indicating the presence of both viable and nonviable myocardium<sup>[9]</sup>. On the other side, in non-ischemic dilated cardiomyopathy fibrosis is present only in about 30%-40% of cases and it shows a “midwall” pattern, mostly located in the interventricular septum<sup>[17]</sup> (Figure 1). From an etiological and therapeutical point of view, this is a very important issue: non-ischemic cardiomyopathy on the basis of a traditional definition (clinical history, ECG, echocardiogram and coronary angiography) may be reclassified as ischemic cardiomyopathy thanks to CMR in about 20% of cases<sup>[15]</sup>.

Numerous studies have demonstrated that LGE is a powerful predictor of VA events both in ischemic and non-ischemic cardiomyopathy patients, with moderately to severely depressed LVEF<sup>[18-21]</sup>. An overview of 19 studies, all with an arrhythmic endpoint, for a total of 2692 patients, indicated that the presence and extension of myocardial fibrosis, documented by LGE, predicted VA both in ischemic and non-ischemic diseases, even in patients with only mildly depressed LVEF<sup>[9,18,19]</sup>. Furthermore, CMR increased the negative predictive

value for SCD prediction to 95%<sup>[9,20-22]</sup>.

Taking into account only non-ischemic dilated cardiomyopathy, the cut-off for risk definition was the presence or absence of fibrosis and its midwall location. These markers were successfully used to dichotomize patients at high vs low risk of ventricular arrhythmic events<sup>[23-32]</sup>. The largest prospective study in non-ischemic cardiomyopathy by Gulati *et al.*<sup>[26]</sup> included 472 patients followed for > 5 years. In this paper midwall fibrosis was an independent risk factor for ventricular tachyarrhythmias [hazard ratio (HR) = 4.61], while combining ventricular fibrosis with LVEF significantly improved risk reclassification for the arrhythmic endpoint. A recent meta-analysis of 29 studies including 2948 patients with idiopathic dilated cardiomyopathy<sup>[32,33]</sup> confirmed that the presence of ventricular fibrosis, identified by LGE, was an important risk factor for arrhythmic endpoints (SCD, VT, VF and ICD therapies): Clinical events occurred in 21% of LGE positive vs 4.7% of LGE negative patients, with an annual event rate of 6.9% and 1.6%, respectively.

In ischemic dilated cardiomyopathy, the issue is more complex: The majority of studies evaluating total LGE or "gray zone" (peri-infarct area) reported a statistically significant dose-response effect for arrhythmic risk, with larger and more heterogeneous scar associated with the higher risk of VA during follow-up<sup>[34-39]</sup>. Currently, there is not a definite cut-off value of fibrosis/scar extent to adequately differentiate patients at high vs low risk of arrhythmic events, especially in ischemic etiology<sup>[18]</sup>. The presence of a large amount of ventricular fibrosis/scar has been generally used as a marker of higher risk. However, a great variety of analysis methods and diagnostic thresholds exists<sup>[34-39]</sup>: Standardization of LGE-CMR should be a target to reach before spreading practical use of this technique for arrhythmic risk stratification. Moreover, no randomized study has been concluded so far: The DETERMINE study<sup>[40]</sup> was planned to demonstrate the role of LGE-CMR in decision-making for ICD implantation in patients with ischemic cardiomyopathy, but it was prematurely terminated due to a low rate of patient enrollment.

Even with the above limitations, a polyparametric approach, using a combination of different risk markers (including LGE-CMR), could help to refine risk stratification in at least two subsets of patients who are not adequately assessed by current guidelines<sup>[9]</sup>.

The first group is represented by patients with LVEF less than 35% and high risk of death due to heart failure or non-cardiac causes. In this setting, the absence of LGE-CMR (non-ischemic etiology) or a small extension of fibrosis/scar (ischemic etiology), especially if coupled with negative T-wave alternans test, identifies patients with a relatively low risk of sudden arrhythmic death (about 1%/year) for whom ICD implantation should be critically considered because they will hardly have a benefit<sup>[9,21,22,32]</sup>.

The second group includes patients with LVEF of 35%-50% and high risk of SCD defined by: (1) presence

or high burden of fibrosis on LGE-CMR; (2) VT/VF inducibility by programmed ventricular stimulation in post-infarction etiology; and (3) lamin A/C pathological mutation associated with familial sudden death in idiopathic cardiomyopathy. For these patients, even if the current guidelines do not recommend the use of ICD, such a therapy could be critically evaluated, discussed and offered case by case<sup>[9,37,38]</sup>.

Finally, a small portion of patients without LGE at CMR will suffer from sudden death, especially in non-ischemic disease. LGE imaging is not suited to detect diffuse fibrosis that may be present in idiopathic dilated cardiomyopathy. New imaging techniques, such as T1 mapping, are able to detect and quantify diffuse fibrosis by means of extracellular volume fraction and preliminary data show that this pattern is associated with worse outcome in non-ischemic patients<sup>[41]</sup>.

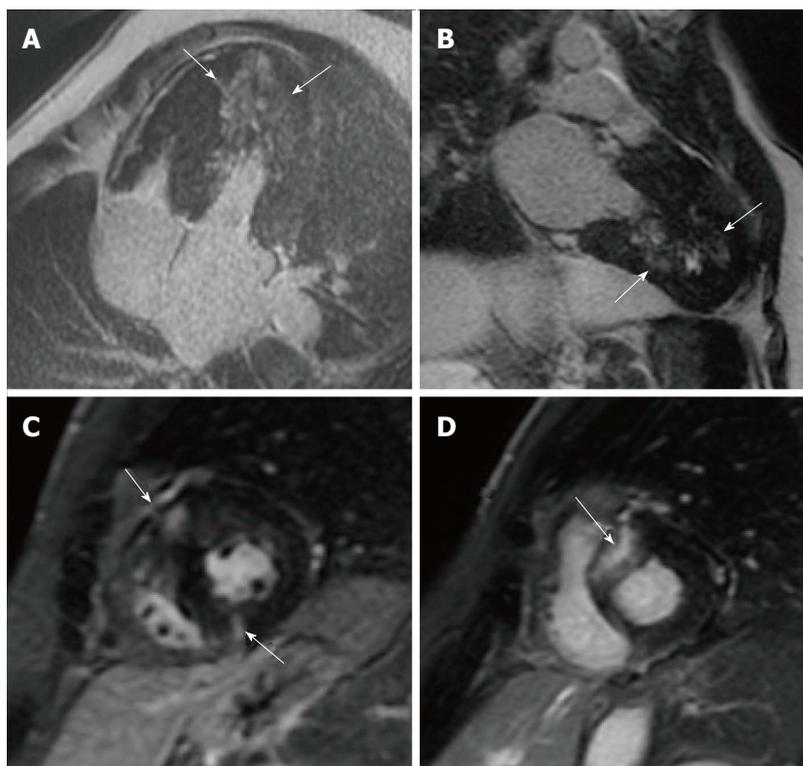

Currently, neither American nor European guidelines support CMR as a first-line tool for risk stratification in dilated cardiomyopathies, so further studies are needed to define its role in this context.

### **Hypertrophic cardiomyopathy**

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiomyopathy and cause of SCD in young people, including competitive athletes. It is caused by mutations in genes encoding cardiac sarcomere proteins and has a prevalence of 1:500 in the general population<sup>[42]</sup>. HCM is defined by the presence of unexplained LV hypertrophy (wall thickness  $\geq 15$  mm), associated with non-dilated ventricular chambers, in the absence of other cardiac or systemic diseases that might cause hypertrophy<sup>[42,43]</sup>. Hypertrophied myocytes are arranged in a chaotic architecture with increased extracellular matrix<sup>[42]</sup>. The myocardium may also present ischemic areas, caused by microvasculature obstruction, with replacement fibrosis and scar<sup>[42-44]</sup>. This modified cardiac structure predisposes to the risk of malignant VA such as VT and VF<sup>[42,43]</sup>.

SCD represents the most feared complication, occurring in about 5% of patients<sup>[43,44]</sup>. In patients with HCM, at high risk for SCD, ICD reduces mortality rate to 0.5% per year<sup>[44]</sup>. A primary prevention risk model has been proposed to identify high risk patients and guide ICD implant<sup>[43,44]</sup>, based on: (1) family history of premature HCM-related SCD, in close or multiple relatives; (2) unexplained non-reflex syncope, particularly if recent and in young patients; (3) nonsustained VTs on ambulatory ECG, particularly if multiple, repetitive or prolonged; (4) hypotensive or attenuated blood pressure in response to exercise; and (5) extreme hypertrophy (wall thickness  $\geq 30$  mm). Although current risk factor model is effective, not all high-risk patients are identified and the absence of conventional risk factors does not eliminate the risk of SCD.

In this context, CMR is increasingly considered an important tool, in particular for the evaluation of fibrotic areas (LGE-CMR) and wall thickness<sup>[44]</sup>. Moreover, it allows more precise characterization of the phenotype,

**Figure 2** Late gadolinium enhancement patterns in hypertrophic cardiomyopathy patients. A: LGE in the lateral wall (small arrows) and in the interventricular ventricular septum; B: LGE in the LV apex and inferior wall; C: LGE localized to the insertion area of the RV wall into the anterior and posterior ventricular septum; D: Transmurular LGE involving the ventricular septum. LGE: Late gadolinium enhancement.

which helps to differentiate HCM from other causes of LV hypertrophy.

Approximately 50%-60% of HCM patients demonstrate LGE-CMR which, when present, occupies on average 10% of the LV myocardial mass. LGE can be observed in any location or distribution, although most frequently in the ventricular septum and free wall (> 30% of patients), with mid-myocardial distribution, and less often involving the apex and the right ventricular insertion into ventricular septum<sup>[42]</sup> (Figure 2). Moreover, patients with LGE have greater maximal LV wall thickness and LV mass index than patients without<sup>[43]</sup>. A large number of studies demonstrated that the presence of LGE-CMR identifies areas of myocardial fibrosis where life-threatening VA can originate and is associated with a significant higher risk of SCD, even in patients without conventional risk factors<sup>[45-50]</sup>. LGE extension, expressed as a percentage of myocardial mass, correlates with the risk of developing life-threatening VA, in particular if LGE exceeds 15% of LV mass<sup>[50]</sup>. On the contrary, patients without LGE have a low arrhythmic risk and can be reassured.

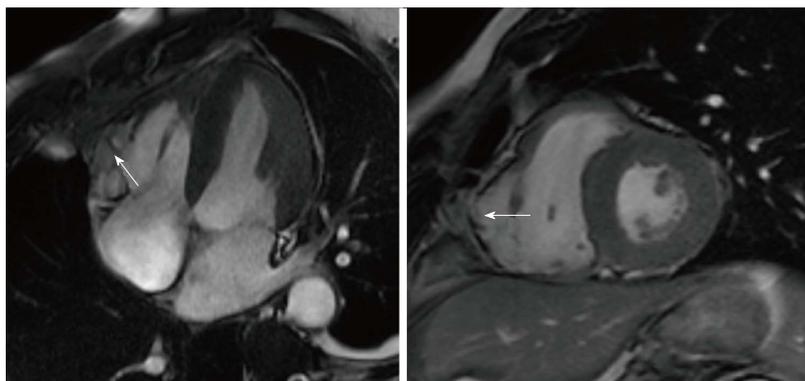

CMR also enables the identification of other high-risk subsets of patients such as those with massive LV hypertrophy and apical aneurysms (the latter being a subgroup at increased risk for VA and thromboembolic stroke)<sup>[51,52]</sup>. Notably apical HCM may be overlooked by echocardiography, while CMR can precisely visualize apical segments and detect hypertrophy and aneurysms.

Current schemes for SCD risk determination, such

as American algorithm<sup>[51]</sup> and ESC risk calculator<sup>[53]</sup>, are not completely effective and precise in risk evaluation. CMR, instead, has shown to improve stratification, providing additional information in patients for whom the current markers underestimate the risk (for example, young asymptomatic patients without conventional risk factors but with LGE) and in patients for whom decision-making about ICD implantation is difficult and ambiguous (for example, patients with a single risk factor and at intermediated risk), and potentially acting as an "arbitrator". Anyway, at the moment, neither American nor European guidelines support CMR as a first-line tool for risk stratification in HCM<sup>[51,53]</sup>.

### **Arrhythmogenic cardiomyopathy**

Arrhythmogenic cardiomyopathy (AC) is a group of heart muscle disease clinically characterized by life-threatening VA and pathologically by a progressive dystrophy of the ventricular myocardium with fibrofatty replacement<sup>[54,55]</sup>. AC affects mostly young males < 40 years old. Its estimated prevalence ranges between 1:2000 and 1:5000, therefore it is considered among rare diseases<sup>[54,55]</sup>. It is mostly caused by autosomal dominant genetic mutations (with incomplete penetrance and variable expressivity) of desmosomal proteins like desmoplakin and plakoglobin<sup>[56,57]</sup>. The desmosomal complex, situated in the cardiac intercalated disk, is responsible for tissue strength and stability, binding cells to one another. Consequently, a defective desmosomal complex can cause cell loss with fibro-fatty tissue

**Figure 3** Subtricuspid involvement in arrhythmogenic right ventricular cardiomyopathy. Dilated right ventricle with bulging of the subtricuspid region (arrow). The right ventricular apex is relatively spared.

replacement<sup>[58-60]</sup>. In its most common form the disease affects the right ventricle, but in a minority of patients it may affect both ventricles or only the left ventricle, thus supporting the use of the more general term AC<sup>[54,55]</sup>. Clinical manifestations differ in the different phases of the disease, from asymptomatic patients to patients with heart failure and VA or SCD<sup>[56-60]</sup>. AC is a major cause of sudden death in young and athletes, with VT and VF occurring at any stage<sup>[54-61]</sup>.

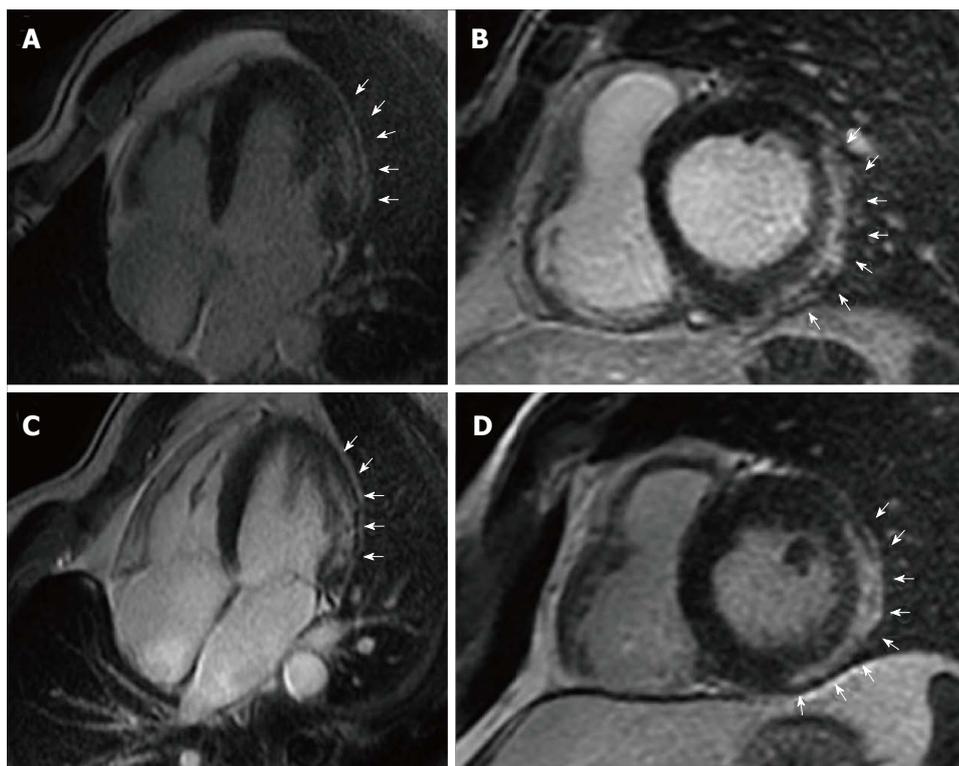

Considering the most frequent variant, arrhythmogenic right ventricular cardiomyopathy (ARVC), the diagnosis is based on a score obtained from the assessment of several parameters combined into major and minor criteria<sup>[56-59]</sup>, as there is no single gold standard diagnostic test. CMR has an important role for a comprehensive and precise assessment of right ventricular volumes, function and kinesis<sup>[56-59]</sup>. Typically, in ARVC myocardial disarray involves the entire ventricular wall, in particular the subtricuspid region and the right ventricle outflow tract ("triangle of dysplasia"), leading to aneurysm formation. In these regions wall motion abnormalities (akinesia or dyskinesia) and aneurysms can be detected by CMR, representing one of the criteria for diagnosis (Figure 3). The usefulness of CMR to detect fatty replacement or fibrosis is limited because the right ventricle has a thin wall and the differentiation between normal epicardial and intramyocardial infiltration is challenging. Therefore, to date, tissue characterization by CMR is not considered in the diagnostic work-up for ARVC<sup>[54-59]</sup>. Arrhythmic risk stratification in ARVC is based on multiparametric evaluation mainly based on clinical variables; patients at higher risk indicated for ICD implantation are those resuscitated after cardiac arrest, those with sustained and unstable monomorphic VT or exercise-induced unexplained syncope<sup>[60,61]</sup>. The role of CMR for risk stratification in ARVC is marginal, although significant: the extension of the disease to the left ventricle, identified by LGE-CMR, seems to be associated with a worse arrhythmic outcome and must be looked for<sup>[60-62]</sup>.

On the other side, and even more rare, left-dominant arrhythmogenic cardiomyopathy (LDAC) is characterized by epicardial or midmyocardial fibrotic or fibro-fatty replacement in postero-infero-lateral LV wall ("isolated

nonischemic scar") associated with life-threatening VA exceeding the degree of LV dysfunction (LVEF is often normal)<sup>[63-65]</sup>. LDAC is increasingly recognized as a cause of SCD in young athletes<sup>[66-68]</sup>. ECG often shows T-wave inversion in infero-lateral leads and low-voltage QRS complexes; VTs have right bundle branch block configuration and are often exercise-induced. In genetic familiar forms, usually autosomal-dominant, gene mutation mostly concerns components of cardiac desmosomes. In non-familiar forms LDAC phenotype can be the result of myocarditis leading to disruption of desmosomal architecture<sup>[63-65]</sup>. LGE-CMR plays a major diagnostic role because subepicardial/midmyocardial scar location is usually missed by echocardiography (Figure 4). Risk stratification is not well defined: By extrapolation from ARVC, ICD is indicated in patients who survived VF, with poorly tolerated sustained VT, or exercise-induced syncope. LGE-CMR also helps in risk stratification because a "stria" pattern in postero-lateral LV wall has been recently associated with a higher arrhythmic risk compared to the "benign" junctional "spotty" pattern, in a population of young athletes<sup>[68]</sup>.

#### **Some other pathological conditions at risk of SCD**

Sarcoidosis is an idiopathic non-caseating granulomatous disease that affects several organs, mostly the lungs, but also the heart, skin, liver, spleen, eye, and lymph nodes. Sarcoidosis occurs worldwide, being more frequent in African-American and Northern Europeans, especially women. Disease prevalence ranges between 4.7 and 64 in 100000<sup>[69]</sup>. Cardiac involvement is clinically evident in approximately 5% of patients, in form of: (1) conduction abnormalities; (2) VA including unexpected SCD; and (3) heart failure with reduced LVEF. Moreover, about 25% of patients with systemic sarcoidosis have asymptomatic cardiac involvement. At CMR cardiac sarcoidosis can appear as LGE in a patchy pattern or in longitudinal striae in the midwall or subepicardium, usually located in basal septum or LV wall. Delayed enhancement represents focal scarring, while inflammation areas can be detected with T2-weighted and STIR sequences<sup>[70,71]</sup>. CMR is also useful for differential diagnosis with ARVC that sometimes can resemble cardiac sarcoidosis. A recent

**Figure 4** Left dominant arrhythmogenic cardiomyopathy. Long-axis (A and C) and short-axis (B and D) postcontrast CMR views of two 34-year-old identical twin brothers showing a subepicardial/midmyocardial stria of LGE involving the lateral and inferolateral left ventricular wall (white arrows). CMR: Cardiac magnetic resonance; LGE: Late gadolinium enhancement.

consensus document<sup>[69]</sup> provided guidance for diagnosis and management of this disease, with a particular focus on arrhythmias. There are few data to help with SCD risk stratification<sup>[71]</sup>; in general, evidence from major randomized ICD trials of dilated cardiomyopathy is applicable, both in primary and secondary prevention. The presence of inflammation in both ventricles may increase ventricular arrhythmic risk; indeed, patients with implanted ICD have more frequent therapies from their devices, compared to other non-ischemic cardiomyopathies<sup>[69,70]</sup>. Current consensus recommendations<sup>[69]</sup> consider the use of CMR and the presence/absence of LGE (combined with electrophysiological study) to guide decision-making about ICD implant.

Amyloidosis is a disease characterized by protein misfold, aggregating into fibrils, and depositing extracellularly with disruption of organ architecture and function. There are two main types which affect the heart: Light chain (AL) amyloidosis and transthyretin cardiac amyloidosis (ATTR), both associated with the risk of VA and SCD<sup>[72,73]</sup>. Systemic amyloidosis occurs in more than 10 per million person-years in the United States population, with about 2000 new cases of AL amyloidosis occurring each year, approximately half of whom with significant cardiac involvement. The median age at presentation is 55–60 years, especially affecting women. The gold standard for diagnosis is endomyocardial biopsy, but CMR is increasingly used because it provides an accurate tissue characterization without the invasiveness of biopsy. At CMR the most frequent finding is a global

subendocardial and circumferential LGE that is specific for cardiac amyloidosis. CMR findings (in particular LGE) have also been associated with prognosis and arrhythmic risk stratification, with the potential for guiding decision about ICD implant<sup>[73]</sup>.

Left ventricular non-compaction (LVNC) is a relatively rare congenital disease, caused by an embryogenesis arrest, in which LV seems to be spongy. Ventricular wall anatomy is characterized by prominent LV trabeculae, a thin compacted layer, and deep intertrabecular recesses<sup>[74]</sup>. Clinical symptoms are related to neuromuscular disorders, heart failure with reduced LVEF, ventricular arrhythmic events and systemic thromboembolism. CMR can accurately identify this pathology, delineating hypertrabeculations of the apex and the LV lateral wall with subendocardial, midwall or transmural LGE<sup>[75]</sup>. CMR also helps to differentiate true LVNC from normal variants of increased trabeculations that can be found especially in young athletes. There are also recent data about the role of CMR for risk stratification. In a recent prospective multicenter study<sup>[75]</sup>, 113 patients underwent CMR, looking for diagnostic criterion of noncompacted/compacted ratio > 2.3 in end-diastole and LGE assessment. At a mean follow-up of  $48 \pm 24$  mo the degree of LV trabeculation had no prognostic impact on the primary outcome (a composite of thromboembolic events, heart failure hospitalizations, VA and cardiac death) above LV dilation and dysfunction. LGE-CMR, instead, showed a significant correlation with life-threatening VA events and SCD.

Myocarditis is a group of heart-specific immune diseases

classified by clinical and histopathological manifestations. Myocarditis may resolve spontaneously, recur or become chronic, leading about 30%-40% of biopsy-proven cases to dilated cardiomyopathy (DCM), death or heart transplantation. In the 2013 ESC myocarditis Task Force report<sup>[76]</sup>, the disease was defined histologically as an inflammatory disease of the myocardium diagnosed on endomyocardial biopsy (EMB). Although EMB remains the diagnostic gold standard for diagnosis, it is not widely used. Traditionally, when the diagnosis is only based upon the histological Dallas criteria, myocarditis results to be a relatively rare disease. However, the use of highly sensitive immunohistochemical and molecular tools applied to EMB and of CMR suggests that there is a substantial clinical underestimation of its frequency and of its role in DCM<sup>[77,78]</sup>. CMR sequences have important diagnostic and prognostic value. T<sub>2</sub>-weighted CMR sequences detect edema or water, and T<sub>1</sub>-weighted sequences detect inflammation or fibrosis. LGE imaging can help in distinguishing nonischemic patterns of myocyte damage and fibrosis from ischemic injury, and T<sub>2</sub>-weighted and early gadolinium enhancement imaging detect other inflammatory features of edema, capillary leakage and hyperemia<sup>[78,79]</sup>. LGE has been associated with a higher (3.7%/year) risk of a composite of cardiovascular adverse events and its extent also predicted a composite endpoint of cardiac death, heart failure hospitalization, VT, and sudden death<sup>[80]</sup>.

Anderson-Fabry disease is a X-linked disorder due to a deficiency of the alpha-galactosidase enzyme that causes an inability to catabolize glycosphingolipids, leading to their accumulation in several organs, including the heart<sup>[81]</sup>. The storage of lipids causes an increase of the ventricular wall thickness that simulates HCM and leads to heart failure<sup>[81,82]</sup>. Diagnosis can be made with CMR showing LGE within the basal infero-lateral wall but typically sparing the endocardium, related to myocardial collagen scarring that represents the substrate for re-entry mechanism and SCD. Patients who have significant fibrosis on MRI and those with nonsustained VT are at higher risk for arrhythmic complications and may be considered for ICD<sup>[82,83]</sup>.

## DECISION-MAKING IN CRT DEVICE IMPLANTATION

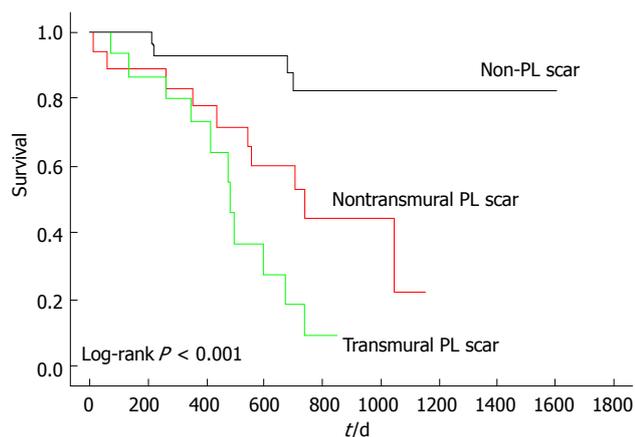

CRT is a well-established therapy in patients with heart failure with reduced LVEF (< 35%) and a wide QRS (> 120 ms), usually with left bundle branch block<sup>[84]</sup>. In this setting, compared to optimal medical therapy, CRT reduces all-cause mortality and heart failure hospitalization, both in ischemic and non-ischemic cardiomyopathy, with larger benefit in non-ischemic etiology<sup>[84,85]</sup>. However, about 30%-40% of patients implanted according to current guidelines<sup>[86]</sup> do not show any benefit from CRT or even get worse<sup>[87]</sup>. This is hardly acceptable considering costs and risk of the procedure. There are several reasons explaining suboptimal CRT response: (1) patient's characteristics (absence of ventricular dyssynchrony,

too advanced heart disease to get a benefit, severe right ventricular dysfunction, untreated arrhythmias, severe medical co-pathologies, etc.); (2) suboptimal LV lead position at implant; (3) suboptimal CRT device programming during subsequent course<sup>[87,88]</sup>.

The LV pacing site is an important determinant of a good outcome after CRT<sup>[88]</sup>. According to current guidelines, LV lead should be placed in non-apical posterolateral region to pace the latest activated areas<sup>[86]</sup>. Intuitively, deploying the LV lead over the latest electrical or (preferably) mechanical activated segments is likely to maximize the effects of CRT. However, recent evidence suggests that there is a large interindividual variability as concerns the latest activated areas and, subsequently, optimal LV pacing site<sup>[89-91]</sup>. Indeed, the latest mechanical activation is localized in posterolateral regions in 85%-90% of patients with non-ischemic dilated cardiomyopathy, but only in 10% of those with ischemic etiology<sup>[15]</sup>.

Moreover, scar in proximity of LV pacing stimulus interferes with resynchronization, leading to QRS fragmentation and prolongation, and this is true both in ischemic and non-ischemic etiologies<sup>[92,93]</sup>. Chalil<sup>[94]</sup> showed that pacing over scar was associated with a higher risk of cardiac mortality or heart failure hospitalizations compared with pacing viable myocardium (Figure 5). In a study of 559 patients undergoing CRT, Leyva<sup>[95]</sup> found that LV lead positions over scar was associated with poorer CRT response, higher risk of cardiovascular death, heart failure hospitalizations and SCD at follow-up.

In this context, a multimodality imaging approach<sup>[96-98]</sup> is emerging with a dedicated "CRT team"<sup>[99-102]</sup>, composed of electrophysiologists, cardiac imaging specialists and radiologists working together to identify the target areas (the most delayed and viable region) for LV pacing, by using CMR, myocardial perfusion imaging and newer echocardiographic techniques (such as longitudinal myocardial strain). Recent studies applying this method have demonstrated better clinical outcomes with the LV lead positioned at the latest mechanically activated region and away from myocardial scar<sup>[99-102]</sup>. In a study by Bertini *et al.*<sup>[102]</sup>, 100 patients with ischemic and non-ischemic dilated cardiomyopathy were enrolled: Group 1 with 50 consecutive patients scheduled for CRT and prospectively included, and group 2 (control) including 50 patients with a CRT device implanted according to standard clinical practice. In group 1, patients underwent two-dimensional speckle-tracking assessment of longitudinal myocardial strain and CMR imaging to identify the target area for LV lead. A positive response to CRT was defined as a  $\geq 15\%$  reduction of LV end-systolic volume at 6-mo follow-up. The result was that 78% of patients in group 1 were classified as responders to CRT compared to only 56% in group 2 ( $P = 0.019$ ). The "CRT team" identified as target for LV pacing the lateral area in 60% of patients, but notably, in 16% of patients, the target was far from the lateral area, in the anterior or posterior regions. The patients with concordant position showed the highest positive response (93.1%) to CRT. These encouraging results need further

**Figure 5** Left ventricular lead position, transmuralty of scar, and outcome after cardiac resynchronization therapy. PL: Posterolateral.

validation in future larger multicenter trials with longer follow-up.

Placement of the LV lead is restricted by variable cardiac venous anatomy. Retrograde cardiac venography *via* the coronary sinus, at the time of implantation, is the gold-standard approach to imaging the coronary veins. It has been suggested that coronary vein imaging before CRT implantation could be useful and, in this respect, coronary venography is feasible with both CMR and computed tomography (CT)<sup>[15,96]</sup>. However, this approach has major limitations because it is technically challenging and can miss little veins that are beyond the spatial resolution of CMR and CT, but anyway these veins could be suitable for implantation. In addition, neither CMR nor CT provides adequate imaging of Thebesian and Vieussens valves or vein stenoses<sup>[15,96]</sup>.

## ARRHYTHMIC SUBSTRATE IDENTIFICATION AND ABLATION

Catheter ablation is a well-established therapy for patients with scar-related sustained monomorphic VT, usually seen after myocardial infarction, and for atrial fibrillation (AF), the most common cardiac arrhythmia. Anyway, these arrhythmias are the most complex and challenging for the electrophysiologist<sup>[103]</sup>.

For a successful ablation, the correct identification of underlying arrhythmogenic substrates is critical. With the use of standard electroanatomic mapping techniques, substrates are identified only indirectly, with local voltage amplitudes as a surrogate of the state of surrounding myocardium<sup>[103]</sup>. This approach, in addition to being time-consuming, lacks sensitivity for deep scar and lacks specificity when there is poor catheter contact or thinner myocardium<sup>[103]</sup>. Therefore, improved strategies to define arrhythmogenic scar substrates would be welcome. In this context, CMR could give an important contribution due to its ability to characterize cardiac anatomy and function without exposing the patient to additional radiation<sup>[7,41]</sup>. As validated histopathologically,

CMR can visualize fibrosis and scar by delayed imaging of gadolinium contrast agents that accumulate in the extracellular matrix and have slower washout from scar than from normal myocardium<sup>[7,8,14]</sup>. Thanks to newer mapping technologies, CMR images can be merged with electrograms acquired from the conventional electrophysiologic study, thus creating an anatomic roadmap to guide ablation procedure<sup>[103]</sup>.

Myocardial scar, the most common substrate for reentrant VA, can be easily displayed by LGE-CMR, allowing to shorten the procedure time devoted to substrate identification and enabling ablation of hemodynamically unstable VT (when conventional electrophysiologic and point-by-point voltage mapping is impossible)<sup>[104]</sup>. Moreover, a better understanding of the physiologic conduction characteristics associated with various anatomic scar substrates may improve patient selection for ablation, avoiding the procedure when scar burden is too high and complex, with few chances of success<sup>[105]</sup>.

In the setting of AF ablation, LGE-CMR could be useful for patient selection, guidance of ablation procedure and post-ablation follow-up. Importantly, atrial LGE-CMR may allow improved patient selection so that unnecessary procedures are avoided in cases with little chance of procedural success<sup>[106]</sup>: Extensive left atrial LGE (> 35%) has been associated with a high rate (96%) of AF recurrence after catheter ablation<sup>[107]</sup>. Moreover, when procedure is planned in patients with a high burden of LGE, a more extensive ablation strategy could be pursued in addition to isolation of the pulmonary veins<sup>[108]</sup>. During the follow-up period, CMR can be useful to assess ablation success, for example, in terms of complete/incomplete isolation of pulmonary veins.

The main limitations for such approach are the added costs and expertise required for adequate image acquisition and analyses, the need for dedicated software, as well as inadequate spatial resolution in the atria. Moreover, CMR can create potential problems in patients already implanted with a cardiac device (pacemaker, ICD and CRT). Even when the device is "MRI safe" and CMR is technically feasible, lead artifacts can significantly alter image integrity and its clinical utility.

Hopefully, with improving techniques, accurate pre-procedural identification of the arrhythmogenic substrate by CMR may become in the near future an important adjunct for patient selection, procedural planning and post-procedural evaluation.

## CONCLUSION

Cardiac MRI is revolutionizing the approach to the arrhythmologic patients both in diagnostic and therapeutic work-up. It provides information that other diagnostic imaging techniques do not allow to obtain, without radiation exposure, facilitating the initial evaluation and, once established a diagnosis, the choice of the most appropriate treatment. Current limitations are: (1) the paucity of randomized studies evaluating the outcome of

patients treated with a CMR-based approach; (2) CMR is time-consuming, expensive, and requires experienced personnel for image acquisition and analysis; and (3) CMR still has inadequate spatial resolution in the left atrium and right ventricle, limiting its routine use for most arrhythmias arising from these chambers.

Lastly, a mention has to be made to nephrogenic systemic fibrosis that is a devastating (albeit extremely rare) potential complication in patients exposed to gadolinium-based contrast agents. This complication occurs almost exclusively in patients with moderate to severe kidney disease, particularly those on dialysis with incidences, in this latter group, ranging from 2.5% to 5%<sup>[109]</sup>.

Based on the current literature and waiting for more data from future studies, it is foreseeable that CMR use in daily arrhythmologic practice will be increasingly implemented.

**Abstract****AIM**

To determine whether the need for additional tricuspid valve repair is an independent risk factor when surgery is required for a left-sided heart disease.

**METHODS**

One hundred and eighty patients (68 ± 12 years, 79 males) underwent tricuspid annuoplasty. Cox proportional-hazards regression model for multivariate analysis was performed for variables found significant in univariate analyses.

**RESULTS**

Tricuspid regurgitation etiology was functional in 154 cases (86%), organic in 16 cases (9%), and mixed in

10 cases (6%), respectively. Postoperative mortality at 30 days was 11.7%. Mean follow-up was 51.7 mo with survival at 5 years of 73.5%. Risk factors for mortality were acute endocarditis [hazard ratio (HR) = 9.22 (95%CI: 2.87-29.62),  $P < 0.001$ ], ischemic heart disease requiring myocardial revascularization [HR = 2.79 (1.26-6.20),  $P = 0.012$ ], and aortic valve stenosis [HR = 2.6 (1.15-5.85),  $P = 0.021$ ]. Significant predictive factors from univariate analyses were double-valve replacement combined with tricuspid annuloplasty [HR = 2.21 (1.11-4.39),  $P = 0.003$ ] and preoperatively impaired ejection fraction [HR = 1.98 (1.04-3.92),  $P = 0.044$ ]. However, successful mitral valve repair showed a protective effect [HR = 0.32 (0.10-0.98),  $P = 0.046$ ]. Additionally, in instances where tricuspid regurgitation required the need for concomitant tricuspid valve repair, mortality predictor scores such as Euroscore 2 could be shortened to a simple Euroscore-tricuspid comprised of only 7 inputs. The explanation may lie in the fact that significant tricuspid regurgitation following left-sided heart disease represents an independent risk factor encompassing several other factors such as pulmonary arterial hypertension and dyspnea.

### CONCLUSION

Tricuspid annuloplasty should be used more often as a concomitant procedure in the presence of relevant tricuspid regurgitation, although it usually reveals an overly delayed correction of a left-sided heart disease.

**Key words:** Tricuspid regurgitation; Patient outcome assessment; Valvular annuloplasty; Infective endocarditis; Mitral valve annuloplasty

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Tricuspid valve repair with flexible ring is easy to achieve in patients undergoing heart surgery. Predictor scores such as Euroscore 2 could be shortened to a simple Euroscore-tricuspid of only 7 inputs. A significant tricuspid regurgitation following a left-sided heart disease is an independent risk factor that encompasses several other factors such as pulmonary arterial hypertension and dyspnea. Patients with functional damage of the right side of the heart and significant functional tricuspid regurgitation have poor mid-term results with high mortality. A concomitant tricuspid regurgitation usually reveals a delayed correction of a left-sided heart disease.

Azarnoush K, Nadeemy AS, Pereira B, Leesar MA, Lambert C, Azhari A, Eljezi V, Dauphin N, Geoffroy E, Camilleri L. Clinical outcomes of tricuspid valve repair accompanying left-sided heart disease. *World J Cardiol* 2017; 9(10): 787-793 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i10/787.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i10.787>

### INTRODUCTION

The concomitant correction of functional tricuspid regur-

gitation secondary to left heart disease requiring surgery remains underused<sup>[1]</sup> despite recent data showing late development of severe tricuspid regurgitation in patients with mild regurgitation at the time of cardiac procedures (e.g., mitral valve surgery)<sup>[2]</sup>. Several factors including pulmonary arterial hypertension, right ventricular dilatation, increased tricuspid annulus diameter and the occurrence of right-sided heart failure promote persistent or even deteriorating functional tricuspid insufficiency<sup>[3,4]</sup>. Associated tricuspid regurgitation is present in almost 50% of patients undergoing mitral-valve surgery<sup>[5]</sup>. Most patients presenting with significant tricuspid regurgitation suffer from functional regurgitation due to dilatation of the tricuspid annulus, caused by dilatation of the right ventricle<sup>[6]</sup>.

Rare organic tricuspid insufficiencies may be secondary to iatrogenic injury (*i.e.*, pacing leads), or of rheumatic, infectious, congenital or carcinoid origin<sup>[7]</sup>.

Data on concomitant tricuspid valve annuloplasty are rare and usually focus on different techniques for repair. A recent review seemingly demonstrated evidence for tricuspid annuloplasty to be a low-risk procedure<sup>[8]</sup>. However, as highlighted in the present work, a concomitant tricuspid regurgitation reveals a delayed correction of left-sided heart disease. Our data demonstrate that standard Euroscore 2 mortality risk factors such as gender, pulmonary hypertension, renal impairment or weight of the intervention should no longer be taken into account when significant tricuspid regurgitation appears prior to surgery of left-sided heart disease and the need for tricuspid repair becomes an independent mortality risk factor.

The present study aimed to confirm that the need of concomitant tricuspid annuloplasty according to guidelines represents a far too late treatment. Patients should be addressed to heart surgery centers for an early correction of the left-side heart disease before the need of additional tricuspid valve repair procedure.

### MATERIALS AND METHODS

All patients undergoing concomitant tricuspid valve annuloplasty between January 2005 and December 2009 were included in this retrospective, single-center study. The study was approved by the local ethics committee and all patients gave their written informed consent for the procedure as well as for inclusion in this retrospective study<sup>[9]</sup>.

All surgeries were performed using full median sternotomy and extracorporeal circulation with cardiac arrest using blood cardioplegia. Tricuspid annuloplasty was performed either with a De Vega tricuspid repair<sup>[10]</sup>, a flexible Sovering® ring (Sorin Biomedica Cardio S.r.l., Saluggia, Italy) sized 26 to 36 mm<sup>[11]</sup>, or a flexible Bex® linear reducer (Gamida, France)<sup>[12]</sup>, respectively. If necessary, annuloplasty was combined with concomitant procedures to the tricuspid valve such as resection of vegetations in case of endocarditis, implantation of artificial chords or tricuspid pillar reinsertion in case of prolapse.

The patients' health status was obtained through a questionnaire submitted to the cardiologist, to the attending physician or, in the absence of the latter, by interviewing the patient or his/her relatives by phone (if the patient was deceased).

### Statistical analysis

Data are presented as the mean ± SD for continuous data and as the number of patients and associated percentages for categorical parameters. Cox proportional-hazards regression model was performed to evaluate the impact of several covariates on mortality in a multivariate context and define prognostic factors (using a stepwise backward and forward algorithm, from variables with a  $P < 0.10$  in univariate analyses) according to the results of univariate analysis and clinical relevance.

All analyses were conducted using Stata v12® (Stata Corp, College Station, United States). The tests were two-sided, with a type I error set at  $\alpha = 0.05$  (except for multiple comparisons).

## RESULTS

Between January 2005 and December 2009, a total 180 consecutive patients underwent tricuspid valve annuloplasty in our institution. During the same period, another 3 patients underwent isolated tricuspid valve replacement and were not included in the present study. Among the 180 included patients, there were 79 males (44%) and 101 females (56%). Age ranged from 12 to 89 years; mean age was  $68.3 \pm 12.4$  years (Table 1).

Tricuspid valve regurgitation etiology was classified as functional in 154 cases (86%), organic in 16 cases (9%) and mixed in 10 cases (6%). In instances of functional tricuspid regurgitation, the main cause was degenerative mitral valve disease. In instances of organic tricuspid regurgitation, the predominant pathologies were rheumatism disease and infectious endocarditis, 9 of which required urgent surgery for acute endocarditis (Table 1).

Ninety-seven patients (45%) suffered from at least one heart failure episode, 22 with left-sided HF, 15 with right-sided HF, and 60 with global heart failure, respectively. Eighty-five patients (47%) suffered from persistent atrial fibrillation preoperatively. Further cardiovascular risk factors of the study patients are summarized in Table 1, along with preoperative echocardiographic findings in Table 2.

Tricuspid annuloplasty with a prosthetic ring was performed in 176 patients; a Sovering® ring was used in 156 cases and a Bex® linear reducer in 20 cases. In 20 cases, annuloplasty was combined with concomitant procedures for tricuspid valve: Valve repair (leaflet slit or cleft closure), vegetation resection, implantation of a Gore-Tex® cord, and one tricuspid pillar reinsertion for iatrogenic tricuspid incompetence as a consequence of pacemaker lead removal. Four 4 De Vega tricuspid repairs were performed while the remaining procedures consisted of the following: Aortic valve replacement in 29 cases (16%), mitral valve replacement in 67 cases (37%), double mitro-aortic valvular replacement in 42 cases (23%), mitral valve repair in 38 cases (21%), pulmonary valve replacement in one case (0.6%), coronary artery bypass grafting in 26 cases (14%), and other procedures in 21 cases. Only 9 patients (5%) underwent surgery for isolated tricuspid regurgitation. These patients presented with preoperative grade III or IV tricuspid incompetence. Three of these patients had a previous history of mitral or aortic valvular surgery, with tricuspid insufficiency appearing within two years postoperatively. Two of these patients had a preoperative pulmonary artery hypertension with peak gradients over 60 mmHg at their first operation. The other five patients did not present any associated left-sided heart disease.

Mean hospital stay was  $17.8 \pm 19.3$  d (range 2 to 165 d). Postoperative complications were reoperation for bleeding in 15 cases (8%) and one postoperative stroke. A total of 21 patients (11.7%) died within 30 d.

**Table 2** Preoperative and postoperative characteristics of the study patients

	mean $\pm$ SD	n (%)
Preoperative parameter		
Left ventricular ejection fraction (%)	58.6 $\pm$ 12.5	
Systolic pulmonary arterial pressure (mmHg)	58.0 $\pm$ 16.7	
Tricuspid regurgitation		
I		9 (5)
II		69 (38)
III		70 (39)
IV		32 (18)
Left ventricular end-diastolic diameter (mm)	52.7 $\pm$ 9.5 (29-74)	
Left ventricular end-systolic diameter (mm)	34.4 $\pm$ 9.3 (17-63)	
Postoperative parameter		
Left ventricular ejection fraction (%)	54.4 $\pm$ 12.2 (10-82)	
Systolic pulmonary arterial pressure (mmHg)	38.6 $\pm$ 10.6 (19-76)	
Tricuspid regurgitation		
0- I		150 (83)
II		28 (15)
III		1 (0.6)
IV		1 (0.6)
Left ventricular end-diastolic diameter (mm)	50.4 $\pm$ 7.4	
Left ventricular end-systolic diameter (mm)	35.2 $\pm$ 8.3	

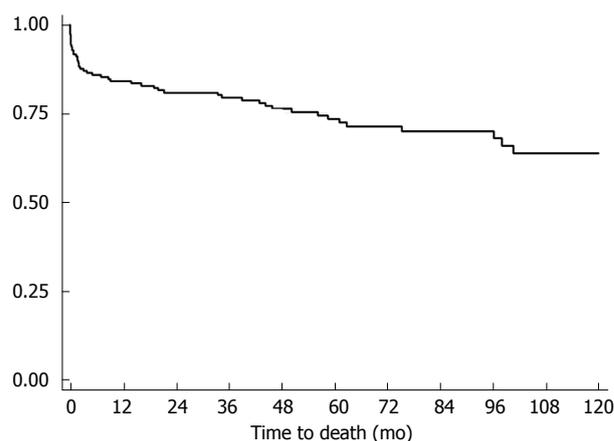

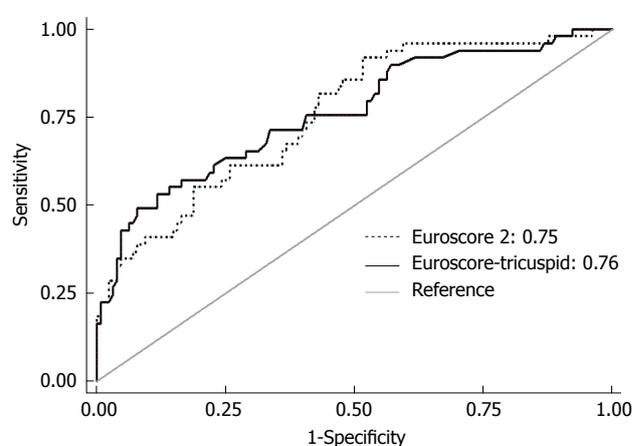

The main causes of death were multi-organ failure in 20 cases, two of whom were from massive bleeding, and one unexplained sudden death.

All patients underwent early postoperative echocardiography, demonstrating marked reduction in both tricuspid insufficiency and in systolic pulmonary artery pressure (Table 2).

Among hospital survivors, two patients (1%) were lost at follow-up, the initial analysis thus resulting in a 99% follow-up. Data from these two patients were subsequently collected in 2014. One patient living in Kathmandu returned for a control cardiology visit in our university hospital and the second patient had a control consultation in the thoracic surgery department in Clermont-Ferrand, allowing us to complete the initial follow-up. Mean follow-up was 51.7  $\pm$  39 mo with 5-year survival at 73.5% and 10-year survival at 63.8% (Figure 1). The main cause of death during the follow-up was heart failure. Only one tricuspid valve repair failed. Eight patients had a cerebrovascular event during the study period and seven patients presented with a late complete atrioventricular block requiring pacemaker implantation.

Univariate and multivariate analyses and parameters affecting global mortality (in-hospital and post-discharge) are detailed in Tables 3 and 4.

Of note, there was no significant correlation between death and several Euroscore factors such as gender, pulmonary hypertension, NYHA dyspnea level, chronic lung disease, renal impairment or weight of the intervention (Table 3). From multivariate analyses (Table 4), the adverse factors for mortality were the presence

**Figure 1** Overall patient survival.**Figure 2** ROC curve comparing Euroscore 2 and Euroscore-tricuspid.

of acute endocarditis, ischemic heart disease that required myocardial revascularization, and aortic valve stenosis, respectively. In contrast, a successful mitral valve repair appeared to have a protective effect.

When taking into account a tricuspid valve regurgitation requiring an additional tricuspid valve repair accompanying a left-sided heart disease surgery, the 18 predictive risk factors of Euroscore 2 could be reduced to a Euroscore-tricuspid of only 7 factors with an at least equivalent statistical power (Figure 2). This new Euroscore-tricuspid would require only the following patient data: Age, ischemic heart disease, insulin-treated diabetes, previous cardiac surgery (redo intervention), active endocarditis, critical preoperative state and left ventricle function less than 50%.

## DISCUSSION

Both the current American and European guidelines recommend correction of relevant functional tricuspid insufficiency if other cardiac diseases are corrected surgically<sup>[4,7]</sup> since functional tricuspid regurgitation, a frequent finding in patients undergoing cardiac surgery for other reasons<sup>[5]</sup>, has proven to increase over time when not corrected during first surgery<sup>[2]</sup>, mainly due to

**Table 3** Univariate analyses: Parameters affecting global mortality

Variable	n (%)	Univariate HR	P
Gender (male)	79 (44)	1.38 [0.77-2.44]	0.27
Age ( $\geq$ 75 yr)	63 (35)	1.75 [0.98-3.11]	0.06

progressive annular dilatation<sup>[3]</sup>. However, although factors influencing the natural course of tricuspid regurgitation over time<sup>[4]</sup> and even during long-term follow-up of over 5 years<sup>[13]</sup> as well as its deleterious effect on mortality<sup>[14]</sup> are well known, its concomitant correction has yet to be performed to an adequate extent<sup>[1]</sup>. In the present study, the conducting of a successful mitral valve repair was found to be a protective factor when tricuspid annuloplasty was performed in patients with significant mitral regurgitation.

Acute endocarditis, associated ischemic heart disease and double valve replacement combined with tricuspid regurgitation were the main risk factors for hospital mortality in this study. Surprisingly, there was no correlation between elevated pulmonary arterial pressure, advanced age, preexisting arrhythmias and mid-term mortality results as conversely reported by

others<sup>[15]</sup>.

The 11.7% hospital mortality rate observed herein, mainly driven by multi-organ failure, is a reflection of the high rate of concomitant procedures. Other studies have reported hospital mortality rates of up to 35% in patients undergoing tricuspid valve repair as a concomitant procedure to other cardiac surgery<sup>[16,17]</sup>.

The use of a flexible ring represented the technique of choice in the present series. Easy implantation, avoidance of a suture close to the conduction system, measured reduction of the tricuspid annulus and preservation of the valve's normal physiological shape are among the related advantages of this approach<sup>[18]</sup>. For dilatation of the tricuspid annulus, annuloplasty alone provides excellent results in the absence of valvular or subvalvular disease<sup>[3]</sup>; however, it is no longer effective in correcting tricuspid regurgitation if there is also damage

of the leaflets and of the subvalvular apparatus, and/or in instances where additional procedures are required<sup>[18,19]</sup>. Accordingly, less-than-moderate tricuspid regurgitation prior to discharge after tricuspid annuloplasty during redo valve surgery additionally proved to be an independent risk factor for better long-term outcome in terms of survival in a recent retrospective analysis<sup>[20]</sup>. Furthermore, concomitant tricuspid annuloplasty using flexible bands offered improved durability as compared to suture annuloplasty for preventing postoperative tricuspid regurgitation progression in two retrospective comparative analyses<sup>[21,22]</sup>. In the current series, 20 patients underwent a concomitant valvular or subvalvular procedure, without any added mortality or morbidity.

Recent clinical studies have demonstrated that moderate to severe residual tricuspid regurgitation still persists in 10% of patients who have undergone surgical repair<sup>[18]</sup>. Tricuspid regurgitation is related to the degree of limited leaflet motion and to the severity of the dilatation of the tricuspid annulus. The severity of preoperative tricuspid regurgitation, together with right ventricular dysfunction, contributes to postoperative residual insufficiency. Risk factors for recurrent tricuspid regurgitation are preoperative severe regurgitation, tricuspid repair without a prosthetic ring or with an oversized ring (large tricuspid valve), pacemaker catheters that pass through the tricuspid valve, mitral valve replacement rather than mitral repair, left ventricular dysfunction associated or not with advanced remodeling, cardiomegaly and atrial fibrillation<sup>[19]</sup>.

Finally and surprisingly, we found that mortality predictor scores such as Euroscore 2 could be shortened to a simple Euroscore-tricuspid of only 7 inputs. From our standpoint, the explanation may reside in the fact that significant tricuspid regurgitation following a left-sided heart disease is an independent risk factor encompassing several other factors such as pulmonary arterial hypertension and dyspnea. Such finding has been reported in several studies of other diseases with regard to aortic and mitral valve diseases which also corroborate the present data embodying multiple diseases at once<sup>[23-25]</sup>.

The present study demonstrates the efficacy and durability of tricuspid annuloplasty with an open flexible ring. This procedure may be performed in patients with severe left-sided valve disease. Patients with functional damage of the right side of the heart combined with significant functional tricuspid regurgitation have poor mid-term results along with high mortality. A concomitant tricuspid regurgitation typically reveals a delayed correction of left-sided heart disease.

## COMMENTS

### Background

The concomitant correction of functional tricuspid regurgitation secondary to left heart disease requiring surgery remains underused and an associated functional tricuspid regurgitation typically reveals a delayed correction of left-sided heart disease.

### Research frontiers

Functional tricuspid valve regurgitation concerns patients who are referred

to heart surgery for left-sided heart disease too late. Results of this study contribute to clarify these patients' clinical situation.

### Innovations and breakthroughs

In this study, when a tricuspid regurgitation required the need for concomitant tricuspid valve repair, mortality predictor scores such as Euroscore 2 could be shortened to a simple Euroscore-tricuspid comprised of only 7 inputs. The explanation may lie in the fact that significant tricuspid regurgitation following left-sided heart disease represents an independent risk factor encompassing several other factors such as pulmonary arterial hypertension and dyspnea.

### Applications

The present study demonstrates the efficacy and durability of tricuspid annuloplasty with an open flexible ring.

### Peer-review

The study aimed the need of concomitant tricuspid annuloplasty for an early correction of the left-side heart disease. The author conducted retrospective multivariate analysis for significant variables in univariate analyses in 180 cases with tricuspid annuloplasty. The 5-10 years follow-up observation find out the risk factors for mortality were acute endocarditis, ischemic heart disease requiring myocardial revascularization, and aortic valve stenosis. Significant predictive factors from univariate analyses were double-valve replacement combined with tricuspid annuloplasty and preoperatively impaired erection fraction. The author concluded that tricuspid annuloplasty should be used more often as concomitant procedure if relevant tricuspid regurgitation is present. The study suggests that the predictor scores could be shorten to a simple Euroscore-tricuspid of only 7 inputs. Functional tricuspid regurgitation may be frequently found in patients undergoing cardiac surgery from other reasons. It will become more severe over time if not corrected during first surgery. It is significant to have a investigation on the outcomes of tricuspid valve repair accompanying left-sided heart disease surgery. This manuscript retrospectively investigated this topic, discussed the advantages of the correction surgery at the same time, analyzed the risk factors and concluded to simplify using the predictive factors.

### Abstract

Smoking cessation is challenging and lack of positive support is a known major barrier to quitting cigarettes. Previous studies have suggested that social influences might increase smokers' awareness of social norms for appropriate behavior, which might lead to smoking cessation. Although social media use is increasing among young adults in the United States, research on the relationship between social media use and smoking cessation is lacking. Twitter has provided a rich source of information for researchers, but no overview exists as to how the field uses Twitter in smoking cessation research. To the best of our knowledge, this study conducted a data mining analysis of Twitter to assess barriers to smoking cessation. In conclusion, Twitter is a cost-effective tool with the potential to disseminate information on the benefits of smoking cessation and updated research to the Twitter community on a global scale.

**Key words:** Smoking cessation; Stop smoking; Smoking; Twitter; Tweets

**Core tip:** Twitter use is increasing globally, research on the relationship between Twitter use and smoking cessation is lacking. This study is to the best of our knowledge the first Twitter analytic study of smoking cessation. Twitter is a cost-effective tool with the potential to disseminate information on the benefits of smoking cessation and updated research to the Twitter community on a global scale. Digital health interventions through Twitter that educate the health community are still needed.

## TO THE EDITOR

Smoking cessation is challenging and lack of positive support is a known major barrier to quitting cigarettes. Previous studies have suggested that social influences might increase smokers' awareness of social norms for appropriate behavior, which might lead to smoking cessation<sup>[1,2]</sup>. Although social media use is increasing among young adults in the United States, research on the relationship between social media use and smoking cessation is lacking. Recent studies have shown that Twitter data mining can have broad implications on cardiovascular health research<sup>[3,4]</sup>. We report on an assessment of barriers to smoking cessation by performing data mining in Twitter.

Twitter (<https://twitter.com/>) postings containing the terms "quit smoking", "smoking cessation", and "stop smoking" were obtained for July 23, 2009, through November 22, 2016. All analyses relied on public, anonymized data and adhere to the terms and conditions, terms of use, and privacy policies of Twitter. No exact tweets are included in this report. Data mining were performed with R version 3.2.3.

We identified 39731 tweets associated with smoking cessation and identified insights into people's perceptions of quitting smoking and some barriers to cessation. In the sample, 12375 retweets (reposted or forwarded messages) were excluded from the analysis. The results found 13099 negative statements, 4425 positive statements, and 9832 ambiguous or unclear statements. Reasons to not quit smoking were found in 965 tweets. For example, "someone dies from smoking, someone dies from a heart attack, what's the difference both are dead". Some tweets reported a social influence on smoking

cessation, such as "sometimes I think people only quit smoking for the Facebook likes". Some tweets did not report barriers to smoking cessation. For example, "I wonder how many times I'm going to quit smoking". A few tweets stated a need for more information from the community, such as "yoo is there anyone on here who has quit smoking successfully and can give me sum tips". Several academic institutions have been using Twitter to deliver health messages to the community. For example, "smoking increases the risk of death from lung cancer, heart attack and stroke by 200%".

Overall, Twitter is a cost-effective tool with the potential to disseminate information on the benefits of smoking cessation and updated research to the Twitter community on a global scale. Digital health interventions through Twitter that educate the health community are still needed.

**REVIEW**

- 796 Effects of energy drinks on the cardiovascular system

*Wassef B, Kohansieh M, Makaryus AN*

**ORIGINAL ARTICLE**

**Randomized Clinical Trial**

- 807 Randomized study comparing incidence of radial artery occlusion post-percutaneous coronary intervention between two conventional compression devices using a novel air-inflation technique

*Voon V, Ayyaz Ul Haq M, Cahill C, Mannix K, Ahern C, Hennessy T, Arnous S, Kiernan T*

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Ping-Yen Liu, FACC, MD, PhD, Associate Professor, Institute of Clinical Medicine and Division of Cardiology, Internal Medicine, National Cheng Kung University, Tainan 70401, Taiwan

**AIM AND SCOPE**

*World Journal of Cardiology* (*World J Cardiol*, *WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Throughout the last decade, the use of energy drinks has been increasingly looked upon with caution as potentially dangerous due to their perceived strong concentration of caffeine aside from other substances such as taurine, guarana, and L-carnitine that are largely unknown to the general public. In addition, a large number of energy drink intoxications have been reported all over the world including cases of seizures and arrhythmias. In this paper, we focus on the effect of energy drinks on the cardiovascular system and whether the current ongoing call for the products' sales and regulation of their contents should continue.

**Key words:** Energy drinks; Caffeine; Taurine; Guarana; Cardiovascular effects

**Core tip:** The last decade has witnessed a great surge in the consumption of energy drinks which coincided with an increased rate of reported cases of intoxications resulting in cardiovascular adverse effects especially arrhythmias, although most of such cases were associated with alcohol, stimulants, or rapid consumption in a short period of time. In our paper, we summarized the research pertaining to the most common components of the energy drinks in an attempt to evaluate whether the call for control of the products is merited, some of which had surprising possible health benefits.

9(11): 796-806 Available from: URL: <http://www.wjnet.com/1949-8462/full/v9/i11/796.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i11.796>

## INTRODUCTION

The last decade has witnessed the greatest rise in the consumption of non-steroidal energy supplements for the specific purpose of boosting athletic performance and concentration. For many years, the use of energy drinks (ED) has been perceived as potentially dangerous due to their strong concentration of caffeine and presence of other substances such as taurine, guarana, and L-carnitine amongst others. In France, the use of Red Bull™ was banned at one point until the rule was reversed by the European Union on claims of the lack of evidence for its toxicity. The controversy surrounding energy drinks heightened recently due to the increasing reports of energy drink toxicities, most alarmingly in regard to heart rhythm and central nervous system abnormalities such as atrial fibrillation and seizures, respectively. We aim to focus on the effect of energy drinks on the cardiovascular system and whether the call for the products' sales and regulation of their contents has merit.

## SCOPE OF THE ISSUE

In recent years, the market for energy drinks has thrived and after 50 years in the market, the consumption of these beverages has increased exponentially<sup>[1]</sup>. Along with a growing global market, emergency room visits due to the consumption of energy drinks have increased as well. The Substance Abuse and Mental Health Services Administration revealed that 20783 people visited the emergency department with complaints involving caffeine rich energy drinks in 2011. Over the period from 2007-2011, ED-related emergency department visits in the United States doubled<sup>[2]</sup>. Due to their high consumption, lack of evidence, and occasional acute adverse health effects, the safety of energy drinks has been called into question. Our review will specifically focus on the cardiovascular effects of the ingredients contained in EDs.

As promisors of prolonged arousal, boosted athletic performance, and increased concentration, energy drinks have become popular supplements in the past few years. A recent study of 1620 nursing students noted 78.1% reported ED use. The students consumed an average of 1.6 cans per week, ranging from 1 to 30 cans per week<sup>[3]</sup>. Certain ED company claims have been found to be true. One placebo controlled study found that certain important aspects of cognitive function can be improved by a single energy shot. The study was performed on partially sleep-deprived healthy individuals and the effect was noted to last

for up to 6 h<sup>[4]</sup>. Another study found that subjective ratings of vigor and fatigue were improved after the consumption of energy drinks, although, objective performance did not improve and, in fact, seemed to worsen over time<sup>[5]</sup>.

With increased stress to perform academically, athletically, and socially, it is not surprising that most consumers of EDs are teenagers and young male adults<sup>[6,7]</sup>. It should be noted that ED consumption cannot be looked at as a separate entity as co-ingestion with alcohol, drugs, and other pharmaceuticals has become a widespread practice. A cross-sectional survey conducted in 2012 reported that 85 emergency department patients, that were there for ED related events, showed that illicit stimulants such as cocaine and methamphetamine were often co-ingested<sup>[8]</sup>. Another study found that males were more likely to co-ingest alcohol or drugs, whereas in females, co-ingestion of other medications was more common<sup>[9]</sup>. It should be noted that the half-life of caffeine was found to increase by up to 72% with its coingestion with alcohol, thereby enhancing the effects of EDs<sup>[10]</sup>.

## PURPORTED EFFECTS OF ENERGY DRINKS AND THEIR CAFFEINE-RELATED CAUSAL ROLES ON THE CARDIOVASCULAR SYSTEM (FIGURE 1)

### *Physiologic effects on vital signs*

Evidence of reported energy drinks-related cardiovascular adverse effects has helped to further raise suspicion of these beverages. It is widely believed that caffeine, particularly at high doses, is associated with multiple cardiac comorbidities including palpitations and a number of arrhythmias such as atrial fibrillation and supraventricular and ventricular ectopy. Caffeine's effect in acutely raising the blood pressure is also thought to stress the cardiovascular system, furthering the likelihood of it causing arrhythmia. Such an elevation in blood pressure has been also shown to be more prominent in the elderly and those with underlying hypertension. A study of 20 young healthy humans explored the effects of Red Bull along with induced mental stress. It was found that compared with the ingestion of water, ingestion of a 355 mL can of Red Bull imposes a cumulative cardiovascular load, increasing systolic BP by about 10 mmHg, diastolic BP by about 7 mmHg, and heart rate by 20 beats/min, and decreasing cerebral blood flow velocity by -7 cm/s<sup>[11]</sup>.

Several studies have found energy drinks have been shown to induce hypertension compared to placebo. A recent study asked fifteen recreational runners to complete five exercise trials. The subjects ingested one of three energy drinks or a placebo one hour prior to testing. Results showed that the fifteen minute systolic BP readings were significantly higher in the three energy drink trials (163.87, 166.47, and

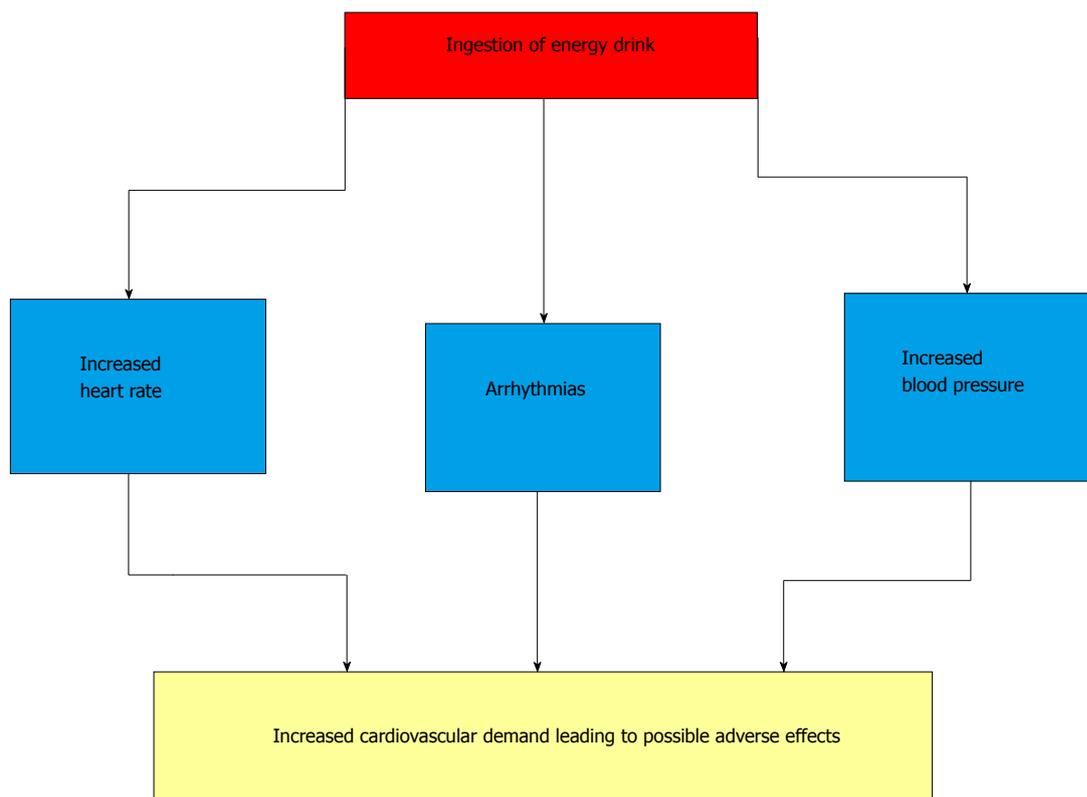

Figure 1 Effects of energy drinks on the cardiovascular system.

165.00) compared to the placebo trials (156)<sup>[12]</sup>. Other studies have found the same effect as well. Elitok *et al*<sup>[13]</sup> studied 50 young, healthy subjects and found that 2 h after consumption of 355 mL of Red Bull their systolic blood pressure increased from 112 to 121 mmHg, and diastolic blood pressure 73 to 76 mmHg. Grasser *et al*<sup>[14]</sup> conducted a randomized crossover study of twenty-five young non-obese and healthy subjects and showed that both systolic and diastolic blood pressure increased as a result of Red Bull consumption. The water control load did not. The study also showed increases in cerebrovascular resistance and breathing frequency, in addition to decreases in cerebral blood flow velocity and end-tidal carbon dioxide<sup>[14]</sup>.

A recent comprehensive and systematic review of case studies related to EDs and their adverse health effects has found that the most common adverse events affect the neurological and cardiovascular systems. The neurological effects were most commonly seizures but also included neuro psychotic agitation, aggressive behavior, and suicidal ideation. That may be because caffeine and taurine are known psychoactive agents. The cardiac related events included reports of: Arrhythmias (highest percent 35% with the others being rare), coronary vasospasm, aortic aneurysm dissection, cardiac arrest, QT prolongation, acute cardiomyopathies, accelerated hypertension, reversible postural tachycardia syndrome, acute coronary thrombosis, and ST-elevation myocardial infarction.

The authors attribute the cardiovascular adverse effects to the ingredients in ED, such as caffeine and taurine which have shown to increase platelet aggregation, disturb the endothelial function, and possibly causing vasospasm in association with hypertension<sup>[15]</sup>. Although there has been a link between energy drink consumption and platelet aggregation and endothelial dysfunction, the exact agent that is causing the effects is still unknown<sup>[16]</sup>. It should be noted that many of the adverse events described in these case reports have been linked to haphazard use of ED's and ED use combined with alcohol and other substances. Thus, emergency department case reports offer a hurdle to clearly understanding the adverse effects of EDs alone.

Another study was conducted with fifteen healthy adults. Their blood pressures were taken after abstaining from caffeine for 48 h, and, baseline BP, HR, and electrocardiographic (ECG) parameters were measured. Participants were asked to consume 500 mL of an energy drink and measurements were repeated 30 min, 1 h, 2 h, 3 h, and 4 h later, then drank 500 mL of energy drink daily for the next 5 d and measurements taken again on the final day. No significant ECG changes were noted, yet HR and SBP measurements increased by 5-7 beats/min and 10 mmHg, respectively. The cardiovascular effects were greater after five days of consumption than after the first day of consumption<sup>[17]</sup>.

Another study enrolled fourteen volunteers, who completed a three-session study. In each session,

they received a 2oz. 5-h Energy shot, 2oz. Ocean Spray™ Diet Cranberry Juice as the placebo, or no drink with BP readings measured each hour. The energy shot condition showed diastolic BP readings that were significantly higher when compared to both the no drink and placebo drink conditions. Interestingly, it was also significantly higher at 240 and 360 min when compared to 60 min. There was no difference in BP between the placebo and no drink<sup>[5]</sup>.

### **Physiologic effects on heart rhythm and induction of arrhythmia**

A number of documented cases correlated the consumption of energy drinks to the development of atrial fibrillation such as: Atrial fibrillation in a 16-year-old Caucasian boy after consuming an unknown amount of Red Bull™ mixed with vodka<sup>[18]</sup>. A case of atrial fibrillation in a patient with dilated cardiomyopathy that experienced seizures after the cessation of his excessive caffeine consumption<sup>[19]</sup>, and, atrial fibrillation in a 14-year-old Caucasian boy after an athletic event where he consumed an unknown amount of energy drink. He noted that he felt the same fluttering feeling 5 d before as well when he ingested a Red Bull™<sup>[18]</sup>. It is noteworthy that in all of such cases, there is a high suspicion for the excessive consumption of the beverages as the causal event.

## **CAFFEINE CONTENT AND DOSE**

The caffeine content of energy drinks has been the center of the controversy, as it is widely believed that most such products contain a significantly higher concentration of caffeine than what is found in an average cup of coffee. The cardiovascular effects of caffeine have been heavily studied. Caffeine's inotropic effect on the heart muscle has been long looked at with suspicion as a possible culprit for heart disease in some people<sup>[20]</sup>. The last couple of decades saw coffee be linked with various harmful effects such as hypertension, gastric ulcers, palpitations, anxiety, tremulousness, and, ultimately, heart disease<sup>[21-23]</sup>. Hence, caffeine has an essential role in understanding the possible dangers of energy drinks.

In healthy individuals, caffeine, a methylxanthine, increases sympathetic nerve activity. Caffeine's molecular mechanism lies in its competitive inhibition of phosphodiesterase. This results in an elevation in myocardial cyclic AMP and, as a consequence, the positive inotropic action on the myocardium. On the other hand, the inhibition of adenosine receptors prevents the negative inotropic effect elicited by adenosine, namely, blocking the vasodilatory effect of adenosine and adenosine's inhibitory effects in platelet aggregation, catecholamine levels, renin release, and lipolysis. Thus, acute caffeine administration may increase blood pressure and increase levels of plasma

catecholamine, renin, and free fatty acid<sup>[24]</sup>.

As noted above, there is an extensive amount of literature that reveals that caffeine moderately increases blood pressure and heart rate<sup>[25-28]</sup> and also linked to a drop in myocardial blood flow<sup>[29,30]</sup>. However, caffeine has also been shown to have some positive benefits as well. One study showed that caffeine consumption was associated with a significant increase in flow-mediated dilation and a decrease in hs-CRP level in healthy volunteers and volunteers with coronary artery disease alike. It is noteworthy that these positive effects in endothelial dysfunction and inflammation were not seen with nitroglycerin application<sup>[31]</sup>. While these results seem promising, other studies have found negative effects that caffeine may have on endothelial function, such as a study conducted by Papamichael *et al.*<sup>[32]</sup> they found that after ingestion of 80 mg of caffeine by healthy individuals, flow-mediated dilation was decreased in these individuals, most acutely in the first hour after ingestion. These results may not come as a surprise, as caffeine has been known to promote endothelial dysfunction through sympathetic activation<sup>[33]</sup>.

A large prospective study followed 130054 members of a healthcare plan in Northern California gathering subjects from 1978 to 1985 and following them until 2008 to note the amount of coffee consumed by each individual and whether that added a risk for hospitalization for arrhythmias or any other cardiomyopathy. Results showed a strong inverse relationship of coffee consumption to risk of hospitalization for arrhythmia. The inverse relationship was consistent in men, women, whites, blacks, and persons younger or older than 60 years old at baseline<sup>[34]</sup>. This result shows that participants who consumed more cups of coffee generally were significantly less likely to develop cardiac arrhythmias. This shows the reverse of the idea traditionally held of increased caffeine consumption leading to more cardiac arrhythmias. Additionally, a comprehensive literature review dealing with the effects of habitual caffeine consumption on the cardiovascular system found that moderate consumption resulted in beneficial to neutral effects<sup>[35]</sup>.

There is evidence, however, that point to caffeine's possible adverse effects especially when consumed at high doses. Toxic doses may affect conductance and refractoriness on the heart, which results in the development of various arrhythmias<sup>[36]</sup>. Symptoms of caffeine overdose also include palpitation, hypertension, irritability, insomnia, tremors, and seizures. In addition, the hypertensive effects of caffeine should not be overlooked as they may lead to hazardous cardiovascular events. The HARVEST study found that when after adjusting for possible confounding variables, cardiovascular events were more common among coffee drinkers than non-coffee drinkers. The authors suggested that hypertensive patients should be discouraged from drinking coffee<sup>[6]</sup>.

Table 1 Caffeine concentration in common drinks

Caffeinated beverage	Amount of caffeine/drink, mg
5-h energy™ bottle	215
Arizona Iced Black Tea (16oz)	30
Bang Energy (16oz)	357
Caffeine Powder (1/16 Tsp.)	200
Coca Cola, Coke Zero, Diet Pepsi (12oz)	34
Dannon Coffee Yogurt (6oz)	30
Dunkin Donuts™ Medium Brewed Coffee (14oz)	178
Dunkin Donuts™ Medium Latte (14oz)	97
FDA official limit for cola and pepper soft drinks(12oz)	71
Herbal Tea (8oz)	0
Lipton Decaffeinated Black Tea (8oz)	5
Maxwell House Decaf Ground Coffee (2 Tbs. makes 12oz)	2-10
Maxwell House Light Ground Coffee (2 Tbs. makes 12oz)	50-100
Monster Energy™ (16oz)	160
Mountain Dew (12oz)	54
Pepsi (12oz)	38
Red Bull™ (8.4oz)	80
Rockstar™ (16oz)	160
Snapple Lemon Tea (16 oz)	37
Starbucks Grande Chai Latte (16oz)	95
Starbucks Hot Chocolate (16oz)	25
Starbucks Refreshers Can (12oz)	50
Starbucks™ Grande Caffè Americano (16oz)	225
Starbucks™ Grande Caffè Mocha (16oz)	175
Starbucks™ Grande Coffee Frappuccino (16oz)	95
Starbucks™ Grande Ice coffee (16oz)	165

There is a widespread belief that caffeine may be arrhythmogenic in those who regularly consume it. However, a large-scale Danish study did not find a higher risk for atrial fibrillation/flutter with different amounts of caffeine consumed<sup>[37]</sup>. In addition, the stimulant effects of caffeine seems to vary amongst individuals, in fact, the degree of tolerance and dependence to it is likely heritable and may be linked to polymorphisms<sup>[38]</sup>.

Two comprehensive meta-analyses both determined that caffeine is unlikely to promote cardiovascular disease. In fact, the opposite may be true. The first review, conducted by Cheng *et al.*<sup>[39]</sup> found an inverse relation was found between habitual caffeine intake and risk of atrial fibrillation. For every 300 mg per day increment in habitual caffeine intake, incidence of AF was found to drop by 6%. One explanation for these results is caffeine's association with lower risks of obesity, and metabolic disease. Thus, adverse cardiovascular effects of caffeine seem to represent itself with a J-shaped curve, with higher doses increasing the risks of heart disease, and normal doses proving to be beneficial<sup>[40]</sup>.

The discrepancies in these studies can be difficult to reconcile although some of the variation in results may be attributed to differences in study design, varied caffeine dosages administered, and different study cohorts. Most studies do an inclusion criteria exercise for their cohorts. However, many did not take into account the regular coffee consumption

of volunteers prior to the study. This is important because coffee metabolism is extremely variable in humans; thus, the effects of caffeine are not uniform. The half-life is 4.9 h, however absorption rates are largely based on the individual's genes, age, sex, liver health, and drug uptake, such as use of oral contraception, antidepressants, and antiarrhythmics, as well as their tolerance to the stimulant<sup>[41]</sup>. Caffeine is primarily metabolized through the liver's cytochrome P450 1A2 (CYP1A2) enzyme and defects in such an enzyme have been implicated in the population's variation in metabolism and half-life. Hence, genetic polymorphisms in the CYP1A2 pathway may explain some of the inconsistencies in studies of coffee and its effects on health<sup>[42]</sup>.

To examine the caffeine amounts, Table 1 shows the caffeine concentrations of some popular drinks at Starbucks™ and Dunkin Donuts™ along with some of the most popular caffeine containing drinks<sup>[43]</sup>. Note that all EDs or energy shots surpass the FDA official soft drink concentration limit of 71 mg per twelve-ounce drink, sometimes by over triple the amount. According to the Mayo Clinic and the US food and Drug Administration up to 400 mg of caffeine a day appears to be safe for most healthy adults<sup>[44,45]</sup>. One study that supports this quantity mentions that maximum safe caffeine intake for pregnant women, children, and those taking medications is still undetermined<sup>[9,46]</sup>. Unfortunately, proper labeling has also been an issue, with companies reportedly falsely labeling caffeine content on their products, and

misguiding consumers<sup>[47]</sup>.

## OTHER ACTIVE INGREDIENTS IN ENERGY DRINKS AND THEIR ADDED EFFECTS

### Taurine

Taurine is a derivative of the amino acid cysteine, and is found in high quantities in heart and skeletal muscle<sup>[48]</sup>. It is added in a large number of energy drinks such as 5-h energy™ and Red Bull™. Although taurine is considered an essential nutrient for humans, clinical studies evaluating the effects of taurine are limited. Taurine has been shown to be beneficial in improving the lipid profile by increasing the transcription of CYP7A1, an important enzyme in bile conjugation<sup>[49]</sup>, as well increasing the liver's LDL uptake and up-regulation of LDL receptors<sup>[50]</sup>. Its supplementation has also been linked with a decrease in blood pressure possibly through the attenuation of angiotensin II, which causes vasoconstriction<sup>[51]</sup> or by "enhancing" the kinin-kallikrein system, which normally causes vasodilation<sup>[52]</sup>. An ethnic Chinese study found an inverse correlation between twenty-four hour taurine excretion and diastolic blood pressure in Han (the major Chinese ethnic group) individuals and a decrease in both systolic and diastolic BPs in Tibetan subjects when consumed<sup>[53]</sup>. Similarly, there was a significant decrease in systolic and diastolic BPs in 19 borderline hypertensive subjects<sup>[54]</sup>.

In addition, taurine deficiency was found to be associated with a decrease in the sensitivity of the cardiac muscle to Ca<sup>2+</sup>, and, hence, a decreased inotropic capability of the organ<sup>[48]</sup>. This may be the reason for the supplements alleged boost in physical performance through an improved blood supply to the rest of the organs, specifically the musculoskeletal system. Interestingly, concentration of taurine have been found to be higher in the left ventricular muscle of hearts of patients who died of chronic congestive heart failure than that of patients who died of other causes and had no cardiac pathology<sup>[55]</sup>. The study hints that taurine may, in fact, have an inotropic effect which may shed some light on the cardiovascular adverse effects of energy drinks.

Certain studies have compared the effects of energy drinks containing just caffeine, and those containing caffeine and taurine. One study randomized nine volunteers to receive either an ED containing 80 mg of caffeine and 1000 mg of taurine or a control that contained 80 mg of caffeine solution in water. They were asked to consume their respective drink every 3-4 h for a single day. Mean 24-h systolic blood pressure, diastolic blood pressure, and mean arterial pressure recordings were significantly higher in the ED group than in the control (123.2 mmHg vs 117.4 mmHg, 73.6 mmHg vs 68.2 mmHg, 90.1

mmHg vs 84.8 mmHg, respectively)<sup>[56]</sup>. Another study asked 13 athletes to ingest either Red Bull, a similar caffeinated drink without taurine, or a placebo prior to performance of exhaustive endurance exercises. ECGs performed before ingestion, before exercise, after ingestion, during the recovery period showed that the only significant increase in stroke volume during the recovery period was the group that consumed taurine containing Red Bull. This study suggests that taurine and caffeine may interact together to increase cardiac contractility<sup>[57]</sup>. A third study explored the peak systolic strain in 32 healthy individuals at baseline, and one hour after consumption of an ED containing caffeine and taurine, or just caffeine. While the drink with caffeine did not seem to have any significant cardiovascular effects shown by magnetic resonance imaging, those that ingested the combination of caffeine and taurine had a significant increase in peak systolic strain<sup>[58]</sup>.

Schaffer *et al.*<sup>[59]</sup> conducted a comprehensive literature review regarding the interaction between taurine and caffeine and in agreement with the European Union's Scientific Committee on Food, they concluded that taurine should neutralize several untoward effects of caffeine excess. They noted that the physiological functions of taurine appear to be inconsistent with the adverse cardiovascular symptoms associated with excessive consumption of beverages containing caffeine and taurine.

### B vitamins

Referred to as vitamin B complex, the eight B vitamins, thiamine (B1), riboflavin (B2), niacin (B3), pantothenic acid (B5), pyridoxine hydrochloride (B6), biotin (B7), inositol (B8), and cyanocobalamin (B12), act as coenzymes for proper cell function, especially mitochondrial function and energy production. Thus, some believe that B vitamins may increase energy expenditure<sup>[60]</sup>. One study has shown lower fat mass in men who regularly consumed multivitamins<sup>[61]</sup>. Energy drinks often contain a large quantity of B-group vitamins, often at larger doses than the recommended daily intake for healthy individuals.

Studies have shown that high dietary intakes of folate and vitamin B6 has been linked with reduced risk of mortality from stroke, coronary heart disease, and heart failure<sup>[62]</sup>. B vitamins have also been shown to reduce levels of the amino acid homocysteine whose elevation have been linked to numerous comorbidities including pregnancy complications, cognitive impairment and mental disorders, as well as cardiovascular risks<sup>[63-65]</sup>.

A meta-analysis established that while B vitamin supplementation the B vitamin reduced homocysteine levels and has a significant protective effect on stroke, no benefit was found to reduce cardiovascular disease, myocardial infarction, coronary artery disease,

cardiovascular death, or all-cause mortality<sup>[66]</sup>.

### **Guarana**

*Paullinia cupana*, also known as guarana, is a South American plant that has been mentioned as early as 1872 for the treatment of "Sick-Headache"<sup>[67]</sup>. The Amazonians have used the seeds of its fruit to increase awareness and energy<sup>[68]</sup>. Guarana's stimulant effect is due to its similar chemical composition to that of caffeine. There is 2%-4.5% caffeine in the guarana seeds, compared to 1%-2% in the coffee bean<sup>[69]</sup>. The effect of guarana is not yet known. Whether it is of additive or synergistic effect when combined with caffeine is not clear. Guarana in a 16 ounce energy drink ranges from 1.4 mg to as much as 300 mg. The FDA generally recognizes guarana as safe, although there are no established dosages and it is unclear how much guarana is in each drink because many companies do not list a milligram amount. Therefore, it should be assumed that the amount of caffeine in the products is, in reality, larger than the amount of caffeine noted especially when guarana is present. It is not surprising that young adults have been admitted to emergency departments with cardiovascular adverse effects after excessive ingestion of guarana-based EDs<sup>[70]</sup>.

### **L-carnitine**

A meta-analysis on the effect of the L-carnitine supplement on the cardiovascular system found a 40% reduction in angina (RR, 0.60; 95%CI, 0.50-0.72;  $P < 0.00001$ ;  $I^2 = 0\%$ ). Compared with placebo or control, L-carnitine was found to be associated with a highly significant 65% reduction in ventricular arrhythmias (RR = 0.35; 95%CI: 0.21-0.58,  $P < 0.0001$ ,  $I^2 = 0\%$ )<sup>[71]</sup>. An increase in cardiac output after intravenous administration of L-carnitine in normotensive coronary artery disease patients has also been observed<sup>[72]</sup>. Another study showed that L-carnitine supplementation increased the left ventricular ejection fraction in studied individuals. The mean percent of increase of ejection fraction in the L-carnitine group was  $12.5\% \pm 8.3\%$  ( $P < 0.01$ ), while the control group had an increase of ejection fraction of  $6.1\% \pm 4.3\%$  ( $P < 0.01$ )<sup>[73]</sup>. In addition, the supplementation of L-carnitine has been shown to decrease left ventricular remodeling in post-myocardial infarction patients<sup>[74]</sup>. However, Koeth *et al.*<sup>[75]</sup> recently found a possible link of L-carnitine in red meat with cardiovascular disease through the development of atherosclerosis. This effect may simply be due to the long acknowledged negative effect of red meat on the cardiovascular system instead of L-carnitine itself.

L-carnitine is a naturally occurring amino acid made predominantly by the liver and kidneys. It is involved in B-oxidation of fatty acids and is thus linked to changes in metabolism and energy levels. It is commonly added to energy drinks to help promote

muscle function and physical performance. It is found in energy drinks such as Monster™ and Rockstar™ energy drinks.

L-carnitine's popularity in EDs is due to its possible ability to burn more fat and increase endurance during exercise, however, those claims remain elusive. Some data has indicated that L-carnitine plays an important role in the prevention of cellular damage and positively affects recovery from exercise stress. Uptake of L-carnitine by blood cells has been implicated in stimulation of hematopoiesis, a dose-dependent inhibition of collagen-induced platelet aggregation; and the prevention of programmed cell death in immune cells. Carnitine was recently shown to have direct effects in the regulation of gene expression and is potentially involved in modulating intracellular fatty acid concentration. Hence, there is evidence for a positive effect of L-carnitine supplementation. It may be especially beneficial in training and recovery from strenuous exercise<sup>[76]</sup>. In high doses, L-carnitine has been shown to have a side effect of nausea, vomiting, abdominal pain, and diarrhea; in addition, it has been associated with seizures in patients with no known disease and to increase seizure frequency in patients with seizure disorder<sup>[9]</sup>. However, as with ginseng, the amount of L-carnitine in energy drinks is likely not high enough to be of concern.

### **Ginseng**

This East Asian herb is one of the most popular herbal supplements in the world and has also been a popular additive in EDs. The claims about ginseng range far and wide-reducing stress, curing diabetes, insomnia, erectile dysfunction, improving memory, and increasing stamina are all purported benefits of the herb. However, very few claims are rooted in scientific research. A recent review concluded that evidence of enhanced physical performance after ginseng administration in well-designed investigations remains to be demonstrated<sup>[77]</sup>.

In 2013, one Mayo Clinic study did show that after eight weeks of taking 2000 milligrams of pure American ginseng root in a capsule, patients undergoing cancer treatment found a sudden jump in the general energy levels reported by the group on ginseng when compared to the placebo control group<sup>[78]</sup>.

Interestingly, several studies in rats have results suggesting that oral administration of ginseng root may increase insulin sensitivity and help with weight loss. Researchers at the University of Chicago administered daily intraperitoneal injections of Panax ginseng berry extract to rats and on day 12, extract-treated *ob/ob* mice became normoglycemic and were found to have significantly improved glucose tolerance. A more than twofold increase in the rate of insulin-stimulated glucose disposal in treated *ob/ob* mice was noted in hyperinsulinemic-euglycemic clamp study. The mice also lost a significant amount of weight which was

believed to be associated with the reduced food intake and the increase in body temperature and energy expenditure. Other studies revealed that ginsenoside Re plays a significant role in antihyperglycemic action. Interestingly, this antidiabetic effect of ginsenoside Re was not associated with body weight changes, suggesting that other components in the extract have distinct pharmacological mechanisms on energy metabolism. Additionally, plasma cholesterol levels were notably reduced following the treatment with the extract<sup>[79]</sup>.

Excessive amounts of ginseng ingestion may cause diarrhea, vaginal bleeding, headache, vertigo, mania, hypertension, rashes, insomnia, irritability, Stevens-Johnson syndrome, and agranulocytosis. However, some of these symptoms may be related to contaminants, such as phenylbutazone and aminopyrine that are used in its production<sup>[6]</sup>. However, the amounts of ginseng found in EDs are thought to be less than the amount needed to deliver the suggested therapeutic benefits or cause adverse events<sup>[80]</sup>.

### **Glucuronolactone**

Glucuronolactone is a glucose derivative, metabolized in the liver. In the sixties, the Japanese were particularly interested in its performance enhancing properties. They conducted one published study by injecting glucuronolactone, glucose, glycogen, and some other substances directly into the gut of lab rats, and recording the rats' ability to swim 30 min post injection. They repeated the procedure three times. In two of the three trials, the animals injected with glucuronolactone were able to swim longer than those injected with the other substances. The study also noted that the human equivalent of the dose would be between 1 and 2 g of glucuronolactone compared to the 600 mg found in a can of Red Bull<sup>[81]</sup>. These results may be due to glucuronolactone detoxification effects as supplementation with glucuronolactone may favor the body's natural defense mechanism for eliminating carcinogens and tumor promoters and their effects<sup>[82]</sup>.

Glucuronolactone has shown to act as an anti-platelet aggregative compound<sup>[83]</sup>, however, this outcome has not been proven to be effective when mixed in energy drinks, as after consumption an overall increase in platelet aggregation appears without any apparent effect of platelet anti-aggregation of the glucuronolactone<sup>[16]</sup>. There has been minimal suggested significant contribution towards energy by glucuronolactone on humans in the scientific literature and, therefore, no definitive conclusion can be made of its safety<sup>[84]</sup>.

## **OVERALL ASSESSMENT**

The increasing number of energy drink and caffeine-related overdoses clearly shows that there seems to be a real risk for adverse health effects such as

arrhythmias. However, under moderate use and without combining other stimulants or alcohol, the lack of a similar number of case reports makes the risk for such side effects seem negligible. It is noteworthy that a large number of serious health risks resulted were due to overconsumption of the products or their ingestion in a short period of time. Therefore, it may well be important for energy drink companies to place warnings on their products to avoid such habits.

The exact amounts and concentrations that are ideal in order to minimize the health risks are largely unknown. Patients with underlying illnesses such as hepatic failure or cardiomyopathy should likely avoid such products or, at least, be cautious by consuming small amounts. In addition, since there seems to be variation amongst individuals in the enzymatic activity of CYP1A2 and since testing for such enzymatic activity is not routinely performed, it is of great importance for each consumer to cease consuming the energy drinks if symptoms of an overdose develop. Producers should place a warning that includes such symptoms.

As for the constituents of the energy drinks themselves, the concentrations of caffeine seem to be comparable or even lower than many popular coffee drinks making the amount of caffeine itself an unlikely reason to not consume the products. In fact, medical research has shown that moderate consumption of caffeine is strongly related to a reduced risk of arrhythmias.

As for taurine and L-carnitine, the medical literature shows an overall positive health effect especially for the cardiovascular system, hence, making it unlikely that they can cause harm to that same system. In fact, it may be reasonable to consider those two compounds for future supplementation to those at risk for hyperlipidemia, hypertension, and cardiomyopathy. Guarana, on the other hand, may have a synergistic caffeine-like effect added to the caffeine already in these products and more information is needed on their combined effect.

## **CONCLUSION**

The last decade has seen an exponential increase in the number of energy drink products as well as the number of reported cases of arrhythmias and other health hazards caused by their consumption. Our review has found that the vast majority of the cases were due to excessive consumption of the drinks in a short period of time or when co-ingested with other stimulants such as alcohol and indicates that such drinks may be relatively safe when consumed moderately and separately. Additionally, the research covering the components of the beverages, such as caffeine, taurine, L-carnitine, glucuronolactone, ginseng, and guarana, seems to have a neutral to positive health effect unlike previously thought. However, it may be important for energy drink

producers to place warning labels of symptoms associated with an overdose in order to promote their recognition. Until the FDA sanctions these energy drink products, it is strongly encouraged that individuals research energy drink consumption and consult their physician in order to ensure safe consumption. Also, those with underlying cardiovascular disease should be careful by limiting the amount consumed or avoiding altogether, as they may be at increased risk for arrhythmias or other cardiovascular events.

With the exception of the effects of caffeine, the ingredients in energy drinks have not been thoroughly studied to confirm the cardiovascular safety or the proclaimed energy-boosting benefits. There is an overwhelming lack of evidence to substantiate claims that components of EDs, contribute to the enhancement of physical or cognitive performance. Additional well-designed, randomized, placebo-controlled studies are needed in order to assess claims made for these products and further elucidate potential adverse effects.

**Abstract****AIM**

To compare post-percutaneous coronary intervention (PCI) radial artery occlusion (RAO) incidence between two conventional radial artery compression devices using a novel air-inflation technique.

**METHODS**

One hundred consecutive patients post-PCI were randomized 1:1 to Safeguard or TR band compression devices. Post-radial sheath removal, each compression device was inflated with additional 2 mL of air above index bleeding point during air-filled device application and gradually down-titrated accordingly. RAO was defined as absence of Doppler flow signal performed at 24 h and at 6 wk post-PCI. Patients with missing data were excluded. Statistical significance was defined as  $P < 0.05$ .

## RESULTS

All patients had 6F radial sheath inserted. No significant differences were observed between Safeguard Radial ( $n = 42$ ) vs TR band ( $n = 42$ ) in terms of age ( $63 \pm 11$  years vs  $67 \pm 11$  years), clinical presentation (electives,  $n = 18$  vs  $n = 16$ ; acute coronary syndrome,  $n = 24$  vs  $n = 26$ ) and total procedural heparin ( $7778 \pm 2704$  IU vs  $7825 \pm 2450$  IU). RAO incidence was not significantly different between groups at 24 h (2% vs 0%,  $P = 0.32$ ) and 6 wk (0%, both).

## CONCLUSION

Safeguard Radial and TR band did not demonstrate significant between-group differences in short-term RAO incidence. Lack of evidence of RAO in all post-PCI patients at 6 wk follow-up, regardless of radial compression device indicate advantage of using the novel and pragmatic air-inflation technique. Further work is required to more accurately confirm these findings.

**Key words:** Radial artery; Arterial occlusive disease; Cardiac catheterization

**Core tip:** Radial artery occlusion (RAO) is a rare but significant complication post-transradial percutaneous coronary intervention (PCI). We found that post-PCI Doppler flow signal-detected RAO incidence was not significantly different between Safeguard Radial and TR band compression devices. However, with the use of a novel air-inflation technique, we observed significantly lower incidence of RAO in all patients regardless radial compression device, in the short-term compared to current literature. Therefore, this novel air-inflation technique may offer a pragmatic and effective solution in reducing RAO incidence.

## INTRODUCTION

Radial artery occlusion (RAO) is an increasingly recognized and significant vascular complication among those observed post-hemostatic compression device application for transradial percutaneous coronary intervention (PCI), the recommended access route in current guidelines<sup>[1]</sup>. As a consequence of RAO, ipsilateral limb transradial access may be

rendered unusable for future procedures. This may be particularly crucial in post-PCI patients, a cohort at higher risk of requiring further coronary angiography, conduit for coronary artery bypass surgery or arterio-venous fistula formation for hemodialysis. Furthermore, ipsilateral ulnar artery access may be unusable due to ischemic limb risk on arterial cannulation.

Several studies have reported rates of RAO from 1%-30%<sup>[2-9]</sup>. These figures reflect the complex pathophysiology involved in RAO, particularly impaired vascular remodeling and thrombo-inflammatory alterations post-arterial injury. In addition, reports to date have been confounded by multiple external factors. These factors include heterogeneity of study designs, targeted patient populations, parameters for assessing RAO, anticoagulation as well as compression devices and techniques<sup>[10]</sup>.

While several compression bands and techniques tested have demonstrated a modest reduction in RAO, a more pragmatic and effective approach remains to be defined<sup>[11]</sup>. Therefore, we aimed to prospectively compare incidence of RAO between two conventional hemostatic compression devices (Safeguard Radial and TR band) using a pragmatic and novel air-inflation technique, in patients post-transradial PCI.

## MATERIALS AND METHODS

Ethics approval was obtained from University Hospital Limerick Ethics committee for our study, which conformed to the principles of the Helsinki Declaration. A total of 107 consecutive patients who had undergone transradial percutaneous coronary intervention at University Hospital Limerick, were screened and eligible patients were recruited into the study. Patients gave written informed consent prior to PCI and were prospectively randomized to either Safeguard Radial or TR band compression device *via* a pre-specified 1:1 automated randomization. Exclusion criteria were patients less than 18 years old, pregnancy, inability to consent, inability to attend follow-up clinic and difficult radial access requiring femoral access. Patient demographics and angiographic profiles were collected. All patients received dual anti-platelet therapy prior to PCI. Radial artery procedural preparation and management as well as RAO assessment are described below.

### Radial artery cannulation

After sterile preparation, 1% lidocaine was injected at puncture site. The radial artery was punctured at the anterior wall with a 21-gauge arterial needle through which a 0.018-inch straight floppy tip guidewire (40-cm length) was advanced upon appearance of pulsatile flow. Following this, the needle was withdrawn and a hydrophilic 6F introducer sheath (11-cm length) with dilator length of 16 cm (Prelude, Merit Medical

Figure 1 TR band compression device.

Systems) was inserted over the guidewire into the radial artery. Subsequently, the wire and dilator were removed. According to operator preference, a “radial cocktail” consisting of intra-arterial 100-200 mcg nitroglycerin, 250 mcg verapamil and heparin 2000-4000 IU, was given. All patients had total procedural heparin 70-100 IU/kg given as part of the PCI procedure.

#### **Radial sheath removal and hemostatic compression technique**

Patients were randomized to either TR band (Terumo Interventional Systems) or Safeguard Radial (Merit Medical) hemostatic compression device groups (Figures 1 and 2). Immediately post-PCI, the radial sheaths were pulled out 4-5 cm and chosen hemostatic compression device band was placed around wrist, with the transparent bladder immediately over the puncture site. We utilized a novel and pragmatic air-inflation technique that involved initial syringe-guided inflation of 2-5 mL of air into device transparent bladder *via* a cuff-valve system, with careful simultaneous removal of sheath. Continued inflation up to 5-10 mL of air was done to stop bleeding after complete removal of sheath. This was followed by immediate release of air, using similar syringe until bleeding/oozing point, at which an additional 2 mL of air was inflated into device bladder. This is contrary to current non-personalized air-inflation techniques utilizing standard 15 mL and 7 mL of air in TR band and Safeguard respectively, as per manufacturer’s instructions. Subsequent gradual down-titration of air (1 mL of air removed every 30 min) was performed by nursing staff until completion of hemostasis.

#### **Activated clotting time measurement**

Activated clotting time (ACT) is the routine method of choice for monitoring heparin therapy during

PCI. At the end of PCI, for all patients, 5 mL of fresh arterial blood sample was obtained in a 5 mL syringe after initially discarding 10 mL of blood from radial sheath prior to sheath removal. The fresh blood was immediately measured for ACT, by using a disposable single-use point-of-care assay. The assay consists of a cuvette containing manufacturer reagents and is measured by the accompanying battery-operated, hand-held device Hemochron Jr Signature + Whole Blood Microcoagulation System (International Technidyne) as per manufacturer’s instructions.

#### **RAO assessment**

The handheld ultrasonic Doppler signal flow detector 2 MHz (FD1, Huntleigh, Sonicaid) probe was applied above the puncture site of radial artery of resting and extended forearm. RAO was defined as absence of Doppler signal flow. This was performed at 24 h and 6 wk post-PCI by operators blinded to randomization process.

#### **Outcome measures**

Primary endpoint was RAO at 24 h post-procedure and 6 wk follow-up. Secondary endpoints were bleeding requiring transfusion/surgical intervention, hematoma and pain/numbness at radial access site.

#### **Statistical analysis**

As a pilot study evaluating this technique, exploratory analyses was performed. Continuous normal data were expressed as mean  $\pm$  SD. Continuous non-normal and categorical variables were expressed as mean (25<sup>th</sup>, 75<sup>th</sup> percentile) or frequencies (and percentages). Accordingly, between-group comparisons were compared using unpaired t-testing, Mann-Whitney rank sum test or Pearson chi-square tests. All patients with missing data were excluded from analyses. All analyses were performed using SPSS version 18 statistical software (SPSS Inc, Chicago, IL, United states).  $P < 0.05$  was considered significant (two-tailed significance).

## **RESULTS**

Baseline demographics of patient cohort are presented in Table 1. A total 84 patients were included for analyses after excluding patients who were not eligible ( $n = 5$ )/refused ( $n = 2$ ), had missing data ( $n = 16$ ). No significant differences were observed between-groups in terms of demographics or procedural profiles (Table 2). Approximately 60% of patients presented with an acute coronary syndrome. All patients had 6F radial sheaths inserted. Despite no significant between-group differences in post-procedural outcomes measures, both Safeguard Radial and TR band groups demonstrated very low incidence of RAO at 24 h (2% vs 0%) and 6 wk (0%, both) (Table 3). No significant

BMI: Body mass index; CKD: Chronic kidney disease; PAD: Peripheral arterial disease; UA: Unstable angina; NSTEMI: Non-ST elevation myocardial infarction; STEMI: ST-elevation myocardial infarction.

differences in secondary outcome measures were observed.

## DISCUSSION

This study has demonstrated no significant difference in incidence of short-term RAO between Safeguard and TR band devices. However, we have for the first time demonstrated significantly lower incidence of RAO at 24 h and at 6 wk post-PCI compared to current literature, regardless of type of conventional hemostatic compression device using the novel air-inflation technique. Among the few studies that have reported short-term RAO, some have observed RAO incidence as high as 9.2% at discharge<sup>[9]</sup>. Pancholy and colleagues reported RAO incidence of 4.4% at 24 h and 3.2% at 30 d using TR band in a cohort using 5F radial sheaths<sup>[8]</sup>. Dai *et al.*<sup>[11]</sup> demonstrated that in post-transradial PCI patients, incidence of RAO was at least 11% at 24 h and 10% at 30 d. The study showed that air titration based compression strategy using TR band was superior to non-air titration strategies. However, the study utilized a non-specific, non-personalized method using manufacturer’s instructions.

In our experience, additional 2 mL of air above point

of bleeding/oozing provides personalized and adequate temporary patent hemostasis without the need of conventional methods to monitor radial patency. This has been shown despite different surface area of compression bladder of both devices. This magnitude of air may provide sufficient compression on muscle, adipose tissue and artery although impact of higher magnitudes of air remains to be determined. This technique requires confirmation in future studies.

To further support this technique, our study involved a cohort presenting predominantly with acute coronary syndrome, a more prothrombotic state, compared to previous studies. Only 29.7% of transradial PCI-treated patients presented with acute coronary syndrome in a study by Rathore and colleagues<sup>[9]</sup>. The study demonstrated a higher incidence of RAO as aforementioned with manufacturer’s technique of compression device air inflation. However, several techniques to measure RAO were used and only 50% of patients had hydrophilic radial sheaths compared to our study. Some may argue that lack of sheath hydrophilicity may account for such results.

Furthermore, sheath size has also been regarded as a contributing factor to RAO. Larger diameter sheaths have been reported to have increase RAO

**Table 2** Procedural profiles of Safeguard Radial *vs* TR band groups

Radial artery occlusion at 24 h	2%	0%	0.32
Radial artery occlusion at 6 wk	0%	0%	1

incidence<sup>[12-14]</sup>. This effect was not observed in our study which used 6F sheaths in all patients who required PCI. Despite that, further studies involving improved imaging modalities are required to more accurately characterize vessel to sheath ratio. This is because the higher prothrombotic effects due to possible oversized sheaths may be offset by heparin therapy that all patients received in our study.

Heparin itself has been shown to reduce incidence of RAO. The lack of procedural heparin is an independent predictor of RAO<sup>[9]</sup>. Rathore and colleagues demonstrated RAO incidence of 24.1% at 4-6 mo follow-up in those without heparin administration. The study showed that in 92% of patients who had transradial PCI with 6F sheaths, RAO incidence was 8.9% at discharge and 5.6% at follow-up in the TR band group, which demonstrated lesser RAO between compression devices compared. Lefvre *et al*<sup>[15]</sup> reported 30% RAO with 1000 IU of heparin. This requires further confirmation, particularly at different comparator doses. However, the results of our study again emphasize the impact of the novel air-inflation technique in reducing RAO beyond conventional anticoagulation.

Several limitations were observed during the study. Firstly, we observed a high prevalence of missing data due to procedures performed out-of-hours. However, both groups were well matched in baseline demographics to negate group bias effects. Second, as with all exploratory studies, type I error may contribute to the results. Despite our study demonstrating consistent results at discharge and follow-up, this requires further confirmation. Third, Allen's test was not routinely performed pre-PCI. However, conventional methods of assessment *via* plethysmography and oximetry have not yielded consistent results due to influence of collaterals from palmar arches and recanalization<sup>[6,16]</sup>. Lastly, a known confounding factor that was not measured but critical for vascular management, was increased vigilance using our personalized air-inflation strategy to reduce RAO.

In conclusion, Safeguard Radial and TR band did not demonstrate significant between-group differences in short-term RAO incidence. Lack of evidence of RAO in all post-PCI patients at 6 wk follow-up, regardless of radial compression device indicate advantage of

using the novel and pragmatic air-inflation technique. Further work is required to more accurately confirm these findings.

## COMMENTS

### Background

Radial artery occlusion is a rare but significant complication post-transradial percutaneous coronary intervention, which is increasing in its use, globally. Therefore, better radial artery compression techniques are required to reduce such complication.

### Research frontiers

Conventional radial artery compression devices by varying air-inflation techniques have shown different results in reducing the incidence of radial artery occlusion post-percutaneous coronary intervention. These suggest that novel air-inflation techniques using such devices may yield better results in reducing incidence of radial artery occlusion.

### Innovations and breakthroughs

The authors have shown a much lower short-term incidence of post-percutaneous coronary intervention radial artery occlusion, compared to current literature, using a novel and pragmatic air-inflation technique in two conventional radial compression devices, Safeguard Radial and TR band.

### Applications

This pilot study's methods and results of this study could be used in a larger prospective study aiming to the impact of this novel air-inflation technique with two conventional radial compression devices in different settings of transradial percutaneous coronary intervention.

### Terminology

Radial artery occlusion is a rare but significant complication of transradial percutaneous coronary intervention. Novel and pragmatic radial compression techniques are required to reduce the incidence of such complication.

### Peer-review

This is an interesting manuscript about the comparison of post-percutaneous coronary intervention radial artery occlusion incidence between two conventional radial artery compression devices using a novel air-inflation technique, Safeguard Radial and TR band.

**ORIGINAL ARTICLE****Clinical Trials Study**

- 813 Delineation of epicardial stenosis in patients with microvascular disease using pressure drop coefficient: A pilot outcome study

*Hebbar UU, Effat MA, Peelukhana SV, Arif I, Banerjee RK*

**Observational Study**

- 822 Endothelin-1 activation in pediatric patients undergoing surgical coarctation of the aorta repair

*Frank BS, Urban TT, Tong S, Cassidy C, Mitchell MB, Nichols CS, Davidson JA*

**META-ANALYSIS**

- 830 Erythropoietin therapy after out-of-hospital cardiac arrest: A systematic review and meta-analysis

*Chaudhary R, Garg J, Krishnamoorthy P, Bliden K, Shah N, Agarwal N, Gupta R, Sharma A, Kern KB, Patel NC, Gurbel P*

**CASE REPORT**

- 838 Artefactual angulated lesion on angiography: A case report and review of literature

*Edroos SA, Sayer JW*

- 842 Successful recanalization of long femoro-crural occlusive disease after failed bypass surgery

*Korosoglou G, Eisele T, Raupp D, Eisenbach C, Giusca S*

- 848 Transposition of the great arteries - a phenotype associated with 16p11.2 duplications?

*Karunanithi Z, Vestergaard EM, Lauridsen MH*

**LETTERS TO THE EDITOR**

- 853 Transcatheter aortic valve implantation operators - get involved in imaging!

*Brinkert M, Toggweiler S*

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Dr. Howard S Weber, MD, Professor, Pediatric Cardiology, Penn State Hershey Childrens Hospital, Hershey, PA 17033, United States

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

## Abstract

### AIM

To investigate the patient-outcomes of newly developed pressure drop coefficient (CDP) in diagnosing epicardial stenosis (ES) in the presence of concomitant microvascular disease (MVD).

### METHODS

Patients from our clinical trial were divided into two subgroups with: (1) cut-off of coronary flow reserve

(CFR) < 2.0; and (2) diabetes. First, correlations were performed for both subgroups between CDP and hyperemic microvascular resistance (HMR), a diagnostic parameter for assessing the severity of MVD. Linear regression analysis was used for these correlations. Further, in each of the subgroups, comparisons were made between fractional flow reserve (FFR) < 0.75 and CDP > 27.9 groups for assessing major adverse cardiac events (MACE: Primary outcome). Comparisons were also made between the survival curves for FFR < 0.75 and CDP > 27.9 groups. Two tailed chi-squared and Fischer's exact tests were performed for comparison of the primary outcomes, and the log-rank test was used to compare the Kaplan-Meier survival curves.  $P < 0.05$  for all tests was considered statistically significant.

### RESULTS

Significant linear correlations were observed between CDP and HMR for both CFR < 2.0 ( $r = 0.58$ ,  $P < 0.001$ ) and diabetic ( $r = 0.61$ ,  $P < 0.001$ ) patients. In the CFR < 2.0 subgroup, the %MACE (primary outcomes) for CDP > 27.9 group (7.7%, 2/26) was lower than FFR < 0.75 group (3/14, 21.4%);  $P = 0.21$ . Similarly, in the diabetic subgroup, the %MACE for CDP > 27.9 group (12.5%, 2/16) was lower than FFR < 0.75 group (18.2%, 2/11);  $P = 0.69$ . Survival analysis for CFR < 2.0 subgroup indicated better event-free survival for CDP > 27.9 group ( $n = 26$ ) when compared with FFR < 0.75 group ( $n = 14$ );  $P = 0.10$ . Similarly, for the diabetic subgroup, CDP > 27.9 group ( $n = 16$ ) showed higher survival times compared to FFR group ( $n = 11$ );  $P = 0.58$ .

### CONCLUSION

CDP correlated significantly with HMR and resulted in better %MACE as well as survival rates in comparison to FFR. These positive trends demonstrate that CDP could be a potential diagnostic endpoint for delineating MVD with or without ES.

**Key words:** Fractional flow reserve; Pressure drop coefficient; Microvascular disease; Intermediate coronary stenosis; Interventional cardiology

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Fractional flow reserve (FFR), a functional diagnostic index, is currently the gold standard for decision making in the catheterization laboratory. However, FFR can be confounded by concomitant microvascular disease (MVD). In this subgroup analysis study, pressure drop coefficient (CDP) showed improved clinical outcomes for patients with MVD compared to FFR, potentially making CDP a better diagnostic endpoint compared to FFR.

Delineation of epicardial stenosis in patients with microvascular disease using pressure drop coefficient: A pilot outcome study. *World J Cardiol* 2017; 9(12): 813-821 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i12/813.htm> DOI:

## INTRODUCTION

A persistent clinical challenge for interventional cardiologists today is the accurate assessment of intermediate coronary stenosis. While multiple quantitative anatomical methods were proposed, their applicability remains in question<sup>[1]</sup>. Functional diagnostic indices such as fractional flow reserve (FFR) and coronary flow reserve (CFR) agree well with non-invasive stress testing<sup>[2-4]</sup>, although their efficacy is limited in the presence of significant microvascular disease (MVD) as FFR and CFR depend solely on either pressure or flow measurements<sup>[5,6]</sup>.

### Current functional diagnostic indices

FFR, the current gold standard for the functional evaluation of epicardial stenosis (ES) is defined as the ratio of distal and proximal pressures along an ES<sup>[7-9]</sup>. The parameter ranges from "0", indicating a completely blocked vessel to "1" which indicates no obstruction. Earlier clinical outcome trials have established a cut-off value of 0.75<sup>[8]</sup> for significant coronary stenosis in the presence of single-vessel disease. However, FFR suffers from limitations, such as the zero-central venous pressure assumption as well as its dependence on the patient achieving maximal hyperemia. Also, constant minimum microvascular resistance may not be achieved in the case of sub-maximal hyperemia, leading to under-estimation of pressure drop and overestimation of FFR across the lesion<sup>[10]</sup>.

CFR, the flow-derived parameter is defined as the ratio of hyperemic blood flow to basal (or resting) flow. The CFR values agreed well with non-invasive stress testing at a cut-off value of 2.0<sup>[2]</sup>, and CFR < 2.0 was associated with reversible myocardial perfusion defects with high sensitivity and specificity<sup>[2]</sup>. It is worth noting that while CFR can provide the combined effect of ES and MVD, it cannot differentiate between the two conditions.

### Need for alternate functional indices

FFR and CFR are based solely on pressure measurements and flow measurements, respectively. Thus, both the indices can be misleading in the presence of extended MVD<sup>[5,6]</sup>. Hybrid parameters based on pressure and flow were proposed to overcome these limitations of FFR and CFR. However, such a parameter, *e.g.*, hyperemic stenosis resistance index (HSR; ratio of pressure drop across the lesion to the distal velocity)<sup>[3]</sup> evaluates only ES. On a similar note, hyperemic microvascular resistance index (HMR; ratio of mean distal pressure and distal hyperemic velocity)<sup>[11]</sup> assesses MVD only.

To simultaneously detect ES and MVD using a single parameter, we recently introduced pressure drop coefficient (CDP), a functional diagnostic index which utilizes pressure as well as flow measurements. CDP

was validated *via in vitro*<sup>[12,13]</sup> as well as *in vivo* animal studies<sup>[12-18]</sup>, and could differentiate between ES and MVD. The CDP was recently employed to differentiate between degrees of stenotic severity in a patient population<sup>[19]</sup>. In order to make interventional decisions, an equivalent cut-off to FFR < 0.75 for single vessel disease was established for CDP (CDP > 27.9)<sup>[20,21]</sup> as a marker for significant ES.

Our earlier pilot clinical study<sup>[22]</sup> validated the proposed cut-off value for CDP with positive clinical outcomes associated with the CDP > 27.9 group when compared with the FFR < 0.75 group. The objective of the current study is to assess the efficacy of CDP in delineating ES within patient subgroups suffering from MVD only. Therefore, this follow-up pilot study compares the outcomes between CDP > 27.9 and FFR < 0.75 for MVD patient subgroups extracted from the complete patient data analyzed previously<sup>[22]</sup>. Accordingly, two subgroups having possible MVD were studied: One consisting of patients with abnormal CFR (CFR < 2.0), and the other consisting of patients suffering from diabetes. Both of these subgroups were correlated with possible microvascular dysfunction in literature<sup>[23-28]</sup>. Survival curves were also compared between the FFR < 0.75 and CDP > 27.9 groups for both subgroups. Additionally, CDP was correlated with HMR - another index that uses both pressure and flow measurements to evaluate MVD. This correlation was done in both subgroups to evaluate CDP's ability to delineate MVD in the presence of ES.

## MATERIALS AND METHODS

### Study patients

The protocol<sup>[19]</sup> for the study was approved by the institutional review board at the University of Cincinnati (UC) and Cincinnati Veteran Affairs Medical Center (CVAMC), and informed consent was obtained from all the participants. Patients who underwent exercise testing and myocardial perfusion scans were consented based on the inclusion and exclusion criteria, which are reported in detail in our earlier study for the complete patient group<sup>[22]</sup>. The study population consisted of 86 patients enrolled at the UC and CVAMC. Table 1 summarizes the clinical characteristics of the enrolled patients in the complete patient group.

### Cardiac catheterization and hemodynamic measurement

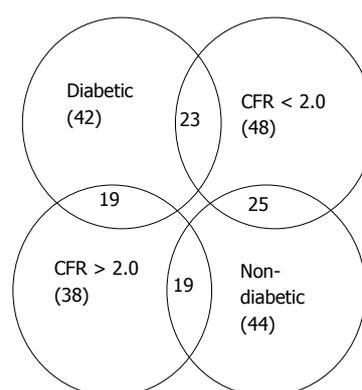

Standard-of-care catheterization techniques<sup>[22]</sup> were utilized to obtain intra-coronary pressure and flow measurements across the stenosis. All signals were recorded continuously through rest, and induction as well as decline of maximal hyperemia.

### CDP calculation

CDP is defined as the ratio of trans-stenotic pressure drop to distal dynamic pressure.

$$CDP = \Delta p / (0.5 \times \rho \times APV^2) \quad (1)$$

where,  $\Delta p$  is the pressure drop across the lesion; the

**Figure 1** Overlap of the various patient subgroups. The graphic highlights the intersection of the diabetic and CFR < 2.0 patient subgroups as well as the overlap between other subgroups. CFR: Coronary flow reserve.

distal dynamic pressure is the product of  $\rho$ , blood density (assumed to be a constant value of 1.05 g/cm<sup>3</sup>), the square of average peak flow velocity (APV) and a constant value of 0.5.

### Patient follow-up and study endpoints

The follow-up for the consented patients was performed through either chart review, a phone call, and/or a questionnaire. A minimum of 1-year follow-up was ensured. Over the follow-up period, the primary outcomes, which consisted of major adverse cardiac events (MACE) were determined. MACE was defined as the composite of all-cause mortality, myocardial infarction (MI), and repeat revascularization (Table 2).

### Sub-group methodology

In order to perform the subgroup analysis for patients suffering from possible MVD, two subgroups were extracted from the complete patient group data: One subgroup was composed of patients who exhibited an abnormal CFR value (CFR < 2.0); the other subgroup was composed of patients suffering from diabetes. Figure 1 summarizes the patient data *via* a Venn diagram showing overlap of the various patient subgroups.

### Statistical analysis

The authors had sufficient prior biostatistics background, as evidenced by previous publications<sup>[19-22]</sup>. First, correlations were performed between CDP and HMR in the diabetic and CFR < 2.0 subgroups using linear regression to evaluate the agreement of CDP with HMR, a parameter reported to identify the severity of MVD.

The patient data for each subgroup was then divided per the cut-off value of FFR < 0.75 for significant ES. On a similar note, CDP > 27.9<sup>[20,21]</sup> was used as an equivalent cut-off for significant stenosis. In the primary outcome study, for each subgroup (CFR < 2.0 and diabetic), the %MACE in the FFR < 0.75 group was quantified and compared with the %MACE in the corresponding CDP > 27.9 group. All comparisons were performed using the two-tailed  $\chi^2$  test and further

evaluated using the Fischer’s exact test.

Kaplan-Meier survival curves were generated to compare the long-term event free survival of the FFR < 0.75 patient group and the CDP > 27.9 patient group. This analysis was performed for both subgroups in the study. The duration between the index procedure, and the time when the patient was last followed-up was recorded. Any patient who reached the primary outcome (MACE) was recorded as positive. Patients lost to follow-up or who did not reach the primary outcome were considered as censored data. The generated survival curves were compared using the log-rank test for statistically significant difference.

All statistical analyses were performed using MedCalc (V10.2, Mariakerke, Belgium). All results obtained were considered statistically significant if *P* < 0.05.

## RESULTS

CDP was first correlated with HMR to identify its efficacy in evaluating MVD in patients suffering from concomitant ES. Further, to test the efficacy of CDP cut-off values (CDP > 27.9) as a guide for decisions on clinical intervention in patients with ES in presence of microvascular impairment, the %MACE outcomes for a CDP based strategy were statistically compared with those for a FFR based strategy (FFR < 0.75) using the two-tailed  $\chi^2$  test. The results for the Fischer’s exact test were also computed to account for the lower sample size. Comparisons were performed for both subgroup methodologies: The diabetic subgroup, and the CFR < 2.0 subgroup. Further, Kaplan-Meier survival curves were generated and comparisons were made for both subgroups.

### Correlation with HMR

The results for the correlation between CDP and HMR

are presented in Figure 2. For the CFR < 2.0 subgroup, CDP showed a moderate but significant correlation (Figure 2A) with HMR (*r* = 0.58, *P* < 0.001). In the diabetic subgroup (Figure 2B), CDP again correlated moderately with HMR and the correlation was statistically significant (*r* = 0.61, *P* < 0.001). These results further highlight the ability of CDP to delineate severity of MVD in patients who suffer from concomitant epicardial lesions.

### Comparison of %MACE outcomes

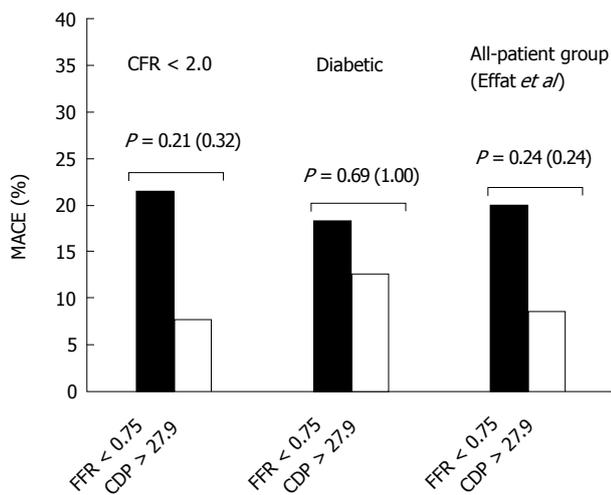

The comparison of %MACE outcomes between the FFR and CDP based cut-offs for the two subgroup analyses are summarized in Figure 3. Further, the comparison performed in our earlier outcome study<sup>[22]</sup> for the complete patient group is also presented. For the CFR < 2.0 subgroup, the %MACE outcomes in the FFR < 0.75 group (3 out of 14, 21.4%) were higher than the corresponding values for the CDP > 27.9 group (7.7%, 2 out of 26) although the results were not statistically significant as per the chi-squared test (*P* = 0.21) and the Fischer’s exact test (*P* = 0.32). On a similar note, for the diabetic subgroup, the %MACE in the FFR < 0.75 group (18.2%, 2 out of 11) was higher than the %MACE seen in the CDP > 27.9 group (12.5%, 2 out of 16), but the results were not statistically significant as per the chi-squared test (*P* = 0.69). The Fischer’s exact test resulted in a *P*-value of 1 due to the smaller sample size. Similar to the findings in this study, the analysis performed in our earlier study<sup>[22]</sup> for the complete patient group yielded a lower %MACE outcome for the CDP > 27.9 group though the results were not significant (*P* = 0.24) for both the chi-squared test and the Fischer’s exact test. These initial results suggest that if a CDP-based strategy were to be implemented, reduced %MACE outcomes would be observed when compared with the FFR-based strategy for the patient group with lower CFR values, as well as diabetic patients, who are known to suffer from MVD.

### Survival analysis

Figure 4A summarizes the Kaplan-Meier survival analysis

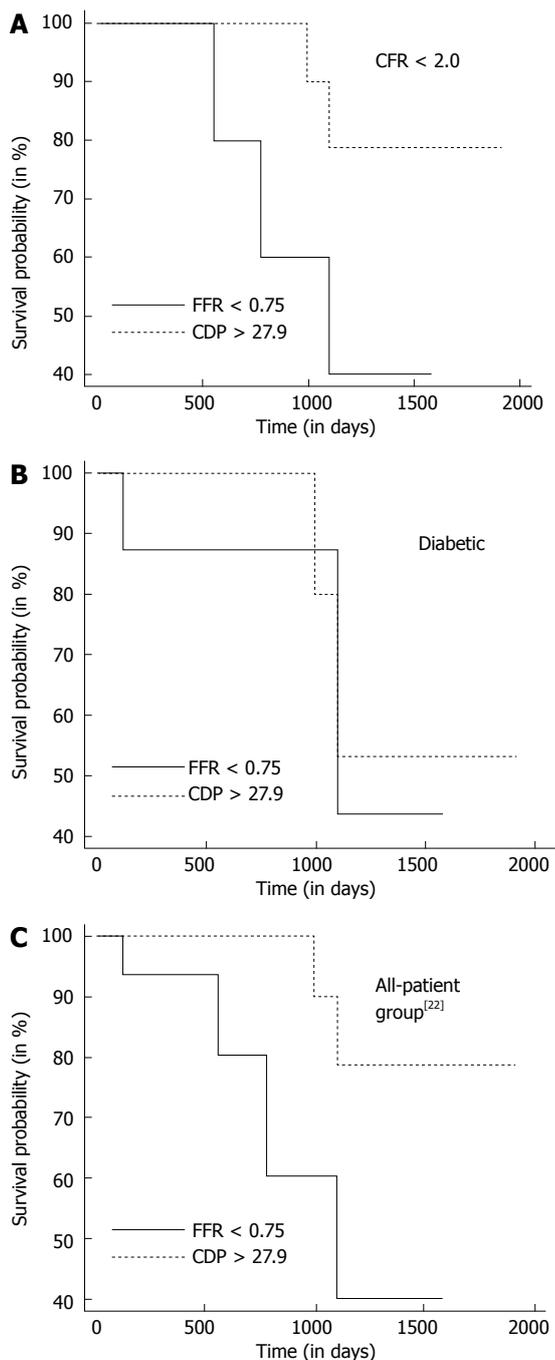

**Figure 2** Correlation of pressure drop coefficient with hyperemic microvascular resistance. A: The linear regression performed between CDP and HMR for the CFR < 2.0 subgroup. The equation, *R*-value and the *P*-value are provided for the comparison; B: Similar regression performed for the diabetic subgroup. CFR: Coronary flow reserve; CDP: Pressure drop coefficient; HMR: Hyperemic microvascular resistance.

**Figure 3** Comparison of %MACE between fractional flow reserve < 0.75 and pressure drop coefficient > 27.9 groups for the coronary flow reserve < 2.0 subgroup and diabetic subgroup. These patient subgroups are obtained from the complete patient group analyzed in Effat *et al*<sup>[22]</sup>. The *P*-values are provided for the  $\chi^2$  test, and the *P*-values for the Fischer's exact test are provided in parentheses. CDP: Pressure drop coefficient; FFR: Fractional flow reserve.

was computed to be 0.26 (95%CI: 0.04-1.82) implying that the survival probability in the CDP > 27.9 group is 3.85 times the corresponding probability in the FFR < 0.75 group. The difference in survival time for the FFR < 0.75 group (*n* = 14) compared with the CDP > 27.9 group (*n* = 26) was borderline significant (*P* = 0.10). On a similar note, Figure 4B summarizes the survival analysis performed for the diabetic subgroup. The computed hazard ratio was 0.60 (95%CI: 0.08-4.57), indicating higher survival probability for the CDP > 27.9 group. The survival time for the FFR < 0.75 group (*n* = 11) was not statistically different (*P* = 0.58) compared to the CDP > 27.9 group (*n* = 16). Figure 4C shows the survival analysis performed for the complete patient group in our previous study<sup>[22]</sup>. The hazard ratio was computed to be 0.22 (95%CI: 0.06-1.24), again indicating higher survival probability for the CDP > 27.9 group. In this comparison, a statistically significant improvement in survival time for the CDP > 27.9 group was observed when compared with the FFR < 0.75 group (*P* = 0.048). In summary, the survival analysis indicates better survival times for the CDP > 27.9 group when compared with the FFR < 0.75 group for the complete patient group as well as for patients suffering

performed for the CFR < 2.0 subgroup. The hazard ratio

**Figure 4** Comparison of Kaplan - Meier survival curves between fractional flow reserve < 0.75 and pressure drop coefficient > 27.9 groups. from MVD.

## DISCUSSION

The advantages of using CDP, a combined pressure-flow diagnostic endpoint, have been reported in earlier studies<sup>[14,20-22]</sup>. However, the applicability of such a parameter in clinically relevant scenarios, particularly in the presence of MVD needs further assessment.

### Correlation with HMR

HMR is a dimensional diagnostic index which utilizes pressure and flow measurements to specifically evaluate the severity of MVD in patients. In contrast, CDP is a unique non-dimensional parameter developed from fluid dynamics principles that combines pressure and flow measurements to evaluate the severity of both ES and MVD. CDP showed a moderate but significant correlation with HMR for both CFR < 2.0 and diabetic patient-subgroups, further strengthening the hypothesis that CDP can be used to evaluate the severity of MVD, with or without the presence of concomitant ES.

### Comparison of %MACE outcomes

One of the significant contributors to improved quality of life is reduced incidence of MACE. Therefore, the comparison of %MACE in the FFR-based group and the CDP-based group was one of the primary results of this study. The first methodology used in the subgroup analysis was based on CFR values. It is well documented that abnormally low CFR (< 2.0) values is associated with possible MVD<sup>[23]</sup> and an inability to achieve peak hyperemia. Under this scenario, constant minimal microvascular resistance is not assured, leading to an underestimation of the pressure drop which in turn results in an overestimation of FFR values<sup>[24]</sup>. It is worth noting that in the presence of MVD and submaximal hyperemia, both blood flow as well as pressure drop over the stenosis are affected in a similar manner. Physiologically, the reduction seen in the peak hyperemic blood flow due to MVD dominates over the corresponding reduction effected by ES<sup>[14]</sup>. The formulation of CDP accounts for this effect though the square of the maximal hyperemic flow in the denominator, thus providing improved resolution for accurate evaluation of the status of the stenosis. The results for the %MACE comparisons between the FFR-based strategy and the CDP-based strategy in the study show the improved resolving power for the CDP-based patient group *via* the lower %MACE. However, considering the low rates of MACE and the relatively lower sample size in this study, a prospective randomized trial with larger patient population is required to confirm the outcomes of this pilot study.

Similar to patients with abnormal CFR, patients with diabetes are also associated with potential MVD. Previous studies of the arterioles and small arteries of diabetic patients have indicated functional microvasculature damage evidenced by reduced vasodilation of the coronary arterioles. This could be the result of a decrease in activity of ATP sensitive potassium channels<sup>[25-28]</sup>. As an additional confirmation of our hypothesis, a subsequent analysis was performed on a subgroup consisting of diabetic patients by evaluating and comparing the %MACE outcomes between the FFR-based strategy and the CDP-based strategy. The results indicated a similar trend as in the case of the CFR (< 2.0) based subgroup analysis. Additionally, the comparisons performed for the complete patient group in our previous study<sup>[22]</sup> report

similar results of reduced %MACE outcomes for the CDP group, thereby strengthening the argument that CDP can accurately delineate the status of ES, particularly in the presence of concomitant MVD. Again, these results require further assessment using a prospective randomized clinical trial with larger sample size.

### Survival analysis

Another significant measure which affects the quality of life for patients suffering from cardiovascular disease is long-term event-free survival. Comparisons of the Kaplan-Meier survival curves using the log-rank test were performed between the FFR based group and the CDP based group for both subgroup methodologies discussed above. The results indicated improved long-term event free survival for the CDP-based groups in both the subgroup analyses. Furthermore, the survival curves comparison performed for the complete patient group in our previous study<sup>[22]</sup> indicated a significant improvement in long-term event free survival for the CDP group, lending further strength to the resolving power of CDP in diagnosing the status of ES with concomitant MVD.

### Clinical advantages of CDP

CDP, a non-dimensional parameter based on fundamental fluid dynamics is defined as the ratio of coronary trans-lesional pressure drop ( $\Delta p$ ) to the distal dynamic pressure ( $0.5 \text{ blood density APV}^2$ ) where APV (average peak blood flow velocity) is measured during peak hyperemia. In the presence of increased microvascular resistance, FFR and CFR along an ES are affected in opposite directions. Therefore, ischemic assessment performed by measuring FFR and CFR in such a coronary artery with concomitant diseases might potentially lead to discordant results in up to 40% of the cases<sup>[29]</sup>. A possible explanation would be the presence of diffuse epicardial lesions wherein lower CFR would be observed without notable changes in FFR values. On the other hand, healthy microvasculature and auto-regulatory function could allow for normal CFR values while leading to abnormal FFR values. The complex interaction of pressure and flow seen in such scenarios may not be captured adequately by FFR or CFR alone, since these parameters depend solely on pressure and flow, respectively. In contrast, CDP is a combined physiological parameter derived from fundamental fluid dynamics principles involving both pressure and flow measurements, and can adequately distinguish between ES and MVD<sup>[20]</sup>.

Considering the numerous advantages afforded by CDP, we believe that this parameter has a potentially significant role in modern clinical practice. However, it is worth mentioning that the dual-sensor wires necessary for computing CDP has not become prevalent in catheterization laboratories. Nevertheless, the use of these guidewires is expected to increase with: (1) technological advancement; and (2) mounting evidence of better clinical outcomes. This would make

the measurement of functional diagnostic indices such as CDP standard-of-care with reduced complexities. Several prior studies have validated the clinical application of functional measures such as FFR in treatment of coronary stenosis. These include the DEFER study<sup>[24]</sup>, the FAME trial<sup>[30]</sup> and the FAME 2 trial<sup>[31]</sup>, which confirmed the role of FFR as a guide to management of coronary artery disease. This study proposes CDP as an improved measure over FFR for accurate prediction of major ischemic events as well as long-term event-free survival in the presence of confounding scenarios such as MVD. While statistical significance was not reached, consistent improved outcomes were observed over all the measures. Significant statistical significance in the comparisons may be observed on repeating the analysis for a larger patient group and longer follow-up periods.

### Limitations

All the clinical decisions in this study were made based on FFR values alone. Thus, a larger sample size and a prospective randomized clinical trial is needed. This will allow improved evaluation of the performance of CDP compared to FFR under clinical settings and confirm the patient outcomes of this current cohort study.

In this follow-up pilot study to our earlier clinical trial<sup>[22]</sup>, a subgroup analysis was performed with two subgroups: one consisting of patients exhibiting CFR < 2.0, and the other consisting of diabetic patients. CDP showed moderate but significant correlation with HMR in both the diabetic and CFR < 2.0 subgroups. Comparison of primary (%MACE) outcomes led to lower %MACE in the CDP > 27.9 groups in comparison to the FFR < 0.75 groups for both subgroups, although statistical significance was not reached. Further, event-free survival rates in the CDP > 27.9 group were higher when compared with the FFR < 0.75 group for both subgroups, with the difference being borderline significant for the CFR < 2.0 subgroup. Further clinical trials with a larger patient population and longer follow-up periods could validate the positive trends seen for the CDP group in this study, while proving the efficacy of CDP as a useful clinical endpoint for decision making in the cardiac catheterization laboratory.

## ARTICLE HIGHLIGHTS

### Research background

Accurate assessment of coronary stenosis is an important aspect of interventional cardiology. Although existing functional diagnostic indices such as fractional flow reserve (FFR) and coronary flow reserve (CFR) have been validated extensively via clinical trials, their efficacy is limited in the presence of concomitant microvascular disease (MVD) as they depend solely on pressure or flow measurements. This pilot study explores the efficacy of a combined pressure-flow diagnostic endpoint, pressure drop coefficient (CDP) compared to pressure-based FFR. It was hypothesized that CDP would show better clinical outcomes compared to FFR for patient subgroups with MVD.

### Research motivation

Diagnosis of epicardial stenosis (ES) with concomitant MVD is a challenge with existing diagnostic indices (such as FFR, CFR) as they depend solely on

pressure or flow. Pressure-based FFR can be overestimated in the presence of concomitant MVD, leading to possible misdiagnosis of severity of the stenosis, while CFR cannot differentiate between the effects of the stenosis and MVD. There is a need for combined pressure-flow diagnostic endpoints (such as CDP) to better diagnose coronary stenosis, particularly in the presence of MVD.

### Research objectives

The primary objective of this research was to compare the clinical outcomes of patients with stenosis and possible MVD evaluated using FFR and CDP. Secondly, CDP was correlated with an existing index (HMR) used to evaluate the severity of MVD. CDP showed better clinical outcomes compared to FFR, as well as longer survival times for the patients. Also, CDP showed significant correlation with HMR, validating its efficacy at evaluation of MVD. It is to be noted that larger sample sizes and a randomized clinical trial is required to further confirm the results of this exploratory pilot study.

### Research methods

Patients from our clinical trial was divided into two subgroups with: (1) cut-off of CFR < 2.0; and (2) diabetes. First, correlations were performed for both subgroups between CDP and HMR, a diagnostic parameter for assessing the severity of MVD. Linear regression analysis was used for these correlations. Further, in each of the subgroups, comparisons were made between FFR < 0.75 and CDP > 27.9 groups for assessing major adverse cardiac events (MACE: primary outcome). Comparisons were also made between the survival curves for FFR < 0.75 and CDP > 27.9 groups. Two tailed chi-squared and Fischer's exact tests were performed for comparison of the primary outcomes, and the log-rank test was used to compare the Kaplan-Meier survival curves.  $P < 0.05$  for all tests was considered statistically significant.

### Research results

Significant linear correlations were observed between CDP and HMR for both CFR < 2.0 ( $r = 0.58$ ,  $P < 0.001$ ) and diabetic ( $r = 0.61$ ,  $P < 0.001$ ) patients. In the CFR < 2.0 subgroup, the %MACE (primary outcomes) for CDP > 27.9 group (7.7%, 2/26) was lower than FFR < 0.75 group (3/14, 21.4%);  $P = 0.21$ . Similarly, in the diabetic subgroup, the %MACE for CDP > 27.9 group (12.5%, 2/16) was lower than FFR < 0.75 group (18.2%, 2/11);  $P = 0.69$ . Survival analysis for CFR < 2.0 subgroup indicated better event-free survival for CDP > 27.9 group ( $n = 26$ ) when compared with FFR < 0.75 group ( $n = 14$ );  $P = 0.10$ . Similarly, for the diabetic subgroup, CDP > 27.9 group ( $n = 16$ ) showed higher survival times compared to FFR group ( $n = 11$ );  $P = 0.58$ .

### Research conclusions

CDP correlated significantly with HMR and resulted in better %MACE as well as survival rates in comparison to FFR. These positive trends demonstrate that CDP could be a potential diagnostic endpoint for delineating MVD with or without ES.

### Research perspectives

This study highlights the ability of CDP in delineating MVD in patients with or without ES. In this patient subgroup analysis, CDP showed better clinical outcomes and higher survival rates compared to FFR, which is the current gold standard in functional diagnosis of coronary artery disease. There is a clear need for functional diagnostic endpoints which can better evaluate ES with concomitant MVD. In future, a large scale randomized clinical trial comparing the outcomes of CDP and FFR is required.

## ACKNOWLEDGMENTS

The authors would like to acknowledge Dr. Kranthi Kolli's work in initial data assimilation, Dr. Jason Meunier, Rachel Mardis, and Ginger Conway for their assistance in data assimilation. Further, the authors would like to acknowledge Drs. Leesar and Helmy for the clinical catheterization procedure and data acquisition, as reported in previous publications.

## Abstract

### AIM

To determine endothelin-1 (ET-1) concentration before and after surgical coarctectomy and evaluate its association with left ventricular geometric change.

### METHODS

A prospective, cohort study of 24 patients aged 2 d to 10 years with coarctation of the aorta undergoing surgical repair. A sub-cohort of patients with age < 1 mo was classified as "neonates". Echocardiograms were performed just prior to surgery and in the immediate post-op period to assess left ventricle mass index and relative wall thickness (RWT). Plasma ET-1 levels were assessed at both time points. Association between ET-1 levels and ventricular remodeling was assessed.

### RESULTS

Patients < 1 year demonstrated higher pre-op ET-1 than post-op (2.8 pg/mL *vs* 1.9 pg/mL,  $P = 0.02$ ). Conversely, patients > 1 year had no change in ET-1 concentration before and after surgery (1.1 *vs* 1.4, NS). Pre-op, patients < 1 year demonstrated significantly higher ET-1 than older children (2.8 *vs* 1.1,  $P = 0.001$ ). Post-op there was no difference between the age groups (1.9 *vs* 1.4, NS). Neither RWT nor left ventricle mass index (LVMI) varied from pre-op to post-op. The subset of neonates showed a strong positive correlation between pre-op ET-1 and RWT ( $r = 0.92$ ,  $P = 0.001$ ). Patients with ET-1 > 2 pg/mL pre-op demonstrated higher LVMI (65.7 g/m<sup>2.7</sup> *vs* 38.5 g/m<sup>2.7</sup>,  $P = 0.004$ ) and a trend towards higher RWT (45% *vs* 39%,  $P = 0.07$ ) prior to repair than those with lower ET-1 concentration.

### CONCLUSION

ET-1 concentration is significantly variable in the perioperative period surrounding coarctectomy. Older children and infants have different responses to surgical repair suggesting different mechanisms of activation.

**Key words:** Biomarkers; Cardiac remodeling; Pediatric; Neonate; Left ventricular hypertrophy

**Core tip:** Patients with coarctation of the aorta are at risk for a variety of short- and long-term complications after surgical repair. Endothelin-1 (ET-1) is a peptide hormone known to cause both cardiac myocyte hypertrophy and vasoconstriction that has been linked to late ventricular hypertrophy in this population. Peri-operative endothelin concentration in this population has not been previously defined. We demonstrate that neonates with coarctation of the aorta have high pre-operative ET-1 levels that decrease post-operatively. Older coarctation patients have more modest ET-1 activation that is unchanged post-operatively. These findings suggest two distinct patterns of ET-1 activation within this population.

Endothelin-1 activation in pediatric patients undergoing surgical coarctation of the aorta repair. *World J Cardiol* 2017; 9(12): 822-829 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i12/822.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i12.822>

## INTRODUCTION

Isolated coarctation of the aorta (CoA) is found in 800 of every million live births, approximately 8% of all congenital heart disease<sup>[1]</sup>. Open surgical repair *via* thoracotomy or sternotomy is required for most patients presenting with severe obstruction. Although perioperative mortality is low in the modern era, the post-operative course is frequently complicated by either low cardiac output syndrome or recalcitrant hypertension<sup>[2,3]</sup>. Additionally, these children are at significant risk for long-term complications including persistent hypertension, a hypertensive response to exercise, altered cardiac mechanics, and left ventricular (LV) hypertrophy<sup>[4,5]</sup>.

Vascular and cardiac changes are, in many cases, already present at the time of initial surgery. Pre-operatively, approximately 65% of all children with CoA will have LV hypertrophy and 33% of the subset who are diagnosed as neonates will have evidence of pulmonary hypertension<sup>[6]</sup>. Such echocardiographic evidence of physiologic derangements, present at diagnosis, suggests that there may be early activation of critical pathologic pathways. Better understanding of such pathways and their patterns of activation offers significant promise to understand the mechanisms of disease progression, improve prognostic accuracy, and guide future therapy.

Endothelin-1 (ET-1) is a 21-amino acid vasoactive peptide hormone with endocrine and paracrine effects. Previous mechanistic *in vitro* studies have demonstrated the capacity for ET-1 to cause vasoconstriction in both the pulmonary and systemic vasculature<sup>[7]</sup> as well as cardiac myocyte hypertrophy<sup>[8,9]</sup>. Additionally, a recent study showed increased ET-1 blood concentration was associated with left ventricular hypertrophy in a mouse model of coarctation of the aorta<sup>[10]</sup>. Clinical data in human subjects, however, are quite limited. While ET-1 concentration is increased compared to controls at late follow-up after coarctation repair<sup>[11]</sup>, the clinical implications of this finding are yet to be evaluated. Further, no prior study has assessed either ET-1 concentration or its association with cardiovascular pathology at the time of initial surgery for CoA. While ET-1 activation is not thought to be causative of coarctation of the aorta, defining ET-1 activation in the perioperative period could offer significant insight as a marker of the variable short and long term physiologic responses to coarctation seen in this population.

**Table 1** Demographics *n* (%)

Gender	
Male	17 (70.8)
Female	7 (29.2)

Here we present a prospective, cohort study of ET-1 concentration and pathologic myocardial remodeling both prior to surgical correction of coarctation/aortic arch obstruction and in the immediate post-operative period. We sought to define pre-operative ET-1 activation, perioperative changes in concentrations with surgical relief, and the association with early myocardial change.

## MATERIALS AND METHODS

The Colorado Multiple Institution Review Board approved this study. Written informed consent was obtained from the study subjects' parents in all cases. Written assent was obtained from all subjects aged between seven years and eighteen years.

### Subjects

We prospectively enrolled consecutive subjects (aged 0 to 18 years) undergoing surgical relief of coarctation of the aorta with or without associated transverse arch hypoplasia at Children's Hospital Colorado from September 2015 through January 2017. Exclusion criteria included patients with significant co-morbid heart disease, those with a prior intervention (surgical or trans-catheter) on their aortic arch, and those weighing less than 2 kg, due to limitations in acceptable sample blood volumes for research.

### Clinical data

Clinical information was extracted from the electronic medical record (Epic Systems, Verona, WI). Demographic variables, peri-operative details, and key clinical variables were recorded. Study data were collected and managed using REDCap electronic data capture tools hosted at University of Colorado<sup>[12]</sup>.

### Laboratory data

Blood samples were obtained immediately prior to surgery and between 12-48 h post-operatively. Extracted plasma aliquots were then stored at -80 °C for batch analysis.

ET-1 and B-type natriuretic peptide (BNP) analysis were performed by enzyme-linked immunosorbent assay (ELISA) per manufacturer's recommendations (R and D Systems, Inc. Minneapolis, MN).

### Echocardiographic data

Echocardiograms were obtained immediately prior to surgical repair and between 24 and 72 h post-operatively. All images were obtained with a GE Vivid E9 or E95 machine (General Electric, Chicago, Ill). Relative wall thickness (RWT) was measured at end-diastole from the parasternal short axis view as the ratio of the sum of the posterior and septal mural thickness to the left ventricular internal end-diastolic diameter; a value of 41% is conventionally taken as the upper limit of normal for RWT<sup>[4]</sup>. LV mass was calculated by the area-length (AL) method, indexed to height<sup>2.7</sup>, and compared to previously published normal values<sup>[13,14]</sup>.

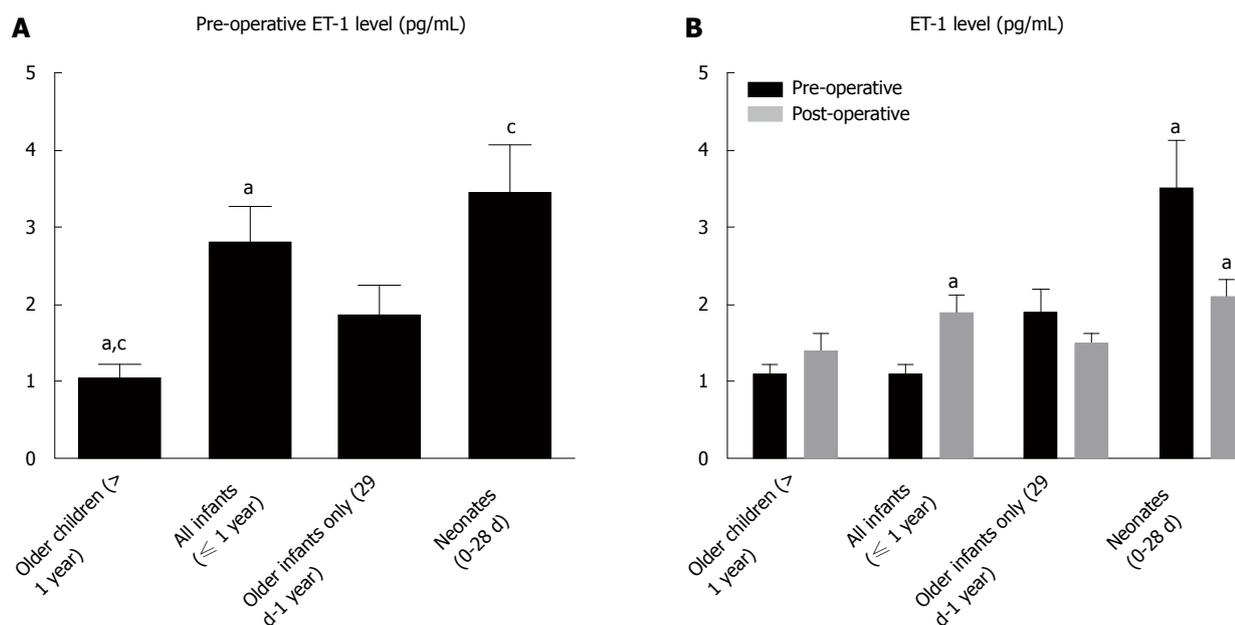

### Statistical analysis

Demographics were summarized using descriptive statistics as indicated by the distribution of the data. Changes in echocardiographic indices were compared using the Signed-Rank test. Pearson's correlation test, two-sample *T*-Test, and general linear modeling compared ET-1 levels among groups and correlation with echocardiographic indices. All the statistical analyses were performed with SAS V9.4. The primary outcome for analysis was change in ET-1 concentration from the pre-operative to the post-operative sample. Other associations were tested as secondary outcomes. Statistician S Tong from University of Colorado, Denver reviewed the statistical methods of this study.

## RESULTS

Twenty-four patients were enrolled in the study. Their demographics and baseline/surgical characteristics are presented in Table 1, represented as median (range) or *n* (%). Five patients, all < 1 mo in age, underwent aortic arch reconstruction on cardio-pulmonary bypass, while the other nineteen underwent coarctectomy by lateral thoracotomy without bypass. Six patients (all in the neonatal cohort) had evidence of a patent ductus arteriosus on echocardiogram and were on prostaglandin infusion at the time of repair. In each of those six patients, ductal flow was right-to-left in systole, indicating that pressure in the pulmonary artery was equal to or greater than pressure in the aorta. One patient was on continuous milrinone. No patient received an endothelin receptor antagonist during the study period.

Clinical presentation varied by age at diagnosis. Five of the neonates were diagnosed prenatally, started on prostaglandin within the first hours of life, and remained stable until repair. Two neonates presented within the first week of life with clinical evidence of decreased systemic perfusion and were medically stabilized before proceeding to operative repair. The patients between one month and one year of life had the greatest variability in

**Figure 1 Serum endothelin-1 concentration.** A: Pre-operative ET-1 concentration by age group; B: Comparison between pre-operative and post-operative levels for each age group. <sup>a,c</sup>*P* < 0.05. Scale bars represent standard deviation. ET-1: Endothelin-1.

clinical presentation, ranging from asymptomatic murmur to symptomatic left ventricular failure with decreased tissue oxygen delivery. Children older than one year were all clinically stable at presentation, referred for right upper extremity hypertension, decreased femoral pulses, or an asymptomatic murmur.

#### Pre-operative ET-1 concentration

Pre-op ET-1 level in our entire cohort was 1.9 pg/mL (Figure 1). Patients < 1-year-old showed significantly higher concentrations when compared to the older cohort. This effect was most pronounced among neonates, who demonstrated the highest levels.

#### Post-operative change in ET-1 concentration

Analysis within age cohorts demonstrated two distinct patterns. Patients < 1-year-old showed an immediate decline in ET-1 level post-op (Figure 1). Conversely, older children demonstrated no significant change between pre-op and post-op. Overall, patients with the highest levels of ET-1 pre-op demonstrated the greatest post-op decline while those with more modest ET-1 concentration pre-op tended to have unchanged levels after repair (Figure 2).

#### B-type natriuretic peptide concentration

For the entire population taken together, BNP concentration followed a right skewed distribution. Median pre-op BNP concentration was 73 pg/mL (upper limit of normal 99 pg/mL, range 21-4915). Neonatal subjects demonstrated significantly higher BNP levels than older children [1752 (30-4915) pg/mL vs 35 (21-74) pg/mL, *P* < 0.0001, represented as median (range)]. Pre-operative BNP was moderately correlated with pre-operative ET-1 (*r* = 0.65; *P* = 0.0002). Post-operatively,

neonatal patients demonstrated a significant decrease in BNP level [1752 (30-4915) pg/mL vs 977 (192-2732) pg/mL, *P* = 0.02] while the concentration was unchanged among older children [35 (21-74) pg/mL vs 161 (124-451) pg/mL, NS]. Post-operative BNP was moderately correlated with post-operative ET-1 (*r* = 0.73; *P* = 0.0001).

#### Echocardiography

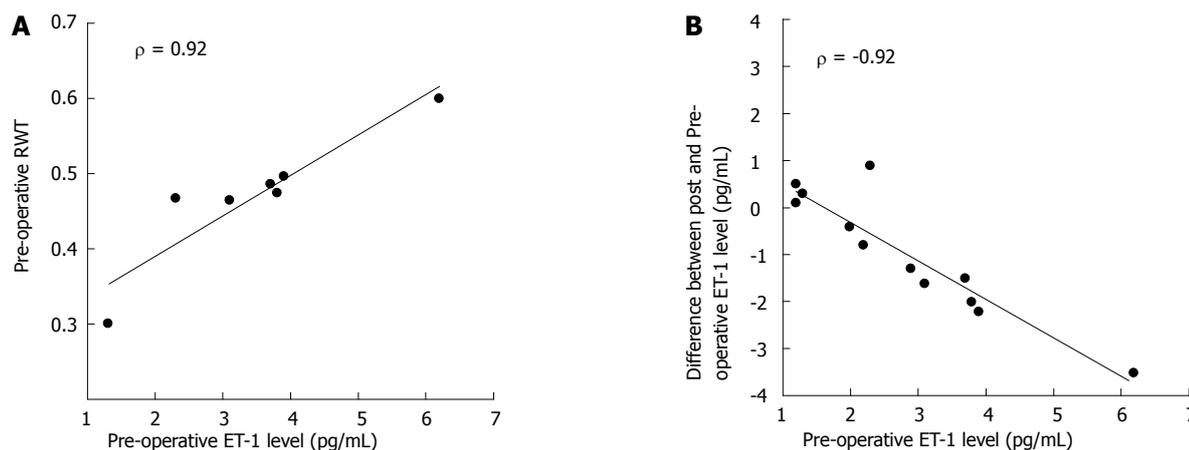

Mean RWT (%) and left ventricle mass index (LVMI) (g/m<sup>2.7</sup>) were increased compared to normal values for all time points (Table 2). As expected, there was no significant change in RWT or LVMI between the pre-op and post-operative echocardiograms. Overall, infants showed higher LVMI compared to older children but no significant difference in RWT.

#### ET-1 as a biomarker of remodeling

Including the entire cohort, RWT and LVMI were compared between patients with lower and higher levels of ET-1. Patients with ET-1 > 2 pg/mL pre-op demonstrated higher LVMI (65.7 g/m<sup>2.7</sup> vs 38.5 g/m<sup>2.7</sup>, *P* = 0.004) and a trend towards higher RWT (45% vs 39%, *P* = 0.07) prior to repair. Additionally, pre-op ET-1 > 2 pg/mL was associated with higher post-op LVMI and RWT. Among the neonatal cohort, pre-operative ET-1 showed a strong positive correlation with post-op RWT (Figure 2).

## DISCUSSION

This study is the first to assess early ET-1 activation and its association with LV remodeling at the time of surgery for coarctation of the aorta. Key findings include increased concentration among neonates preoperatively

**Figure 2 Pre-Operative Endothelin-1 as a predictor.** A: Correlation between pre-operative ET-1 concentration and post-operative RWT in the subset cohort of neonatal patients; B: Correlation between pre-operative ET-1 concentration and change in level from pre-operative to post-operative sample in the full cohort of patients. Points represent individual patients. ET-1: Endothelin-1; RWT: Relative wall thickness.

**Table 2 Echocardiographic markers of left ventricle remodeling prior to and immediately following surgical coarctectomy**

	Subjects	Preop	Posop	P value
Relative wall thickness				
All subjects	24	0.41 (0.09)	0.42 (0.10)	NS
Neonates (0-28 d)	7	0.44 (0.09)	0.47 (0.09)	NS
Infants (29 d-1 yr)	5	0.43 (0.08)	0.40 (0.14)	NS
Children (> 1 yr)	12	0.39 (0.09)	0.39 (0.09)	NS
LV mass index				
All subjects	24	49.4 (24.6)	51.6 (17.5)	NS
Neonates (0-28 d)	7	50.2 (22.3)	57.6 (12.9)	NS
Infants (29 d-1 yr)	5	79.7 (31.1)	72.0 (19.9)	NS
Children (> 1 yr)	12	36.4 (6.3)	39.6 (7.1)	NS

LV: Left ventricle.

with a decline after anatomic correction. This pattern is contrasted with more modest ET-1 level before surgery in older children and no significant post-operative change. Taking all patients together, our population also shows higher levels of ET-1 concentration than previously reported normal controls<sup>[11]</sup>. Similar changes in ET-1 level surrounding anatomic correction of a congenital heart lesion have not previously been described. The variable pattern of ET-1 concentration seen among patients with similar anatomic lesions but different physiologies is also a novel finding.

Increasing evidence suggests that ET-1 activation is regulated in part by pulmonary vascular stress. While data conflict on whether pulmonary artery pressure or pulmonary blood flow is the primary effector, abnormalities in pulmonary vascular physiology are known to associate with alterations in serum ET-1 concentration<sup>[15-18]</sup>. Sub-group analysis of our data supports this relationship. The youngest subset of patients demonstrated the highest pre-operative ET-1 levels; these patients, in addition to manifesting high LV afterload, all demonstrated elevated pressure in the pulmonary arteries due either to ductal dependent systemic blood flow or as an upstream consequence of left atrial hypertension. Those same

patients also had a post-operative decline in ET-1 level associated with the acute physiologic change (rapid normalization of pulmonary hemodynamics). The older children, with isolated high LV afterload physiology that is slower to resolve, experienced no change in ET-1 concentration from pre-op to post-op. The variable activation pattern between neonatal and older patients supports a role for the different pulmonary artery mechanics between the two subgroups affecting the variable ET-1 levels seen.

One potential confounder in the different pre-op to post-op ET-1 patterns described is the role of cardio-pulmonary bypass in post-op ET-1 concentration (a majority of neonates were repaired on bypass while all older children were repaired off pump). However, prior studies of pediatric patients undergoing bypass for the Fontan operation<sup>[19]</sup> and adult patients undergoing bypass for coronary artery bypass grafting<sup>[20]</sup> have demonstrated, on average, higher plasma ET-1 concentrations after bypass. And, the two neonates who underwent coarctectomy without bypass showed the same pattern of ET-1 concentration as the rest of the neonatal cohort. The observation that patients with different pre- and post-op physiologies undergoing bypass have widely variable peri-op ET-1 concentration patterns further supports the conclusion that the peri-op physiology likely plays the dominant role in ET-1 level, rather than bypass alone.

Our data also provide preliminary evidence for a separate pathway of ET-1 regulation associated with LV afterload. All patients in our cohort, including older coarctation subjects with isolated high LV afterload and otherwise normal physiology, have higher ET-1 concentration than previously reported normal controls<sup>[11]</sup>. Previous studies have suggested such a correlation in a similar population, showing increased ET-1 levels compared to controls in hypertensive adults with high afterload physiology<sup>[21]</sup>. One possible driver of ET-1 activation in this group is sympathetic nervous system activation. Norepinephrine, an endogenous catecholamine

and effector of the sympathetic nervous system, is known both to be over-expressed in hypertensive patients<sup>[22]</sup> and to stimulate ET-1 production by the vascular endothelium<sup>[23]</sup>. Given the normal pulmonary hemodynamics in our older cohort and the mechanistic explanation offered by previous work, we posit that the ET-1 levels seen in this sub-group could reflect sympathetic activation due to the abnormality in LV and systemic vascular physiology. Future studies will be needed to confirm this hypothesis.

Individual patients who deviated from the typical clinical presentation for their age cohort provide further evidence for the two distinct mechanisms of ET-1 regulation. A neonate with a severe coarctation, acutely decreased LV function, and normal pulmonary artery pressure developed post-operative low cardiac output syndrome and his function was slow to recover. His ET-1 concentration increased slightly from the pre-operative to post-operative sample, consistent with the pattern typical of older children whose ET-1 level is likely driven by LV stress. An eight month old with severe coarctation, a dilated LV with poor systolic function, and near-systemic pulmonary artery pressure secondary to longstanding LV failure demonstrated rapidly improved pulmonary hypertension and LV function post-operatively. As would be expected, ET-1 activation in this patient more closely mirrored those in the neonatal cohort: Pre-operative ET-1 concentration was quite high and post-operative level was well below the pre-operative value.

Measured BNP concentration follows a similar trend to ET-1 concentration in this patient population. Neonatal patients have higher pre-operative BNP levels than their older counterparts and show a significant post-operative decline. Older children have lower BNP levels (normal in many cases) pre-operatively with no statistical change after surgical correction. These data suggest that neonates and some older infants experience a broad neuro-hormonal activation prior to coarctation repair in response to ventricular and potentially pulmonary artery stress and that surgical repair can result in early reversal of this neuro-hormonal activation in many patients. The specific role of BNP in this pathophysiology is not fully defined, and future studies will be needed to clarify the relationship with ET-1 and other markers of neuro-hormonal activation.

The echocardiographic data provide another layer of evidence for ET-1's potential role in the physiologic response to coarctation. Average LVMI and RWT in our patient population were significantly higher than previously published normal values and did not vary significantly through the perioperative period. This finding supports prior work demonstrating concentric LV remodeling and hypertrophy in the face of chronically high afterload with no immediate resolution following afterload reduction<sup>[6,24,25]</sup>. Mechanistically, animal studies have demonstrated that chronic ET-1 exposure induces cardiomyocyte hypertrophy *via* increased production of Extracellular Signal-Regulated Kinases 1 and 2 (ERK

1/2)<sup>[8,9,26]</sup>. Our data aligns with this finding, as patients with higher levels of ET-1 had more abnormal cardiac geometry. This novel finding combined with a biologically plausible link between ET-1 and myocyte hypertrophy raises the possibility that ET-1 could be not only a useful marker of LV remodeling but potentially an effector as well. Further, longitudinal studies will be needed to evaluate ET-1's role both in myocyte hypertrophy prior to repair and reverse remodeling after surgical correction.

In summary, we conclude that ET-1 concentration is significantly altered in patients with coarctation of the aorta undergoing surgical repair. We find preliminary evidence supporting two potentially distinct stimuli for ET-1: One mechanism, associated with high LV afterload and sympathetic nervous system activation, persists through the immediate post-operative period and the other, likely driven by altered pulmonary artery physiology, is rapidly reversible. We further find preliminary evidence supporting an association between ET-1 activity and early pathologic LV remodeling.

### Limitations

This study is prospective, single center, and targets a relatively rare patient population. As such, statistical power was limited, particularly in sub-cohort analysis. Biological heterogeneity, particularly among patients between 1 mo and 1 year of age, also limited statistical analysis. Therefore, validation of these findings in similar cohorts at other centers will be of great importance. Our study design does not allow for conclusions regarding causality in the relationship between ET-1 level and LV remodeling. Due to the young age of the subject population, control serum samples for ET-1 analysis were not obtained. While historical controls from previous studies were noted for discussion, an ideal comparison including unaffected, age-matched controls will be a goal of future studies. Additionally, small patient size and safety concerns preclude routine direct clinical monitoring of pulmonary artery and left atrial pressure in the perioperative period. While hemodynamic inferences can be drawn from available clinical data, future animal studies will be helpful to directly measure these pressures and more precisely elucidate their role in the physiology described.

## ARTICLE HIGHLIGHTS

### Research background

Patients with coarctation of the aorta are at risk for a variety of short- and long-term complications after surgical repair. Endothelin-1 (ET-1) is a peptide hormone known to cause both cardiac myocyte hypertrophy and vasoconstriction that has been linked to late ventricular hypertrophy in this population. Peri-operative endothelin concentration in this population has not been previously defined.

### Research motivation

Defining ET-1 activation in the perioperative period could offer significant insight into the variable short and long term physiologic responses to coarctation seen in this population.

### Research objectives

The authors sought to define pre-operative ET-1 activation, perioperative changes in concentrations with surgical relief, and the association with early myocardial change.

### Research methods

Here authors present a prospective, cohort study of ET-1 concentration and pathologic myocardial remodeling both prior to surgical correction of coarctation/aortic arch obstruction and in the immediate post-operative period. ET-1 analysis was performed by ELISA. Echocardiograms were obtained immediately prior to surgical repair and between 24 and 72 h post-operatively. All images were obtained with a GE Vivid E9 or E95 machine (General Electric, Chicago, Ill). Relative wall thickness (RWT) was measured at end-diastole from the parasternal short axis view as the ratio of the sum of the posterior and septal mural thickness to the left ventricular internal end-diastolic diameter; a value of 41% is conventionally taken as the upper limit of normal for RWT. LV mass was calculated by the area-length (AL) method, indexed to height<sup>2.7</sup>, and compared to previously published normal values.

### Research results

The authors demonstrate that neonates with coarctation of the aorta have high pre-operative ET-1 levels that decrease post-operatively. Older coarctation patients have more modest ET-1 activation that is unchanged post-operatively.

### Research conclusions

This study is the first to assess early ET-1 activation and its association with LV remodeling at the time of surgery for coarctation of the aorta. Key findings include increased concentration among neonates preoperatively with a decline after anatomic correction. This pattern is contrasted with more modest ET-1 level before surgery in older children and no significant post-operative change. The authors find preliminary evidence supporting two potentially distinct stimuli for ET-1: One mechanism, associated with high LV afterload and sympathetic nervous system activation, persists through the immediate post-operative period and the other, likely driven by altered pulmonary artery physiology, is rapidly reversible. The authors further find preliminary evidence supporting an association between ET-1 activity and early pathologic LV remodeling.

### Research perspectives

Longitudinal studies will be needed to evaluate ET-1's role both in myocyte hypertrophy prior to repair and reverse remodeling after surgical correction. Given the normal pulmonary hemodynamics in the author's older cohort and the mechanistic explanation offered by previous work, the authors posit that the ET-1 levels seen in this sub-group could reflect sympathetic activation due to the abnormality in LV and systemic vascular physiology. Future studies will be needed to confirm this hypothesis. The variable activation pattern between neonatal and older patients supports a role for the different pulmonary artery mechanics between the two subgroups affecting the variable ET-1 levels seen. Further studies will be needed to clarify the role of pulmonary artery pressure and pulmonary blood flow on ET-1 concentration.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the Children's Hospital Colorado Core Laboratory and specifically Mary Harrington, MTASCP who performed the ET-1 ELISAs for all study samples. The authors would also like to acknowledge the University of Colorado Hospital Core Laboratory and specifically Karen Morgenthaler, MTASCP who performed the BNP ELISAs for all study samples.

### Abstract

#### AIM

To assess safety and efficacy of early erythropoietin (Epo) administration in patients with out-of-hospital cardiac arrest (OHCA).

#### METHODS

A systematic literature search was performed using PubMed, MEDLINE, EMBASE, EBSCO, CINAHL, Web of Science and Cochrane databases, of all studies published from the inception through October 10, 2016. Inclusion criteria included: (1) Adult humans with OHCA and successful sustained return of spontaneous circulation; and (2) studies including mortality/brain death, acute thrombotic events as their end points. Primary efficacy

outcome was "brain death or Cerebral Performance Category (CPC) score of 5". Secondary outcomes were "CPC score 1, and 2-4", "overall thrombotic events" and "acute coronary stent thrombosis".

### RESULTS

We analyzed a total of 606 participants ( $n = 276$  received Epo and  $n = 330$  with standard of care alone) who experienced OHCA enrolled in 3 clinical trials. No significant difference was observed between the Epo and no Epo group in brain death or CPC score 5 (OR = 0.77; 95%CI: 0.42-1.39), CPC score 1 (OR = 1.16, 95%CI: 0.82-1.64), and CPC score 2-4 (OR = 0.77, 95%CI: 0.44-1.36). Epo group was associated with increased thrombotic complications (OR = 2.41, 95%CI: 1.26-4.62) and acute coronary stent thrombosis (OR = 8.16, 95%CI: 1.39-47.99). No publication bias was observed.

### CONCLUSION

Our study demonstrates no improvement in neurological outcomes and increased incidence of thrombotic events and acute coronary stent thrombosis in OHCA patients who were treated with Epo in addition to standard therapy.

**Key words:** Erythropoietin; Thrombosis; Cardiac arrest; Cardiopulmonary resuscitation

**Core tip:** This manuscript suggested that: (1) No improvement in neurological outcomes with erythropoietin (Epo) administration after out of hospital cardiac arrest; and (2) Epo administration was also associated with increased thrombotic events and acute stent thrombosis.

Chaudhary R, Garg J, Krishnamoorthy P, Bliden K, Shah N, Agarwal N, Gupta R, Sharma A, Kern KB, Patel NC, Gurbel P. Erythropoietin therapy after out-of-hospital cardiac arrest: A systematic review and meta-analysis. *World J Cardiol* 2017; 9(12): 830-837 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i12/830.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i12.830>

## INTRODUCTION

Patients who undergo out-of-hospital cardiac arrest (OHCA) frequently have post-anoxic encephalopathy, even after successful initial resuscitation. This brain insult can be either transient or definitive, and is the major cause of mortality<sup>[1]</sup>. Even after successful resuscitation and restoration of cerebral perfusion, brain injury continues to progress due to reperfusion injury. At present, apart from targeted therapeutic hypothermia, no other modalities have demonstrated a reduction in cerebral anoxic brain ischemia after OHCA<sup>[2,3]</sup>. In

recent years, pre-clinical studies have suggested tissue protective effects of erythropoietin (Epo) and its analogues especially after brain and myocardial damage from ischemia-reperfusion injury<sup>[4,5]</sup>. However, this did not translate into a significant clinical benefit in patients with either acute myocardial infarction or stroke<sup>[6-8]</sup>. In the setting of OHCA, there is whole body ischemia and clinical studies have shown conflicting results with 2 studies demonstrating mortality benefit with early Epo administration<sup>[9,10]</sup> and a recent randomized controlled trial with no significant benefit<sup>[11]</sup>. In view of these studies, we aim to perform a meta-analysis to assess for any significant mortality benefit of early Epo administration in patients with OHCA.

## MATERIALS AND METHODS

The present review was performed according to Cochrane Collaboration and Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statements<sup>[12]</sup>.

### Search strategy

We carried out a literature search using PubMed, MEDLINE, EMBASE, EBSCO, CINAHL, Web of Science and Cochrane databases, of all studies published from the inception through October 10, 2016 comparing early Epo administration in addition to standard care in patients with OHCA with standard care alone. We combined the terms ("out of hospital cardiac arrest" OR "cardiac arrest" OR "OHCA") AND ("erythropoietin" OR "EPO") as keywords or medical subject heading terms in different combinations. All references of the retrieved articles were reviewed for further identification of potentially relevant studies. The identified studies were systematically assessed using the inclusion and exclusion criteria described below.

The studies had to fulfill the following criteria to be included in the analysis: (1) adult human subjects with OHCA and successful sustained return of spontaneous circulation (ROSC); and (2) studies including mortality/brain death, acute thrombotic events as their end points. All studies with retrospective design, abstracts, case reports, conference presentations, editorials, reviews, and expert opinions were excluded from our analysis. Longest available follow-up data from individual studies was used for our analysis.

### Data extractions and quality appraisal

Two authors (Rahul Chaudhary and Jalaj Garg) searched the studies and extracted the data independently and in duplicate. The abstractors (Jalaj Garg and Rahul Chaudhary) independently assessed the quality items, and any discrepancies were resolved by discussion and consensus with the third author (PK). Final results were reviewed by senior investigator (NP) (Figure 1).

Assessment of risk of bias for each selected study was performed according to PRISMA 2009 guidelines.

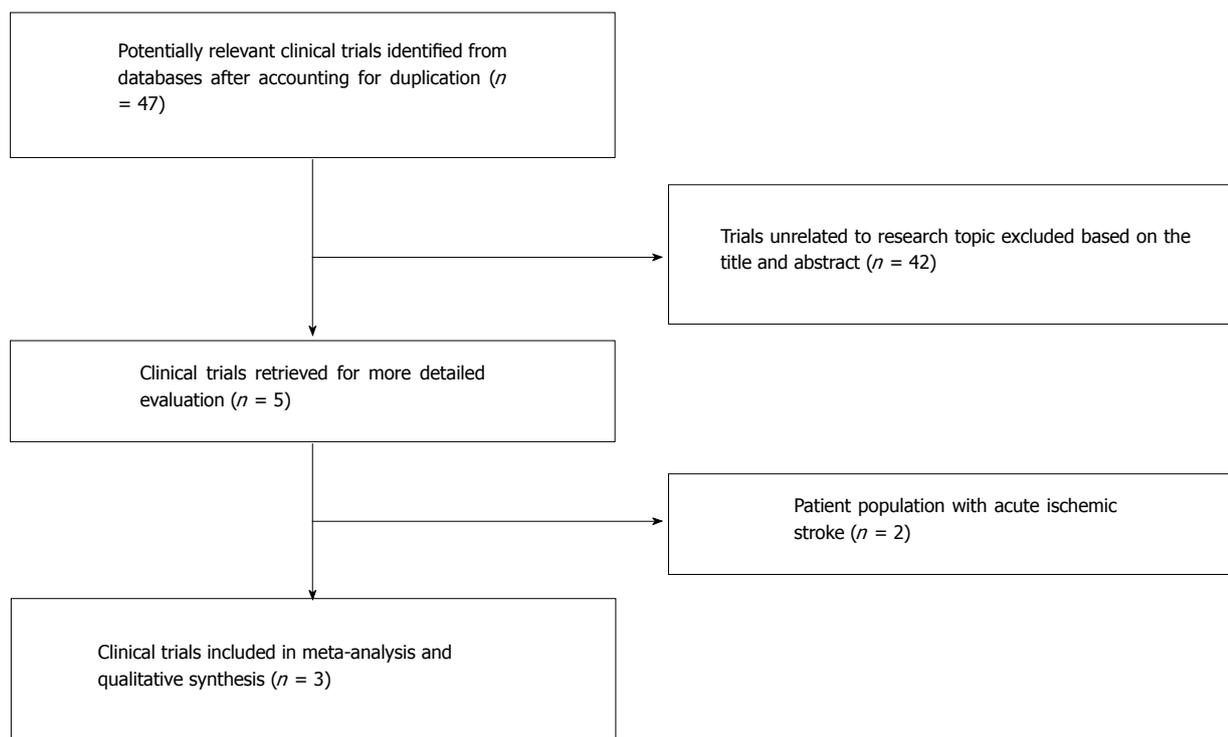

Figure 1 Process of study selection for randomized and prospective trials (PRISMA Statement).

Qualitative evaluation of bias using the following key parameters were performed for each study: (1) clear definition of study population; (2) clear definition of outcomes and outcome assessment; (3) independent assessment of outcome parameters; (4) sufficient duration of follow-up; (5) selective loss during follow-up; and (6) important confounders and prognostic factors identified. The quality of non-randomized studies were evaluated using the Newcastle-Ottawa quality assessment scale<sup>[13]</sup> and randomized controlled trials were evaluated using Cochrane Risk of Bias tool.

### Outcomes

The primary efficacy outcome in our study was "brain death or Cerebral Performance Category (CPC) score of 5". Briefly, the CPC scale ranges between 1 and 5. A score of 1 represents good cerebral performance or minor disability, 2 moderate disability, 3 severe disability, 4 coma or vegetative state, and 5 represent brain death<sup>[14]</sup>. Secondary outcome assessed in our study were "CPC score 1 and 2-4", "overall thrombotic events" (defined as a combination of venous thrombosis, acute coronary stent thrombosis and other arterial thrombosis) and "acute coronary stent thrombosis".

### Statistical analysis

Descriptive statistics are presented as means and SDs for continuous variables and as number of cases and percentages for dichotomous and categorical variables. Data were summarized across treatment arms using the Mantel-Haenszel odds ratio (OR) fixed effects model. Between-study heterogeneity was analyzed by means of

Higgins  $I^2$  statistic<sup>[15]</sup>. In cases of heterogeneity (defined as  $I^2 > 25\%$ ), random effects models of DerSimonian and Laird were used<sup>[16]</sup>. Funnel plot were evaluated visually to assess for any publication bias<sup>[17]</sup>. If any bias was observed, further bias quantification was measured using the Begg-Mazumdar Test<sup>[18]</sup>, Egger Test<sup>[19]</sup> and Duval-Tweedie test<sup>[20]</sup>. The statistical analysis was performed using the Cochrane Collaborative software, RevMan 5.3.

## RESULTS

A total of 47 studies were identified after exclusion of duplicate or irrelevant references (Figure 1). After detailed evaluation, 3 clinical trials (2 case-controlled studies and 1 randomized controlled study) with a total of 606 patients (276 patients received Epo in conjunction to standard of care compared to 330 patients with standard of care alone) were included in our analysis<sup>[9-11]</sup>. The characteristics of these trials and mean follow-up periods are described in Table 1.

### Quality assessment and publication bias

Overall, there were clear definitions of the study population, outcomes, and assessment in the component studies. The quality assessment of individual trials is listed in Table 2. Funnel plots did not reveal publication bias for comparison of CPC score 5 and CPC score 1-4 (Figure 2).

### Baseline characteristics

In the participant studies, there were no significant

Allocation concealment (selection bias)	Low risk	Quote: "Randomization was performed centrally with the use of a computer-generated assignment sequence Intervention assignments were made in permuted blocks of varying size and were stratified according to site"
Blinding of participants and personnel (performance bias)	High risk	Comment: Probably done Quote: "Single-blinded"; "physicians performing neurological follow-up and final outcome measurement, as well as study administrators and statisticians, were unaware of the intervention assignments" Comment: Probably done. However, only single blinding performed
Blinding of outcome assessment (detection bias) (patient-reported outcomes)	Low risk	Quote: "Single-blinded"
Blinding of outcome assessment (detection bias) (mortality)	Low risk	Comment: Probably done Obtained from medical records; Quote "CPC was assessed by face-to-face contact with patients still hospitalized, and through phone interviews in discharged patients using a standardized protocol"
Incomplete outcome data addressed (attrition bias) (Longer-term outcomes, > 6 wk)	Low risk	Review authors do not believe this will introduce bias 60 d: 1/234 missing from intervention group ("lost to follow-up"); 0/242 missing from control group
Selective reporting (reporting bias)	Low risk	A single scale to assess neurological outcomes was used and reported (CPC score)

differences between the two groups in terms of age, gender, and initial rhythm (pulseless electrical activity or asystole and ventricular fibrillation or ventricular tachycardia). No significant heterogeneity was observed (Table 3). The mean age of our study population was 59.1 years (range 58 to 60.5 years) with 80% males.

In the component studies, standard of care included use of therapeutic hypothermia immediately upon ICU admission (or continued if initiated pre-hospital) using external or internal cooling during the first 24 h in order to obtain a target temperature between 32 °C and 34 °C. Normothermia between 37 °C and 37.5 °C

**Figure 2 Forest plot demonstrating the primary and secondary outcomes in patients with out of hospital cardiac arrest who received erythropoietin compared to no erythropoietin group. was then achieved using passive rewarming and maintained for the next 48 h. In patients with a high suspicion of acute coronary syndrome as the cause of OHCA, coronary angiograms were performed at hospital admission and followed by immediate percutaneous coronary interventions (PCIs) when indicated. Vaso-pressor agents were used, when indicated to keep the

mean arterial blood pressure above 65 mmHg.

**Summary of results from individual trials**

In the first clinical trial evaluating use of Epo, in addition to standard therapy, for patients with OHCA, Cariou *et al*<sup>[9]</sup> showed a non-significant improvement in survival rates (55% vs 47.5%,  $P = 0.17$ ) and rates of full

**Table 3** Baseline demographics of study population

Baseline characteristic	Epo	No Epo	n	Studies (n)	P for overall effect
Age, yr	59.5	58.9	606	3	0.22
Males, %	79.2	81.4	606	3	0.93
Initial rhythm PEA/asystole, %	33.8	32.2	606	3	0.85
Initial rhythm VF/VT, %	62.7	63.3	606	3	0.45

Epo: Erythropoietin; PEA: Pulseless electrical activity; VF: Ventricular fibrillation; VT: Ventricular tachycardia.

neurological recovery (55% vs 37.5%,  $P > 0.05$ ) in a case-control study of 58 patients ( $n = 18$  in Epo group and  $n = 40$  in control group)<sup>[9]</sup>. In 2009, Grmec *et al*<sup>[10]</sup> showed an association of early Epo administration in patients with OHCA with higher incidence of return of spontaneous circulation (92% vs 71%,  $P = 0.06$ ), 24-h survival (83% vs 52%,  $P = 0.01$ ) and hospital survival (54% vs 31%,  $P = 0.06$ ) in a study of 72 patients ( $n = 24$  in Epo group and  $n = 48$  in control group). After adjustment for pretreatment covariates all the above-mentioned outcomes were statistically significant<sup>[7]</sup>. In 2016, Cariou *et al*<sup>[11]</sup> performed a large-scale multicenter, single blind, randomized controlled trial (RCT), of 476 patients followed for a period of 60 d. They demonstrated no improvement in neurological outcomes (CPC score 1 in patients in Epo group 32.4% vs 43.1% in no Epo group; OR = 1.01, 95%CI: 0.68-1.48) and reported no differences between the mortality rate and proportion of patients in each CPC level between the two groups at any time points. Additionally, they observed a higher incidence of more serious adverse events with Epo administration compared to controls (22.6% vs 14.9%;  $P = 0.03$ ), particularly thrombotic complications (12.4% vs 5.8%;  $P = 0.01$ )<sup>[11]</sup>.

### Primary outcomes

Brain death or CPC score of 5 was observed in 55% (153/276) of patients in Epo group compared to 57% (190/330) in control with no significant difference between the two groups (OR = 0.77; 95%CI: 0.42-1.39;  $I^2 = 43%$ ) (Figure 2A).

### Secondary outcomes

No significant differences were observed between the Epo and No Epo group with CPC scores 1 (34% vs 31% respectively, OR = 1.16, 95%CI: 0.82-1.64;  $I^2 = 22%$ ), and CPC score 2-4 (9% vs 11% respectively; OR = 0.77, 95%CI: 0.44-1.36;  $I^2 = 0%$ ) (Figure 2B).

Erythropoietin therapy was associated with a significant increase in overall thrombotic events (12% vs 5% for Epo and control group respectively; OR = 2.41, 95%CI: 1.26-4.62;  $I^2 = 0%$ ) and acute coronary stent thrombosis (3% vs 0.3% for Epo and control group respectively; OR = 8.16, 95%CI: 1.39-47.99;  $I^2 = 0%$ ) (Figure 2C).

## DISCUSSION

To best of our knowledge, this is the first meta-analysis

comparing early use of Epo in conjunction to standard therapy with standard therapy alone in patients with out-of-hospital cardiac arrest. The major findings in our study are as follows: (1) Epo plus standard therapy was not associated with any improved neurologic recovery (brain death, *i.e.*, CPC score 5, CPC score 1-4); and (2) Epo plus standard therapy was significantly associated with increased incidence of overall thrombotic complications and acute coronary stent thrombosis.

Use of Epo as a neuroprotective agent emerged from animal models demonstrating Epo induced neuronal and vascular protection from ischemia-reperfusion injury<sup>[4,21]</sup>. Although promising, these results did not translate into improvement in clinical outcomes in patients with ischemic stroke or acute MI<sup>[6-8]</sup>. In 2008, Cariou *et al*<sup>[9]</sup> reported the first clinical study evaluating early use of Epo plus standard therapy in patients with OHCA. This study demonstrated encouraging results with a higher rate of full neurological recovery in Epo treated patients (55% vs 37.5%) with no significant difference mortality benefit. Similarly, Ehrenreich *et al*<sup>[7]</sup>, in 2009 observed higher incidence of return of spontaneous circulation, 24-h survival and hospital survival with early administration of Epo in patients with OHCA. However, both these studies were case-control, single centered and non-randomized with a small patient population. Recently, Cariou *et al*<sup>[11]</sup> performed a large-scale multicenter, single blind, randomized controlled trial (RCT), which did not show any improvement in neurological outcomes with early administration of Epo. The results in our study are consistent with this recent RCT and other major RCTs evaluating the role of Epo in a similar setting, *i.e.*, acute MI and acute ischemic stroke<sup>[6-8]</sup>. The discrepancy between animal and human studies could be due to inter-species variability in action of Epo and mechanism of neurological injury<sup>[11]</sup>.

In addition, our study demonstrated an increased incidence of overall thrombotic events and acute coronary stent thrombosis. In prior studies, Epo has been associated with increased thrombotic events including stent thrombosis in patients treated for cancer associated anemia<sup>[22]</sup> and acute myocardial infarction<sup>[6]</sup>. The underlying mechanisms involved with increased thrombogenicity with Epo in patients with OHCA remains unclear. Several mechanism have been proposed to explain stent thrombosis in patients undergoing therapeutic hypothermia - impaired drug metabolism and reduced bioavailability<sup>[23,24]</sup>, increased platelet

activation<sup>[25]</sup>, ineffective platelet inhibition, hypothermia induced mast cell degranulation<sup>[26]</sup>. In a recently published article from our group, we demonstrated no statistical significant difference in stent thrombosis in patients undergoing therapeutic hypothermia<sup>[27]</sup>. Also, Epo or its analogues have not been shown to enhance platelet activation<sup>[28]</sup> or activation of coagulation factors<sup>[29]</sup>. Thus it is possible increased thrombotic events in the Epo arm may be due to additional factors that were not accounted in our study (*i.e.*, erythropoietin induced increase in blood viscosity, vasoconstriction and elevated blood pressure<sup>[22,30]</sup>, timing of dual antiplatelet therapy, hemodynamic circulatory support, presence of congestive heart failure, cardiogenic shock and number of stents)<sup>[27]</sup>.

A major limitation of the current meta-analysis includes paucity of data from RCT's - with data from 2 case-controlled studies and only 1 RCT with a small patient population. Despite, differences in trials design, no significant heterogeneity was observed.

In conclusion, this study demonstrates no improvement in neurological outcomes and increased incidence of thrombotic events and acute coronary stent thrombosis in OHCA patients who were treated with Epo in addition to standard therapy.

## ARTICLE HIGHLIGHTS

### Research background

Patients with out-of-hospital cardiac arrest (OHCA) frequently have post-anoxic encephalopathy, even after successful initial resuscitation. This brain insult can be either transient or definitive, and is the major cause of mortality. Even after successful resuscitation and restoration of cerebral perfusion, brain injury continues to progress due to reperfusion injury.

### Research motivation

In the setting of OHCA, there is whole body ischemia and clinical studies have shown conflicting results with 2 studies demonstrating mortality benefit with early Erythropoietin (Epo) administration and a recent randomized controlled trial with no significant benefit. In view of these studies, the authors aim to perform a meta-analysis to assess for any significant mortality benefit of early Epo administration in patients with OHCA.

### Research objectives

The primary efficacy outcome in this study was "brain death or Cerebral Performance Category (CPC) score of 5". Secondary outcomes assessed in this study were "CPC scores 1 and 2-4", "overall thrombotic events" and "acute coronary stent thrombosis".

### Research methods

A systematic literature search was performed using PubMed, MEDLINE, EMBASE, EBSCO, CINAHL, Web of Science and Cochrane databases, of all studies published from the inception through October 10, 2016. The included trials were evaluated for publication bias and data summarized across treatment arms using the random effects model as odds ratio (OR).

### Research results

No significant differences were observed between the two groups in brain death or CPC score of 5 (OR = 0.77; 95%CI: 0.42-1.39;  $I^2 = 43\%$ ), CPC score 1 (OR = 1.16, 95%CI: 0.82-1.64;  $I^2 = 22\%$ ), and CPC score 2-4 (OR = 0.77, 95%CI: 0.44-1.36;  $I^2 = 0\%$ ). Epo therapy was associated with a significant increase in overall thrombotic events (OR = 2.41, 95%CI: 1.26-4.62;  $I^2 = 0\%$ ) and acute coronary stent thrombosis (OR = 8.16, 95%CI: 1.39-47.99;  $I^2 = 0\%$ ).

## Research conclusions

This study demonstrates no improvement in neurological outcomes and increased incidence of thrombotic events and acute coronary stent thrombosis in OHCA patients who were treated with Epo in addition to standard therapy.

## Research perspectives

Epo administration in patients with OHCA demonstrated an increase in adverse events with no mortality benefit in addition to current standard of care. Based on the currently available literature and this systematic review, further studies are needed in order to assess the safety and efficacy of Epo in Out-Of-Cardiac-Arrest patients.

### Abstract

We present a case of a patient who presented with chest pain, and on diagnostic coronary angiography appeared to have a grossly angulated yet significant coronary stenosis. This was proven to be an artefactual appearance on further assessment with intravascular ultrasound imaging. We describe the causes and associations of coronary tortuosity with other arteriopathy, and highlight challenges in the interpretation of tortuous vessels to accurately assess luminal narrowing and suitability for coronary intervention. We describe a case of artefactual coronary stenosis, and its thorough assessment with intravascular ultrasound. A literature review describes the pathogenesis of coronary tortuosity, and links with other cardiovascular disease. Readers will gain an understanding of the challenge in determining the severity of luminal stenosis based on coronary angiography alone in tortuous coronary anatomy, the use of intravascular ultrasound in this setting, and the allied vasculopathies of interest.

**Core tip:** Coronary arteries are inherently tortuous, and are assessed at angiography, compressing a 3D structure into a 2D picture. An overly tortuous artery may resemble true luminal stenosis, rather than mere angulation, and may be interpreted as a significant coronary stenosis. We present a remarkably angulated coronary artery, which appeared to bear a significant stenosis. On further assessment with pressure wire study and intravascular ultrasound we found there to be no significant lesion. We demonstrate an artefactual false-positive finding, and describe our clinical approach to avoid mistaking such a lesion for one that requires intervention, with a review of

the literature.

## INTRODUCTION

Coronary artery tortuosity poses many challenges in its assessment and further investigation. We present a case with ambiguous appearances at coronary angiography, clarified with intravascular imaging, and discuss the possible underpinning causes to consider when evaluating a tortuous epicardial artery.

## CASE REPORT

An 80-year-old Caucasian hypertensive patient presented with atypical chest discomfort that was present both at rest and on exercise. She had no cardiovascular risk factors. She was normotensive, with BP 126/72, and heart rate 70. Her ECG was normal. Transthoracic echocardiography demonstrated preserved left ventricular function. A coronary angiogram appeared to show a severe lesion in the proximal left anterior descending coronary artery, at its origin (Figure 1). She underwent a pressure wire study to this territory, to confirm its significance, with plans to carry out further intracoronary imaging to determine whether percutaneous intervention was feasible in view of the lesion's ostial location and extreme angulation.

The pressure wire study was repeatedly negative, with instantaneous wave-free ratio of 0.97 and fractional flow reserve of 0.92 at maximal hyperaemia with systemic adenosine. Intravascular ultrasound demonstrated a normal calibre vessel throughout, with no significant atheroma seen (Video 1), contrary to the angiographic profile of the vessel.

## DISCUSSION

Arteries are rarely straight, and a degree of curvature is inevitable in their path from the heart to distal tissue beds. Angulated or widespread coronary tortuosity is often seen, though its relevance is dependent on the context in which it is found, with coexistent congenital diseases and the possibility of an artefactual appearance, as described here, complicating interpretation.

### **Degenerative coronary tortuosity**

An inordinate degree of tortuosity has been observed in ageing, hypertension, diabetes mellitus and atherosclerosis, where it may be seen in all arterial vessels, from aorta to arteriole, and throughout the venous system. Arterial tortuosity may be quantified by a number of

tortuosity indices, which in general assimilate the number of curvatures of an artery away from its overall direction of travel, measured in end-diastole. Though arterial curvature is usually benign, severe tortuosity may impede blood flow in coexistent atherosclerotic disease, embolus or systemic hypoperfusion predisposing to end organ ischaemia<sup>[1]</sup>.

### **Heritable syndromes with arterial tortuosity**

Degenerative arterial tortuosity is distinct from a group of inherited arteriopathies. Extreme arterial tortuosity has been seen in a number of congenital syndromes, including Loeys-Dietz syndrome, with genetic mutations of the transforming growth factor- $\beta$  receptor, Marfan Syndrome, affecting fibrillin-1, and Arterial Tortuosity Syndrome, with mutation of the SLC2A10 gene. The underlying mechanism for the effects of these deletions is unclear. They manifest as gross, diffuse arterial sinuosity affecting coronary, great vessels, carotid and vertebral arteries, and are associated with cerebrovascular infarct or aneurysm, aortic dissection and adverse overall cardiovascular outcomes<sup>[2]</sup>.

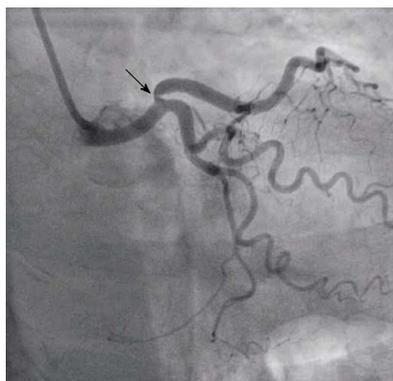

### **Cardiovascular events in patients with coronary tortuosity**

In a prospective study of coronary tortuosity in 1010 patients presenting for diagnostic coronary angiography, the incidence of epicardial coronary artery tortuosity appears to be higher in females, and its presence was correlated with hypertension yet negatively correlated with hyperlipidaemia, smoking and atherosclerosis. No significant difference was seen in major adverse cardiovascular events over a 4 year follow-up period between those with or without coronary tortuosity<sup>[3]</sup>. Conversely tortuous microvessels induce increased shear forces on blood transiting through its conduit, inducing platelet activation. This is thought to be thrombogenic, with higher mural thrombus and platelet activation seen in preclinical modelling of tortuous arterioles<sup>[4]</sup>.

There appears to be an underlying genetic cause linking a continuum of arterial phenotypes from coronary tortuosity, *via* fibromuscular dysplasia and culminating in spontaneous coronary artery dissection (SCAD) with myocardial infarction. Patients with SCAD have been observed to have a high prevalence of coronary tortuosity, and this is higher still in those with recurrent SCAD. Fibromuscular dysplasia is associated with SCAD, with a recent report of *SMAD3* gene deletion underpinning a presentation of SCAD<sup>[5-7]</sup>.

### **Challenges of assessing coronary atherosclerosis in arterial tortuosity**

Native tortuosity of an epicardial coronary artery may resemble a significant luminal stenosis when straightened through passage of a guidewire. The guidewire induces a linear shape to a conduit that is normally curved, and there is invagination of the redundant tissue which impinges on the vessel lumen. This appearance disappears when the

**Figure 1 Artefactual angulated lesion on angiography.** The coronary angiogram, shown here in the AP caudal view, appears to demonstrate a significant lesion in the proximal left anterior descending coronary artery (arrow). There was no significant impediment to flow on pressure wire study, with no significant lesion seen on intravascular ultrasound.

guidewire is retracted and the natural curvature of the vessel is restored, confirming an artefactual stenosis. This has been termed the “accordion effect”. The right coronary artery has scant surrounding tissue in the atrioventricular groove in comparison to the left coronary system, and is thought to be particularly prone to this appearance with instrumentation<sup>[8]</sup>. Our case demonstrates a normal vessel lumen that appears to resemble coronary stenosis on angiographic views due to its angulation.

We demonstrate the importance of intravascular imaging in excluding a significant atherosclerotic process. The use of intravascular ultrasound has previously been described as a gold standard test, above coronary angiography, in clarifying the course of a segment of ambiguous coronary anatomy and its relationship with other vessels<sup>[9]</sup>. However these measurements are reliant on the passage of a guidewire through a curved artery, and care must be taken in intracoronary measurements in tortuous vessels. Coronary tortuosity has recently been described as a potential cause of foreshortening of vessel length in Optical Coherence Tomography (OCT), and overestimation of vessel diameter by up to 12%, due an eccentric position of the OCT catheter in a nonlinear segment of vessel, and/or the straightening effect and movement of redundant tissues as seen with the accordion effect. This effect was minimised by using a floppy rather than a stiff guidewire in this OCT study<sup>[10]</sup>.

We conclude that the appearances of severe coronary stenosis in this angulated and tortuous vessel is an artefactual appearance, which was proven to have neither arteriosclerosis nor significant intraluminal narrowing on further assessment. This case highlights the importance of multimodality assessment of tortuous vessels, where luminal stenosis may be overestimated by coronary angiography. The accordion effect at coronary angiography, and underestimation of vessel length with overestimation of vessel diameter at intracoronary imaging, require careful interpretation of data for correct diagnosis. The links between coronary tortuosity and other arteriopathies are currently the

subject of investigation, with a possible underpinning genetic aetiology.

## ARTICLE HIGHLIGHTS

### Case characteristics

The patient described atypical exertional chest pain, with no prior cardiovascular risk factors.

### Clinical diagnosis

Coronary angiography initially appeared to demonstrate a severe lesion in the proximal left anterior descending coronary artery, which was demonstrated to be a false positive finding in an angulated artery with no significant coronary stenosis, through further physiological and anatomical testing.

### Differential diagnosis

Further assessment of a lesion of this nature may be carried out using functional assessment, with a pressure wire study, or anatomical assessment, with intravascular ultrasound, as demonstrated here.

### Imaging diagnosis

The authors used intravascular ultrasound to demonstrate a normal calibre of coronary artery. An alternative modality of optical coherence tomography may be used.

### Treatment

The above approach identified a false positive finding of possible coronary stenosis, which when ruled out prevented inappropriate treatment with a coronary artery stent.

### Related reports

The authors describe the aetiology of coronary angulation, which may be degenerative or heritable, and though epicardial tortuosity has not been shown to be associated with an increase in major adverse cardiovascular events an association with spontaneous coronary artery dissection, and the potential for misinterpretation of angulation as luminal stenosis, are important considerations when assessing lesions.

### Experiences and lessons

The authors learned the importance of multimodality assessment of apparent coronary lesions to justify, and subsequently rule out, the need for intervention in a case of marked coronary artery curvature, and present an approach to prevent mis-interpretation.

### Abstract

Patients with critical limb ischemia necessitate immediate intervention to restore blood flow to the affected limb. Endovascular procedures are currently preferred for these patients. We describe the case of an 80-year-old female patient who presented to our department with ischemic rest pain and ulceration of the left limb. The patient had history of left femoral popliteal bypass surgery, femoral thromboendarterectomy and patch angioplasty of the same limb 2 years ago. Doppler sonography and magnetic resonance angiography revealed an occlusion of the left superficial femoral artery (SFA) and popliteal artery and of all three infra-popliteal arteries. Due to severe comorbidities, the patient was scheduled for a digital subtraction angiography. An antegrade approach was first attempted, however the occlusion could not be passed. After revision of the angiography acquisition, a stent was identified at the level of the mid SFA, which was subsequently directly punctured, facilitating the retrograde crossing of the occlusion. Thereafter, balloon angioplasty was performed in the SFA, popliteal artery and posterior tibial artery. The result was considered suboptimal, but due to the large amount of contrast agent used, a second angiography was planned in 4 wk. In the second session, drug coated balloons were used to optimize treatment of the SFA, combined with recanalization of the left fibular artery, to optimize outflow. The post-procedural course was uneventful. Ischemic pain resolved completely after the procedure and at 8 wk of follow-up and the foot ulceration completely healed.

**Core tip:** Herein, we present a patient with critical ischemia of the lower limb, due to long occlusive disease of the femoro-popliteal and below-the-knee arteries who was successfully treated using an endovascular approach after failed bypass surgery and using the direct stent puncture technique. This case demonstrates that an endovascular approach may be extremely valuable even in very long, complex occlusive peripheral artery disease. This may further shift treatment from surgical to endovascular treatment in the near future.

## INTRODUCTION

The prevalence and mortality of peripheral artery disease (PAD) rapidly increased during the last years due to prolonged life expectancy and is estimated to affect  $\geq 30\%$  of older patients within the next few years<sup>[1,2]</sup>. Particularly patients with critical limb ischemia (CLI) show poor outcome with high risk for major amputation and high death rates within the first year after diagnosis<sup>[3,4]</sup>. Such patients very frequently suffer from comorbidities, like renal failure and diabetes mellitus<sup>[5]</sup> and are at high risk for septic shock if perfusion is not promptly re-established.

In patients with CLI, arterial revascularization should be performed without delay. Current guidelines provided by the task force for the treatment of PAD recommend an "endovascular first" approach in patients with CLI, taking the potential risk and the anticipated success rate of interventional treatment option into account<sup>[6]</sup>. Procedural decision should also consider the localization, complexity and length of the vascular lesions, as well as local expertise, comorbidities such as diabetes mellitus and renal failure and patients' preferences<sup>[7]</sup>.

Herein, we present the case of an 80-year-old female patient with CLI due to long occlusive disease of the femoral superficial, popliteal and all 3 infra-popliteal arteries, who was successfully treated endovascularly in 2 sessions.

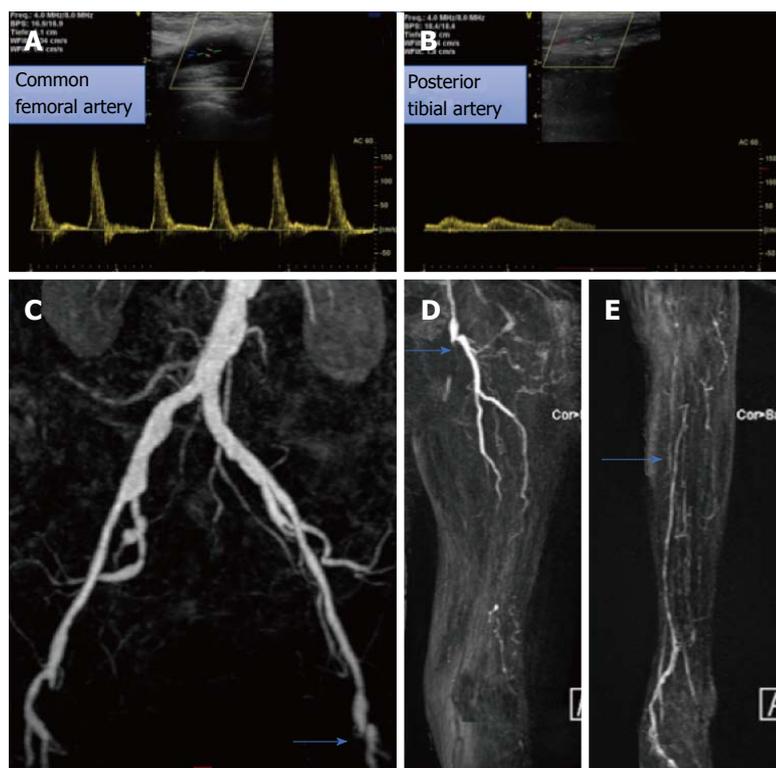

## CASE REPORT

An 80-year-old female patient was referred to our department due to CLI with ulceration of the left limb (Rutherford Class 5), accompanied by ischemic rest pain.

The patient had history of multi-vessel coronary artery disease with non-ST elevation myocardial infarction 3 mo ago. Left ventricular function was moderately reduced. In addition, she had history of arterial hypertension, hyperlipidemia, prior cigarette smoking and type 2 diabetes mellitus. Furthermore, atrial fibrillation was present. The laboratory markers showed reduced renal function with a creatinine of 1.4 mg/dL with an estimated glomerular filtration rate of  $GFR = 36 \text{ mL/min per } 1.73 \text{ m}^2$ . White blood count and C-reactive protein were increased (12300/ $\mu\text{L}$  and 18.3 mg/L, respectively) at the time of presentation. Clinical inspection revealed the presence of a forefoot ulcer without presence of gangrenous necrosis. The patient had history of left femoral popliteal bypass surgery as well as femoral thromboendarterectomy and patch angioplasty surgery 2 years ago. Duplex sonography relieved biphasic flow in the left iliac external and common femoral artery and a long occlusion of the femoral and popliteal artery with blunted monophasic flow in the posterior tibial artery (Figure 1A and B). No flow was present in the anterior tibial and in the fibular arteries. The ankle-brachial-index was severely reduced at 0.30. Magnetic resonance angiography (MRA) confirmed these findings, exhibiting no stenosis of the iliac arteries (Figure 1C), a long total occlusion of the left superficial femoral (SFA) (blue arrow in D showing flush occlusion of the SFA) and of the popliteal artery with collateral filling to the proximal part of the posterior tibial artery (blue arrow in Figure 1E) and occlusion of the anterior tibial, the tibiofibular tract and of the fibular artery (Figure 1D and E).

The patient had a history of chronic renal disease (creatinine = 1.4 mg/dL,  $GFR = 35 \text{ mL/min per } 1.73 \text{ m}^2$ ), atrial fibrillation, chronic obstructive lung disease (GOLD Class 3), type 2 diabetes mellitus and multi-vessel coronary artery disease with prior non-ST elevation infarction 3 mo ago.

Due to history of failed bypass surgery and severe cardio-pulmonary comorbidities the patient was scheduled for invasive digital subtraction angiography (DSA). After inserting a 6F guiding cross-over introducer sheath (Terumo Destination®, Terumo interventional systems, Eschborn, Germany) by puncture of the right CFA, DSA confirmed flush occlusion of the left SFA (Figure 2A) with no native vessels depicted in the upper leg and in the proximal lower leg (Figure 2B and C) and with scarce filling of the posterior tibial artery (blue arrow in Figure 2D) (Video 1). Subsequently, 500 mg aspirin and 5000 IU of heparin were injected and antegrade recanalization was attempted using different hydrophilic tapered and non-tapered guidewires. However, antegrade crossing of the occlusion failed, possibly due to presence of scarred tissue in this area after surgery. After careful revision of the initial moving table non-DSA acquisition (Video 1), a stent was identified at the level of the mid SFA, which was subsequently directly punctured, facilitating the retrograde insertion of a 0.035" advantage guidewire (Terumo interventional systems, Eschborn, Germany) (Figure 2E

**Figure 1 Duplex sonography and magnetic resonance angiography findings.** A: Biphasic flow in the left common femoral artery; B: Blunted monophasic flow in the posterior tibial artery due to long occlusive disease; C: Absence of flow limiting stenosis in iliac arteries by magnetic resonance angiography; D: Long total occlusion of the SFA (blue arrow) and of the popliteal artery; E: Collateral filling in the proximal part of the posterior tibial artery (blue arrow). SFA: Superficial femoral artery.

and Video 1). Subsequently, retrograde passage of a 0.018" advantage guidewire was achieved over a 0.035" TrailBlazer support catheter, which was then snared in the 6F guiding cross-over sheath. Then, the retrograde 0.035" support catheter was pulled back and a second antegrade 0.035" support catheter was inserted over the 6F guiding cross-over sheath, which passed over the SFA through the punctured stent and was advanced to the level of the popliteal artery (blue arrow in Figure 2F). Over this 0.035" support catheter, a 0.014" advantage guidewire was advanced to the proximal anterior tibial artery and its intraluminal localization was confirmed by DSA (Figure 2G). Balloon angioplasty was then performed using a 2.5 mm × 200 mm Armada balloon (Figure 2H) in the infra-popliteal level and 5.0 mm × 200 mm and 6.0 mm × 200 mm Armada balloons (Figure 2I) (Abbott Vascular Deutschland GmbH) in the popliteal and SFA, respectively. Due to extensive dissection of the proximal SFA a 6.0 mm × 80 mm Innova self-expanding bare metal stent was placed (Boston Scientific, Ratingen, Germany). The final angiographic result, which can be depicted in Figure 2J-L was judged as suboptimal due to the absence of outflow in the lower leg. However, intervention was stopped at this point due to contrast agent administration of approximately 200 mL with chronic renal disease. The patient was put on treatment with 100 mg aspirin, 75 mg clopidogrel and 5 mg fondaparinux daily and was scheduled for re-angiography after 4 wk.

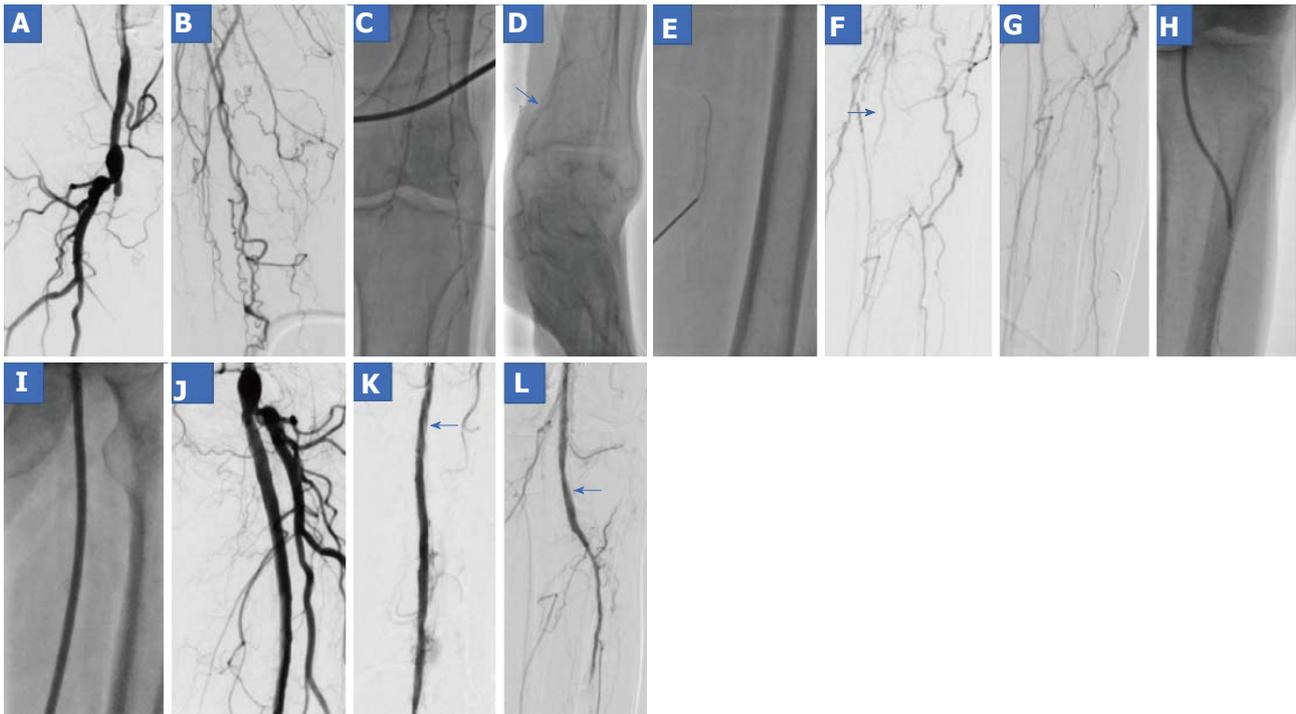

In the second session antegrade puncture of the

left CFA was performed directly above the implanted stent in the proximal SFA with subsequent insertion of a short 6F guiding introducer sheath. DSA revealed moderate restenosis of the mid SFA and of the popliteal artery, which were treated using 5.0 mm × 120 mm and 6.0 mm × 120 mm Impact Pacific (Medtronic GmbH, Meerbusch, Germany) drug coated balloons, respectively. In addition, recanalization of the fibular artery was performed, resulting in functional 2 vessel out-flow of the shortly occluded posterior tibial and of the fibular artery to the left foot. Final DSA images can be appreciated in Figure 3.

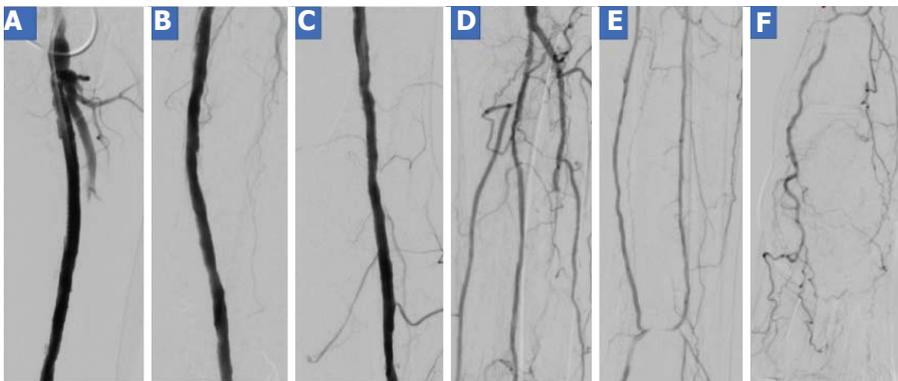

The clinical course of the patient was uneventful, and she was discharged at the following day. Ischemic pain had resolved completely, and the foot ulceration healed after 3 wk. The ankle-brachial-index increased to 0.98. The patient was set on treatment with 5 mg ramipril, 20 mg atorvastatin, 5 mg bisoprolol, 75 mg clopidogrel and 15 mg rivaroxaban per day. After 8 wk, duplex sonography exhibited a well perfused SFA with biphasic flow in the distal SFA and in the popliteal artery and monophasic flow of the distal fibular and posterior tibial artery (Figure 4).

## DISCUSSION

This is a case reporting on the usefulness of interventional treatment by the direct stent puncture technique in a very complex lesion with long occlusive disease of the

SFA, popliteal artery and below-the-knee arteries.

CLI is associated with high amputation and mortality rates, depending on concomitant risk factors and treatment options<sup>[8]</sup>. From a pathophysiologic point of view, ischemia of the limb is reversible, but causes irreversible tissue death, if left untreated. In patients presenting with CLI, current guidelines by the task force for the treatment of PAD recommend an "endovascular first" approach depending on the anatomy and complexity of the underlying lesions. However, with long occlusion of the SFA and popliteal artery bypass surgery should be considered due to rather poor technical success rates and high risk for re-occlusion, especially in segments with predicted poor patency rates

in the distal downstream segments<sup>[7]</sup>. In our case, long femoro-popliteal occlusive disease was present along with occlusion of the proximal tibial posterior artery and total occlusion of the tibiofibular tract, of the fibular and the anterior tibial artery. Despite the complexity of the lesion, we chose an interventional approach due to failed bypass surgery and cardiac comorbidities. We used the direct stent puncture technique, which was previously described as an efficient and safe option for intraluminal stent recanalization in femoro-popliteal occlusive lesions<sup>[9,10]</sup>, exhibiting high technical success rates and low rates of peri- and postprocedural complications, such as distal embolization and hematoma at the puncture site<sup>[11]</sup>. Like previously reported cases, we punctured

**Figure 4 Duplex sonography at follow-up.** A, B: Well perfused SFA with biphasic flow in the distal SFA and in the popliteal artery; C, D: Monophasic flow in the distal posterior tibial and fibular arteries. SFA: Superficial femoral artery.

an occluded stent in the mid SFA, facilitating retrograde recanalization. In contrast to most of the reported cases however, the lesion in our patient was more complex, as it did not end in the femoro-popliteal segment, but also involved the proximal and mid part of crural arteries. Thus, due lesion complexity and chronic renal disease, we decided to tackle the lesion in 2 sessions to minimize the risk for contrast induced nephropathy. Indeed, a high amount of contrast agent was necessary within the first recanalization session. Although the final angiographic results after the first session was not optimal due to remaining dissections in the SFA and poor outflow in the crural arteries, vasculature remained open during pharmacologic treatment with aspirin, clopidogrel and fondaparinux for 4 wk. During the second session, further treatment with drug coated balloons was possible, along with recanalization of a crural artery, leading to much better outflow to the foot. This case demonstrates that an “endovascular first” approach may be a valuable and ultimately successful even in very long, complex occlusive lesions, which may further shift treatment from surgical to endovascular treatment procedures in the future.

**ARTICLE HIGHLIGHTS**

**Case characteristics**

An 80-year-old female patient with peripheral artery disease (PAD) and long occlusion of the femoro-popliteal artery and below-the-knee arteries after failed bypass surgery, who presented with critical limb ischemia (CLI).

**Clinical diagnosis**

PAD with CLI (Rutherford Class 5).

**Differential diagnosis**

Venous ulcer, neuropathic diabetic ulcer.

**Laboratory diagnosis**

Laboratory markers showed increased inflammation due to the arterial ulcer. In addition, a reduced renal function with an estimated glomerular filtration rate of 36 mL/min per 1.73 m<sup>2</sup> was noticed.

**Imaging diagnosis**

PAD was diagnosed by duplex sonography and magnetic resonance angiography (MRA) and was confirmed by digital subtraction angiography (DSA).

**Pathological diagnosis**

PAD with CLI (Rutherford Class 5).

**Treatment**

Endovascular strategy using percutaneous balloon angioplasty and without stent placement.

**Related reports**

The direct stent puncture technique has been used for the recanalization of complex femoro-popliteal occlusive disease in cases where an antegrade recanalization is not successful. The lesion in the patient was more complex, as it did not end in the femoro-popliteal segment, but also involved the proximal and mid part of crural arteries.

**Term explanation**

CLI is a life-threatening condition due to advanced occlusive PAD, usually

accompanied by ischemic rest pain, arterial ulcers and gangrene. If left untreated this condition will in major amputation, sepsis and death.

### Experiences and lessons

In patients with complex femoro-popliteal occlusive disease, the direct stent puncture technique may facilitate recanalization of very long occlusive lesions without the need of bypass surgery. An endovascular first approach needs to be considered in such patients, who usually are bad candidates for surgery due to cardiopulmonary disease and other comorbidities.

### Abstract

Genetic analyses of patients with transposition of the great arteries have identified rare copy number variations, suggesting that they may be significant to the aetiology of the disease. This paper reports the identification of a 16p11.2 microduplication, a variation that has yet to be reported in association with transposition of the great arteries. The 16p11.2 microduplication is associated with autism spectrum disorder and developmental delay, but with highly variable phenotypic effects. Autism and attention deficit disorders are observed more frequently in children with congenital heart disease than in the general population. Neonatal surgery is proposed as a risk factor, but as yet unidentified genetic abnormalities should also be taken into account. Thus, congenital heart abnormalities may constitute a part of the phenotypic spectrum associated with duplications at 16p11.2. We suggest chromosomal microarray be considered part of the diagnostic work-up in patients with transposition of the great arteries.

**Key words:** Transposition of the great arteries; Copy number variation; Genetics; 16p11.2; Microduplication

**Core tip:** Rare copy number variations may be of significance to the aetiology of transposition of the great arteries. This paper reports, for the first time, the finding of a 16p11.2 microduplication in a patient with transposition of the great arteries. Recognizing a possible genetic association to transposition of the great arteries will spur investigations into associated phenotypic effects such as developmental delays, thus allowing for earlier identification and treatment. We recommend that chromosomal microarray be considered part of the diagnostic work-up in patients with transposition of the great arteries.

## INTRODUCTION

Structural gene mutations are emerging as important causes of congenital heart diseases<sup>[1]</sup>. Transposition of the great arteries is a rare, life-threatening form of congenital heart disease. In contrast to some congenital heart defects, such as atrioventricular septal defects and tetralogy of Fallot, simple transposition of the great arteries is rarely associated with syndromes<sup>[2]</sup>.

Although the aetiology of the disease is currently unknown, rare copy number variations have recently been identified in patients with transposition of the great arteries<sup>[1,3-5]</sup> (Table 1). To investigate this further, we screened 13 patients with transposition of the great arteries for copy number variations using high-resolution chromosomal microarray analyses. Approximately half of the screened patients had additional congenital heart diseases.

## CASE REPORT

Here, we present the case of a young patient with a genetic mutation that has yet to be reported in association with transposition of the great arteries.

Blood samples were collected from patients and their parents during planned visits. Informed consent to perform chromosomal microarray was obtained. Chromosomal microarray (Agilent Technologies Inc., Santa Clara, CA, United States; 180K CGH for nine patients or 400K CGH + SNP for four patients) was performed on DNA extracted from blood leucocytes as per the manufacturer's protocol.

In one patient, the chromosomal microarray revealed

a 0.5 Mb duplication at chromosome 16p11.2 {arr(hg19) 16p11.2 [(29664529-30198600)] × 3 mat} covering the region involved in chromosome 16p11.2 duplication syndrome (OMIM 614671). This microduplication was subsequently detected in the patient's 35-year-old Caucasian mother, who was phenotypically unaffected. The mother was without any cardiac symptoms or murmurs and was not interested in further examinations of her heart.

The patient was born at gestational age 40 wk, weighing 3.06 kg and measuring 50 cm in length. The patient's Apgar score was 9 at one minute and 10 at five minutes. In addition to transposition of the great arteries, a pulmonary valve stenosis and ventricular and atrial septal defects were present. The patient had an arterial switch operation at birth and the Nikaidoh procedure at 7 years of age. Postoperatively, the patient achieved a relatively high level of activity and had no cardiac or respiratory discomfort. At 8 years of age, the patient was diagnosed with attention deficit hyperactive disorder. The patient was followed until the age of 9.5 years.

The 16p11.2 microduplication is associated with autism spectrum disorder and developmental delay, but with highly variable phenotypic effects. This duplication does not always result in severe impairment and may be inherited from a parent with minimal or no clinical features<sup>[6]</sup>. The 16p11.2 microduplication has not previously been associated with transposition of the great arteries. In the Decipher database, two cases of persistent arterial duct and one case of ventricular septal defect were seen among all patients with a 16p11.2 microduplication<sup>[7]</sup>.

## DISCUSSION

Transposition of the great arteries is one of the more severe congenital cardiac defects, but only few studies have investigated the possible aetiology of this defect<sup>[1,2]</sup>. Two clinical reports have documented a variety of genetic variations associated with transposition of the great arteries<sup>[4,5]</sup>. On a review of the literature, Unolt *et al.*<sup>[3]</sup> identified frequent syndromes, such as Turner and Noonan, that were rarely associated with transposition of the great arteries; however, a sporadic association with several other genetic variations is possible (Table 1). Costain *et al.*<sup>[2]</sup> studied a cohort of patients with transposition of the great arteries ( $n = 101$ ) and identified 11 different rare copy number variations, none of which were found in the control group ( $n = 10528$ )<sup>[2]</sup>. Osoegawa *et al.*<sup>[8]</sup> searched for candidate gene loci and sex chromosome aneuploidy among patients with conotruncal cardiac anomalies, of which 194 patients had transposition of the great arteries. They identified a 22q11.22 microdeletion in one patient, an 8p23.2 micro duplication in another patient, and sex chromosome abnormalities (47XYY and

47XXY) in two patients with transposition of the great arteries.

We are the first to document the presence of a 16p 11.2 microduplication in a patient with transposition of the great arteries. Deletions and duplications of the recurrent 600 base pair region on chromosome 16p11.2 are frequent findings in patients with autism spectrum disorders and the concomitant finding of congenital heart disease may be an incidental finding not caused by the microduplication<sup>[9]</sup>. It is, however, well known that congenital abnormalities can occur in the context of recurrent duplications associated with susceptibility to intellectual disability.

Autism and attention deficit disorders are observed more frequently in children with congenital heart disease than in the general population<sup>[10]</sup>. Neonatal surgery is proposed as a risk factor<sup>[11]</sup>, but as yet unidentified genetic abnormalities should also be taken into account.

Thus, congenital heart abnormalities may constitute a part of the phenotypic spectrum associated with duplications at 16p11.2. We suggest chromosomal microarray be considered part of the diagnostic work-up in patients with transposition of the great arteries.

In conclusion, rare copy number variations may be of significance to the aetiology of transposition of the great arteries. This paper reports, for the first time, the finding of a 16p11.2 microduplication in a patient with transposition of the great arteries. Recognizing

a possible genetic association to transposition of the great arteries will spur investigations into associated phenotypic effects such as developmental delays, thus allowing for earlier identification and treatment. We therefore recommend that chromosomal microarray be considered part of the diagnostic work-up in patients with transposition of the great arteries.

**ARTICLE HIGHLIGHTS**

**Case characteristics**

Young patient diagnosed with transposition of the great arteries and a 16p11.2 microduplication.

**Clinical diagnosis**

The child deteriorated after birth, when the arterial duct closed. Echocardiography revealed transposition of the great arteries, pulmonary valve stenosis and ventricular and atrial septal defects. Around school age the child was diagnosed with attention deficit disorder.

**Differential diagnosis**

Regarding deterioration after birth, differential diagnoses are: Neonatal sepsis, metabolic disease, and other cyanotic heart defects. Neonatal surgery is a risk factor for attention deficit disorder.

**Laboratory diagnosis**

Chromosomal microarray revealed the 0.5 Mb chromosomal duplication at chromosome 16p11.2.

**Imaging diagnosis**

The congenital heart diseases were diagnosed using echocardiography.

### Treatment

The transposition of the great arteries was treated with an arterial switch operation at birth and the Nikaidoh procedure at the age of 7 years.

### Related reports

Transposition of the great arteries is rarely associated with genetic variations. Transposition of the great arteries have once before been associated with a 16p13.11 duplication (Ref. [19]). The authors are the first to report the 16p11.2 microduplication in association with transposition of the great arteries.

### Term explanation

Copy number variation: A structural variation in the DNA that results in the cell having an abnormal number of copies of one or more sections of the DNA.

### Experiences and lessons

The case document that copy number variations may be of significance in transposition of the great arteries and chromosomal microarray should be considered part of the diagnostic work-up in these patients.

## ACKNOWLEDGMENTS

We thank professor Vibeke Hjortdal at the Department of Cardiothoracic and Vascular Surgery, Aarhus University Hospital, Denmark, and Rikke Christensen and Ida Vogel, both at the Department of Clinical Genetics, Aarhus University Hospital, Denmark for help with initiating the study, collecting blood samples, analysing data, and helping prepare the manuscript. We thank research nurse Vibeke Laursen at the Department of Cardiothoracic and Vascular surgery for collecting blood samples and secretary Jette Breiner at the Department of Cardiothoracic and Vascular surgery for administrating bills and translating patient information.

### Abstract

Pre-procedural planning is the key element of trans-

catheter aortic valve implantation (TAVI). Multislice computed tomography of the chest, abdomen and pelvis with the ability to perform a 3-dimensional reconstruction has become the cornerstone of pre-procedural planning. We would like to encourage TAVI operators (interventional cardiologist and surgeons) to get involved in imaging. All TAVI operators should know how to assess the annulus, the annular root, and the iliofemoral access. We strongly believe that this will improve outcomes of this evolving procedure.

**Key words:** Aortic stenosis; Transcatheter aortic valve implantation; Transcatheter aortic valve replacement; Imaging; Computed tomography

**Core tip:** We have noticed that only a minority of interventional cardiologists and cardiac surgeons routinely look at their patients MDCTs and know how to perform a three dimensional multiplanar reconstruction. With this editorial, we would like to encourage all transcatheter aortic valve implantation (TAVI) operators to get involved in cardiac imaging. We do believe that this will improve outcomes. In case a complication occurs, TAVI operators will be more likely to understand the nature of the complication and learn from it. And this again will lead to improved outcomes in future.

### TO THE EDITOR

Transcatheter aortic valve implantation (TAVI) is now routinely performed in inoperable, high-risk, and

**Figure 1** Example of a multiplanar reconstruction of the aortic annulus. A and B: Double-oblique MSCT images at the basal insertion of the calcified native cusps; C: Double-oblique reconstruction at the level of the aortic annulus. The aortic valve leaflets are just barely visible at the level of the ventriculoarterial junction; D: Measurement of the short and long diameter at the level of the aortic annulus. MSCT: Multislice computed tomography.

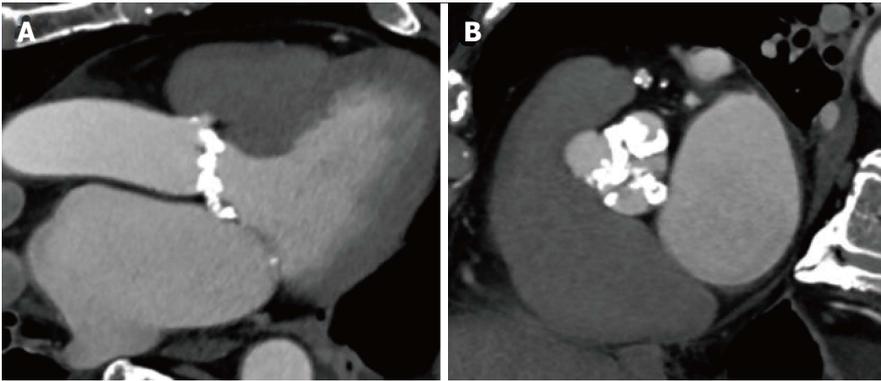

intermediate risk patients with low mortality- and complication rates<sup>[1,2]</sup>. Some of the key elements contributing to these impressive results are pre-procedural patient evaluation by the multidisciplinary HeartTeam, and pre-procedural imaging<sup>[3,4]</sup>.

The important role of multislice computed tomography (MSCT). MSCT of the chest, abdomen and pelvis with 3-dimensional reconstruction has become the cornerstone of pre-procedural planning. MSCT is now routinely performed to assess the aortic annulus, the distance between the aortic annulus and the coronary ostia and the suitability for the transfemoral access<sup>[3,5]</sup>. Nowadays matured post-processing imaging software is widely available to perform these measurements automatically and create standardized reports<sup>[6]</sup>. However, automatic measurements may not include the degree and distribution of calcification and may not take into account all aspects of the anatomy. Most of the TAVI operators rely on such reports or on numbers and measurements reported by the radiologist<sup>[7-9]</sup>. Therefore, we would like to encourage all TAVI operators to get involved in imaging and learn how to perform a 3-dimensional multiplanar reconstruction.

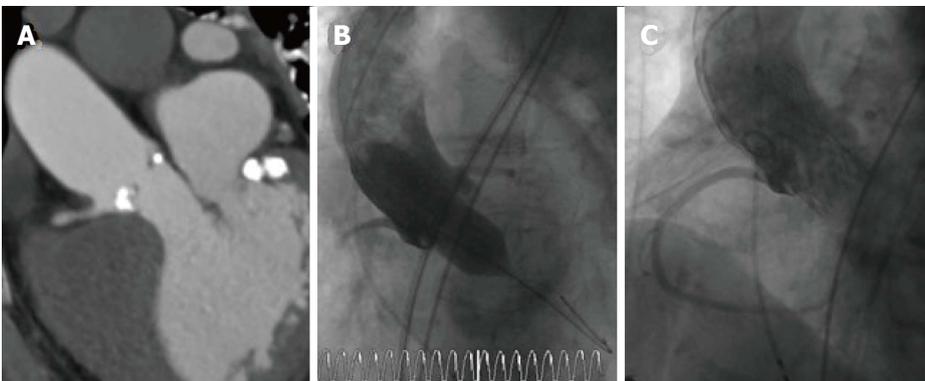

Choosing the valve type and size. It has been shown that left ventricular outflow tract (LVOT) calcification is associated with an increased risk for annular rupture during TAVI with balloon-expandable prostheses<sup>[10]</sup>. Extensive calcifications at the native aortic valve may increase the risk for paravalvular regurgitation or need for a permanent pacemaker<sup>[11,12]</sup>. As an interventional

cardiologist or cardiac surgeon, we can easily perform multiplanar reconstructions of the aortic annulus not only to measure the dimensions of the annulus but also to get an impression of the distribution of calcification of the valve leaflets and the LVOT (Figure 1)<sup>[13]</sup>. Based on all information including the annular perimeter, area, distribution of calcification and anatomy of the aortic root, valve type and size can be chosen more specifically as part of a patient tailored therapy (Figure 2).

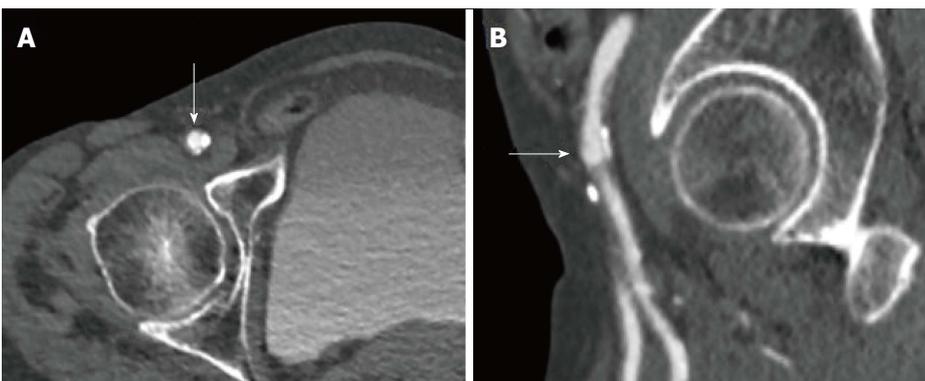

Assessment of the coronary artery height. The "Instructions for use" of different valves include specific recommendations for the minimal coronary artery height. However, the risk for coronary obstruction is greatly increased in patients with bulky atheroma or calcifications at the tip of the leaflets, a smaller sinus of valsalva diameter, narrow sinotubular junction and different patient characteristics like female gender or patients with previous surgical bioprosthesis<sup>[14]</sup>. Measuring the coronary artery height with MSCT is a great screening tool, but "virtual implantation" by the operator comparing the length of the leaflets with the distance between annulus and coronary ostia and also assessing the distribution of calcifications may allow much better risk stratification (Figure 3). Radial strength depends largely on the valve type. Whereas the widely used balloon-expandable valves consist of cobalt chromium, self-expanding valves are composed of nitinol thus applying less radial force to the tissue<sup>[14]</sup>. Accordingly, a self-expandable and retrievable valve might be preferable in patients at risk for coronary obstruction. Moreover, in case of borderline

**Figure 2** Cardiac multislice computed tomography showing a patient with heavy calcifications extending into the left ventricular outflow tract and a shallow sinus. This anatomy is associated with increased risk for annular rupture in patients undergoing TAVI with a balloon expandable valve. A: Three chamber view of the heart showing a patient with heavy calcification extending from the aortic annulus into the LVOT and a shallow sinus; B: Short axis view of the aortic valve showing heavy calcified aortic leaflets. LVOT: Left ventricular outflow tract; TAVI: Transcatheter aortic valve implantation.

**Figure 3** Patient undergoing transfemoral transcatheter aortic valve implantation with a very low ostium of the right coronary artery. A: Patient with a very low ostium of the right coronary artery but potentially a large enough sinus valsalva for TAVI; B: Balloonvalvuloplasty with simultaneous injection of contrast media to estimate the risk for coronary obstruction; C: Successful implantation of an Evolut R. Supraannular injection shows a patent right coronary artery. TAVI: Transcatheter aortic valve implantation.

**Figure 4** Multislice computed tomography showing calcified right common femoral artery in a patient undergoing transfemoral transcatheter aortic valve implantation. A: Right common femoral artery with an arrow pointing at the ideal puncture site above the calcification; B: Right common femoral artery with an arrow pointing at the ideal puncture site above the height of bifurcation of the common femoral artery in relationship to the femoral head.

anatomy, balloonvalvuloplasty with simultaneous contrast media injection may allow to estimate the risk for coronary obstruction during valve deployment. In patients considered at high risk for coronary obstruction placing a coaxial guiding catheter extension such as the GuideLiner catheter (Cascular Solutions Inc., Minneapolis,

MN, United States) in the coronary artery during valve deployment may allow emergent percutaneous coronary intervention.

Choosing the ideal puncture site. Finally MSCT is routinely used to evaluate size, tortuosity and calcifications of the iliofemoral arteries and to determine

the feasibility of transfemoral access<sup>[15]</sup>. MSCT provides detailed information about the height of the bifurcation of the common femoral artery in relationship to the femoral head. Furthermore, it allows visualization of the inferior epigastric artery which is located within the inguinal ligament. Finally, MSCT shows the extent of calcification at the level of the potential puncture site (Figure 4). Knowing your patients anatomy allows to perform a precise puncture under fluoroscopy guidance thus minimizing the risk for vascular injury<sup>[16,17]</sup>.

How to get involved in imaging, and why? Potential TAVI candidates are discussed by the interdisciplinary HeartTeam consisting of non-invasive cardiologists specialized in cardiac imaging, interventional cardiologists and cardiac surgeon to define the best treatment option for the individual patient. Evaluation of associated comorbidities that may limit the life expectancy or the recovery after the procedure is of particular importance. Results from pre-procedural invasive angiogram, echocardiogram and MSCT are reviewed for each patient. We would like to encourage all TAVI operators to review their patients MSCT again immediately before the procedure. Look at the iliofemoral access to choose the better side with less calcification or tortuosity, and choose the ideal puncture site. Then, perform a three dimensional multiplanar reconstruction of the annulus, measure the annular diameters, perimeter, and the area. Look for calcification at the level of the annulus, but also at the level of the LVOT. Finally, review the root and the coronary arteries. With routine, this can be performed in 2-3 min in most patients. There are two potential advantages of being able to analyze your patient's images. First, you may improve your patient's outcomes. Second, if you have a complication, you are more likely to understand it and learn from it. And this will again lead to better outcomes in the future.
