

# World Journal of *Cardiology*

*World J Cardiol* 2017 January 26; 9(1): 1-75

## Editorial Board

2014-2017

The *World Journal of Cardiology* Editorial Board consists of 416 members, representing a team of worldwide experts in cardiology. They are from 46 countries, including Argentina (3), Australia (7), Austria (6), Belgium (2), Brazil (8), Canada (11), China (37), Croatia (1), Cuba (1), Cyprus (1), Czech Republic (2), Denmark (3), Egypt (1), Finland (3), France (3), Germany (32), Greece (10), Hungary (5), India (4), Iran (2), Ireland (1), Israel (5), Italy (63), Japan (32), Kosovo (1), Malaysia (1), Mexico (1), Morocco (1), Netherlands (9), New Zealand (1), Nigeria (2), Norway (2), Poland (8), Portugal (2), Saudi Arabia (2), Singapore (3), Slovenia (1), South Korea (9), Spain (14), Switzerland (3), Thailand (3), Turkey (13), United Arab Emirates (1), United Kingdom (20), United States (73), Uruguay (2), and Venezuela (1).

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Jan Sochman, MD, PhD, Associate Professor, Clinic of Cardiology, Institute for Clinical and Experimental Medicine, 14000 Prague, Czech Republic

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Statins have become a cornerstone of risk modification for ischaemic heart disease patients. A number of studies have shown that they are effective and safe.

However studies have observed an early benefit in terms of a reduction in recurrent infarct and or death after a myocardial infarction, prior to any significant change in lipid profile. Therefore, pleiotropic mechanisms, other than lowering lipid profile alone, must account for this effect. One such proposed pleiotropic mechanism is the ability of statins to augment both number and function of endothelial progenitor cells. The ability to augment repair and maintenance of a functioning endothelium may have profound beneficial effect on vascular repair and potentially a positive impact on clinical outcomes in patients with cardiovascular disease. The following literature review will discuss issues surrounding endothelial progenitor cell (EPC) identification, role in vascular repair, factors affecting EPC numbers, the role of statins in current medical practice and their effects on EPC number.

**Core tip:** Statin therapy is a cornerstone of current management in coronary artery disease. Conventional thinking of stain therapy is for reduction of low-density lipoproteins. However a number of studies have observed an early benefit prior to any significant change in lipid profile. Therefore alternative pleiotropic mechanisms to account for this have been proposed. One such proposed mechanism is the ability of statins to augment both number and function of endothelial progenitor cells (EPCs). The following literature review discusses issues surrounding EPC identification, role in vascular repair, the role of statins in current medical practice and their effects on EPCs.

## INTRODUCTION

The maintenance of endothelial integrity is essential for the preservation of a healthy vasculature<sup>[1]</sup>. This integrity results from a balance between on-going endothelial damage and the rate of vascular repair. Disruption of endothelial integrity or impairment of endothelial repair mechanisms is a central step in both the initiation and progression of atherosclerosis<sup>[2]</sup>. Endothelial repair is dependent on undifferentiated cells migrating to sites of vascular injury<sup>[3-5]</sup> then differentiating into mature endothelial cells<sup>[6-13]</sup>. These undifferentiated cells are called endothelial progenitor cells (EPCs) have a central role in vascular repair by virtue of their ability to proliferate, migrate to site of vascular injury and then differentiate into mature vascular endothelium<sup>[13,14]</sup>. EPCs perpetuate this cycle by secreting pro-angiogenic cytokines<sup>[15]</sup>.

Statins form the corner stone of treatment of coronary artery disease. The safety and efficacy of statins in reducing cardiac events by decreasing serum LDL-cholesterol has been well described<sup>[16-18]</sup>. Recently however studies have shown the early beneficial effect of statins occurs before any significant change in lipid profile. This led to the hypothesis that cardiovascular benefits of statins may occur *via* alternative mechanisms other than reduction of LDL-cholesterol alone<sup>[19,20]</sup>. One such proposed mechanism is the ability of statins to augment both number and function of EPCs.

The following literature review discusses issues surrounding EPC identification, role in vascular repair, factors affecting EPC numbers, the role of statins in current medical practice and their effects on EPC number.

## RESEARCH AND LITERATURE

We performed a review of various studies within the literature available on endothelial progenitor cell and statins. The authors searched various databases (EMBASE, OVID, PubMed) using the keywords: "Endothelial progenitor cells", "statin", "pleiotropic effects". We studied the various publications that we obtained from the search results. Full text manuscripts were obtained. We only included papers in the English language.

## EPCS

Cellular identification and staging of differentiation has been made possible by specific surface receptors called epitopes that allow immunophenotyping. This

process allows identification of subset of cellular surface molecule termed cluster of differentiation (CD). Cellular subtypes may be defined by the presence or absence of a particular CD molecule. Therefore "CD" may be "+ "or "-" denoting either presence or absence of a particular CD, and is used to describe stem cells rather than fully differentiated cell types. Certain cell types may have variable CD marker expression during maturation for example, and therefore classed as bright (high), mid (mid) or dim (low) denoting intensity of expression<sup>[21,22]</sup>.

Vascular repair had previously been thought to be due to migration and proliferation of fully differentiated endothelial cells, in a process called angiogenesis<sup>[23]</sup>. Asahara *et al*<sup>[24]</sup> identified putative cells with cell surface marker CD34<sup>+</sup>, alternately named kinase insert domain receptor (KDR/VEGFR) markers capable of differentiating into endothelial cells both *in vitro* and *in vivo*<sup>[24-26]</sup>. Subsequent studies recognised that in fact undifferentiated cells subsequently termed EPCs migrated to sites of neovascularization and then differentiate into endothelial cells<sup>[24,26]</sup> in a process called vasculogenesis<sup>[27]</sup>. EPCs are derived from pluripotential stem cells within the bone marrow. These then evolve into mature endothelial cells<sup>[24]</sup> accounting for only 0.001%-0.0001% of peripheral blood cells in an unstressed state<sup>[28]</sup>. Circulating EPCs may be isolated from bone marrow or the circulation as mononuclear cells<sup>[24,29,30]</sup>, expressing a variety of endothelial surface markers<sup>[31]</sup>. However, there currently remains a lack of consensus on phenotypic and functional definition of endothelial precursor cells<sup>[32,33]</sup>.

EPCs are a diverse group of cells of different lineages that have angiogenic potential, but are not always necessarily able to differentiate into functional endothelial cells as would be suggested from their name<sup>[32]</sup>. EPCs are derived from CD34<sup>+</sup> hematopoietic progenitor cells<sup>[6,24,29,31]</sup>, with the subset of EPCs characterized by co-expression of endothelial marker proteins<sup>[6,29,31]</sup>. Studies have identified 3 markers associated with early functional EPCs including CD133, CD34, and the vascular endothelial growth factor receptor-2 (VEGFR-2) also known as kinase insert domain receptor (KDR, Flk-1 or CD309)<sup>[7,31]</sup>. Therefore EPCs express markers of both hematopoietic stem cells (CD34 and CD133) and endothelial cells (CD146, vWF, and VEGFR2)<sup>[26,28,29,31,34-37]</sup>. The presence of certain cell surface markers are depend on the stage of maturations of the EPC. For example the cell surface marker CD133, a 120-kDa trans-membrane polypeptide, is expressed on bone marrow derived hematopoietic stem and progenitor cells in peripheral blood<sup>[37]</sup>. The expression of CD133 on EPCs declines during maturation within the peripheral circulation. Currently there remains some uncertainty as to when EPCs lose the CD133 surface marker, whether during transmigration from bone marrow to circulation or later whilst in the peripheral blood system<sup>[38]</sup>. Nevertheless the loss of CD133 represents the transformation into more mature EPCs that are endothelial-like cells<sup>[37]</sup>.

**Table 1** Table to show cell markers during development of endothelial progenitor cell

	Endothelial progenitor cells		
	Bone marrow	Circulation	
		Early EPCs	Mature EPCs
CD133 <sup>+</sup>	+	+/-	-
CD34 <sup>+</sup>	+	+	+
VEGFR2 <sup>+</sup>	+	++	+++
CD31 <sup>+</sup>	-	+	+
VE-cadherin	-	+	+
vWF	-	+	+

EPC: Endothelial progenitor cell; VEGFR: Vascular endothelial growth factor receptor.

Whereas the expression of CD34 a cell surface marker found on immature pluripotential stem cells<sup>[31]</sup> that acts as an adhesion molecule, although the precise function remains unclear, gradually increases as the CD133 decreases as the EPC matures<sup>[37]</sup>. During the course of maturity EPCs begin to have increased expression of other markers specific to endothelial cells such as VEGFR-2, VE-cadherin, and von Willebrand factor (vWF)<sup>[37]</sup>.

The expression of CD34<sup>+</sup>, CD133<sup>+</sup>, and/or VEGF2<sup>+</sup> has been used as identifying markers of EPCs in a number of studies<sup>[28,32,39-41]</sup>. Whereas as other studies advocate the use of CD133<sup>+</sup> either alone or in combination with CD34<sup>+</sup>/VEGFR-2<sup>+</sup> cells for identification of EPCs<sup>[31,42]</sup>. In contrast, other studies have suggested that CD133<sup>+</sup> are haematopoietic cell lines and have not been identified in and therefore unable to form endothelial phenotypic EPCs<sup>[7,40,43]</sup>. Ingram *et al.*<sup>[28]</sup> proposed that CD45<sup>-</sup> cells incorporated "true" circulating EPCs and verified by other studies<sup>[28,39,40,43]</sup>. Interestingly, CD34<sup>+</sup>/VEGFR2<sup>+</sup> and diminished (dim) CD45 (CD45<sup>dim</sup>) cells have been found to have greater correlation with coronary heart disease severity and response to statin therapy<sup>[44,45]</sup>.

In summary, the maturity of the EPC is marked by the gradual loss of CD133, gradual increased expression of CD34<sup>+</sup> and the appearance of CD31, VE-cadherin and vWF cell surface markers (Table 1).

## EPCS AND CORONARY ARTERY DISEASE

Endothelial integrity is essential for healthy vasculature, and can be thought of as a balance between continued endothelial damage and the capacity to repair by a pool of EPCs<sup>[9,46]</sup>. It is now generally accepted that cardiovascular risk correlates with EPC numbers. Highlighting the integral relationship between endothelium and atherosclerosis<sup>[47-51]</sup>, disruption of endothelial integrity by endothelial cell injury has been shown to be a stimulus for the development of atherosclerosis<sup>[2]</sup>, but also as a stimulus for augmentation of EPC number and function<sup>[9,52,53]</sup>. Continued endothelial damage<sup>[54]</sup> may lead to an eventual reduction of the number of EPCs. Elevated EPC numbers have been shown to be

associated with augmented formation of collaterals in coronary artery disease<sup>[55]</sup> and restoration of endothelial vasodilator function<sup>[9]</sup>. A reduction in EPC numbers may lead to deficient endothelial repair and progression of atherosclerosis, with further EPC depletion and perpetuation of atherosclerosis<sup>[9,56]</sup>. However, it is uncertain whether low numbers of circulating EPCs represents enhanced usage by vascular repair processes, or reduced production by bone marrow.

CD34<sup>+</sup> VEGFR2<sup>+</sup> EPCs cells have been shown to be reduced in patients with atherosclerotic coronary and peripheral disease<sup>[57]</sup>. Vasa *et al.*<sup>[56]</sup> found not only reduced numbers, but also impaired function of EPCs in patients with coronary artery disease. Elevated numbers of EPC have been associated with freedom from myocardial infarction, hospitalization, revascularization and cardiovascular death in patients with coronary artery disease<sup>[56,58]</sup>. Furthermore the predictive value of EPC count has been shown to be independent of traditional cardiovascular risk factors<sup>[9,46,59]</sup>. In fact, the extent of the reduction in EPC numbers has been associated not only with coronary artery disease burden<sup>[60]</sup>, but also the presence of symptoms<sup>[61,62]</sup>.

Finally, elevated numbers of circulating CD34<sup>+</sup>/CD133<sup>+</sup>/VEGFR2 EPCs have been observed after an acute myocardial infarction<sup>[42,63]</sup>. This may be regarded as a consequence of cardiac ischaemia together with raised inflammatory and haematopoietic cytokines stimulating EPC mobilisation from the bone marrow<sup>[64-66]</sup>. A similar response is seen following coronary angioplasty<sup>[67]</sup>, and interestingly, the combination of an acute coronary syndrome (ACS) treated by angioplasty provoked an enhanced EPC response<sup>[68]</sup>. Therefore, EPC may have a central role not only in repairing coronary vessels after plaque rupture, but also after any coronary intervention.

## STATIN THERAPY

Statins act by competitively inhibiting 3 hydroxy-3-methylglutaryl Coenzyme A (HMG CoA) reductase, the rate limiting step in the mevalonate pathway producing isoprenoids including cholesterol. The competitive inhibition of HMG CoA reductase induces the expression of LDL receptors within the liver, thereby increasing the catabolism of plasma LDL, with a consequent decrease in LDL-cholesterol levels<sup>[69]</sup>.

The safety and efficacy of statins in reducing cardiac events by decreasing serum LDL-cholesterol has been well described<sup>[16-18]</sup>. Statin therapy has been shown to reduce death and cardiovascular events in primary prevention of atherosclerosis<sup>[70]</sup>, stable coronary artery disease<sup>[16,71-73]</sup>, ACS<sup>[74,75]</sup> and secondary prevention<sup>[72]</sup>. Statins also appear to reduce development of atherosclerotic lesions<sup>[76,77]</sup> and decrease plaque burden<sup>[13,78]</sup>.

The beneficial effect of intensive statin therapy was studied in a prospective meta-analysis of 90056 patients from 14 randomised trials and found greater

cholesterol reduction was associated with better patient outcomes<sup>[19]</sup>. The study found that the 5-year incidence of major adverse cardiac events, coronary revascularization and stroke was reduced by one fifth for every millimoles per liter reduction in LDL cholesterol, which was irrespective of the initial lipid profile<sup>[19]</sup>.

Another meta-analysis found aggressive statin therapy was associated with reduced peri-procedural myocardial infarction and a 44% risk reduction in major adverse cardiovascular events at 30-d irrespective of clinical presentation<sup>[79]</sup>. Moreover, the ARMYDA-RECAPTURE study<sup>[80]</sup> found reloading of the high dose statin, atorvastatin 80 mg in 383 NSTEMI and stable angina patients on chronic therapy prior to percutaneous coronary intervention (PCI) had a 50% reduction in 30-d major adverse cardiac events in both group with a greater reduction in NSTEMI group<sup>[80]</sup>.

These studies led to the universal adoption of statin therapy in patients with coronary artery disease irrespective of presentation from stable angina to ACSs<sup>[81,82]</sup>.

## THE EFFECT OF STATIN THERAPY ON EPCS

Several studies have shown the early beneficial effect of statins occurs before any significant change in lipid profile. This led to the hypothesis that cardiovascular benefits of statins may occur *via* alternative mechanisms other than reduction of LDL-cholesterol alone<sup>[19,20]</sup>. These potential beneficial effect(s) may represent a potential therapeutic target for ischemic heart disease patients, and therefore is of great interest. There have been a number of mechanisms proposed to account for pleiotropic effects of statin therapy. These include reduction in vascular inflammation<sup>[83]</sup>, reduction of platelet aggregability and thrombus deposition<sup>[77,84-86]</sup>, enhancement of fibrinolysis<sup>[87]</sup> and increased endothelium derived NO production<sup>[88-90]</sup>. However the mechanism that has evoked the most interest is the impact of statins on EPCs<sup>[70]</sup>.

Statin therapy has been associated with greater numbers of circulating EPCs by enhancing mobilization, differentiation, increasing longevity, enhance homing to sites of vascular injury with augmentation of re-endothelisation by enhancing expression of adhesion molecules on EPC cell surface membrane<sup>[3,70,91-94]</sup>.

However, the duration of the effect on EPC number by statin therapy continues to remain contentious.

In one study, atorvastatin therapy was shown to significantly increase circulating EPC as soon as 1 wk with plateauing after 3-4 wk with a 3-fold increase of EPCs from baseline in a stable angina population was also observed<sup>[70]</sup>. Whereas Deschaseaux *et al*<sup>[95]</sup> investigated whether EPCs could be firstly detected and secondly characterized in patients receiving long-term statin therapy defined as 4 wk. The group found a significantly greater number of CD34<sup>+</sup>, CD34<sup>+</sup>/CD144<sup>+</sup>

circulating EPC in patients receiving statin therapy compared to statin naïve patients. Interestingly two types of EPCs were detected, early and late EPCs. The early EPCs were found to form elongated cells whereas the late EPC population gave rise to cobblestone-like colonies with strong proliferation capacities seen *in-vitro* cell culture. The numbers of early EPCs were significantly higher in patients not receiving statin therapy whereas late EPCs were significantly higher in patients receiving statin therapy. The study also observed that long term statin therapy specifically maintained late EPCs in circulation with a CD34<sup>+</sup>/CD144<sup>+</sup> phenotype. Rodent studies have found rosuvastatin resulted in a greater than 3 fold increase in EPC numbers when compared with placebo as long as 10 wk after myocardial infarction<sup>[56]</sup>. Long-term atorvastatin 10 mg for 12 mo markedly increased EPC number with an associated decrease in oxidative DNA damage<sup>[35]</sup>. However to the contrary, Hristov *et al*<sup>[96]</sup> found reduced numbers of circulating EPCs in CHD patients on long-term statin treatment.

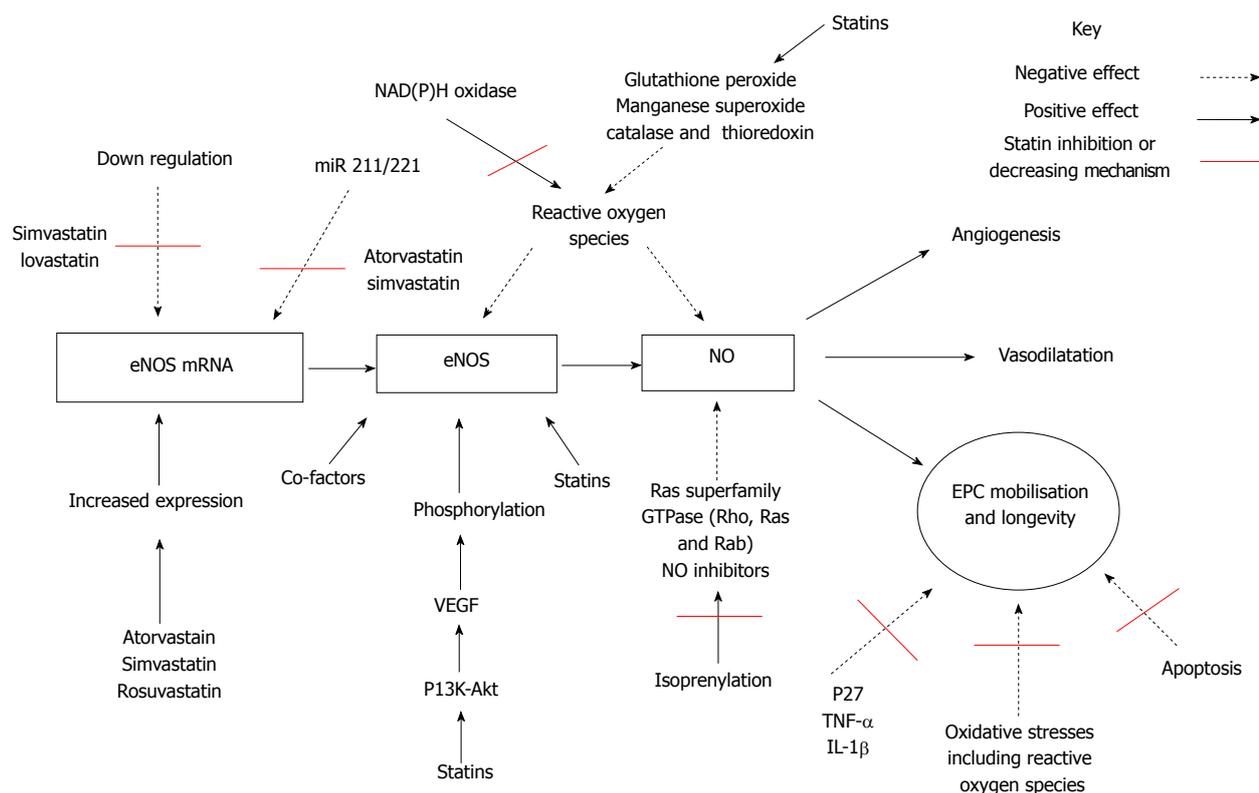

Statins appear to have a dose dependant effect on EPC count. A double blinded randomised pilot study found greater number of circulating CD34<sup>+</sup> VEGFR-2<sup>+</sup> EPCs after 12 wk of therapy with pravastatin 20 mg when compared to atorvastatin 10 mg<sup>[97]</sup>. Similarly, in ACS patients' intensive statin therapy with atorvastatin 80 mg after primary or rescue PCI was associated with greater EPC count at 4-mo follow up as compared to 20 mg atorvastatin. The authors found no beneficial effect in an improvement of LV function<sup>[98]</sup>. Furthermore statin reloading in patients on moderate statin therapy undergoing percutaneous coronary intervention has been shown to increase EPC count<sup>[99,100]</sup> this correlates with the beneficial effect of statin reloading of high dose statin in patients on chronic therapy<sup>[80]</sup> mentioned above.

## PLEIOTROPIC EFFECTS OF STATIN THERAPY

Several proposed intracellular signaling mechanisms accounting for the pleiotropic effect of statin therapy have been put forward. Figure 1 below summarizes the positive and negative effects on EPC proliferation, mobilisation and longevity but also the effect of statin therapy.

### Nitric oxide pathway

The first proposed intracellular signaling mechanisms involves nitric oxide pathway. The endothelium releases nitric oxide (NO), a primary mediator of smooth muscle tone that causes vasodilatation through the activity of endothelial-type nitric oxide synthase (eNOS)<sup>[101-104]</sup>. NO has an central role in vascular homeostasis with its bioavailability dependent on expression of endothelial eNOS<sup>[105]</sup>, presence of eNOS substrate and or co-factors<sup>[106]</sup>, phosphorylation of eNOS<sup>[107,108]</sup> or due to excessive depletion of NO such as seen with presence of

**Figure 1** Simplified diagram illustrating the positive and negative effects on endothelial progenitor cell proliferation, mobilisation and longevity together with proposed mechanisms of action of statin therapy. EPC: Endothelial progenitor cell; NO: Nitric oxide; eNOS: Endothelial nitric oxide synthase; VEGF: Vascular endothelial growth factor; mRNA: Messenger ribonucleic acid; TNF: Tumor necrosis factor alpha; IL-1: Interleukin 1; P13k-AKT: Phosphoinositide 3-kinase - protein kinase B pathway; NAD(P)H oxidase: Nicotinamide adenine dinucleotide phosphate-oxidase; miR : Micro non-coding ribonucleic acid.

excessive reactive oxygen species<sup>[109]</sup>. However the main functions of NO is as a cellular signaling molecule<sup>[101]</sup>, an angiogenic factor involved in stimulation, promotion, and stabilization of new blood vessels together with VEGFs, FGFs, Angiopoietins, PDGF, MCP-1, TGF, various integrins, VE-cadherin<sup>[110-113]</sup>. Statin therapy has been proposed to both enhance expression and activity of eNOS<sup>[114]</sup> a prerequisite stage for statin-mediated EPC mobilisation<sup>[115]</sup>. Statins are known to augment eNOS activity<sup>[116-118]</sup>, increase eNOS expression and restoration of endothelial function<sup>[104,119-121]</sup>. Statins have also been associated with increased EPC longevity *via* several pathways including inhibition of p27<sup>[122]</sup>, down regulating TNF- $\alpha$  or IL-1 $\beta$  expression<sup>[123]</sup> and prolonging eNOS expression<sup>[122]</sup> and finally by increasing eNOS mRNA half-life<sup>[124,125]</sup>. Kosmidou *et al*<sup>[126]</sup> found simvastatin and rosuvastatin prolonged expression by increasing 3' polyadenylation of eNOS mRNA. Laufs *et al*<sup>[88,124]</sup> firstly noted simvastatin and lovastatin reversed the down-regulation of eNOS expression caused by hypoxia and secondly simvastatin reversed down regulation of eNOS expression induced by oxidized LDL<sup>[88,124]</sup> a recognised cause of atherosclerosis.

#### **miR 221 and miR 222 levels**

A second observed pleiotropic mechanism of statin therapy has been a decreased level of micro non-coding RNAs called miR 221 and miR 222. These negatively

regulate protein expression at post-transcriptional stage<sup>[127]</sup>. This down regulating effect occurs by targeting 3' untranslated regions resulting in either degradation of target mRNA or impairing translation<sup>[128]</sup>. Furthermore miR-221 and miR-222 have been observed to regulate proliferation and differentiation of CD34-positive haematopoietic progenitor cells by reducing expression of *c-kit* receptor factor impairs haematopoietic progenitor cell proliferation<sup>[129]</sup>. Increased miR-221 and or miR-221 expression in EPC down regulates EPC differentiation and mobilisation *via* *c-kit* and or eNOS pathways in coronary artery disease patients<sup>[127]</sup>. Atorvastatin has been shown firstly to decrease miR 221 and miR 222, and secondly increase EPC numbers<sup>[127]</sup>. Cerda *et al*<sup>[130]</sup> found both atorvastatin and simvastatin increased NO levels and NOS3 mRNA expression, whereas ezetimibe did not. Atorvastatin, simvastatin and ezetimibe have all been shown to down-regulate the expression of miR-221, whereas miR-222 was reduced only after atorvastatin treatment. The magnitude of the reduction of miR-221 and miR-222 after treatment with statins correlated with an increment in NOS3 mRNA levels<sup>[130]</sup>. The eNOS and miR221/222 are thought likely to be components of the same pathway<sup>[131]</sup>.

#### **The PI3K/Akt/mTOR pathway**

The third proposed pleiotropic mechanism involves the phosphoinositide 3-kinase (PI3K)/protein kinase B

(Akt)/mammalian target of rapamycin (mTOR) signaling pathway plays. The PI3K/Akt/mTOR pathway plays a central role in multiple cellular processes, including cell proliferation, angiogenesis, metabolism, differentiation and longevity<sup>[132,133]</sup>. PI3K generates phosphatidylinositol 3,4,5-triphosphate (PIP3) an important lipid secondary messenger which in turn plays a central role in several signal transduction pathways<sup>[134,135]</sup> including activation of the serine/threonine kinases PDK1 and Akt. Akt controls protein synthesis and cell growth *via* the phosphorylation of mTOR<sup>[136]</sup>. The PI3K/Akt pathway has been associated with angiogenesis through the regulation of the NO signaling pathway<sup>[137]</sup>. The PI3K pathway releases a group of angiogenic factors including VEGF. VEGFR2 has a central role in VEGF-induced angiogenesis<sup>[138]</sup>. VEGF is required for the migration of endothelial cells and *via* PI3K-Akt dependent manner allows formation of capillary like structures<sup>[139]</sup>. Studies have shown that NO production may be induced by VEGF and appears to be attenuated by the inhibition of PI3K<sup>[140]</sup>. This is thought to occur *via* phosphorylation of eNOS at the serine 1177 residue by Akt<sup>[107,141]</sup>, required for the VEGF induced endothelial cell migration<sup>[142]</sup>. Factors that stimulate the PI3K/Akt protein kinase pathway, including statins, have been shown also to activate eNOS<sup>[87,141,143]</sup>. In turn, the expression of eNOS appears to be fundamental for mobilization of EPC and any impairment in PI3K/Akt/eNOS/NO signaling pathway may result in decreased EPC number<sup>[91,92]</sup>.

The PI3K/Akt/mTOR intracellular pathway *via* inhibition of the Rho kinase has also been shown to preserve mitochondrial permeability transition pore preventing mitochondrial apoptosis, and therefore death, while conserving cardiomyocyte function<sup>[144,145]</sup>.

These proposed mechanisms may account for difference in the effect of statin therapy in acute or chronic therapy. Statins given during acute ischaemic stress have been shown to firstly potentiate adenosine receptors<sup>[146,147]</sup> eventually leading to downstream regulation of eNOS and therefore increases NO production. Secondly statins augment activation of the reperfusion injury salvage kinase (RISK) pathway<sup>[148]</sup>. This results in enhanced activity of the PI3K/Akt/mTOR intracellular signal pathways<sup>[149]</sup>, leading to preservation of mitochondrial function and cardio-protection. Short-term high dose statin therapy have shown an increase in both EPC mobilisation from bone marrow and augmented function<sup>[92,150-154]</sup>.

Whereas chronic statin therapy has been linked to a phenomenon termed pre-ischaemic conditioning, protecting the myocardium against ischaemia<sup>[155]</sup>. This is believed to be secondary to statin induced NO availability by up regulation of eNOS and stabilisation of eNOS mRNA. Secondly, by increased production of NO and superoxide radicals improves vascular function and reducing vascular inflammation respectively<sup>[88,156]</sup>. Statins also inhibit isoprenylation of a number of Ras superfamily GTPase including Rho, Ras and Rab<sup>[157]</sup> NO inhibitors resulting in increased NO bioavailability.

Thirdly, by preventing mitochondrial apoptosis and preservation of cardiomyocyte function *via* the up-regulation of the PI3K/Akt/mTOR intracellular signalling pathway by inhibition of Rho kinase<sup>[144,145]</sup>. However, the RISK pathway has been shown the down regulated with chronic statin therapy<sup>[158]</sup> and has been shown to become reactivated by statin re-loading<sup>[159]</sup>. The latter may account for the increase in EPC count in patients on chronic statin therapy reloaded with statin therapy<sup>[80,99,100]</sup>.

### **Oxidative stresses**

Finally, EPC mobilisation and or function may also be affected by oxidative stress<sup>[153,160]</sup>. Oxidative stresses occur secondary to generation of oxygen free radicals or reactive oxygen species (ROS). Oxidative stress has a central role in cardiovascular disease, and a pivotal role in atherosclerosis<sup>[161]</sup>. Cellular oxidative stress seen with oxidized low-density lipoprotein (ox-LDL) has a central role in the pathogenesis of atherosclerosis. LDL is oxidised by reactive oxygen species from both circulating cells and cells on vascular walls<sup>[162,163]</sup>. In essence, LDL oxidation is a result of a chain reaction of free radicals converting polyunsaturated fatty acids into lipid peroxides and as a consequence, formation of active aldehydes<sup>[164]</sup>. The biochemical reaction forming ox-LDL have been found to cause senescence of EPCs<sup>[165]</sup>. Whereas high density lipoprotein is regarded as atheroprotective due to some part of its antioxidant properties also has a positive effect on EPC number and function<sup>[166]</sup>. There are a number of endogenous antioxidants exerting protective effects by scavenging ROS. An indirect way ROS effects EPCs includes ROS reacting with NO forming a potent oxidant<sup>[167]</sup> with a consequent decrease in NO. Decrease in NO either by excessive oxidation or impaired production reduces EPC mobilisation and/or function<sup>[161,168]</sup>. Secondly, direct exposure to oxidative stresses or in disease conditions with high oxidative stress, for example diabetes, is associated with induced EPC apoptosis with significant reduction in EPC numbers<sup>[168,169]</sup>, mobilisation, function<sup>[170]</sup> and reduced ability to migrate and or integrate into vasculature<sup>[161,171]</sup>.

In an attempt to counteract the effects of oxidative stress EPCs produce superoxide dismutase<sup>[172]</sup>. Interestingly, cardiovascular risk factors have been found to alter and or reduce the EPC antioxidant ability. Healthy volunteers have found to express higher levels of antioxidative enzyme catalases including glutathione peroxidase and manganese superoxide dismutase when comparing patients with cardiovascular disease<sup>[173,174]</sup>. The underlying pathophysiological mechanism currently remains undetermined. The antioxidant pleiotropic effect of statins may include indirect mechanism increasing NO bioavailability accounting for antioxidant properties contributing to an increase in EPC mobilisation and or function<sup>[114,175]</sup>. Secondly statin therapy has also been shown to inhibit activation of NAD(P)H oxidase and ROS release<sup>[176]</sup> but also activate catalase and thioredoxin

ROS scavenging mechanisms<sup>[176,177]</sup>. Finally, statins appear to have a direct effect by significantly reducing peroxide induced apoptosis of EPCs<sup>[169]</sup> and decreasing the oxidative damage to DNA in EPCs<sup>[178]</sup>.

### G proteins and G protein-coupled receptors

G protein-coupled receptors (GPCR) are comprised of seven trans-membrane domain proteins and are a super family consisting of a large and diverse number of proteins encoded by approximately 5% of human genes<sup>[179]</sup>. There have been a number of classification systems proposed the most recent "GRAFS" (Glutamate, Rhodopsin, Adhesion, Frizzled/Taste2 and Secretin)<sup>[180]</sup>. In mammals there are five main families<sup>[181]</sup>. GPCRs have an integral role in transfer of extracellular stimuli to within the cell by conformational changes in trans-membrane domain structure<sup>[182-185]</sup>. They regulate physiological responses to a myriad of endogenous ligands including amines, glycoproteins, peptides and lipids. Therefore, not surprisingly that GPCRs have been implicated in regulation of cellular maintenance, differentiation, proliferation and migration of various stem cells<sup>[186-189]</sup>.

GPCRs modulate activity of intracellular signaling *via* G proteins. There are currently four known G protein subfamilies each able to potentiate a number of downstream effectors triggering a number of signaling pathways<sup>[182]</sup>. These include activation of Rho associated kinases<sup>[190,191]</sup>, activation or inhibition of cyclic AMP production<sup>[192]</sup> and PI3Ks and therefore modulate the PI3K/Akt pathway<sup>[193,194]</sup>. The aforementioned have been implicated in EPC proliferation and function as described above. GPCRs have evoked great interest as a possible target for novel drug therapy<sup>[195]</sup> as an estimated 50% of all currently prescribed drugs target only a small proportion of GPCRs<sup>[196]</sup>. They are also becoming increasingly recognised as having a major role in stem cell signaling<sup>[197]</sup>. The role of GPCR in regulation and function of EPCs and the effect of statin therapy remains yet to be elucidated however current evidence suggests that they may have a pivotal role.

### CONCLUSION

EPCs have a pivotal role in the maintenance of vascular integrity. However, factors that influence EPC number, migration and function are now becoming recognised and have potentially a significant role in management of ischaemic heart disease patients. Statins once thought to modify cardiovascular risk only by lowering LDL-cholesterol are now being acknowledged as having alternative mechanisms that appear to have beneficial pleiotropic effects. One such mechanism may be mediated by EPCs. A number of studies have shown positive pleiotropic effect of statins on EPCs, both function and number. There appears to be a complex interaction between statins and EPC that is only now becoming recognised. Despite great progress since Asahara's pioneering work, there remain gaps within our

knowledge regarding the pleiotropic effect(s) of statins on EPCs. Further studies are required to elucidate and fully understand any pleiotropic effect and this may guide future beneficial therapeutic interventions.

### Abstract

Vitamin D deficiency is a prevalent condition, cutting across all ethnicities and among all age groups, and occurring in about 30%-50% of the population. Besides vitamin D established role in calcium homeostasis, its deficiency is emerging as a new risk factor for coronary artery disease. Notably, clinical investigations have suggested that there is an association between

hypovitaminosis D and acute myocardial infarction (AMI). Not only has it been linked to incident AMI, but also to increased morbidity and mortality in this clinical setting. Moreover, vitamin D deficiency seems to predispose to recurrent adverse cardiovascular events, as it is associated with post-infarction complications and cardiac remodeling in patients with AMI. Several mechanisms underlying the association between vitamin D and AMI risk can be involved. Despite these observational and mechanistic data, interventional trials with supplementation of vitamin D are controversial. In this review, we will discuss the evidence on the association between vitamin D deficiency and AMI, in terms of prevalence and prognostic impact, and the possible mechanisms mediating it. Further research in this direction is warranted and it is likely to open up new avenues for reducing the risk of AMI.

**Key words:** Vitamin D; Acute myocardial infarction; Incidence; Prognosis

## INTRODUCTION

Cardiovascular disease, and specifically acute myocardial infarction (AMI), is the main cause of morbidity and mortality in western countries, despite current preventive and therapeutic strategies<sup>[1,2]</sup>.

Besides the traditional, most recognized risk factors for AMI development, new risk factors are emerging with potential relevant therapeutic implications. Among them, hypovitaminosis D has been the focus of recent interest. It is well known that vitamin D insufficiency, or deficiency, is highly prevalent in the general population<sup>[3-7]</sup>. Traditionally, the most characterized consequences of vitamin D depletion have involved bone metabolism and calcium homeostasis<sup>[8]</sup>. However, its close association with major cardiovascular risk factors, such as diabetes, hypertension, and chronic kidney disease, and the detection of nuclear vitamin D receptors (VDR) on vascular endothelial cells and cardiomyocytes have paved the way to studies investigating the intriguing link between hypovitaminosis D and cardiac disease<sup>[9-11]</sup>.

Deficiency of vitamin D was shown to be common in AMI, and preliminary studies indicate a possible association with their short-term and long-term prognosis<sup>[12-14]</sup>. Indeed, vitamin D deficiency seems to predispose to in-hospital and recurrent adverse cardiac events, since it is associated with the number of affected coronary arteries, AMI complications, and cardiac remodeling in patients with AMI<sup>[12-14]</sup>.

In this review, we provide an overview on the currently available evidence supporting the relationship between hypovitaminosis D and AMI, its prognostic relevance, and the possible underlying mechanisms. Finally, we will try to identify challenges and future investigative perspectives in this field.

### Vitamin D metabolism

There are two major forms of vitamin D: Vitamin D<sub>2</sub>, which is contained in plants and fortified foods, and vitamin D<sub>3</sub>, which is obtained from aliments or through the conversion of dehydrocholesterol in the skin<sup>[11,15]</sup>. Of note, the cutaneous synthesis of vitamin D<sub>3</sub> from sunlight exposure is the main source of vitamin D in humans. Vitamin D undergoes hydroxylation in the liver to 25-hydroxyvitamin D - its main circulating form in the blood - and then in the kidney to 1,25-dihydroxyvitamin D. The 1,25(OH) vitamin D<sub>3</sub> reaches the nucleus where, by binding to its receptors, it regulates the transcription and function of more than 200 genes<sup>[16,17]</sup>. The VDR, which are expressed in enterocytes, osteoblasts, parathyroid glands, distal renal tubule cells, regulate calcium homeostasis and bone metabolism. Recent investigations have also demonstrated their presence on endothelial cells, lymphocytes, macrophages,

smooth vascular muscle cells, beta-pancreatic cells and cardiomyocytes, through which vitamin D<sub>3</sub> mediates cardiovascular effects<sup>[18-20]</sup>.

There is no consensus on how to define vitamin D deficiency, and this introduces significant difficulties in conducting epidemiological studies in this field<sup>[21-24]</sup>. The most widely accepted definition for normal vitamin D serum levels, according to the United States Endocrine Society guideline recommendations, is  $\geq 30$  ng/mL. Vitamin D insufficiency is characterized by levels of 21-29 ng/mL, while its deficiency by levels  $\leq 20$  ng/mL<sup>[25]</sup>. Vitamin D deficiency is the most common nutritional deficiency worldwide in both children and adults<sup>[26]</sup>. In the United States and Europe, > 40% of the adult population has low vitamin D levels<sup>[26]</sup>. The Third National Health and Examination Survey (NHANES III) reports a high prevalence of vitamin D deficiency and its rapid increase, going from 55% in the period 1988-1994 to 77% in the years 2001-2004<sup>[27,28]</sup>. The main causes of vitamin D deficiency are listed in Table 1.

### Rationale for the link between vitamin D and AMI

A growing amount of data has highlighted the potential link between vitamin D and cardiovascular disease. Firstly, VDR have been found in the myocardium, as well as in vascular cells<sup>[18,29,30]</sup>. Secondly, epidemiological studies demonstrated that the incidence of coronary artery disease, diabetes, hypertension, and hypovitaminosis D, increase in proportion to distance from the equator<sup>[31]</sup>. Cardiac death and prevalence of vitamin D deficiency have also been reported to be at their highest during periods of decreased sunlight exposure (*i.e.*, winter months)<sup>[32]</sup>. Thirdly, new evidence suggests that vitamin D deficiency has a role in the development of different cardiovascular risk factors, in particular hypertension<sup>[33,34]</sup>, metabolic syndrome<sup>[35]</sup>, and diabetes mellitus<sup>[36-38]</sup>. Finally, patients with conditions known to be associated with vitamin D deficiency, such as chronic kidney disease and primary hyperparathyroidism, die more frequently from cardiovascular causes than from those related to their underlying disease<sup>[39]</sup>.

Taken together, these findings strongly support the

notion that vitamin D is involved in cardiac risk factor development, finally leading to an increased burden in coronary artery disease and to a worse short-term and long-term outcome in AMI patients.

### **Clinical studies on vitamin D in AMI**

An initial Danish report in 1978 examined vitamin D levels in 75 patients with stable angina, in 53 patients with AMI, and in 409 healthy subjects, and it found that vitamin D levels were significantly lower in patients with angina or AMI than in controls<sup>[40]</sup>. In 1990, a case control study showed that AMI patients had lower vitamin D levels than controls, and this difference was more pronounced in the winter-spring period<sup>[41]</sup>. Of note, the relative risk of AMI decreased across increasing quartiles of vitamin D, suggesting an inverse correlation between vitamin D levels and AMI risk<sup>[41]</sup>. These figures have also been confirmed in more contemporary cohorts. Among 1739 Framingham Offspring Study healthy participants, the rates of major cardiovascular events were 50% and 80% higher in those with vitamin D insufficiency and deficiency, respectively<sup>[42]</sup>. In particular, subjects with no history of coronary artery disease and vitamin D levels < 10 ng/mL experienced a hazard ratio of 1.8 for developing a first cardiovascular event during a 5-year follow-up compared with subjects with levels > 15 ng/mL<sup>[43]</sup>. Finally, in 18225 men in the Health Professionals Follow-up Study, low vitamin D levels were associated with a higher risk of AMI, even after controlling for other cardiovascular risk factors and, at 10-year follow-up, subjects with normal vitamin D levels (> 30 ng/mL) had approximately half the risk of AMI<sup>[43]</sup>. These findings have been recently confirmed in a large meta-analysis that showed an adjusted pooled relative risk of 1.52 for total cardiovascular events when comparing the lowest to the highest categories of baseline circulating vitamin D concentration<sup>[44]</sup>. Thus, there is growing evidence suggesting that vitamin D deficiency represents a novel risk factor for AMI.

In agreement with these epidemiological data, prospective reports have found a high prevalence of vitamin D deficiency in patients hospitalized with AMI. A multicenter study performed in 239 acute coronary syndrome patients showed that 96% of them had vitamin D levels < 30 ng/mL at hospital presentation<sup>[45]</sup>. In line with this, Ng *et al.*<sup>[13]</sup> demonstrated that 74% of AMI patients had low vitamin D levels and, of note, 36% of them had a severe deficiency. Correia *et al.*<sup>[46]</sup> reported a median serum concentration of vitamin D of 18.5 ng/mL in a cohort of 206 AMI patients (7% with STEMI), and a severe deficiency in 10% of the sample analyzed. Similar findings were also observed by De Metrio *et al.*<sup>[12]</sup> and Aleksova *et al.*<sup>[14]</sup>, who reported a prevalence of hypovitaminosis D in AMI patients of 89% and 68%, respectively.

Low vitamin D levels seem to be not only a prevalent independent risk factor for AMI, but also to be associated with a worse outcome when it occurs (Table 2). Correia

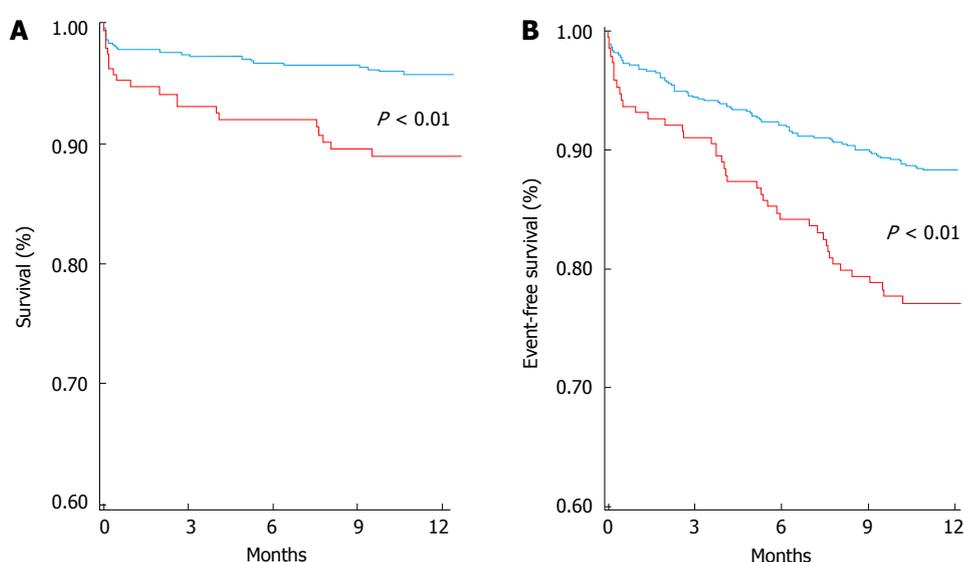

*et al.*<sup>[46]</sup> provided the first evidence of the potential independent association between severe deficiency of vitamin D and in-hospital mortality in patients with acute coronary syndromes. Indeed, patients with vitamin D levels < 10 ng/mL had a 24% in-hospital cardiovascular mortality rate, significantly higher than that observed in the remaining patients (4.9%, with a relative risk 4.3). A possible association between hypovitaminosis D and higher in-hospital mortality was also reported by Khalili *et al.*<sup>[47]</sup> in 139 STEMI patients. However, the study was underpowered to show statistically significant difference in in-hospital mortality between patients with normal and low vitamin D<sup>[48]</sup>. More robust data have been provided on the long-term clinical implications of low vitamin D levels in AMI. Thus far, the largest study assessing vitamin D and prognosis in 1259 acute coronary syndrome patients is that by Ng *et al.*<sup>[13]</sup>. In their study, the lowest vitamin D quartile (< 7.3 ng/mL) was associated with long-term major adverse cardiovascular events. Notably, the association was predominantly with re-hospitalization for acute decompensated heart failure or for successive acute coronary syndrome<sup>[13]</sup>. In agreement with these findings, in our cohort of AMI patients, the lowest quartile of vitamin D was a strong predictor of 1-year mortality (Figure 1)<sup>[12]</sup>. Of note, vitamin D deficiency was again a borderline independent predictor of in-hospital mortality, possibly due to the relatively low in-hospital mortality rate of our population, and it was associated with the highest risk of several in-hospital major adverse cardiac events. Interestingly, the lowest vitamin D quartile was associated with a higher incidence of bleeding requiring transfusion, although similar baseline hemoglobin values<sup>[12]</sup>. This is a crucial issue in the setting of AMI, as potent antithrombotic therapy is the mainstay of treatment, and bleeding and transfusions have a detrimental role on outcomes. We also found an association between the lowest vitamin D quartile and acute respiratory insufficiency rate<sup>[12]</sup>. The higher occurrence of these threatening complications might have contributed to the higher in-hospital mortality risk found in AMI patients and low vitamin D levels.

The causal relationship between vitamin D status and outcomes in AMI remains to be elucidated. Indeed, in more than 3000 patients undergoing coronary angiography, a significant association between hypovitaminosis D and lower left ventricular function was shown<sup>[49]</sup>. Of note, in this report, vitamin D deficiency was associated with deaths due to heart failure and with sudden cardiac deaths<sup>[50]</sup>. This highlights the possible relevance of vitamin D contribution to several aspects of AMI, such as acute ventricular dysfunction, heart failure progression, post-AMI ventricular remodeling, inflammation, thrombotic/bleeding balance and arrhythmias, which should be more deeply investigated through well-designed studies. Taking together, these considerations, along with older age, higher incidence of well-known cardiovascular risk factors, and lower rate of

Reproduced from De Metrio *et al*<sup>[12]</sup>.  
<sup>1</sup>Combined end point: death, major bleeding (requiring blood transfusion), acute pulmonary edema, cardiogenic shock, clinically significant tachyarrhythmias and bradyarrhythmias, and acute kidney injury.

reperfusion strategy, might explain the worse outcome of AMI patients presenting with low vitamin D levels (Figure 2). A similar prognostic relevance has also been reported in critically ill patients, in whom a low vitamin D status was significantly associated with disease severity and

mortality<sup>[50-52]</sup>.

#### Potential therapeutic implications

Although many studies suggest a higher cardiovascular risk associated with low vitamin D levels, the data

**Figure 2** Potential factors impacting on acute myocardial infarction occurrence and outcome associated with low vitamin D levels. AKI: Acute kidney injury; CA/PCI: Coronary angiography/percutaneous coronary intervention; LV: Left ventricular; RAAS: Renin-angiotensin-aldosterone system.

regarding vitamin D supplementation are more sparse and controversial, in terms of primary prevention<sup>[53-57]</sup>. The potential benefit of vitamin D administration in the early phase of AMI has not been investigated yet. From a clinical point of view, vitamin D levels can be rapidly determined by blood testing and treated by supplementation. It has been demonstrated that a single oral ultra-high dose of vitamin D is able to restore normal levels in 2 d in critically ill patients, with no adverse effects, potentially providing an easy-to-administer dosing regimen for intervention trials in acute cardiovascular settings<sup>[58]</sup>. Although this evidence was not focused on AMI patients, it may pave the way for new investigations based on the use of a high oral loading dose regimen of vitamin D for restoration of adequate levels within few days. Notably, a dose-response association with cardiovascular risk and mortality has been demonstrated by Wang *et al.*<sup>[44]</sup>, and this was particularly true when short-term outcomes were considered.

Data on vitamin D supplementation in the setting of secondary prevention of AMI are also lacking. Yet, it has been recently demonstrated that high-dose vitamin D supplementation for 1-year in patients with chronic heart failure due to left ventricular systolic dysfunction and vitamin D deficiency, on contemporary optimal medical therapy, resulted in a significant improvement in left ventricular structure and function<sup>[59]</sup>. Of note, in almost 60% of these patients, the etiology was ischemic heart disease, suggesting a possible beneficial effect on post-AMI ventricular dysfunction<sup>[59]</sup>.

Some studies have also proposed a possible association between low vitamin D and increased levels of cholesterol and of inflammatory markers, in particular C-reactive protein, in the setting of AMI<sup>[12,46]</sup>. Interestingly, 1-year atorvastatin treatment in patients with AMI determined a marked decrease in cholesterol and an unexpected increase in vitamin D levels, reinforcing the interplay among inflammation, low vitamin D and

dyslipidemia<sup>[60,61]</sup>.

### Future perspectives and conclusions

Thus far, evidences in this field have been mainly driven by observational cohort studies, and these data are hypothesis-generating. Therefore, whether vitamin D is a risk factor or marker in this clinical setting cannot be inferred from the current literature. Larger studies are needed in order to shed lights on this issue. Because of their health status, frail patients with a high cardiovascular risk burden may spend mostly of their time indoors, which leads to low levels of vitamin D. This is also supported by the fact that such a similar observation has been found in patients with cancer, multiple sclerosis, and psychiatric diseases, potentially supporting the notion that hypovitaminosis D may be simply a marker of health<sup>[62]</sup>. However, even when adjusted for major confounders, vitamin D status still remains an independent risk factor, as it is significantly linked to incident AMI, worse short-term outcome, and recurrent major adverse cardiovascular events.

Whether vitamin D supplementation can counteract this increased risk in AMI patients is still an unanswered question, which should be investigated in large, well-designed, adequately powered interventional trials.

### Abstract

Heart failure (HF) is an emerging epidemic associate with significant morbidity, mortality, and health care expenditure. Although there were major advances in pharmacologic and device based therapies for the management of HF, mortality of this condition remains high. Accurate monitoring of HF patients for exacerbations is very important to reduce recurrent hospitalizations and its associated complications. With the failure of clinical signs, tele-monitoring, and laboratory bio-markers to function as early markers of HF exacerbations, more sophisticated techniques were sought to accurately predict the circulatory status in HF patients in order to execute timely pharmacological intervention to reduce frequent hospitalizations. CardioMEMS™ (St. Jude Medical, Inc., Saint Paul, Minnesota) is an implantable, wireless pulmonary arterial pressure (PAP) monitoring system which transmits the patient's continuous PAPs to the treating health care provider in the ambulatory setting. PAP-guided medical therapy modification has been shown to significantly reduce HF-related hospitalization and overall mortality. In advanced stages of HF, wireless access to hemodynamic information correlated with earlier left ventricular assist device implantation and shorter time to heart transplantation.

**Key words:** CardioMEMS; Heart failure; Remote heart failure monitoring; Pulmonary arterial pressure monitoring; Left ventricular assist device

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Traditional heart failure monitoring methods have failed to accurately and timely identify worsening heart failure. Remote pulmonary artery pressure monitoring *via* CardioMEMS™ heart failure system identified heart failure exacerbations earlier and more accurately than clinical signs, and timely medical

interventions resulted in reduced hospitalizations and mortality. Remote pulmonary artery pressure monitoring appears to have positive clinical implications in patients with mechanical circulatory support.

## INTRODUCTION

Heart failure (HF) is a chronic debilitating condition which impairs the ability of the heart to effectively pump the blood to the body to meet its metabolic requirements. HF is an emerging epidemic with an estimated prevalence of 5.8 million in the United States, and over 23 million worldwide<sup>[1]</sup>. Within the United States, the incidence of HF exceeds 650000 each year with an estimated annual financial burden of around 30.7 billion dollars<sup>[2,3]</sup>. Although there were major advances in pharmacologic and device based therapies for the management of HF which improved the overall survival over time, mortality of this condition remains high. The estimated survival after the diagnosis of HF is 50% at 5 years and 10% at 10 years<sup>[1]</sup>. Hospitalization for acute decompensated HF serves as a poor prognostic indicator with an approximate 30% and 50% readmission rates at 1-mo and 6-mo, respectively<sup>[1,3]</sup>. With improved survival of patients after acute myocardial infarction, a growing elderly population, and frequent hospitalizations in the HF population owing to acute exacerbations, HF continues to be one of the leading causes of morbidity, mortality, and health care expenditures in the United States and worldwide.

Around 150000-250000 Americans suffer from advanced stage HF<sup>[4]</sup>. Although cardiac transplantation is the gold standard treatment in such patients, limited organ availability restricts the number of heart transplants to around 2500 per year ([https://www.unos.org/data/transplant-trends/#transplants\\_by\\_organ](https://www.unos.org/data/transplant-trends/#transplants_by_organ)). More than 4000 patients are currently on the waiting list for a cardiac transplant ([www.unos.org/data/transplant-trends/#waitlists\\_by\\_organ](http://www.unos.org/data/transplant-trends/#waitlists_by_organ)), a number which is expected to increase significantly because of the increasing number of patients living with advanced HF and an increasing elderly population. Left ventricle assist device (LVAD) has emerged as a life-saving option for these patients as either bridge to transplant, bridge to decision, bridge to recovery or as destination therapy. Around 15000 HF patients across the world are currently supported with LVADs<sup>[5]</sup>. LVAD serves as destination therapy in more than 45% of the patients living with the device<sup>[5]</sup>.

## PREVIOUSLY TESTED METHODS FOR MONITORING HF PATIENTS

Identification of physical manifestations such as weight gain, extremity edema, fatigue, shortness of breath, orthopnea, paroxysmal nocturnal dyspnea, jugular venous distention, third heart sounds, and rales, *etc.* have poor to moderate sensitivities and are often late manifestations of worsening HF, thereby, relying on these markers have limited impact on reducing HF hospitalizations<sup>[6]</sup>. Also, such efforts largely employ patient self-management strategies, including diuretic dose adjustments based on clinical worsening, and are unsuccessful in patients with poor self-care skills and compliance<sup>[6]</sup>. Two large trials which investigated the benefits of tele-monitoring in HF population failed to show any significant decrease in the all-cause mortality and HF hospitalizations in the tele-monitored group<sup>[6]</sup>. A smart-phone based electrocardiographic monitoring of HF has been recently proposed, but there is not much data exploring this idea<sup>[7]</sup>.

Lainchbury *et al.*<sup>[8]</sup> compared N-terminal pro-B-type natriuretic (NT-proBNP) guided titration of medical therapy in HF patients with intensive clinical management and with usual care in a randomized sample of 564 patients. There was a reduction in the 3-year mortality in the NT-proBNP-guided group compared to the clinically-guided group (30.9%;  $P = 0.048$ ) and to those with usual care (31.3%;  $P = 0.021$ ). These benefits were selectively seen in patients  $\leq 75$  years of age. However, there was no statistically significant difference in the overall hospitalizations for HF and the secondary outcomes among all the groups<sup>[8]</sup>. Another study monitored plasma B-type natriuretic peptide (BNP) levels in up to 558 chronic stable HF patients in an ambulatory setting to predict imminent decompensation<sup>[9]</sup>. The study showed that both symptomatic and asymptomatic HF patients had a wide range of plasma BNP levels. Interestingly, 21% of symptomatic decompensated HF patients had BNP levels below the diagnostic threshold of  $< 100$  pg/mL<sup>[9]</sup>.

## REMOTE HEMODYNAMIC MONITORING IN HF PATIENTS

With the failure of reliable clinical symptoms/signs, tele-monitoring, and laboratory bio-markers to help reduce the hospitalizations, and health care expenditure in the HF population, more sophisticated techniques were sought to accurately predict the circulatory status in HF patients in order to execute timely pharmacological intervention to prevent the primary onus of this disease, *i.e.*, hospitalizations. Echocardiography is being used as a monitoring system in the hospitalized and ambulatory population, but it is associated with significant costs, less accuracy, and observer variability. Traditionally, in hospitalized HF patients, right heart catheterization

(RHC) provides invaluable information regarding the volume status and filling pressures which can form the basis of successful medical management. However, RHC is not routinely recommended to aid in the management of hospitalized decompensated HF patients owing to its invasive nature and associated risks. We had no such accurate monitoring systems in the ambulatory setting until scientific advances led to the development of implantable hemodynamic monitors (IHMs) which provided hemodynamic information comparable to the information obtained from a RHC<sup>[10]</sup>. The idea of IHM based monitoring and necessary interventions in HF patients was innovative and exiting.

Earlier trials of implantable hemodynamic monitoring in HF patients did not show significant clinical benefit or were unable to adequately assess clinical efficacy. The COMPASS-HF (Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure) trial using Chronicle (Medtronic Inc., Minneapolis, Minnesota) to estimate right ventricular pressures and guide medical therapy, did not show a significant reduction in HF-related events when compared to the control group<sup>[11]</sup>. The Reducing Decompensation Events Utilizing Intracardiac Pressures in Patients With Chronic Heart Failure (REDUCEhf) study employed a device combining IHM and implantable cardioverter-defibrillator technology to measure right ventricular pressures and guide medical therapy<sup>[12]</sup>. The REDUCEhf study was unable to test clinical efficacy end points adequately and findings from this study did not show a difference in the rate of HF-equivalents when medical therapy was guided based on the information obtained from the IHM<sup>[12]</sup>.

The Hemodynamically Guided Home Self-Therapy in Severe Heart Failure Patients (HOMEOSTASIS) trial is a small study of 40 patients in which the benefit of physician-directed patient self-management of left atrial pressures as measured with the implantable HeartPOD (St. Jude Medical Inc, Minneapolis, Minnesota) was investigated<sup>[13]</sup>. Left atrial pressure guided medical therapy was associated with an improved event-free survival (death or hospitalization for acute decompensated HF), reduced mean daily left atrial pressures, improved New York Heart Association (NYHA) functional class, improved left ventricular ejection fraction, increased doses of neuro-hormonal antagonists, and reduced diuretic doses<sup>[13]</sup>. Encouraging results from this smaller study formed the basis of the larger and currently ongoing LAPTOP-HF trial which will investigate the role of implantable left atrial pressure monitoring in conjunction with a new HF treatment paradigm across the spectrum of HF patients<sup>[14]</sup>.

pressure monitoring system. It measures PA pressures from a battery free capacitive electromechanical sensor which is permanently implanted with a delivery system in the distal pulmonary artery with a RHC *via* transvenous access. An electronic system transmits the generated data to a secure network where it is readily available for interpretation by the treating clinician. Verdejo *et al*<sup>[15]</sup> showed that wireless PA pressure monitoring using the CardioMEMS sensor correlated with Swan-Ganz catheter and echocardiographic PA pressure measurements. The outcomes of remote management of HF patients guided by wireless PA pressure monitoring was investigated in the landmark CHAMPION (CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients) trial<sup>[16]</sup>.

The CHAMPION trial is a randomized, controlled, multi-center, single-blind trial in which 550 NYHA class III HF patients were implanted with the wireless CardioMEMS HF pressure sensor system<sup>[16]</sup>. Physicians had access to the PA pressures of the patients in the treatment group only, in which medications were adjusted based on the generated data. The control group received traditional HF management. The primary efficacy endpoint was the rate of HF-related hospitalizations at 6 mo. In comparison to the control group, there was a remarkable 28% reduction in HF-related hospitalizations at 6 mo, and 37% at 15 mo in the treatment group (Hazard ratio 0.63,  $P < 0.0001$ )<sup>[17]</sup>. There were no pressure sensor failures and 98.6% of the study population was free from device-related or system-related complications<sup>[17]</sup>. A sub-analysis of the original trial in HF with preserved ejection fraction (HFpEF) patients showed that there was a 50% reduction ( $P < 0.0001$ ) in HF-related hospitalizations at 17 mo in the treatment group<sup>[18]</sup>. These landmark findings led to the Food and Drug Administration approval of the CardioMEMS™ HF system for ambulatory hemodynamic monitoring in NYHA class III HF with reduced ejection fraction (HFrEF) and HFpEF patients, who are on optimal medical therapy, and had a HF hospitalization in the previous year<sup>[19]</sup>. In the 2016 European society of Cardiology guidelines, CardioMEMS received a Class IIb recommendation for directed therapy management and monitoring tool in HF patients<sup>[20]</sup>.

Numerous sub-analyses supported the encouraging results obtained from the original CHAMPION trial. The reduced HF-related hospitalization rate was postulated to be from physician controlled effective changes in diuretic dosing in the treatment group ( $P < 0.0001$  for more frequent diuretic dose changes in treatment group compared to control)<sup>[21]</sup>. Wireless PA pressure-guided HF management was superior to clinical signs-guided management with a 67% relative risk reduction ( $P = 0.0007$ ) in HF hospitalizations when diuretic doses were adjusted based on PA pressure alone vs clinical signs alone<sup>[22]</sup>. At 6 mo, the target group experienced a higher frequency of medication adjustments with significant increases in the doses of diuretics, vasodilators, and

---

## CARDIOMEMS™ AND REMOTE PULMONARY ARTERIAL PRESSURE MONITORING

---

CardioMEMS™ (St. Jude Medical, Inc., Saint Paul, Minnesota) is a wireless pulmonary arterial (PA)

neuro-hormonal antagonists with preserved renal function despite intensification of diuretic therapy<sup>[23]</sup>. Remote PA pressure-guided treatment resulted in similar reductions in HF hospitalization in HFrEF patients with and without a cardiac resynchronization therapy (CRT) device, suggesting that HF management guided by PA pressures may provide additive benefits to CRT<sup>[24]</sup>.

Wireless PA-pressure monitoring on top of guideline-directed medical therapy and CRT or ICD, had an additive effect in improving HF hospitalizations and mortality<sup>[25]</sup>. There were significant reductions in all-cause hospitalization ( $P < 0.0032$ ), and in the number of deaths or all-cause hospitalization in the treatment group ( $P = 0.0017$ )<sup>[26]</sup>. Interestingly, it was observed that measurement of PA pressures using RHC alone may result in under-diagnosing pulmonary hypertension related to HF. Of the 217 patients who did not meet criteria for pulmonary hypertension during implantation RHC, 49% met criteria for pulmonary hypertension based in the first week IHM data<sup>[27]</sup>. Alam *et al.*<sup>[27]</sup> compared 34 HF patients who had an implanted CardioMEMS HF system with 32 HF patients without an IHM, and reported a three-fold improvement in the Kansas City Cardiomyopathy Questionnaire scores ( $P < 0.001$ ) and increased 6-min walk distance ( $P < 0.001$ ) in the CardioMEMS group. These findings represent improved quality of life and exercise capacity. Results from the CHAMPION trial and subsequent sub-analysis confirmed that early and appropriate medical interventions following early detection of elevated PA pressures resulted in a significant reduction of HF-related hospitalizations, readmission rates and mortality.

There is an increasing trend in the number of HF patients living with LVADs and an increasing use of LVAD as destination therapy for advanced HF patients. Feldman *et al.*<sup>[29]</sup> conducted a sub-analysis of the CHAMPION trial to determine the validity of remote PA pressure directed therapy on optimization of medications, pump parameters, and timing of heart transplantation in patients receiving a LVAD. Of the 27 patients who received an LVAD, 15 patients were assigned to the treatment group where their medical therapy was modified based on PA pressures and 12 patients in the control group received standard care. The data obtained from CardioMEMS HF system led to significantly more medication changes in the treatment arm ( $P = 0.025$ ). Wireless access to hemodynamic information correlated with earlier LVAD implantation ( $P = 0.001$ ) and shorter time to transplantation ( $P = 0.001$ ) in the treatment arm<sup>[29]</sup>.

Over the last few decades, efforts have been directed at reducing recurrent hospitalizations for worsening HF in this patient population. A variety of markers varying from clinical symptoms and signs to laboratory testing have been investigated to identify acute decompensated HF early enough to prevent hospitalizations, subsequent morbidity, and health care expenditure. Daily weight monitoring is a cornerstone for managing HF patients. It has been shown that increases in body weight begin at

least 1 week before a HF hospitalization<sup>[30]</sup>. However, less than a half of the HF patients including those recently discharged after a hospitalization for HF exacerbation check their weight on a daily basis<sup>[31]</sup>. Daily electronic body weight transmission to a HF clinic in patients with severe HF who had a recent HF hospitalization did not show any benefit in reducing HF re-hospitalization or death<sup>[32]</sup>.

## CONCLUSION

HF continues to be a major public health problem with a significant financial burden. As more and more people are living with HF, it is important have a simple, reliable, and valid monitoring system to aid in the early identification and appropriate management of worsening HF in the ambulatory setting. IHM is an innovative and exciting monitoring system for HF management. CardioMEMS has steered HF research into a new direction which will serve as the gateway to future therapies and innovations in the management of chronic HF patients. Also with increasing number of people living with LVADs and LVAD being used as destination therapy in a large percentage of the LVAD population, CardioMEMS will be a promising monitoring system to better manage HF as well as the LVAD device in this population. However, given the small number of participants involved in many of the available trials, large multicenter randomized clinical trials are needed to make valid recommendations in an effort to lower mortality and improve quality of life in the chronically sick HF population. Wireless left atrial pressure-guided and PA pressure-guided management of HF can have a substantial positive effect on reducing the financial burden of HF and improving the overall morbidity and mortality in this population.

### Abstract

#### AIM

To assess the prevalence of depressed heart rate variability (HRV) after an acute myocardial infarction (MI), and to evaluate its prognostic significance in the present era of immediate reperfusion.

#### METHODS

Time-domain HRV (obtained from 24-h Holter recordings) was assessed in 326 patients ( $63.5 \pm 12.1$  years old; 80% males), two weeks after a complicated MI treated by early reperfusion: 208 ST-elevation myocardial infarction (STEMI) patients (in which reperfusion was

successfully obtained within 6 h of symptoms in 94% of cases) and 118 non-ST-elevation myocardial infarction (NSTEMI) patients (percutaneous coronary intervention was performed within 24 h and successful in 73% of cases). Follow-up of the patients was performed *via* telephone interviews a median of 25 mo after the index event (95%CI of the mean 23.3-28.0). Primary end-point was occurrence of all-cause or cardiac death; secondary end-point was occurrence of major clinical events (MCE, defined as mortality or readmission for new MI, new revascularization, episodes of heart failure or stroke). Possible correlations between HRV parameters (mainly the standard deviation of all normal RR intervals, SDNN), clinical features (age, sex, type of MI, history of diabetes, left ventricle ejection fraction), angiographic characteristics (number of coronary arteries with critical stenoses, success and completeness of revascularization) and long-term outcomes were analysed.

## RESULTS

Markedly depressed HRV parameters were present in a relatively small percentage of patients: SDNN < 70 ms was found in 16% and SDNN < 50 ms in 4% of cases. No significant differences were present between STEMI and NSTEMI cases as regards to their distribution among quartiles of SDNN ( $\chi^2 = 1.536$ ,  $P = 0.674$ ). Female sex and history of diabetes maintained a significant correlation with lower values of SDNN at multivariate Cox regression analysis (respectively:  $P = 0.008$  and  $P = 0.008$ ), while no correlation was found between depressed SDNN and history of previous MI ( $P = 0.999$ ) or number of diseased coronary arteries ( $P = 0.428$ ) or unsuccessful percutaneous coronary intervention (PCI) ( $P = 0.691$ ). Patients with left ventricle ejection fraction (LVEF) < 40% presented more often SDNN values in the lowest quartile ( $P < 0.001$ ). After > 2 years from infarction, a total of 10 patients (3.1%) were lost to follow-up. Overall incidence of MCE at follow-up was similar between STEMI and NSTEMI ( $P = 0.141$ ), although all-cause and cardiac mortality were higher among NSTEMI cases (respectively: 14% *vs* 2%,  $P = 0.001$ ; and 10% *vs* 1.5%,  $P = 0.001$ ). The Kaplan-Meier survival curves for all-cause mortality and for cardiac deaths did not reveal significant differences between patients with SDNN in the lowest quartile and other quartiles of SDNN (respectively:  $P = 0.137$  and  $P = 0.527$ ). Also the MCE-free survival curves were similar between the group of patients with SDNN in the lowest quartile *vs* the patients of the other SDNN quartiles ( $P = 0.540$ ), with no difference for STEMI ( $P = 0.180$ ) or NSTEMI patients ( $P = 0.541$ ). By the contrary, events-free survival was worse if patients presented with LVEF < 40% ( $P = 0.001$ ).

## CONCLUSION

In our group of patients with a recent complicated MI, abnormal autonomic parameters have been found with a prevalence that was similar for STEMI and NSTEMI cases, and substantially unchanged in comparison to what reported in the pre-primary-PCI era. Long-term outcomes did not correlate with level of depression of

HRV parameters recorded in the subacute phase of the disease, both in STEMI and in NSTEMI patients. These results support lack of prognostic significance of traditional HRV parameters when immediate coronary reperfusion is utilised.

**Core tip:** Depressed heart rate variability (HRV) is usually considered a negative long-term prognostic factor after an acute myocardial infarction (MI). Anyway, most of the supporting research was conducted before the era of immediate reperfusion by percutaneous coronary intervention. In our study, in MI patients treated by early reperfusion abnormal values of HRV are present in a low percentage of cases. Low HRV does not correlate with long term-prognosis, both in ST-elevation and non-ST-elevation MI patients. Abnormal HRV seems to have lost prognostic significance in the present era of primary percutaneous revascularization.

Compostella L, Lakusic N, Compostella C, Truong LVS, Iliceto S, Bellotto F. Does heart rate variability correlate with long-term prognosis in myocardial infarction patients treated by early revascularization? *World J Cardiol* 2017; 9(1): 27-38 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/27.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.27>

## INTRODUCTION

The first clinical evidence that one measure of heart rate variability (HRV), the standard deviation of all normal RR intervals (SDNN), was a powerful predictor of cardiac mortality after an acute myocardial infarction (AMI) was given by the wide longitudinal study by Kleiger *et al*<sup>[1]</sup> in 1987. Since then, marked abnormalities of various parameters of HRV, indicating profound derangement of the cardiac autonomic system, have been often described after AMI and have been confirmed to be reliable predictors of poor long-term prognosis<sup>[2,3]</sup>. The large multicentre ATRAMI study conducted in 1998 demonstrated that 15% of AMI patients observed during the first 4 week of the acute event, presented a SDNN < 70 ms, and that among the group with depressed SDNN long-term mortality was 5 times higher than in the patients with better preserved HRV parameters<sup>[4]</sup>. These results confirmed the findings of previous studies, such as the GISSI-2 study that used similar evaluation parameters<sup>[5]</sup>. Other studies used various and different methods to assess HRV (time and frequency domain

measures, discriminant analysis, fractal and other non-linear HRV analysis, with both short-term and long-term evaluations) and observed AMI patients at variable periods of time after the index event; they reported a wide range of prevalence of reduced HRV parameters (ranging from 7% to 34%)<sup>[6,7]</sup>, and different incidence of long-term mortality (ranging from 0% to 45%)<sup>[8-10]</sup>. Despite this, the cited studies mainly confirmed that abnormal HRV holds a negative predictive value on both short and long-term prognosis, with HRV parameters holding high specificity, but poor sensitivity<sup>[11]</sup>.

A limitation of the reported studies is that the majority of them did not provide data of how patients with ST-elevation myocardial infarction (STEMI) behave separately from non-ST-elevation myocardial infarction (NSTEMI) patients. Furthermore, the majority of studies on HRV in patients with a recent AMI have been conducted in an era prior to that of immediate reperfusion by percutaneous coronary intervention (PCI). Among 21 papers analyzed in the recent review by Brateanu *et al.*<sup>[10]</sup>, patients had been treated by primary PCI only in 5 studies and in widely variable percentages (ranging from 18% up to 95% of cases)<sup>[6,12]</sup>, so, little information is currently available on prevalence and prognostic significance of depressed HRV in present day AMI patients.

Aims of this study were to assess the prevalence of severely decreased HRV in patients during the subacute phase of a STEMI treated by primary PCI, and to evaluate if HRV maintains a prognostic value in the current era of immediate percutaneous reperfusion, comparing results with those of NSTEMI cases.

## MATERIALS AND METHODS

### **Design of the study**

We retrospectively reviewed the clinical files of 326 consecutive patients which were part of a larger study on the effects of cardiac rehabilitation (CR) after AMI. All had suffered a complicated AMI (208 STEMI, 118 NSTEMI) and had been admitted to our CR unit for a period of residential, exercise-based rehabilitation, a median of 13.5 d (95%CI of the mean 15.2-17.3) after the index event. All patients had undergone coronary angiography on initial admission to the Intensive Coronary Care Unit, within 24 h from beginning of AMI symptoms: 194 (94%) STEMI underwent successful PCI of the culprit coronary artery within 6 h of symptoms<sup>[13]</sup>, while only a small percentage of them (14 cases, 6%) could not be revascularized due to unfavourable coronary anatomy and had to be placed on medical therapy; NSTEMI patients underwent coronary angiography within 24 h<sup>[14]</sup>, with successful PCI in 86 cases (73%) and medical therapy in the remaining 32 cases. Of the primary-PCI STEMI patients, 67 (32%) had also been immediately treated on non-culprit coronary lesions; 42 (36%) NSTEMI patients were similarly also immediately treated on non-culprit

coronary lesions. Eight (4%) STEMI and 4 (3%) NSTEMI patients received further elective percutaneous revascularization during the initial stay in the Cardiology Department. Overall, at the time of transferral to the CR unit, 121 (58%) STEMI patients and 54 (46%) NSTEMI patients had a complete revascularization, while 87 STEMI and 64 NSTEMI patients were still incompletely revascularized.

Patients were selected for referral to our CR program if they suffered a complicated AMI (cardiogenic shock or pulmonary edema, episode of cardiac arrest, complex ventricular arrhythmias), or if they had incomplete revascularization (because of unfavorable coronary anatomy or technical failure)<sup>[15]</sup>. Low risk patients were referred as out-patients to a CR program in a different centre and excluded from this study.

Echo- or cardiac MRI- documented intracavitary thrombosis, extreme thinning or intra-myocardial bleeding and/or suspected rupture of the ventricular wall were other exclusion criteria from referral to the CR program.

The following clinical variables were recorded for each patient: Age, gender, body mass index, cardiovascular risk factors, site of infarction, culprit coronary artery vessel, number of diseased coronary artery vessels (defined as presence of diameter stenosis > 50%), history of previous PCI or coronary or valvular surgery, presence of ancillary diseases (renal failure, thyroid dysfunction, known diabetes or abnormal glucose metabolism, pulmonary diseases, history or presence of neoplastic diseases, carotid and peripheral vascular disease) and previous and concurrent drug therapy. During their hospitalisation in CR, all patients without previous diagnosis of diabetes underwent an oral glucose tolerance test to identify subclinical abnormal glucose metabolism. Left ventricular ejection fraction (LVEF) was measured before discharge by 2-D echocardiography, following the Simpson method.

### **Holter monitoring**

On the day of admittance to CR, all patients underwent 24-h ECG Holter recording, using 3-channel digital recorders (Lifecard CF, Del Mar Reynolds, Irvine, CA, United States), monitoring chest leads CM5, CM3 and modified aVF. Recordings were analyzed using a commercial Holter device system (Del Mar-Reynolds Impresario Holter Analysis System, vers. 2.8.0024; Time-domain HRV Analyzer, vers. 1.0.8.4, CENTUM and Del Mar Reynolds Medical Inc., Irvine, CA, United States; sampling rate of 128 Hz).

After cleansing of arrhythmias and artefacts, the usual time domain HRV variables were assessed including: Standard deviation of all normal-to-normal (NN) intervals (SDNN), standard deviation of all 5-min mean NN intervals (SDANN), root mean square of successive differences (RMSSD), and mean of the standard deviations of all RR intervals of all 5-min segments in the 24 h (SDNN-i). For the purposes of

this study, the main variable that was considered in the correlations with other clinical parameters was the SDNN, as it is usually considered a measure of total variance in heart rate; it is also the variable most widely used in previous studies<sup>[10]</sup> and more strongly associated with mortality compared to other variables<sup>[11]</sup>. SDNN parameters were analyzed for the entire 24 h period; analysis of day and night hours was also done separately. "Day" was defined as the time period between 06:00 and 22:59 and "night" as the period between 23:00 and 05:59.

Patients with atrial fibrillation, or rhythm disturbances that could interfere with accurate HRV analysis (e.g., frequent ectopic beats, rhythm induced by pacemaker) were excluded from the study, as were patients with inadequate/inaccurate recordings.

### End points and follow-up

The primary outcome measure was the occurrence of cardiac death; the secondary end-point was occurrence of major clinical events (MCE), defined as death (all-cause mortality, cardiac mortality) or readmission for a new AMI, new revascularization, episodes of heart failure or stroke. At the time of follow-up, the clinical status of the patients was assessed by telephonic interviews, performed either by a doctor or a trained team nurse. In case of clinical events, detailed information was obtained from the patient or his/her relatives. Outcomes were analyzed by intention to treat.

### Statistical analysis

Continuous variables were expressed as a mean  $\pm$  standard deviation (SD) and compared using an unpaired *t* test; otherwise, variables were expressed with median and interquartile range (IQR) and compared using a Wilcoxon-Mann-Whitney test. Categorical variables were expressed as frequencies and percentages and were compared between groups by a  $\chi^2$  test. The relationships between continuous variables were evaluated by Pearson's correlation coefficient. A Cox regression multivariate analysis was also performed to determine the influence of different factors on HRV parameters, including in the multivariable model only variables with a *P* value  $\leq$  0.1 at univariate analysis. HRV variables were initially analyzed as continuous variables; subsequently, HRV variables that showed a significant association with other factors at multivariate analysis were dichotomized and analyzed according to the lowest quartile value. Kaplan-Meier estimates of the distribution of times from baseline to death were computed, and Mantel-Cox Log-Rank analysis was performed to compare the survival curves between the groups. All reported probability values are two-tailed and the significance level was set at 0.05. Statistical analyses were performed using SPSS 18 software package (SPSS Inc, Chicago, IL, United States).

### Statement

During CR hospitalization, all participants had been fully

informed on the procedures they were undergoing; a written consent was obtained from all patients before performance of the medical procedures. The routine diagnostic examinations and follow-up protocol for CR were applied; no special tests or treatments were performed. The research was conducted in accordance with the ethical guidelines of the 1975 Declaration of Helsinki. This study is part of a larger follow-up study on patients admitted to CR; approval of the Provincial Ethics Committee (Provincial Health Directorate, Belluno, Italy) was obtained for the main research.

## RESULTS

### General findings and HRV parameters

Main patients' characteristics are presented in Table 1, together with the medical therapy prescribed at the time of discharge from hospital. Patients with NSTEMI were older than those with STEMI, and presented more often history of hypertension, previous MI and coronary revascularization procedures, and clinical signs of metabolic syndrome. Patients with NSTEMI had greater number of critical coronary stenoses, revascularization was more often incomplete, and such patients presented more often with symptoms of heart failure on initial admission to the coronary care unit.

In the same Table 1, time-domain HRV parameters are also reported. In spite of the above described clinical differences, all main HRV parameters did not show significant differences between STEMI and NSTEMI patients, except for mean heart rate that was lower in NSTEMI cases.

In a total of 52 patients (16% of the whole group; 16% of STEMI and 15% of NSTEMI:  $\chi^2 = 0.067$ , *P* = 0.796), SDNN was  $< 70$  ms, and in 13 (4% of the whole group; STEMI 5.3%, NSTEMI 1.7%:  $\chi^2 = 2.539$ , *P* = 0.111) it was  $< 50$  ms. When subdivided into 4 quartiles according to the value of SDNN, the 81 patients in the lowest quartile presented a mean SDNN of  $63.7 \pm 11.8$  ms (vs a mean of  $119.4 \pm 35.0$  ms of the other quartiles; *P*  $< 0.001$ ). Patients with STEMI or NSTEMI were equally distributed between quartiles of SDNN ( $\chi^2 = 1.536$ , *P* = 0.674).

On average, SDNN was higher during night hours than during day-time (*P*  $< 0.001$ ), although in 109 patients the day-night variation was insignificant or negative; patients with STEMI or NSTEMI behaved in the same way as regards day vs night SDNN.

Female patients presented on average lower values of SDNN than male patients ( $97.1 \pm 42.2$  ms vs  $107.9 \pm 38.1$  ms; *P* = 0.046), and in 24 out of 65 cases they presented SDNN values in the lower quartile (females 37% vs males 17%;  $\chi^2 = 6.723$ , *P* = 0.010).

SDNN values in the lower quartile were present more frequently in patients older than 65 years ( $\chi^2 = 4.478$ , *P* = 0.034), as well as in patients with known diabetes ( $\chi^2 = 10.859$ , *P* = 0.001) but not in patients with abnormal glucose metabolism detected during the rehabilitation period ( $\chi^2 = 0.762$ , *P* = 0.383). Patients

<sup>1</sup>Level of significance from unpaired *t* tests for STEMI and NSTEMI patients; <sup>2</sup>Level of significance from  $\chi^2$  tests for STEMI and NSTEMI patients. ms: Milliseconds; STEMI: ST-elevation myocardial infarction; NSTEMI: Non-ST-elevation myocardial infarction; CABG: Coronary artery by-pass graft; PCI: Percutaneous coronary intervention; AMI: Acute myocardial infarction; BMI: Body mass index; LVEF: Left ventricle ejection fraction; ACE: Angiotensin converting enzyme; AT-II: Angiotensin II receptor type 2; HRV: Heart rate variability; SDNN: Standard deviation of all normal-to-normal intervals; RMSSD: Root mean square of successive differences between normal-to-normal intervals.

with known diabetes presented also absence of the day/night variation of SDNN (SDNN day: 85.2 ± 32.2 ms in diabetic patients vs 99.5 ± 35.7 ms in non-diabetics,  $P = 0.002$ ; SDNN night: 85.3 ± 31.0 ms in diabetic patients vs 109.8 ± 42.2 ms in non-diabetic patients,  $P < 0.001$ ; SDNN day vs night:  $P = 0.975$  in diabetic vs  $P < 0.001$  in non-diabetic patients).

Patients with history of previous MI, or previous CABG or previous PCI were equally distributed among quartiles of SDNN (respectively:  $\chi^2 = 0.017$ ,  $P = 0.999$ ;  $\chi^2 = 1.306$ ,  $P = 0.728$ ;  $\chi^2 = 1.729$ ,  $P = 0.631$ ).

No correlation was found between number of diseased coronary arteries and quartiles of SDNN (whole group:  $\rho -0.044$ ,  $P = 0.428$ ; STEMI:  $\rho 0.001$ ,  $P = 0.985$ ;

NSTEMI:  $\rho$  -0.120,  $P = 0.199$ ). Patients with complete or incomplete coronary revascularization did not differ as regards distribution among quartile of SDNN ( $\chi^2 = 0.059$ ,  $P = 0.807$ ).

Similarly, no correlation was found between quartile of SDNN and successful vs unsuccessful primary PCI (whole group:  $\chi^2 = 0.158$ ,  $P = 0.691$ ; STEMI:  $\chi^2 = 0.031$ ,  $P = 0.861$ ; NSTEMI:  $\chi^2 = 0.684$ ,  $P = 0.408$ ). Overall, patients with unsuccessful primary PCI presented markedly reduced variation of SDNN values between day and night (SDNN day  $94.7 \pm 39.3$  ms; SDNN night  $102.9 \pm 37.9$  ms;  $P = 0.092$ ); by the contrary, such variations persisted in patients with successful primary PCI (SDNN day  $96.2 \pm 34.6$  ms; SDNN night  $103.9 \pm 41.5$  ms;  $P < 0.001$ ).

In the whole group of patients, a linear correlation was found between LVEF and the values of some HRV parameters (SDNN:  $\rho$  0.168,  $P = 0.002$ ; SDANN:  $\rho$  0.225,  $P < 0.001$ ), but not with other HRV parameters such as RMSSD, SDNN Index, Triangular Index and pNN50. Patients with lower LVEF ( $< 40\%$ ) presented more often values of SDNN in the lowest quartile ( $\chi^2 = 12.668$ ;  $P < 0.001$ ). Mean heart rate during the 24 h of Holter recording was lower in patients with higher LVEF ( $\rho$  -0.310,  $P < 0.001$ ).

The 37 patients that presented symptoms of heart failure during the acute phase of AMI showed SDNN values in the lower quartile more often than the remaining patients ( $\chi^2 = 7.884$ ;  $P = 0.005$ ), with SDNN  $< 70$  ms in 32% of cases (vs 14% of the patients without initial symptoms of heart failure;  $\chi^2 = 8.457$ ;  $P = 0.004$ ).

At multivariate Cox regression analysis, a significant correlation with the lowest quartile of SDNN was maintained only by female sex, history of diabetes mellitus and LVEF  $< 40\%$  (respectively:  $\beta = -0.143$ ,  $P = 0.008$ ;  $\beta = 0.146$ ,  $P = 0.008$ ;  $\beta = -0.179$ ,  $P = 0.001$ ).

### Clinical features and outcome

Ten (3.1%) patients were lost to follow up, which occurred a median of 25.0 mo after the index event (95%CI of the mean: 23.3-28.0).

Of the 316 patients which could be interviewed, MCE occurred in 56 (17.2%) of which 20 deaths (6.3%; 14 cardiac deaths), 9 cases of new non fatal AMI (3.0%), 5 patients with stroke (1.6%) and 17 cases of successful elective revascularization (5.4%: 4 CABG, 13 elective PCI); 21 (6.6%) patients had one or more hospital readmissions for heart failure.

No significant difference in overall incidence of MCE at follow-up was evident between cases with STEMI vs NSTEMI ( $\chi^2 = 2.166$ ,  $P = 0.141$ ), although all-cause mortality was higher among NSTEMI patients (14% vs 2%;  $\chi^2 = 17.863$ ,  $P < 0.001$ ) as well as cardiac mortality (10% vs 1.5%;  $\chi^2 = 11.471$ ,  $P = 0.001$ ). Only after one and a half year of follow-up, the Kaplan-Meier MCE-free survival curves begin to diverge, with NSTEMI patients presenting worse outcomes (Mantel-Cox Log-

Rank:  $\chi^2 = 5.525$ ,  $P = 0.019$ ); Figure 1A.

Patients with a 3-vessel disease and those who received an incomplete revascularization had a greater incidence of MCE during the period of follow-up (respectively:  $\chi^2 = 14.369$ ,  $P = 0.006$ ; and  $\chi^2 = 6.987$ ,  $P = 0.008$ ). A significant correlation was evident between all-cause deaths or cardiovascular deaths and number of diseased vessels (respectively:  $\chi^2 = 19.218$ ,  $P = 0.001$ ; and  $\chi^2 = 13.077$ ,  $P = 0.011$ ). Incomplete revascularization showed a correlation with all-cause deaths ( $\chi^2 = 4.732$ ,  $P = 0.030$ ) but not with cardiac deaths ( $\chi^2 = 1.859$ ,  $P = 0.173$ ) at follow-up.

The 234 patients that maintained a better preserved myocardial function, as suggested by LVEF  $> 40\%$ , had lower number of MCE (32) and cardiovascular deaths (3) in the follow-up, than patients with more compromised LVEF, that suffered 24 MCEs and 11 cardiovascular deaths among 82 patients (for MCE:  $\chi^2 = 10.126$ ,  $P = 0.001$ , and OR = 0.383, 95%CI: 0.209-0.701; for cardiovascular deaths:  $\chi^2 = 21.110$ ,  $P < 0.001$ , and OR = 0.084, 95%CI: 0.023-0.309).

At multivariate Cox regression analysis, the variables that showed predictive value for MCE were presence of a three-vessel disease ( $\beta = 0.062$ ,  $P = 0.013$ ), elective PCI ( $\beta = 0.250$ ,  $P = 0.021$ ), known diabetes mellitus ( $\beta = 0.124$ ,  $P = 0.013$ ) and LVEF  $< 40\%$  ( $\beta = -0.114$ ,  $P = 0.017$ ), while no significant correlation was found with age, sex, number of vessels treated by PCI ( $\beta = -0.032$ ,  $P = 0.229$ ), history of incomplete revascularization, STEMI vs NSTEMI ( $\beta = -0.002$ ,  $P = 0.970$ ), site of infarction or presence of signs of heart failure during initial admission.

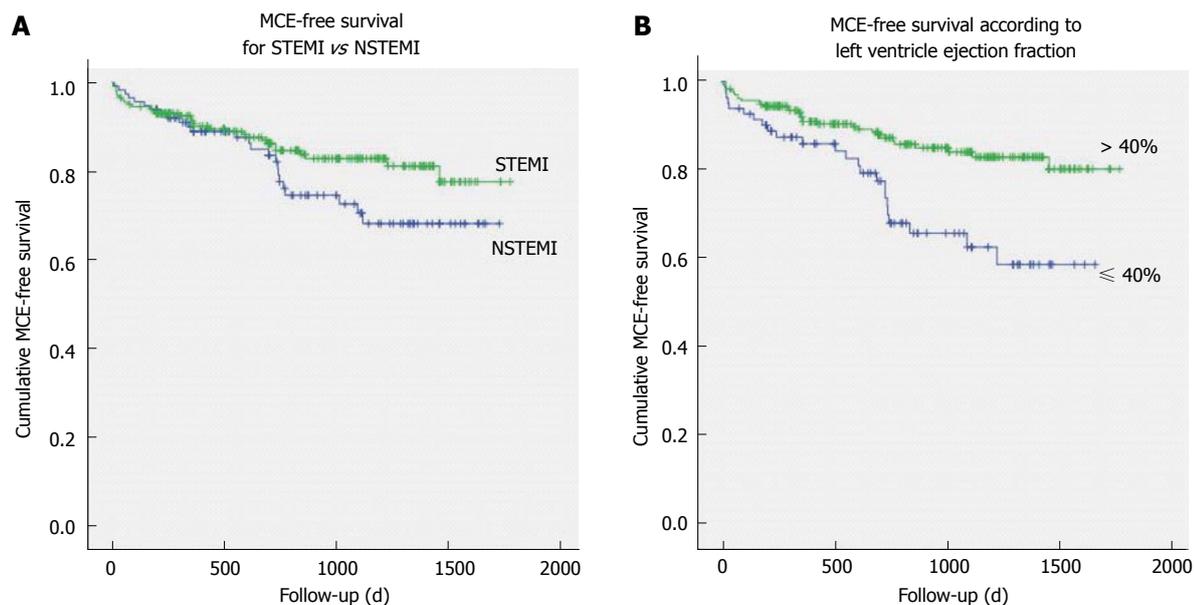

In Figure 1B, the Kaplan-Meier events-free survival curves are presented for patients stratified according to LVEF  $\leq 40\%$  vs LVEF  $> 40\%$ ; the Mantel-Cox Log-Rank demonstrated statistically significant differences between the curves ( $\chi^2 = 10.896$ ,  $P = 0.001$ ).

### HRV and outcome

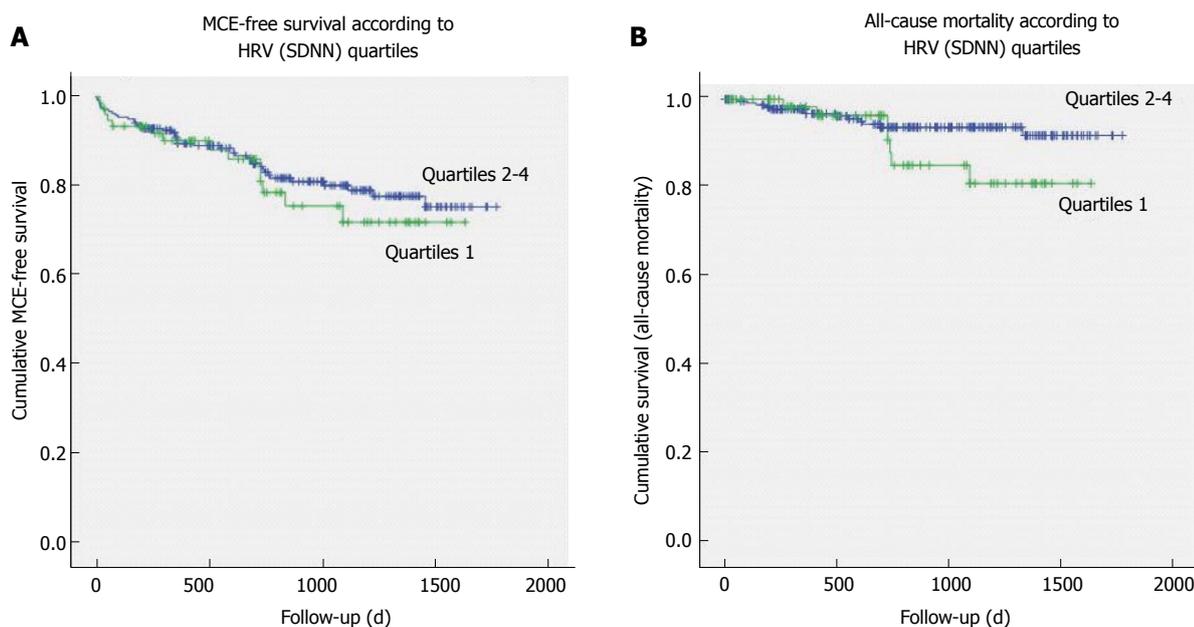

Even in the subgroup in the lower quartile of SDNN, no difference was found in incidence of MCE (14/76 cases) in comparison with other subgroups (42/240 cases), ( $\chi^2 = 0.034$ ,  $P = 0.855$ ); this finding was similar for STEMI and NSTEMI patients (respectively: 10 MCE among 52 STEMI patients with lower quartile of SDNN vs 21/150 of the other quartiles,  $\chi^2 = 0.813$ ,  $P = 0.367$ ; and 4 MCE among 24 NSTEMI patients with lower quartile of SDNN vs 21/90 of the other quartiles,  $\chi^2 = 0.492$ ,  $P = 0.483$ ).

Patients with negative day-night variations of SDNN presented long-term events similar to patients with positive SDNN day-night variations ( $\chi^2 = 2.107$ ,  $P = 0.147$ ).

The Kaplan-Meier MCE-free survival curves were similar between the group of patients with SDNN in the lowest quartile vs the patients of the other SDNN quartiles (Log-Rank  $\chi^2 = 0.376$ ,  $P = 0.540$ ; Figure 2A), with no difference for STEMI (Log-Rank  $\chi^2 = 1.801$ ,  $P =$

**Figure 1** Kaplan-Meier major clinical events-free survival curves for: Patients with recent ST-elevation myocardial infarction vs patients with recent non-ST-elevation myocardial infarction (A), patients with preserved left ventricle ejection fraction (> 40%) vs patients with depressed left ventricle ejection fraction ( $\leq$  40%) (B). STEMI: ST-elevation myocardial infarction; NSTEMI: Non-ST-elevation myocardial infarction; MCE: Major clinical events.

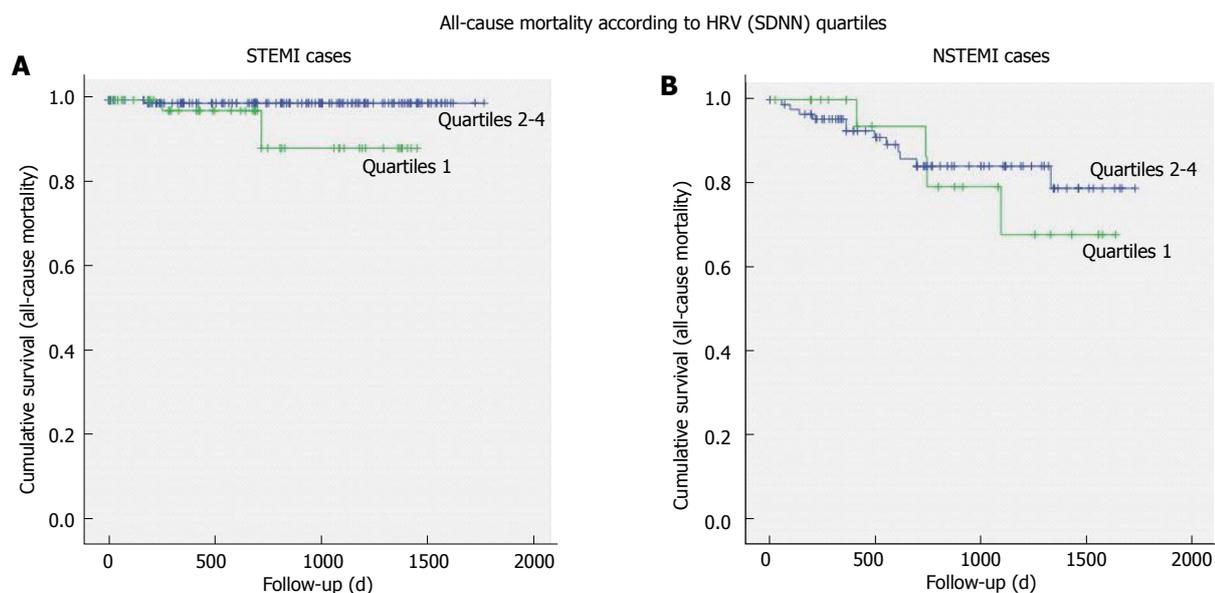

**Figure 2** Kaplan-Meier survival curves for patients with lowest quartile of standard deviation of all normal-to-normal intervals vs patients in the other standard deviation of all normal-to-normal intervals quartiles: Major clinical events-free survival curves (A), all-cause mortality curves (B). HRV: Heart rate variability; SDNN: Standard deviation of all normal-to-normal intervals; MCE: Major clinical events.

0.180) or NSTEMI patients (Log-Rank  $\chi^2 = 0.373$ ,  $P = 0.541$ ). In particular, no correlation was found between quartile of SDNN and recurrence of MI during the follow-up period ( $\chi^2 = 0.489$ ,  $P = 0.484$ ).

As regards to death for all causes, 7 out of 20 deaths occurred among patients with lowest quartile of SDNN ( $\chi^2 = 1.401$ ,  $P = 0.236$ ); analyzing the whole group of AMI patients, the Kaplan-Meier survival curves for all-cause mortality (Figure 2B) and for cardiac deaths did not evidence significant differences between patients

with SDNN in the lowest quartile and other quartiles of SDNN (Mantel-Cox log rank, respectively:  $\chi^2 = 2.207$ ,  $P = 0.137$ ; and  $\chi^2 = 0.399$ ,  $P = 0.527$ ). After separating STEMI from NSTEMI patients, different survival curves have been observed only for all-cause mortality (Figure 3), but not for cardiac mortality: STEMI patients with SDNN in the lowest quartile presented 3 out of 4 all-cause deaths (Mantel-Cox log rank  $\chi^2 = 6.591$ ,  $P = 0.010$ ) and 2 out of 3 cardiac deaths (Log-Rank  $\chi^2 = 3.685$ ,  $P = 0.055$ ), while among NSTEMI patients no

**Figure 3** Kaplan-Meier all-cause mortality curves for ST-elevation myocardial infarction patients (A) and non-ST-elevation myocardial infarction patients (B) divided between cases with lowest quartile of standard deviation of all normal-to-normal intervals vs cases in the other standard deviation of all normal-to-normal intervals quartiles. HRV: Heart rate variability; SDNN: Standard deviation of all normal-to-normal intervals; STEMI: ST-elevation myocardial infarction; NSTEMI: Non-ST-elevation myocardial infarction.

difference in the survival curves was observed between patients with SDNN in the lowest quartile vs the other quartiles (all-cause mortality: Log-Rank  $\chi^2 = 0.195$ ,  $P = 0.659$ ; cardiac deaths: Log rank  $\chi^2 = 0.040$ ,  $P = 0.842$ ).

Analysis of the long term outcomes of patients with low values of RMSSD gave similar results as those described for low SDNN values: Kaplan-Meier events free survival did not differ between patients with RSDNN in lowest quartile vs the other quartiles, both for incidence of MCE ( $\chi^2 = 0.849$ ,  $P = 0.357$ ) and all-cause or cardiac mortality (respectively:  $\chi^2 = 0.060$ ,  $P = 0.806$ ; and  $\chi^2 = 0.245$ ,  $P = 0.621$ ).

#### Patients lost to follow-up

Patients' main clinical parameters (age, sex, time from STEMI to CR, site of infarction, number of diseased vessels, fasting glucose, HbA1c, haemoglobin level at admission, LVEF) and HRV values (SDNN, RMSSD, SDNNi, SDANN) have been compared between the 10 cases lost to follow-up and the 314 patients that completed the study. Patients lost to follow-up presented more elevated average values of HbA1c ( $7.2\% \pm 2.0\%$  vs  $6.4\% \pm 1.1\%$ ;  $P = 0.022$ ) but not of fasting glucose ( $109.5 \pm 37.9$  mg/dL vs  $95.2 \pm 22.5$  mg/dL;  $P = 0.085$ ) at admission. All the other clinical and HRV parameters were not significantly different in comparison to followed-up patients.

## DISCUSSION

In studied patients with STEMI, treatment by primary PCI did not demonstrate a clear effect in reduction of the prevalence of marked depression of HRV in comparison to what was reported in studies performed

in the pre-primary-PCI era: The prevalence of 16% of STEMI patients with SDNN < 70 ms at 2 wk from the acute event is the same as that recorded in the GISSI-2 and the ATRAMI studies, in which patients had been treated conservatively or by thrombolysis<sup>[4,5]</sup>. It is however much lower than that reported by Wiliński *et al*<sup>[7]</sup> in patients treated by primary PCI (21% in patients < 65 years old and 34% in those  $\geq 65$  years old), as well as in other smaller dimension studies in which patients had also been treated by primary PCI<sup>[9,16]</sup>. When considering the subgroup of patients with even more depressed HRV (using the cut-off of SDNN < 50 ms, as in the pivotal study by Kleiger *et al*<sup>[11]</sup>), the prevalence of this abnormal parameter was lower in our STEMI patients (5% in our study vs 15% in Kleiger's study), being somehow similar to that observed also by Erdogan *et al*<sup>[6]</sup> (7%) in patients treated by immediate revascularization. A number of other studies investigating HRV in the post-acute phase of MI have been conducted in the last 15 years. In such studies the percentage of patients treated by primary PCI varied between 18% and 70%, so that their results about the effects of early revascularization on HRV parameters are not easily comparable between them and with our ones<sup>[11,12,17-19]</sup>.

Even if the percentage of patients with markedly depressed SDNN was not clearly reduced by the immediate reperfusion strategy, the overall derangement of HRV parameters in our cases was limited, in spite of our study population being constituted by patients that suffered a complicated AMI: On average, mean HRV values were only slightly lower than those reported in literature for healthy persons of the same age group<sup>[20]</sup>. In fact, in previous studies, it has been observed that

autonomic function is better preserved in patients treated by primary PCI, in comparison to patients who receive fibrinolysis or are treated conservatively<sup>[21]</sup>. It must also be added that all our patients were under treatment with ACE-inhibitors and beta-blockers, drugs that may impact on HRV in post-infarction patients<sup>[22-25]</sup>.

Patients with NSTEMI did not show significant differences in the analyzed HRV parameters in comparison to STEMI patients, even though they presented various factors that may have lead to more depressed HRV (older age, greater prevalence of previous AMI, multiple risk factors, heart failure complicating the initial phase of AMI, often a 3-vessel disease and incomplete revascularization). To the best of our knowledge, before the present study no information was available in the literature regarding HRV in NSTEMI patients, when considered separately.

In 13 follow-up studies conducted between 1987 and 1999 where HRV was analyzed in AMI patients not treated with immediate PCI reperfusion, the reported incidence of long-term mortality ranged widely between 3.4% and 45% of study cases; from the data provided in the papers mortality can be estimated on average to be around 10%<sup>[1,4,5,8,26-34]</sup>. Almost all these studies included both STEMI and NSTEMI patients. More recently, only STEMI patients have been analysed, following treatment by primary PCI: Their long-term mortality rate was reported to be substantially lower than in the pre-primary-PCI era, being possible to calculate it on average around 5% of cases<sup>[6,9,16]</sup>.

In spite of our patients having experienced various kinds of major complications during the initial phase of MI, in STEMI cases both the overall mortality and cardiac mortality at long-term follow-up were rather low, and significantly lower than the long-term mortality of NSTEMI patients. The timely reperfusion strategy, with consequent reduction of infarct size and salvage of more heart muscle, as well as the multiple pharmacological therapy used, may have contributed to the better long-term survival of our STEMI patients<sup>[35]</sup>; the period of intensive and comprehensive exercise-based cardiac rehabilitation followed by our patients may also have contributed to their better prognosis<sup>[36]</sup>.

Low values of SDNN (lowest quartile) recorded at two weeks from the index event did not possess a predictive value for cardiac mortality in our STEMI patients, or in NSTEMI patients, or in the group of MI patients considered as a whole. In the pivotal study by Kleiger *et al.*<sup>[1]</sup>, the finding of a markedly depressed SDNN was a predictor of long-term mortality more than 5 times higher than in patients with preserved SDNN; identical results have been confirmed in the ATRAMI study<sup>[4]</sup>, and substantially similar outcomes have also been reported in other studies performed in the pre-primary-PCI era<sup>[5,29,30]</sup>, as well as in studies that included low percentage of PCI-treated patients<sup>[17]</sup>.

Among primary-PCI treated patients, Erdogan *et al.*<sup>[6]</sup> found that SDNN was lower in non-survivors

than in survivors after a mean follow-up of  $4.3 \pm 3$  years, but this HRV parameter predicted only 1 in 24 cardiac deaths, indicating that the predictive value of a depressed SDNN is low. Our results indicate that the limited derangement of HRV parameters and the low long-term mortality recorded among our patients do not allow to identify if a markedly depressed HRV (as estimated by low SDNN) could still be considered an indicator of poor survival in patients treated by primary PCI.

In the attempt to identify possible differences in secondary outcomes linked to different levels of HRV derangement among AMI patients treated by primary PCI, we studied the long-term incidence of Major Clinical Events, which is a composite parameter that has recently been used in other studies<sup>[9,16]</sup>. Other than mortality (cardiovascular and all-cause deaths), it includes also non-fatal events, such as new AMI, new coronary revascularization, episodes of heart failure, episodes of stroke.

Amongst our cases, patients with more depressed SDNN did not show any significant difference of MCE-free outcomes in comparison to patients with preserved parameters, after a median follow-up period of 25 mo (a period that is in range with most of the previous studies)<sup>[10]</sup>. This is quite a different finding in comparison to other recent small scale studies, that confirmed that abnormal HRV retains some (although low) negative predictive value on long-term prognosis also in primary-PCI treated AMI patients<sup>[9,16]</sup>.

Almost all our patients had been submitted to revascularization of the coronary culprit lesion during the initial phases of their AMI, and a substantial percentage of them had also received revascularization of other critically stenosed coronary arteries, before transferral to CR and recording of 24-h Holter. These facts, together with the pharmacological treatment with beta-blockers and ACE-inhibitors or AT-II-antagonists in use at the time of Holter recording, could have reduced both the autonomic derangement during the subacute phase of the MI and the risk of adverse events in the long-term follow-up.

### Limitations of the study

Criteria of exclusion from this study included presence of atrial fibrillation or flutter, a rhythm induced by the pacemaker, or inadequate Holter recordings. Although such patients may have had significant autonomic dysfunction, HRV could not be measured in them. Consequently it is not known if a depressed HRV could have had any long-term impact on their prognosis.

The degrees of autonomic derangement presented by our patients, that may have been conditioned by the kind of complications suffered during the initial phase of their disease, may possibly not be generalized to the other complicated or uncomplicated STEMI patients.

HRV was performed only in time domain; no analysis was available in the frequency domain. However, it is

already known that time-domain HRV indices measured over a 24-h period are well correlated with frequency domain indices in coronary artery disease patients<sup>[34]</sup>. Among time-domain parameters, SDNN was identified as having the same high predictive value as the frequency-domain LF amplitude in post-AMI patients<sup>[16]</sup>.

### Conclusions

In conclusion, in our group of patients with a recent complicated MI, abnormal autonomic parameters (evidenced by low HRV) have been found with a prevalence that was similar for STEMI and NSTEMI cases, and substantially unchanged in comparison to what reported in the pre-primary-PCI era.

Long-term outcomes in PCI-treated STEMI patients were more favorable than in old cohorts of patients. They did not correlate with the level of depression of HRV parameters recorded in the subacute phase of the disease, both in STEMI and in NSTEMI patients. Traditional HRV parameters seem to have lost their prognostic significance in the present era of immediate coronary reperfusion.

## COMMENTS

### Background

After an acute myocardial infarction (AMI), overactivation of the sympathetic component and relative suppression of the parasympathetic component of the autonomic nervous system occur, leading to a marked imbalance of cardiac autonomic regulation. Such sympatho-vagal imbalance is usually considered to be linked to increased short and long-term mortality. Clinically, cardiac autonomic modulation can be evaluated observing the fluctuations of instantaneous heart rate (intervals between normal RR complexes) during variable periods of time (often 24 h). The most simple and widely used parameter for evaluation of heart rate variability (HRV) is the SDNN (standard deviation of all normal RR intervals), that gives an overall estimate of cardiac autonomic control. In the last 30 years, various studies confirmed that depressed values of SDNN indicate poor prognosis after an AMI. Unfortunately, most of these studies on the prognostic value of depressed HRV in post-AMI patients have been conducted before the primary-PCI era: So, their results may not be easily applied to present day patients, in which early reperfusion (that may lead to salvage of cardiac muscle and preservation of better heart function), multiple pharmacological therapies and cardiac rehabilitation may impact on autonomic balance, quality of life and long-term survival.

### Research frontiers

A few small-scale studies have been conducted so far on AMI patients treated by primary PCI, investigating if depressed HRV maintains a correlation with long-term prognosis. Such studies did not reach clear conclusions. With the present work, the authors aimed at contributing and clarifying if parameters of HRV (in particular SDNN) could still be considered reliable prognostic indicators in primary-PCI-treated AMI patients.

### Innovations and breakthroughs

While in the past depressed HRV had been identified as a reliable marker of poor prognosis after an AMI, this paper demonstrates that nowadays in AMI patients treated by early revascularization HRV has lost its prognostic significance. In addition, the paper is the first to report HRV parameters separately for patients with ST-elevation and Non-ST-elevation myocardial infarction.

### Applications

The evaluation of simple HRV parameters does not seem to hold any more prognostic significance in AMI patients treated by early revascularization. Further

studies are needed in these patients to identify reliable long-term prognostic indicators.

### Terminology

HRV refers to the evaluation of the oscillations in the intervals between consecutive heart beats. They are determined by cyclic variations of sympathetic and parasympathetic autonomic influences on cardiac pace-maker cells, modulated by central and peripheral mechanisms (respiratory and vasomotor centres, fluctuations in arterial pressure, humoral factors). After an AMI, HRV usually presents various degrees of depression, linked to a marked increase of the sympathetic activity (probably due to abnormal geometry of the beating heart and consequent distortion of autonomic nervous endings). The most simple method of evaluating HRV is by statistical analysis of the time intervals between consecutive normal RR beats ("time domain" method); the standard deviation of these intervals (SDNN) has been used in our study. SDNN reflects all the cyclic components responsible for variability in the period of recording; for this reason, it has been used in various studies for assessment of risk after AMI.

### Peer-review

The authors analysed the potential prognosis of HRV in patients treated with primary PCI.

**Author contributions:** Gotzmann M was the guarantor and designed the study; Gotzmann M, Sprenger I, Ewers A and Bösche L participated in the acquisition, analysis, and interpretation of the data; Gotzmann M drafted the initial manuscript; Mügge A and Bösche L critically revised the article for important intellectual content.

**Institutional review board statement:** The study was reviewed and approved by the Ruhr-University Bochum Institutional Review Board.

**Informed consent statement:** All patients provided oral and written informed consent with respect to the intervention. However, due to the retrospective nature of the study, there was no written consent of patients prior to study enrolment. The study was approved by the Ruhr-University Bochum Institutional Review Board. All patient data were anonymized.

**Conflict-of-interest statement:** There are no conflicts of interest to report.

**Data sharing statement:** No additional data are available.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. ## Abstract

### AIM

To investigate one-year outcomes after percutaneous mitral valve repair with MitraClip® in patients with severe mitral regurgitation (MR).

### METHODS

Our study investigated consecutive patients with symptomatic severe MR who underwent MitraClip® implantation at the University Hospital Bergmannsheil from 2012 to 2014. The primary study end-point was all-cause mortality. Secondary end-points were degree of MR and functional status after percutaneous mitral valve repair.

### RESULTS

The study population consisted of 46 consecutive patients (mean logistic EuroSCORE 32% ± 21%). The degree of MR decreased significantly (severe MR before MitraClip® 100% vs after MitraClip® 13%;  $P < 0.001$ ), and the NYHA functional classes improved (NYHA III/IV before MitraClip® 98% vs after MitraClip® 35%;  $P < 0.001$ ). The mortality rates 30 d and one year after percutaneous mitral valve repair were 4.3% and 19.5%,

respectively. During the follow-up of  $473 \pm 274$  d, 11 patients died (90% due to cardiovascular death). A pre-procedural plasma B-type natriuretic peptide level  $> 817$  pg/mL was associated with all-cause mortality (hazard ratio, 6.074; 95%CI: 1.257-29.239;  $P = 0.012$ ).

### CONCLUSION

Percutaneous mitral valve repair with MitraClip® has positive effects on hemodynamics and symptoms. Despite the study patients' multiple comorbidities and extremely high operative risk, one-year outcomes after MitraClip® are favorable. Elevated B-type natriuretic peptide levels indicate poorer mid-term survival.

**Key words:** Severe mitral regurgitation; Percutaneous mitral valve repair; MitraClip®; One-year outcome

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Percutaneous mitral valve repair with the MitraClip® device has positive effects on hemodynamics and symptoms. Despite the multiple comorbidities and extremely high operative risk of the study patients, mid-term outcomes after MitraClip® implantation are favorable. Elevated B-type natriuretic peptide ( $> 817$  pg/mL) levels are indicative of poorer long-term survival.

One-year outcome of percutaneous mitral valve repair in patients with severe symptomatic mitral valve regurgitation. *World J Cardiol* 2017; 9(1): 39-46 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/39.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.39>

## INTRODUCTION

Severe mitral regurgitation (MR) is a common valvular heart disease that has an unfavorable prognosis<sup>[1]</sup>. When possible, mitral valve repair is considered the optimal surgical treatment<sup>[1]</sup>.

In the last few years, percutaneous mitral valve repair has developed into an alternative technique for patients with severe MR, with more than 20000 procedures worldwide<sup>[2,3]</sup>. However, the Everest II study is the only randomized trial that has compared percutaneous repair with heart surgery, and it mainly included patients with degenerative MR who did not have an elevated operative risk<sup>[2]</sup>. By contrast, the current European Society of Cardiology guidelines recommend applying MitraClip® only in symptomatic high-risk patients with severe functional MR (level of evidence IIb)<sup>[1]</sup>.

In recent years, some registry studies<sup>[4-6]</sup> and several smaller studies<sup>[7-11]</sup> concerning MitraClip® have been published. However, relatively little is known about the long-term results of percutaneous mitral valve repair. Therefore, the aim of this study was to assess the one-

year outcome after percutaneous mitral valve repair with MitraClip®.

## MATERIALS AND METHODS

We performed a retrospective study to evaluate the effects of percutaneous mitral valve repair using MitraClip® (Abbott Vascular, Menlo Park, California, United States) on symptoms, hemodynamics and outcomes. The primary study endpoint was all-cause mortality. The secondary endpoints were functional status and degree of MR after percutaneous mitral valve repair.

This study included consecutive patients with symptomatic severe MR who underwent MitraClip® implantation from May 2012 to December 2014 at the University Hospital Bergmannsheil. The risk of mitral valve surgery was estimated using the logistic EuroSCORE I<sup>[12]</sup> and the logistic EuroSCORE II<sup>[13]</sup>. All patient cases were discussed by the cardiology team. The decision to perform percutaneous mitral valve repair was based on: (1) a high EuroSCORE I ( $> 20\%$ ); and (2) serious comorbidities with a considerable risk for heart surgery [for example, porcelain aorta, left ventricular ejection fraction (LVEF)  $< 30\%$ , previous chest radiation and severe chronic obstructive pulmonary disease]. The contraindications were active endocarditis, intracardiac thrombus, limited life expectancy ( $< 1$  year) and unsuitable mitral valve morphology, according to the EVEREST criteria<sup>[2]</sup>.

Written informed consent was given by all patients to receive percutaneous mitral valve repair with the MitraClip®. The study was reviewed and approved by the Ruhr-University Bochum Institutional Review Board.

### Pre-procedural investigations

The pre-procedural examinations of study patients comprised an anamnesis, assessment of functional capacity (NYHA class), laboratory measurements, transthoracic and transesophageal echocardiography and coronary angiography. The diagnosis of coronary artery disease was made in patients with a coronary artery stenosis  $> 50\%$  in the pre-procedural coronary angiography, previous myocardial infarction, coronary artery bypass grafting, or percutaneous coronary intervention.

We measured plasma B-type natriuretic peptide levels on the same day as clinical and echocardiographical examinations. By using a chemiluminescent immunoassay kit (Biosite Triage, San Diego, CA, United States) we analyzed the levels of plasma B-type natriuretic peptide.

All patients underwent transthoracic and transesophageal echocardiography (Vivid 7 or Vivid 9, General Electrics, Horton, Norway) according to the guidelines of the American Society of Echocardiography<sup>[14]</sup>. Using the modified Devereux formula left ventricular myocardial mass was calculated. The Simpson method (using 4- and 2-chamber views) was applied to measure LVEF<sup>[14]</sup>.

According to the American Society of Echocardiography, MR and tricuspid regurgitation was graded as mild, moderate or severe<sup>[15]</sup>. In addition, MR was classified as degenerative, functional or mixed<sup>[15]</sup>. According to the current recommendations, systolic pulmonary pressure and tricuspid annular plane systolic excursion were measured<sup>[16]</sup>.

### **Percutaneous mitral valve repair**

Percutaneous mitral valve repair with the MitraClip® device was executed under general anesthesia without hemodynamic support using a femoral vein. The transeptal puncture and positioning of the device were performed under transesophageal echocardiography and fluoroscopic guidance. After positioning a clip, the remaining MR and mean transmitral gradient were assessed. If the reduction in MR was unsatisfactory, a second clip was positioned. A maximum mean transmitral gradient of 5 mmHg was accepted. Before and after implantation, left atrial pressure was measured invasively. The procedure and MitraClip® system have been previously described in detail<sup>[2,3]</sup>.

Patients were treated with aspirin for 6 mo and with clopidogrel for 30 d<sup>[2]</sup>. When clinically indicated (mainly due to atrial fibrillation), patients also received oral anticoagulation.

### **Postprocedural investigations**

The procedural and in-hospital difficulties were reported according to current recommendations<sup>[17]</sup>. Within 48 h after the MitraClip® procedure, a transthoracic echocardiography was performed.

Follow-up examinations of all surviving study patients were conducted  $3 \pm 2$  mo after the MitraClip® implantation and comprised an assessment of functional capacity (NYHA class) and a transthoracic echocardiography. Any changes in MR, left atrial volume and diameter and left ventricular geometry and function were documented. The follow-up of patients was at least 12 mo and death, myocardial infarction, stroke and hospitalization due to heart failure were documented. During routine ambulatory visits follow-up information was obtained. In case of patients' death, we contacted their physicians to get information about reasons of death.

### **Statistical analysis**

Numerical values were expressed as mean  $\pm$  SD. For the comparison of continuous variables we used unpaired *t* tests or Mann-Whitney *U* test, where appropriate. In order to compare categorical variables we performed  $\chi^2$  analysis. To examine continuous variables before and after MitraClip® implantation, we applied paired Student's *t* test (for normally distributed variables) or Wilcoxon test (for non-normally distributed variables). For categorical variables, we used McNemar's test to measure changes before and after MitraClip® implantation. Univariate Cox proportional hazards model was performed to assess predictors of all-cause death. For

this, all the parameters in Tables 1 and 2 were included in the analysis.

In order to determine cut-off values for plasma B-type natriuretic peptide (BNP), receiver operating characteristic (ROC) curves were performed. The Kaplan-Meier method was used for analysis of all-cause mortality. A comparison of survival between different groups of patients was assumed with log-rank tests. A *P* value  $< 0.05$  was considered to be statistically significant. All probability values reported were two-sided. A statistical review of the study was performed by a biomedical statistician. The analyses were done using SPSS software (version 20.0; SPSS Inc., Chicago, IL, United States).

## **RESULTS**

A total of 48 consecutive patients with native MR who underwent percutaneous mitral valve repair with the MitraClip® device were enrolled between May 2012 and December 2014. During the procedures, no patients died and no cases of stroke or myocardial infarction occurred. In one patient, positioning of the MitraClip® was not possible, and the procedure was thus abandoned. In another patient, leaflet detachment occurred after implantation of the clip. One day after the unsuccessful procedure, this patient received surgical mitral valve repair. Therefore, these two patients were not included in the analysis. The final study cohort consisted of 46 patients. Clip embolization, acute conversion to open surgery, pericardial tamponade, need for resuscitation, need for dialysis, respiratory failure and major bleeding did not occur after MitraClip® implantation.

### **Study cohort and procedure**

The mean age of the study patients (21 women, 25 men) was  $76.5 \pm 9.4$  years, and the mean logistic EuroSCORE I was  $32\% \pm 21\%$ . Plasma BNP was measured in 36 of the 46 patients. The baseline characteristics of the patients are provided in Table 1.

The mean procedure time was  $143 \pm 34$  min (door-to-door time, including general anesthesia). One clip was implanted in 31 patients (67%), and two clips were implanted in 15 patients (33%). Immediately after the percutaneous mitral valve repair, transesophageal echocardiography revealed remaining severe MR in 2 patients (4%). There were no cases of post-procedural mitral stenosis (the transmitral gradient was  $\leq 5$  mmHg in all patients). The invasive hemodynamic measurements demonstrated a significant decrease in mean left atrial pressure (left atrial pressure before procedure  $27 \pm 10$  mmHg vs left atrial pressure after procedure  $23 \pm 10$  mmHg, *P* = 0.018).

### **Clinical follow-up**

The mean duration of hospitalization after MitraClip® procedure was  $11 \pm 8$  d. Within 30 d after the MitraClip® implantation, 2 patients suffered from death due to heart failure. Follow-up examinations were done in

the remaining 44 patients (the mean follow-up was 95 d after the percutaneous mitral valve repair).

Prior to the procedure, 98% of our study population was considered NYHA functional class III or IV. After the percutaneous mitral valve repairs, the NYHA functional classes and degree of MR improved significantly (both *P* < 0.001) (Figure 1). Additionally, the left atrial diameter, left atrial volume and systolic pulmonary artery pressure decreased. By contrast, the left ventricular dimensions and LVEF remained unchanged (Table 2). In our study, there were no differences in clinical course after mitral valve repair between patients with organic and with functional MR.

### Mortality and morbidity

The all-cause mortality rate 30 d after percutaneous mitral valve repair was 4.3% (*n* = 2), and this rate increased to 19.5% (*n* = 9) at one year. In the first year after the MitraClip® implantation, no cases of

myocardial infarction occurred, but 2 patients suffered from ischemic stroke. One of these patients had atrial fibrillation and received aspirin and coumarin at the time of stroke. This patient died within the first year. The other patient was in sinus rhythm and received monotherapy with aspirin. Hospitalization due to heart failure occurred in 16 patients (35% of study patients), and of these patients, 7 died within the first year after MitraClip® implantation.

During the follow-up of 473 ± 274 d, the primary endpoint (all-cause mortality) was attained in 11 patients (24%). Reasons for death included heart failure (*n* = 7), myocardial infarction (*n* = 1), unknown causes (*n* = 2) and malignancy (*n* = 1). Kaplan-Meier curves were created for the analysis of all-cause mortality (Figure 2A).

### Predictors of outcome

In the univariate Cox analysis, only plasma BNP was

**Table 2** New York Heart Association class and hemodynamics before and after MitraClip implantation (*n* = 44)

	Before MitraClip	After MitraClip	<i>P</i> value
NYHA class III and IV, <i>n</i> (%)	43 (98)	16 (35)	< 0.001
Mitral regurgitation (severe)	44 (100)	6 (14)	< 0.001
Left atrial diameter (mm)	50 ± 6	49 ± 7	0.039
Left atrial volume (mL)	114 ± 43	102 ± 42	0.008
LV end-diastolic diameter (mm)	55 ± 10	54 ± 11	0.308
LV end-systolic diameter (mm)	42 ± 12	41 ± 12	0.367
LV end-diastolic volume (mL)	158 ± 69	159 ± 75	0.866
LV end-systolic volume (mL)	95 ± 63	95 ± 61	0.993
LV ejection fraction (%)	42 ± 15	44 ± 13	0.216
Severe tricuspid regurgitation, <i>n</i> (%)	12 (27)	9 (20)	0.763
sPAP (mmHg)	44 ± 13	27 ± 10	0.027

LV: Left ventricular; sPAP: Systolic pulmonary artery pressure.

significantly associated to the primary study endpoint. Patients who died after percutaneous mitral valve repair had significantly higher pre-procedural BNP levels compared to patients who survived (Table 1). The ability of BNP to predict all cause-mortality was assessed using ROC curve analysis. Using a cut-off point of BNP > 817 pg/mL, the sensitivity was 78% and the specificity was 70% [area under the ROC curve (AUC) = 0.778, (95%CI: 0.621-0.936; *P* < 0.001)]. A pre-procedural plasma BNP level > 817 pg/mL was associated with all-cause mortality (HR = 6.074; 95%CI: 1.257-29.239; *P* = 0.012) (Figure 2B).

## DISCUSSION

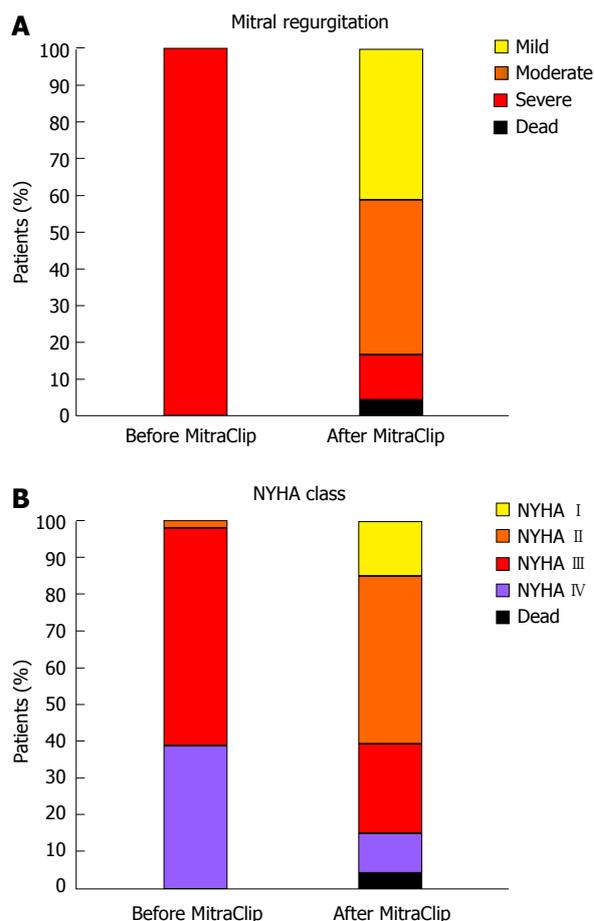

The main result of this study was an improvement in hemodynamics (Figure 1A and Table 2) and symptoms (Figure 1B) in patients with severe symptomatic MR after receiving percutaneous mitral valve repair with the MitraClip® system. However, the relatively high one-year mortality rate (19.5%) observed in the present study must be mentioned (Figure 2A). Preexisting comorbidities of these selected patients who had a very high mean logistic EuroSCORE I of 31.8% (Table 1) is the most likely explanation. Several previous studies reported comparable mortality rates after MitraClip® implantation<sup>[3-11]</sup>.

Additionally, our study suggests that pre-procedural plasma BNP is an independent predictor of all-cause mortality after percutaneous mitral valve repair (Figure 2B).

### Symptoms and hemodynamics

Since the first description of percutaneous mitral valve repair with the MitraClip® device, this technique has now widely used. Today, it is a recognized treatment for high-risk patients with severe and symptomatic MR<sup>[1]</sup>.

Several studies demonstrate symptomatic benefits of percutaneous mitral valve repair in terms of changes in NYHA functional class<sup>[3-11,18,19]</sup>. Vakil *et al*<sup>[18]</sup> found that three-quarters of patients were in NYHA class I or

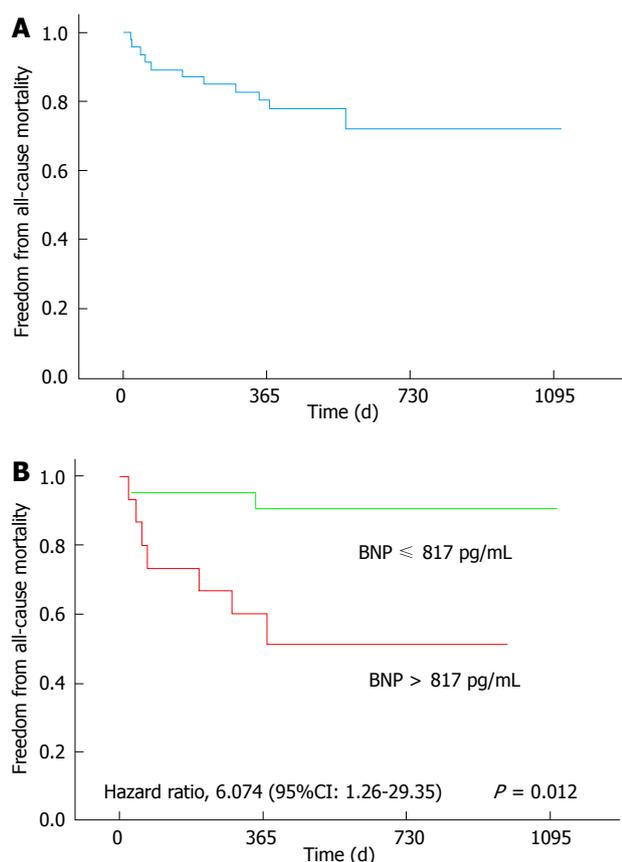

**Figure 1** Changes in mitral regurgitation and New York Heart Association functional class. A: Degree of mitral regurgitation before and after percutaneous mitral valve repair with the MitraClip® system in all study patients (*n* = 46); B: NYHA functional classes before and after percutaneous mitral valve repair with the MitraClip® system in all study patients (*n* = 46). NYHA: New York Heart Association functional class.

II after MitraClip® implantation. Our study confirmed a significant enhancement in NYHA class after MitraClip® implantation (Figure 1B and Table 2).

Other than the fact that percutaneous mitral valve repair is beneficial for treating the symptoms of valvular heart failure, some studies have additionally demonstrated favorable effects of repair on reverse cardiac remodeling<sup>[2,8,10,19]</sup>.

Taramasso *et al*<sup>[19]</sup> revealed an enhancement in LVEF after MitraClip® implantation in patients with heart failure. By contrast, Feldman *et al*<sup>[2]</sup> reported a reduction in left ventricular volumes and LVEF after MitraClip®. These different findings may be explained by the fact that patients with functional and degenerative MR have different types of reverse remodeling. In patients with degenerative MR, end-systolic volume remains stable, whereas left ventricular end-diastolic volume decreases. In contrast, in patients with functional MR, a significant decrease in left ventricular end-diastolic and end-systolic volume is observed<sup>[20]</sup>. Therefore, LVEF decreases slightly in degenerative MR<sup>[2]</sup> and remains constant or increased in functional MR<sup>[19,20]</sup>.

**Figure 2 All-cause mortality and B-type natriuretic peptide.** A: Kaplan-Meier estimates of freedom from all-cause mortality; B: Kaplan-Meier estimates of freedom from all-cause mortality according to low pre-procedural BNP levels (BNP ≤ 817 pg/mL) and high pre-procedural BNP levels (BNP > 817 pg/mL). BNP: B-type natriuretic peptide.

In our study, the proportion of patients with functional and degenerative MR was approximately equal (Table 1). There were no differences in clinical course after mitral valve repair between patients with organic and functional MR. Potentially due to the relatively small number of patients, we observed that the LVEF, the left ventricular end-systolic and end-diastolic volumes remained nearly constant (Table 2).

Our study demonstrated a clear reduction in the severity of MR (Figure 1A), a reduction in left atrial volume and size and a decline in systolic pulmonary artery pressure (Table 2).

### 30-d and one-year outcomes

The all-cause mortality rate 30 d after percutaneous mitral valve repair was 4.3%, and this rate was 19.5% at one year. During the follow-up of  $473 \pm 274$  d, 11 patients (24%) died. Cardiovascular mortality accounted for the majority of the deaths at follow-up (90%). Patients' various cardiac and non-cardiac diseases may explain the relatively high long-term mortality. Similar one-year mortality rates have been reported in several other studies<sup>[3-11]</sup>. However, it should be emphasized that the patients in our study had an extremely high operative risk (mean logistic EuroSCORE I > 31%).

Thus, the risk profile of our patient cohort was less favorable than those of most other studies<sup>[3-11]</sup>. Our study suggests that even patients with an extremely high operative risk can be successfully treated with the MitraClip® system.

### BNP and outcome

Plasma BNP levels have a prognostic impact in patients undergoing surgical mitral surgery<sup>[21]</sup>. In patients undergoing percutaneous mitral valve repair with the MitraClip® device, Taramasso *et al.*<sup>[19]</sup> found that pre-procedural pro-BNP levels (pro-BNP level ≥ 1600 pg/mL) were an independent predictor of mortality. Furthermore, Neuss *et al.*<sup>[22]</sup> demonstrated that among patients with end-stage heart failure and NT-proBNP values > 10000 pg/mL, the mortality rate was extremely high, despite a successful percutaneous mitral valve repair with MitraClip®. Our results are in line with these studies. Although pre-procedural measurements of plasma BNP were performed in only 36 of the 46 patients, we found that BNP levels > 817 pg/mL were related with a considerably higher long-term mortality rate (Figure 2B). Notably, plasma BNP was the only independent predictor of long-term mortality. On the other hand, our study suggests that patients with plasma BNP levels ≤ 817 pg/mL have favorable long-term results after MitraClip® implantation (Figure 2B).

### Limitations

The main limitation of our study is the relatively small number of patients and the fact that this study was conducted only at one center. However, the percutaneous repair of the mitral valve is a relatively new technique. There are still few long-term results of MitraClip® implantation. Another important limitation is the absence of a control group in our study. A comparison with conservatively treated patients, or patients undergoing heart surgery would give a more rigorous investigation of the effects of percutaneous mitral valve repair. As our study examined relatively few patients, the associations found in this paper must still be considered preliminary.

## COMMENTS

### Background

Mitral regurgitation (MR) is the most common heart valve disease and the second most common reason for heart valve surgery. When feasible, mitral valve repair is considered the optimal surgical treatment. However, a considerable portion of patients with severe MR cannot receive surgical treatment because of their co-morbidities and high surgical risks. In the last few years, percutaneous mitral valve repair has become an alternative technique for patients with severe MR.

### Research frontiers

In the last few years, percutaneous mitral valve repair has become an alternative technique for patients with severe MR, with more than 20000 procedures worldwide. However, the Everest II study is the only randomized trial that has compared percutaneous repair with heart surgery, and it mainly included patients with degenerative MR and without an elevated operative risk. By contrast, the

current European Society of Cardiology guidelines recommend applying the MitraClip® only in symptomatic high-risk patients with severe functional MR (level of evidence IIb). In recent years, some registry studies and several smaller studies concerning MitraClip® have been published. However, relatively little is known about the mid- and long-term results of percutaneous mitral valve repair.

### Innovations and breakthroughs

The aim of the present study was to assess the mid-term outcomes after percutaneous mitral valve repair with MitraClip®. The study demonstrates that percutaneous mitral valve repair with MitraClip® had positive effects on hemodynamics and symptoms. Despite the multiple comorbidities and extremely high operative risk of the study patients, the mid-term outcome after MitraClip® was favorable. Elevated BNP levels were indicative of a poorer long-term survival.

### Applications

The data in this study suggest that patients with an extremely high risk can also be successfully treated with the MitraClip® system. In addition, pre-procedural plasma BNP levels > 817 pg/mL were associated with significantly higher long-term mortality. On the other hand, the study suggests that patients with plasma BNP levels ≤ 817 pg/mL had favorable long-term results after MitraClip®.

### Terminology

MR is a valvular heart disease that is characterized by an abnormal systolic blood flow into the left atrium and a volume overload of the left ventricle. The reasons for this condition include defects of the valve (usually referred to as degenerative mitral valve regurgitation) or heart failure with dilatation of the ventricle (usually called functional mitral valve regurgitation). Mitral valve repair is the standard therapy. Percutaneous mitral valve repair has emerged as an alternative technique.

### Peer-review

Good article, well written, interesting for the reader, with a useful "take home message".

**Abstract****AIM**

To evaluate the prevalence of salt sensitivity and the impact of cardiometabolic and psychological characteristics on salt sensitivity in normotensive population.

**METHODS**

Of all participants, anthropometric measurements and fasting venous blood samples were collected, and study questionnaires were completed. Salt Sensitivity was defined based on the difference in mean arterial pressure with infusion of 2 L of normal saline followed by a low sodium diet and administration of three doses

of oral furosemide the day after.

## RESULTS

Of 131 participants, 56 (42.7%) were diagnosed with salt sensitivity. Crude and age and sex adjusted regression analysis showed that low-density lipoprotein cholesterol and depression were positively associated with salt sensitivity (OR = 1.02, 95%CI: 1.01-1.04 and OR = 1.15, 95%CI: 1.00-1.34, respectively).

## CONCLUSION

The high prevalence of salt sensitivity and its significant relation with prevalent risk factors necessitates considering its reduction actions at the population level and the need for further research.

**Key words:** Salt sensitivity; Cardiovascular disease risk factors

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Mean blood pressure can be reduced following a decrease in sodium intake in both hypertensive and normotensive individuals. Normotensive individuals with salt sensitivity trait are more likely to develop hypertension and other health problems. A relatively high prevalence of salt sensitivity has been indicated among Iranian adults. Low-density lipoprotein cholesterol was found to have strong positive association with salt sensitivity. Depressive individuals were more salt sensitive.

How far cardio metabolic and psychological factors affect salt sensitivity in normotensive adult population? *World J Cardiol* 2017; 9(1): 47-54 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/47.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.47>

## INTRODUCTION

Hypertension is a prevalent well-documented risk factor for cardiovascular disease and premature mortality and therefore is an important public health issue<sup>[1]</sup>. Essential hypertension is a common disorder in areas with average daily sodium intake of over 100 meq/d (2.3 g sodium), however, is rarely seen with average daily sodium intake of less than 50 meq/d (1.2 g sodium)<sup>[2,3]</sup>.

It has been demonstrated in multiple studies that mean blood pressure (BP) can be reduced following a decrease in sodium intake in both hypertensive and normotensive individuals<sup>[4,5]</sup>. Based on these reports, a minimum level of dietary sodium independent of other risk factors is required for development of hypertension<sup>[6,7]</sup>.

There is an important clinical benefit to identify

and target individuals who are more sensitive to alterations in dietary sodium intake by implementing dietary sodium reduction interventions. BP variations in response to changes in dietary sodium intake are known as Salt Sensitivity. This responsiveness of BP, however, may vary significantly from individual to individual<sup>[8,9]</sup>. Normotensive individuals with this trait of salt sensitivity are said to be more likely to develop hypertension and other health problems including Cardiovascular, Respiratory, and renal disorders independent of hypertension later in life<sup>[10,11]</sup>.

Although incompletely understood, multiple mechanisms for sodium sensitivity have been demonstrated, from impaired renal sodium excretion, abnormalities in signaling and vascular tone, to the role of genetics in sodium regulation<sup>[12,13]</sup>.

In spite of the fact that the protocols and methods of salt sensitivity definition vary in different studies, there is a general accordance in the main observations. Salt sensitivity appears to be a reproducible phenomenon with different measurement techniques<sup>[14]</sup>.

Salt sensitivity is a practical clinical concept in spite of all the difficulties in measurement and identifying the sensitive individuals. This fact that is evident by positive outcomes of the recommended dietary approaches for the prevention and treatment of hypertension (HTN) (DASH diet)<sup>[15]</sup> There are certain traits and disorders that are markedly associated with salt sensitivity including African American ethnicity, obesity, chronic kidney disease, and cardiovascular risk factors<sup>[9,16]</sup>.

Previous studies conducted in the Eastern Mediterranean region (EMR) demonstrate a substantially high incidence rate of almost all cardiovascular diseases particularly HTN and increased rate of mortality even in treated subjects<sup>[17-20]</sup>. These findings along with the increasing trend of salt intake at the population level<sup>[21]</sup>, beside the lack of evidence of salt sensitivity of BP in Iran and in the region, highlight the importance of conducting this study. Therefore, we aimed to evaluate the prevalence of salt sensitivity in a normotensive Iranian adult population and to investigate the impact of cardiometabolic risk factors and psychological characteristics, on salt sensitivity.

## MATERIALS AND METHODS

### Participants and studied variables

The study was conducted by the hypertension research center affiliated to Cardiovascular Research Institute (a WHO collaborating center in the EMR) from July to October 2014. In order to find potential volunteers from community, we used a wide range of materials from flyers and brochures to posters. A total of 140 healthy participants volunteered to take part in this cross-sectional study. Eligibility requirements included willingness to participate in the study, age 18 years and older, normal BP defined as systolic BP below 140 mmHg and diastolic BP below 90 mmHg based on 3 screening visits of 1 wk apart. The exclusion criteria was

history of hypertension; history of special diet including low salt diets; history of taking antihypertensive medications and diuretics for any reason, oral contraceptives and nonsteroidal anti-inflammatory drugs; any history of myocardial infarction, heart failure, cerebrovascular accidents and renal failure. Written informed consents were obtained from each participant and the study protocol was approved by the ethical committee of Cardiovascular Research Institute.

A questionnaire was used at the baseline observation by trained staff to collect information on demographic characteristics as well as family history of hypertension, coronary artery disease, and lifestyle habits including regular physical activity, dietary pattern and smoking status. The Hospital Anxiety and Depression Scale questionnaire was also used to determine the score of anxiety and depression. This scale consists of seven items for anxiety and seven items for depression, with scores ranging from 0 to 21. The higher scores demonstrate more intensity in anxiety or depression level. Scores higher than 7, in both domains indicate that participants are likely to be depressed or suffer from anxiety<sup>[22,23]</sup>.

Anthropometric measurements of weight, height, waist and hip circumferences were obtained during baseline examination with the individual in minimal clothing. The WHO STEPS Surveillance Manual (The WHO STEP wise Approach to Chronic Disease Risk Factor Surveillance) was used for measuring waist and hip circumference<sup>[24]</sup>. Body mass index (BMI) was calculated as weight (in kilograms) over height squared (in meters).

Venous blood samples after fasting for at least 8 h were taken for measurement of fasting blood sugar (FBS), serum blood urea nitrogen (BUN), creatinine (Cr), uric acid (UA), sodium (Na), potassium (K) levels, and lipid profile including low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglycerides (TG), and total cholesterol (TC). Plasma measurements were assessed using commercially available kits (Parsazmoun). BP was measured by trained staff for each participant using an automated mercury sphygmomanometer with the individual in sitting position and 5 min of rest. All the participants were asked to avoid consumption of alcohol, tea, or coffee, physical exercise or smoking for at least one hour prior to admission. Mean arterial pressure (MAP) was calculated as  $[(2 \times \text{diastolic}) + \text{systolic}]/3$  and reported for each measurement.

We considered the following definitions for cardiovascular risk factors: Current smoking of at least one cigarette per day; lack of regular physical activity (less than 30 min a day, five days a week); raised blood glucose (FBS > 126 mg/dL); elevated blood cholesterol [TC > 200 mg/dL, TG > 150 mg/dL, LDL > 130 mg/dL, HDL below 40 mg/dL (male) and less than 50 mg/dL (female)]; and being overweight or obese (BMI > 25 kg/m<sup>2</sup>, waist circumference > 92 cm in males and > 88 cm in females)<sup>[25]</sup>.

### Study design

The study was conducted in two days. On the first day of the study, individuals were admitted at 8 AM and were put on a low calorie and low sodium diet (10 mmol/d). At this time, venous blood samples were obtained, anthropometric measurements were calculated, and the questionnaires were filled out from participants by trained staff. Two hours after the admission, three measurements of BP were obtained with five minutes intervals and the mean of them was recorded as the baseline BP.

After obtaining the baseline BP, 2 L of normal saline was administered intravenously over 4 h (500 mL/h). Two hours after normal saline infusion, BP was obtained and post-saline MAP was calculated. Then participants were discharged and were asked to return back to the clinic the next morning.

To ensure compliance to the study protocol, individuals were required to eat pre-packaged foods that were prepared according to the protocol including low-carbohydrate, low-fat, and low-sodium diet (10 mmol/d) and were instructed to avoid any foods that were not provided by the study staff. Participants were also followed up over the night by telephone to evaluate any potential side effects and to ensure their adherence to the study dietary protocol.

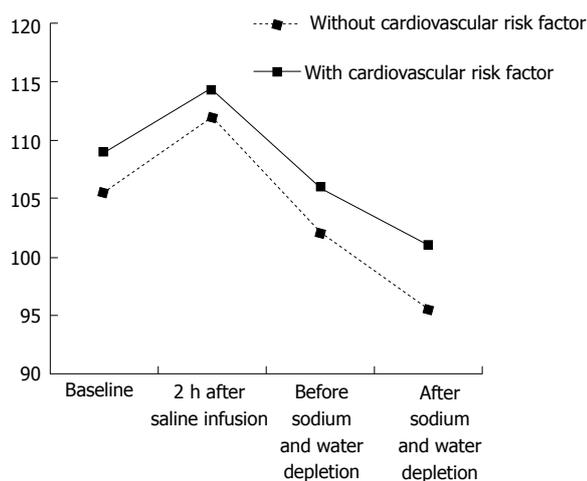

On the following day, participants were admitted again at 8 AM and BPs were obtained. Sodium and volume depletion was then induced by a low sodium diet (10 mmol/d) and administration of three doses of oral furosemide (40 mg each dose, at 10 AM, 2 PM and 6 PM). Two hours after completion of the last dose of furosemide, BP was measured according to the study protocol. The MAP after sodium and volume depletion was compared with the post-saline MAP.

Individuals who demonstrated a decrease in MAP  $\geq$  10 mmHg were defined as "salt sensitive". Those with MAP decrease < 10 mmHg were categorized as "salt insensitive" including both the salt resistant ( $\Delta$ MAP < 6 mmHg) and intermediate ( $\Delta$ MAP 6-10 mmHg) with respect to sodium sensitivity.

### Statistical analysis

All data were analyzed by SPSS, version 15 (SPSS Inc, Chicago, IL, United States). Respectively, a *P* value  $\leq$  0.05 and *P* value  $\leq$  0.1 were considered as statistically and marginally significant for all analyses. Student's *t* test for continuous variables and  $\chi^2$  test for discrete variables were used. Man-Whitney test was applied where appropriate. Multiple Logistic Regression model was carried out to examine the association between demographic, anthropometric, psychological characteristics and laboratory studies of those with the salt sensitivity. Odds ratios (ORs) were reported with the corresponding 95%CI. Repeated measure ANOVA was used for comparing the means of systolic BP in different times.

The dependent variable was salt sensitivity. Inde-

**Figure 1** Means of systolic blood pressure mmHg (vertical axes), measurements at: (1) baseline; (2) 2 h after saline infusion; (3) before sodium and water depletion; and (4) after sodium and water depletion (horizontal axes), among individuals without or with at least one cardiovascular risk factor.

pendent variables included demographic, anthropometric, psychosocial characteristics, laboratory studies, and cardiovascular risk factors of those adjusted based on age and sex. The statistical methods of the study were reviewed by biomedical statistician.

## RESULTS

Of the total of 140 participants, 9 who failed to adhere to dietary protocol or did not complete the intervention were excluded from the study. Among the 131 individuals included in the study, 56 participants (42.7%) were diagnosed with salt sensitivity while 75 (57.3%) participants including 52 (39.7%) salt resistant and 23 (17.6%) intermediate were determined as salt insensitive group. Of participants, hundred were male and 31 were female, with a mean age of  $25.70 \pm 5.71$ . Significant differences were not statistically detected in the age or sex distribution between both groups.

Table 1 shows the baseline demographic, psychological and anthropometric characteristics of participants as well as laboratory evaluations. Lipid profile tests revealed that LDL cholesterol level was significantly higher in Salt Sensitive group compared with Salt Insensitive one ( $P = 0.038$ ). In the Salt Sensitive group, BMI, FBS, BUN, and Cr levels were higher than those in the Salt Insensitive group with a marginally significant difference ( $P = 0.057, 0.072, 0.077, 0.067$ , respectively). There wasn't any significant difference in the Depression or Anxiety Score between two groups.

Table 2 shows the Crude, and age and sex-adjusted logistic regression analysis with salt sensitivity as an outcome. As shown in Table 2, with adjusted logistic regression analysis, LDL along with Depression were found to be the only two variables of significance (OR = 1.02, 95%CI: 1.01-1.04 and OR = 1.15,

95%CI: 1.00-1.34, respectively). At last, multiple logistic regression model with variables including, WC, Depression, FBS, LDL, Cr, age and sex was performed. Finding showed that there were not statistically difference between the result of multiple logistic regression model and age and sex adjusted logistic regression analysis and depression and LDL was still significant.

Means of systolic and diastolic BP measurements in participants without any cardiovascular risk factor compared with those with at least one risk factor at the baseline observation, 2 h after saline infusion, and before and after sodium and water depletion is shown in Figure 1. It has been founded that there is significant difference between baseline, 2 h after saline infusion and before and after sodium and water depletion ( $F = 102.02, P \leq 0.001$ ). No significant interaction was observed between groups and times. ( $F = 0.99, P = 0.39$ ).

## DISCUSSION

As a whole, 131 normotensive individuals properly completed the study protocol and were included in the study analysis. This study showed a relatively high prevalence of salt sensitivity among Iranian adults as well as significant and positive association between the level of LDL cholesterol and salt sensitivity. Based on age and sex adjusted logistic regression analysis, LDL cholesterol and depression were found to have strong positive association with salt sensitivity.

Multiple studies conducted in the EMR have shown high incidence rate of hypertension and its low control level in the region<sup>[18-20]</sup>. This factor along with high average intake of sodium in the Iranian diet<sup>[21]</sup> highlight the importance of integrating salt sensitivity in risk assessment and management of hypertension in the region.

The heterogeneity and susceptibility of individual BP response to Sodium intake is the basis for development of salt sensitivity and appears to be a common, normally distributed biological concept in populations<sup>[10,26]</sup>. The salt sensitivity definition and categorizing individuals to salt sensitive or insensitive is arbitrary and several methods exist to measure salt sensitivity. It can be defined as BP variations in response to a change in dietary salt or as the difference in MAP with infusion of normal saline followed by a low sodium diet and loop diuretic administration the day after<sup>[15,16]</sup>. Our protocol, with salt loading and depletion, allowed us to maximize the follow-up and adherence to the protocol with a more practical and controllable intervention. Despite the differences in the measurement or definition methods, there has been accordance in several findings<sup>[26,27]</sup>.

Overall, 42.7% of participants in our study were diagnosed with salt sensitivity. Even though relatively high, it is still in line with previous reports. The salt sensitivity has been observed in 25%-50% of normotensives and 40%-75% of hypertensive patients

**Table 1** Baseline demographic, cardiometabolic and psychological characteristics of participants with respect to salt sensitivity

Variable	Salt insensitive <i>n</i> = 75	Salt sensitive <i>n</i> = 56	<i>P</i> value
Sex (male) (%)	55 (73.3)	45 (80.4)	0.349 <sup>1</sup>

HTN: Hypertension.

depending on the measurement techniques and geographic variation of studies in different ethnic populations<sup>[4,5,28]</sup>.

Several mechanisms for sodium sensitivity have been demonstrated<sup>[29]</sup>. Impaired renal sodium excretion with resultant sodium retention that leads to volume expansion has been suggested as one of the underlying mechanism<sup>[30-32]</sup>. Abnormalities in signaling and vascular tone in response to sodium intake are another possible process<sup>[13,14]</sup>. Multiple genes are shown to be associated with sodium regulation and salt sensitivity<sup>[33,34]</sup>. This genetic predisposition is thought to be responsible for several relations seen in the salt sensitive group.

The strong, positive association of LDL cholesterol level with salt sensitivity presented in Table 2 can be interpreted by the role of genetic predisposition. In a study by Hoffmann *et al.*<sup>[35]</sup>, the endothelial nitric oxide synthase (*ENOS*) gene polymorphism was shown to be associated with higher levels of LDL cholesterol and reduced levels of nitric oxide (NO) production that can be responsible for the increased BP sensitivity to salt. Several previous studies have also revealed that the alpha-adducin gene polymorphisms may increase the LDL cholesterol levels and are probably responsible for salt sensitivity of BP<sup>[33,36,37]</sup>.

In the present study, depression was found to

be a potential predictive variable for salt sensitivity. The mechanism by which depression is related to salt sensitivity is not clearly understood and further studies are required. However, this association can be explained by the role of stress as a predisposing factor to depression in susceptibility of BP to salt. Previous studies have demonstrated the contribution of the stress and sympathetic nervous system to salt sensitivity<sup>[10,38,39]</sup>. One mechanism might be the impaired stress-induced renin-angiotensin-aldosterone system regulation<sup>[40]</sup>.

Depression and elevated LDL cholesterol level are reported to be highly prevalent among the Iranian population<sup>[41]</sup>. The fact that makes the importance of these two factors in salt sensitivity was even more significant among Iranian population.

Our findings showed that in the crude model, BMI, FBS, BUN and Cr levels were related to salt sensitivity with a marginally significant difference. The association between BMI and salt sensitivity has been noted in previous studies<sup>[39,42]</sup>. This relation may be explained by the higher sodium renal tubular reabsorption in obese individuals or due to drinking more soft drinks while eating salty products. Multiple previous studies have identified strong association between the plasma glucose level as a metabolic risk factor with salt sensitivity of BP independent of BMI, physical activity and hypertension<sup>[43]</sup>. Reduced renal function, which can be monitored with the level of BUN and Cr, has been also shown in previous observations to be associated with salt sensitivity<sup>[31]</sup>.

The prevalence of salt sensitivity is increased among older individuals with a family history of hypertension<sup>[11,29]</sup>, however, our results failed to show an association between higher age or positive family history of HTN and salt sensitivity. Multiple Factors such as including only normotensive participants, and relatively small sample size of the study can be considered as the reason for these inconclusive observations or differences found in our study compared to others.

The limitations of our study include relatively small sample size, the measurement method used for defining salt sensitivity, and exclusion of hypertensive individuals from the study. Even though all these factors were intentionally incorporated into the study design to enhance the practicality, feasibility and efficacy of the study, they ought to be considered as the limitations of the study.

According to our knowledge, this study is the first to investigate and report the prevalence and characteristics of salt sensitivity in our country and the EMR. The important clinical and public health implications of our study necessitate the need for more studies with larger sample size and to consider hypertensive patients too.

## ACKNOWLEDGMENTS

Authors wish to thank all study volunteers who participated to this study and the staff of Cardiovascular

Research Institute for their kind cooperation.

## COMMENTS

### Background

Blood pressure (BP) can be reduced following a decrease in sodium intake in both hypertensive and normotensive individuals. There is an important clinical benefit to identify and target individuals who are more sensitive to alterations in dietary sodium intake by implementing dietary sodium reduction interventions. Normotensive individuals more likely develop hypertension and other health problems including cardiovascular, respiratory, and renal disorders independent of hypertension later in life.

### Research frontiers

Increasing trend of salt intake at the population level beside the lack of evidence of salt sensitivity of BP in Iran and in the region, highlight the importance of conducting this study.

### Innovations and breakthroughs

This study evaluates the prevalence of salt sensitivity in a normotensive Iranian adult population and to investigate the impact of cardiometabolic risk factors and psychological characteristics, on salt sensitivity. According to our knowledge, this study is the first to investigate and report the prevalence and characteristics of salt sensitivity in our country and the Eastern Mediterranean Region.

### Applications

Salt sensitivity is a practical clinical concept in spite of all the difficulties in measurement and identifying the sensitive individuals.

### Terminology

Salt sensitivity is a measure of how your BP responds to salt intake. People are either salt-sensitive or salt-resistant. Salt sensitive individuals are more likely to have high BP than those who are resistant to salt; Normotensive having or denoting a normal BP.

### Peer-review

This is an interesting manuscript about the relations of salt sensitivity to cardiometabolic risk factors and psychological characteristics.

### Abstract

Many clinicians caring for patients with continuous flow left ventricular assist devices (CF-LVAD) use ramp right heart catheterization (RHC) studies to optimize pump speed and also to troubleshoot CF-LVAD malfunction. An investigational device, the ReliantHeart Heart Assist 5 (Houston, TX), provides the added benefit of an ultrasonic flow probe on the outflow graft that directly measures flow through the CF-LVAD. We performed a simultaneous ramp RHC and echocardiogram on a patient who received the above CF-LVAD to optimize pump parameters and investigate elevated flow through the CF-LVAD as measured by the flow probe. We found that the patient's hemodynamics were optimized at their baseline pump speed, and that the measured cardiac output *via* the Fick principle was lower than that measured by the flow probe. Right heart catheterization may be useful to investigate discrepancies between flow measured by a CF-LVAD and a patient's clinical presentation, particularly in investigational devices where little clinical experience exists. More data is needed to elucidate the correlation between the flow measured by an ultrasonic probe and cardiac output as measured by RHC.

**Core tip:** Commercially available left ventricular assist

devices estimate flow through the device, but a new investigational device with an ultrasonic flow probe directly measures flow. Despite a reported accuracy in the flow probe's measurement of flow, we found that this value was inaccurate in a patient whose flows were discrepant to the patient's clinical status by performing echocardiography and right heart catheterization. Care should be taken to verify technical advances in mechanical circulatory support, and both imaging and hemodynamic evaluations can help clinicians make more informed decisions.

Simultaneous ramp right heart catheterization and echocardiography in a ReliantHeart left ventricular assist device. *World J Cardiol* 2017; 9(1): 55-59 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/55.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.55>

## INTRODUCTION

To optimize the function of continuous left ventricular assist devices (CF-LVAD) after implantation, we and others<sup>[1]</sup> routinely use ramp right heart catheterization (RHC) protocols. These studies may provide added data beyond ramp echocardiogram protocols<sup>[2]</sup>, since a ramp RHC can simultaneously measure right and left sided filling pressures (central venous pressure and pulmonary capillary wedge pressure, respectively). While use of echocardiography has proven useful for optimization of HeartMate II (Pleasanton, CA) CF-LVAD pump speed, this has not proven helpful for other CF-LVADs<sup>[3]</sup>. As new CF-LVADs are developed and implanted, ramp RHC studies can be particularly helpful in defining optimal pump speed, since there is little clinical experience to turn to for guidance.

An investigational CF-LVAD, the ReliantHeart Heart Assist 5 (Houston, TX), incorporates an ultrasonic flow probe around the outflow graft that directly measures flow with a high reported accuracy<sup>[4]</sup>. There is no initial calibration with echo of RHC required, nor is there calibration based on blood viscosity (hematocrit) or patient's heart rhythm.

Here we provide the initial report of a combined ramp RHC and ramp echocardiogram in a patient after ReliantHeart implantation, and provide a comparison of measured flow through the CF-LVAD to cardiac output measured by right heart catheterization.

A 50-year-old man underwent placement of a ReliantHeart LVAD as a bridge to cardiac transplantation at our hospital. In the intensive care unit his flow through the CF-LVAD as measured by the flow probe ranged between 5 and 6 L/min, with cardiac output measured *via* the Fick principle in the 7-8 L/min range, and cardiac output by thermodilution in the 7-8 L/min range as well. The flow through the CF-LVAD as measured by

the flow probe increased to a range of 8-9 L/min on post-operative day 8, just prior to transfer out of the intensive care unit. Serum lactate dehydrogenase (LDH) levels were normal, and there were no signs of hemolysis in laboratory studies. The elevated measured flows with concomitant elevation in power consumption to 7-8 W raised a concern for pump malfunction, and we performed simultaneous ramp RHC and ramp echocardiography for further evaluation.

## CASE REPORT

The patient was brought to the catheterization laboratory in the post-absorptive state. A Swan-Ganz catheter was placed *via* the right internal jugular vein *via* the Seldinger technique, and two pressure transducers were attached to the catheter to measure central venous pressure and pulmonary capillary wedge pressure simultaneously. We changed the speed by 400 revolutions per minute (rpm) and waited two minutes at each setting before measuring intracardiac pressures and cardiac output (CO) *via* an assumed Fick determination ( $CO = VO_{2\max} / (\text{oxygen concentration of arterial blood} - \text{oxygen concentration of mixed venous blood})$ ).  $VO_{2\max}$  was assumed at 125 mL O<sub>2</sub>/BSA. At each setting, we also performed transthoracic echocardiography, measuring left ventricular end diastolic dimension, septal positioning, frequency of aortic valve opening, and the degree of mitral regurgitation.

Table 1 displays the measured changes in hemodynamic parameters with changes in RPM.

The baseline speed was 9100 RPM. We changed speed by 400 RPM increments to determine the best hemodynamics (normal biventricular filling pressures with normal cardiac output), as well as optimal aortic valve opening (aortic valve opening frequency of at least 1:3 cardiac cycles).

Biventricular filling pressures declined with an increase in pump speed, while cardiac output increased. The "v-wave" in the PCWP tracing was present at lower speeds (Figure 1A), but was reduced at 9100 RPM (Figure 1B). The flow measured through the CF-LVAD was consistently higher than the measured cardiac output by the Fick principle.

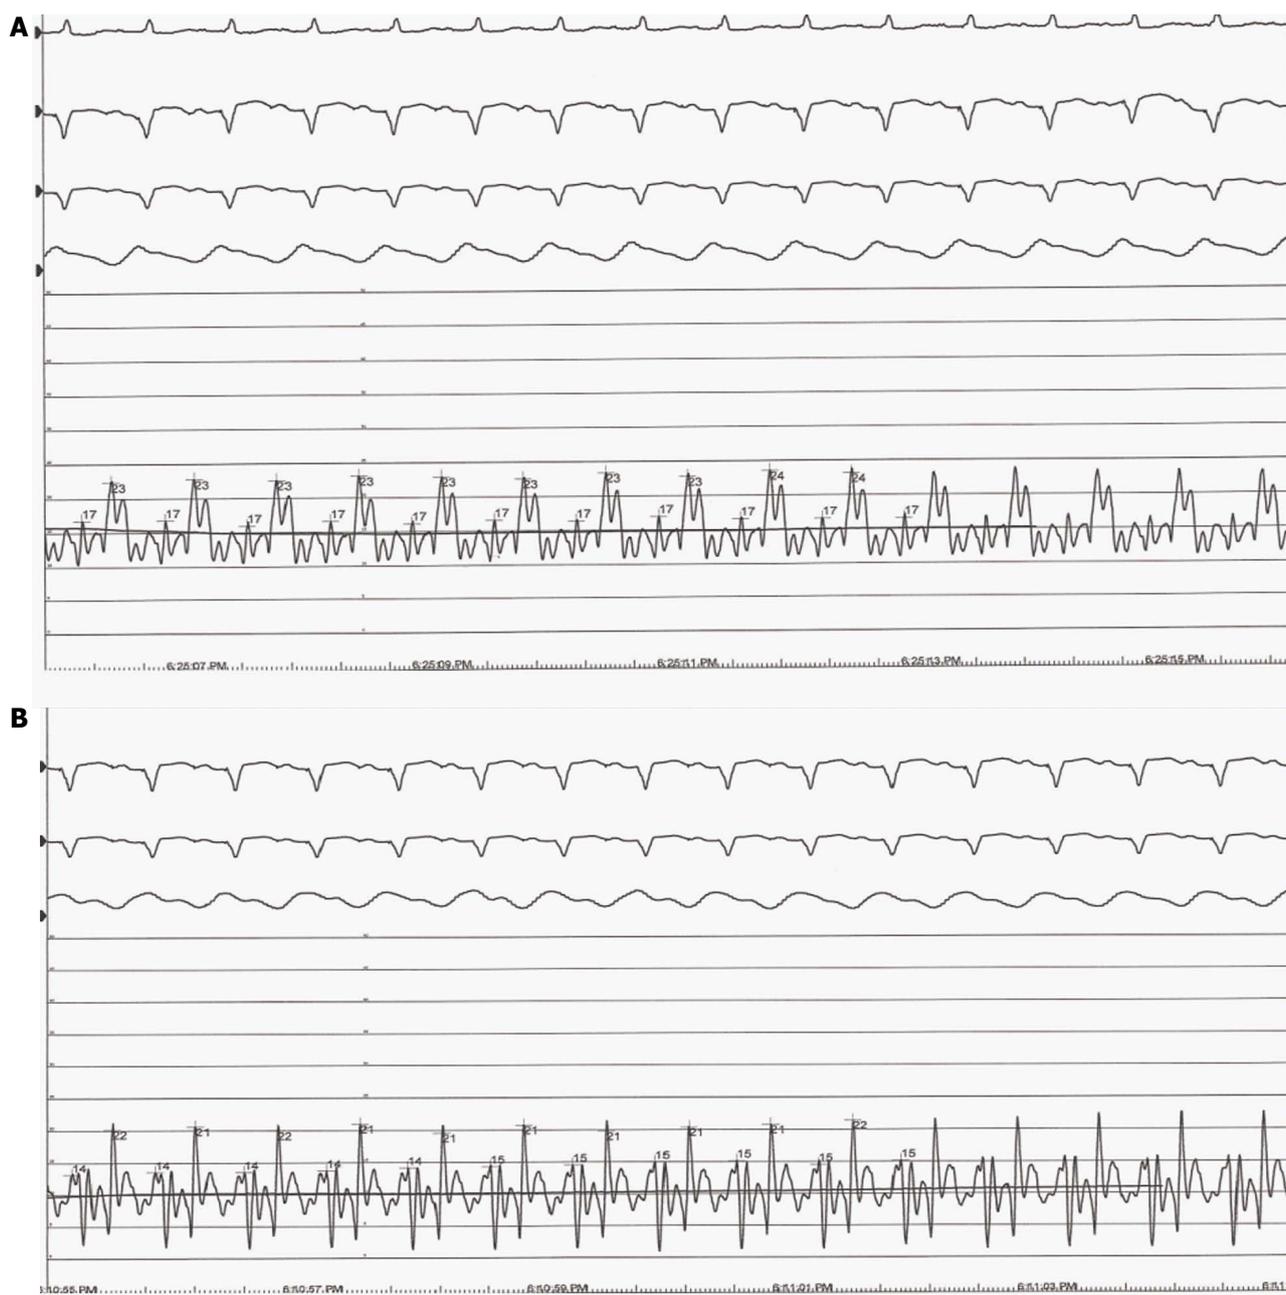

Echocardiography revealed that at 8300 RPM the aortic valve opened with every cardiac cycle, at 8700 RPM the valve opened 1:2 cardiac cycles, and the valve remained closed at 9100 RPM. At baseline RPM the left ventricular end diastolic dimension (LVIDd) was 8.0 cm and the interventricular septum (IVS) bowed mildly toward the LV. As pump speed increased, the degree of mitral regurgitation decreased, the LVIDd decreased further to 7.8 cm but the IVS shifted even more toward the LV. At lower speeds the IVS was midline, and at 8300 RPM the LVIDd was 8.3 cm. There was no evidence of aortic insufficiency or intracardiac shunting.

As a result, given acceptable hemodynamics at 8700 RPM and intermittent aortic valve opening with optimal

**Table 1** Changes in hemodynamic parameters with changes in speed of the ReliantHeart continuous flow left ventricular assist devices

RPM	RAP (mmHg)	RVP	PAP	PCWP	CO (L/min)	CI (L/min per meters square)	Flow (L/min)	Power (W)
8300	11		44/20/28	15	6.3	2.2	7.3	6.4
8700	10		40/18/25	14	6.4	2.5	7.9	7.1
9100 baseline	7	30/15	33/15/21	10	6.5	2.8	8.4	7.8
9500	6		35/15/22	10	6.7	2.9	8.7	8.6

RPM: Revolutions per minute; RAP: Right atrial pressure; RVP: Right ventricular pressure; PAP: Pulmonary arterial pressure; PCWP: Pulmonary capillary wedge pressure; CO: Cardiac output; CI: Cardiac index.

**Figure 1** This figure shows the effect of increasing pump speed on the pulmonary capillary wedge pressure tracing. In 8700 RPM (A), the PCWP is measured at 14 mmHg with a pronounced “v” wave. At 9100 RPM (B), the “V-wave” disappears, and the PCWP has decreased to 10 mmHg. Flow and Power refer to flow measured by the LVAD and power consumed by the LVAD, respectively. LVAD: Left ventricular assist devices.

position of the IVS, the speed was changed to 8700 RPM at the conclusion of the study.

## DISCUSSION

We here report, to our knowledge, the first combined ramp RHC and ramp echocardiogram procedure in a patient receiving the ReliantHeart investigational CF-LVAD. This study reinforces the importance of incorporating simultaneous hemodynamic and echocardiographic data into defining the optimal pump speed for a patient with a CF-LVAD.

Our group commonly performs both ramp RHC and ramp echocardiography in patients for speed optimization post CF-LVAD placement, in the post-operative setting, as well as annually, and with clinical and laboratory data concerning for possible pump thrombosis. Published results corroborate the finding of our clinical practice. Ramp RHC in particular can demonstrate inadequate unloading of the left ventricle in patients who seem well compensated by clinical examination, or those with significant right ventricular dysfunction.

Ramp RHC can also be used to troubleshoot abnormal CF-LVAD parameters that are discrepant from clinical evaluation. In other CF-LVADs, high pump flows may signify pump thrombus or septic physiology. In this case, because an ultrasonic flow probe measured high flow, we worried the patient could indeed be in high flow state concerning for sepsis, intra-cardiac shunt or aortic regurgitation. On invasive hemodynamic assessment, we found the patient was adequately unloaded by the CF-LVAD (normal filling pressures and cardiac output) at the baseline RPM. After increasing the RPM, the loss of the V-wave on the PCWP tracing, coupled with aortic valve closure by echocardiogram, argued against the presence of a high cardiac output state, as these suggest further unloading by the CF-LVAD.

Interestingly, the flows measured by the flow probe at the time of the study were higher than the total cardiac output, suggesting a degree of inaccuracy in the flow probe measurement. We would have expected the measured flow through the CF-LVAD to be lower than the total cardiac output as measured by the Fick principle, as the total cardiac output should account for both flow through the native heart and flow through the CF-LVAD. That relationship was seen earlier in the patient's hospital course, but was lost by the time the patient left the intensive care unit.

We do not have extensive data detailing the correlation between flow as measured by the ultrasonic flow probe of this investigational device and measured cardiac output *via* the Fick principle. We did note that the device's power consumption also increased after implant to 8 W, although this was within the manufacturer specifications. This is an investigational device, and expected pump parameters still need to be described. In any case, early high pump powers are not necessarily indicative of future adverse events<sup>[5]</sup>, and our patient had stable serum LDH values and no other evidence of pump thrombus.

One potential explanation for the unexpectedly high flows as measured by the flow probe is pressure drift,

a slow change in the sensor that can shift its calibration and lead to inaccurate readings<sup>[6]</sup>. This drift has been seen in implantable left atrial pressure sensors over time. In addition, intraoperative placement of the flow probe is important. If the graft is not contacting the flow probe, then the measured flow may not be accurate. Shift of the flow probe over time could also lead to a shift in measured flow. Clinicians should use corroborative techniques (such as RHC) to confirm abnormal changes in CF-LVAD flows before acting on that data, both for CF-LVADs that estimate flows and those that directly measure flows.

One limitation of our study was the use of an assumed Fick calculation. We felt that was mitigated somewhat by the concomitant thermodilution data in the intensive care unit, which closely correlated with the Fick cardiac output. Simultaneous measurement of Fick and thermodilution cardiac outputs in the catheterization laboratory, as well as the use of metabolic cart to calculate peak oxygen consumption would more directly address this limitation.

In summary, we report here the utility of combined ramp RHC and ramp echocardiography to optimize speed in a patient receiving an investigational CF-LVAD, and troubleshoot abnormal parameters reported by that CF-LVAD. More data is needed to elucidate the correlation between the flow measured by the ultrasonic probe and cardiac output as measured by RHC.

## COMMENTS

### Case characteristics

A 59-year-old man with a severe nonischemic cardiomyopathy presented with elevated left ventricular assist device flows as measured by an ultrasonic flow probe despite normal clinical status.

### Clinical diagnosis

Inaccurate flow estimation by ultrasonic flow probe.

### Differential diagnosis

Left ventricular assist devices (LVAD) pump thrombus, LVAD outflow graft malposition, infection.

### Laboratory diagnosis

All laboratory studies were within normal limits.

### Imaging diagnosis

Echocardiogram revealed normal LVAD function with appropriate decompression of the left ventricle as speed increased.

### Related reports

Pressure drift has been noted in other pressure sensors, such as left atrial and pulmonary artery pressure monitors.

### Term explanation

Ultrasonic.

### Experience and lessons

Ultrasonic flow probes may provide inaccurate measures of flow through left ventricular assist devices, and more data is needed to elucidate the correlation

between the flow measured by the ultrasonic probe and cardiac output as measured by right heart catheterization.

### Peer-review

The paper is well written.

### Abstract

In the current case series we describe two cases of longitudinal stent deformation in ostial lesions treated with a new generation zotarolimus eluting stent and review current literature on longitudinal stent deformation. Historically not a common occurrence, longitudinal deformation occurred mainly in Promus Element everolimus eluting stents, which had only two rather than the commonly used 3 links between stent rings. Longitudinal deformation commonly occurs secondary to compression of the proximal edge of the stent by either the guide catheters, or intravascular balloons and imaging catheters. The degree of deformation however, depends on the longitudinal strength and design of the stent.

Longitudinal deformation of a third generation zotarolimus eluting stent: "The concertina returns!" *World J Cardiol* 2017; 9(1): 60-64 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/60.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.60>

## INTRODUCTION

Over the last decade there has been remarkable progress in coronary stent design and materials. Early generation stents were stainless steel followed by the use of cobalt chromium and platinum chromium alloys, enabling stents to be thinner and more flexible, hence improving deliverability and conformability. In addition, thin stent struts have been associated with improved outcomes in drug eluting stents<sup>[1-3]</sup>. With the reduction in strut thickness, innovative designs have enabled maintenance of radial strength, however, longitudinal stent strength may have been compromised.

A recently observed complication includes longitudinal stent deformation, defined as the distortion or shortening of a stent in the longitudinal axis following successful stent deployment<sup>[4]</sup>. Longitudinal stent strength is dependent on the architectural composition - number, orientation, shape, thickness and material of the crest (or ring) and links. For example, the reduction in number of links between cells may enhance deliverability (by allowing more lateral bending) but as a consequence may compromise longitudinal strength. Longitudinal deformation can result in protrusion of struts into lumen. Extensive malapposition of struts may result in disruption of blood flow and increased risk of stent thrombosis<sup>[5,6]</sup>. In addition, longitudinal deformation of drug eluting stents may result in uneven drug delivery that can result in higher rates of in-stent restenosis<sup>[7]</sup>.

In the current case series and review we describe two cases of longitudinal deformation with the new Resolute Onyx (Medtronic Inc., United States) zotarolimus eluting stents (ZES) and review the literature on longitudinal deformation. This new generation ZES has a novel design, manufactured from a single strand of core wire (platinum iridium) shaped into a continuous sinusoidal waveform. The strut thickness is 81  $\mu\text{m}$ , rendering it extremely trackable and conformable. Every 4<sup>th</sup> crown is laser fused to provide uniform longitudinal strength across the length of the stent.

## CASE REPORT

### Case 1

A 78-year-old male with diabetes mellitus, hypertension, hypercholesterolemia, and chronic renal failure presented with stable angina. Elective coronary angiography demonstrated significant lesions in the ostial and mid segments of a tortuous right coronary artery (RCA) (Figure 1A). The Judkins Right 4 catheter

did not provide sufficient support therefore a 3 dimensional (3D) right coronary (Williams) guide catheter was used to intubate the RCA. This provided improved, yet suboptimal support, therefore a buddy wire was used to facilitate the implantation of a ZES (Resolute Onyx 2.75 mm  $\times$  38 mm, Medtronic) in the mid segment. Subsequently, the ostial-proximal lesion was pre-dilated, stented with a Resolute Onyx 3.0 mm  $\times$  22 mm ZES and post-dilated with a 3.0 mm non-compliant (NC) balloon (Figure 1B). Following stent deployment and removal of the buddy wire, significant longitudinal deformation was noted (Figure 1C), which was treated with non-compliant balloon dilatation and third ZES insertion (Resolute Onyx 3.0 mm  $\times$  18 mm) all the way to the ostium (Figure 1D).

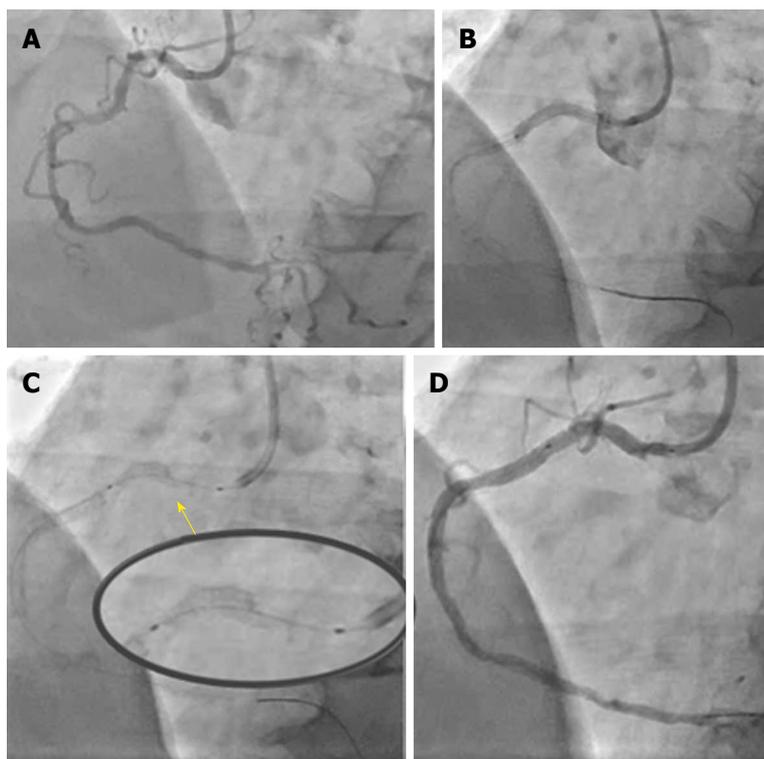

### Case 2

A 85-year-old male with end stage renal failure and severely impaired left ventricular systolic function presented with rapidly conducted atrial fibrillation and raised troponin (6000, upper normal limits 30) with inferolateral ST depression on electrocardiogram. On coronary angiography, he had severe three-vessel and left main disease. After being turned down for surgery, his proximal tight RCA lesion was stented with a Resolute Onyx 4.5 mm  $\times$  12 mm and post-dilated with a 5 mm non-compliant balloon. In view of the heavily calcified ostial/distal left main stem (LMS) and proximal left anterior descending (LAD) disease (Figure 2A) and bursting non-compliant balloons, decision was made to rotablate the lesions first with 1.5 mm burr. Subsequently a 3.0 mm non-compliant balloon was used to pre-dilate all lesions successfully. The proximal LAD was stented with a Resolute Onyx 3.0 mm  $\times$  26 mm stent. The whole length of the LMS into the proximal LAD was stented with a 3.5 mm  $\times$  34 mm Resolute Onyx covering the LMS ostium (Figure 2B and C). The LMS segment of the stent was post-dilated with a 4.5 mm NC balloon. Immediately after and despite taking care in removing the trapped LCx wire, there was longitudinal deformation of the stent, which no longer covered the LMS ostium (Figure 2D). After ballooning the deformed stent with a 4.5 mm non-compliant balloon the ostium was covered with another 4.0 mm  $\times$  8 mm stent and post-dilated with 4.5 mm NC balloon with an excellent final result (Figure 2E).

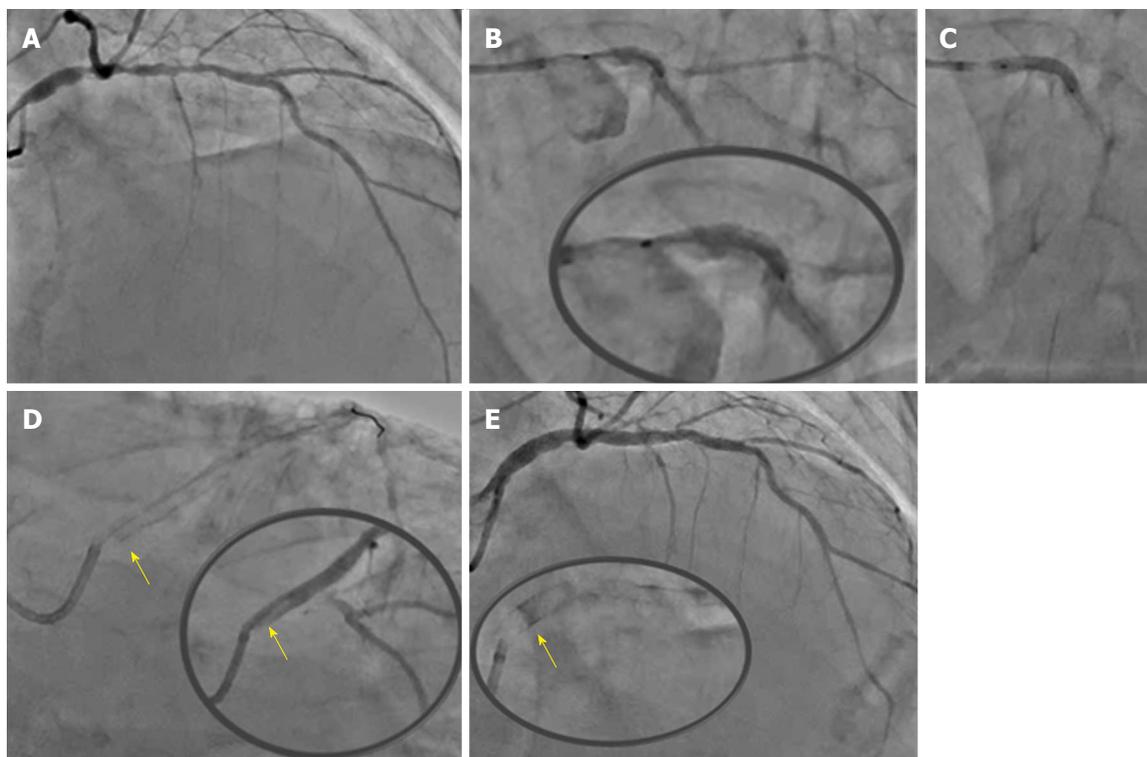

## DISCUSSION

To our knowledge this case series demonstrates the first reported cases of longitudinal deformation in patients treated with the new Resolute Onyx stent platform.

Traditionally, longitudinal strength was not considered standard characteristics for stent performance. However, recent evidence has highlighted possible complications since longitudinal deformation was first reported by Hanratty *et al*<sup>[8]</sup>, describing 3 cases where longitudinal compression of a previously deployed stent resulted in

**Figure 1** Longitudinal deformation of a stent implanted at the ostium of the right coronary artery. A: Initial angiogram showing severe calcific lesions in proximal and mid right coronary artery; B: Proximal lesion stented all the way to cover the ostium with a Resolute Onyx 3.0 mm × 22 mm stent; C: Longitudinal deformation of proximal stent treated with 3.0 non-compliant balloon and another 3.0 mm × 18 mm Resolute Onyx stent; D: Final angiographic result.

**Figure 2** Longitudinal deformation of an ostial left main stem stent. A: Initial angiogram showing significant calcific ostial and distal left main lesions with further significant proximal LAD calcific disease; B: After 1.5 burr rotablation, LMS into proximal LAD was stented with a 3.5 mm × 34 mm Resolute Onyx (B) to 14atm covering the LMS ostium (C). The LMS segment of the stent was post-dilated with a 4.5 NC balloon and the jailed LCx wire removed; D: Longitudinal deformation of the ostial LMS stent (yellow arrow pointing at the proximal deformed edge of the stent); E: Final angiographic result after covering the ostial LMS with a 4.0 mm × 8 mm Resolute Onyx stent. LAD: Left anterior descending; LMS: Left main stem.

stent deformation. Two were identified angiographically and one with the aid of intravascular imaging. It was first documented with the Promus Element (Boston Scientific) stent which was related to guide catheter compression of stents deployed in an ostial location<sup>[8]</sup>. However, Hanratty *et al.*<sup>[8]</sup> have observed this phenomenon in other drug eluting stents. A retrospective analysis of 4455 interventional cases over a four-year period showed stent deformation occurred in 0.2% of patients affecting 0.097% of stents deployed<sup>[7]</sup>. In 6 cases, Promus Element was involved, and there was 1 case each involving Endeavor (Medtronic), Biomatrix (Biosensors Interventional Technologies), and TAXUS Liberté (Boston Scientific) stents. The rate of stent deformation varied from 0% in several other stent types to 0.86% in the case of the Promus Element stent. In the same series, there was one case of late stent thrombosis attributable to longitudinal stent deformation<sup>[7]</sup>. In the DUTCH-PEERS study 906 patients were assigned to receive third generation zotarolimus-eluting stents (Resolute Integrity, Medtronic) and 905 to receive everolimus-eluting stents (Promus Element, Boston Scientific)<sup>[9]</sup>. Longitudinal stent deformation was seen only in the everolimus-eluting stent group [nine (1.0%) of 905 vs 0 of 906,  $P = 0.002$ ; nine of 1591 (0.6%) everolimus-eluting stents implanted became deformed], but was not associated with any adverse events.

Despite drug eluting stents having improved remarkably the safety and efficacy of revascularization procedures, stent design is a continuously developing field that aims to balance numerous performance attributes such as stent flexibility, shortening on expansion, trackability, scaffolding, radiopacity, longitudinal strength, radial strength and recoil. An experimental evaluation of longitudinal strength of four commercially available stent design families demonstrated that a 50 g force

resulted in longitudinal compression of 1.25–5.30 mm (4.46%–18.93%, compared with the nominal expanded stent length). The Promus Element stent platform had an average longitudinal compression of 13.20 mm (47.07%), demonstrating marked lower resistance to longitudinal compression (Table 1)<sup>[10]</sup>. Newer stent platforms with ultrathin struts (down to 60 µm) have shown non-inferiority to established everolimus platforms<sup>[11]</sup> but their longitudinal strength has yet to be assessed on the bench.

In our series both cases of longitudinal deformation occurred in the hands of very experienced operators implanting the scaffold at an ostial location. Potential reasons behind the deformation could include guide catheter compression of the proximal edge of the ostial stent post removal of jailed wires (case 1 or 2) or aggressive post-dilatation of the stent with a significantly larger NC balloon causing longitudinal shortening (case 2). It is unclear whether laser fusion provides less support compared to traditional links and further evidence is required prior to drawing any conclusions.

In conclusion, longitudinal stent deformation can occur even with new generation ZES and identification is important as, if left untreated, it may associate with a risk of future stent thrombosis, restenosis, and challenges in rewiring and retreating these lesions in the future.

## COMMENTS

### Case characteristics

The authors presented two cases, one with stable angina and one presenting with a non ST elevation myocardial infarction, requiring treatment of ostial lesions with new generation drug eluting stents.

### Treatment

Both cases were treated with the third generation zotarolimus eluting stent

Resolut Onyx, and in both cases longitudinal deformation of the stents was observed. This was managed with further ballooning and stenting.

### Experiences and lessons

Longitudinal stent deformation can occur even with new generation ZES and identification is important.

### Peer-review

This manuscript reports two cases of longitudinal deformation of a 22-mm and 34-mm third generation zotarolimus eluting stent. The issue brought up by the authors is interesting and the cases well documented.

### Abstract

In patients with history of coronary artery disease angina pectoris is usually attributed to the progression of atherosclerotic lesions. However, in patients with previous coronary artery bypass graft operation (CABG) using internal mammary artery grafts, great vessel disease should also be considered. Herein we present two patients with history of CABG whose symptoms were suspicious for coronary ischemia. During cardiac catheterization reverse blood flow was observed from the left artery disease to the left internal mammary artery (LIMA) graft in both cases. After angioplasty and stent implantation of the left subclavian artery antegrade flow was restored in the LIMA grafts and both patients had complete resolution of symptoms.

**Key words:** Coronary steal syndrome; Coronary artery bypass graft; Left subclavian artery; Reverse blood flow; Cardiac catheterization

## INTRODUCTION

Coronary and peripheral artery disease (CAD and PAD) are both comorbidities which exhibit a high prevalence and increasing morbidity and mortality in the western world<sup>[1]</sup>. Especially PAD is estimated to affect over 200 million people worldwide, and around 30% of primary care individuals over 70 years old<sup>[2,3]</sup>. Patients with symptomatic PAD exhibit a life expectancy of 80% at 5 years of follow-up, whereas 20% of such patients experience non-fatal cardiovascular complications<sup>[4,5]</sup>. Interestingly, PAD patients have significantly less chance of receiving appropriate risk factor modification (*e.g.*, statin therapy) and antithrombotic treatment compared to patients with CAD<sup>[1]</sup>. In addition, the prevalence of unrecognised PAD is extremely high (68%) in patients referred for coronary angiography for suspected CAD, especially in individuals with low socioeconomic status<sup>[6]</sup>.

In patients with history of CAD and previous coronary revascularization, angina pectoris is usually attributed to the progression of atherosclerotic lesions. However, in patients who previously underwent coronary artery bypass graft operation (CABG) using internal mammary artery grafts, great vessel disease, for example of the subclavian artery, should also be considered. In this regard, the coronary subclavian steal syndrome is a rare complication after CABG when the left internal mammary artery (LIMA) graft is used. This disease is characterized by retrograde flow from the LIMA graft to the distal post-stenotic part of the subclavian artery during muscle work and increased oxygen and blood demand of the arm in order to maintain adequate perfusion of the left hand. As a result, patients with such a condition may develop typical symptoms of myocardial ischemia despite patency of the grafted vessels.

## CASE REPORT

Herein we present a mini series of two patients (Patient A, Patient B) with suspected progress of the known multi-vessel CAD. Both patients had history of previous CABG including a LIMA graft to the left artery disease (LAD). Baseline characteristics of our patients are provided in Table 1.

Patient A was referred to our department for an elective coronary angiography due to typical angina symptoms (CCS class III) during exertion since 4 wk. He had a history of multi vessel disease with prior CABG 14 years ago.

The initial coronary angiography revealed a 75% ostial stenosis of the left main coronary artery. Despite the presence of significant left main stenosis, reverse blood flow was observed from the LAD to the LIMA

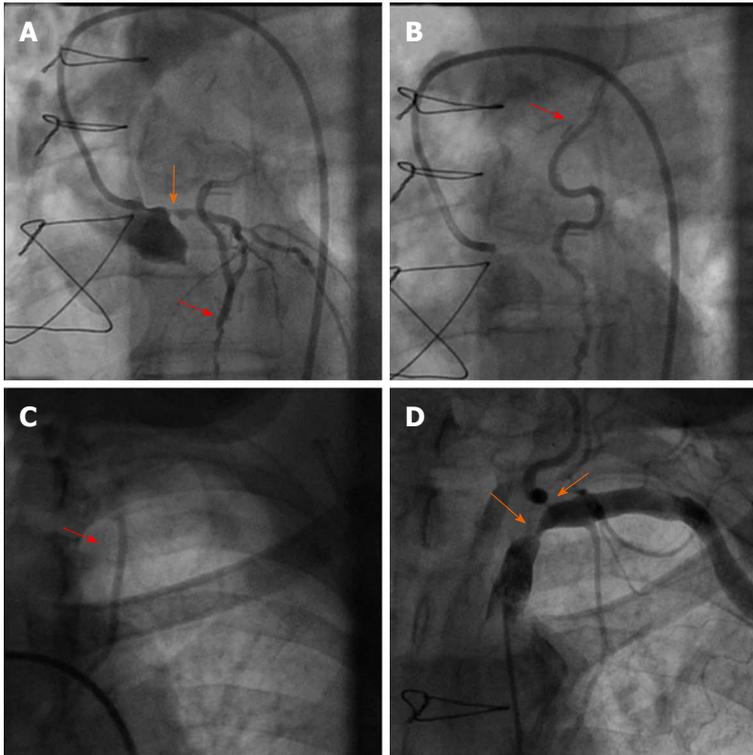

**Table 1** Baseline characteristics of our 2 patients: Typical angina symptoms indicate Canadian Cardiovascular Society

	Patient A	Patient B
Sex	Male	Male
Age (yr)	75	78
Cardiovascular risk factors	Arterial hypertension Hyperlipidemia Obesity	Arterial hypertension Hyperlipidemia Previous smoker
CAD CABG	Known 3-vessel-disease 14 yr ago LIMA graft to the LAD Venous grafts to the right coronary (RCA) and the LCX	Known 2-vessel disease 9 yr ago LIMA graft to the LAD Venous graft to the first marginal branch
Left ventricular function	Mildly impaired	Mildly impaired
PAD history	Previous recanalization of left (2009) and right (2010) superficial femoral artery	Surgical endarterectomy of the left internal carotid artery 2013 High grade lesions in the left vertebral artery and left subclavian artery (accidental finding in a computed tomography performed one year earlier)
Initial symptoms	Typical angina symptoms (CCS III)	Presyncope and atypical angina
Baseline medication	Aspirin β-blocker Angiotensin converting enzyme inhibitor Statin	Aspirin β-blocker Angiotensin converting enzyme inhibitor Statin Calcium antagonist Diuretics

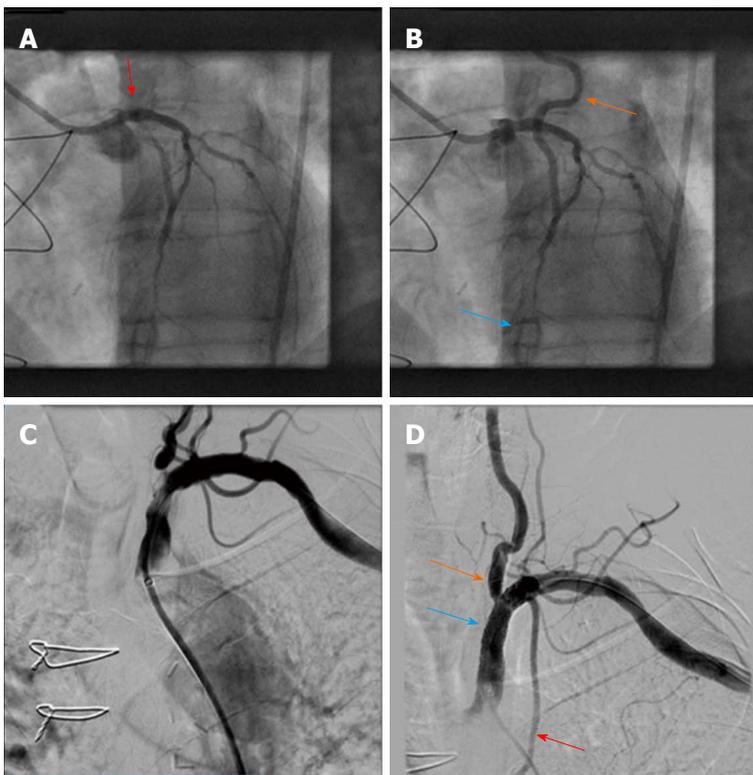

LIMA: Left internal mammary artery; LCX: Left circumflex artery; LAD: Left anterior descending; CAD: Coronary artery disease; CABG: Coronary artery bypass graft operation.

graft. Thus, contrast opacification could be followed up to the insertion of the graft at the subclavian artery (Figure 1). Both the 2 vein grafts to the left circumflex and the right coronary artery were patent. In addition, angiography of the subclavian artery revealed high grade lesions in the subclavian and the origin of the left vertebral artery (Figure 1). Hereby, con-current retrograde flow from the LAD was observed during contrast agent injection.

Due to typical angina and significant left main disease, PCI of left main artery and stent placement (Promus Element 4.0 mm × 20 mm, Boston Scientific) was performed in patient A with a good angiographic result (Figure 2). However, retrograde flow from the LAD to the LIMA graft remained after percutaneous coronary intervention (PCI), and sparse flow was seen in the distal LAD despite successful left main PCI (orange and blue arrows in Figure 2, respectively). After 4 wk the patient was scheduled for PCI of his left subclavian artery due to suspected LIMA steal syndrome. Interestingly, at that time he reported on persistence of CCS class III anginal symptoms. Angioplasty could be performed successfully, followed by bifurcation stent

**Figure 1** Reverse blood flow was observed from the left artery disease to the left internal mammary artery graft. During coronary angiography (red arrows in A and B) despite 75% stenosis of the left main coronary artery (orange arrow in A), contrast injection could be followed up to the insertion of the graft in the subclavian artery (red arrow in C). Angiography of the subclavian artery revealed high grade lesions in the subclavian and left vertebral artery (orange arrows in D).

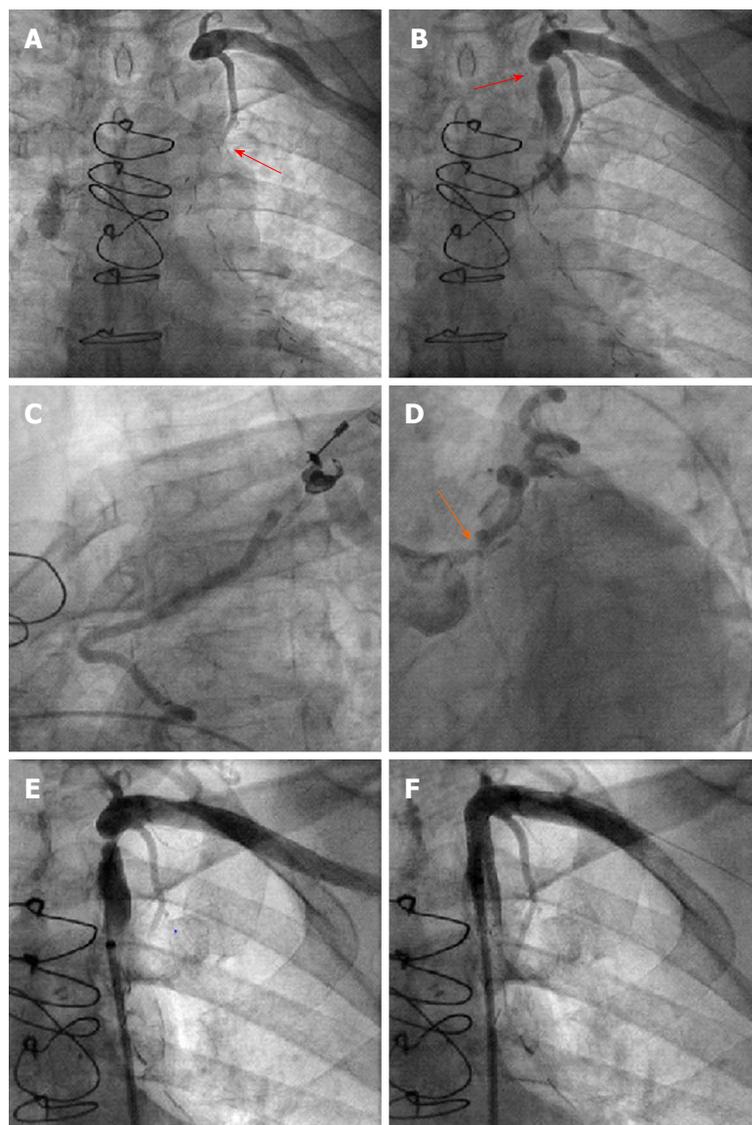

**Figure 2** Percutaneous coronary intervention of left main artery and stent placement. It was performed with a good angiographic result (red arrow in A) However, retrograde flow from the left artery disease LAD to the LIMA graft remained after PCI, and sparse flow was seen in the distal LAD (orange and blue arrows in B, respectively). DSA confirmed the presence of high grades stenosis of the left subclavian and vertebral artery (C). After angioplasty and bifurcation stent implantation a good angiographic result can be appreciated (orange and blue arrows in D) with normal opacification of the LIMA graft (red arrow in D). PCI: Percutaneous coronary intervention; LAD: Left artery disease; LIMA: Left internal mammary artery; DSA: Digital subtraction angiography.

implantation of the stenotic subclavian and vertebral arteries (balloon expandable Visi-Pro 8.0 mm × 27 mm, Covidien for the subclavian and Taxus Element 4.5 mm × 12 mm, Boston Scientific for the vertebral artery) and final kissing balloon inflation. Subsequently, a good angiographic result was observed with restored antegrade flow indicated in the LIMA graft (Figure 2).

For patient B, the initial cause for admission to our

hospital was a presyncopal episode and atypical angina. Cardiac catheterization was performed due to the high risk profile of the patient, including known multi-vessel disease and CABG 9 years ago. After selection of a left radial access for coronary angiography and wire insertion into the subclavian artery, we proceeded with selective contrast injection into the LIMA graft to the LAD. Surprisingly, contrast opacification was not possible

**Figure 3** After selective contrast injection into the left internal mammary artery graft no contrast opacification. It was shown in the left artery disease (red arrow in A). Subsequently, a high grade stenosis of the left subclavian artery was observed (red arrow in B). During coronary angiography retrograde flow from the left artery disease up to the origin of the LIMA graft could be demonstrated (C), despite left main stenosis (orange arrow in D). After angioplasty and stent placement (E) antegrade flow could be re-established in the subclavian artery (F). LIMA: Left internal mammary artery.

despite selective contrast injection into the presumably patent vessel (Figure 3). Subsequently, angiography of the left subclavian artery was performed, confirming high grade stenosis of the left subclavian artery (Figure 3), which was already accidentally diagnosed one year earlier during a computed tomography scan. Consistently an interarm blood pressure difference of 20 mmHg (left < right) could be measured with this patient. The subclavian stenosis was located proximally to the origin of the LIMA graft, thus possibly causing a coronary steal syndrome. Coronary angiography confirmed this diagnosis demonstrating retrograde flow from the LAD up to the insertion of the LIMA graft into the subclavian artery (Figure 3) despite the presence of significant left main disease (Figure 3). On the following day, stress echocardiography was performed, demonstrating an inducible hypokinesia in the anterior LV-wall by arm exertion (“hand grip method”), compatible with inducible ischemia in the LAD territory. Subsequently, balloon angioplasty and stent placement of the left subclavian artery was performed using an Armada 6.0 mm × 20 mm balloon and an 8.0 mm × 27

mm VisiPro-Stent with good angiographic result (Figure 3). Importantly, antegrade flow could be reestablished in the subclavian artery after interventional treatment (Figure 3).

Both patients were discharged the day after the procedure. During clinical follow-up patient A showed complete resolution of his angina symptoms, whereas repeated stress echocardiography showed no signs of inducible ischemia in patient B.

## DISCUSSION

Subclavian artery stenosis is a relatively frequent disease, which is more commonly described in patients with diabetes mellitus and was shown to be predictive of poor cardiovascular outcomes<sup>[7]</sup>. Known PAD accompanied by an interarm blood pressure difference greater than 10% has been suggested as a specific, but unfortunately less sensitive indicator for a subclavian stenosis<sup>[8]</sup>. The presence of subclavian artery stenosis in patients with previous CABG, who have received a LIMA graft can lead to angina symptoms independent

of atherosclerosis progression in native coronary arteries and bypass grafts. Although several cases of subclavian artery causing a so-called LIMA steal syndrome have been reported in the literature, this syndrome is still considered as relatively uncommon in patients after myocardial revascularization. However, in light of the greater number of LIMA grafts currently used and their long life expectancy its incidence may be higher than expected. In a retrospective study including 226 patients scheduled for CABG, 6 (3%) patients had significant left subclavian artery stenosis, which was successfully treated by angioplasty and stent placement in all cases before bypass surgery<sup>[9]</sup>. In our case the presence of subclavian artery stenosis was not investigated prior to CABG in our 2 cases. However, due to the long time duration between CABG and angina symptoms of the patient (A: 14 years, B: 9 years) it is more likely that subclavian stenosis developed after CABG. Thus, pre-CABG angiography would probably not have been helpful in our cases.

In the past years, significant technical developments have occurred with endovascular therapy, which offer several distinct advantages over open surgical revascularization techniques in selected lesions<sup>[10]</sup>. Although no head-to-head trials comparing interventional vs surgical treatment of the proximal subclavian artery stenosis are present so far, the effectiveness of percutaneous revascularization seems to be at least equivalent to surgery and that PCI and stent placement may be associated with fewer procedure-related serious complications<sup>[11]</sup>. In our patients subclavian (in both patients) and vertebral artery stenosis (in patient B) could be successfully treated by balloon angioplasty and stent placement. This caused restoration of the antegrade flow into the LIMA graft, resulting in resolution of anginal symptoms with patient A and restoration of the inducible wall motion abnormality by echocardiography in patient B. In patient A treatment of the subclavian artery stenosis may have been enough to restore antegrade perfusion of the LAD territory *via* the anatomically patent LIMA graft, without requiring PCI of the left main. However, PCI of the left main had already been performed in the initial session during diagnostic coronary angiography. Due to the fact that symptoms remained, we decided to perform stenting of the subclavian artery stenosis in a second session.

In patients with previous myocardial revascularization apart from CAD, great vessel disease resulting to coronary steal syndromes needs to be considered as a rare but important alternative diagnosis. In such cases, interventional treatment by angioplasty and stent placement may lead to complete resolution of symptoms and possible prevention of ischemic complications.

## COMMENTS

### Case characteristics

A 75- and 78-year-old male patient, both with known coronary artery disease, peripheral artery disease and prior coronary artery bypass graft who presented

with symptoms of myocardial ischemia.

### Clinical diagnosis

Peripheral artery disease with subclavian artery stenosis causing coronary steal syndrome.

### Differential diagnosis

Progression of coronary artery disease.

### Laboratory diagnosis

All labs were within normal limits.

### Imaging diagnosis

Peripheral artery disease was diagnosed in both patients by digital subtraction angiography.

### Pathological diagnosis

Coronary steal syndrome due to subclavian artery disease.

### Treatment

Percutaneous balloon angioplasty and stent placement in the left subclavian artery.

### Related reports

Coronary steal syndrome is a pathologic entity, which has been previously reported quite rarely so far in the current literature. This disease can sometimes be confused with coronary artery disease due to typical symptoms of myocardial ischemia in such patients.

### Term explanation

Coronary steal syndrome is a relatively rare condition, where subclavian artery stenosis causes myocardial ischemia due to reduced blood flow to the left internal mammary artery coronary graft after coronary artery bypass graft operation.

### Experiences and lessons

In patients with previous myocardial revascularization apart from coronary artery disease, great vessel disease resulting to coronary steal syndromes needs to be considered as a rare but important alternative diagnosis.

### Peer-review

The authors present 2 rare case reports of coronary subclavian steal syndrome after coronary artery bypass graft. The authors have demonstrated that interventional treatment may lead to complete resolution of symptoms and possible prevention of ischemic complications. This manuscript is nicely structured and well written.

### Abstract

A 56-year-old man experienced an aborted sudden death followed by an arrhythmic storm. Angiography revealed a non-severe lesion on the left circumflex artery that was treated medically but an arrhythmic storm recurred. A repeat angiogram was comparable but optical coherence tomography imaging revealed a ruptured plaque with intraluminal thrombosis. Percutaneous coronary intervention was performed and no arrhythmia recurred.

**Key words:** Optical coherence tomography; Arrhythmic storm; Sudden death

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** A 56-year-old man presented to a community hospital after an aborted sudden death. After initial resuscitation, he presented an arrhythmic storm with multiple episodes of ventricular fibrillation refractory to intravenous amiodarone. Coronary angiogram showed a nonobstructive intermediate lesion in the mid left circumflex artery. Because of repeated ventricular fibrillation episodes, an optical coherence tomography (OCT) was performed and revealed a ruptured thin-cap fibroatheroma with an intraluminal thrombosis at the level of the intermediate lesion. This case suggests that performing OCT to detect vulnerable culprit lesion of less than severe angiographic severity when an ischemic event is likely, such as an aborted sudden death or arrhythmic storm, may be of diagnostic value and alter therapeutic decisions.

Couture EL, Bérubé S, Daneault B. Optical coherence tomography to identify the cause of an arrhythmic storm: A case report. *World J Cardiol* 2017; 9(1): 71-75 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i1/71.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i1.71>

## INTRODUCTION

Triggers for arrhythmic storms are found in a minority of them. Careful assessment is required as some causes are reversible such as myocardial ischemia. We report the first case of an arrhythmic storm where the trigger was revealed by optical coherence tomography.

## CASE REPORT

A 56-year-old man known for smoking presented to a community hospital after an aborted sudden death. A witness immediately began cardiopulmonary resuscitation and the patient received 7 shocks from an automated external defibrillator prior to emergency arrival. Repeated electrocardiograms and a head CT-scan were normal. Five ventricular fibrillation (VF) episodes recurred and were treated with defibrillation and intravenous amiodarone. Given the refractory arrhythmia, the patient was transferred to our center to exclude myocardial ischemia.

Angiogram showed an intermediate lesion (50% stenosis) on the left circumflex artery (LCX) with a TIMI grade 3 flow (Figure 1A and B). The LCX lesion was therefore not judged as the culprit and he was admitted to the intensive care unit (ICU) with a plan to perform cardiovascular magnetic resonance after therapeutic hypothermia. Initial ICU laboratories revealed a hs-TnT of 732 ng/mL as well as normal electrolytes. A transthoracic echocardiogram demonstrated diffuse hypokinesis with a left ventricular ejection fraction of 35%. Within 24 h, 10 episodes of VF recurred and were treated with defibrillation and intravenous xylocaine. Between VF episodes, electrocardiogram transiently revealed inferior and posterior ST-elevation. Emergent angiogram was repeated and was unchanged from the day prior (Figure 1C). Optical coherence tomography (OCT) imaging study was performed in the LCX. OCT revealed a ruptured thin-cap lipid-rich plaque with intraluminal thrombosis (Figure 2). Minimal lumen area was 2.9 mm<sup>2</sup>. Because of the unstable characteristics of the plaque and clinical presentation, percutaneous coronary intervention (PCI) with a drug-eluting stent was performed (Figure 3B). Adequate stent expansion and strut apposition was confirmed by OCT (Figure 3A and C). After PCI, no arrhythmia recurred and the patient was discharged home 8 d after admission without neurological deficits and without an implantable cardioverter-defibrillator. Ten months later, he is asymptomatic with no recurrent cardiovascular event.

## DISCUSSION

Although coronary artery disease and especially acute coronary occlusion represent the most common cause of sudden cardiac arrest (SCD), diagnosis and treatment of the underlying mechanism remains a challenge<sup>[1]</sup>. In this case, because of the initial normal ECGs and the coronary angiogram showing a non-obstructive

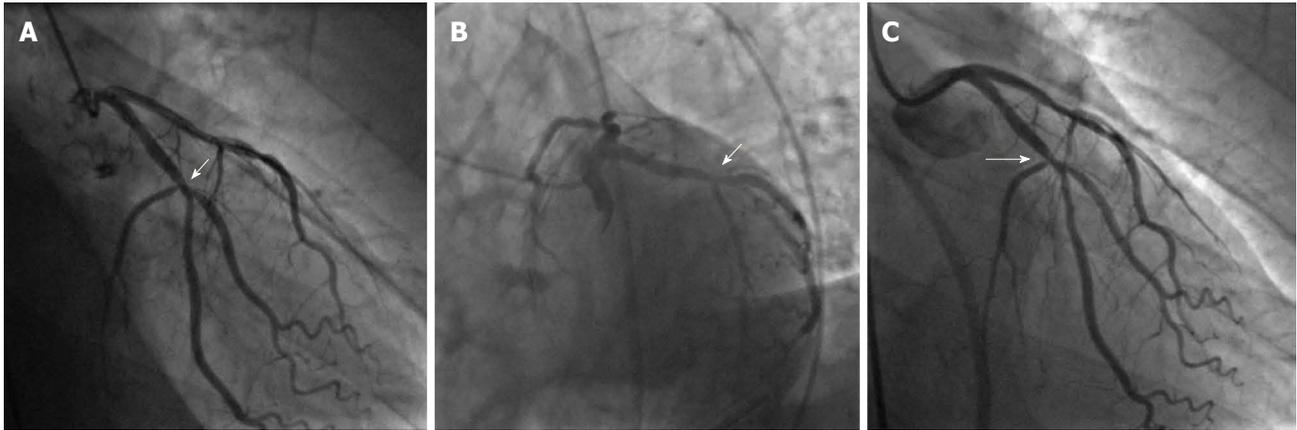

lesion, it was judged that this lesion did not cause active resting ischemia and therefore, was not the cause of the arrhythmia. Subsequent VF recurrences and transient ST-elevation in leads corresponding to the LCX prompted a repeat angiogram and the use of intravascular imaging. The unstable plaque characteristics revealed by OCT lead us to treat the lesion with PCI and the subsequent evolution proved that the arrhythmia's trigger had been effectively treated.

This case is interesting for a multitude of factors. It highlights the limitation of post-resuscitation ECG for the selection of patients who could benefit from immediate coronary angiography. When initial post-resuscitation ECGs do not demonstrate ST-segment elevation or presumably new left bundle branch block, it remains controversial to proceed to immediate coronary angiography. However, as demonstrated recently in SCD survivors, a culprit lesion (defined as > 90% coronary stenosis) was found in 19% of patients presenting with no ECG signs indicating myocardial ischemia<sup>[2]</sup>. In this case, transient ST-elevation was only documented once despite continuous ECG monitoring and 22 VF episodes.

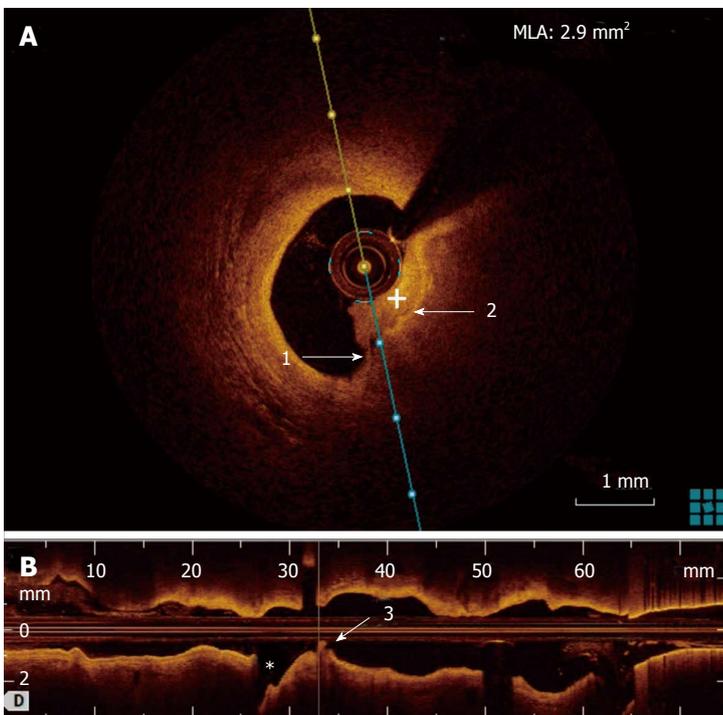

It also suggests that immediate angiography may have a central role in the management algorithm of SCD. Among initial survivors of SCD caused by VF or pulseless VT, it has been suggested that early coronary angiography was associated with higher rate of survival to discharge and favorable neurological outcome<sup>[3]</sup>. These observations are however retrospective and need to be validated in adequate trials.

Another important aspect of this case is the normal flow found in the culprit artery. In the PAMI trials, 16% of patients had TIMI 3 flow before PCI indicating spontaneous reperfusion<sup>[4]</sup>. Therefore, plaque rupture must be seen as a dynamic event as flow could be transiently occluded by thrombus with spontaneous fibrinolysis or by transient vasospasm. In this case, we supposed the arrhythmic storm was caused by multiple transient occlusive coronary spasms triggered by the plaque rupture. This phenomenon increases the difficulty in identifying ischemic causes of SCD and culprit lesion when ECGs are normal. This case demonstrated the additive value of OCT to further stratify intermediate non-obstructive lesion when an ischemic event is likely. Intravascular ultrasound (IVUS) also has been reported to reveal culprit lesion in SCD<sup>[5]</sup>. In a study of 12 survivors of SCD and high probability of coronary artery disease who underwent cardiac catheterization, 4 of them showed non-obstructive lesion a (< 50% stenosis and TIMI 3 flow) but all had intraluminal thrombosis revealed by intravascular ultrasound. However, none of the previous reports were accompanied by a such an arrhythmic storm<sup>[5,6]</sup>. Moreover, to rule out plaque rupture in survivors of SCD with non-obstructive intermediate lesion, OCT own a potential advantage over IVUS given its higher spatial resolution. Other modality such as near infrared spectroscopy could be of value in the future<sup>[7,8]</sup>.

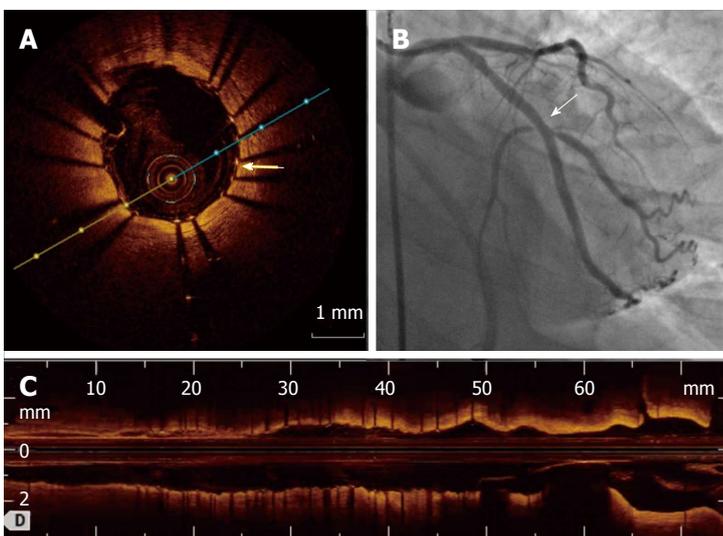

The optimal treatment of unstable plaque with

**Figure 1 Angiography images at presentation.** A, B: First angiogram. Arrows show a 50% lesion on the left circumflex artery with a TIMI grade 3 flow in the RAO/caudal view (A) and LAO/caudal view (B). After documentation of transmural ischemia and recurrence of the arrhythmic storm, the second angiogram revealed the same non-occlusive and intermediate lesion highlighted by the arrow in RAO/caudal view (C). RAO: Right anterior oblique; LAO: Left anterior oblique.

**Figure 2 Optical coherence tomography performed during the repeated angiogram.** A: OCT showing cross-section lumen reconstruction at the level of the plaque rupture. An intraluminal non-occlusive thrombus (+) is visualized. Arrow 1 shows rupture thin-cap fibroatheroma as visualized by the loss of continuity of the normal intima show by Arrow 2; B: OCT longitudinal lumen reconstruction at the mid left circumflex artery level. Arrow 3 highlights both plaque rupture and intraluminal thrombus be just before the bifurcation with the first marginal (asterisk). OCT: Optical coherence tomography.

**Figure 3 Angiogram and optical coherence tomography images after percutaneous coronary intervention.** A, C: OCT confirming stent expansion and apposition in the cross-sectional (A) and longitudinal (C) lumen reconstruction. Arrow in A highlights good strut apposition to the vessel wall and B is final angiogram. The arrow in B highlights the level of the previous stenosis and the percutaneous coronary intervention success. OCT: Optical coherence tomography.

adequate residual lumen area is however uncertain. Prior reports suggest that medical management could be adequate in these circumstances<sup>[9]</sup>. However, in our case, PCI clearly was of additional value to medical therapy. With the evolution of drug eluting stents and especially bioresorbable vascular scaffold, these technologies may impact the treatment of vulnerable lesions in the future. Large trials will be needed to evaluate the optimal diagnostic modalities and treatments for these unstable lesions.

In conclusion, this case suggests that performing OCT to detect vulnerable culprit lesion of less than severe angiographic severity when an ischemic event is likely, such as an aborted sudden death or arrhythmic storm, may be of diagnostic value and alter therapeutic decisions.

## COMMENTS

### Case characteristics

A 56-year-old man known for smoking presented to a community hospital after an aborted sudden death.

### Clinical diagnosis

Arrhythmic storm (ventricular fibrillation) episodes refractory to intravenous amiodarone.

### Differential diagnosis

Ischemic secondary to acute coronary syndrome, electrolytes abnormalities, primary cardiomyopathy.

### Laboratory diagnosis

Electrolytes were all normal at intensive care unit arrival, but hs-TnT was elevated.

### Imaging diagnosis

Coronary angiogram showed a nonobstructive intermediate lesion in the mid left circumflex artery. Optical coherence tomography (OCT) revealed ruptured thin-cap fibroatheroma with an intraluminal thrombus at the level of an angiographic intermediate lesion in the mid left circumflex artery.

### Pathological diagnosis

Acute coronary syndrome with a plaque rupture.

### Treatment

Percutaneous coronary intervention with a drug-eluting stent.

### Related reports

Very few cases of sudden death caused by a plaque rupture only detected with intravascular imaging have been described but never with a so dramatic presentation as in this case.

### Term explanation

OCT is an intravascular imaging modality that uses light to capture micrometer-resolution, three-dimensional images from within optical scattering media (e.g., coronary artery). Spatial resolution is between 2-10  $\mu\text{m}$  and its penetration varied between 1-10 mm.

### Experiences and lessons

This case suggests that performing optical coherence tomography to detect vulnerable culprit lesion of less than severe angiographic severity when an ischemic event is likely, such as an aborted sudden death or arrhythmic storm, may be of diagnostic value and alter therapeutic decisions.

## Peer-review

The paper is well written.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Gustav Steinhoff, MD, PhD, Director, Professor, Surgeon, Clinic and Policlinic of Cardiac Surgery, University Medicine Rostock, 18057 Rostock, Germany

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Hyperlipidemia is a well-established risk factor for developing cardiovascular disease (CVD). The recent

American College of Cardiology and American Heart Association guidelines on lipid management emphasize treatment of individuals at increased risk for developing CVD events with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) at doses proven to reduce CVD events. However, there are limited options for patients who are either intolerant to statin therapy, develop CVD despite being on maximally tolerated statin therapy, or have severe hypercholesterolemia. Recently the Food and Drug Administration approved two novel medications for low-density lipoprotein (LDL)-cholesterol reduction: Evolocumab and Alirocumab. These agents target and inactivate proprotein convertase subtilisin-kexin type 9 (PCSK9), a hepatic protease that attaches and internalizes LDL receptors into lysosomes hence promoting their destruction. By preventing LDL receptor destruction, LDL-C levels can be lowered 50%-60% above that achieved by statin therapy alone. This review explores PCSK-9 biology and the mechanisms available to alter it; clinical trials targeting PCSK9 activity, and the current state of clinically available inhibitors of PCSK9.

**Key words:** Hyperlipidemia; Statins; Proprotein convertase subtilisin-kexin type 9

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hyperlipidemia is a well-established risk factor for developing cardiovascular disease (CVD). However, there are limited options for patients who are either intolerant to statin therapy, develop CVD despite being on maximally tolerated statin therapy, or have severe hypercholesterolemia. The Food and Drug Administration has approved two novel medications for low-density lipoprotein (LDL)-cholesterol reduction in this patient population: Evolocumab and Alirocumab. These agents target and inactivate proprotein convertase subtilisin-kexin type 9 (PCSK9), a hepatic protease that attaches and internalizes LDL receptors into lysosomes hence promoting their destruction. By preventing LDL receptor destruction, LDL-C levels can be lowered 50%-60% above that achieved by statin therapy alone. PCSK9 inhibitors are

an exciting agent for reducing LDL-C and have ushered in a new era of lipid lowering therapy.

Chaudhary R, Garg J, Shah N, Sumner A. PCSK9 inhibitors: A new era of lipid lowering therapy. *World J Cardiol* 2017; 9(2): 76-91 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/76.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.76>

## INTRODUCTION

Hyperlipidemia is a well-established risk factor for developing cardiovascular disease (CVD)<sup>[1]</sup>. Multiple double blind placebo controlled trials have shown that treatment with HMG CoA Reductase inhibitors (statins) lowers low-density lipoprotein (LDL)-C levels and reduces CVD events in individuals with CVD or those at high risk for developing it<sup>[2,3]</sup>. However, CVD events continue to occur in some patients on statins, despite receiving maximal tolerated therapy. Other patients develop side effects from statins that limit their use. Hence, newer modalities of treatment to lower LDL-C are needed in clinical practice. Recently the Food and Drug Administration (FDA) approved two medications which target a novel pathway to reduce LDL-C. They are monoclonal antibodies that inactivate proprotein convertase subtilisin-kexin type 9 (PCSK9). This review will explore the biology of PCSK 9, clinical trials targeting PCSK9 activity, and the current state of clinically available inhibitors of PCSK9.

## LDL-CHOLESTEROL METABOLISM

LDL-C has been the target of therapy for improving outcomes in patients at high risk for developing CVD and has been considered a surrogate endpoint for clinical events by the FDA<sup>[1]</sup>. Reviewing LDL cholesterol metabolism is therefore important in understanding therapeutic approaches to treat hyperlipidemia.

The lipid cycle begins with the release of immature very low-density lipoprotein (VLDL) or nascent VLDL from the liver. Nascent VLDL contains apolipoprotein-B100 (apoB-100), apolipoprotein E (apoE), apolipoprotein C1 (apoC1), cholesteryl esters, cholesterol, and triglycerides. While circulating in blood, high-density lipoprotein (HDL) donates apolipoprotein C-II (apoC-II) to nascent VLDL that leads to its maturation. Mature VLDL interacts with lipoprotein lipase (LPL) in the capillary beds of adipose tissues, cardiac muscle and skeletal muscle cells, which leads to extraction of triglycerides from VLDL for storage or energy production in these tissues. VLDL combines with HDL again and an interchange occurs where apoC-II is transferred back to HDL along with phospholipids and triglycerides in exchange for cholesteryl esters *via* cholesteryl-ester-transfer protein (CETP). This exchange and removal of triglycerides leads to conversion of VLDL to intermediate-density lipoprotein (IDL)<sup>[4]</sup>. Half of IDLs are recognized and endocytosed by liver cells due to

apoB-100 and apoE. The remaining IDL lose apoE, and with an increased concentration of cholesterol compared to triglyceride, transform into low-density lipoproteins (LDL). LDL particles thus formed contain apoB-100, which acts as a ligand for binding to LDL receptors (LDLR). Once LDL binds to LDLR, LDL/LDLR complex is internalized by endocytosis into clathrin coated vesicles. In the cytosol, LDL and LDLR separate with recycling of LDLR to the cell surface. LDLR recycling is a continuous process and each receptor recycles up to 150 times after which they are endocytosed and metabolized<sup>[5]</sup>. Statins act by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which is involved in intracellular production of cholesterol. This lowers the levels of intracellular cholesterol leading to increased expression of LDLR on cell surfaces causing a reduction in serum LDL-cholesterol<sup>[6]</sup>.

Seidah and colleagues discovered that proprotein convertase subtilisin/kexin type 9 (PCSK9) regulates LDLR degradation and could potentially be a target for modulating LDLR expression and consequently LDL-C levels<sup>[7,8]</sup>. PCSK9 is a hepatic protease that attaches to and internalizes LDLR into lysosomes hence promoting their destruction<sup>[9]</sup>. Clinical studies have shown that PCSK9 gain of function mutation is associated with familial hypercholesterolemia and premature CVD<sup>[10,11]</sup>. Conversely, individuals with loss of function mutations in PCSK9 have been observed to have lower lifetime levels of LDL-C and lower prevalence of CVD<sup>[12,13]</sup>.

Since the discovery of PCSK9, results from preclinical mice studies demonstrated that sterol regulatory element binding protein-2 (SREBP-2) plays a key role in regulating cholesterol metabolism. Low level of intracellular cholesterol activates SREBP-2 and leads to LDLR gene expression. This increases LDLR concentration thus enhancing LDL clearance from circulation<sup>[8,14]</sup>. At the same time SREBP-2 also induces the expression of PCSK9, which promotes LDLR degradation. Thus, the coordinated interplay of SREBP-2 induced transcription of both LDLR and PCSK9 regulates circulating LDL levels<sup>[15,16]</sup>. These discoveries resulted in the exploration and development of therapeutic agents to lower LDL levels by targeting PCSK9 activity.

## FUNCTIONAL MECHANICS OF PCSK9

Hepatocytes are the predominant site for PCSK9 production, with other sites being intestines and kidneys<sup>[17,18]</sup>. PCSK9 reduces the number of LDLR in hepatocytes by promoting their metabolism and subsequent degradation<sup>[14]</sup>. PCSK9 has been shown to act both intracellularly (playing a role as a chaperone) as well as a secreted factor promoting LDLR internalization from the hepatocellular surface. Under normal circumstances, the LDL/LDLR complex is endocytosed by endosomes. The acidic pH of the endosome reduces the affinity of LDL for LDLR with rearrangement of the LDLR's extracellular domain into a hairpin structure, aiding in its recycling

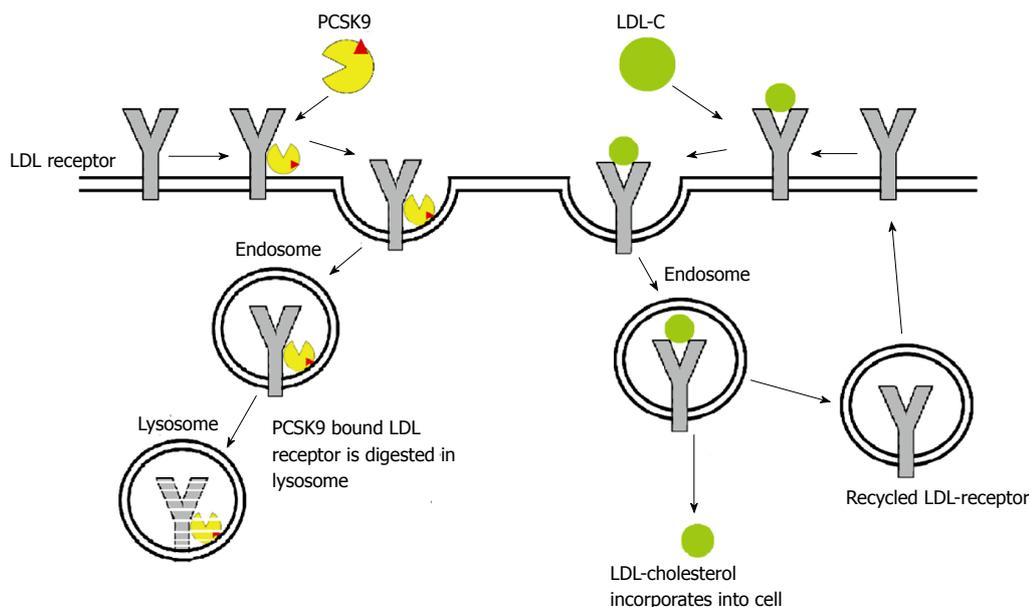

Figure 1 Mechanism and role of PCSK9 in low-density lipoprotein-cholesterol metabolism. LDL: Low-density lipoprotein.

back to plasma membrane. PCSK9 binding inhibits this change and locks the LDLR in an open conformation which prevents its recycling. The LDLR is then routed to lysosomes for degradation (Figure 1)<sup>[19,20]</sup>. The secreted form of PCSK9 circulates in the bloodstream and can be inactivated by cleavage from proprotein convertase. At a molecular level, the secretion of prodomain and catalytically inactive PCSK9 promotes regular degradation of LDLR implying that PCSK9 acts as a chaperone protein rather than an active catalytic enzyme<sup>[21,22]</sup>.

As described above, hepatic expression of PCSK9 and LDLR are closely regulated by SREBP-2 and intracellular levels of cholesterol<sup>[23,24]</sup>. Lipid lowering therapy with statins<sup>[25-27]</sup>, ezetimibe<sup>[28]</sup> and bile acid binding resins<sup>[29]</sup> cause induction of SREBP-2 and hence co-induces both PCSK9 and LDLR. The slight increase in PCSK9 activity seen with statins does not negate their therapeutic effectiveness.

## OTHER FUNCTIONS AND LOCATIONS OF PCSK9

Apart from hepatocytes, PCSK9 is also expressed in intestine, central nervous system, and mesenchymal cells of the kidney. *In vitro* studies on human intestinal epithelium have reported recombinant PCSK9 to enhance cholesterol uptake in the human intestinal epithelial cells (Caco-2/15 cell line) *via* the up regulation of the protein expression of NPC1L1 and CD36 (involved in cholesterol absorption in intestinal cells) along with an increased expression of cholesterol transporters<sup>[30,31]</sup> and reduced cholesterol synthesis (by reducing HMG-CoA reductase activity)<sup>[32]</sup>. PCSK9 has been shown to have a role in the metabolism of triglycerides and their accumulation in visceral adipose tissue<sup>[33]</sup>. It also promotes chylomicron secretion and helps regulate enterocyte cholesterol

balance<sup>[32]</sup>. Studies have evaluated PCSK9 and their association with increased susceptibility to hepatitis C viral infection. Labonté *et al.*<sup>[34]</sup> demonstrated a reduced expression of CD81 (CD81 is a co-receptor for Hepatitis C virus infection) by PCSK9 leading to protection against infection by hepatitis C. Therefore, PCSK9 inhibitors (Alirocumab) could increase CD81 expression resulting in greater infectivity. However, *in vitro* and *in vivo* studies in mice showed that PCSK9 did not reduce CD81 expression and had no effect on HCV infectivity. Hence, the literature remains inconclusive about this potential effect of PCSK9 inhibition<sup>[34]</sup>. Mbikay *et al.*<sup>[35]</sup> demonstrated that PCSK9 inhibition in mouse pancreatic islet  $\beta$  cells led to hypoinsulinemia, hyperglycemia and glucose-intolerance. Additionally the islet cells exhibited signs of malformation, apoptosis and inflammation. Current clinical data has failed to show this as a complication with PCSK9 inhibition.

## PCSK9 INHIBITION STRATEGIES

Preclinical studies demonstrate that statin-induced LDL reduction occurs through increased LDLR expression on hepatocytes along with increased LDL turnover, which leads to its enhanced clearance from the circulation. However, statins also induce PCSK9 expression, which dampens the effective LDL clearing by promoting LDLR degradation<sup>[23]</sup>. Since PCSK9 is expressed both intracellularly and in the circulation, multiple potential targets exist for its inhibition. Various modalities to inhibit PCSK9 have been studied including: (1) inhibition of production by gene silencing through antisense oligonucleotides<sup>[36]</sup> or small interfering RNA<sup>[37]</sup>; (2) prevention of PCSK9 binding to LDLR using monoclonal antibodies<sup>[38]</sup>, epidermal growth factor-like repeat A (EGF-A), mimetic peptides<sup>[39]</sup> or adnectins; and (3) inhibition of PCSK autocatalytic sites.

### Gene silencing via antisense oligonucleotides or small interfering RNA

This approach targets intracellular PCSK9 activity by utilizing antisense oligonucleotide to reduce intracellular expression of PCSK9. Preclinical trials on hyperlipidemic mice evaluating two such compounds were promising with a reduction in LDL by 38% at six weeks of therapy while doubling LDLR expression in the liver<sup>[38]</sup>. However, the phase I trials evaluating two of these agents were terminated prematurely and further development of the drug (BMS-84442) was not continued (NCT01082562). Two additional drugs: SPC5001 and SPC4061 showed successful reduction in LDL by 50% during preclinical testing in primates<sup>[40]</sup>. However, the first phase I trial in healthy human subjects and individuals with familial hypercholesterolemia were terminated early (NCT01350960)<sup>[41,42]</sup>. SPC5001 was seen to cause mild to moderate injection site reactions and renal tubular toxicity<sup>[43]</sup>. Further development of SPC4061 was discontinued for undisclosed reasons.

Similarly, small interfering RNA (siRNA) administration has been shown to significantly reduce plasma PCSK9 and LDL levels in cynomolgus monkeys<sup>[37,38,43]</sup>. ALN-PCS is a siRNA, which was tested by delivery through second-generation lipid nanoparticles. In a study by Fitzgerald *et al.*<sup>[44]</sup>, ALN-PCS demonstrated a dose dependent reduction in PCSK9 and LDL levels with a reduction of up to 70% in PCSK9 levels and 40% in LDL levels at doses of 0.4 mg/kg. This was the first study to demonstrate intracellular PCSK9 inhibition translated into reduction of circulating LDL levels.

### Monoclonal antibodies

Utilization of monoclonal antibodies has been the most effective approach thus far in inhibiting PCSK9 and reducing LDL levels. Currently, at least six monoclonal antibodies (mAb) have been or are being developed and tested: Alirocumab (formerly called SAR236553/REGN727), Evolocumab (formerly called AMG145), RG7652<sup>[45]</sup>, LGT209 (NCT01979601, NCT01859455), 1B20<sup>[46]</sup> and Bococizumab (formerly called RN316/PF-04950615). Alirocumab and Evolocumab have recently been approved by the FDA. The major clinical studies leading up to their approval are outlined later in this paper.

Bococizumab is a unique mAb, which utilizes pH sensitive binding to PCSK9 and was developed for a longer serum half-life and duration of action on LDL reduction<sup>[47]</sup>. In phase I studies, single intravenous or subcutaneous dosages significantly reduced LDL in patients with hypercholesterolemia, both with and without concomitant atorvastatin therapy<sup>[48]</sup>. In a phase II trial by Gumbiner *et al.*<sup>[48]</sup>, patients on statin therapy not at target LDL-C were enrolled and observed a 60% reduction in LDL-C after 12 wk of therapy. Five phase III trials are ongoing for Bococizumab including SPIRE-HF (evaluating the efficacy of this agent in heterozygous familial hypercholesterolemia NCT01968980); SPIRE-HR (NCT01968954) and SPIRE-LDL (NCT01968967) trials are comparing Bococizumab

to statin therapy in patients with high atherosclerotic cardiovascular risk with a follow up period of up to 12 wk. SPIRE-1 (NCT01975376) and 2 (NCT01975389) have a follow up period of up to 5 years collecting data on safety and efficacy of this drug<sup>[49]</sup>. Recently, the preliminary results of a study of Bococizumab delivery using an auto-injector device (SPIRE-AI) reported successfully meeting co-primary endpoints of percent change from baseline in fasting LDL-C at week 12 and the delivery system success rate, defined as the percent of patients whose attempts to operate the pre-filled pen. SPIRE-AI is a 12-wk, double-blind, placebo-controlled, randomized, parallel-group, multicenter, phase III clinical trial in 299 patients with hyperlipidemia or mixed dyslipidemia receiving statin therapy and whose LDL-C  $\geq 70$  mg/dL and assessed the efficacy, safety, tolerability and subcutaneous administration of Bococizumab 150 mg and 75 mg with a pre-filled pen<sup>[50]</sup>.

Along similar lines, adnectins (also known as monobody) and small peptide inhibitors have been investigated for LDL reduction in phase I clinical trials. The results in healthy patients and those with hypercholesterolemia demonstrated a maximal dose related reduction of LDL-C by up to 48%<sup>[51]</sup>. The advantage of developing adnectins is that they are smaller than mAb, making them cheaper and easier to produce. Their pharmacokinetics have been shown to be favorable with a rapid onset of action in preclinical models, further trials are awaited to see the development of this agent<sup>[52]</sup>.

### Inhibition of autocatalytic site

This mechanism as a therapeutic target was first proposed after discovering a loss of function mutation in the autocatalytic cleavage site of PCSK9<sup>[53,54]</sup>. This approach is still under preclinical investigational phase.

---

## FDA APPROVAL STATUS OF PCSK9 INHIBITORS

---

The FDA approved Alirocumab (Praluent) in July 2015 for adult patients with heterozygous familial hypercholesterolemia or in patients with clinically significant atherosclerotic CVD requiring additional LDL lowering after being on diet control and maximally tolerated statin therapy. Evolocumab (Repatha) was also approved in August, 2015 for use in adult patients with heterozygous familial hypercholesterolemia, homozygous familial hypercholesterolemia, or clinical atherosclerotic CVD requiring additional lowering of LDL cholesterol after being on a controlled diet and maximally-tolerated statin therapy.

### Alirocumab (status: FDA approved)

Alirocumab has been studied in three phase I trials. In two of these trials, healthy volunteers were administered Alirocumab intravenously ( $n = 40$ ) or subcutaneously ( $n = 32$ ) which reduced LDL-C in a dose-dependent fashion with a reduction of up to 65% at maximal doses<sup>[55]</sup>. The

third trial evaluated patients with non-familial hypercholesterolemia on atorvastatin and LDL > 100 mg/dL or with LDL > 130 mg/dL being managed by diet alone. Alirocumab reduced LDL-C up to 65% in patients on statins and up to 60% in patients being managed on diet alone. It was observed that Alirocumab remained effective for a longer period of time in patients not on statins<sup>[55]</sup>.

Three phase II trials<sup>[56-58]</sup> evaluated the efficacy of Alirocumab in patients with familial hypercholesterolemia. Stein *et al.*<sup>[58]</sup> evaluated 77 patients on statin therapy with LDL-C greater than 100 mg/dL and found that Alirocumab reduced LDL-C in a dose-dependent manner by up to 43% with a maximum dosage of 300 mg every 4 wk. However, the reduction was even greater (up to 70%) at a dosage regimen of 150 mg every 2 wk. Additionally, these patients had a significant reduction in apoB levels and non-high density lipoprotein cholesterol and also had increases in HDL. McKenney *et al.*<sup>[56]</sup>, in their study of 183 patients confirmed a dose dependent reduction of LDL-C with the most efficacious regimen being 150 mg every 2 wk (with LDL reduction up to 70%). Interestingly, different doses of atorvastatin did not make a significant difference in LDL-C reduction. These results were further corroborated by Roth *et al.*<sup>[57]</sup> in their study of 92 patients with LDL-C > 100 mg/dL. They showed that there was significant and comparable LDL reduction irrespective of the dosage of atorvastatin (10 mg vs 80 mg) when added to Alirocumab 150 mg every 2 wk<sup>[57]</sup>.

The phase III randomized, double-blinded ODYSSEY trials were designed to evaluate Alirocumab for long-term safety, efficacy and adverse events (Table 1) and include CHOICE I, CHOICE II, OLE, LONG TERM, COMBO I, COMBO II, FH I, FH II, HIGH FH, MONO, ALTERNATIVE, OPTIONS I and OPTIONS II. The dosage of Alirocumab administered was 150 mg every 2 wk in ODYSSEY LONG TERM and HIGH FH trials and 75 mg (titrated up to 150 mg to reach pre-specified LDL goals) in ODYSSEY ALTERNATIVE, OPTIONS I, OPTIONS II and COMBO I trials.

CHOICE I study evaluated Alirocumab vs placebo in 803 patients with poorly controlled hypercholesterolemia. Alirocumab reduced LDL by 52% in statin-naïve patients and by 59% in patients on maximally tolerated statins as compared to placebo ( $P < 0.001$ )<sup>[59]</sup>. Similarly, COMBO I and II trials evaluated 316 patients and 720 patients respectively with LDL > 70 mg/dL and high cardiovascular risk on maximally tolerated statin therapy. COMBO I showed Alirocumab reduced LDL-C up to 50% (vs 2% with placebo) after 24 wk of treatment. COMBO II compared ezetimibe to Alirocumab in patients on background statin therapy and found a 50% LDL reduction with Alirocumab vs 20% reduction with ezetimibe at 24 wk<sup>[60]</sup>. OPTIONS I trial<sup>[61]</sup> published in August 2015, randomized 355 patients with hypercholesterolemia and LDL > 70 and found the addition of Alirocumab to atorvastatin had the greatest reduction in LDL as compared to addition of ezetimibe, doubling atorvastatin

dose or switching to rosuvastatin. Atorvastatin at 20 mg and 40 mg/d regimens reduced LDL by 44% and 54% with addition of Alirocumab respectively vs 21% and 23% with addition of ezetimibe respectively vs 5% and 5% with doubling atorvastatin dose respectively compared to 21% with switching to rosuvastatin 40 mg/d. In the OPTIONS II trial, rosuvastatin was studied using a similar protocol and showed that the addition of Alirocumab had the most significant reduction in LDL-C after 24 wk of therapy as opposed to addition of ezetimibe or doubling the dose of rosuvastatin<sup>[62,63]</sup>. Another study evaluating the efficacy of Alirocumab as monotherapy (MONO study)<sup>[64]</sup> compared to ezetimibe in patients with hypercholesterolemia and moderate cardiovascular risk to monotherapy with Alirocumab and found that Alirocumab reduced LDL-C 47% vs 16% by ezetimibe after 24 wk of therapy ( $P < 0.0001$ ).

CHOICE II study evaluated Alirocumab in patients intolerant to statin therapy. Two hundred and thirty one patients with a history of statin intolerance were shown to have a 56% reduction in LDL with Alirocumab (vs placebo;  $P < 0.001$ )<sup>[59]</sup>. Another study evaluating Alirocumab in patients intolerant to statin therapy is the ODYSSEY ALTERNATIVE trial. Three hundred and fourteen patients completed this randomized controlled trial, which compared Alirocumab 75 mg every 2 wk ( $n = 126$ ) to ezetimibe 10 mg/d ( $n = 125$ ) and atorvastatin 20 mg/d ( $n = 63$ ) for 24 wk. At 24 wk, the data showed a 45% reduction in LDL with Alirocumab as opposed to 15% reduction in LDL with ezetimibe. This trial demonstrated fewer skeletal muscle adverse events in the Alirocumab group as compared to atorvastatin arm [32.5% vs 46% respectively, HR = 0.61 (0.38-0.99;  $P = 0.042$ )], with no significant difference when compared to the ezetimibe group (41%) [HR 0.71 (0.47 to 1.06;  $P = 0.09$ )]<sup>[65]</sup>.

Alirocumab has also been shown to be effective in lowering LDL-C in patients with familial hypercholesterolemia. The FH I and FH II studies evaluated a total of 735 patients ( $n = 486$  and 249 respectively) with heterozygous familial hypercholesterolemia inadequately controlled on lipid lowering therapy and found Alirocumab to reduce LDL levels 48.8% (vs a 9.1% increase in placebo: FH I study) and 48.7% (vs 2.8% increase in LDL with placebo: FH II study) from baseline<sup>[66]</sup>. ODYSSEY HIGH FH trial reported 105 patients with familial hypercholesterolemia on maximally tolerated statin therapy and LDL > 160 demonstrating a 46% reduction of LDL (vs 7% with placebo) at 24 wk ( $P < 0.001$ )<sup>[67]</sup>. OLE trial (NCT01954394) is currently ongoing with results anticipated by June 2017. This trial is recruiting patients with heterozygous familial hypercholesterolemia who have completed one of the other studies and evaluating for safety parameters including adverse events, laboratory data and vital signs.

ODYSSEY LONG TERM trial was recently published and is a 78-wk follow-up of 2341 patients with hypercholesterolemia and LDL > 70 mg/dL on maximally tolerated statins. The patients receiving 150 mg Alirocumab every 2 wk were shown to have a 62% reduction

Table 1 Summary of phase III ODYSSEY trials with Alirocumab

Name of trial	Ref. Allocation and blinding	No. of patients	Inclusion criteria	Study arms (with dosing)	Primary end point	Results
LONG TERM (NCT01507831)	Seidah <i>et al</i> <sup>[7]</sup> ; Randomized double blinded trial	2341	Either 1 or 2 below and who aren't adequately controlled with their LLT: (1) Patients with heFH with or without CHD or CHD risk equivalents OR (2) Patients with HCL with CHD or CHD risk equivalents	Alirocumab (SC) ( <i>n</i> = 1553) vs Placebo (SC) ( <i>n</i> = 788) both with background LLT	Percentage change in calculated LDL cholesterol level from baseline to week 24	-61.0% change with Alirocumab vs +0.8% change with placebo (CI: -64.3 to -59.4; <i>P</i> < 0.001)
FH I (NCT01623115)	Kastelein <i>et al</i> <sup>[66]</sup> ; Randomized double blinded	486	Patients with heterozygous familial hypercholesterolemia who are not adequately controlled with their lipid-modifying therapy	Alirocumab (SC) vs Placebo (SC) both with background LLT	Percent change in calculated LDL-C at week 24	-48.8% for Alirocumab compared with 9.1% for placebo ( <i>P</i> < 0.0001)
FH II (NCT01709500)	Kastelein <i>et al</i> <sup>[66]</sup> ; Randomized double blinded	249	Patients with heFH who are not adequately controlled with their LLT	Alirocumab (SC) vs Placebo (SC) both with background LLT	Percent change in LDL-C to week 24	-48.7% for Alirocumab compared with 2.8% for placebo ( <i>P</i> < 0.0001)
HIGH FH (NCT01617655)	Kastelein <i>et al</i> <sup>[67]</sup> ; Randomized double blinded	107	Patients with heterozygous familial hypercholesterolemia who are not adequately controlled with their lipid-modifying therapy with LDL > 160	Alirocumab (SC) ( <i>n</i> = 72) vs Placebo (SC) ( <i>n</i> = 35) both with background LLT	Percent change in calculated LDL-C at week 24	Percent decrease from baseline was 45.7% vs 6.6%, difference 39.1, <i>P</i> < 0.0001 Absolute difference in values of LDL-C at 24 wk 107 mg/dL vs 182 mg/dL
COMBO I (NCT01644175)	Colhoun <i>et al</i> <sup>[60]</sup> ; Randomized double blinded	316	Patients with hypercholesterolemia and establ CHD or CHD risk equivalents; not controlled with a maximally tolerated LLT, both at stable dose for at least 4 to 6 wk prior to screening	Alirocumab (SC) ( <i>n</i> = 205) vs Placebo (SC) ( <i>n</i> = 106)	Percent change in calculated LDL-C at week 24	-48.2% with Alirocumab (CI: -52.0% to -44.4%) and -2.3% with placebo (CI: -7.6% to 3.1%) for Alirocumab and placebo, respectively, an estimated mean difference of -45.9% (CI: -52.5% to -39.3%) ( <i>P</i> < 0.0001)
COMBO II (NCT01644188)	Moriarty <i>et al</i> <sup>[65]</sup> ; Randomized double blind	720	Patients with hypercholesterolemia and established CHD or CHD risk equivalents who are not adequately controlled with a maximally tolerated daily dose of statin at stable dose for at least 4 wk prior to the screening visit	Alirocumab (SC) + placebo (for ezetimibe) orally + background statin therapy ( <i>n</i> = 467) vs Placebo (SC) + ezetimibe orally + Background statin therapy ( <i>n</i> = 240)	Percent change in calculated LDL-C at week 24	Reductions in LDL-C from baseline were 50.6% ± 1.4% for Alirocumab vs 20.7% ± 1.9% for ezetimibe (difference 29.8% ± 2.3%; <i>P</i> < 0.0001)
OPTIONS I (NCT01730053)	Robinson <i>et al</i> <sup>[63]</sup> ; Randomized double-blinded	355	Patients with prior CV disease + LDL-C ≥ 70 mg/dL, or CV risk factors + LDL-C ≥ 100 mg/dL	Alirocumab with atorvastatin 20 mg vs Ezetimibe with atorvastatin 20 mg vs Atorvastatin 40 mg Alirocumab with atorvastatin 40 mg vs ezetimibe with atorvastatin 40 mg vs atorvastatin 80 mg vs rosuvastatin 20 mg	Percent change in calculated LDL-C to week 24	Percent reduction from baseline 44.1% (Alirocumab) vs 20.5% (ezetimibe) vs 5.0% (atorvastatin 40); <i>P</i> < 0.0001  Percent reduction from baseline 54% (Alirocumab) vs 22.6% (Ezetimibe) vs 4.8% (Atorvastatin 80) vs 21.4% (rosuvastatin 40); <i>P</i> < 0.0001

OPTIONS II	Robinson <i>et al</i> <sup>[63]</sup> ; Randomized double-blinded	305	Patients with prior CV disease + LDL-C $\geq$ 70 mg/dL, or CV risk factors + LDL-C $\geq$ 100 mg/dL	Alirocumab with rosuvastatin 10 mg vs ezetimibe with rosuvastatin 10 vs rosuvastatin 20 Alirocumab with rosuvastatin 20 mg vs ezetimibe with rosuvastatin 20 vs Rosuvastatin 40	Percent change in calculated LDL-C to wk 24	Percent reduction from baseline 50.6% (Alirocumab) vs 14.4% (ezetimibe) vs 16.3% (rosuvastatin 20); $P < 0.0001$
ALTERNATIVE (NCT01709513)	Moriarty <i>et al</i> <sup>[65]</sup> ; Randomized double-blinded	314	Primary heFH with moderate, high or very high CV risk and history of statin intolerance	Alirocumab + oral placebo vs ezetimibe (10 mg/d) + sc placebo vs atorvastatin (20 mg/d) + sc placebo	Percent change in calculated LDL-C to week 24 in intention to treat group	Percent reduction from baseline 45% (Alirocumab) vs 14.6% (Ezetimibe) with a mean difference of -30.4%; $P < 0.0001$
CHOICE I (NCT01926782)	Stroes <i>et al</i> <sup>[78]</sup> ; Randomized, double-blinded	803	Patients not having adequate control of their hypercholesterolemia based on their individual level of CVD risk	Alirocumab at q4 week regimen vs Placebo	Percent change in LDL from baseline to week 24 for Alirocumab q4w vs placebo in patients with hypercholesterolemia at moderate, high, or very high CVD risk with concomitant statin therapy ( $n = 547$ ) Percent change in LDL from baseline to week 24 for Alirocumab q4w vs placebo in patients with hypercholesterolemia not on concomitant statin therapy ( $n = 256$ )	LDL was reduced by 58.7% with Alirocumab in patients on maximally tolerated statins ( $P < 0.001$ ) LDL was reduced by 52.4% with Alirocumab in statin naïve patients vs placebo ( $P < 0.001$ )
CHOICE II (NCT02023879)	Stroes <i>et al</i> <sup>[78]</sup> ; Randomized, double-blinded	231	Patients with primary hypercholesterolemia (heFH or non-FH) not adequately controlled with their non statin lipid modifying therapy or diet and statin intolerance	Alirocumab (SC) vs placebo (SC)	The percent change in LDL-C from baseline to week 24	Alirocumab reduced LDL-C by 56.4% ( $P < 0.0001$ ) vs placebo
LONG TERM (NCT01507831)	Robinson <i>et al</i> <sup>[62]</sup> ; Randomized, double-blinded	2341	Either A or B below and who are not adequately controlled with their LLT: (1) Patients with heFH with or without established CHD or CHD risk equivalents OR (2) Patients with hypercholesterolemia together with established CHD or CHD risk equivalents	Alirocumab (SC) 150 mg every 2 wk vs placebo (SC) every 2 wk	Percentage change in calculated LDL cholesterol level from baseline to week 24, analyzed with the use of an intention-to-treat approach	150 mg Alirocumab every 2 wk had a 62% reduction in LDL as opposed to a 1% increase in LDL with placebo at 24 wk

SC: Subcutaneous; LLT: Lipid lowering therapy; heFH: Heterozygous familial hypercholesterolemia; CHD: Coronary heart disease; HCL: Hypercholesterolemia; MACE: Major adverse cardiovascular events; MI: Myocardial infarction; UA: Unstable angina; HR: Hazards ratio; CI: Confidence interval.

in LDL as opposed to a 1% increase in LDL with placebo at 24 wk. These results persisted at 78 wk. In a post-

hoc analysis, the reduction in LDL was also associated with reduction in the combined end-point of death from coronary artery disease, nonfatal myocardial infarction, fatal or nonfatal ischemic stroke or unstable angina requiring hospitalization (1.7% with Alirocumab vs 3.3% with placebo; HR = 0.52; 95%CI: 0.31-0.9;  $P = 0.02$ )<sup>[68]</sup>. The ODYSSEY Outcomes trial (NCT01663402) is ongoing is closed to recruitment, and will assess the effects of Alirocumab on CVD events in 18000 patients on maximally tolerated statin therapy. Results of this trial are expected in February 2018.

### **Evolocumab (status: FDA approved)**

Evolocumab has been studied in two phase I studies. Dias *et al*<sup>[69]</sup> evaluated healthy volunteers in phase I a and showed a short-term dose-dependent reduction in LDL by up to 65% and after 6 to 8 wk of therapy by up to 75% with a maximally administered dose of 420 mg subcutaneously/intravenously. Phase I b trial similarly demonstrated up to 75% reduction in LDL as compared to placebo over 1 to 4 wk in healthy volunteers.

Four phase II trials were subsequently performed that continued to show the benefits of Evolocumab with a dose-dependent reduction of LDL (maximal dosing up to 420 mg) when added to maximally tolerated statin therapy in patients with hypercholesterolemia (including familial hypercholesterolemia)<sup>[70-72]</sup>. In LAPLACE-TIMI57 trial<sup>[70]</sup>, Evolocumab was tested at varying doses ranging from 70 to 140 mg every 2 wk or 280 to 420 mg every 4 wk in 631 patients on stable statin therapy and LDL more than 85 mg/dL. LDL reduction up to 65% was observed with the every two-week regimen as compared to approximately 50% LDL reduction with the every 4-wk regimen. Evolocumab has also been studied as monotherapy in 160 patients with hypercholesterolemia and intolerance to statins in the GAUSS trial<sup>[73]</sup>. At doses of 420 mg every 4 wk, it was shown to reduce LDL by 40% to 50%. Furthermore, addition of ezetimibe reduced LDL by up to 65%. Subsequently, the MENDEL trial<sup>[71]</sup> showed a similar efficacy in LDL-C lowering when Evolocumab was used as monotherapy in 406 patients with hypercholesterolemia. Based on these trials, the optimal frequency of Evolocumab therapy was determined to be twice monthly to achieve a 50% to 60% reduction in LDL in combination with statins. However, when used as a monotherapy therapy, a frequency of once every 4 wk would be acceptable. Stein *et al*<sup>[74]</sup> evaluated 8 patients with homozygous familial hypercholesterolemia, and found Evolocumab (at 420 mg every 2 wk) to reduce LDL by approximately 25% vs 20% when used every 4 wk.

Evolocumab has further been evaluated in PROFICIO (Program to reduce LDL-C and cardiovascular outcomes following inhibition of PCSK9 in different populations) phase III trials (Table 2). The PROFICIO program includes 14 trials where Evolocumab is being evaluated in patients with hyperlipidemia in combination with statins (LAPLACE-2 and YUKAWA-2); hyperlipidemic

patients intolerant to statins (GAUSS-2 and GAUSS-3); standalone in hyperlipidemia (MENDEL-2); heterozygous familial hypercholesterolemia (RUTHERFORD-2 and TAUSSIG); homozygous familial hypercholesterolemia (TESLA and TAUSSIG); with primary hyperlipidemia or mixed cholesterol disorder (THOMAS-1 and THOMAS-2: Device trials). Also, long-term safety and efficacy data is being evaluated by the five following studies: DESCARTES; FOURIER; OSLER-2 trial; GLAGOV trial and TAUSSIG study.

In LAPLACE-2 study 1896 patients with fasting LDL  $\geq 150$  (when not on statins) or LDL  $\geq 100$  (on non-intensive regimen of statins) or LDL  $\geq 70$  (on intensive statin therapy) were randomized to a daily moderate or high-intensity statin regimen and after 4 wk, further randomized to receive Evolocumab, ezetimibe or placebo. Evolocumab was shown to reduce LDL levels by 66% to 75% (on every 2 wk regimen) and by 63% to 75% (on once monthly regimen) when compared to placebo in moderate- and high intensity statin groups. In moderate and high intensity statin groups, Evolocumab led to significant reduction in absolute LDL values in both regimens of Evolocumab (every 2 wk and monthly). Adverse events reported were comparable in all groups<sup>[75]</sup>. YUKAWA-2 study showed a similar reduction in LDL in 404 Japanese patients when Evolocumab regimens (140 mg once every 2 wk and 420 mg once a month) were compared to placebo on 2 regimens of low-dose background statin therapy (5 mg/d and 20 mg/d atorvastatin). Interestingly, the reduction in LDL appeared to be similar irrespective of statin dosage (in combination with Evolocumab) and showed a 67% to 76% LDL reduction at 12 wk<sup>[76]</sup>. MENDEL-2 trial compared the efficacy of Evolocumab with ezetimibe and placebo in 614 patients with LDL between 100 mg/dL and 190 mg/dL and low risk on Framingham scale ( $\leq 10\%$ ). Evolocumab was shown to reduce LDL by up to 57% more than placebo and 40% more than ezetimibe after 12 wk of therapy<sup>[77]</sup>.

GAUSS-2 trial evaluated 307 patients with statin intolerance and compared the 2 regimens of Evolocumab (140 mg once every 2 wk and 420 mg once a month) to daily oral or subcutaneous placebo (both placebo groups on ezetimibe). At 12 wk, Evolocumab group showed a reduction in LDL by 56% vs 39% in the other groups (placebo + ezetimibe arm)<sup>[78]</sup>. Along similar lines, GAUSS-3 trial evaluated the efficacy of Evolocumab in 218 statin intolerant patients compared to ezetimibe. The initial phase of the study included administration of atorvastatin (20 mg) for 10 wk and placebo randomized in a 1:1 fashion, followed by a 2-wk washout period and crossover to alternate therapy for another 10 wk. The patients who experienced muscle related adverse effects while on statin therapy and not on placebo were further enrolled in the second phase of the study, which was a 24 wk double blinded randomized controlled trial to compare Evolocumab (420 mg/mo divided in 3 doses) with ezetimibe (10 mg/d). At 24 wk, LDL-C was

**Table 2 Summary of important phase III PROFICIO (Program to Reduce LDL-C and Cardiovascular Outcomes Following Inhibition of PCSK9 In Different Populations) trials with Evolocumab**

Name of trial	Ref. Allocation and blinding	No. of patients	Inclusion criteria	Study arms (with dosing)	Primary end point	Results
LAPLACE-2 (NCT01763866)	Robinson <i>et al</i> <sup>[75]</sup> ; Randomized double blinded trial	1896	Individuals with LDL > 150 mg/dL (not on statin); or LDL > 100 mg/dL (on non-intensive statin); or LDL ≥ 80 mg/dL (with intensive statin therapy)	Initially randomized to daily moderate or high intensity atorvastatin for 4 wk. Patients were again randomized to Evolocumab (sc) <i>vs</i> ezetimibe <i>vs</i> placebo	Percentage change in calculated LDL cholesterol level from baseline to week 12	Evolocumab q2w and qmonthly: 63% to 75% reduction in LDL <i>vs</i> placebo Ezetimibe 19% to 32% reduction in LDL <i>vs</i> placebo
YUKAWA-2 (NCT01953328)	Kiyosue <i>et al</i> <sup>[76]</sup> ; Randomized double blinded	404	Japanese patients with LDL > 70 on stable dose statins for > 4 wk and high cardiovascular risk	Initially randomized to daily atorvastatin of 5 mg or 20 mg for 4 wk. They were further randomized to Evolocumab (sc) at q2 week and qmonthly <i>vs</i> placebo	Percent change in calculated LDL-C from baseline at week 12	-67.0% to -76% reduction with Evolocumab compared to placebo ( <i>P</i> < 0.0001)
GAUSS-2 (NCT01763905)	Stroes <i>et al</i> <sup>[78]</sup> ; Randomized double blinded	307	Patients with LDL not at goal according to their cardiovascular risk and not on statin or low dose statin due to history of statin intolerance (> 2 statins) with stable LLT > 4 wk	Evolocumab (SC) at q2 week and qmonthly dosing <i>vs</i> Placebo (SC) + Ezetimibe (10 mg/d) daily	Percent change in LDL-C from baseline at the mean of weeks 10 and 12 and at week 12 Change from baseline LDL at week 12	-55.3% to -56.1% for Evolocumab compared with -16.6% to -19.2% for ezetimibe ( <i>P</i> < 0.0001) -103.6 to -105.4 (Evolocumab) <i>vs</i> -33 to -39 (mg/dL)
MENDEL-2 (NCT01763827)	Koren <i>et al</i> <sup>[77]</sup> ; Randomized double-blinded	614	NCEP ATP III Framingham risk score of < 10% Fasting LDL-C ≥ 100 mg/dL and < 190 mg/dL	Oral placebo to SC placebo; ezetimibe to SC placebo and oral placebo to SC Evolocumab at dosing regimens of 140 mg biweekly and 420 mg monthly	Percent change from baseline in LDL-C level averaged at weeks 10 and 12 Percent change from baseline in LDL-C level at week 12	Percent LDL change from baseline averaged at weeks 10 and 12 in the: Once per 2 wk arm: -56.9% (with Evolocumab) <i>vs</i> -17.5 (with ezetimibe) <i>vs</i> -0.4% (placebo) For monthly arm: -58.8% (with evolocumab) <i>vs</i> -19.1 (with ezetimibe) <i>vs</i> -1.4% (placebo) Percent LDL change from baseline averaged at weeks 12: Once per 2 wk arm: -57% (with Evolocumab) <i>vs</i> -17.8 (with ezetimibe) <i>vs</i> 0.1% (placebo) For monthly arm: -56.1% (with Evolocumab) <i>vs</i> -18.6 (with ezetimibe) <i>vs</i> -1.3% (placebo)
RUTHERFORD-2 (NCT01763918)	Raal <i>et al</i> <sup>[72]</sup> ; Randomized double blinded	329	Patients with heterozygous familial hypercholesterolemia who are on stable LLT for 4 wk and LDL > 100 mg/dL	Evolocumab (SC) at 140 mg q2 weeks <i>vs</i> placebo SC q2w AND Evolocumab SC qmonthly <i>vs</i> Placebo (SC)	Percent change from baseline in LDL-C level averaged at weeks 10 and 12 Percent change from baseline in LDL-C level at week 12	Percent LDL change from baseline averaged at weeks 12 in the: Once per 2 wk arm: -61.2% (with Evolocumab) <i>vs</i> -1.1% (with placebo) For monthly arm: -63.3% (with evolocumab) <i>vs</i> 2.3% (with placebo) Percent LDL change from baseline averaged at weeks 10 and 12 in the: Once per 2 wk arm: -61.3% (with Evolocumab) <i>vs</i> -2% (with placebo) For monthly arm: -55.7% (with Evolocumab) <i>vs</i> 5.5% (with placebo)

TESLA (NCT01588496)	Raal <i>et al</i> <sup>[82]</sup> ; Randomized double-blinded	50	Homozygous familial hypercholesterolemia, on stable lipid-regulating therapy for at least 4 wk, LDL cholesterol $\geq$ 130 mg/dL (3.4 mmol/L); Triglyceride $\leq$ 400 mg/dL (4.5 mmol/L); Body weight of $\geq$ 40 kg at screening, and not receiving lipoprotein apheresis	Evolocumab (SC) 420 mg every 4 wk vs placebo (SC)	Percentage change in ultracentrifugation LDL cholesterol from baseline at week 12 compared with placebo, analyzed by intention-to-treat Percent change from baseline in LDL-C at week 52	Evolocumab significantly reduced ultracentrifugation LDL cholesterol at 12 wk by 30.9% (95%CI: -43.9% to -18.0%; $P < 0.0001$ ) vs placebo
DESCARTES (NCT01516879)	Blom <i>et al</i> <sup>[80]</sup> ; Randomized, double-blinded	901	Fasting LDL $\geq$ 75 mg/dL and meeting the following on background LLT: (1) $<$ 100 mg/dL for subjects with diagnosed CHD or CHD risk equivalent; (2) $<$ 130 mg/dL for subjects without diagnosed CHD or CHD risk equivalent; (3) on maximal background LLT defined as atorvastatin 80 mg PO QD and ezetimibe 10 mg PO QD Fasting triglycerides $\leq$ 400 mg/dL	Evolocumab (SC) 420 mg every 4 wk with diet alone vs placebo with diet Evolocumab (SC) 420 mg every 4 wk with diet + atorvastatin 10 mg/d vs placebo with diet and atorvastatin 10 mg/d Evolocumab (SC) 420 mg every 4 wk + atorvastatin 80 mg/d vs placebo + atorvastatin 80 mg/d Evolocumab (SC) 420 mg every 4 wk + atorvastatin 80 mg/d + ezetimibe 10 mg/d vs placebo + atorvastatin 80 mg/d + ezetimibe 10 mg/d	Addition of Evolocumab resulted in LDL reduction by: (1) 51% to 60% in diet alone group; (2) 59% to 64% in patients on 10 mg atorvastatin (3) 51% to 62% in patients on 80 mg atorvastatin (4) 43% to 54% in patients with atorvastatin 80 mg/d and ezetimibe 10 mg/d ( $P < 0.001$ for all)	

SC: Subcutaneous; LLT: Lipid lowering therapy; heFH: Heterozygous familial hypercholesterolemia; CHD: Coronary heart disease; HCL: Hypercholesterolemia; MACE: Major adverse Cardiovascular Events; MI: Myocardial infarction; UA: Unstable angina; HR: Hazards ratio; CI: Confidence interval.

reduced by 53% with Evolocumab compared to 17% with ezetimibe. Muscle-related side effects were reported in 21% patients on Evolocumab compared to 29% with ezetimibe with stoppage of drug administration due to muscle symptoms in 1% of patients in Evolocumab and 7% of patients on ezetimibe<sup>[79]</sup>.

DESCARTES trial<sup>[80]</sup> evaluated 901 patients with hyperlipidemia, comparing Evolocumab (420 mg once a month subcutaneous) plus background lipid lowering therapy vs placebo plus background lipid lowering therapy for a period of 52 wk. Background lipid lowering therapy included: Diet alone, low intensity atorvastatin (10 mg), high intensity atorvastatin (80 mg) or atorvastatin 80 mg/d. All patients had fasting LDL-C  $>$  75 mg/dL on background lipid lowering therapy. Addition of Evolocumab resulted in LDL reduction by 51% to 60% in diet alone group, 59% to 64% in patients on 10 mg atorvastatin, 51% to 62% in patients on 80 mg atorvastatin and 43% to 54% in patients with atorvastatin 80 mg/d and ezetimibe 10 mg/d ( $P < 0.001$  for all).

Evolocumab has also been shown to be efficacious in patients with heterozygous and homozygous familial hypercholesterolemia. In the RUTHERFORD-2 trial, 329 patients with heterozygous familial hypercholesterolemia were randomized to receive Evolocumab (140 and 420 mg respectively) or placebo at two weekly and monthly regimens. Evolocumab showed a significant reduction

in LDL with both regimens: 140 mg every 2 wk led to 59.2% reduction (CI: 53.4% to 65.1%) and 420 mg once a month led to LDL reduction by 61.3% (CI: 53.6% to 69%) as compared to placebo after 12 wk ( $P < 0.001$  for all)<sup>[81]</sup>. The TESLA trial examined 50 patients with homozygous familial hypercholesterolemia on stable lipid lowering therapy and evaluated monthly Evolocumab (420 mg) vs placebo therapy for 12 wk. Addition of Evolocumab led to a significant reduction in LDL-C by up to 31% (CI: -44% to -18%;  $P < 0.0001$ )<sup>[82]</sup>.

In the Open-Label Study of Long-Term Evaluation Against LDL-C (OSLER) 1 and 2 trials 4465 patients were enrolled who had completed 1 of the phase 2 or phase 3 studies of Evolocumab (MENDEL-1, LAPLACE TIMI 57, GAUSS-1, RUTHERFORD-1, YUKAWA-1, MENDEL-2, LAPLACE-2, GAUSS-2, RUTHERFORD-2, DESCARTES, THOMAS-1 or THOMAS-2) and randomized to receive either Evolocumab (420 mg/mo in OSLER-1 and 140 mg every 2 wk or 420 mg once a month in OSLER-2 trial) plus standard therapy ( $n = 2976$ ) or standard therapy ( $n = 1489$ ). The median follow-up was 11.1 mo. This study showed a 61% reduction in LDL-C with Evolocumab compared to standard therapy (95%CI: 59% to 63%;  $P < 0.001$ ). Overall adverse events were in 69% of patients in Evolocumab group compared to 65% in standard therapy group. Of note, the neurocognitive adverse events were low, but were more frequent in Evolocumab group and appeared

to be unrelated to LDL level at the time of treatment. Composite adverse cardiovascular events (all-cause death, coronary events including myocardial infarction, unstable angina requiring hospitalization, or coronary revascularization, cerebrovascular events including stroke or transient ischemic attack, and heart failure requiring hospitalization) were significantly lower in patients with Evolocumab compared to standard therapy (HR = 0.47; 95%CI: 0.28 to 0.78;  $P = 0.003$ )<sup>[83,84]</sup>.

The TAUSSIG trial (NCT01624142) is evaluating Evolocumab therapy in 300 patients with severe familial hypercholesterolemia to determine its efficacy and side effect profile. The results of this study are anticipated by March 2020. Preliminary results reported by Stein *et al.*<sup>[74]</sup> on 8 patients with LDLR-negative or LDLR defective homozygous familial hypercholesterolemia on stable drug therapy when treated with Evolocumab at 420 mg monthly for  $\geq 12$  wk, followed by 420 mg every 2 wk for another 12 wk showed LDL reduction by 14% to 16% at 12 wk with 2 wk and 4 wk dosing regimens respectively with no serious adverse events reported<sup>[75]</sup>. Finally, the preliminary results of GLAGOV study (NCT01813422) evaluating 950 patients with coronary artery disease on lipid lowering therapy undergoing cardiac catheterization for changes in percentage atheroma volume after 78 wk of Evolocumab therapy met primary and secondary endpoints and final results are to be reported in American Heart Association (AHA) conference in November, 2016.

## PHARMACOKINETICS AND PHARMACODYNAMICS

The pharmacokinetic and pharmacodynamics parameters of PCSK9 inhibitors are described below<sup>[85,86]</sup>.

### **Alirocumab**

The time taken to reach maximum serum concentration is 3-7 d with similar serum concentration - time profiles between abdomen, upper arm or thigh as the sites of injection. Steady state concentrations are reached at an average of 3 to 4 doses. The volume of distribution following intravenous administration is 0.04 to 0.05 L/kg. The median half-life ( $t_{1/2}$ ) observed was between 17 to 20 d at 75 or 150 mg dosing every 2 wk. Alirocumab is eliminated in two phases depending upon its plasma concentration. The predominant mode of elimination at lower concentrations is *via* saturation of the targets (PCSK9) bound to the antibodies; however, at higher concentrations it is primarily through proteolytic pathways<sup>[81]</sup>. There have been no metabolism studies conducted since it has been previously demonstrated that reticuloendothelial system is responsible for metabolizing antibodies to small peptides and amino acids<sup>[87]</sup>. The maximum reduction in free plasma PCSK9 levels and LDL was observed within 3 and 15 d respectively, after drug administration with no difference noted between different sites. No dose adjustment is needed for patients with mild or moderately impaired renal or hepatic function.

No data are available in patients with severe renal and hepatic impairment.

### **Evolocumab**

The pharmacokinetic and pharmacodynamics properties of Evolocumab<sup>[83]</sup> demonstrate non-linear pharmacokinetics in absorption at doses below 140 mg; however, between doses of 140 to 420 mg linear pharmacokinetics is observed. The time to reach maximum concentration is 3 to 4 d after a single dose. After a single 420 mg dosage, its volume of distribution has been estimated to be 3.3 L  $\pm$  0.5 L. A steady state in serum is observed after about 12 wk of dosing. The  $t_{1/2}$  of Evolocumab is between 11 to 17 d. The maximum reduction of LDL after therapy was similar after dosing of 140 mg every 2 wk or 420 mg once a month with effect within 14 d. Clinical studies have not revealed a difference in pharmacokinetics of Evolocumab in mild or moderate renal and hepatic impairment. However, subjects with severe renal and hepatic impairment have not been studied.

## ADVERSE EFFECTS AND CONTRAINDICATIONS

The following side effects have been reported by data gathered from over 7000 patients ( $n = 2476$  for Alirocumab and  $n = 5416$  for Evolocumab) evaluated in the clinical trials mentioned above. Major side effects observed for Alirocumab and Evolocumab are described below.

### **Alirocumab**

Alirocumab is contraindicated in patients who develop serious hypersensitivity reactions like hypersensitivity vasculitis or allergic reactions requiring hospitalization with its usage. The most common adverse effects observed with Alirocumab include nasopharyngitis (11.3% vs 11.1% in placebo), injection site reactions (erythema, itchiness, swelling, pain or tenderness) (7.2% vs 5.1% in placebo), influenza (5.7% vs 4.6% in placebo), urinary tract infection (4.8% vs 4.6% in placebo), diarrhea (4.7% vs 4.4% in placebo), bronchitis (4.3% vs 3.8% in placebo), myalgia (4.2% vs 3.4% in placebo), muscle spasms (3.1% vs 2.4% in placebo), sinusitis (3% vs 2.7% in placebo), cough (2.5% vs 2.3% in placebo), contusion (2.1% vs 1.3% in placebo) and musculoskeletal pain (2.1% vs 1.6% in placebo). The most common adverse events that lead to drug discontinuation were allergic reactions (0.6% for Alirocumab vs 0.2% for placebo) and elevated liver enzymes (0.3% in Alirocumab vs < 0.1% in placebo).

### **Evolocumab**

Contraindications for Evolocumab are similar to Alirocumab. The overall incidence of adverse effects with Evolocumab 140 mg every 2 wk as compared to placebo were 43.6% vs 41% respectively. The most common adverse effects were nasopharyngitis (5.9% vs 4.8% in placebo), upper respiratory tract infection (3.2% vs 2.7%

in placebo), back pain (3% vs 2.7% in placebo) and nausea (2.1% vs 1.8% in placebo). Of note the most common adverse events leading to drug discontinuation include myalgia, nausea and dizziness. Other serious adverse events noted were cardiac disorders in 2.4% individuals including palpitations (0.6% vs 0.3% in placebo), angina pectoris (0.3% vs 0.2% in placebo), and ventricular extra systoles (0.3% vs 0.1% in placebo).

In addition, data from trials evaluating Evolocumab and Alirocumab have shown a higher incidence of cognitive adverse events in patients treated with PCSK9 inhibitors (0.9% vs 0.3% for Evolocumab compared to standard care<sup>[83]</sup> and 1.2% vs 0.5% for Alirocumab compared to placebo<sup>[69]</sup>). It has been suggested that responder and ascertainment bias might have played a role in reporting of adverse cognitive events in the OSLER trial since the adverse events were not related to the degree of LDL-C lowering with no clustering in the LDL-C < 25 mg/dL group relative to the 25-50 mg/dL or > 50 mg/dL groups<sup>[88]</sup>. However, patients in ODYSSEY LONG TERM trial were blinded to treatment and followed for nearly 18 mo. Also, the neurocognitive adverse events were measured subjectively and not verified by neurocognitive testing. A dedicated study evaluating neurocognitive adverse events with PCSK9 inhibitors is underway: Evaluating PCSK9 Binding anti-Body Influence on Cognitive Health in High Cardiovascular Risk Subjects (EBBINGHAUS) (NCT02207634). It is enrolling individuals without dementia or mild cognitive impairment at baseline randomized in a double-blind, placebo-controlled fashion to evaluate Evolocumab on background statin therapy vs statin therapy alone. The primary outcome being measured is Spatial Working Memory test; an assessment of executive function and the results are expected in September 2017.

Another potential and significant complication with drugs that are monoclonal antibodies is the development of anti-drug antibodies that may interfere with clinical efficacy and increase adverse events<sup>[89]</sup>. This complication has not been reported in the trials to date using PCSK9 inhibitors.

## CLINICAL USE OF PCSK9 INHIBITORS

The 2013 American College of Cardiology/American Heart Association recommendations on cholesterol management centered on identifying patients who would have a reduction in CVD events with statin treatment. The focus shifted from treating to a specific LDL-C level, to treating at risk individuals with a treatment (statin) proven to reduce future CVD events. Subsequently, the IMPROVE-IT trial demonstrated that addition of ezetimibe to simvastatin lowers LDL-C more than that achieved by simvastatin alone and that this reduction in LDL-C was associated with a greater reduction in CVD events compared with simvastatin alone<sup>[86,90]</sup>. This study raises the issue of LDL-C treatment targets with a lower level of LDL-C corresponding to a lower risk of CVD events. The introduction of PCSK9 inhibitors will necessitate re-evaluation of existing cholesterol treatment recom-

mendations.

PCSK9 inhibitors are especially beneficial in the treatment of familial hypercholesterolemic patients who are intolerant to statins or have an elevated LDL-C level despite being on maximally tolerated statin therapy. Intuitively, addition of a PCSK9 inhibitor to low dose statin therapy will be more effective in lowering LDL and avoiding the side effects of statins, since low dose and high dose statin regimens have yielded similar efficacy when combined with PCSK9 inhibitors.

Several potential barriers exist that may impede the widespread use of these medicines. First, statins have a proven effectiveness that has been demonstrated in multiple long-term studies. Statins have been shown to reduce cardiovascular mortality by 30% and incidence of stroke by 20% in multiple long-term studies<sup>[91,92]</sup>. PCSK9 inhibitors are effective in reducing LDL-C levels but currently lack data demonstrating their use reduces CVD events. Trials evaluating the effect of PCSK9 inhibitors on long-term CVD events, however, are currently underway: FOURIER (Further cardiovascular outcomes research with PCSK9 inhibition in subjects with elevated risk;  $n = 22500$ ) for Evolocumab (NCT01764633) and ODYSSEY-OUTCOMES (ODYSSEY outcomes: Evaluation of cardiovascular outcomes after an acute coronary syndrome during treatment with alirocumab SAR236553) (NCT01663402) for Alirocumab. However, their data will not be available until December 2017 (for Alirocumab) and February 2018 (for Evolocumab).

Another potential barrier to widespread use of PCSK9 inhibitors is their cost. The Institute for Clinical and Economic Review (ICER) reported that the number needed to treat for 5 years to avoid one major adverse cardiovascular event (NNT5) is 28. However, a list price of \$ 14350 per year generates a cost-effectiveness ratio which far exceeds the accepted threshold of \$ 100000/quality-adjusted life-years<sup>[93]</sup>. To achieve cost-effectiveness at this threshold would require a price reduction by 60% to 65% of the current price. At the conclusion of their report, the ICER suggested a reduction by 85% to an annual cost of \$2177 might be required to avoid excessive cost burdens to the health care system<sup>[94]</sup>. It should be noted that since there are limited data on clinical adverse cardiovascular events, cost effectiveness data might change once results from ongoing CVD endpoint studies are available.

PCSK9 therapy is a welcome treatment option for statin intolerant patients who require treatment of their hyperlipidemia. It will be important that busy practitioners do not under-prescribe statins nor be dissuaded from attempting to find a dose of and statin agent that is tolerated by the patient because PCSK9 inhibitors are available. Despite these obstacles, PCSK9 inhibitors are an exciting agent for reducing LDL-C hyperlipidemia and have ushered in a new era of lipid lowering therapy.

### Abstract

Coronary artery disease (CAD) is a leading cause of death and disability worldwide. Cardiovascular magnetic

resonance (CMR) is established in clinical practice guidelines with a growing evidence base supporting its use to aid the diagnosis and management of patients with suspected or established CAD. CMR is a multi-parametric imaging modality that yields high spatial resolution images that can be acquired in any plane for the assessment of global and regional cardiac function, myocardial perfusion and viability, tissue characterisation and coronary artery anatomy, all within a single study protocol and without exposure to ionising radiation. Advances in technology and acquisition techniques continue to progress the utility of CMR across a wide spectrum of cardiovascular disease, and the publication of large scale clinical trials continues to strengthen the role of CMR in daily cardiology practice. This article aims to review current practice and explore the future directions of multi-parametric CMR imaging in the investigation of stable CAD.

## INTRODUCTION

Coronary artery disease (CAD) is a leading cause of death and disability worldwide<sup>[1]</sup>. Despite major advances in the treatment of CAD resulting in significantly decreased mortality rates, CAD remains the single most common cause of death in the European Union, leading to 19% of deaths in men and 20% of deaths in women<sup>[2]</sup>; in the United States, CAD causes 1 in every 7 deaths, accounting for 370213 deaths in 2013<sup>[3]</sup>. The economic health burden of CAD is substantial with an estimated cost of CAD management at €60 billion in the European Union<sup>[4]</sup>, and \$182 billion in the United States<sup>[3]</sup>. Cardiovascular medicine benefits from a myriad of diagnostic methods that can guide intervention and clinical decision-making. Invasive coronary X-ray angiography delineates coronary anatomy in patients presenting with stable chest pain, however there is a low yield of obstructive CAD in those referred, and there are associated risks, albeit low, from major complications and ionising radiation<sup>[5]</sup>. Furthermore unless measurement of fractional flow reserve (FFR) is performed, routine coronary angiography does not give information on ischaemia burden, which according to current guidelines, is required to guide revascularisation decisions. Non-invasive functional imaging modalities such as single-photon emission computed tomography (SPECT), dobutamine stress echocardiography (DSE), cardiovascular magnetic resonance (CMR) or positron emission tomography (PET) are used to diagnose CAD, guide clinical decision making and confer prognostic information and consequently are well established for these roles in clinical practice guidelines<sup>[6,7]</sup>.

CMR is a unique multi-parametric imaging modality producing high spatial resolution images that can be acquired in any plane for the assessment of global and regional cardiac function, myocardial perfusion and viability, tissue characterisation and proximal coronary artery anatomy, all within a single study and without exposure to ionising radiation (Figure 1). Historically, long scanning times, limited scanner availability and narrow bore sizes restricted the use of CMR, but these issues have been largely resolved, such that CMR has become a first line investigation for suspected stable angina in many centres in the United Kingdom and Europe. Consequently CMR is part of international clinical practice guidelines for the assessment of known and unknown stable CAD and for the identification of those who may benefit from revascularisation<sup>[6-9]</sup>. This review aims to focus on the current utility of CMR for the diagnosis of suspected stable CAD and potential future developments and applications of CMR in this role.

## CMR IN STABLE CAD

A CMR protocol for the investigation of stable CAD will typically take between 30-60 min and involves the acquisition of cine images in multiple planes for the assessment of left ventricular function and volumes, stress and rest myocardial perfusion imaging and late gadolinium enhancement (LGE) imaging for the assessment of myocardial viability and scar quantification (Figure 2).

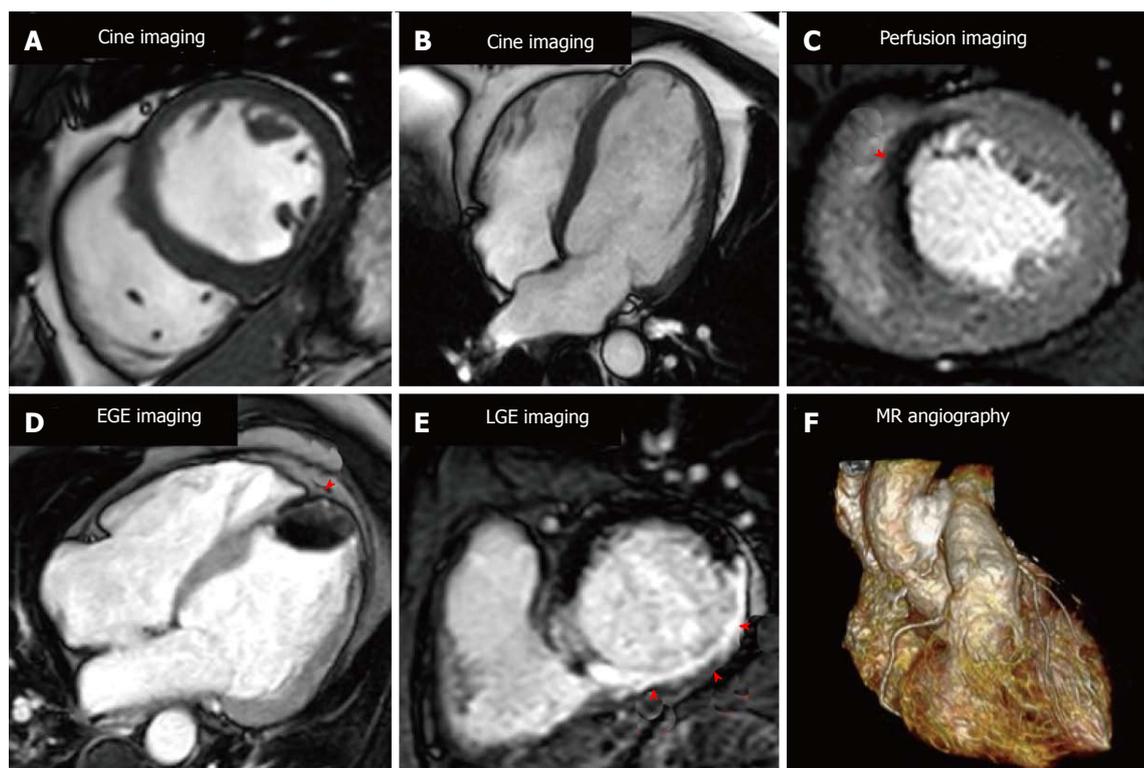

CMR is the reference standard non-invasive technique for the measurement of left ventricular (LV) and right ventricular (RV) volumes, and ejection fraction, with high intra- and inter-observer reproducibility<sup>[10,11]</sup>. Steady state free precession cine imaging is typically performed for the assessment of LV function to enable visual assessment of global and regional myocardial function in a similar manner to echocardiography; however there are no limitations due to poor acoustic windows or large body habitus degrading image quality. CMR volumetric analysis is performed by acquiring a stack of contiguous breath held cine images from the base of the heart to the apex; the endocardial and epicardial borders are subsequently contoured giving mass, volumes and function. Thus CMR provides a true 3D analysis of LV and RV function unlike 2D echocardiography that relies on geometric assumptions for volumetric calculations. Furthermore specific myocardial tagging pulse sequences can be performed that enable more detailed assessment of intra-myocardial mechanics beyond ejection fraction, including torsion, twist, strain and strain rates<sup>[12]</sup>. Additionally, feature tracking is a novel post-processing method of quantitatively assessing strain and strain rate using standard cine images without having to acquire further imaging sequences as is the case with standard CMR tissue tagging<sup>[12,13]</sup>.

## DIAGNOSIS OF CAD

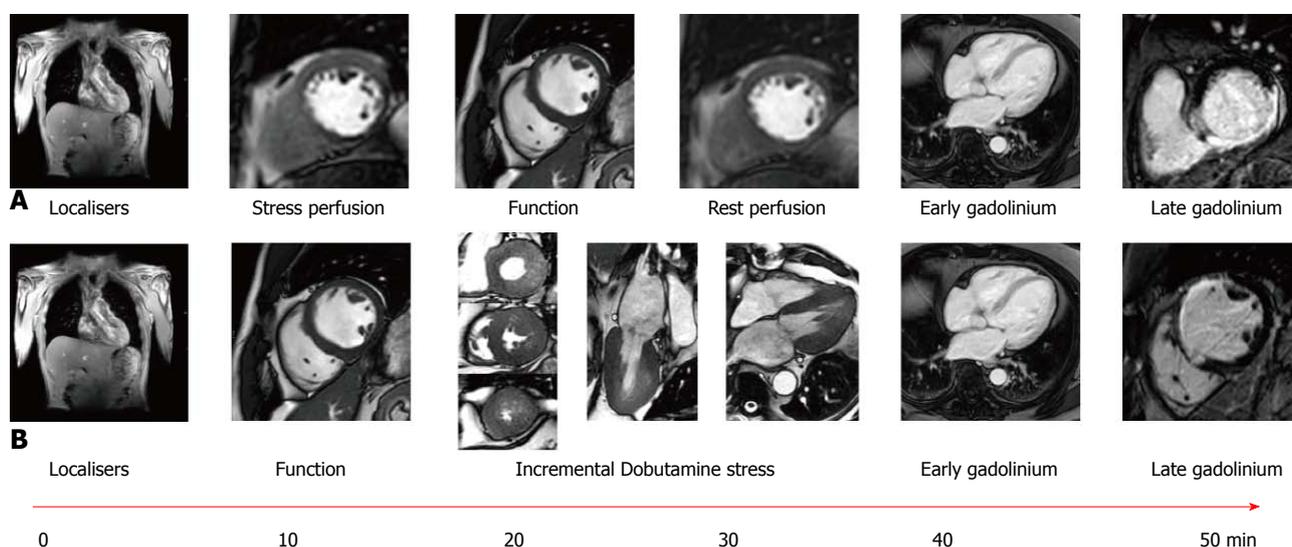

Ischaemia detection by CMR is performed using either vasodilator or inotropic stress. Ischaemia detection by CMR is recommended as a first line strategy for investigating suspected angina in patients with an intermediate pre-test likelihood of CAD in both the current European Society of Cardiology (ESC) and National Institute for Health and Care Excellence (NICE) guidelines (Table 1)<sup>[6,14]</sup>, whilst the United States guidelines are more conservative and give a grade IIa recommendation for stress perfusion CMR in patients with uninterpretable ECGs or unable to exercise<sup>[7]</sup>.

## STRESS PERFUSION CMR

Stress perfusion CMR requires the induction of hyperaemia by a vasodilating agent, and then observation of the passage of a gadolinium based contrast agent (GBCA) through the myocardium to identify perfusion defects. Typically the vasodilating agent used is adenosine though regadenoson and less commonly dipyridamole and nicorandil are also

**Figure 1 Cardiovascular magnetic resonance imaging techniques.** A and B show short axis and 4 chamber cine images respectively for anatomical and functional assessment; C shows stress perfusion with a septal perfusion defect (arrow); D shows early gadolinium enhancement imaging with a large apical thrombus (arrow); E is late gadolinium enhanced imaging with a transmural inferior infarction (arrows); F is 3D whole heart magnetic resonance angiography. LGE: Late gadolinium enhancement; EGE: Early gadolinium enhancement.

**Figure 2 Cardiovascular magnetic resonance multi-parametric protocols for the investigation of suspected coronary artery disease.** A shows a typical multi-parametric cardiovascular magnetic resonance protocol for the investigation of stable coronary artery disease with adenosine stress perfusion; and B with incremental dose dobutamine stress.

used. Adenosine produces vasodilatation in most vascular beds, including the coronary circulation, *via* A2A and A2B receptors<sup>[15]</sup>. Adenosine is given as an intravenous infusion typically at a rate of 140 mcg/kg per minute, though this can be increased if there is no haemodynamic response; the main side effects of adenosine are transient heart block, and bronchospasm can be caused in those with reversible

airways disease<sup>[15]</sup>. Regadenoson is a new selective A2A adenosine receptor agonist that is given *via* an intravenous bolus, has less respiratory side effects than adenosine, and has recently been approved by both the FDA and in Europe for this indication<sup>[16,17]</sup>. The coronary micro-vasculature can dilate up to 4 or 5 times from the resting state to ensure adequate tissue perfusion for example during exercise.

**Table 1** European Society of Cardiology and American College of Cardiology Foundation/American Heart Association Recommendations for cardiovascular magnetic resonance in stable coronary artery disease

ESC guidelines	
Suspected/stable coronary artery disease <sup>[6]</sup>	
In patients with suspected stable coronary artery disease and pretest probability of 15%-85% stress imaging is preferred as the initial test option if local expertise and availability permit	Class I
An imaging stress test is recommended in patients with resting ECG abnormalities, which prevent accurate interpretation of ECG changes during stress	Class I
CMR should be considered in symptomatic patients with prior revascularisation (PCI or CABG)	Class II a
Risk stratification is recommended based on clinical assessment and the results of the stress test initially employed for making a diagnosis of stable coronary artery disease	Class I
CMR is recommended in the presence of recurrent or new symptoms once instability has been ruled out	Class I
In symptomatic patients with revascularised stable coronary artery disease, CMR is indicated rather than stress ECG	Class I
CMR is recommended for risk stratification in patients with known stable coronary artery disease and a deterioration in symptoms if the site and extent of ischemia would influence clinical decision making	Class I
Recommendations for imaging to determine ischemia to plan revascularisation <sup>[6,144]</sup>	
An imaging stress test should be considered to assess the functional severity of intermediate lesions on coronary arteriography	Class II a
To achieve a prognostic benefit by revascularisation in patients with coronary artery disease, ischemia has to be documented by non-invasive imaging	Class I
Following MI with multivessel disease, or in whom revascularisation of other vessels is considered, CMR for ischaemia and viability is indicated before or after discharge	Class I
Heart failure <sup>[8]</sup>	
CMR should be considered in patients with HF thought to have CAD, and who are considered suitable for coronary revascularization, to determine whether there is reversible myocardial ischaemia and viable myocardium	Class II a
AHA guidelines	
Diagnosis and management of stable coronary artery disease <sup>[7]</sup>	
CMR can be used for patients with an intermediate (10%-90%) to high (> 90%) pretest probability of obstructive IHD who have an uninterpretable ECG and at least moderate physical functioning or no disabling comorbidity	Class II a
CMR is reasonable for patients with an intermediate to high pretest probability of IHD who are incapable of at least moderate physical functioning or have disabling comorbidity	Class II a
Pharmacological stress CMR is reasonable for risk assessment in patients with SIHD who are unable to exercise to an adequate workload regardless of interpretability of ECG	Class II a
CMR is reasonable in patients with known SIHD who have new or worsening symptoms (not unstable) and who are incapable of at least moderate physical functioning or have disabling comorbidity	Class II a

ESC: European Society of Cardiology; CMR: Cardiovascular magnetic resonance; ECG: Electrocardiogram; CABG: Coronary artery bypass graft; PCI: Percutaneous coronary intervention; AHA: American Heart Association; IHD: Ischemic heart disease; SIHD: Stable ischemic heart disease.

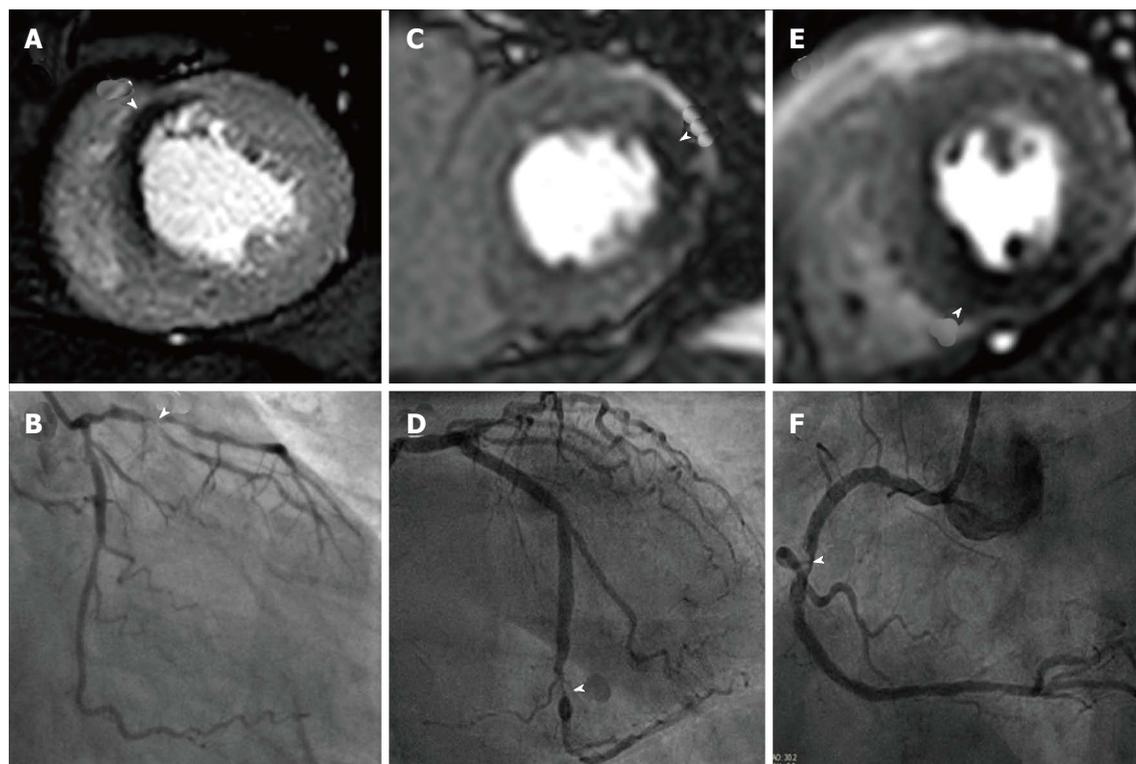

However the microvasculature distal to a stenosed coronary artery is already near-maximally vasodilated at rest and consequently when hyperaemia is provoked a coronary steal effect is caused. GBCAs increase the signal intensity in T1 weighted images and the passage of GBCAs through the myocardium causes healthy myocardium to become brighter while regions of hypoperfusion ("ischaemia") remain dark (Figure 3).

The diagnostic accuracy of stress perfusion CMR for the detection of CAD is well validated. A meta-analysis of 37 studies demonstrated a combined sensitivity of 89% (95%CI: 88%-91%) and specificity of 76% (95%CI: 73%-78%) for perfusion CMR for the diagnosis of CAD<sup>[18]</sup>. The CE-MARC study ( $n = 752$ ), the largest prospective randomised single-centre trial of CMR in this context showed superiority of perfusion CMR over SPECT, with a higher sensitivity (87% vs 67%,  $P < 0.0001$ ) and negative predictive value (91% vs 79%,  $P < 0.0001$ ) but similar specificity (83% vs 83%  $P = 0.916$ ) and positive predictive values (77% vs 71%,  $P = 0.061$ )<sup>[19,20]</sup>. Furthermore in a pre-specified gender sub analysis of CE-MARC, CMR showed similar sensitivity for CAD detection in both males and females, whilst SPECT had significantly lower sensitivity in females compared to males<sup>[21]</sup>.

The multi-centre, multi-vendor MR-IMPACT II trial

( $n = 515$ ) also confirmed CMR's superior sensitivity compared to SPECT (67% vs 59%,  $P = 0.024$ ) but with a lower specificity (61% vs 72%,  $P = 0.038$ )<sup>[22]</sup>; however unlike CE-MARC only the stress/rest perfusion component of the CMR protocol was analysed. CE-MARC included analysis of LGE for scar detection, cine imaging for regional ventricular function and magnetic resonance angiography (MRA) for coronary artery anatomy, and a subsequent sub-analysis of CE-MARC demonstrated the additive diagnostic accuracy of the summation of these components of the multi-parametric protocol<sup>[23]</sup>.

Stress perfusion CMR has also been validated against FFR in a recent meta-analysis with a pooled sensitivity and specificity of 0.90 (95%CI: 0.86-0.93) and 0.87 (95%CI: 0.82-0.90) at the patient level and 0.89 (95%CI: 0.83-0.92) and 0.86 (95%CI: 0.77-0.92) at the coronary artery and territory levels<sup>[24]</sup>. Furthermore CMR stress perfusion had comparable sensitivity and specificity to cardiac CT and PET in a recent meta-analysis of non-invasive imaging modalities, and was superior to both SPECT and DSE when using FFR as the reference standard<sup>[25]</sup>. Most trials thus far have excluded patients with arrhythmia amid concerns regarding ECG gating, however the diagnostic accuracy of stress perfusion CMR remains high in suspected CAD patients with AF or

**Figure 3 Cardiovascular magnetic resonance perfusion techniques.** A is a high spatial resolution *k-t* BLAST stress perfusion CMR study at 3.0T showing an antero-septal perfusion defect with corresponding left anterior descending lesion in B; C shows a transmural lateral perfusion defect at standard resolution at 1.5T with corresponding circumflex lesion in D; E shows a transmural inferior perfusion defect at standard resolution at 1.5T with corresponding right coronary artery lesion in F. BLAST: Broad-use linear acquisition speed-up technique; CMR: Cardiovascular magnetic resonance.

frequent ectopy (sensitivity 80%, specificity 74%)<sup>[26]</sup>.

### 1.5T VS 3.0T FIELD STRENGTH

Although 1.5T remains the standard field strength used in clinical CMR, imaging at a higher field strength of 3.0T offers increased signal to noise and contrast to noise ratios thereby giving improved spatial and temporal enhancement<sup>[27]</sup>. Consequently the diagnostic accuracy of perfusion imaging at 3.0T may be improved, and in a small direct comparison of CMR perfusion at 1.5T, 3.0T ( $n = 61$ ) showed greater diagnostic accuracy in both single vessel (AUC: 0.89 vs 0.70;  $P < 0.05$ ) and multi-vessel disease (AUC: 0.95 vs 0.82,  $P < 0.05$ )<sup>[28]</sup>. Furthermore, 3.0T has been compared to 1.5T using FFR as reference standard, corroborating its superior diagnostic accuracy<sup>[29,30]</sup>. The higher 3.0T field strength does however pose challenges with greater field inhomogeneity, susceptibility artefacts and higher local energy deposition. Also, many implants deemed "MR compatible" at 1.5T cannot be scanned at 3.0T<sup>[31]</sup>. These issues are however being overcome with improved technology and the use of multi-transmit radiofrequency CMR techniques improving field homogeneity<sup>[32]</sup>.

### IMPROVING PERFUSION IMAGING

Currently typical CMR perfusion imaging acquires 3 short axis slices of the left ventricle with an in-plane spatial

resolution of 2-3 mm. Developments in CMR technology however now allow faster scan speeds; these novel acquisition techniques allow accelerated data acquisition based on spatio-temporal undersampling (*k-t* SENSE or *k-t* BLAST and highly constrained back projection HYPR, compressed sensing and others)<sup>[33]</sup>. These faster data acquisition techniques have been applied to achieve in-plane spatial resolution  $< 2$  mm or full-coverage of the LV using 3D whole-heart perfusion imaging. High spatial-resolution imaging offers benefits by significantly reducing dark rim artefacts, as these are directly proportional to voxel size<sup>[34]</sup>. Moreover there is improved ability to detect sub-endocardial ischaemia which is critical in multi-vessel disease where there is a lack of reference healthy myocardium for comparison<sup>[35,36]</sup>. High spatial-resolution perfusion CMR has been validated at both 1.5T and 3.0T against quantitative coronary angiography (QCA) with improved diagnostic accuracy at both field strengths compared to standard resolution perfusion imaging<sup>[27,36,37]</sup>. Furthermore validation against FFR gave sensitivity and specificity to detect stenoses at a threshold of FFR  $< 0.75$  of 0.82 and 0.94 ( $P < 0.0001$ ) respectively, and an area under the curve of 0.92 ( $P < 0.0001$ )<sup>[38]</sup>.

Conventional stress perfusion CMR is typically acquired in 3 short-axis slices, and thus unlike SPECT does not truly calculate global ischaemia burden. Accelerated acquisition techniques can also be employed to achieve full LV coverage using a 3D whole-heart single shot acquisition.

Such 3D acquisitions can overcome the assumptions made about “missing” myocardium between the slices from conventional 2D multi-slice perfusion imaging. Two studies have validated the feasibility and diagnostic accuracy of 3D stress perfusion CMR against FFR; at 1.5T 3D perfusion demonstrated a sensitivity, specificity and diagnostic accuracy of 90%, 82% and 87% respectively and 91%, 90% and 91% respectively at 3.0T<sup>[39,40]</sup>. Furthermore in a recent multicentre trial of 3D stress perfusion at 3.0T, sensitivity and specificity were 84.7% and 90.8% relative to the FFR reference<sup>[41]</sup>. The main motivation for 3D perfusion is to give a more accurate quantification of total myocardial ischaemia burden; evidence from SPECT suggests a prognostic benefit for revascularisation in those with an ischaemia burden > 10%, with an ischaemia burden of 10% conferring a risk of approximately 5% for death or MI per year<sup>[42,43]</sup>. Ischaemia burden as measured by 3D stress perfusion CMR has been compared to SPECT and showed good correlation ( $r_s = 0.70$ ,  $P < 0.001$ )<sup>[44]</sup>. Intriguingly a recent pilot study compared ischaemia burden by high-resolution perfusion (using 3 short axis slices) and 3D perfusion imaging (providing whole heart coverage) suggesting that there was also a good correlation between the techniques ( $r = 0.72$ ;  $P = 0.001$ ), and that therefore the two methods are potentially interchangeable<sup>[45]</sup>.

## QUANTITATIVE PERFUSION

CMR stress perfusion studies are normally reported in a qualitative manner; however this can prove challenging in diffuse or multi-vessel disease where there is no healthy reference myocardium to use as a visual comparator. These situations can introduce subjectivity into the analysis and consequently quantitative measurement techniques have been developed to provide an objective assessment of myocardial blood flow. A number of different methods of quantitative analysis have been assessed with the Fermi deconvolution method showing most accuracy when compared to microspheres in an explanted porcine model at 1.5T and mice at 3.0T<sup>[46,47]</sup>, and when compared to SPECT and with QCA<sup>[48]</sup>. When compared to angiography with FFR, an MPR threshold of 1.58 detected a stenosis with an FFR < 0.75 with a sensitivity of 0.80, specificity of 0.89 ( $P < 0.0001$ ), and area under the curve of 0.89 ( $P < 0.0001$ )<sup>[38]</sup>. Myocardial perfusion reserve derived from quantitative CMR perfusion has also shown good correlation to PET imaging, the imaging modality that is widely regarded as the reference standard non-invasive measure of myocardial blood flow<sup>[49,50]</sup>. Currently, time consuming post-processing has limited quantitative perfusion methods to a research tool, but automated methods are being developed that may potentially overcome this<sup>[51]</sup>.

## DOBUTAMINE STRESS CMR

GBCAs have an excellent safety profile<sup>[52]</sup>, but in patients with poor renal clearance (*e.g.*, on dialysis) there is

a risk of nephrogenic systemic fibrosis<sup>[53]</sup>. In those patients unable to have GBCAs inotropic stress CMR is an alternative. Inotropic stress CMR is typically performed with dobutamine in a similar manner to DSE with inducible regional wall motion abnormalities identified in territories supplied by a stenosed coronary artery at peak stress. Unlike DSE however, DSMR's accuracy is not limited by body habitus or in those with poor acoustic windows and in a single centre study DSMR was shown to have significantly greater diagnostic performance to DSE in this context<sup>[54]</sup>. However echocardiography in this study was performed without harmonic imaging and contrast agents, so that the performance of DSE is likely to be underreported compared with contemporaneous methods. DSMR has a comparable safety profile to DSE with an event rate of 0.1% for sustained VT and 0.4% for non-sustained VT, and 1.6% for atrial fibrillation; patients thus require close monitoring during scanning and resuscitation equipment needs to be available<sup>[55]</sup>. DSMR has been shown to have high diagnostic accuracy for the detection of CAD with one meta-analysis of 14 trials showing a pooled sensitivity of 0.83 (95%CI: 0.79-0.88) and specificity of 0.86 (95%CI: 0.81-0.91)<sup>[56]</sup>; furthermore a single centre trial of DSMR vs perfusion CMR showed similar diagnostic accuracy<sup>[57]</sup>. First-pass perfusion can be performed additionally at peak dobutamine stress to provide incremental diagnostic accuracy<sup>[58]</sup>, and can be a useful adjunct in challenging patient groups such as those with pre-existing wall motion abnormalities or dyssynchrony from left bundle branch block<sup>[59]</sup>.

Exercise is commonly used rather than pharmacological agents as the stressor in echocardiography, and gives useful prognostic information such as workload in metabolic equivalent (METs) in addition to ischaemia testing<sup>[60,61]</sup>. CMR is limited in this respect due to the need for supine scanning and consistent positioning within the scanner. Recent studies however have assessed the feasibility of exercise stress CMR and showed comparable accuracy to echocardiography, though it has yet to reach mainstream clinical use<sup>[62,63]</sup>. Promising developments are “steppers” and cycle ergometers that can attach directly to the MRI scanner, and thereby eliminate the need to transfer the patient from the exercise equipment into the scanner<sup>[64,65]</sup>.

## Prognosis from stress CMR

Both perfusion CMR and DSMR provide excellent prognostic information, and this has recently been shown in two large meta-analyses. One meta-analysis of 14 studies including 12178 patients showed that a negative stress CMR was associated with a 1.03% annualised event rate, comparable to the normal population<sup>[66]</sup>. A further meta-analysis of 19 studies including 11636 patients showed a similar annualised event rate of 0.8% for a negative stress CMR over a mean follow up of 32 mo<sup>[67]</sup>. In a large prospective study of 1229 patients undergoing adenosine stress with a mean follow-up period of  $4.2 \pm 2.1$  years, patients with reversible perfusion deficits had a 3-fold

increased risk of major adverse cardiovascular events, with significantly more cardiac deaths ( $P < 0.0001$ ) and nonfatal myocardial infarctions ( $P < 0.001$ )<sup>[68]</sup>. Similarly the data from DSMR mirrors the results of first-pass perfusion CMR with a negative study conferring an equally low annual event rate of 1.3%<sup>[66,69]</sup>. Recently the five-year outcome data from CE-MARC were published with prognostic data for both CMR and SPECT in the same patient population. The analysis showed that although an abnormal result from both tests was a strong indicator of future major adverse cardiovascular events (MACE), CMR was superior at predicting time to MACE in this population<sup>[70]</sup>. Furthermore CMR remained the only independent predictor of outcome after adjustment for major cardiovascular risk factors, stratification for initial patient treatment and coronary angiographic findings<sup>[70]</sup>. These findings likely reflect CMR's overall greater diagnostic accuracy, combined with CMR's higher spatial resolution enabling greater identification of subendocardial scar compared to SPECT<sup>[71]</sup>; a feature known to confer prognostic significance beyond ejection fraction, and clinical or angiographic features<sup>[72]</sup>.

## EARLY AND LATE GADOLINIUM ENHANCEMENT IMAGING

GBCAs have a large molecular weight and cannot penetrate an intact cell membrane; consequently GBCAs are constrained to the extracellular space. In healthy myocardium the extracellular space is limited and contrast enters and clears rapidly. The extracellular space in infarcted myocardium however is substantially increased compared to normal myocardium and is less vascular. Thus in chronic myocardial infarction scar tissue composed of a matrix of collagen fibres has significantly increased extracellular space, leading to GBCA accumulation (slow washout), whilst in acute infarction GBCAs passively diffuse across disrupted myocardial cell membranes and into the intracellular space (greater volume of distribution)<sup>[73]</sup>. Thus both acute and chronic myocardial infarction retain more GBCAs. Imaged with T1 sensitive acquisition methods, this results in a higher signal.

Early gadolinium enhancement imaging is performed immediately following contrast administration; this allows mainly the visualisation of ventricular thrombi that appear "dark/black" due to a lack of contrast uptake as they are non-vascular (Figure 4). CMR has been shown to be superior to both trans-thoracic echocardiography and trans-oesophageal echocardiography for the identification of ventricular thrombi<sup>[74,75]</sup>. LGE imaging is performed between 10-20 min after contrast administration, an appropriate inversion time is set to null the normal myocardium and the areas where gadolinium is retained enhances (Figure 4). Typically a stack of short axis slices, a 4-chamber view and VLA are acquired. Alternatively, 3D LGE CMR imaging enables whole heart quantification of scar burden to be acquired in a shorter time period (although with a reduction in image quality), which may

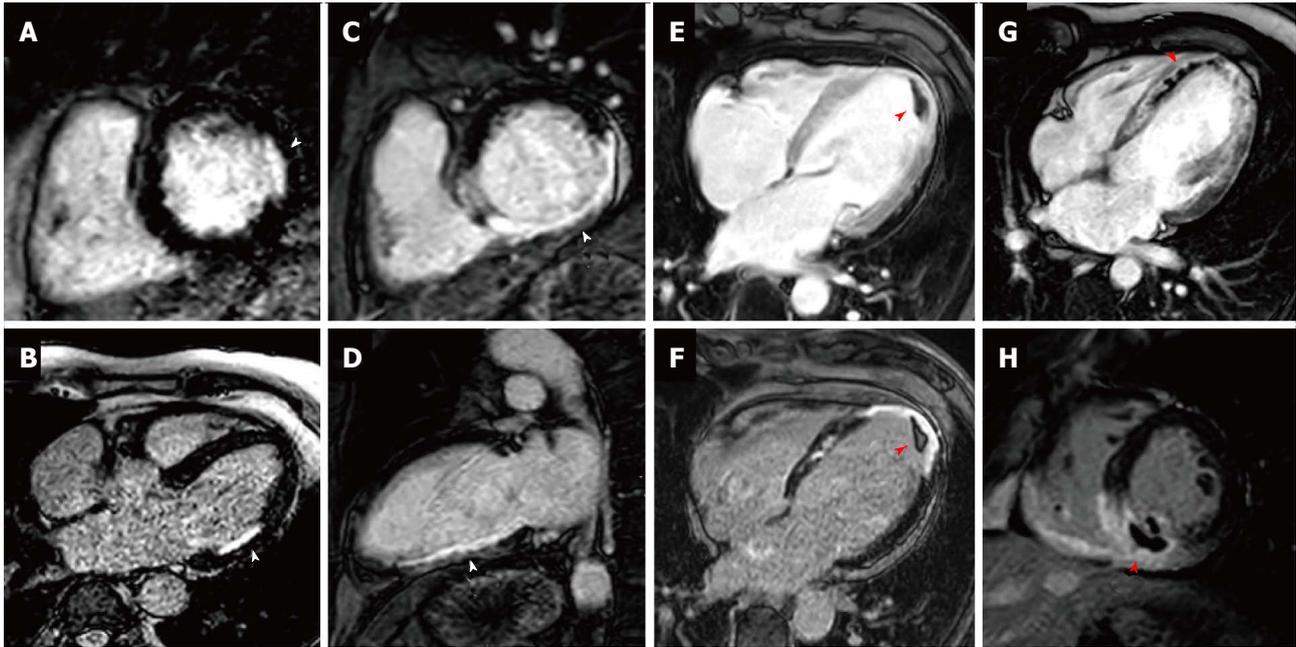

provide an alternative for patients that struggle to breath-hold<sup>[76,77]</sup>.

## VIABILITY ASSESSMENT

CMR viability assessment using LGE enables the accurate detection, and extent and trans-murality of previous myocardial infarction to be determined, and identifies regions with potential to recover function following revascularisation. Hibernating myocardium is dysfunctional myocardium that has been down-regulated through a process of chronic/repetitive ischaemia and which has the potential for functional recovery when blood flow is restored. LGE imaging detects replacement of normal viable myocytes by focal necrosis or fibrosis with high spatial resolution, and has excellent correlation to histopathology<sup>[73]</sup>. Furthermore the degree of transmural extent of hyper-enhancement on LGE imaging has a direct association to the potential for functional recovery following revascularisation; Kim *et al*<sup>[78]</sup> demonstrated that segments with less than 25% hyper-enhancement were most likely to attain functional recovery whilst segments with over 75% hyper-enhancement were unlikely to improve, notably this was irrespective of whether the region was initially hypokinetic, dyskinetic or akinetic. A meta-analysis of 331 patients using 50% trans-murality of hyper-enhancement reported a sensitivity of 95% (95%CI: 93%-97%) and specificity of 51% (40%-62%) for predicting functional recovery<sup>[79]</sup>.

CMR viability assessment is not however limited to just LGE imaging; whilst LGE identifies the transmural extent of scarring, the use of low-dose dobutamine (LDD) identifies the contractile reserve. Myocardium is considered viable if there is a 2 mm or more increase in systolic wall thickening within a segment following administration of LDD (5-10 mcg/kg per minute)<sup>[80]</sup>. While scar burden on LGE has been shown to be most sensitive method for assessment for functional recovery compared to LDD and diastolic wall thickness<sup>[81]</sup>, LDD CMR offers higher specificity and PPV for prediction of functional recovery (91% and 93%, respectively)<sup>[79]</sup>. Consequently a stepwise approach utilising LGE first followed by LDD if the trans-mural extent of LGE in the territory of the diseased coronary is between 1%-50% has been proposed<sup>[82]</sup>. Recently both tissue tagging and feature tracking have been used to give quantitative viability assessment with LDD and have been suggested as possible methods to reduce reliance on operator experience in what is currently a qualitative method of assessment<sup>[83-85]</sup>.

LGE imaging has a grade A recommendation to determine myocardial viability prior to revascularisation in the ACCF/AHA/SCMR appropriate use guidelines<sup>[86]</sup>, though viability assessment by LGE is currently not recommended for this indication in ESC or US practice guidelines for management of stable CAD or coronary revascularisation<sup>[6,7,9,87]</sup>. The utility of viability assessment has been questioned recently following the results of the STICH trial and the subsequently published viability sub-study that showed no mortality benefit from re-

**Figure 4** Early and late gadolinium enhancement. A and B show a lateral sub-endocardial infarction on short axis and 4 chamber LGE respectively; C and D show a full thickness inferior infarction on LGE imaging on short axis and VLA respectively; E and F show EGE and LGE imaging respectively of a full thickness apical infarction with an apical thrombus appearing black (highlighted by red arrow); G shows an extensive acute antero-apical infarction with a core of microvascular obstruction visible within the hyperenhancement on EGE (red arrow); H shows an acute inferior wall infarction with MVO and extension into the right ventricle on LGE (red arrow) imaging. LGE: Late gadolinium enhancement; EGE: Early gadolinium enhancement; MVO: Mitral orifice.

vascularisation following viability assessment<sup>[88,89]</sup>. This is contrary to prior observational data in large meta-analyses including over 3000 patients with viability; revascularisation was associated with 79.6% reduction in annual mortality ( $P < 0.0001$ ) compared with medical treatment<sup>[90,91]</sup> and presence of dysfunctional viable myocardium by LGE-CMR without revascularisation is an independent predictor of mortality in patients with ischemic LV dysfunction<sup>[92]</sup>. Questions have been asked however whether the STICH sub-study results would have been different if CMR had been used rather than SPECT, and consequently in Europe the third highest indication for CMR remains the assessment of viability<sup>[93]</sup>.

## SCAR BEYOND VIABILITY ASSESSMENT

In addition to identifying viable myocardium, the presence and extent of LGE provides valuable prognostic information, and the extent of scar burden by LGE is readily quantified and reproducible on CMR<sup>[94]</sup>. Impairment of left ventricular ejection fraction is well recognized as an independent risk factor in those with coronary artery disease<sup>[8,95]</sup>; LGE can provide additive prognostication in these patients and a recent study of 1560 patients established that the presence of scar by LGE irrespective of LVEF identified those at risk of increased mortality<sup>[96]</sup>. Furthermore a meta-analysis showed that the presence of LGE increases the risk of death by 4.77% and MACE by 3.9% and that each gram of scar measured by LGE increased the hazards of death and MACE by 4% and 5%, respectively<sup>[97]</sup>. Additionally the identification of previously unrecognized MI by LGE confers a significantly increased

risk of both mortality and MACE<sup>[72,98]</sup>.

The extent of scar burden by LGE in patients with ischaemic heart disease has also been identified in a number of studies to be an independent predictor of ventricular arrhythmias in patients with internal cardiac defibrillators (ICD)<sup>[99-101]</sup>, and a recent meta-analysis of 1105 patients with ICDs determined that the extent of LGE was predictive of ventricular arrhythmia whilst LVEF was not<sup>[102]</sup>. Additionally in a high risk cohort of patients with a mean LVEF of 35% being considered for ICD implantation, LGE demonstrated that significant scarring ( $> 5\%$  LV) in patients with LVEF  $> 30\%$ , conferred a risk similar to those with LVEF  $\leq 30\%$ <sup>[103]</sup>. Equally, in patients with LVEF  $\leq 30\%$ , minimal or no scar burden established a lower risk cohort similar to those with LVEF  $> 30\%$ <sup>[103]</sup>. Other studies have identified the presence of a "grey zone" on LGE imaging, a heterogeneous region of viable and non-viable myocardium at the infarct periphery, as predictive of VT<sup>[104,105]</sup>.

LGE and quantification of scar burden has also been used to predict responsiveness to cardiac resynchronization therapy (CRT)<sup>[106]</sup>, and identification of scarring in the pacing region of the LV lead has been associated with non-response to device therapy<sup>[107,108]</sup>. In a similar method to imaging the coronary artery anatomy, coronary venous anatomy can be reliably demonstrated using GBCAs, which can potentially aid planning of device implantation<sup>[109]</sup>. The combination of coronary venous imaging, assessment of ventricular function and LGE may be a useful adjunct in the management of patients with ischaemic cardiomyopathy being considered for CRT, as well as risk stratifying those being considered for

defibrillator therapy.

## COST EFFECTIVENESS

The economic burden of CAD is enormous with £6.8 billion spent in 2012 in the United Kingdom; in the United States over 15 million people have CAD costing the US economy \$108.9 billion/year<sup>[110,111]</sup>. Cost effectiveness analyses help to inform optimal management pathways in order to maximise health care benefit within the constraints of limited resources. In the United States a low yield has been reported at diagnostic angiography with just over 40% of patients referred having obstructive CAD<sup>[5]</sup>. CMR can act as a potential gatekeeper to invasive coronary angiography in order to reduce downstream costs as well as reduce risk from unnecessary invasive assessments.

Health economic analyses based on the CE-MARC dataset identified that despite the higher initial cost of CMR to SPECT, the superior diagnostic accuracy of CMR lead to an overall greater cost effectiveness in models of the United Kingdom, German and Swiss healthcare systems<sup>[112-114]</sup>. A study of 1158 German patients being investigated for suspected CAD were randomised to either DSMR prior to angiography or direct to angiography; DSMR prior to invasive angiography led to a saving of 12466€ of hospital costs per life year, furthermore this cost saving was maintained through a median period of 7.9 years follow-up<sup>[115]</sup>.

In a cost analysis comparing CMR and X-ray angiography vs angiography and FFR to determine the need for revascularisation, CMR and angiography was more cost-effective below a CAD prevalence of 62%, 65%, 83% and 82% for the Swiss, German, United Kingdom, and the United States health care systems, respectively<sup>[116]</sup>. These studies confirm that as well as the established high diagnostic accuracy, CMR is also a financially advantageous investigative strategy in patients with CAD.

## RECENTLY PUBLISHED AND FUTURE STUDIES

Studies thus far have predominantly focused on the diagnostic accuracy of CMR; forthcoming multi-centre clinical effectiveness trials are however focused on evaluating clinical pathways to improve patient outcomes. The recently published CE-MARC 2 trial is a prospective, multi-centre, 3-arm parallel group, randomised controlled trial comparing multi-parametric CMR vs UK NICE CG95 guidance<sup>[14]</sup> vs AHA/ACCF SPECT appropriate-use criteria<sup>[117]</sup> to investigate patients with suspected CAD (pre-test likelihood 10%-90%) requiring further investigation<sup>[118,119]</sup>. The primary outcome measure was FFR defined unnecessary angiography (FFR > 0.8) with the important safety secondary outcome measure of MACE at 1 and 3 years. CE-MARC 2 showed overall that CMR guided care resulted in significantly reduced rates of

unnecessary angiography at 12 mo compared to routine guideline directed care<sup>[119]</sup>.

Contemporary registry data from the United States suggests roughly 12%-26% of elective PCI are deemed inappropriate with considerable variation in practice between sites<sup>[120,121]</sup>. Both FAME and DEFER showed improved outcomes using FFR guided revascularisation based on ischaemia detection, compared to reliance on visual assessment at angiography<sup>[122,123]</sup>. These trials would suggest that a better way of selecting patients prior to invasive revascularisation procedures is required. CMR offers a non-invasive ischaemia assessment and the MR-INFORM trial aims to establish if perfusion CMR could act as a non-invasive surrogate to FFR to determine the need for revascularisation in patients with stable CAD<sup>[124]</sup>. MR-INFORM is a multi-centre, non-inferiority study comparing adenosine perfusion CMR vs angiography with FFR measurement to guide revascularisation decisions in patients with stable angina and moderate to high probability of CAD; the primary endpoint is the occurrence of MACE at one year. The trial has completed recruitment and is expected to report in 2017.

The prognostic benefit of revascularisation in stable coronary artery disease is a topic of debate; both the COURAGE trial and BARI-2D failed to show any prognostic benefit of revascularisation over optimal medical therapy (OMT) in patients with stable CAD<sup>[125,126]</sup>. Determination of extent of ischaemia in both these 2 trials was however limited; in COURAGE only 33% of patients had moderate/severe ischaemia and moreover around 40% had < 5% ischaemia<sup>[127]</sup>. In both trials however those with a higher residual ischaemia burden had a worse prognosis<sup>[127-129]</sup>. The ISCHEMIA trial aims to test the hypothesis that a routine invasive strategy with early cardiac catheterisation and revascularisation plus OMT is superior to a conservative management strategy of OMT for patients with moderate or severe ischemia<sup>[42]</sup>. The trial aims to recruit over 8000 patients worldwide with ischaemia determined by non-invasive imaging (CMR, stress echocardiography, SPECT) with a primary endpoint of time to cardiovascular death or non-fatal myocardial infarction.

### Coronary artery evaluation

Coronary MRA (CMRA) allows the non-invasive anatomical assessment of coronary arteries; currently clinical indications are limited to the detection of aberrant origin of coronary arteries, coronary ectasia and/or aneurysms (class I indication) and evaluation of bypass grafts (class II indication)<sup>[130,131]</sup>. CMRA for diagnosis of CAD is not presently part of routine clinical practice. The initial multi-centre experience using CMRA in this context showed interpretable image quality in 84% of proximal and middle coronary artery segments, though with a specificity of 42%; CMRA did however exclude triple-vessel disease and left main coronary artery stenosis with a negative predictive value of 100%<sup>[132]</sup>. Progress in CMRA techniques have improved significantly however, and a recent multi-centre study showed that CMRA at 1.5T detects significant

CAD with a sensitivity of 88% and specificity of 72% and a negative predictive value of 88%<sup>[133]</sup>. Furthermore one study showed in a direct comparison between CMRA and CT coronary angiography (CTCA) there was no significant difference between coronary imaging at 3.0T and 64-slice CTCA for the detection of CAD with a sensitivity of 87% vs 90% ( $P = 0.16$ ) and specificity of 77% vs 83% ( $P = 0.06$ ) respectively<sup>[134]</sup>.

Currently CMRA techniques are time consuming and there are questions over the incremental diagnostic merit they provide in addition to established perfusion protocols; the CE-MARC study found no additional diagnostic benefit by including CMRA into a full multi-parametric protocol vs the perfusion/LV function/LGE combination (overall accuracy 84.6% vs 84.2% ( $P = 0.5316$ ))<sup>[23]</sup>. Moreover there was no significant improvement in diagnostic accuracy when CMRA was added to perfusion imaging at 1.5T and compared to FFR as the reference standard<sup>[135]</sup>.

## FUTURE DIRECTIONS

### *T1 mapping*

Native T1, T1 mapping, and extra cellular volume fraction quantification are novel methods for CMR tissue characterisation. These techniques are currently research tools that have shown promise for diagnosis and prognostication in acute coronary syndromes and other rare disease processes (*e.g.*, Amyloid and Fabry's disease), presently however they do not have an established role in the diagnosis or management of stable ischaemic heart disease<sup>[136,137]</sup>. Post myocardial infarction however a role for these imaging "biomarkers" is being established in predicting both prognosis and adverse LV remodelling<sup>[138,139]</sup>.

### *Blood oxygen level dependent*

CMR uses the paramagnetic properties of deoxyhaemoglobin as an endogenous contrast agent; increasing deoxyhaemoglobin content leads to a reduction of signal intensity on T2 or T2\* weighted images<sup>[140]</sup>. The magnitude of the BOLD effect depends on the static magnetic field strength, with an exponential increase at 3.0T from 1.5T; consequently most studies have used 3.0T. Thus far BOLD has shown good correlation with QCA and conventional CMR perfusion imaging, but studies are generally small and single centre, limiting its clinical validation<sup>[141,142]</sup>.

Finally hyperpolarised CMR is making the transition from animal studies to human applications. Hyperpolarisation methods artificially increase the number of molecules in one orientation resulting in a significant increase in MR signal; combined with <sup>13</sup>C enriched metabolic tracers enable real time imaging of *in vivo* substrate metabolism, coronary angiography and quantitative perfusion imaging<sup>[143]</sup>. The results of human hyperpolarisation studies are eagerly awaited.

## CONCLUSION

Over the last decade the evidence base for the diag-

nostic accuracy of CMR for the investigation of stable coronary artery disease has been confirmed through the publication of large-scale clinical trials and meta-analyses, and CMR is now firmly established in clinical practice guidelines. CMR enables assessment of cardiac dimensions, function, ischaemia, scar burden and tissue viability in a single study without exposure to ionising radiation. CMR also offers prognostic information with a normal stress CMR associated with a < 1% risk of death or MI at 2 years, whilst the presence of LGE confers added prognostication above and beyond simple LV ejection fraction. New technical developments continue apace and ongoing large clinical trials will further clarify the role of CMR in routine clinical practice and guide the future development of international guidelines.

### Abstract

Cardiovascular magnetic resonance (CMR) imaging

uniquely characterizes myocardial and microvascular injury in acute myocardial infarction (AMI), providing powerful surrogate markers of outcomes. The last 10 years have seen an exponential increase in AMI studies utilizing CMR based endpoints. This article provides a contemporary, comprehensive review of the powerful role of CMR imaging in the assessment of outcomes in AMI. The theory, assessment techniques, chronology, importance in predicting left ventricular function and remodelling, and prognostic value of each CMR surrogate marker is described in detail. Major studies illustrating the importance of the markers are summarized, providing an up to date review of the literature base in CMR imaging in AMI.

**Key words:** Myocardial infarction; Infarct; Cardiovascular magnetic resonance; Left ventricular remodelling; Prognosis

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Cardiovascular magnetic resonance (CMR) imaging uniquely characterizes myocardial and microvascular injury in acute myocardial infarction (AMI). Contrast-enhanced CMR offers robust, validated and reproducible surrogate markers, providing an accurate representation of pathophysiology, assessment of myocardial function and injury, and predictive value for medium to long-term LV function, remodelling and prognosis following primary percutaneous coronary intervention for STEMI. These qualities significantly increase the statistical power of studies using CMR endpoints and has resulted in an exponential increase in AMI studies utilizing CMR based endpoints. An understanding of the role of CMR in the assessment of outcomes in AMI is of key importance not only to interventional and imaging cardiologists, but to the cardiology community as a whole.

## INTRODUCTION

Cardiovascular magnetic resonance (CMR) imaging uniquely characterises myocardial and microvascular injury in acute myocardial infarction (AMI), providing powerful surrogate markers of outcomes. The last 10 years have seen an exponential increase in studies utilising CMR based endpoints in patients with AMI undergoing primary percutaneous intervention. This article provides a contemporary, comprehensive review of the powerful role of CMR imaging in the assessment of outcomes in AMI. The theory, assessment techniques, chronology, importance in predicting left ventricular function and remodelling, and prognostic value of each CMR surrogate marker is described in detail. Major studies illustrating the importance of the markers are summarised, providing an up to date review of the literature base in CMR imaging in AMI.

## MARKERS OF OUTCOMES FOLLOWING PRIMARY PERCUTANEOUS CORONARY INTERVENTION IN AMI

Prognostic studies using clinical outcomes, in particular mortality require large sample sizes. Surrogate biomarkers of outcome are directly measured alternative endpoints used as a substitute for biological processes and clinical outcomes<sup>[1,2]</sup>. CMR imaging uniquely characterises myocardial and microvascular injury in AMI due to its accuracy, reliability and validity (Figure 1)<sup>[2-4]</sup>. This significantly increases the statistical power of studies, allowing sample size requirements to be reduced. CMR data are strong surrogate markers of outcome following primary percutaneous coronary intervention (PPCI) in acute ST-segment elevation MI.

## LV EJECTION FRACTION AND VOLUMES IN AMI

### Background

In the medium-term following STEMI, LV end-diastolic volume (LVEDV) increases, LV end-systolic volume (LVESV) decreases<sup>[5-7]</sup> and there can be compensatory hypertrophy of remote myocardium<sup>[8,9]</sup> in order to preserve stroke volume and ejection fraction (LVEF). Adverse remodelling results from an inability of the heart to maintain geometry post MI in the context of large infarcts and increased wall stresses<sup>[10,11]</sup>. An increase in LVEDVI > 20%<sup>[12,13]</sup> and increase in LVESVI > 15%<sup>[14]</sup> at follow-up are the most commonly used criteria for adverse remodelling.

### CMR assessment of LV volumes and ejection fraction

CMR is the gold standard modality for the assessment of ventricular function and volumes. It has higher spatial

resolution than single-photon emission computed tomography (SPECT) (approximately 1.8 mm × 1.8 mm × 8 mm vs 10 mm × 10 mm × 10 mm)<sup>[15]</sup>, and suffers from little subjectivity or reliance on patient body habitus<sup>[16]</sup>.

Volumes and mass are assessed on analysis of a 3D cine stack of short-axis biventricular contiguous slices. Modern cine sequences use breath-hold, electrocardiographic-gated, segmented steady-state free precession (SSFP) to produce high spatial resolution images with excellent myocardium-blood contrast. Regional systolic function can alternatively be assessed using wall motion scoring<sup>[17]</sup>.

CMR studies have demonstrated that recovery of LVEF occurs relatively early post STEMI. Ripa showed that improvement in LVEF and systolic wall thickening occurred by 1 mo, with no further change at 6 mo<sup>[5]</sup>. The majority of improvement in LVEF occurred between day 2 and 1 wk in the study by Mather<sup>[18]</sup>, with a final increase by 3 mo. Beek showed that 55% of segments with initially impaired systolic wall thickness improved at 13-wk<sup>[19]</sup>. Ganame *et al*<sup>[20]</sup> and Dall'Armellina *et al*<sup>[21]</sup> however showed that LVEF underwent no significant change by 6 and 12 mo post PPCI respectively. This may be because their subjects sustained less myocardial damage, represented by relatively preserved LVEF and thus lower potential for improvement<sup>[21]</sup>.

Volumetric changes occur more slowly. Ripa *et al*<sup>[5]</sup> showed a continued increase in LVEDV and reduction in LVESV until 6 mo. Engblom *et al*<sup>[7]</sup> demonstrated similar sequelae to 12-mo. Ganame showed progressive significant changes in LVEDV and LVESV and resulting LV sphericity at all timepoints to 12 mo<sup>[20]</sup>. These studies have important implications for optimising timing of follow-up CMR studies assessing remodelling.

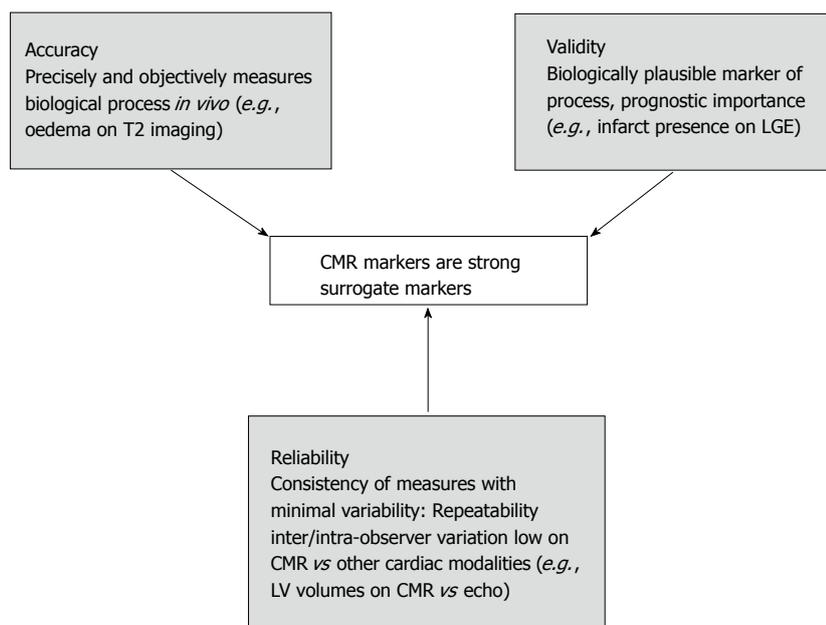

The degree of impairment of LVEF and changes in volume depend on a number of CMR-based markers including infarct size (IS)<sup>[22]</sup>, microvascular obstruction (MVO)<sup>[23,24]</sup>, intramyocardial haemorrhage (IMH)<sup>[25]</sup> and myocardial salvage [non-infarcted proportion of ischaemic area at risk (AAR)]<sup>[26,27]</sup>. Anterior STEMI results in larger IS and lower LVEF due to the greater ischaemic AAR<sup>[28]</sup>.

### Prognostic importance of LVEF and volumes in AMI

Norris *et al*<sup>[29]</sup> and White *et al*<sup>[30]</sup> first illustrated the prognostic importance of LVEF (strongest independent predictor of survival at 3.5 years) and LVESV (only independent predictor of long-term mortality at 6 years) respectively, using invasive ventriculography. Burns first demonstrated the prognostic importance of LVEF and LV volumes and their strong correlation with each other, using radionuclide analysis<sup>[31]</sup>.

A large evidence base has emerged for the prognostic impact of impaired systolic function based on reduced CMR-derived LVEF (Table 1).

In addition to LVEF-based global systolic function, Bodi demonstrated that the number of dysfunctional segments on CMR at 1-wk post STEMI was an independent predictor of combined MACE at a median follow-up of 553 d<sup>[38]</sup>. The evidence base for the prognostic importance of LV volumes is largely historical, based on large echocardiographic

and radionuclide studies, demonstrating the negative prognostic impact of ventricular dilatation and remodelling as summarised in Table 2.

Negative LV remodelling has demonstrated prognostic importance in two studies, based on the cut-off of LVEDVI dilation of > 20% at 6-mo follow-up<sup>[12,13]</sup>.

**Figure 2 Cardiovascular magnetic resonance assessment of strain using tissue tagging.** Cine SSFP images in end-diastole (A) and end-systole (C), with corresponding Spatial Modulation of Motion (SPAMM) tagged images (B and D). Grid lines (tags) are visible and contours drawn at 3 myocardial levels [green (epicardial), red (mid myocardial), yellow (endocardial)] allow tracking of myocardial motion and strain (circumferential), here using Harmonic Phase Analysis.

Recently, left ventricular global performance index has been proposed as a CMR marker of cardiac performance, incorporating LVEF, LV volumes and mass. It has been assessed in one study in STEMI and correlated strongly with IS, MSI, MVO and IMH extent, and had incremental prognostic value to LVEF in predicting 12-mo MACE<sup>[42]</sup>. Further work is needed to investigate its prognostic value in STEMI.

## MYOCARDIAL STRAIN IN AMI

CMR-measured myocardial strain (tissue deformity) is the gold standard non-invasive measure of systolic and diastolic myocardial function<sup>[43]</sup>. Circumferential strain (Ecc) describes shortening of fibres (contraction) in a short-axis plane tangential to the epicardium; longitudinal strain (E<sub>ll</sub>) describes shortening in the long axis, and radial strain (Err) describes lengthening (thickening) of fibres towards the centre of the ventricle. Torsion is wringing of the ventricle caused by clockwise rotation at the base, and anticlockwise at the apex.

Strain offers greater accuracy in detecting myocardial dysfunction compared with global (LVEF) and regional (visual wall-motion scoring, segmental wall thickening)<sup>[44]</sup> measures.

### CMR assessment of myocardial strain

In 1989, Axel *et al*<sup>[45]</sup> developed a T1 spoiled gradient echo sequence, creating "tags" formed by saturation of thin myocardial lines running in perpendicular directions in-plane to form a myocardial grid. These lines act as tissue markers, tracking myocardial deformation as shown in Figure 2. Peak systolic strain and peak diastolic strain

rate (relaxation rate of strain) provide very sensitive measures of systolic and diastolic function respectively. Its accuracy has been validated on comparison with sonomicrometry<sup>[46,47]</sup>. Harmonic Phase Analysis (HARP) is currently the most widely used CMR strain method<sup>[48]</sup>.

Feature tracking (FT) has been introduced as an alternative method to tagging for assessing strain on CMR. FT tracks anatomical features of interest along contour lines on routinely acquired SSFP cine images analogous to echocardiographic Speckle Tracking, obviating the need for additional tagging sequences<sup>[49]</sup>. FT-derived strain has been compared to tagging in acute STEMI and shown greater feasibility, accuracy and observer agreement<sup>[50]</sup> and remains an exciting prospect.

### CMR LV strain as a predictor of LV function and remodelling in AMI

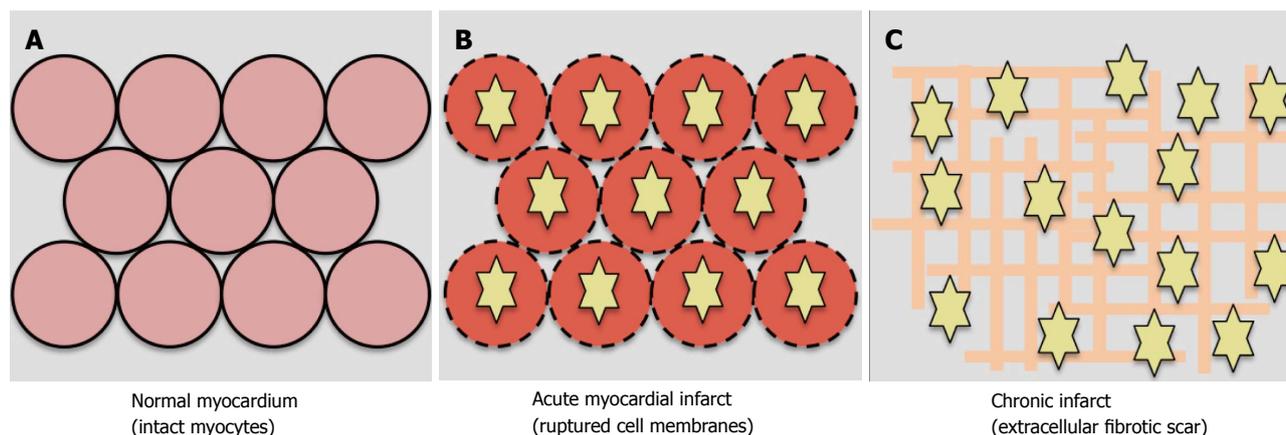

Strain could improve our understanding of the mechanics underlying LV dysfunction associated with prognostic CMR surrogate markers of myocardial damage in STEMI (e.g., MVO, IMH, oedema).

Systolic function is also in remote (non-infarcted) segments, and LV mechanics outside of the infarct zone are also affected during infarction and contribute to remodelling<sup>[44,51,52]</sup>. MVO had the highest predictive value for persistent dysfunction on circumferential strain at 7-mo post STEMI and may result in systolic dysfunction due to direct mechanical effects (myocardial stiffness)<sup>[53]</sup>. Baseline segmental circumferential strain was the strongest predictor of segmental functional recovery at 3-mo in a model containing infarct transmuralty and MVO<sup>[54]</sup>. FT-derived global circumferential strain assessed acutely post PPCI was recently shown to correlated strongly with

**Table 3** Studies illustrating the prognostic importance of left ventricular strain in acute myocardial infarction

Ref.	Year	n	Modality	Main findings	Follow-up

**Figure 3** Mechanism of late gadolinium enhancement. Gadolinium is extracellular. A: In normal myocardium, gadolinium washes out approximately 10 min post administration and there is no late gadolinium enhancement (LGE); B: In acute infarct, gadolinium (yellow stars) enters ruptured cell membranes and causes LGE; C: In chronic infarct, LGE results from increased extracellular space due to fibrotic scar deposition.

acute IS on late gadolinium enhancement (LGE) imaging ( $r = 0.75$ ) and final LVEF at 6 mo ( $r = -0.71$ ). Global circumferential strain was a stronger predictor of functional recovery (LVEF > 50%) at 6 mo than global longitudinal strain, age, diabetes and baseline LVEF, and was of similar predictive value to acute IS [AUC 0.86 (Ecc) vs 0.92 (IS)]<sup>[55]</sup>.

### Prognostic importance of LV strain in AMI

The evidence base for the prognostic importance of LV strain post STEMI is currently based on echocardiographic studies demonstrating that global longitudinal predicts medium and long-term using Speckle Tracking analysis as summarised in Table 3.

## INFARCT SIZE IN AMI

### Background

The "ischaemic cascade" is the sequence of pathophysiological effects developing immediately following coronary occlusion. Aerobic respiration loses efficiency resulting in cellular oedema. With increasing ischaemic time, cell membranes rupture. Following healing, necrotic cells are replaced by extracellular collagen deposition (scar). The acute and chronic phases are characterised by increased myocardial extracellular volume<sup>[60-62]</sup>.

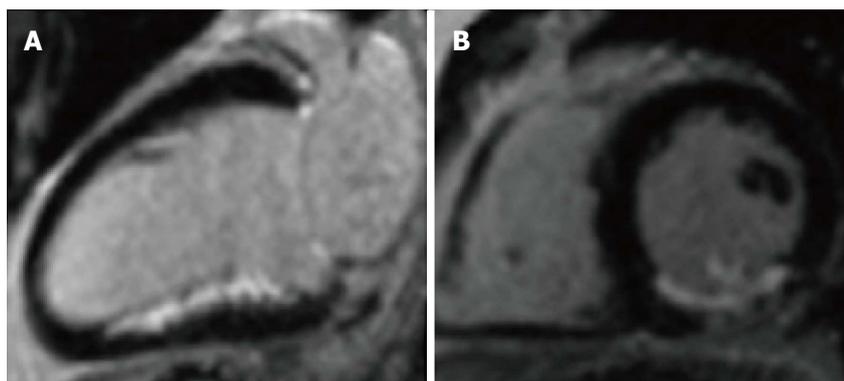

### CMR assessment of IS in AMI

Gadolinium contrast agents are large extracellular

molecules (Figure 3). Infarct can be visualised on T1-weighted imaging approximately 10 min after intravenous contrast administration, known as LGE imaging.

In acute infarct, LGE results from gadolinium entering ruptured cell membranes. In chronic infarction, LGE results from increased extracellular space due to collagen deposition and prolonged washout due to reduced capillary density within myocardium<sup>[60,63]</sup>. Gadolinium shortens T1, causing infarcted myocardium to appear bright, and normal myocardium to appear black (Figure 4)<sup>[63,64]</sup>. Normal myocardium is progressively nulled using the appropriate inversion time to provide optimal contrast between infarct and normal myocardium.

Typically, a high spatial resolution of approximately 1.4 mm × 1.6 mm × 6-8 mm is achieved<sup>[15]</sup>. IS is typically expressed as a percentage of total LV mass. Delineation of infarct can be performed visually (manual quantification)<sup>[6,9,22]</sup>, however most groups use semi-automated methods to reduce observer variability. These include enhancing myocardium exceeding a pre-defined signal intensity (SI) threshold, typically > 2-6 standard deviations above that of remote (non-infarcted) myocardium<sup>[2,65]</sup>. Currently, the semi-automated full-width at half-maximum (FWHM) method is commonly used<sup>[66-70]</sup>, defining infarct as myocardium with SI > 50% of the peak SI in the infarct core. Amado demonstrated that FWHM had the highest interobserver agreement and closest correlation with TTC-stained infarct in a dog model of acute infarction ( $r^2 = 0.94$ ), compared with standard

**Figure 4** Late gadolinium enhancement of acute infarct. Infarct appears white (enhanced) in the inferior wall, with unaffected myocardium black (nulled). A: 2-chamber long-axis view; B: Short-axis view, mid ventricular level. The posteromedial papillary muscle is also infarcted in the short-axis view.

**Table 4** Temporal changes in cardiovascular magnetic resonance-derived infarct size in acute myocardial infarction

Ref.	Year	n	CMR times post STEMI	Relative LGE IS reduction	LGE method	Main findings
Carrick <i>et al</i> <sup>[74]</sup>	2016	30	8 h → 3 d → 10 d → 7 mo	26%	Automated	Significant decrease d3 to d10 (20% ± 13% to 14% ± 10% LV mass). No change at 7 mo
Dall'Armellina <i>et al</i> <sup>[21]</sup>	2011	30	2 d → 6 mo	22%	> 2SD	IS reduced at times from 27% ± 15% LV mass 24 h post PPCI, to 21% ± 11% at 6 mo
Mather <i>et al</i> <sup>[18]</sup>	2011	48	2 d → 1 wk → 30 d → 3 mo	37%	> 2SD	27% IS drop between d2 and d7 post PPCI, no change at 3 mo

deviation methods<sup>[66]</sup>. This may be because FWHM is less prone to IS overestimation in the presence of oedema, and partial volume effects giving rise to intermediate signal intensities<sup>[18,71]</sup>. Comparing techniques in STEMI patients showed that FWHM quantification had the lowest intraobserver and interobserver variability, and greatest agreement with LVEF<sup>[72]</sup>.

CMR measurement of IS on LGE is well validated<sup>[63,64]</sup>. Kim demonstrated that IS in dog myocardium on *ex-vivo* CMR corresponded closely with IS derived from tetrazolium (TTC) staining ( $r = 0.99$ )<sup>[15,64]</sup>. LGE has higher sensitivity for infarct detection compared with SPECT. In an experimental model of MI, CMR LGE detected 92% of all segments with subendocardial infarction (< 50% transmural) compared with only 28% with SPECT<sup>[15]</sup>. In patients with MI, SPECT only detects approximately 50% of the infarcts seen on LGE. The superior sensitivity is due to the increased spatial resolution and reproducibility of CMR<sup>[60]</sup>.

Since gadolinium is distributed throughout the extracellular space, gadolinium contrast agents are not specific to necrosis. Acutely, the area of LGE detects not only necrotic cells but also the increased (oedematous) interstitium surrounding viable cells, and thus can over-

estimate true IS. Studies of IS chronology in humans corroborate this (Table 4). Indeed, severely dysfunctional segments with minimal myocardial salvage early post STEMI can show significant functional improvement at follow-up<sup>[73]</sup>.

The majority of IS reduction occurs relatively early post STEMI, particularly by 1 wk. Indeed IS assessed at 1 wk has been shown to closely correlate with final IS<sup>[7,9,18]</sup>. Overestimation of necrosis by LGE-derived IS early post STEMI is due to a combination of oedema, infarct resorption and partial volume effects. Oedema results in an overestimation of LGE IS due to increased extracellular water content and thus volume of distribution of contrast agent<sup>[66,75]</sup>.

Infarct resorption results from the healing process where collagenous scar tissue is produced to provide stability and tensile strength to necrotic myocardium<sup>[7,11]</sup>. This was confirmed in a canine model where a 3.4-fold decrease in infarct volume was seen between day 3 and 8-wk post infarct on *ex-vivo* LGE and TTC-stained slices<sup>[64]</sup>. The degree of infarct resorption has been shown to be proportional to initial IS ( $r = 0.65$ ) and presence of LV remodelling ( $r = 0.41$ )<sup>[10]</sup>. The greater degree of infarct resorption relative to total myocardial

mass and volume results in an inability to maintain LV geometry in light of mechanical stresses post STEMI, resulting in adverse LV remodelling and sphericity<sup>[10,76]</sup>.

Factors known to affect IS include AAR extent<sup>[77-79]</sup>; collateral flow to the AAR<sup>[79,80]</sup>; MVO<sup>[81]</sup>; time to reperfusion<sup>[82]</sup> and hyperglycaemia<sup>[83]</sup>.

### CMR IS as a predictor of LV function and remodelling in AMI

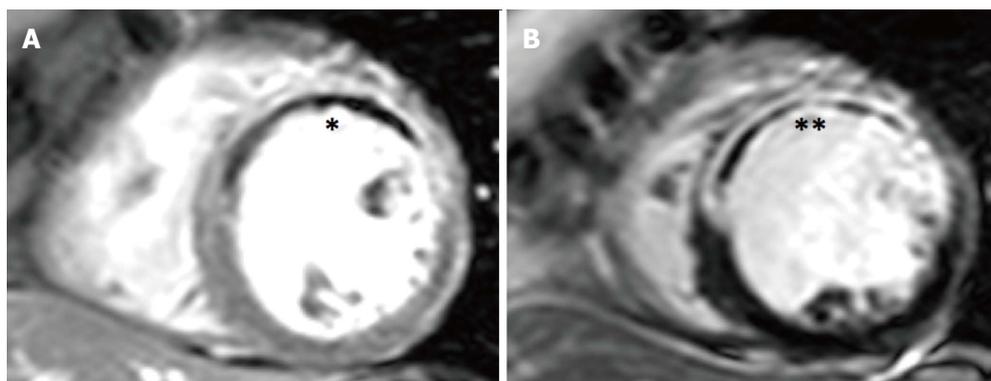

**Segmental function:** Kim illustrated in stable patients awaiting revascularisation, that LGE transmural strongly predicted recovery of systolic function in dysfunctional segments. Only 2% of segments with > 75% transmural improved after revascularisation<sup>[84]</sup>. Segmental extent of LGE has also been shown to negatively predict functional

recovery in dysfunctional segments following PPCI for acute STEMI, as summarised in Table 5.

**Global function:** IS is a powerful independent predictor of global LV function and adverse LV remodelling in the medium to long-term post STEMI as summarised in Table 6.

### Prognostic importance of CMR-derived IS in AMI

The goal of STEMI management is early reperfusion in order to minimise IS and thus maximise myocardial salvage<sup>[95]</sup>. There is a strong evidence base for the prognostic importance of CMR-derived IS post STEMI, as summarised in Table 7. IS strongly predicts medium to long-term clinical outcomes.

**Figure 5** Early and late microvascular obstruction on cardiovascular magnetic resonance. A: Early gadolinium imaging at 1-min post contrast with hyperperfusion in anteroseptal, anterior and anterolateral segments, consistent with early MVO (E-MVO, \*); B: Corresponding late gadolinium image showing transmural infarction with a hypointense late MVO core (L-MVO, \*\*) co-localising with E-MVO. MVO: Microvascular obstruction.

## MVO IN AMI

### Background

Despite prompt IRA recanalization, perfusion of the microcirculatory bed does not always ensue. Histopathological studies have demonstrated that the infarct core (endocardial) perishes first as necrosis spreads transmurally towards the epicardium. This is known as the “wavefront theory”<sup>[100]</sup>. At the infarct core, necrosis occurs rapidly with myocardial and capillary endothelial cells perishing simultaneously. Capillaries can become obstructed by cellular debris, resulting in non-perfusion of the infarct core, despite IRA patency<sup>[101]</sup>. This is known as MVO and can be indicated at angiography, as “no reflow”<sup>[101]</sup>.

### CMR assessment of MVO in AMI

Three CMR methods demonstrate MVO (Figure 5). MVO extent is typically expressed as a percentage of LV mass: (1) Qualitative first-pass rest perfusion. A modified version involves quantification of myocardial blood flow (SI-time curve) and time to 50% of maximal SI<sup>[102,103]</sup>; (2) Hypoperfusion on inversion recovery images between 1-3

min post contrast. A fixed inversion time of approximately 440 ms nulls MVO and retains intermediate signal in normal myocardium. This is known as “early MVO (E-MVO)”<sup>[28,104]</sup>; and (3) Hypointensity within infarct core on LGE due to absence contrast perfusion, known as “late MVO (L-MVO)”. L-MVO occurs in upto 60% of patients on CMR within the first week post STEMI<sup>[5,6,18,20]</sup>. This is the preferred method of MVO demonstration in contemporary clinical practice and research.

L-MVO extent is maximal at 48 h post infarct<sup>[8,18]</sup>, and then decreases. It exists for at least 1 wk, and for up to 1 mo<sup>[8,18]</sup> and then resolves in the medium-term in humans (Table 8). Animal models corroborate these findings<sup>[105,106]</sup>.

The extent of MVO on CMR has been shown to correlate with IS<sup>[82,94,107,108]</sup>, oedema, IMH, TIMI-flow pre PCI<sup>[35,109]</sup> and time to reperfusion<sup>[35,82,110]</sup>.

### CMR MVO as a predictor of LV function and remodelling in AMI

L-MVO is a strong independent predictor of medium-term LV function and adverse remodelling (Table 9). It

**Table 8 Temporal changes in cardiovascular magnetic resonance late microvascular obstruction in acute myocardial infarction**

Ref.	Year	<i>n</i>	CMR timepoints	LGE method	Main findings

Kidambi <i>et al</i> <sup>[115]</sup>	2013	39	> 2SD	L-MVO only IP of impaired infarct strain. Model with IS, TIMI flow, diabetes, transmural	3 d	3 mo
Wong <i>et al</i> <sup>[103]</sup>	2012	40	Manual	L-MVO extent only IP for LVEF at 3 mo in model including E-MVO, IS and myocardial blood flow on perfusion	3 d	3 mo
Ezekowitz <i>et al</i> <sup>[92]</sup>	2010	64	Manual	L-MVO extent was IP of LVEF in model with IS and NT-proBNP	7 d	4 mo
Weir <i>et al</i> <sup>[112]</sup>	2010	100	Manual	L-MVO extent was only IP of LVR in model with TIMI post PCI, E-MVO, IS	4 d	6 mo
Ganame <i>et al</i> <sup>[25]</sup>	2009	98	Manual	L-MVO extent was IP of LVR in model with IS, troponin-I, TTR	2 d	6 mo
Nijveldt <i>et al</i> <sup>[111]</sup>	2008	60	Manual	L-MVO presence strongest IP of LVEF change and LVR in model with TTR, IS, LVEF, E-MVO	5 d	4 mo
Hombach <i>et al</i> <sup>[6]</sup>	2005	110	Manual	L-MVO extent IP for LVR in model with baseline IS, infarct transmural	6 d	225 d

MVO: Microvascular obstruction; IS: Infarct size; IP: Independent predictor; TTR: Time to revascularisation; LVR: Left ventricular remodelling; LVEF: Left ventricular ejection fraction; LVEDVI: Left-ventricular end diastolic volume index; LVESVI: Left-ventricular end systolic volume index.

is likely that this is because L-MVO reflects more severe microvascular and myocardial damage than E-MVO<sup>[28,36]</sup>. In most studies demonstrating the independent predictive value of L-MVO on LV function and remodelling, E-MVO was not a predictor<sup>[103,111,112]</sup>. L-MVO was a predictor independent of baseline IS<sup>[6,20,92,111-113]</sup>. Monocyte recruitment, crucial in cellular debris removal and scar formation, is impaired in areas of L-MVO in rat myocardium and may contribute to the adverse remodelling<sup>[114]</sup>.

### Prognostic importance of CMR MVO in AMI

An increasing evidence base demonstrates the strong medium-term prognostic value of L-MVO following STEMI, independent of IS and LVEF<sup>[6,36,37,116]</sup> (Table 10). The 2 studies featuring both L-MVO and E-MVO showed that L-MVO was a stronger prognostic indicator<sup>[36,37]</sup>. Regenfus *et al*<sup>[117]</sup> demonstrated that L-MVO was the strongest IP of long-term combined MACE at 6 years follow-up in a model including CMR-assessed LVEF and IS (HR 3.9), providing incremental prognostic value over traditional CMR markers of myocardial damage. A meta-analysis<sup>[118]</sup> (8 studies, *n* = 1025) demonstrated that L-MVO presence was the strongest independent predictor of medium-term combined MACE (HR 3.7) and

cardiovascular death (HR 13.2) at 2 years independent of IS and LV volumes.

The strong adverse prognostic value of L-MVO may be due to its negative effects on LV function, wall thickness and stiffness, and remodelling, and subsequent risk of heart failure and arrhythmias<sup>[6,20,92,111-113]</sup>.

## IMH IN AMI

### Background

IMH is a reperfusion injury occurring when restored blood flow into damaged capillaries extravasates erythrocytes into myocardium<sup>[121,122]</sup>. CMR-derived IMH was first described in reperfused canine myocardium on *ex-vivo* T2-weighted spin-echo (T2w-TSE) imaging with excellent agreement with histology (*r* = 0.96 for IMH extent)<sup>[123]</sup>.

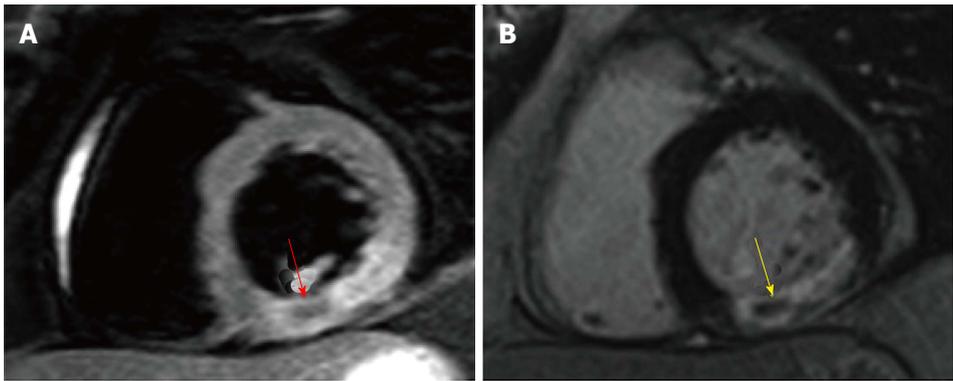

### CMR assessment of IMH in AMI

Paramagnetic haemoglobin breakdown products shorten T2 relaxation times<sup>[123,124]</sup>. IMH is seen as hypointense zones within hyperintense oedematous myocardium on T2w-TSE sequences. It shows good histological correlation in canine myocardium (*ex-vivo* MRI, *r* = 0.96)<sup>[123]</sup> and in an human autopsy case series (*in-vivo* MRI, *r* = 0.97)<sup>[124]</sup>.

**Table 10 Cardiovascular magnetic resonance studies illustrating the prognostic importance of late microvascular obstruction in acute myocardial infarction**

Ref.	Year	n	LGE method	Main findings	Time of prognostic CMR post STEMI	Follow-up
Regenfus <i>et al</i> <sup>[117]</sup>	2015	249	Manual	L-MVO extent strongest IP for MACE in model including IS, LVEF, TIMI pre and post PPCI and no. diseased vessels	3.7 d	72 mo

de Waha <i>et al</i> <sup>[120]</sup>	2012	438	Manual	L-MVO extent IP for combined MACE in model including IS, LV volumes (only other IP was LVEF). L-MVO/IS strongest IP in model including L-MVO extent, LVEF, IS, LV volumes	3 d	19 mo
de Waha <i>et al</i> <sup>[36]</sup>	2010	438	Manual	Presence and extent of L-MVO were strongest IPs for MACE and mortality in models with IS, LVEF, ST-res, TIMI-flow post PCI. E-MVO was not an IP	3 d	19 mo
Cochet <i>et al</i> <sup>[37]</sup>	2009	184	Manual	L-MVO strongest IP for MACE, in models including GRACE score, IS, LVEF. L-MVO stronger IP than E-MVO (OR 8.7 vs 2.5)	“3-7 d”	12 mo
Bruder <i>et al</i> <sup>[116]</sup>	2008	143	Manual	Only extent of L-MVO > 0.5% LV mass was IP for MACE; model included IS, LVEF, age, DM, sex	4.5 d	12 mo
Hombach <i>et al</i> <sup>[6]</sup>	2005	110	Manual	L-MVO IP for MACE ( <i>P</i> = 0.04) in model including LV end-diastolic volume and LVEF	6 d	268 d

MVO: Microvascular obstruction; LVEF: Left ventricular ejection fraction; IS: Infarct size; PCI: Percutaneous coronary intervention; MACE: Major adverse cardiovascular events; IP: Independent predictor.

**Figure 6 Intramyocardial haemorrhage on cardiovascular magnetic resonance.** A: T2-weighted spin-echo image with hypointensity corresponding with IMH within the hyperintense oedematous region in the inferior wall (red arrow); B: Corresponding LGE image showing co-localisation of IMH and L-MVO (yellow arrow). IMH: Intramyocardial haemorrhage; LGE: Late gadolinium enhancement; MVO: Microvascular obstruction.

IMH occurs exclusively in areas of L-MVO (*r*<sup>2</sup> for co-localisation approximately 0.9) (Figure 6)<sup>[25,33,125,126]</sup>.

Newer sequences based on direct quantification of T2 and T2\*<sup>[74,126-129]</sup> allow IMH to be quantified without the limitations of T2w-TSE imaging. Initial studies have been promising and shown that these sequences are reproducible and appear more sensitive and accurate than T2w-TSE for IMH detection<sup>[126,130,131]</sup>. O’Regan *et al*<sup>[126]</sup> showed that T2\* had 100% sensitivity for IMH detection compared to 90% for T2w-TSE, where the “gold standard” was co-localisation with L-MVO. In canines, T2\* in haemorrhagic infarcts closely correlates with iron levels on spectrometry, and T2\*-detected IMH co-localises with iron deposition on Perl’s staining<sup>[132]</sup> and extravasated erythrocytes on Haematoxylin-Eosin staining<sup>[128]</sup>. In pigs, regions of IMH on T2\* imaging showed vessel degeneration and iron deposition<sup>[8]</sup>.

There is a paucity of data on temporal changes in CMR-detected IMH. Mather *et al*<sup>[18]</sup> showed that IMH on

T2w-TSE was present in 33% of patients, with maximal extent at 48 h post PPCI and progressively resolution by 3 mo. Carrick *et al*<sup>[74]</sup> recently demonstrated that the incidence and extent of IMH on T2\* increased between 8 h and 3 d post PPCI. Its extent was significantly lower at 10 d and was seen in only 13% of patients at 7 mo. The authors also found that MVO was present in all patients with IMH, and its extent peaked earlier at 8 h suggesting that IMH is an ensuing reperfusion injury in regions of MVO.

**CMR IMH as a predictor of LV function and remodelling in AMI**

There is a small evidence base demonstrating that IMH is a strong univariate predictor of medium-term impaired LV function and remodelling, however multivariate analysis reveals mixed results, with some studies suggesting no incremental predictive value of IMH over MVO and IS (Table 11).

**Table 11 Cardiovascular magnetic resonance studies illustrating the importance of intramyocardial haemorrhage on left ventricular function and remodelling in acute myocardial infarction**

Ref.	Year	n	IMH CMR method	Main findings	CMR time post MI	Mean/median F/U CMR
Carrick <i>et al</i> <sup>[74]</sup>	2016	245	T2*	IMH strongest IP for LVR. IMH associated with lower LVEF and greater volumes	3 d	7 mo
Kidambi <i>et al</i> <sup>[115]</sup>	2013	39	T2w-TSE and T2*	IMH associated with attenuation of follow-up infarct strain	3 d	3 mo
Husser <i>et al</i> <sup>[33]</sup>	2012	304	T2w-TSE	IMH strongest IP for LVR in model with LVEF, IS, LV vol, L-MVO	6 d	189 d
Mather <i>et al</i> <sup>[131]</sup>	2011	48	T2w-TSE and T2*	IMH strongest IP of LVR in model with IS, LVEF, LVESV, E-MVO, MSI	2 d	3 mo
Beek <i>et al</i> <sup>[24]</sup>	2010	45	T2w-TSE	IMH was a univariate predictor of LVEF. However no prognostic significance beyond baseline LVEF and MVO in predicting final LVEF	5 d	4 mo
Bekkers <i>et al</i> <sup>[121]</sup>	2010	90	T2w-TSE	Acute MSI and LVEF increase at follow-up lowest if IMH present. But IMH no prognostic significance beyond MVO in predicting LVEF	5 d	103 d
O'Regan <i>et al</i> <sup>[126]</sup>	2010	50	T2*	IMH presence univariate predictor of LVEF and LV volumes. However only IS independently predicted LVEF	3 d	N/A
Ganame <i>et al</i> <sup>[25]</sup>	2009	98	T2w-TSE	IMH extent strongest IP of LVR in model with IS, E-MVO, Troponin-I, AAR, TTR, IS	2 d	4 mo

IS: Infarct size; IP: Independent predictor; LVR: Left ventricular remodelling; MVO: Microvascular obstruction; LVEF: Left ventricular ejection fraction; LVESVI: Left ventricular end systolic volume index; T2w-TSE: T2-weighted turbo spin-echo; AAR: Area at risk; MSI: Myocardial salvage index; N/A: Not applicable.

### Prognostic importance of CMR IMH in AMI

Multivariate analyses including IMH as a prognostic indicator also show mixed results. Amabile *et al*<sup>[133]</sup> demonstrated that IMH on T2w-TSE at 4 d post STEMI was the strongest independent predictor of MACE at 1-year (HR 2.8) in a model including LVEF, ST-resolution and L-MVO. Husser *et al*<sup>[33]</sup> showed that only LVEF and IMH extent on T2w-TSE independently predicted MACE at 140 wk follow-up in a model containing LV volumes, AAR, IS and L-MVO. However IMH and MVO extent showed strong correlation ( $r = 0.95$ ) and adding T2w imaging to a model containing LGE and cine imaging did not improve the predictive power for MACE, supporting a strong concordance of IMH and MVO. Eitel *et al*<sup>[125]</sup> demonstrated that IMH presence on T2w-TSE and LVEF < 53% were the only CMR independent predictors of MACE at 6 mo in a model with lone MVO. Carrick *et al*<sup>[74]</sup> recently demonstrated that IMH on T2\* mapping was the strongest independent predictor of cardiac death and heart failure hospitalisation at 830 d follow-up. In their multivariate model, L-MVO was not a predictor suggesting that IMH reflects extreme microvascular injury.

## ISCHAEMIC AAR AND MYOCARDIAL SALVAGE IN AMI

### Background

Oedema is seen in acute cardiac inflammation. In STEMI, it signifies reversible myocardial injury in the ischaemic cascade. The area of oedematous myocardium defines the ischaemic AAR supplied by the occluded IRA<sup>[61,134]</sup>.

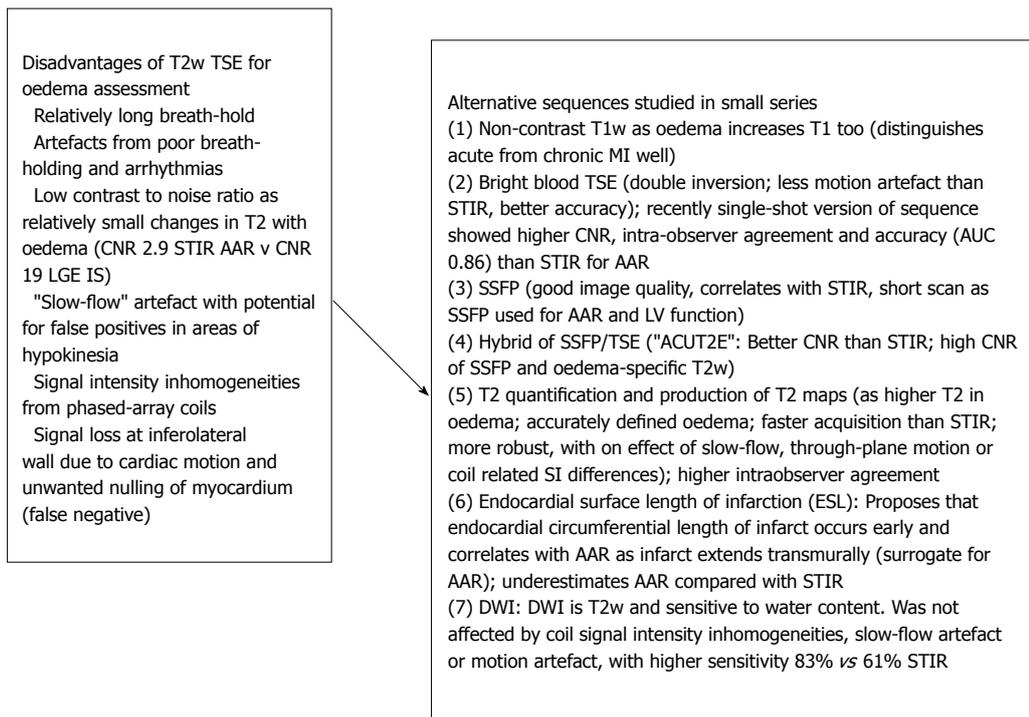

### CMR assessment of AAR and MSI in AMI

The T2 (transverse) relaxation time is increased by

regional water content<sup>[135]</sup>. T2w-TSE sequences illustrate oedema as hyperintensity<sup>[134]</sup> and are currently the mainstay of CMR oedema imaging. Most commonly used is the black-blood T2-weighted short-tau inversion-recovery sequence (T2w-STIR). This uses two initial inversion pulses to null moving blood. This is followed by a third inversion pulse, which nulls tissues with short T1 times (fat) to provide high contrast between blood (nulled) and myocardium<sup>[134,136]</sup>. T2w imaging of myocardial oedema is well-validated in animal studies assessing myocardial water volume on histological assessment<sup>[137]</sup> and fluorescent microspheres<sup>[77]</sup>. T2w oedema assessment is well-validated with SPECT<sup>[138-140]</sup> and angiographic markers of AAR (BARI<sup>[141]</sup>, APPROACHp<sup>[142]</sup> scoring). AAR on T2w can be assessed accurately for upto 1-wk post-PPCI unlike SPECT, which requires radionuclide administration during coronary occlusion and has higher spatial resolution and thus ability to detect subendocardial injury<sup>[138]</sup>.

However T2w-TSE imaging has inherent disadvantages that can compromise image quality and oedema detection. Upto 30% of datasets are non-analysable in studies<sup>[24,143,144]</sup>. New T2w sequences have been studied, with encouraging results (Figure 7).

The aim of prompt reperfusion is to limit IS by minimizing the conversion of reversibly injured myocardial cells (AAR) into necrotic, infarcted tissue (IS)<sup>[95,156]</sup>. Anterior STEMI typically results in larger IS due to the larger coronary bed supplied by the left anterior descending artery<sup>[14,80,82]</sup>. Hence a more accurate assessment of revascularisation strategies can be provided by adjusting IS for the AAR. The resulting myocardial salvage index (MSI) defines the proportion of reversibly injured tissue (AAR) that does not progress to infarction (IS, Equation 1, Figure 8). MSI is expressed as percentage of the initial AAR [0% is no salvage, 100% is complete salvage (aborted

**Figure 7 Alternative sequences to dark-blood T2-weighted turbo spin-echo for visualising oedema.** Left: Inherent disadvantages of T2w-TSE<sup>[134,144-147]</sup>; Right: Sequences compared with T2w-TSE: (1)<sup>[145]</sup>, (2)<sup>[141,142,144,148]</sup>, (3)<sup>[149,150]</sup>, (4)<sup>[144]</sup>, (5)<sup>[151,152]</sup>, (6)<sup>[153,154]</sup>, (7)<sup>[155]</sup>. T2w-TSE: T2-weighted turbo spin-echo; DWI: Diffusion-weighted imaging; AAR: Area at risk.

STEMI)]<sup>[157]</sup>.

Equation 1: Myocardial salvage index (MSI, %) = 100 × [(AAR-IS)/(AAR)].

Desch showed excellent intraobserver and inter-observer agreement for MSI assessment using T2w-STIR and LGE (coefficients of variation approximately 5.0%) and excellent test-retest reproducibility in a study of 20 acute STEMI patients<sup>[158]</sup>.

Other determinants of AAR include TTR<sup>[91,130,159-162]</sup>, extent of collateralised IRA territory flow<sup>[5,80,159,163]</sup>, TIMI-flow pre PPCI, LAD IRA and diabetes<sup>[91]</sup>.

Studies of the chronology of oedema suggest that it occurs very early in the ischaemic cascade. Abdel-Aty confirmed the presence of transmural oedema in canines on *in-vivo* T2w imaging at 28 min post LAD occlusion at which point LGE and troponin release were absent, indicating reversible injury<sup>[164]</sup>. Fernández-Jiménez *et al.*<sup>[165]</sup> however recently demonstrated a bimodal pattern of AAR extent in pigs with T2-mapping CMR and histological water quantification. They showed peak values at 2 h thought to be a direct result of reperfusion, followed by a return to baseline at 2 d and then progressive increase towards peak values at 7 d, with the latter peak felt due to water replacement of cleared cellular debris. Studies of temporal changes in AAR and MSI in humans are summarised in Table 12. Correct timing of oedema imaging is crucial in accurate calculation of AAR and MSI.

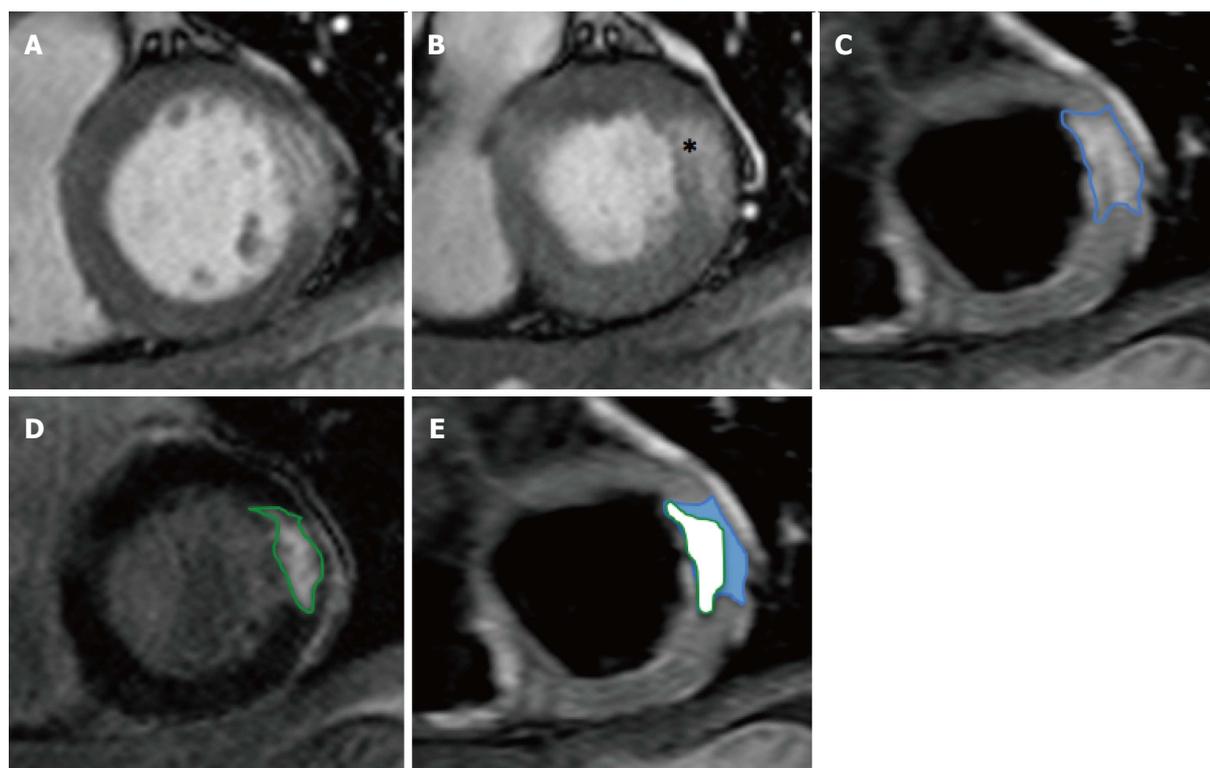

The near-resolution of oedema by 6 mo<sup>[5,18,21,91,138]</sup> allows distinction between acute and chronic infarcts when combined with LGE imaging.

### CMR MSI as a predictor of LV function and remodelling in AMI

Myocardial salvage is a strong univariate predictor of medium-term LV function<sup>[14,166,167]</sup> and adverse LV remodelling post STEMI<sup>[14,27,91,161]</sup>. Multivariate analysis demonstrates mixed results. MSI independently predicted LV remodelling in the work of Mather<sup>[131]</sup> (Table 13). However MSI was not a predictor once IS was added into multivariate models in studies by Monmeneu<sup>[91]</sup> and Masci<sup>[14]</sup>. This, in conjunction with the correlation between MSI and IS, and AAR and IS<sup>[26]</sup> questions whether MSI and IS are truly independent of each other in predicting LV remodelling and prognosis post STEMI. It could be argued that since MSI adjusts IS for the extent of AAR, it may have less inherent variability than IS. Since up to 30% of AAR datasets have been deemed non-diagnostic in previous studies<sup>[24,143,144]</sup>, this may impact on the robustness of MSI quantification whereas IS datasets are exceptionally rarely excluded based on image quality. It is not clear currently whether IS or MSI is the better measure of revascularisation success post PPCI.

### Prognostic importance of CMR MSI in AMI

Historically, the prognostic value of MSI was demonstrated using SPECT. Ndrepa first showed that MSI was the strongest independent predictor of 6-mo mortality<sup>[168]</sup>. MSI was an independent prognostic indicator in the medium term post STEMI in two studies. Although both studies were from the same patient cohort, they have both been

**Figure 8** Calculation of salvaged myocardium. A: SSFP end-diastolic cine image; B: SSFP end-systolic cine image showing hypokinetic basal anterolateral segment (\*); C: T2w-STIR image showing oedema (AAR) in anterolateral wall consistent with circumflex artery occlusion; D: Corresponding LGE image with near-transmural infarction; E: Calculation of salvaged myocardium in blue. SSFP: Steady-state free precession; T2w-STIR: T2-weighted short-tau inversion-recovery sequence; LGE: Late gadolinium enhancement.

**Table 12** Temporal changes in cardiovascular magnetic resonance-derived area at risk and myocardial salvage index in acute myocardial infarction

Ref.	Year	n	CMR timepoints post STEMI	AAR, IS method	Main findings
Mather <i>et al</i> <sup>[18]</sup>	2011	48	2 d → 1 wk → 30 d → 3 mo	> 2SD STIR, > 2SD LGE	AAR reduction at successive timepoints, 1-3 mo (-75%). No change MSI at d2 or 1 wk as IS and AAR decreased proportionally
Dall'Armellina <i>et al</i> <sup>[21]</sup>	2011	30	2 d → 1 wk → 2 wk → 6 mo	> 2SD T2p-BB, > 2SD LGE	100% had oedema at d2. AAR stable over 1st week (37% vs 39% LVM). Decreased by 2 wk and nearly resolved at 6 mo
Carlsson <i>et al</i> <sup>[38]</sup>	2009	16	1 d → 1 wk → 6 wk → 6 mo	Manual STIR, and LGE	AAR at all timepoints. AAR stable in 1st week, correlated with 1 wk SPECT. Decrease by 1 mo (10% LVM), nearly gone by 6 mo
Ripa <i>et al</i> <sup>[5]</sup>	2007	58	2 d → 1 mo → 6 mo	Manual STIR and LGE	All had oedema at d2. AAR decreased at all time points. No data on MSI in this study

AAR: Area at risk; MSI: Myocardial salvage index; AAR, LGE method: SD: Standard deviations; STIR: T2-weighted short-tau inversion recovery imaging; T2p-SS-BB: T2-prepared single-shot bright-blood; 3T: 3.0 tesla field strength; IS: Infarct size.

included in Table 14 due to their differing primary findings.

## T1, T2 AND T2\* QUANTIFICATION AND MAPPING IN AMI

The current mainstay of LGE and T2w techniques for the detection of infarct and oedema rely on semi-quantitative threshold-based quantification methods using arbitrary SI cut-offs compared to user-defined regions of interest, automated algorithms or are based on manual planimetry. There is currently no consensus on the optimal quantification method for IS or AAR using these

sequences. This can lead to subjectivity and dependence upon optimal nulling of normal myocardium and thus potential for error. In addition, commonly used T2w-TSE sequences suffer from non-diagnostic image quality in upto 30% of patients<sup>[24,143,144]</sup>.

T1, T2 and T2\* quantification present an exciting and complementary approach to LGE and T2w imaging. Developed by Messroghli *et al*<sup>[169]</sup> in 2003, their use in MI research has accelerated over the last 5 years. They allow not only the location and extent of infarction, oedema, MVO and IMH to be determined from subsequent parametric myocardial maps, but also the severity of these pathologies to be assessed through the magnitude

**Table 13 Cardiovascular magnetic resonance studies showing the importance of myocardial salvage index on left ventricular function and remodelling in acute myocardial infarction**

Ref.	Year	n	AAR, IS method	Main findings	CMR timepoint post STEMI	Follow-up
Mather <i>et al</i> <sup>[131]</sup>	2011	48	> 2SD STIR, > 2SD LGE	MSI was IP for LVR (OR 0.95) in model including LV volumes, LVEF, IS, IMH, MVO	2 d	3 mo
Monmeneu <i>et al</i> <sup>[91]</sup>	2012	118	> 2SD STIR, > 2SD LGE	MSI univariate predictor of LVR and final LVEF. However not IP of LVR in model with LVESVI, IS, no. transmural segs	6 d	6 mo
Masci <i>et al</i> <sup>[14]</sup>	2011	260	> 2SD STIR, > 5SD LGE	MSI strong univariate predictor of LVR and final LVEF. However not IP in model including IS, MVO	1 wk	4 mo
Masci <i>et al</i> <sup>[26]</sup>	2010	137	> 2SD STIR, > 5SD LGE	MSI strongest IP for LVR However IS and MSI (r = -0.72) and IS and AAR (r = 0.85) correlated	1 wk	4 mo

IS: Infarct size; IP: Independent predictor; LVR: Left ventricular remodelling; MVO: Microvascular obstruction; LVEF: Left ventricular ejection fraction; LVESVI: Left-ventricular end systolic volume index; STIR: T2-weighted short-tau inversion-recovery; LGE: Late gadolinium enhancement.

Ref.	Year	n	AAR, IS method	Main findings	CMR timepoint post STEMI	Follow-up
Eitel <i>et al</i> <sup>[24]</sup>	2011	208	> 2SD -STIR, > 5SD LGE	MSI was only CMR-based IP of mortality in model with age, IS, MVO, LVEF, TIMI- post PPCI, diabetes, age (IS not IP). MSI not IP of MACE (only IS, LVEF, age were)	3 d	19 mo
Eitel <i>et al</i> <sup>[161]</sup>	2010	208	> 2SD STIR, > 5SD LGE	MSI was only IP for MACE and mortality in model including LVEF, MVO, IS, ST-resolution and TIMI-grade post PCI	3 d	6 mo

IS: Infarct size; PCI: Percutaneous coronary intervention; MACE: Major adverse cardiovascular events; IP: Independent predictor; MVO: Microvascular obstruction; LVEF: Left ventricular ejection fraction.

of values obtained<sup>[170,171]</sup>. These methods are not reliant on reference regions of interest and do not suffer from T2w-TSE artefacts.

**T1 mapping (longitudinal relaxation)**

T1 relaxation curves allow calculation of the T1 time (time taken for recovery of 63% of longitudinal magnetization). The currently used curve-fitting sequences used include MOLLI (Modified Look-Locker Inversion Recovery), ShMOLLI (Shortened MOLLI), SASHA (SATuration recovery single-SHot Acquisition) and SAPHIRE (SATuration Pulse Prepared Heart rate independent Inversion REcovery)<sup>[172]</sup>. Infarcted and oedematous myocardium demonstrate prolonged pre-contrast T1 values and reduced post-contrast T1 values compared with normal myocardium, allowing infarct visualisation and quantification<sup>[169,170,173,174]</sup>. Messroghli showed that this technique had high test-retest reproducibility<sup>[175]</sup>, was stable within the range of heart rates commonly seen in clinical practice and showed comparable sensitivity for IS quantification compared with LGE<sup>[169,173,176]</sup>. T1 values within the infarct core were recently shown to demonstrate a strong inverse correlation with L-MVO extent, incidence of LV remodelling and all-cause mortality at 2.5 years<sup>[177]</sup>.

**T2 mapping (transverse relaxation)**

T2w images are generated using a T2-SSFP sequence with log-transformed curve-fitting T2 quantification, with

different T2 preparation (TE) times. T2 mapping has shown excellent reproducibility and no effect of slow-flow, through-plane movement, SI loss, or effects of coil SI inhomogeneities<sup>[151,178]</sup>. T2 mapping accurately assessed oedema in 96% of patients (good image quality in 100%), whereas T2w-STIR detected oedema in only 67% of patients (15% non-diagnostic 15%)<sup>[151]</sup>. High observer agreement and close agreement between T1 (r<sup>2</sup> = 0.94) and T2 maps (r<sup>2</sup> = 0.96), and fluorescent microspheres for AAR detection was seen in canine myocardium<sup>[179]</sup>.

**T2\* mapping (transverse relaxation in presence of field inhomogeneities)**

T2\* mapping allows visualisation and quantification of IMH due to the presence of paramagnetic haemoglobin breakdown products. A cut-off value of < 20 ms has been used to define the presence of IMH<sup>[180]</sup>. Although the evidence base for T2\* mapping in assessing IMH is currently limited, O'Regan demonstrated that it has greater sensitivity than T2w-STIR imaging (100% vs 90%) for IMH. Kali showed good correlation between *in-vivo* T2\* and histological assessment of IMH and iron levels in canine myocardium<sup>[127,128]</sup>. T2\* mapping may improve the specificity of IMH detected on CMR<sup>[131]</sup>.

T1, T2 and T2\* surrogate markers hold promise for improving the accuracy of detection of infarct, oedema and IMH respectively, and further improving statistical power of STEMI studies. However, due to the importance

of protocol standardisation, these techniques are rarely used in multicentre studies at present.

## RIGHT VENTRICULAR INVOLVEMENT IN AMI

### CMR assessment of right ventricular infarction in AMI

CMR is the gold standard imaging modality for the assessment of right ventricular (RV) volumes, function, oedema<sup>[181]</sup> and infarction (RVI)<sup>[182]</sup>. CMR identifies RVI with greater sensitivity than echocardiography, ECG (V4<sub>R</sub> ST-segment elevation) and clinical examination<sup>[183,184]</sup> and demonstrates RV L-MVO<sup>[185,186]</sup>. There is good interobserver and intraobserver agreement for the identification of RV oedema ( $\kappa = 0.62$ ,  $\kappa = 0.62$ , respectively) and very good agreement for RVI ( $\kappa = 0.70$ ,  $\kappa = 0.70$ , respectively)<sup>[181]</sup>.

The high MSI in RVI often  $> 90\%$ <sup>[187,188]</sup> is thought to be due the relatively low RV nutrient needs, direct endocardial oxygen diffusion and good collateral blood supply<sup>[188,189]</sup>.

### Prognostic importance of CMR-derived right ventricular infarction in AMI

RVI confers adverse short-term prognosis, with a large meta-analysis ( $n = 7136$ ) demonstrating that RVI on ECG, echocardiography or radionuclide imaging predicted 30-d mortality and in-hospital MACE<sup>[190]</sup>. Shah demonstrated the prognostic importance of right ventricular infarction on imaging, where RVEF  $< 38\%$  on radionuclide ventriculography post STEMI was a strong independent predictor of 1-year mortality<sup>[191]</sup>. Right ventricular infarction is a strong independent predictor of medium to long-term prognosis in a small number of CMR

**Table 17 Key studies illustrating the independent predictive value of cardiovascular magnetic resonance markers for prognosis**

CMR marker	Ref.	Year	n	CMR quantification	Main findings	Acute CMR time	Follow-up
IS	Husser <i>et al</i> <sup>[96]</sup>	2013	250	> 2SD	Extent of transmural infarction was only IP for MACE	7 d	163 wk

T1	Carrick <i>et al</i> <sup>[177]</sup>	2016	300	T1 map, > 2SD STIR, > 5SD	Infarct core T1 inverse association with risk of mortality and heart failure hospitalisation, in model with LVEF, infarct T2, IMH. Similar prognostic as L-MVO	2 d	2.5 yr

Criteria: Individual studies with  $n \geq 100$  and follow-up CMR  $\geq 6$  mo follow-up. IS: Infarct size; L-MVO: Late microvascular obstruction; IMH: Intramyocardial haemorrhage; MSI: Myocardial salvage index; SD: Standard deviations; STIR: T2-weighted short-tau inversion recovery; LGE: Late gadolinium enhancement; IP: Independent predictor; LV: Left ventricular; LVEF: Left ventricular ejection fraction; AAR: Area at risk; LVEDVI: Left ventricular end-diastolic volume; CK: Creatine kinase; T2w-TSE: T2-weighted turbo spin echo; MACE: Major adverse cardiovascular events; CV: Cardiovascular.

studies (Table 15).

### WHEN IS THE OPTIMAL TIME TO PERFORM CMR ASSESSMENT IN MI?

In acute STEMI, IS, AAR and MSI are best imaged at 7 d post PPCI due to overestimation of necrosis on LGE, and IS at 7 d best predicts final IS, LV remodelling and function and prognosis<sup>[5-7,9,18,20,21]</sup>. Human studies suggest that AAR is stable during the first week<sup>[21,138]</sup>. Although Fernández-Jiménez *et al*<sup>[165]</sup> demonstrated a bimodal AAR peak in pigs, their drop in AAR extent on T2w CMR at 2 d post-reperfusion may be due to a high incidence of IMH in pigs and peak IMH extent at 2 d<sup>[74]</sup>.

Indeed the drop in AAR extent on the gold standard of histological water analysis in their study at 2 d was much less pronounced, and at 7 d AAR extent had returned to stable peak levels. In addition, studies demonstrating close agreement between T2w-derived AAR and the reference non-invasive modality of SPECT<sup>[138,139]</sup> were undertaken at 7 d post STEMI. MVO and IMH extent peak at 48 h then decrease<sup>[18]</sup> but are present at 7 d<sup>[9,18]</sup>. Although undertaking CMR at 7-d may potentially underestimate MVO and IMH extent<sup>[9,18,74]</sup>, this may be minimised by expressing MVO and IMH extent as a proportion of IS rather than LV mass, to correct for the corresponding reduction in IS. Thus, acutely post STEMI for the assessment of IS, MSI, MVO and IMH, imaging at 7 d may provide the best compromise in relation to their

temporal changes<sup>[5-7,9,18,20,21]</sup> for accurate quantification and prediction of LV function, remodelling and prognosis. This needs to be balanced with contemporary clinical practice where patients are typically discharged at 3-4 d post-PPCI, and the risk of early attrition. Using final IS at follow-up as a primary outcome risks underestimating potential differences in treatment strategies due to greater infarct resorption with the larger infarcts.

Data on the chronology of IS suggests that infarct resorption is essentially complete by 3 mo post MI<sup>[9,18,20,74]</sup>. However a key objective of follow-up CMR is to assess LV geometry and remodelling and hence must allow the relatively slower adaptations of ventricular volumes (approximately 12 mo), compared with changes in IS and LVEF to complete. LVEF shows no significant change after 1-mo post STEMI. Follow-up CMR at 3 and 6-mo may fail to provide an accurate assessment of LV volumes and remodelling. The evidence base suggests that in order to allow completion of the trio of IS, LVEF and LV volumetric changes, follow-up CMR should be performed at 12-mo post STEMI<sup>[5,7,18,20,21]</sup>. When correlating CMR and clinical outcomes, the longer timepoint of 12-mo also permits more reliable clinical follow-up.

Standardisation of LGE, AAR and IMH sequences and quantification methods is equally important in light of newer T1, T2 and T2\*-mapping sequences and inherent image quality issues associated with T2w-TSE.

## CONCLUSION

Contrast-enhanced CMR offers robust, validated and reproducible surrogate markers, providing an accurate representation of pathophysiology, assessment of myocardial function and injury, and predictive value for medium to long-term LV function, remodelling and prognosis following PPCI for STEMI. Tables 16 and 17 summarise the key prospective studies illustrating the independent predictive value of CMR markers for LV remodelling (studies where  $n > 100$ , follow-up CMR  $\geq 3$  mo post PPCI) and prognosis (studies where  $n > 100$ ,  $\geq 6$  mo follow-up) respectively.

In the acute phase, CMR can be performed accurately for up to 7 d post PPCI. CMR delivers no radiation to the patient and this makes it ideal for serial studies. The multimodal nature of CMR allows a multiparametric study of cardiac function, structure and volumes within a single study, which can be undertaken within approximately 45 min in the majority of patients. It is likely that CMR will become the mainstay of cardiac imaging, providing an important role in risk stratification and treatment post STEMI. Focus needs to be continued in translating findings on the prognostic importance of surrogate markers to development of therapeutic targets post STEMI.

### Abstract

Physical exercise is one of the most effective methods to help prevent cardiovascular (CV) disease and to promote CV health. Aerobic and anaerobic exercises are two types of exercise that differ based on the intensity, interval and types of muscle fibers incorporated. In this article, we aim to further elaborate on these two categories of physical exercise and to help decipher which provides the most effective means of promoting CV health.

**Key words:** Cardiovascular; Exercise; Training; Aerobic; Anaerobic

Aerobic vs anaerobic exercise training effects on the cardiovascular system. *World J Cardiol* 2017; 9(2): 134-138 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/134.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.134>

### INTRODUCTION

More than 250000 yearly deaths in the United States are

attributed to cardiovascular (CV) disease resulting from a lack of physical activity. On the other hand, physical inactivity is estimated to cause 30% of ischemic heart disease<sup>[1]</sup>. The association between physical inactivity and CV disease gained a foothold in the medical community in 1996, when the American Heart Association (AHA) published information advocating the benefit of physical exercise in regards to improvements in hemodynamic, hormonal, metabolic, neurological and respiratory function<sup>[2]</sup>. As the association between physical inactivity and the increased risk of CV morbidity solidified, further data and studies supported the advantages of exercise on physical well-being. The 2010 recommendations by the World Health Organization (WHO) provided activity recommendations based on three different age groups: Ages 5-17, 18-64, and > 64 years of age. In the age group of 5-17 years, individuals should accrue at least 60 min of moderate activity daily. Those in the group of 18-64 years should perform at least 150 min of moderate activity or at least 75 min of vigorous activity throughout the week. Finally, individuals above the age of 65 years are recommended similar length and intensity exercise programs as the prior group, but with a focus on activities to help enhance balance and to prevent falls<sup>[3]</sup>.

The inherent advantages of physical exercise stem from an increase in the cardiac output and an enhancement of the innate ability of muscles to extract and to utilize oxygen from the blood. This benefit is further compounded by the benefit physical exercise has on high-density lipoprotein cholesterol (HDL-C)<sup>[4]</sup>, adipose tissue distribution<sup>[5]</sup>, increased insulin sensitivity<sup>[6]</sup>, improved cognitive function<sup>[7]</sup>, enhanced response to psychosocial stressors<sup>[8]</sup>, as well as determent of depression<sup>[9]</sup>. With the benefit of physical exercise well established, the question remains which type of exercise provides the most effective and efficient means to help deter CV disease.

A recent meta-analysis published showed a decrease in the risk of all CV outcomes and diabetes mellitus incidence with increasing levels of physical activities<sup>[10]</sup>. Another meta-analysis suggested that high level of leisure time physical activity had a beneficial effect on CV health by reducing the overall risk of incident CHD and stroke among men and women by 20% to 30%, while moderate level of occupational physical activity might reduce 10% to 20% risk of CVD<sup>[11]</sup>.

Furthermore, cardiac rehabilitation, which is physical exercise based, is a promising field which showed a favorable outcome among patients with heart failure and post-CVD events<sup>[12,13]</sup>.

## AEROBIC EXERCISE

The American College of Sports Medicine (ACSM) defines aerobic exercise as any activity that uses large muscle groups, can be maintained continuously and is rhythmic in nature<sup>[10]</sup>. As the name implies, muscle groups activated by this type of exercise rely on aerobic metabolism to extract energy in the form of adenosine triphosphate (ATP) from amino acids, carbohydrates and fatty acids.

Examples of aerobic exercise include cycling, dancing, hiking, jogging/long distance running, swimming and walking. These activities can best be accessed *via* the aerobic capacity, which is defined by the ACSM as the product of the capacity of the cardiorespiratory system to supply oxygen and the capacity of the skeletal muscles to utilize oxygen<sup>[14]</sup>. The criterion measure for aerobic capacity is the peak oxygen consumption (VO<sub>2</sub>), which can be measured either through graded exercise ergometry or treadmill protocols with an oxygen consumption analyzer or *via* mathematical formulas. The value of peak VO<sub>2</sub> can be appreciated by a study performed by Vaitkevicius *et al*<sup>[15]</sup>, in which the VO<sub>2max</sub> was calculated along with other dimensions, to conclude that higher physical conditioning status was directly correlated with reduced arterial stiffness.

Various studies have been published that prove the advantages of aerobic exercise in reversing and preventing CV disease. In 2002, Wisløff *et al*<sup>[16]</sup> were the first to show the benefit of aerobic training in the myocardium after an ischemic event. Their study was performed on adult female Sprague-Dawley rats, which were placed into groups categorized based on induced myocardial infarctions (MI) with and without exercise and controls with and without exercise. Their results showed a 15% reduction in the left ventricle (LV) hypertrophy post-infarction, as well as 12% and 20% decreases in myocyte length and width, respectively, with aerobic exercise. Furthermore, a 60% improvement was noted in myocardial contractility in subjects with a MI who were assigned to the training group, suggesting enhanced myocardial Ca<sup>2+</sup> sensitivity. They were able to conclude the beneficial effects of aerobic training on cardiac remodeling and myocardial contractility<sup>[16]</sup>.

The effect of aerobic exercise were confirmed in human subjects when Wisløff *et al*<sup>[17]</sup> published another study five years later, which incorporated human subjects with post-MI heart failure. Subjects were enrolled in aerobic interval training (AIT), moderate continuous training (MCT) or a control group. The AIT group showed a 46% increase in peak VO<sub>2</sub>, which correlated with a 60% increase in the maximal rate of Ca<sup>2+</sup> reuptake in the sarcoplasmic reticulum in the skeletal muscles. Additionally, cardiac remodeling was evident in humans, much like the rat subjects in the previous study, as LV diameters declined and LV volumes increased in both the diastolic and systolic phases. Moreover, systolic function was noted to increase by 35% in the AIT group<sup>[17]</sup>, thereby further strengthening the advantages of aerobic exercise.

Furthermore, aerobic exercise has been shown to have a positive impact on other dimensions of CV health. Several studies have shown that aerobic exercise improves the lipid profile, particularly increasing the HDL-C<sup>[18]</sup>. In an Australian study, aerobic exercise led to a small but statistically significant reduction in total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) ranging in a span of 0.08 mmol/L to 0.10 mmol/L. They also showed an increase in HDL-C with their aerobic exercise program of about 0.05 mmol/

L<sup>[19]</sup>. Similar results have been documented in children and adolescents, as well<sup>[20]</sup>. In a meta-analysis conducted by Kelley *et al*<sup>[21]</sup>, it was concluded that aerobic exercises contributed to a statistically significant 9% increase in HDL-C and an 11% decline in TG, but no statistically significant changes in TC and LDL-C.

A positive correlation between biochemical signal markers, such as endothelin-I (ET-1) and aerobic exercise was recently speculated by several studies. Vascular endothelial cells produce ET-1, which functions as a vasoconstrictor<sup>[22]</sup> and promoter of atherosclerosis<sup>[23]</sup>. Maeda *et al*<sup>[24]</sup> were able to demonstrate a statistically significant positive linear correlation of increasing age with rising levels of ET-1. They were also able to exhibit a visible reduction in ET-1 levels after a 3 mo aerobic exercise regimen<sup>[24]</sup>.

While aerobic exercise appears to have some beneficial effects, its contribution is limited on frequency and quantity. A very recent publication by a Danish group was able to represent what they called a "U shaped association" between aerobic exercise and mortality. Their research quantified 1 to 2.4 h of exercise over 2 to 3 times per week as the optimal quantity and frequency standard of aerobic exercise to promote improved health. Interestingly, they quantified any amount above that standard as being indifferent to the mortality risk, as that of sedentary individuals<sup>[25]</sup>.

## ANAEROBIC EXERCISE

Anaerobic exercise has been defined by the ACSM as intense physical activity of very short duration, fueled by the energy sources within the contracting muscles and independent of the use of inhaled oxygen as an energy source<sup>[14]</sup>. Without the use of oxygen, our cells revert to the formation of ATP *via* glycolysis and fermentation. This process produces significantly less ATP than its aerobic counterpart and leads to the build-up of lactic acid. Exercises typically thought of as anaerobic consist of fast twitch muscles and include sprinting, high-intensity interval training (HIIT), power-lifting, *etc.* Sustained anaerobic metabolism, in other words, anaerobic exercise, causes a sustained increase in lactate and metabolic acidosis and this transition point is referred to anaerobic threshold (AT)<sup>[26]</sup>. AT can be directly measured *via* frequent blood samples measuring the blood lactate level during a graded-exercise regimen. Once the blood lactate values are plotted, the point at which the curve makes a sudden sharp incline represents the AT. Other methods include portal lactate analyzers and mathematical formulas involving heart rate (HR).

Similar to aerobic exercise, anaerobic exercise may exert a potentially beneficial influence on the CV system. In a Turkish study completed by Akseki Temür *et al*<sup>[27]</sup>, the effects of anaerobic exercise were evaluated with a member of the natriuretic peptide family, known as C-type natriuretic peptide (CNP). CNP is synthesized by the endothelium and offers a protective effect through its effects on the vascular tone of blood vessels,

as well as exerting antifibrotic and antiproliferative properties. It produces a hyperpolarization effect on the smooth muscle layer of blood vessels, which causes vasodilatation<sup>[28]</sup>. CNP has also been reported to exert its nonproliferative effects on cardiac fibroblasts to help prevent cardiac aging through LV fibrosis *via* the cyclic guanosine monophosphate (cGMP) pathway<sup>[29]</sup>. In this study, twelve healthy young male subjects were divided into two groups based on their previous history of exercise. Once categorized into groups, the subjects were asked to participate in a thirty second high intensity exercise program, which encompassed the anaerobic exercise factor. Blood samples were obtained from the subjects before exercise and then one minute, five minutes and thirty minutes after exercise and were tested for the levels of aminoterminal proCNP (NT-proCNP), a biologically inactive peptide of CNP. The results showed a statistically significant increase of NT-proCNP level in the five minute mark post-exercise in the physically active group after anaerobic exercise.

Similar to aerobic exercise and their favorable effect on lipid metabolism, anaerobic exercises have been shown to have a positive influence on the lipid profile. A small European study composed of 16 obese subjects was able to show the increased benefits of an aerobic workout followed by anaerobic training, as compared to aerobic training alone. Subjects who underwent core training with both aerobic and anaerobic exercises showed a larger reduction in non-esterified fatty acids. The same group was also found to have the greatest reduction in their body mass index (BMI)<sup>[30]</sup>.

There are speculations about disadvantages of such an exercise program. One such shortcoming was brought to light by an Iranian study published by Manshouri *et al*<sup>[31]</sup>, which concluded that anaerobic training led to a significant reduction in human growth hormone (HGH). It has long been theorized that long-standing HGH deficiencies can attribute to CV morbidity and mortality through the development of premature atherosclerosis. HGH deficiency has been shown to result in higher BMI and TG, lower concentrations of HDL-C, as well as the development of hypertension (HTN)<sup>[32]</sup>. Furthermore, cardiac structure is affected in HGH deficient subjects, as manifested by reduced LV posterior wall thickness, smaller LV mass index and compromised LV ejection fraction (LVEF)<sup>[33]</sup>. The exact mechanism of action for such changes remains to be determined.

## CONCLUSION

With the high incidence of CV disease worldwide, it is an irrefutable notion that exercise helps deter CV morbidity and mortality. Both aerobic and anaerobic exercises have unique and collective positive correlations towards improved CV health. Despite all the research, further studies are still warranted to delve further into the impact that both aerobic and anaerobic exercise may have on human physiology to unequivocally determine if there is superiority of one type of exercise over

another.

### Abstract

Non-valvular atrial fibrillation is associated with a significantly increased risk of embolic stroke due to blood clot forming predominantly in the left atrial appendage

(LAA). Preventive measures to avoid embolic events are permanent administration of anticoagulants or surgical closure of the LAA. Various clinical trials provide evidence about safety, effectiveness and therapeutic success of LAA occlusion using various cardiac occluder devices. The use of such implants for interventional closure of the LAA is likely to become a valuable alternative for stroke prevention, especially in patients with contraindication for oral anticoagulation as safety, clinical benefit and cost-effectiveness of LAA occlusion has recently been demonstrated.

**Key words:** Left atrial appendage; Thrombus; Occlude; Stroke

**Core tip:** Non-valvular atrial fibrillation is associated with increased risk of embolic stroke. To date, risk-based anticoagulation is the cornerstone to avoid this. However, several patients have got absolute or relative contraindication to this and thus are undertreated. For these patient population the implantation of a local left atrial appendage occluder might be an alternative.

Akin I, Nienaber CA. Left atrial appendage occlusion: A better alternative to anticoagulation? *World J Cardiol* 2017; 9(2): 139-146 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/139.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.139>

### INTRODUCTION

The left atrial appendage (LAA) is an external protrusion of the left atrium located next to the pulmonary trunk<sup>[1,2]</sup>. Compelling evidence points to the LAA as the primary origin of thrombus formation particular in the presence of non-valvular atrial fibrillation (AF); since the major risk of non-valvular AF to suffer from ischemic stroke,

the LAA has drawn much attention in the context of stroke prevention<sup>[3-5]</sup> considering missing awareness and unrecognized AF prior to strokes<sup>[6]</sup>. Thus, the current approach for stroke prevention in patients with non-valvular AF of risk-adjusted prevention *via* oral anticoagulants (OAC) or antiplatelet agents<sup>[7,8]</sup> may be challenged by elective LAA occlusion in selective patients<sup>[3,4,9-12]</sup>. In the past, physical LAA closure required either surgical excision or exclusion by suture or stapler<sup>[10,13]</sup>. With the introduction of cardiac occluder devices open surgery is not required any more and redundant for this purpose<sup>[14-16]</sup>. This review summarizes current knowledge of LAA occlusion as an emerging alternative to chronic OAC therapy for non-valvular AF patients at risk for embolic strokes.

## ANATOMY OF THE LAA

The function of the LAA is not fully understood but it has been linked to secretion of the hormone "atrial natriuretic factor" (ANF) and, hence, could be involved in the regulation and homeostatic control of water, salt and fat<sup>[17,18]</sup>. Regardless, the anatomy of the LAA is highly diverse and was classified into four different morphological types; "chicken wing" was the most frequently identified type (48%) followed by "cactus" (30%), "windsock" (19%), and "cauliflower" (3%)<sup>[19]</sup>. The "chicken wing" type has a dominant lobe, which may have secondary lobes or twigs, and is bent in the proximal or middle part or even folds back on itself at some distance from the orifice. The "cactus" type has a dominant central lobe with secondary lobes extending in both superior and inferior directions, whereas the primary structure of the "windsock" type is a dominant lobe with variation in the location and number of secondary or even tertiary lobes. Lastly, the "cauliflower" type has a short overall length with more complex internal characteristics, lacks a dominant lobe but has variable number of lobes and a more irregular shape of the LAA orifice. Previous studies indicate that the "chicken wing" type poses the lowest risk for embolism in contrast to the "cauliflower" type, which, notably, exhibits the highest degree of structural complexity<sup>[20]</sup>. However, due to the complex anatomy of the LAA, it is difficult to correctly assess length, branches and courses, as well as thrombus formation by transesophageal echocardiography (TEE) and it was demonstrated that the outcome of this visualization is dependent on the selection of the imaging plane<sup>[21]</sup>.

## LIMITATIONS OF ORAL ANTICOAGULANT THERAPY

The current gold standard for stroke prevention in patients with non-valvular AF is the oral administration of anticoagulants to reduce the risk of thrombus formation and prevent any embolic events<sup>[7,8]</sup>. Chronic anticoagulation is carried out by traditional and novel

oral anticoagulants (NOACs) also called directly acting oral anticoagulants (DOACs). Traditional anticoagulants include heparins and coumarins (vitamin K antagonists) of which warfarin is the most common. NOACs are inhibitors of coagulation factors such as factors IIa (*e.g.*, dabigatran) or factor Xa (*e.g.*, rivaroxaban, apixaban and edoxaban)<sup>[22-25]</sup>. However, chronic OAC therapy is not recommended if contraindications are present or potential interference with other therapies. Moreover, difficulties to adjust treatment, dietary restriction, low compliance or even refusal of the patient to follow treatment protocol are considered contraindication for OAC<sup>[10,22-26]</sup>. Therefore, alternative strategies for stroke prevention in patients with AF are required.

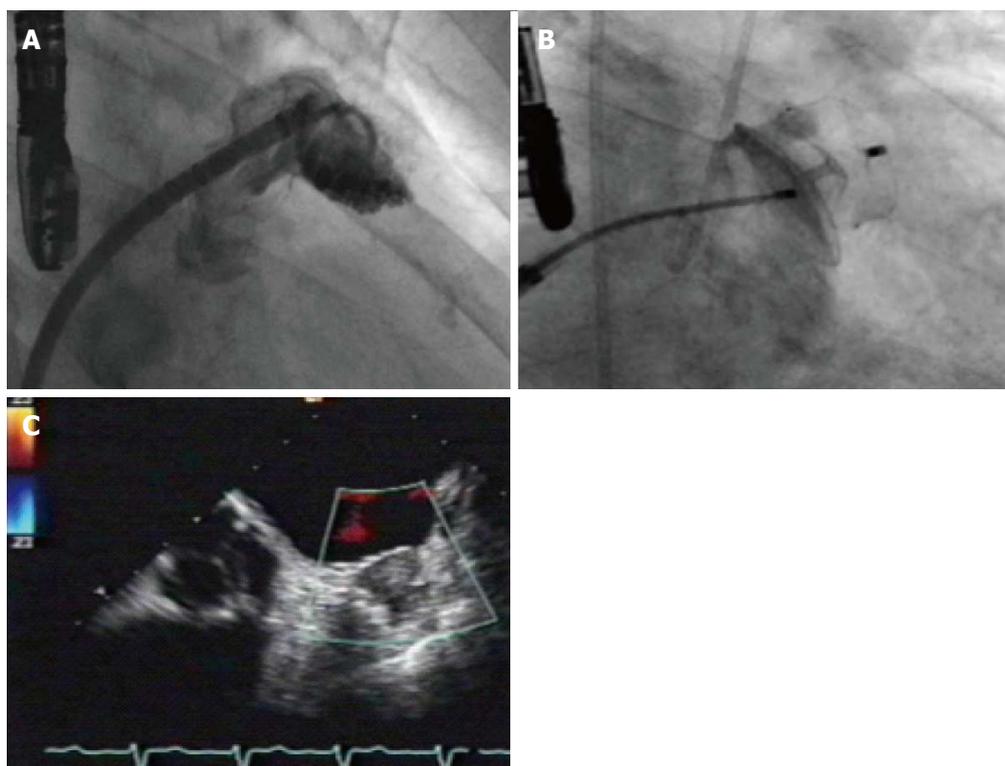

## APPROACHES FOR CLOSURE OF THE LAA

There are two fundamental approaches beyond anticoagulation to avoid emboli in patients with non-valvular AF, *e.g.*, surgical excision of the LAA or exclusion by suture line, stapler or cardiac plug<sup>[10,13]</sup>. Before introduction of cardiac occluder for LAA closure, surgical excision was the superior method while LAA closure requires either suture line<sup>[10,13]</sup>. However, a surgical excision is not risk free and may cause bleeding<sup>[27]</sup>. Nonetheless, surgical excision is still an option mostly in conjunction with other cardiac surgery<sup>[10,27]</sup>. In recent years, an alternative approach for LAA closure was established by sealing the orifice of the LAA with an occluder. Such a LAA occlusion was performed 2001 for the very first time using the PLAATO system which has been taken off market<sup>[28,29]</sup>. The current generation of occluders are the Amplatzer™ Cardiac Plug (ACP), Amplatzer Amulet™ from St. Jude Medical and the Watchman™ device from Boston Scientific<sup>[29,30]</sup>. In addition, a small number of novel devices have been mentioned and applied in the last few years such as the WaveCrest™ device and the Lariat™ device<sup>[31,32]</sup> (Table 1). The ACP-originally used for closure of atrial septal defects<sup>[33]</sup> - consists of a self-expanding flexible nitinol mesh with a distal lobe filled with polyester and is equipped with fixation barbs to adhere of the LAA. The distal lobe is connected *via* a small waist to a proximal disc sealing the orifice of the LAA<sup>[34]</sup>. Similar to the ACP, the Watchman™ device consists of a self-expanding nitinol mesh with fixation barbs and a polyester coating covering the surface facing the left atrium<sup>[35]</sup>.

Implantation of both Watchman™ device and ACP can be performed under local anesthesia and is introduced *via* catheter through the femoral vein by transseptal passage<sup>[33,36-39]</sup>. TEE guiding or intracardiac echocardiography (ICE) during implantation procedure is used to rule out intracardiac thrombus and to facilitate transseptal puncture. After transseptal puncture heparin is administered to achieve an active clotting time of > 250 s. The LAA is fluoroscopically illustrated in at least 2 standard angulations (RAO 30°, RAO 30°/10° caudal) and sized by

**Table 1 Different endocardial left atrial appendage occlusion devices<sup>[3,11]</sup>**

Device name	Company	Design
PLAATO	Appriva Medical Inc.	Single-lobe occluder; nitinol cage; ePTFE membrane hooks
WATCHMAN	Boston Scientific	Single-lobe occluder; nitinol frame; PET membrane; hooks
ACP	St. Jude Medical	Lobe and disc (polyester mesh); nitinol mesh structure; stabilizing wires
Amulet	St. Jude Medical	Lobe and disk (polyester mesh in both); nitinol mesh structure; stabilizing wires
WaveCrest	Coherex Medical	Single-lobe occluder; nitinol frame, polyurethane foam and ePTFE membrane; retractable anchors
Occlutech LAA	Occlutech	Single-lobe occluder; nitinol wire mesh; stabilizing loops; nanomaterial covering
Sideris Patch	Custom Medical Devices	Frameless detachable latex balloon covered with polyurethane
Lambre	Lifetech	Lobe and disk; nitinol; PET membrane; distal barbs anchors
Pfm	PFM Medical	Dual disk (distal anchor, variable middle connector, proximal disk); nitinol frame
Ultrasept	Cardia	Lobe and disk; nitinol frame; Ivalon covering; distal anchors

**Figure 1** Measurement of left atrial appendage (A), implantation of an Amulet device (B) and postinterventional transesophageal echocardiogram revealing good sealing without any leak (C).

TEE measurements and cine angiography. Device size will be chosen according to manufacturer's recommendations 20% larger than the landing zone (measured from left circumflex coronary artery to the ridge delineating the LAA from the left upper pulmonary vein). Optimally, the device should not protrude more than 5 mm beyond the LAA ostium and should cover the entire ostium with no or minimal (less than 5 mm by colour Doppler) residual flow and a compression grade of 8%-30%. After device releasing and sheath removal the puncture site is dealt with a Z-suture or with a pressure band. Periprocedural anticoagulation is managed by heparin or bivalirudin<sup>[14,28,33]</sup> (Figure 1). The implanted device becomes initially coated by fibrin and subsequently covered by endothelial cells forming an endocardial lining, which consequently excludes the LAA from circulating blood<sup>[40]</sup>. In order to allow the process of endothelialization patients have to take warfarin after the intervention for at least 45

d. Warfarin is then replaced by clopidogrel and aspirin for half a year, while aspirin administration is continued life-long<sup>[15]</sup>. According to newer data a dual antiplatelet therapy is more efficacious than the use of anticoagulants<sup>[37,41,42]</sup>. In addition to the general risks of catheter-based interventions including air or blood embolism, an incomplete closure of the orifice, pericardial perforation, dislodgement of the implant or the formation of blood clots on the surface of the device leading to prolonged OAC treatment may occur<sup>[14,28,33,43]</sup>. Finally, since ANF is secreted in the LAA, the LAA closure could interfere with thirst regulation and water retention in the patient, but this theoretical concept has been scarcely investigated so far<sup>[17,18]</sup>.

## STATUS QUO OF LAA OCCLUSION

For several years great effort has been devoted to the use of cardiac plugs in the prevention of AF-related

strokes. A number of studies have been published about the PLAATO system including a five-year follow-up study<sup>[28,44]</sup>. In addition to the PLAATO system, the ACP system which has been used for closure of atrial septal defects for more than 20 years and its features, design and applicability are very well studied and has been reported to be successful for LAA closure<sup>[33,34]</sup>. It is worth mentioning that a large randomized clinical trial to study the ACP for LAA occlusion was recently halted, probably due to the approval of a competitive product (*i.e.*, Watchman device) by the United States Food and Drug Administration (FDA)<sup>[45]</sup>. The successful use of the Watchman device for LAA occlusion has been shown in two large, prospective randomized clinical trials—the PROTECT-AF and the PREVAIL study—in which this implant was compared to chronic OAC therapy using warfarin<sup>[14,15]</sup>. Over five years, the PROTECT-AF study examined about 800 patients, of which 463 had received a Watchman™ device and 244 were left on warfarin<sup>[14]</sup> and demonstrated that the implant is non-inferior to OAC therapy in patients with non-valvular AF being eligible for OAC. In comparison to the OAC treatment group, the incidence of an embolic event was reduced by approximately 30% in the implant group; the overall mortality showed a reduction of the same magnitude. While the per-protocol analysis was in favor of LAA occlusion, the intention-to-treat results were neutral. Furthermore, the safety data also favored warfarin over LAA occlusion, but this was explained by the learning curve phenomenon. The highest risk from LAA occlusion arises from complications associated with the one-time interventional treatment, while the risks from chronic OAC therapy accumulates during time especially with increasing age of the patient. Recently, a 45-mo follow-up of the PROTECT-AF study demonstrated that LAA occlusion is not only as efficient as warfarin treatment but even superior in term of stroke and cardiovascular mortality<sup>[46]</sup>. Further, the safety data showed a considerable reduction in the risk for complications during intervention, likely due to increasing experience of the surgeons. However, the FDA criticized the patient selection and raised questions about the safety of LAA occlusion<sup>[47]</sup>. To address these limitations, a confirmatory randomized trial (PRE-VAIL) comparing LAA occlusion with the Watchman device to warfarin, which mandated inclusion of new operators, slight modifications in inclusion criteria, and elimination of clopidogrel 7 d before implant. In PREVAIL more than 400 patients were randomized to either warfarin ( $n = 138$ ) or occluder device ( $n = 269$ )<sup>[15]</sup>. This study showed that LAA occlusion achieved non-inferiority in stroke prevention compared to warfarin; the difference between both groups was low and not significant. Most importantly, the number of early safety events (*e.g.*, pericardial effusions) was significantly reduced compared to the PROTECT-AF study and, hence, satisfied the predefined goal. Therefore, the PREVAIL study addressed the concerns rose by the FDA and demonstrated the safety of this intervention for LAA occlusion<sup>[15]</sup>. As a result of this study the Watchman

™ device was approved by the FDA in 2015<sup>[48]</sup>. Results from the real-world EWOLUTION registry consisting of 1021 patients being implanted with the Watchman device revealed a procedural success rate of 98.5%<sup>[49]</sup>. During 30-d follow-up 28 subjects experienced serious adverse events with an overall 30-d mortality rate of 0.7%. Serious procedure related complication rates, defined as stroke, pericardial effusion, device embolism and death, were present in 8.7% in PROTECT-AF, 4.1% in CAP registry, 4.2% in PREVAIL and 2.7% in EWOLUTION. However, the average CHADS2 score of 2.8 and CHA2DS2-VASc score of 4.5 in EWOLUTION indicate a relatively higher risk of stroke than either the PROTECT AF (average CHADS2 of 2.2 and CHA2DS2-VASc of 3.4) or PREVAIL (CHADS2 score of 2.6 and CHA2DS2-VASc of 4.0) studies. In addition, 40% of EWOLUTION subjects had a HAS-BLED score of  $\geq 3$ , compared with only 20% of PROTECT AF subjects and 30% of PREVAIL subjects (Table 2). Similar results were obtained in a registry with the ACP device<sup>[50]</sup> and a large meta-analysis<sup>[51]</sup> including 2406 patients from the PROTECT AF, PREVAIL, CAP I and CAP II registries with a mean follow-up of 2.69 years. Patients receiving LAA occlusion with the Watchman device had significantly fewer hemorrhagic strokes [0.15 vs 0.96 events/100 patient-years (PY); hazard ratio (HR): 0.22;  $P < 0.004$ ], cardiovascular/unexplained death (1.1 vs 2.3 events/100 PY; HR: 0.48;  $P < 0.006$ ), and nonprocedural bleeding (6.0% vs 11.3%; HR: 0.51;  $P < 0.006$ ) compared with warfarin. All-cause stroke or systemic embolism was similar between both strategies (1.75 vs 1.87 events/100 PY; HR: 1.02; 95%CI: 0.62 to 1.7;  $P = 0.94$ ). There were more ischemic strokes in the device group (1.6 vs 0.9 and 0.2 vs 1.0 events/100 PY; HR: 1.95 and 0.22, respectively;  $P = 0.05$  and 0.004, respectively)<sup>[51]</sup>.

## COST-EFFECTIVENESS

An analysis of Panikker *et al.*<sup>[16]</sup> on 110 patients being suitable and unsuitable for long-term OAC and outcome analysis from the PROTECT-AF trial and registry study compared warfarin, dabigatran, rivaroxaban, apixaban, aspirin and no treatment using a network meta-analysis. They revealed that stroke and bleeding rates were significantly lower than PROTECT-AF results. Additionally, LAA occlusion achieved cost parity between 4.9 years vs dabigatran 110 mg and 8.4 years vs warfarin and at 10 years, occlusion was cost-saving against all therapies. Similarly, another analysis evaluated the cost effectiveness in patients suffering from AF and absolute contraindication for OAC<sup>[52]</sup>. For this purpose the ASAP study evaluating the Watchman device, the ACTIVE-A trial evaluating aspirin and clopidogrel and the AVERROES trial evaluating apixaban were compared in a cost-effectiveness analysis. At 5 years, LAA occlusion was cost effective compared with aspirin with an incremental cost-effectiveness ratio of 16971 Euro. As compared with apixaban, it was also cost-effective at 7 years with an incremental cost-effectiveness ratio of 9040 Euro. Apart

**Table 2** Summary of data for left atrial appendage occlusion

	PROTECT-AF <sup>[46]</sup>	CAP <sup>[43]</sup>	ASAP <sup>[42]</sup>	EWOLUTION <sup>[49]</sup>	ACP <sup>[50]</sup>
Patients (n)	463	460	150	1021	1047
Follow-up	4 yr	16 mo	14 mo	30 d	13 mo
CHADS-score	2.2	2.4	2.8	2.8	n.a.
CHA2DS2-Vasc score	n.a.	n.a.	4.4	4.5	4.5
Procedural success	88.00%	95.00%	94.70%	98.50%	97.30%
Procedural stroke	1.30%	0	0.70%	n.a.	0.90%
Pericardial effusion	4.80%	2.20%	1.30%	0.50%	1.20%
Device embolization	0.60%	0	1.30%	0.20%	n.a.
Major bleeding	3.50%	n.a.	n.a.	1.60%	1.50%
Long-term stroke	2.30%	1.50%	0.70%	0.30%	2.30%

AF: Atrial fibrillation; n.a.: Not applicable.

**Table 3** Different aspects of left atrial appendage occlusion

Pro	Contra
Non-inferiority to oral anticoagulation	Evaluation of other atherothrombotic sources
Alternative in patients with contraindication for anticoagulation	Unknown hemodynamic impact
Cost-effective	Postprocedural medical treatment not well defined
Reduced cumulative bleeding events during follow-up	No comparison between different devices
Good results in real-world registries	Undefined impact of residual leaks

from the population having an absolute contraindication for OAC similar analysis were performed for patient being eligible for OAC, where LAA occlusion was cost-effective at 7 years and novel oral anticoagulation was cost-effective at 16 years. However, LAA occlusion was superior to novel oral anticoagulation by year 5 and to warfarin by year 10 with respect to cost-effectiveness and cost saving for stroke prevention<sup>[53]</sup>.

## FUTURE CONSIDERATIONS

In 2012, the European Society of Cardiology (ESC) released a focused update of the guidelines for the management of AF<sup>[8]</sup>. Interestingly, the ESC also commented on LAA occlusion for prevention of stroke (class II b recommendation, level of evidence B). Due to insufficient amount of data demonstrating efficacy and safety, the ESC did not recommend an LAA occlusion at this point as a routinely alternative therapy to replace chronic OAC therapy in order to reduce AF-related stroke risk, but recommended to consider this approach for patients with an increased for stroke and contraindications for OAC treatment<sup>[8]</sup>. However, the references cited as evidence for the recommendation are the PROTECT AF study and the CAP registry. Importantly, neither of these studies included patients who had contraindications to long-term anticoagulation, and both enrolled a majority of patients with relatively low estimated stroke risk. A growing body of evidence suggests that LAA occlusion with the Watchman™ device is an important alternative for OAC therapy using warfarin, yet, a perspective randomized study comparing LAA occlusion to the NOAC is still missing and therefore a final conclusion about the general applicability of LAA occlusion using the Watchman implant

cannot be drawn at this point<sup>[49,50,54]</sup>. Additionally, there are not enough data analyzing different patient cohorts (e.g., sex, age, race, renal insufficiency) as there are data revealing a direct correlation between elevated adiponectin levels and the degree of left atrial blood stasis in men but not in women, and there are more extensive left atrial remodeling and deterioration in LAA function in women than in men<sup>[55-57]</sup>. There are some subanalyses revealing higher bleeding events in patients older than 75 years after LAA Occluder implantations compared to younger ones (4.4% vs 1.4%), as well as in males as compared to females (3.0% vs 1.8%)<sup>[58]</sup>. In accordance with the latest recommendations from the ESC, LAA occlusion should definitely be considered if complications with OAC therapy arise or a high bleeding risk exist, regardless if the patient is treated with traditional or novel anticoagulants. This therapeutic approach is even more justified if the patient undergoing chronic OAC therapy suffers a stroke. Under this circumstance and under the light of recent studies about the safety and efficacy of LAA occlusion, this interventional treatment could be a better choice and advisable for this with a CHA2DS2Vasc Score  $\geq 2$  (Table 3). Summing up the current data, LAA occlusion is a very promising treatment to prevent AF-related strokes due to its safety, cost-effectiveness and therapeutic success.

### Abstract

Although the incidence of pediatric heart failure is low, the mortality is relatively high, with severe clinical sym-

ptoms requiring repeated hospitalization or intensive care treatment in the surviving patients. Cardiac biopsy specimens have revealed a higher number of resident human cardiac progenitor cells, with greater proliferation and differentiation capacity, in the neonatal period as compared with adults, demonstrating the regeneration potential of the young heart, with rising interest in cardiac regeneration therapy in critically ill pediatric patients. We review here the available literature data, searching the MEDLINE, Google Scholar and EMBASE database for completed, and [www.clinicaltrials.gov](http://www.clinicaltrials.gov) homepage for ongoing studies involving pediatric cardiac regeneration reports. Because of difficulties conducting randomized blinded clinical trials in pediatric patients, mostly case reports or cohort studies with a limited number of individuals have been published in the field of pediatric regenerative cardiology. The majority of pediatric autologous cell transplantations into the cardiac tissue have been performed in critically ill children with severe or terminal heart failure. Congenital heart disease, myocarditis, and idiopathic hypertrophic or dilated cardiomyopathy leading to congestive heart failure are some possible areas of interest for pediatric cardiac regeneration therapy. Autologous bone marrow mononuclear cells, progenitor cells, or cardiospheres have been applied either intracoronary or percutaneously intramyocardially in severely ill children, leading to a reported clinical benefit of cell-based cardiac therapies. In conclusion, compassionate use of autologous stem cell administration has led to at least short-term improvement in heart function and clinical stability in the majority of the critically ill pediatric patients.

**Core tip:** This review summarizes the available literature data involving pediatric cardiac regeneration reports.

Due to lack of randomized blinded clinical trials in pediatric cardiology patients, mostly case reports with limited number of individuals have been published in the pediatric regenerative cardiology. The majority of pediatric autologous cell transplantations into the cardiac tissue have been performed in children with severe or terminal heart failure, and led to the conclusion, that compassionate use of autologous stem cell administration may lead to at least short-term improvement in heart function and clinical stability in the majority of the critically ill pediatric patients.

## INTRODUCTION

### **Epidemiology of heart failure in children**

The overall prevalence of pediatric heart failure is largely unknown because of the non-unique definition and classification of this disease. According to statistical estimations and pediatric registries, 2.5 million children annually are born with congenital heart disease (CHD) worldwide, and among these children, 15%-25% eventually develop heart failure<sup>[1-4]</sup>.

The incidence of pediatric dilated cardiomyopathy with consequent heart failure is low, calculated as 0.57-2.6 per 100000 children under age 18 years<sup>[5,6]</sup>. In this group, approximately two thirds of cases are idiopathic, and the remaining involve postmyocarditis syndrome or musculoskeletal diseases<sup>[7]</sup>. Dilated cardiomyopathy dominates myocardial disease-related heart failure, followed by hypertrophic cardiomyopathy, with restrictive cardiomyopathy identified least frequently<sup>[8]</sup>. The median age of the patients with dilated cardiomyopathy is approximately 1.8 years when the initial diagnosis is made<sup>[8]</sup>.

The mortality of pediatric heart failure is high, and approximately one third of patients die in the first year following diagnosis<sup>[9,10]</sup>. The surviving children develop progressive heart failure requiring intensive medical care and heart transplantation<sup>[7]</sup>. For those surviving at least 2 years after the diagnosis, mortality and the need for heart transplantation are somewhat lower (13.6%)<sup>[6]</sup>. Approximately 18 of every 100000 children are hospitalized annually because of heart failure, with 0.87 new cases per 100000 children per year<sup>[11]</sup>. The hospital mortality of these pediatric patients is 7%, and numbers are much higher compared to the adult population (4%)<sup>[11,12]</sup>. After the first hospitalization, only 21% of pediatric patients remain free from serious adverse events (rehospitalization, death, or heart transplantation)<sup>[13]</sup>. The lack of sufficient numbers of young donor organs and the relatively high post-transplantation mortality limit the incidence and success of pediatric

heart transplantation.

In addition, the cost of hospital treatment for pediatric heart failure is usually extremely high, exceeding 135000 USD per patient. Underlying CHD involving a single ventricle, for example, expands the costs of in-hospital treatment for heart failure to over 200000 USD<sup>[14]</sup>.

The medical therapy for pediatric heart failure includes the whole armamentarium used in adults; however, the benefit cannot be clearly demonstrated for all interventions in children<sup>[15]</sup>. Some established methods for adult cardiology, such as diverse regenerative therapies or left ventricular assist devices, are rarely available for young patients because of incompatibilities of implant size in growing children. Medical treatment might be insufficient because, as noted, many children end up requiring heart transplantation<sup>[16]</sup>.

### **Spontaneous cardiac regeneration capacity in children**

Newborn mice can regenerate the cardiac apex after resection but only if the resection occurs within the first 7 d after birth<sup>[17]</sup>. Lineage tracing investigations have revealed that cell cycle entry of pre-existing cardiomyocytes in mice is responsible for this regeneration. Gene expression analysis indicates that neonatal cardiomyocytes maintain proliferation capacity only up to 7 d post-birth, this regeneration property is then lost<sup>[17]</sup>. Mishra *et al.*<sup>[18]</sup> investigated the prevalence and proliferation capacity of different stem cell-like cells acquired from cardiac biopsy specimens of children undergoing open heart surgery. They showed that plenty of resident human cardiac progenitor cells (hCPCs, a subpopulation of cardiospheres, CDCs) can be found in the neonatal period but that the number of these cells decreases rapidly with advancing age, from 8.9% to 3.2% in the right atrium and from 0.4% to 0.1% in the right ventricle. In addition, c-kit<sup>+</sup> hCPCs were three times more frequently found in neonates than in children over age 2 years. The proliferation and differentiation potential of the hCPCs was also greater in neonates, as shown by the higher expression levels of c-kit and Ki67, as well as the expression of NKX2, NOTCH1, and NUMB, the genes responsible for proliferation and differentiation. Furthermore, heart tissue samples of children with CHD contained an increased number of c-kit<sup>+</sup> hCPCs and CD133<sup>+</sup> cells, and these cells expressed cardiac lineage and endothelial transcription factors during differentiation under *in vitro* conditions<sup>[19]</sup>. CDCs are a rich source of secreted regenerative substances, such as cytokines and growth factors, *e.g.*, vascular endothelial growth factor, hepatocyte growth factor, or insulin-like growth factor, and exert anti-apoptotic and proangiogenic effects in the myocardium<sup>[20,21]</sup>. CDCs found in infant hearts have higher telomerase activity compared with those of adults.

Together, these data suggest that the regenerative capacity of the heart in children is much greater than that of adults. Additional evidence comes from clinical observations that the younger heart can exhibit morphological changes after volume unloading by surgical correction of CHD<sup>[22]</sup>. Additionally, pressure overload from

a single right ventricle leads to an increase in the number of cardiac stem cells ( $0.41\% \pm 0.24\%$ ) compared to dilated cardiomyopathy ( $0.15\% \pm 0.09\%$ )<sup>[23]</sup>.

### Clinical pediatric cardiac regeneration studies

To establish standardized therapy and guidelines for treatment of diseases, randomized double-blinded clinical studies delivering evidence-based medicine are necessary. In contrast with the huge number of adult clinical trials, in pediatric cardiology, especially for cardiac regenerative therapy, large randomized trials are lacking. In addition to the understandable ethical reasons, other factors also preclude such trials: The relative rarity of heart failure with a limited number of pediatric patients in the stable clinical condition necessary for randomization, a divergence in terminology, proprietary and often incompatible informatics platforms, and variability in data standards in growing children<sup>[24]</sup>. In 2012, the United States Food and Drug Administration Safety and Innovation Act intensified pediatric product development, also enhancing the number of pediatric clinical trials. In Europe, the Pediatric Regulation and Pediatric Therapeutics programs have strengthened the applications of new medicines in evidence-based pediatric clinical studies. In contrast with the very sparse pediatric regenerative cardiology studies, pediatric cancer and HIV/AIDS treatment networks have already been successfully established and developed with standardized data validity and consistency<sup>[24]</sup>. We review here the available literature data, searching the Medline, Google Scholar and Embase database for completed, and www.clinicaltrials.gov homepage for ongoing studies involving pediatric cardiac regeneration reports.

## DISCUSSION

### Cardiac diseases for pediatric cardiac regeneration

In most cases, cardiac cell-based therapy has been applied in children with severe heart failure caused by diverse diseases, predominantly idiopathic dilated cardiomyopathy, post-myocarditis, or chemotherapy-induced dilated cardiomyopathy (Table 1 and Figure 1).

Severe heart failure has been described also with post-myocardial infarction in cases of an anomalous origin of the left coronary artery from the pulmonary artery or Takayasu's arteritis, treated with different kinds of reparative cells. Other congenital diseases such as double outlet right ventricle, pulmonary atresia with ventricular septal defect, or hypoplastic left heart syndrome (HLHS) causing severely depressed heart function, have been considered for treatment with non-committed cells. Table 2 lists the pediatric diseases for which cardiac cell-based regenerative studies might be considered.

For the reasons described, to date, only two randomized clinical cardiac regenerative trials with a low number of included children have been conducted. Both have revealed benefits of cardiac cell-based therapy<sup>[25-29]</sup>. In addition to these currently finished trials, case reports or pilot trial results have been published, mainly based on an indication of compassionate use in severely ill pediatric patients. The majority of children receiving cardiac cell-based therapy were in a critical or terminal status of cardiac decompensation, as evidenced by the fact that some of the children had to undergo heart transplants afterwards<sup>[22]</sup>.

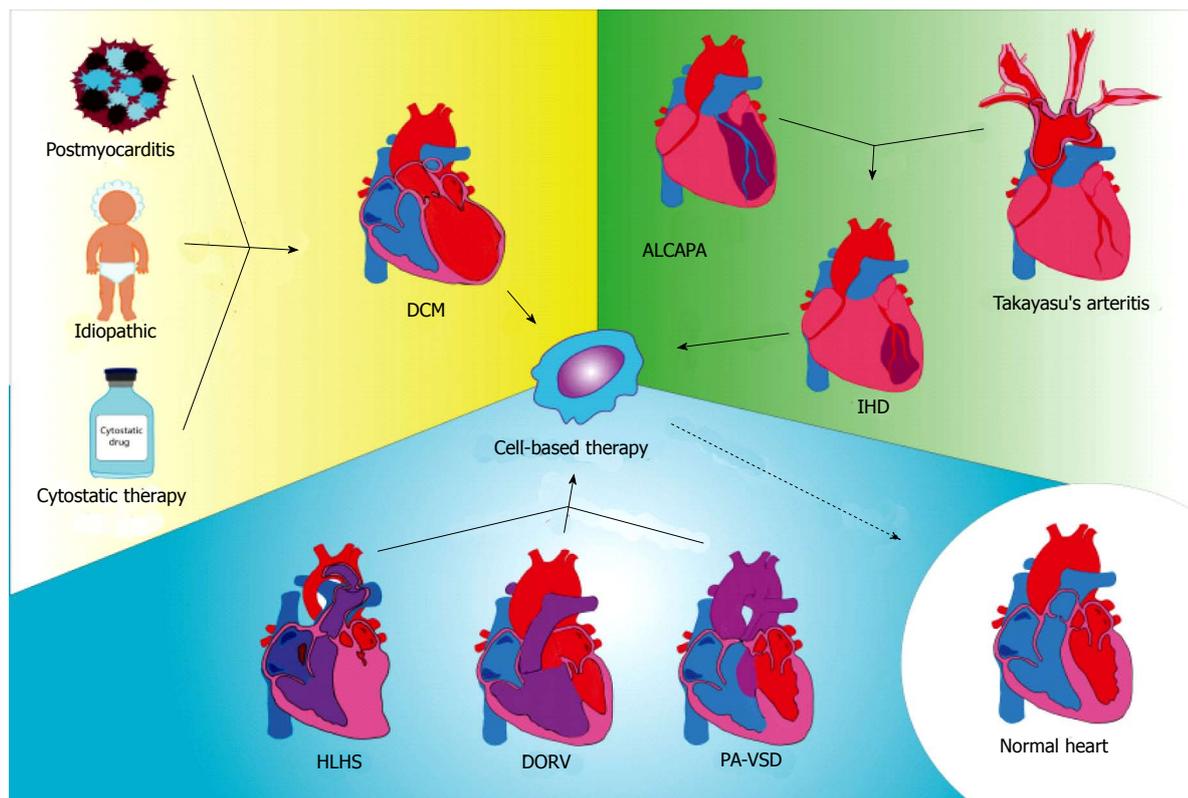

### Cell types and delivery modes

Different types of cells have been used for cardiac regenerative cell therapy in children, such as bone marrow-derived mononuclear cells, cells from leukocyte apheresis, and mesenchymal stem cells. In all cases, autologous cells were used.

Most of the children received the reparative cells *via* intracoronary injections. To ensure retention of the injected cells, echocardiography-guided transcatheter intramyocardial delivery was also used, or a transapical delivery mode was applied<sup>[30]</sup>.

### Clinical studies

The evidence for pediatric cardiac regeneration is mostly anecdotal, deriving from case reports or cohort studies including very limited number of patients (max. nine treated children in Rupp *et al.*<sup>[31]</sup>). In addition, the only comparative study, published by Ishigami *et al.*<sup>[32]</sup> allocated

**Figure 1 Schematic display of cardiac cell-based regeneration therapies in pediatric population.** DCM: Dilated cardiomyopathy; ALCAPA: Anomalous left coronary artery from the pulmonary artery; IHD: Ischemic heart disease; HLHS: Hypoplastic left heart syndrome; DORV: Double outlet right ventricle; PA-VSD: Pulmonary atresia with ventricular septal defect.

14 children with HLHS to receive either autologous CDCs ( $n = 7$ ) or standard therapy ( $n = 7$ ) without randomization. Because of these significant limitations of the available literature, a usual review or meta-analysis of cardiac regenerative studies in children is not reasonable. Thus, this review summarizes the published cases and their conclusions.

Autologous stem cell administration has led to at least short-term improvement in heart function and clinical stability in the majority of patients. Because of the lack of randomization and control groups, an unambiguous interpretation of the results is not possible. At the least, the outcomes indicate a compassionate use of cell-based cardiac regeneration in critically ill patients.

Rupp *et al.*<sup>[33,34]</sup> reported two cases of bone marrow-origin progenitor cell intracoronary injection, one involving a 2-year-old boy with dilated cardiomyopathy and the other an 11-mo-old infant with HLHS; both of them were in a critical clinical condition of heart failure. The bone marrow progenitor cells were injected into the left anterior descending and left circumflex coronary arteries in the first case and into the dominant right coronary artery in the second case, using a stop-flow technique. The cardiac cell therapy led to an increase in the left ventricular ejection fraction from 24% to 45% at 6 mo of follow-up in the first case, and to reverse remodeling and marked improvement in clinical status in the second case.

In further work, Rupp *et al.*<sup>[34]</sup> published a somewhat larger cohort study of nine pediatric patients receiving

intracoronary injections of autologous bone marrow mononuclear cells (BM-MNCs). The reasons for terminal heart failure in these children were anthracycline-induced dilated cardiomyopathy; post-myocarditis, idiopathic, or congenital cardiomyopathy; CHD with poor ventricular function, such as hypoplastic left heart or double outlet right ventricle; and pulmonary atresia with ventricular septal defect after surgical corrections. Three of the nine patients received a heart transplant and one patient died after cell treatment. The surviving children showed an improvement in clinical status during the 24 to 52 mo of follow-up.

De Lezo *et al.*<sup>[35]</sup> presented a case of a 5-mo-old infant with severe heart failure due to extensive myocardial infarction because of an anomalous origin of the left coronary artery. After surgical re-implantation of the left coronary artery to the aorta, the artery was occluded, then stented, then dilated after stent occlusion. Because of the critical clinical situation, during the second percutaneous procedure, autologous bone marrow-origin mononuclear cells were injected into the left main branch, which led to a gradual improvement in clinical status and allowed the discharge of the patient.

After mobilizing stem cells from the bone marrow with granulocyte colony-stimulating factor (G-CSF), Olguntürk *et al.*<sup>[36]</sup> selected peripheral blood-origin stem cells and performed intracoronary injections of these cells into both the left and right coronary arteries in two patients both with dilated cardiomyopathy and severe

BMC: Bone marrow cells; CDC: Cardiosphere-derived cells; BNP: Brain natriuretic peptide; HTX: Heart transplantation; NYHA: New York Heart Association Classification; G-CSF: Granulocyte-colony stimulating factor; CMP: Cardiomyopathy; LV: Left ventricle; EF: Ejection fraction; BM-MNC: Bone marrow mononuclear cell; PBSC: Peripheral blood stem cell; RV: Right ventricle; IC: Intracoronary; IM: Intramyocardial; FUP: Follow-up; NA: Data not available; HLHS: Hypoplastic left heart syndrome; F: Female; M: Male.

congestive heart failure. At the 4-mo follow-up, both children showed impressive improvement, and one of them could be removed from the heart transplantation list.

Similarly, Limsuwan *et al*<sup>[37]</sup> applied the first daily injections of G-CSF, followed by bone marrow aspiration and selection of CD133<sup>+</sup>/CD34<sup>+</sup> cells in an 8.5-year-old girl who had had an acute extensive anterior myocardial infarction related to Takayasu arteritis one year earlier. The selected stem cells were injected into the left anterior descending artery with the stop-flow technique. The 3-mo follow-up showed an increase in ejection fraction from 30% to 47.8% by cardiac magnetic resonance imaging.

Zeinaloo *et al*<sup>[38]</sup> selected autologous bone marrow mesenchymal stem cells in an 11-year-old boy with a diagnosis of dilated cardiomyopathy and injected them into the left and right coronary arteries. The one-year clinical check-up revealed an improvement of the left ventricular ejection fraction from 20% to 42%.

Lacis *et al*<sup>[30]</sup> treated a 3-mo-old child, who was in critical clinical condition with dilated cardiomyopathy, with autologous BM-MNCs *via* echocardiography-guided transcutaneous transapical intramyocardial injections. The ejection fraction increased from 20% to 41% at the

4-mo follow-up, and the child's clinical well-being was obvious.

Rivas *et al*<sup>[39]</sup> treated two children who both had dilated cardiomyopathy and were ages 3 and 4 mo, respectively, by administering peripheral blood progenitor cells, mobilized by G-CSF treatment. One month later, both children presented improvement, but one child developed progression later. This article described a temporary effect of the cell-based cardiac regenerative therapy.

Ishigami *et al*<sup>[32]</sup> published a nonrandomized prospective cohort study comparing data for seven patients treated with intracoronary injection of cardiosphere-derived cells and seven controls treated with standard therapy. All children had HLHS with planned stage 2 or 3 surgical palliation, which allowed the collection of autologous tissue for selection of CDCs in the treated group. The intracoronary injection of CDCs proved to be safe, and the right ventricle ejection fraction increased and remained constant at the 18 mo follow-up.

Bergmane *et al*<sup>[40]</sup> treated seven children with dilated cardiomyopathy with autologous bone marrow cells administered transcutaneously and intramyocardially by subxyphoid needle puncture under echocardiographic guidance. Six of the seven patients showed dramatically

HLHS: Hypoplastic left heart syndrome; CMP: Cardiomyopathy.

increased left ventricular ejection fraction at one year after the treatment, paralleled by a decrease in N-terminal proBNP and improved clinical status.

Burkhardt *et al.*<sup>[41]</sup> injected autologous umbilical cord blood-derived cells directly into the right ventricle during a second palliative operation of a child with HLHS. Three months later, the ejection fraction had increased to 45% with a marked decrease in plasma pro-BNP. Ongoing registered clinical studies are listed in Table 3.

## CONCLUSION

Cell-based cardiac regeneration therapy in pediatric patients has led to at least transient improvement of heart function and improvement of heart failure symptoms in a limited number of pediatric patients included in mostly non-randomized studies or case reports.

The majority of pediatric autologous cell transplantations into the cardiac tissue have been performed in critically ill children with severe or terminal heart failure, indicating that at the moment, this treatment strategy is a supplement after standard therapies have been exhausted. Whether specific age groups or those with structural heart diseases may benefit more than others has to be elucidated.

**Abstract****AIM**

To investigate the impact of timing of same-admission orthotopic heart transplant (OHT) after left ventricular assist device (LVAD) implantation on in-hospital mortality and post-transplant length of stay.

**METHODS**

Using data from the Nationwide Inpatient Sample from 1998 to 2011, we identified patients 18 years of age or older who underwent implantation of a LVAD and for whom the procedure date was available. We calculated in-hospital mortality for those patients who underwent OHT during the same admission as a function of time from LVAD to OHT, adjusting for age, sex, race, household income, and number of comorbid diagnoses. Finally, we analyzed the effect of time to OHT after LVAD implantation on the length of hospital stay post-transplant.

**RESULTS**

Two thousand and two hundred patients underwent implantation of a LVAD in this cohort. One hundred and sixty-four (7.5%) patients also underwent OHT during

the same admission, which occurred on average 32 d (IQR 7.75–66 d) after LVAD implantation. Of patients who underwent OHT, patients who underwent transplantation within 7 d of LVAD implantation (“early”) experienced increased in-hospital mortality (26.8% *vs* 12.2%,  $P = 0.0483$ ) compared to patients who underwent transplant after 8 d (“late”). There was no statistically significant difference in age, sex, race, household income, or number of comorbid diagnoses between the early and late groups. Post-transplant length of stay after LVAD implantation was also not significantly different between patients who underwent early *vs* late OHT.

### CONCLUSION

In this cohort of patients who received LVADs, the rate of in-hospital mortality after OHT was lower for patients who underwent late OHT (at least 8 d after LVAD implantation) compared to patients who underwent early OHT. Delayed timing of OHT after LVAD implantation did not correlate with longer hospital stays post-transplant.

**Core tip:** The optimal timing of same-admission orthotopic heart transplantation (OHT) after the implantation of a left ventricular assist device (LVAD) is unknown. The need for clinical stability and time to recover from surgery is counterbalanced by the risk of LVAD complications and formation of adhesions and scarring, particularly when OHT is considered early after LVAD implantation. We reviewed adult patients in the Nationwide Inpatient Sample who underwent same-admission OHT after LVAD between 1998 and 2011. Compared to early transplantation after LVAD, OHT after 8 d of LVAD implantation was associated with decreased mortality risk without increased post-transplant length of stay.

Optimal timing of same-admission orthotopic heart transplantation after left ventricular assist device implantation. *World J Cardiol* 2017; 9(2): 154-161 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/154.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.154>

### INTRODUCTION

Heart failure (HF) affects an estimated 5.8 million people in the United States and contributes to over 300000 deaths every year<sup>[1,2]</sup>. It is the most common cause of hospital admission and readmission in people greater than 65 years of age, annually accounting for over 2.4 million hospitalizations<sup>[2,3]</sup> and \$39 billion in healthcare costs<sup>[1,4]</sup>. Although most patients respond favorably to standard medical treatment, a considerable number of

patients progress to end-stage HF refractory to medical therapy<sup>[5]</sup>. Currently, orthotopic heart transplant (OHT) is the gold standard therapy for these patients<sup>[6-8]</sup>, but the number of donor hearts available for transplantation is far fewer than the number of patients on the transplant list. For this reason, left ventricular assist devices (LVADs), a class of electromechanical devices used for cardiac circulatory support, are increasingly being used to bridge patients to cardiac transplantation<sup>[5]</sup>.

The REMATCH trial in 2001 showed significant mortality reductions in patients placed on a pulsatile-flow LVAD compared to standard medical treatment<sup>[9]</sup>. Several subsequent studies since have confirmed the survival benefit of both the older pulsatile and newer continuous-flow LVADs<sup>[10-13]</sup>. Although LVADs have substantially reduced mortality in end-stage HF patients, the absolute mortality rates still remain high. A large portion of this mortality is attributable to complications and other occurrences during the patient’s stay in the hospital<sup>[14]</sup>. In-hospital mortality rates as high as 27% have been reported in patients after LVAD surgery<sup>[15-18]</sup>.

As the rate of LVAD implantation in the United States continues to increase<sup>[19-22]</sup>, effective recommendations for the in-hospital management of LVAD implantation are needed. Although the majority of cardiac transplants performed after LVAD implantation occur after a patient has been discharged from hospital, there is an important cohort of patients who cannot be discharged from hospital post-LVAD implant due to severe right ventricular failure, arrhythmias refractory to oral therapy, and infectious complications. Patients bridged to OHT with a LVAD achieve similar survival rates as patients who undergo direct heart transplant<sup>[14]</sup>, but there is little data to guide clinicians on the optimal timing of same-admission OHT after LVAD implantation. Though patients receiving LVADs may be considered for OHT while still inpatients, some have argued that performing OHT early after LVAD placement poses an increased risk of morbidity and mortality to patients.

Past studies on the appropriate use and outcomes of LVADs have been mostly limited to institutional experience and case series of select populations. While such descriptive investigations are useful, they are often limited by small sample size and variation between institutions and comparison groups. We used the Nationwide Inpatient Sample (NIS), the largest national database of hospitalizations in the United States with data from over 36 million hospitalizations, to assess the optimal timing of OHT after LVAD implantation. The NIS dataset complements the UNOS database and INTERMACS dataset with additional information on patient comorbidities, additional same-hospitalization procedures, hospital and center characteristics, and markers of patient’s socioeconomic status including insurance provider and regional income quartiles. In addition, the NIS dataset contains data on both LVAD and inpatient OHT, which are not simultaneously available in the UNOS or INTERMACS databases.

We analyzed a patient cohort who had OHT performed

during the same admission after LVAD implantation. We hypothesized that early OHT after LVAD implantation would be associated with higher mortality than late OHT, and that the hospital length of stay (LOS) after early OHT would be less than LOS after late OHT.

## MATERIALS AND METHODS

### Data source

The NIS, from the Healthcare Cost and Utilization Project sponsored by the Agency for Healthcare Research and Quality is the largest database of all-payer inpatient discharge information, sampling approximately 20% of all non-federal United States hospitals and including approximately 9 million hospital admissions each year. It contains discharge data from over 5000 hospitals located across 45 states, of which approximately 1200 hospitals are sampled each year to create a stratified sample of United States hospitals. Each NIS entry includes all diagnosis and procedure codes of activity during the patient's hospitalization at the time of discharge, as well as patient demographics, hospital characteristics, and short-term complications of the hospitalization.

### Study design and cohorts

This was a retrospective cross-sectional study using the NIS between 1998 and 2011. We identified all hospitalizations from 1998 to 2011 of patients 18 years of age or older who underwent LVAD implantation and for whom the hospital day of each procedure was available. Procedures during the hospitalization in addition to LVAD placement, including OHT, extracorporeal membrane oxygenation, intubation, hemodialysis, invasive hemodynamic monitoring, and surgical revision were identified by associated ICD9 codes (Supplementary Table 1). Additionally, hospital mortality and perioperative morbidity such as post-operative infections, cardiopulmonary complications, and hemorrhagic complications requiring endoscopy were identified.

### Statistical analysis

The statistical methods of this study were reviewed by Dr. David Ouyang from the Stanford University Department of Medicine. Python 2.7 (Python Software Foundation, [www.python.org](http://www.python.org)) and R 2.13 (R Foundation, [www.r-project.org](http://www.r-project.org)) were used for statistical analysis. *P*-values for numerical and count data were calculated by two-sided *t*-tests and  $\chi^2$  tests, respectively, with significance thresholds of 0.05. The multivariate linear model evaluating post-LVAD OHT mortality was performed using a generalized linear model with input variable selection by Bayesian Information Criteria (BIC). The dependent variable was in-hospital mortality. Independent variables of age, gender, median income, race, number of comorbidities, LVAD era, and timing of OHT were evaluated in the model.

## RESULTS

### Baseline patient characteristics

We identified 2200 patients greater than 18 years of

age between 1998 and 2011 who underwent LVAD implantation and for whom hospital day of procedure was listed (66.4% of all LVAD patients in the NIS database 1998-2011). Comparison of baseline characteristics between this study sample and all LVAD patients in the NIS 1998-2011 database confirmed that our study sample is representative of the entire patient population. The two groups were well matched based on age, sex, household income, prevalence of comorbidities, length of stay, and number of comorbidities, however there were more patients without documented race in the overall group (Supplementary Table 2). The mean age of all patients was 53.4 years (SD = 13.7, range = 18-92 years). Baseline patient demographics, patient comorbidities, and hospital characteristics were well matched between LVAD patients with and without same-admission OHT (Table 1). Most LVAD implantations were performed in large (87.8%), urban (99.1%), teaching hospitals (92.4%). The most common comorbidities were diabetes (17.8%), disorders of lipid metabolism (14.1%), hypertension (13.7%), history of or current use of tobacco (6.5%), and BMI  $\geq$  30 kg/m<sup>2</sup> (4.4%). The mean day of LVAD implantation was 9.4 d (SD = 12.5 d) into the hospitalization. The overall in-hospital mortality rate was 26.8%, with respiratory failure, cardiac dysrhythmias, right HF, and renal failure among the most frequent in-hospital complications immediately following LVAD implantation (Table 2).

Our dataset includes patients from both the pulsatile-flow era (1998-2005) and the continuous-flow era (2006-2011) of mechanical support (Table 3). Comparing the two eras, there was significantly less mortality in the continuous-flow era compared to the pulsatile-flow era (20.4% vs 43.0%; *P* < 0.001) even as patients were older (55.4 years vs 53.2 years; *P* < 0.001) and suffering more comorbid diagnoses (13.5 vs 10.6; *P* < 0.001). During the continuous-flow era, fewer patients received OHT during the same admission as LVAD implantation (3.8% vs 17.3%; *P* < 0.001), and mechanical support was more frequently initiated in large (88.8% vs 85.1%; *P* = 0.002), teaching (94.4% vs 87.1%; *P* < 0.001) institutions. Median household income quartile and race distribution also were different between the two eras, although there was no difference in gender ratio of patients.

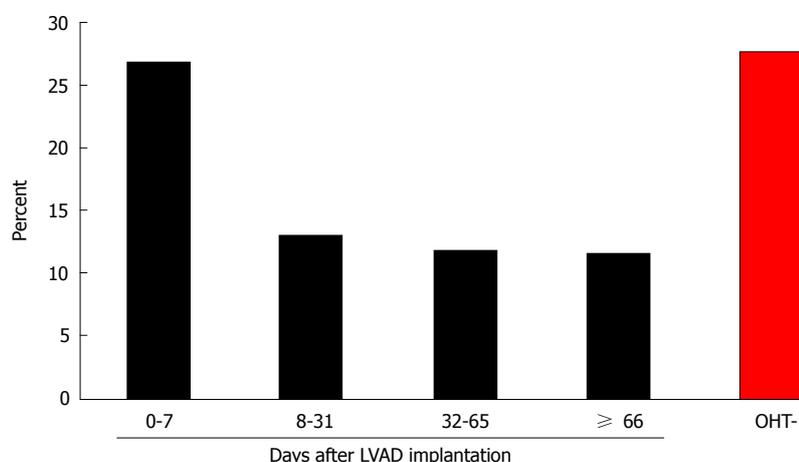

### Timing of post-LVAD OHT

Of the patients who underwent LVAD implantation, 164 (7.5%) also underwent OHT during the same admission. OHT occurred a median of 32 d (IQR 7.75-66 d) after LVAD implantation. Patients who underwent OHT at least 8 d after LVAD implantation experienced significantly lower mortality compared to patients who underwent OHT earlier (26.8% vs 12.2%; *P* = 0.048; Table 1 and Figure 1). Baseline patient demographics, patient comorbidities, and hospital characteristics were similar between the early and late OHT groups. LVAD patients who underwent late OHT also had lower mortality compared to LVAD patients who were not transplanted (12.2% vs 27.0%; *P* < 0.001). However, LVAD patients who underwent early

Early OHT	0.2	0.067	0.004 <sup>a</sup>

<sup>a</sup>P-value < 0.05. OHT: Orthotopic heart transplant.

and continuous-flow eras (9.3% vs 15.8%;  $P = 0.672$ ), although due to small sample numbers in each subgroup, the differences were not statistically significant (Table 2). Multivariate linear model also confirmed the strong association between early OHT after LVAD and in-hospital mortality, independent of patient age, LVAD era, comorbidities, and demographics (Table 4).

Comparing the quartiles of post-LVAD OHT transplant times, there was no statistically significant difference in post-transplant length of stay ( $23.8 \pm 21.4$  d for the first quartile,  $21.7 \pm 15.8$  d for the second quartile,  $27.6 \pm 37.1$  d for the third quartile,  $27.1 \pm 22.8$  d for the fourth quartile;  $P = 0.6571$  comparing first quartile to other quartiles; Table 1). However, as expected, patients who waited longer after LVAD implantation for OHT had longer overall hospital stays ( $39.3 \pm 33.2$  d for the first quartile,  $48.87 \pm 25.6$  d for the second quartile,  $85.8 \pm 40.1$  d for the third quartile,  $151.2 \pm 52.6$  d for the fourth quartile;  $P < 0.001$  comparing first quartile to other quartiles; Table 1).

## DISCUSSION

Our study addresses the difficult question of timing of same-admission OHT after LVAD implantation. Using the inpatient data on procedure timing from the NIS 1998-2011, we show that mortality risk significantly decreases in patients who undergo OHT at least 8 d after LVAD implantation. We also report that post-transplant length of stay is independent of the timing of OHT after LVAD.

For patients who receive an LVAD for bridge to transplant therapy (BTT), the optimal timing of post-LVAD OHT is controversial. The need for clinical stability and time to recover from major surgery is counterbalanced by the risk of LVAD complications and the formation of adhesions and scarring, particularly when OHT is considered early after LVAD implantation.

The high failure rate of the early, pulsatile-flow LVADs had in part led to the initial 1999 UNOS allocation algorithm giving LVAD patients 30 d of IA status on the transplant list. The elective nature of the 30-d IA status allows for optimization of management prior to transplant and suggests the time period immediately post-mechanical support is often not the optimal time for transplant. Our data showing that delaying post-

LVAD transplant can lead to superior outcomes is consistent with the excellent long term outcomes of BTT mechanical support, pushing some groups to question the justification of elective IA status<sup>[23]</sup>.

Our study, using a large national database, solidifies and extends previous findings that early transplantation after initiation of BTT mechanical support is associated with worse outcomes. In the pulsatile-flow era of LVAD, John *et al*<sup>[24]</sup> (2010) had shown that cardiac transplants done less than 6 wk after LVAD confer higher mortality risk in patients, and Gammie *et al*<sup>[25]</sup> (2003) and Ashton *et al*<sup>[26]</sup> (1996) have similarly reported optimal timing to be 2 wk after LVAD implantation. With the advantage of procedural timing data of patients who underwent same admission LVAD implantation and transplant, we add to those findings by showing there is an increased mortality associated with early same-admission transplant after LVAD in the continuous flow era.

During the study period between 1998 and 2011, there was a significant increase in the number of LVAD implantations, but patient characteristics of this population - including timing of LVAD, usage of invasive hemodynamic monitoring, and timing of post-LVAD OHT - has remained relatively unchanged. Our sample patient population is representative of LVAD patients studied in other databases with regards to age, gender, race, and other demographic characteristics and also mortality trends between the pulsatile and continuous-flow eras. Without randomized control trials to better characterize the optimal management and timing of transplant after LVAD, our study describes representative clinical practice and trends in outcomes associated with changing practice patterns.

Our study has a few limitations. First, the NIS is a deidentified administrative database dependent on the appropriate coding of individual ICD-9-CM codes. Studies using such databases are susceptible to errors related to coding such as undercoding complications or variation in the application of diagnostic codes. This database also lacks many details available in registries, and unmeasured confounders cannot be excluded. Additionally, the NIS only captures events during the hospitalization, so complications and adverse events after discharge are not recorded. This limitation is counterbalanced by the larger sample size relative to other studies and the absence of reporting bias as compared to studies relying upon the

institutional experiences from a few specialized centers. Additionally, patients who undergo LVAD implantation have long hospital stays that capture most, if not all, of the acute complications causing morbidity and mortality. Finally, the ability of the NIS to capture detailed LVAD implantation and OHT data provided advantages in answering our central question over either the INTERMACS or UNOS databases, which capture largely LVAD or transplant data, respectively.

It is important to note that our cohort only assessed outcomes of OHT after LVAD placement in hospitalized patients. This represents a minority of patients (7.5%) in practice, as most institutions prefer to wait 2-3 mo after LVAD implantation to list patients for cardiac transplantation. Nevertheless, there will continue to be patients in the future who receive same-admission OHT after LVAD implantation, and our study provides meaningful guidelines on the timing of such OHT.

In conclusion, our analysis suggests that delayed same-admission OHT after LVAD implantation decreases mortality risk without increasing post-transplant length of stay, and, therefore, may be the preferred option in such a clinical setting. This new understanding of the optimal timing of same-admission OHT after LVAD implantation can greatly improve patient outcomes, although prospective data will be needed to enhance the validity of our findings.

## COMMENTS

### Background

Heart failure (HF) affects an estimated 5.8 million people in the United States and contributes to over 300,000 deaths every year. Although most patients respond favorably to standard medical treatment, a considerable number of patients progress to end-stage HF refractory to medical therapy. Orthotopic heart transplant (OHT) is currently the gold standard therapy for these patients, but the number of donor hearts available for transplantation is far fewer than the number of patients on the transplant list. For this reason, left ventricular assist devices (LVADs), a class of electromechanical devices used for cardiac circulatory support, are increasingly being used to bridge patients to OHT. The optimal timing of when patients with LVADs should be bridged to OHT is an important consideration for patient care and has yet to be characterized.

### Research frontiers

As the rate of LVAD implantation in the United States continues to increase, effective recommendations on the in-hospital management of LVAD implantation are needed. The optimal timing of when to bridge patients with LVADs to OHT remains controversial and is an active area of research.

### Innovations and breakthroughs

Few groups have studied the impact of timing of same-admission OHT after LVAD on patient outcomes. Past studies on the appropriate use and outcomes of LVADs have been mostly limited to institutional experience and case series of select populations. The authors used the Nationwide Inpatient Sample (NIS), the largest national database of hospitalizations in the United States with data from over 36 million hospitalizations, to assess the optimal timing of OHT after LVAD implantation. It has been suggested that performing OHT early after LVAD placement confers an increased risk to patient. The study corroborates these claims and concludes that early OHT after LVAD placement (less than 8 d) is associated with increased in-hospital mortality. Therefore, depending on the clinical scenario, it might be reasonable for physicians to defer OHT immediately after LVAD placement.

### Applications

This study offers recommendations for cardiologists and cardiac surgeons on the optimal timing of same-admission OHT after LVAD implantation. It also summarizes the demographics and characteristics of LVAD and post-LVAD OHT patients in the United States.

### Terminology

Left ventricular assist device (LVAD): A class of electromechanical devices that help the left ventricle pump blood to the rest of the body; Orthotopic heart transplant (OHT): A procedure in which the patient's heart is removed and replaced with a donor heart.

### Peer-review

Very interesting and clinically relevant question with novel use of the NIS database. Overall well written with interesting findings.

**Abstract****AIM**

To investigate whether consumption of an energy drink will acutely impair endothelial function in young healthy adults.

**METHODS**

Energy drinks are being consumed more and more worldwide, and have been associated with some deaths in adolescents and young adults, especially when consumed while exercising. After fasting and not smoking for at least 8 h prior, eleven medical students (9 males) received an electrocardiogram, blood pressure and pulse check, and underwent baseline testing (BL) of endothelial function using the technique of endothelium-dependent flow mediated dilatation (FMD) with high-resolution ultrasound

(according to recommended guidelines of the University of Wisconsin Atherosclerosis Imaging Research Program Core Laboratory). The subjects then drank an energy beverage (EB), a 24-oz can of Monster Energy, and the above was repeated at 90 min after consumption. The relative FMD (%) was calculated as the ratio between the average post-cuff release and the baseline diameter. Each image was checked for quality control, and each artery diameter was measured from the media to media points by two experts, 3 measurements at the QRS complex, repeated on 3 separate beats, and then all were averaged.

## RESULTS

Subjects characteristics averages (given with standard deviations) include: Age  $24.5 \pm 1.5$  years, sex 9 male and 2 female, weight  $71.0 \pm 9.1$  kg, height  $176.4 \pm 6.0$  cm, BMI  $22.8 \pm 2.7$  kg/m<sup>2</sup>. The hemodynamics were as follows, BL *vs* EB group respectively (mean  $\pm$  SD): Heart rate  $65.2 \pm 11.3$  *vs*  $68.2 \pm 11.8$  beats per minute, systolic blood pressure  $114.0 \pm 10.4$  mmHg *vs*  $114.1 \pm 10.4$  mmHg, diastolic blood pressure  $68.8 \pm 9.3$  mmHg *vs*  $70.6 \pm 7.1$  mmHg; all were not significantly different. However after drinking the EB, a significantly attenuated peak FMD response was measured (mean  $\pm$  SD): BL group  $5.9\% \pm 4.6\%$  *vs* EB group  $1.9\% \pm 2.1\%$ ;  $P = 0.03$ ). Given the increased consumption of energy beverages associated with exercise in young adults, more research is needed.

## CONCLUSION

Energy beverage consumption has a negative impact on arterial endothelial function in young healthy adults.

**Key words:** Energy drinks; Endothelial function; Exercise; Flow mediated dilatation; Blood pressure

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Energy drinks are being consumed worldwide, and are gaining in popularity, especially amongst youth. We studied the acute effects that one energy drink has on endothelial function, a measure of vascular health. We found that consumption of a single 24-oz can of Monster Energy resulted in attenuation of brachial artery endothelium-dependent flow mediated dilatation in 11 healthy volunteers.

Higgins JP, Yang B, Herrin NE, Yarlaga S, Le GT, Ortiz BL, Ali A, Infanger SC. Consumption of energy beverage is associated with attenuation of arterial endothelial flow-mediated dilatation. *World J Cardiol* 2017; 9(2): 162-166 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/162.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.162>

## INTRODUCTION

Energy beverages are being consumed increasingly

worldwide, and have been associated with deaths in adolescents and young adults, especially when consumed while exercising<sup>[1]</sup>.

What effect these energy drinks have on endothelial cells could help explain its effect on the cardiovascular system. These cells are part of the inner lining of blood vessels and have metabolic and also synthetic functions<sup>[2]</sup>. When endothelial cells are functioning abnormally or "endothelial dysfunction", it is associated with poor vascular reactivity, pro-thrombosis, pro-adhesion, pro-inflammation, and growth promotion<sup>[1,3]</sup>.

Several recent reviews on cardiovascular complications associated with energy drink consumption suggest that the impact on endothelial function could be a factor in subsequent cardiac events<sup>[1,4]</sup>. Some of their ingredients individually or in combination may be associated with reduced endothelial function<sup>[5-7]</sup>.

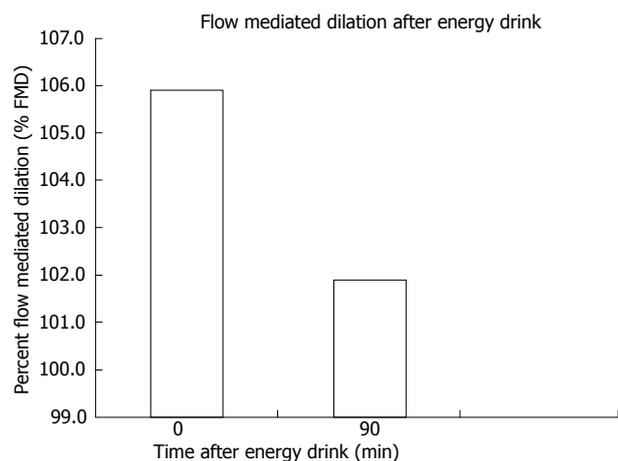

Mechanistically, endothelial dysfunction, where the endothelium's ability in regulating vascular resistance is impaired, may be related to reduced coronary blood flow<sup>[6,8]</sup>. Following exposure to stress such as exposure to cold, mental arithmetic, anger, exercise, cigarette smoking, cocaine, excess food or alcohol, the impaired ability to dilate the coronary arteries could result in supply-demand imbalance or coronary spasm, potentially leading to myocardial ischemia, coronary vasospasm, thrombosis and/or cardiac arrhythmia<sup>[6,9]</sup>. Importantly, this acute endothelial dysfunction could lead to ischemia, which in turn could lead to serious arrhythmia, coronary vasospasm, and myocardial infarction<sup>[1,6,10]</sup>.

This study describes the acute changes of normal endothelial function after consumption of a single can of a popular energy drink<sup>[11]</sup>.

## MATERIALS AND METHODS

After fasting from caffeine for at least 24 h and food for at least 8 h prior, eleven healthy non-smoker medical students (9 males), average age 24.5 years (range 23-27 years), average BMI 22.8, received an electrocardiogram (ECG), blood pressure and pulse check, and underwent baseline testing (BL) of endothelial function using the technique of endothelium-dependent flow-mediated dilatation (FMD) with high-resolution ultrasound according to recommended guidelines of the University of Wisconsin Atherosclerosis Imaging Research Program Core Laboratory by a single registered vascular ultrasonographer who was certified by the University of Wisconsin Atherosclerosis Imaging Research Program Core Laboratory<sup>[12]</sup>.

After resting supine for 10-min in a temperature-controlled room, a blood pressure cuff was placed on the widest part of proximal right forearm approximately 1 cm distal to the antecubital fossa. Using a 10 MHz resolution linear array vascular ultrasound transducer with a Philips iE33 ultrasound machine, the brachial artery was located above the elbow and scanned in longitudinal sections. After recording baseline B-mode digital images of the brachial artery and spectral Doppler images of

**Figure 1** Flow mediated dilation at baseline (0 min) and after energy drink (90 min). Consumption of the EB resulted in a significantly attenuated peak FMD response (mean  $\pm$  SD): BL group 5.9%  $\pm$  4.6% vs EB group 1.9%  $\pm$  2.1%;  $P = 0.03$ . FMD: Flow mediated dilatation; BL: Baseline testing; EB: Energy beverage.

flow, the forearm cuff was inflated to 250 mmHg for 5 min to induce reactive hyperemia. Immediately after deflation, spectral Doppler images are obtained to verify hyperemia. FMD of the brachial artery was measured 60 and 90 s after cuff deflation. The relative FMD (%) was calculated as the ratio between the largest post-cuff release and the baseline diameter. Each image was checked for quality control, and each artery diameter was measured from the media to media points by two experts, 3 measurements at the QRS complex, repeated on 3 separate beats, and then averaged.

The subjects then drank an energy beverage (EB), a 24-oz can of Monster Energy Drink<sup>®</sup> in approximately 1 min. The contents of this can include 54 g Sucrose, glucose, sucralose, maltodextrin, Sodium 360 mg Sodium Citrate Sodium Chloride, Caffeine 240 mg, Taurine 2000 mg, Niacin 40 mg 200% RDA Niacinamide, Pyridoxine 4 mg 200% RDA, Cyanocobalamin (B12) 12 mcg 200% RDA, Riboflavin (B2) 3.4 mg 200% RDA, Ginseng Extract 400 mg, Glucuronolactone, Inositol (B8), Guarana Extract, and L-Carnitine all listed as a part of a 5000 mg "Energy Blend", and Sodium Benzoate.

The subjects had FMD repeated at 90 min after consumption of the EB. The subjects were in the supine position for all ECGs and FMD measurements.

### Statistical analysis

Statistical analyses were performed by John P Higgins and the statistical methods of this study were reviewed by Benjamin Yang using Microsoft Excel 2010 and the Data Analysis ToolPak. We used the *t*-test: Paired Two Sample for Means, and significance was defined as a *P*-value of 0.05 or less.

## RESULTS

Subjects characteristics averages (given with standard deviations) include: Age 24.5  $\pm$  1.5 years, sex 9 male

and 2 female, weight 71.0  $\pm$  9.1 kg, height 176.4  $\pm$  6.0 cm, BMI 22.8  $\pm$  2.7 kg/m<sup>2</sup>.

The hemodynamics were as follows, BL vs EB group respectively (mean  $\pm$  SD): Heart rate 65.2  $\pm$  11.3 vs 68.2  $\pm$  11.8 beats per minute, systolic blood pressure 114.0  $\pm$  10.4 mmHg vs 114.1  $\pm$  10.4 mmHg, Diastolic blood pressure 68.8  $\pm$  9.3 mmHg vs 70.6  $\pm$  7.1 mmHg; all were not significantly different.

With drinking the energy beverage, a significantly attenuated peak FMD response was found (mean  $\pm$  SD): BL group 5.9%  $\pm$  4.6% vs EB group 1.9%  $\pm$  2.1%;  $P = 0.03$  (Figure 1).

## DISCUSSION

There are few studies exploring the effects on endothelial function following consumption of energy drinks.

In one study, fifty healthy volunteers (34 male, aged 22  $\pm$  2 years) consumed either a 250-mL sugar-free energy drink or 250 mL carbonated water (control)<sup>[13]</sup>. They found that an hour after consumption of an energy drink, there was an acute decreased in endothelial function and increased platelet aggregation<sup>[7,13]</sup>.

Another study involving 25 healthy young adults (13 male, aged 22.5  $\pm$  0.6 years) who consumed either 355-mL Red Bull or 355-ml tap water noted that 2 h later, while blood pressure, heart rate and cardiac output were significantly increased, there was no reduction in endothelial function *via* finger skin microcirculation<sup>[14]</sup>.

A 47-year-old healthy Caucasian male was noted to have a progressive attenuation of peak flow-mediated dilatation at 45 and 90 min following consumption of a 24-oz can of Monster Energy Drink<sup>®</sup><sup>[7]</sup>.

Energy drinks likely increase myocardial oxygen demand, and this may be increased under stress. For example, one study has noted that the combination of Red Bull and mental stress results in greater increases in heart rate and blood pressure, *i.e.*, a greater cardiovascular load<sup>[15]</sup>.

While our study has noted a change in endothelial function after consumption of energy drinks, which is consistent with some of the previous studies, it still however conflicts with other studies. A possible explanation for these contrasting results on endothelial function, blood pressure, and heart rate in response to energy drinks include difference in methods of assessing endothelial function, difference in methods of monitoring blood pressure, difference in types of energy drinks consumed, difference in study participant profiles, and varying environmental stimuli<sup>[15,16]</sup>. Further investigations should take in account these differences, and also investigate how energy drink consumption in stress conditions affect endothelial function, as it would help simulate conditions in which energy drinks are used in real-life.

Weaknesses of our study include the fact that human measurement was performed on the arterial segments, which may be less accurate than automated detection methods. However one study analyzing variability and

reproducibility of FMD found that the mean absolute difference in %FMD from baseline FMD assessment was 1.04% and 0.99% for short-term (48 h) and medium-term (3 mo) repeat measurements, respectively<sup>[17]</sup>. Potential improvements in the future include a water load as a control, and having FMD baseline measurements performed on one day, followed by the FMD measurements with energy beverage consumption on the next day. In addition, this was a small sample, and such medical student volunteers may be healthier than the normal population.

Consumption of energy drinks may lead to an acute attenuation of endothelial function. Given the popularity of energy drinks, especially among youth, the combination of their consumption and exercise/extreme sports, and the rise in emergency room visits associated with their consumption, it is important that the specific physiological effects they are having be elucidated. Due to the potential endothelial dysfunction that may occur with energy drinks and the potential morbidity when consumed with exercise, further research is needed to explore these mechanisms and significance of their effects.

## COMMENTS

### Background

Energy drinks are being consumed more and more worldwide, and have been associated with deaths in adolescents and young adults, especially when consumed while exercising. Adverse cardiovascular events can be caused by abnormal endothelial cell function or "endothelial dysfunction". Endothelial cells form the inner lining of blood vessels and have metabolic as well as synthetic functions, which allow them to carry out multiple important tasks such as regulating vascular resistance. Mechanistically, reduced coronary blood flow may be a symptom of endothelial dysfunction, and is associated with poor vascular reactivity, pro-thrombosis, pro-adhesion, pro-inflammation, and growth promotion.

### Research frontiers

There is a paucity of studies describing the effects on endothelial function following consumption of energy drinks. Several recent reviews on cardiovascular complications associated with energy drink consumption suggest that effects on endothelial function may play a role in subsequent cardiac events. Some of their ingredients individually or in combination may be associated with reduced endothelial function.

### Innovations and breakthroughs

The current study describes the acute changes of normal endothelial function following consumption of a single can of a popular energy drink. While the study has noted a change in endothelial function after consumption of energy drinks, which is consistent with some of the previous studies, it still however conflicts with other studies. A possible explanation into these contrasting results on endothelial function, blood pressure, and heart rate in response to energy drinks include a difference in study methods and energy drink types. Further investigations should take in account these differences, and also investigate how energy drink consumption in stress conditions affect endothelial function, as it would help simulate conditions in which energy drinks are used in real-life.

### Applications

Consumption of energy drinks may lead to an acute attenuation of endothelial function. Given the popularity of energy drinks, especially among youth, the combination of their consumption and exercise/extreme sports, and the rise in emergency room visits associated with their consumption, it is important that

the specific physiological effects they are having be elucidated. Further, due to the possibility that endothelial dysfunction may play a role in morbidity with concomitant energy drink intake and exercise, more research is recommended to clarify the mechanisms of and significance of these effects.

### Terminology

Energy drinks are also known as energy beverages. Popular brand names include Monster Energy Drink® and Red Bull Energy Drink® that contain high caffeine content, along with other ingredients. Flow-mediated dilatation is a non-invasive technique using high-resolution ultrasound to assess a vessel's endothelium-dependent (nitric oxide release) vasomotor function.

### Peer-review

In this study, Dr. Higgins and his colleagues have done a very interesting investigation even though the report is very brief. They show a significant result that one kind of the "energy beverage" is associated with endothelial dysfunction. The study is well designed and outcome is enough to warn the lovers of those drinks.

To test of the implantable-cardioverter-defibrillator is done at the time of implantation. We investigate if any testing should be performed.

**METHODS**

All consecutive patients between January 2006 and December 2008 undergoing implantable cardioverter-defibrillator (ICD) implantation/replacement (a total of 634 patients) were included in the retrospective study.

**RESULTS**

Sixteen patients (2.5%) were not tested (9 with LA/LV-thrombus, 7 due to operator's decision). Analyzed were 618 patients [76% men, 66.4 ± 11 years, 24% secondary prevention (SP), 46% with left ventricular ejection fraction (LVEF) < 20%, 56% had coronary artery disease (CAD)] undergoing defibrillation safety testing (SMT) with an energy of 21 ± 2.3 J. In 22/618 patients (3.6%) induced ventricular fibrillation (VF) could not be terminated with maximum energy of the ICD. Six of those (27%) had successful SMT after system modification or shock lead repositioning, 14 patients (64%) received a subcutaneous electrode array. Younger age ( $P = 0.0003$ ), non-CAD ( $P = 0.007$ ) and VF as index event for SP ( $P = 0.05$ ) were associated with a higher incidence of ineffective SMT. LVEF < 20% and incomplete revascularisation in patients with CAD had no impact on SMT.

**CONCLUSION**

Defibrillation testing is well-tolerated. An ineffective SMT occurred in 4% and two third of those needed implantation of a subcutaneous electrode array to pass

a SMT > 10 J.

**Core tip:** The implantable cardioverter defibrillator is crucial for primary and secondary prevention of severe life-threatening ventricular tachyarrhythmia. However the importance concerning intra-operative defibrillation testing and clinical relevance of inadequate testing of implantable cardioverter-defibrillator (ICD) devices remains still under debate. In this study, we analyzed our single-center data of patients undergoing ICD implantation or replacement to determine the number of failed internal defibrillation testing at the time of ICD implantation and the consequences for management. We critically reflect the progressive trend to omit defibrillation testing at the time of ICD placement.

## INTRODUCTION

The implantable cardioverter defibrillator (ICD) is widely accepted for primary<sup>[1,2]</sup> and secondary prevention<sup>[3,4]</sup> of severe life-threatening ventricular tachyarrhythmia. The Heart Rhythm Society updated appropriate use criteria for ICD therapy<sup>[5]</sup>, however the importance concerning intra-operative defibrillation testing and clinical relevance of inadequate testing of ICD devices remains still under debate<sup>[6-10]</sup>.

One limitation of recent observational studies is a bias against testing in patients with more severe illness who are felt to be at increased risk for complications during intra-operative defibrillation testing<sup>[11-14]</sup>. Although severely impaired left ventricular function predicts higher intra-operative defibrillation threshold<sup>[8,15,16]</sup>, patient with lower left ventricular ejection fraction (LVEF) are less likely<sup>[11-14]</sup> or even excluded<sup>[17]</sup> to undergo intra-operative defibrillation testing. Furthermore, severe, non revascularized coronary artery disease (CAD) is described as an absolute or relative contraindication for intra-operative defibrillation testing<sup>[15,18,19]</sup> and were less likely to undergo such testing in recent studies<sup>[12,14,16,19]</sup> although these patients would probably benefit most from an adequate defibrillation threshold.

We analyzed all consecutive patients between January 2006 and December 2008 undergoing ICD im-

plantation or replacement to determine the number of failed internal defibrillation testing at the time of ICD implantation and the consequences for management. Our study extends the existing literature by also including patients excluded in previous studies. We critically reflect the progressive trend to omit defibrillation testing at the time of ICD placement<sup>[9,10,14]</sup>.

## MATERIALS AND METHODS

All consecutive patients undergoing initial ICD implantation or generator replacement from January 2006 to December 2008 were analyzed in this retrospective, single-center analysis.

Devices of all 4 important international companies were implanted. They were implanted in the catheter laboratory by 5 experienced cardiologists. In all patients, adequate ventricular sensing (> 9 mV) and pacing threshold (< 1 V) was confirmed. In the absence of absolute contraindications [e.g., left atrial appendage (LAA) or left ventricular (LV) thrombus], intra-operative ICD testing was routinely performed to confirm correct sensing, processing, shock delivery and termination of T-wave shock-induced VF. Our protocol for intra-operative ICD testing required at least one induction of VF with successful first shock terminating VF at a safety margin of at least 10 Joule (J) below the maximum output of the implanted device. If the first shock was not successful, a second shock at the maximum output of the device was delivered. In case this shock was still not successful, external defibrillation with a 360 J biphasic shock was performed. Patients with the need of a second shock at the maximum output or external defibrillation in order to terminate VF were considered as ineffective safety margin testing (SMT) and were included in our study. Further management of these patients included intra-operative right ventricular lead reposition or ICD-system modification such as addition or subtraction of the superior vena cava (SVC) shock coil and polarity reversal, respectively. In case the SMT was still ineffective, the implantation of a subcutaneous electrode array, considered to be the most effective method for reducing defibrillation threshold<sup>[20]</sup>, was planned.

Clinical characteristics, the consecutive management of pts with ineffective SMT and follow up data were explored by reviewing the medical records. Biplane left ventricular ejection fraction (LVEF) was derived by echocardiography and all measurements were done or supervised independently by an experienced cardiologist specialized in echocardiography. According to our center's standard practice, all patients underwent coronary angiography prior to ICD placement, ascertaining a definite coronary status. The implanted subcutaneous electrode array was solely a Medtronic 6996SQ.

### Statistical analysis

Descriptive data were reported as frequencies, means and standard deviations or median and interquartile

range, respectively. Two-sided *t*-tests for independent samples were used for continuous variables.  $\chi^2$  analysis was used to compare categorical variables and one-way analysis of variance (ANOVA) was used to compare continuous variables. All statistics were computed with SPSS software (SPSS Inc, Chicago, Illinois). All probability values are 2-sided, with values of  $< 0.05$  considered significant.

## RESULTS

### **Patient characteristics**

From 634 analyzed patients, 16 (2.5%) had no intra-operative defibrillation testing (9 patients (1.4%) due to LV- or LAA-thrombus and 7 (1.1%) due to decision of the operator (mainly atrial fibrillation with ineffective oral anticoagulation). Included in this retrospective analysis were 618 consecutive patients who received defibrillation testing after transvenous ICD implantation or ICD replacement. The population is described in Table 1. LVEF was  $\leq 20\%$  in 284 patients (46%). The indications for ICD placement included primary (76%) as well as secondary prevention (24%). The index arrhythmia for secondary prevention was sustained ventricular tachycardia (VT) in 72% and ventricular fibrillation (VF) in 28%, respectively. Patients with coronary artery disease (CAD) were further divided in those completely revascularized (56%) and those with residual significant stenoses  $> 70\%$  or a central occluded main vessel, respectively (29% and 15%, respectively). Further on we distinguished whether one (36%) or more than one main vessel (8%) was not completely revascularized. Patients with the diagnosis of a non-ischemic cardiomyopathy were subdivided whether they suffered from post myocarditis dilated cardiomyopathy (DCM) or from other types of cardiomyopathy (e.g., ARVD, LV non-compaction, HOCM, primary channelopathy).

### **Results of intra-operative defibrillation testing**

Effective defibrillation SMT was performed in 596 patients (96.4%) with a mean energy of  $20.8 \pm 2.3$  J. In 22 patients (3.6%) induced VF could only be terminated with the maximum energy of the implanted device or with an external defibrillation (Table 1). There were no severe complications (death, major or minor strokes or cardiogenic shock) in any of the 618 SMT performed.

In 22 patients (3.6%) a  $> 10$  J SMT could not be achieved intra-operatively with the initial ICD configuration. The patients with ineffective SMT were younger ( $P = 0.003$ ), and in univariate analysis they were less likely to have CAD as underlying diagnosis ( $P = 0.007$ ) or VT as the index arrhythmia ( $P = 0.05$ ) for secondary ICD indication (Table 1).

Variables without impact on the efficiency of SMT in univariate analysis included whether or not patients had a LVEF  $< 20\%$ , had a secondary preventive indication for ICD, were incompletely revascularized, had more than one main coronary vessel significantly diseased and were

taking amiodarone, respectively (Table 1).

### **Management of patients with ineffective initial SMT**

The characteristics of the patients with ineffective SMT are depicted in Table 2. One or more of the following system modifications were initiated: Reprogramming the defibrillation polarity in 21 and deactivation of the SVC shock coil in 19 patients as well as repositioning the right ventricular lead in 12 patients. Six patients (27%) passed subsequent SMT, 16 patients had still ineffective SMT and were planned for a subcutaneous electrode array. Two patients refused further procedures and in the remaining 14 patients an adequate SMT  $> 10$  J was documented post implantation of a subcutaneous electrode array.

### **Tachyarrhythmia events during follow up**

The mean follow up was 23.6 (+21) mo for patients with initially effective SMT and 15.8 (+21) mo for those with initially ineffective SMT. Antiarrhythmic medication was equally balanced between both groups (Table 3). In general, there were significantly more events in patients with CAD (19.6%) compared to patients with non CAD (12.1%)  $P = 0.02$ . There was a trend towards more events in patients with secondary prophylactic ICD indication ( $P = 0.08$ ). No death or resuscitation occurred during the follow-up period, and 124/530 patients (23.4%) with initial effective SMT and 2/22 patients (9.1%) with initially ineffective SMT ( $P = 0.02$ ) experienced tachyarrhythmia events (Table 3).

## DISCUSSION

We analyzed a very large population undergoing intra-operative ICD defibrillation testing<sup>[6]</sup>, including a significant group of patients (284 patients, 46% of total) with an LVEF  $< 20\%$ , a patient group that was unlikely undergoing intra-operative ICD testing<sup>[11-14,16]</sup> or was even excluded from former studies<sup>[17]</sup>.

Our data show several important findings: (1) Ineffective SMT occurred in roughly 4% of ICD implantations. Despite ICD-System reprogramming as well as RV shock lead repositioning, two thirds of those required implantation of a subcutaneous electrode array to pass a SMT  $> 10$  J; (2) SMT can be performed safely and without major complications, even in patients with an LVEF  $< 20\%$ . There was no impact on the efficacy of SMT compared to patients with an LVEF  $> 20\%$ ; (3) Severe coronary 2 or 3 vessel disease with residual significantly stenosed/occluded main vessels showed no impact on safety and efficacy of SMT; and (4) The percentage of patients who are unsuitable for intra-operative defibrillation testing is small (2.5% of our study population).

### **Ineffective intra-operative safety margin testing**

Despite advancements during the last years in ICD systems and lead technology resulting in enhanced defibrillation efficacy, 4% in our patient population failed to

SMT: Safety margin test; n: Number; SD: Standard deviation; IQR: Interquartile range; LVEF: Left ventricular ejection fraction; BMI: Body mass index; pp: Primary prevention; sp: Secondary prevention; VT: Ventricular tachycardia; VF: Ventricular fibrillation; CAD: Coronary artery disease; DCM: Dilated cardiomyopathy; CM: Cardiomyopathy; amio: Amiodarone; n.s.: Not significant; n/a: Not applicable.

achieve the conventional SMT > 10 J. This in line with similar findings of 6%-7% insufficient SMT in older retrospective studies<sup>[11,16]</sup> using less sophisticated ICD-systems, suggesting that an adequate defibrillation threshold is not only dependent on the implanted ICD-system. Russo *et al.*<sup>[16]</sup> found that simply changing to a high output ICD-system to pass an initially insufficient SMT was not enough in 48% of patients. This further highlights the fact that an SMT < 10 J exhibits a more complex problem than just deliver higher shock energy<sup>[9]</sup> and that individual measures have to be taken to reach an acceptable SMT > 10 J. According to our data and in line with previous findings, VF as the index arrhythmia for ICD implantation, the diagnose of a non-ischemic cardiomyopathy and younger age were associated with a higher incidence of ineffective SMT. However, none of these predictors helped to identify the 22 patients of our study who failed to pass

a SMT > 10 J (Table 2). In line with previous findings<sup>[12,16]</sup>, our study revealed that still two third of patients after ICD system modification and RV lead replacement required further measures to reach a subsequent SMT > 10 J. In our study, we implanted a subcutaneous electrode array, a measure that is considered to be the most effective for reducing defibrillation threshold<sup>[15]</sup>. Inconsistent evidence exists regarding long term outcome of patients who do not meet an intra-operative SMT > 10 J<sup>[6,7,18]</sup> or where not tested at all<sup>[9,10]</sup>.

On the other side, the HRS/EHRA/APHS/SOLACE expert consensus statement on ICD programming and testing<sup>[21]</sup> states with a Class IIa recommendation, "that it is reasonable to omit defibrillation testing in patients undergoing initial left pectoral transvenous ICD implantation procedures where appropriate sensing, pacing and impedance values with fluoroscopically

**Table 2** Characteristics of patients with failed intra-operative safety margin test

<i>n</i>	Age at time of implantation (years)	Sex (m/f)	Indication for ICD implantation	LVEF (%)	Primary vs secondary ICD indication	Further management after failed initial SMT

well-positioned RV leads". Furthermore, with a class IIa recommendation the expert consensus state "that defibrillation testing is reasonable in patients undergoing a right pectoral transvenous ICD implantation or ICD pulse generator changes".

For the arguments mentioned above we recommend that a decision to perform intraoperative testing during ICD placement without absolute contraindication should be taken case-by-case. Our data suggest that the intraoperative testing should be considered for patients who are younger, patients with non-CAD as underlying disease and VF as the index arrhythmia for secondary ICD indication. Furthermore patients with HCM, special conditions such as severe obesity, amiodarone use and right pectoral implants as well as pre-existing

RIATA (SJM) leads should be considered to be tested intraoperatively.

#### **Rationale for intra-operative defibrillation testing**

Up to 65% of implantation procedures are performed without any induction test<sup>[6,14]</sup>. Patients less likely to be tested were sicker and therefore more likely to have adverse outcomes, including death<sup>[6,11,13,16]</sup>. The strength of our study is that intra-operative testing was done in 97.5% of all consecutive patients. In contrast to former studies<sup>[11-13,16]</sup> we could show that testing the ICD at the time of placement is safe and effective, even if sicker patients (*e.g.*, LVEF < 20% and severe, non revascularized coronary 2 or 3 vessel disease) were included. Newer ICD systems with advancements in

defibrillator and lead technology and resulting enhanced defibrillation efficacy may be one reason for this finding. Nevertheless, 22 patients (4%) of our study population had an ineffective intra-operative SMT and would have been missed without consequently passing all patients without a clear contraindication through an intra-operative defibrillation test. Even if only a small fraction of patients could potentially benefit from a SMT at ICD-implantation, it poses a forensic issue to prove at least once device efficacy in adequate sensing, computing and termination of VF. In our study, 14/22 patients needed the implantation of a subcutaneous electrode array to achieve adequate DFTs. Although several reasons imply that long term survival may not necessarily be affected whether or not defibrillation testing is done<sup>[6,9,10,18]</sup>, one study suggested that not having a defibrillation test was an independent risk factor of SCD even if sicker patients were the ones not tested<sup>[11]</sup>. However, no study so far was sufficiently powered to establish equivalence or superiority of a strategy of no testing vs SMT at the time of ICD placement as Strickberger *et al.*<sup>[22]</sup> calculated a sample size of approximately 29000 patients that would need to be randomized in a mortality study to achieve definite conclusions on this question with an adequate statistical power.

Two recently published randomised studies showed that defibrillation testing at the time of ICD implantation does not appear to predict total mortality<sup>[9,10]</sup>. But still it remain legal and regulatory considerations: The labelling on all ICD's recommend an assessment of defibrillation efficacy at implant not least to document the defibrillation behaviour with new drugs and the integrity of new ICD systems coming to the market.

For the reasons mentioned above and underlined with the finding of our study, we conclude that defibrillation testing remains an important part of ICD placement and the decision to perform or omit testing should be taken case-by-case.

In conclusion, in the absence of sufficiently powered studies evaluating long term outcome of patients with an ineffective intra-operative defibrillation testing, our findings underline that routine SMT still remains an important part of ICD placement. An ineffective SMT occurs in about 4% of patients, and even after ICD system modification and RV shock lead repositioning three quarter of those need implantation of a subcutaneous electrode array to pass a SMT > 10 J.

## COMMENTS

### Background

The implantable cardioverter defibrillator (ICD) is widely accepted for primary and secondary prevention of severe life-threatening ventricular tachyarrhythmia. However the importance concerning defibrillation testing at the time of implantation and clinical relevance of inadequate testing of ICD devices still remains under debate.

### Research frontiers

Defibrillation testing was done at the time of implantation in randomized trial investigating the efficacy of ICD therapy. They critically reflect the progressive

trend to omit defibrillation testing at the time of ICD placement.

### Innovations and breakthroughs

Two recently published randomised studies showed that ICD implantation without defibrillation testing is non-inferior to implantation with testing. Although one of these studies included 2500 patients, it is still underpowered to address the question of future shock efficacy or reduction of arrhythmogenic death. The authors' study present a large cohort of patients undergoing ICD-implantation and showed that in 4% of the patients the ICD did not terminate induced VT during intraoperative testing. Furthermore their data suggested that intraoperative testing of the ICD is a well-tolerated procedure.

### Applications

The data of their study showed that intraoperative ICD-testing lead in a not negligible percentage of patients to a system modification or even a subcutaneous array implantation to prove correct detection and termination of induced ventricular fibrillation at the time of ICD-implantation.

### Terminology

ICD are routinely implanted since 30 years to prevent sudden cardiac death. The detection of a life-threatening ventricular arrhythmia leads to a biphasic high energy 30-40 J impulse between the RV-coil and the subscapular located aggregate to terminate the arrhythmia. Testing the correct detection and termination of induced ventricular fibrillation at the time of ICD implantation is included as a recommendation in product labels.

### Peer-review

This is a well-written paper.

**Abstract****AIM**

To investigate the association between carotid atherosclerosis and cystatin C (CysC) and to determine the optimal CysC cut-off value.

**METHODS**

One hundred twenty-eight subjects were included in this study. Atherosclerosis was defined as a maximum carotid plaque thickness (MCPT) of greater than 2 mm. A receiver operating characteristic curve analysis was used to determine the diagnostic value of serum CysC for atherosclerosis. The subjects were divided into two groups according to the CysC cut-off value. We screened

for diabetes, hypertension, dyslipidemia, smoking status, alcohol consumption, and exercise behavior. The association between atherosclerosis and CysC levels was assessed using multivariate analysis.

## RESULTS

The subjects were then divided into two groups according to the CysC cut-off value (0.73 mg/L). The median age of the high CysC group was 72 years (85% males), whereas that of the low CysC group was 61 years (63% males). The CysC levels were significantly correlated with Cr and estimated glomerular filtration rate (eGFR) values. Body-mass index, visceral fat area, hypertension, diabetes mellitus, and MCPT were significantly higher in the high CysC group than in the low CysC group. Furthermore, the eGFR was significantly lower in the high CysC group. Regarding lifestyle habits, only the exercise level was lower in the high CysC group than in the low CysC group. Multivariate analysis, adjusted for age and sex, revealed that high CysC levels were significantly associated with an MCPT of  $\geq 2$  mm (odds ratio: 2.92; 95%CI: 1.13-7.99).

## CONCLUSION

Higher CysC levels were associated with an MCPT of  $\geq 2$  mm. The CysC cut-off value of 0.73 mg/L appears to aid in the diagnosis of atherosclerosis.

**Key words:** Cystatin C; Atherosclerosis; Carotid plaque; Maximum carotid plaque thickness; Visceral fat

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Atherosclerosis is a leading worldwide cause of morbidity and mortality. The association between cystatin C (CysC) and atherosclerotic disorders remains controversial, and the cut-off value of CysC for atherosclerosis is unknown. Our study revealed that the optimal CysC cut-off point was 0.73 mg/L by receiver operating characteristic curve analysis. Higher CysC levels were significantly and independently correlated with an maximum carotid plaque thickness of  $\geq 2$  mm in multivariate analysis. Our data indicate that CysC could be a useful laboratory tool for predicting atherosclerosis during health checkups.

Association between high cystatin C levels and carotid atherosclerosis. *World J Cardiol* 2017; 9(2): 174-181 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i2/174.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i2.174>

## INTRODUCTION

Atherosclerosis is a leading worldwide cause of morbidity and mortality<sup>[1,2]</sup>. The incidence of cardiovascular diseases (CVDs), including cerebrovascular, peripheral arterial, and coronary artery disease, is increasing and

accounts for approximately one-fourth of all deaths in World Health Organization member states<sup>[3]</sup>. More than 17 million people die annually from CVDs, and, by 2030, more than 23 million CVD-related deaths are expected to occur worldwide. In Japan, the age-standardized fraction of mortality from CVDs is approximately 30%.

The ankle-brachial index, pulse-wave velocity, flow-mediated dilation, and ultrasonic evaluation have been introduced as methods for assessing the structural and functional effects of atherosclerosis<sup>[4-6]</sup>. Carotid atherosclerosis, estimated by intima-media thickness (IMT), is a sensitive surrogate marker for CVD and can now be non-invasively measured by B-mode ultrasonography<sup>[7,8]</sup>. IMT is a marker for systemic subclinical atherosclerosis and a strong predictor of incident myocardial infarction and ischemic stroke<sup>[9,10]</sup>. Carotid plaque may be an even more powerful predictor of vascular outcomes than IMT<sup>[11,12]</sup>. Maximum carotid plaque thickness (MCPT), widely used for assessing atherosclerotic change, is associated with an increased risk of vascular morbidity<sup>[13]</sup>.

High plasma adiponectin independently predicted death and major adverse cardiovascular events in a large community-based population<sup>[14]</sup>. High-sensitivity C-reactive protein serum levels were reported to be significantly related to the severity of coronary atherosclerosis<sup>[15]</sup>. In addition to these markers, serum cystatin C (CysC) has recently been proposed as a more reliable biomarker for atherosclerosis and chronic renal disease. Furthermore, high CysC levels are indicated as a useful marker for identifying an elevated risk of CVD and a higher total mortality among patients assessed as being at low risk by both creatinine (Cr) and estimated glomerular filtration rate (eGFR) values<sup>[16,17]</sup>. A previous study revealed that atherosclerotic changes associated with inflammation could be one mechanism by which CysC is associated with CVD<sup>[16]</sup>. However, the association between CysC and atherosclerotic disorders remains controversial, the cut-off values of CysC for atherosclerosis are unknown, and previous reports on this association as well as the association between CysC and MCPT are limited<sup>[18-20]</sup>. A diagnostic CysC cut-off value has not been determined. In this study, we examined the association between CysC levels and atherosclerotic changes in Japanese subjects.

## MATERIALS AND METHODS

### Subjects

The present cross-sectional study included 133 Japanese subjects who underwent an inpatient medical health checkup at Juntendo University Hospital, Tokyo from October 2010 to January 2013. Among these subjects, five were excluded because of missing laboratory data. Thus, 128 subjects [98 men and 30 women; median age, 70 years (age range, 39-87 years)] were included.

The subjects were asked to complete a self-administered questionnaire about their sociodemographic characteristics, past medical history (diabetes, hypertension, and dyslipidemia), and lifestyle behaviors (alcohol

consumption, current smoking status, and daily exercise activity).

The body weight, height, and waist circumference of the patients were measured, and the body-mass index [BMI (kg/m<sup>2</sup>)] was calculated. Systolic and diastolic blood pressure were measured in a sitting position after a 15-min rest using a standard mercury sphygmomanometer. Venous blood samples were collected following overnight fasting. Plasma glucose concentrations, hemoglobin A1c (HbA1c), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), triglyceride (TG), Cr, and CysC levels were also measured. Low-density lipoprotein cholesterol was estimated using the Friedewald equation [TC-HDL-C-(TG/5)]. For the assessment of visceral fat accumulation, abdominal fat areas were measured from abdominal CT scans taken at the umbilical level while in the supine position and during late expiration, according to the Japanese Guidelines for Obesity Treatment<sup>[21]</sup>.

The following parameters were calculated: eGFR was calculated using the Japanese GFR inference formula, which was developed by the Japanese Society of Nephrology<sup>[22]</sup>:  $eGFR \text{ (mL/min per } 1.73 \text{ m}^2) = 194 \times \text{serum Cr (mg/dL)} - 1.094 \times \text{age (years)} - 0.287 (\times 0.739 \text{ if female})$ .

HbA1c was calculated as the National Glycohemoglobin Standardization Program (NGSP) value (%), which was developed by the Japan Diabetes Society<sup>[23]</sup>:  $\text{HbA1c} = \text{NGSP} (\%) \times 1.02 + 0.25$ .

Lifestyle-related diseases were defined using several criteria: (1) diabetes mellitus was defined as an HbA1c level of  $\geq 6.5\%$ , a fasting plasma glucose level of  $\geq 126 \text{ mg/dL}$ , or current antidiabetic therapy<sup>[24]</sup>; (2) hypertension was defined by a systolic blood pressure of  $\geq 140 \text{ mmHg}$ , a diastolic blood pressure of  $\geq 90 \text{ mmHg}$ , or current antihypertensive therapy<sup>[25]</sup>; and (3) dyslipidemia was defined as a fasting TG level of  $\geq 150 \text{ mg/dL}$ , a low-density lipoprotein cholesterol level of  $\geq 140 \text{ mg/dL}$ , or an HDL-C level of  $< 40 \text{ mg/dL}$ <sup>[26]</sup>. Three unhealthy lifestyle behaviors were evaluated in this study: Drinking alcohol more than once a week, current smoking, and no regular physical activity.

A detailed protocol for measuring carotid artery atherosclerosis has been published<sup>[27]</sup>. Carotid plaque and IMT were measured using high-resolution B-mode ultrasonography to estimate atherosclerosis in the carotid artery. Eight technicians who were trained by a supervisor physician and who were certified in the protocol assessed carotid plaque and the mean IMT of the common carotid artery. A plaque was defined as a maximum IMT of  $> 1.0 \text{ mm}$ . MCPT was measured at the peak plaque prominence in any of the carotid artery segments. Atherosclerosis was defined on the basis of the severity of carotid atherosclerosis by MCPT at a cut-off level of 2 mm. As previously reported, an MCPT of  $\geq 2 \text{ mm}$  is defined as an atherosclerotic change<sup>[13]</sup>.

### Statistical analysis

The results were expressed as medians of the test

parameters. The Youden index, a point on the receiver operating characteristic (ROC) curve, was used to determine the diagnostic values of serum CysC levels that were indicative of atherosclerosis.

In a second analysis, the subjects were divided into two groups according to CysC levels above and below the cut-off value. Their demographic characteristics were then compared using the *t* test for continuous variables and the chi-square test for categorical variables. Multiple logistic regression analysis with adjustments for age and sex was conducted to determine the correlations between an MCPT of  $\geq 2 \text{ mm}$  and metabolic variables including CysC level. Our study included only 128 subjects, of whom 52 had arteriosclerosis. Because there is a limit to the number of adjusted variables, we combined several metabolic related variables in one item. Variables that were significantly associated with an MCPT of  $\geq 2 \text{ mm}$  were then investigated with multiple logistic regression analysis.

Statistical test results were considered significant when the *P* value was  $< 0.05$ . All calculations were performed using JMP Pro, version 11 (SAS Institute, Cary, NC, United States). The study protocol was approved by the Human Ethics Committee of Juntendo University. The participants' clinical data were retrospectively retrieved from an institutional database. All of the examinations included in this study were performed as a routine part of the program, and none were aimed at specifically collecting data for the current study. The study protocol was approved by the institutional ethics committee, so it was not necessary to obtain informed consent from the participants. A biostatistician reviewed the study.

## RESULTS

The subject characteristics are shown in Table 1. The median age was 70 years (77% males). Twenty-three (18%) subjects smoked, 78 (61%) were alcohol consumers, and 90 (70%) did not exercise regularly. The median visceral fat area was 125.2 cm<sup>2</sup>. Sixty-one (48%) subjects were diagnosed with hypertension, 72 (56%) with dyslipidemia, and 29 (23%) with diabetes mellitus. The ROC analysis conducted to determine the cut-off value of CysC revealed a significantly higher risk of atherosclerosis at 0.73 mg/L (Figure 1) (sensitivity: 82.7%, specificity: 52.6%).

The subjects were then divided into two groups according to the CysC cut-off value (0.73 mg/L). The subjects' characteristics according to the CysC level are shown in Table 2. The median age of the high CysC group was 72 years (85% males), whereas that of the low CysC group was 61 years (63% males). The CysC levels were significantly correlated with Cr and eGFR values. BMI, visceral fat area, hypertension, diabetes mellitus, and MCPT were significantly higher in the high CysC group than in the low CysC group. Furthermore, the eGFR was significantly lower in the high CysC group. Regarding lifestyle habits, only the exercise level was

Diastolic blood pressure (mmHg)	68 (50, 86)
Diagnosed hypertension	61 (48)
Lipid metabolism	
Total cholesterol (mg/dL)	194.5 (115, 727)
High-density lipoprotein cholesterol (mg/dL)	54 (30, 96)
Low-density lipoprotein cholesterol (mg/dL)	111 (41, 205)
Triglycerides (mg/dL)	99.5 (37, 593)
Diagnosed dyslipidemia	72 (56)
Glucose metabolism	
Fasting plasma glucose (mg/dL)	93.5 (74, 226)
Hemoglobin A1c (%)	5.3 (4.5, 8.3)
Diagnosed diabetes mellitus	29 (23)
Kidney function	
Creatinine (mg/dL)	0.75 (0.38, 1.36)
Estimated glomerular filtration rate (mL/min per 1.73 m <sup>2</sup> )	78.4 (38.9, 122.6)
Cystatin C (mg/L)	0.78 (0.49, 1.45)
Carotid ultrasonography	
Right common carotid artery plaque thickness (mm)	0 (0, 3.6)
Right carotid bulb-internal carotid artery plaque thickness (mm)	1.5 (0, 5.5)
Left common carotid artery plaque thickness (mm)	0 (0, 2.8)
Left carotid bulb-internal carotid artery plaque thickness (mm)	1.5 (0, 4.2)
Right common carotid artery maximum intima-media thickness (mm)	1.0 (0.6, 1.9)
Left common carotid artery maximum intima-media thickness (mm)	1.0 (0.7, 2.3)

lower in the high CysC group than in the low CysC group. In addition, sensitivity, specificity, positive predictive value, and negative predictive value as calculated from the data in Table 2 were 83%, 53%, 54% and 82%, respectively.

Next, we compared differences in demographics and clinical variables between subjects with MCPTs of  $\geq 2$  mm or  $< 2$  mm (Table 3). Age, visceral fat area, hypertension, diabetes mellitus, Cr, eGFR, and CysC were significantly higher in the MCPT of  $\geq 2$  mm group than the  $< 2$  mm group. Furthermore, the eGFR was significantly lower in the MCPT of  $\geq 2$  mm group. The two groups did not differ with regard to lifestyle habits.

The factors associated with an MCPT of  $\geq 2$  mm are shown in Table 4. Multivariate analysis, adjusted for age and sex, revealed that high CysC levels were significantly associated with an MCPT of  $\geq 2$  mm (odds ratio: 2.92; 95%CI: 1.13-7.99).

**Figure 1** Receiver operating characteristic curve for predictive value of serum cystatin C levels. The receiver operating characteristic curve for the predictive value of serum CysC levels in detecting a MCPT of  $> 2$  mm in 128 subjects had an area under the curve of 0.724. A serum CysC level of  $\geq 0.73$  mg/L indicated an MCPT of  $> 2$  mm with 82.7% sensitivity and 52.6% specificity. CysC: Cystatin C; MCPT: Maximum carotid plaque thickness.

## DISCUSSION

In this study, multivariate analysis revealed that higher CysC levels were significantly associated with carotid atherosclerosis, as defined by an MCPT of  $\geq 2$  mm, in middle-aged and elderly Japanese subjects. The cut-off CysC value (0.73 mg/L) could aid in the diagnosis of atherosclerosis. To our knowledge, this is the first report demonstrating an association between CysC and carotid atherosclerosis as assessed by MCPT. The CysC cut-off level potentially has promising clinical value in the diagnosis of atherosclerosis.

Our results revealed a significant association between high CysC levels and an MCPT of  $\geq 2$  mm. A meta-analysis previously revealed that CysC is strongly and independently correlated with the risk of subsequent cardiovascular disease<sup>[28]</sup>. Although several studies have revealed an association between high CysC levels and atherosclerosis, their results differed from ours because of the different targets and indicators used. A previous study, which analyzed 637 Japanese subjects without chronic kidney disease, revealed that CysC was positively correlated with the cardio-ankle vascular index in women<sup>[19]</sup>. In a study of 60 Japanese hypertensive patients, serum CysC levels were positively correlated with carotid IMT<sup>[29]</sup>. In data collected *via* 64-slice CT coronary angiography, a high CysC level was found to be significantly correlated with early-stage coronary atherosclerotic plaques in 405 Japanese patients without established chronic kidney dysfunction<sup>[18]</sup>. Our results are in agreement with the previous hypothesis that CysC level is a reliable marker for atherosclerosis.

There are several possible explanations for the association between CysC and atherosclerotic change. First, inflammation may be associated with both CysC and atherosclerosis. The Cardiovascular Health Study<sup>[30]</sup>, which

**Table 2** Subject characteristics associated with cystatin C levels

Variables	Median (min, max) or <i>n</i> (%)		<i>P</i> value

analyzed 4637 ambulatory elderly patients, revealed a significant linear association between CysC and C-reactive protein but not Cr or eGFR<sup>[31]</sup>. It is well known that inflammation plays a role in atherogenesis, atherosclerotic plaque progression, and acute coronary syndrome. Second, CysC plays an important role in maintaining atherosclerotic plaque stability. A previous study<sup>[32]</sup> analyzed 31 plaques removed by endarterectomy, demonstrating with immunohistochemistry that CysC in human carotid plaques localized with collagen and elastin. An imbalance between cysteine proteases and CysC in arterial wall remodeling occurs in vascular diseases, such as atherosclerosis and abdominal aortic aneurysm<sup>[33]</sup>.

Imaging assessments, such as ultrasound and CT, are often performed for assessing arteriosclerotic vascular disease. However, not all institutions can practice such assessments because of the lack of sonographers or

appropriate devices. Therefore, it is potentially important that atherosclerosis can be evaluated using a blood test, such as for CysC levels. A diagnostic CysC cut-off value has not been previously determined. Our study revealed that the CysC cut-off value of 0.73 mg/L could contribute to the diagnosis of atherosclerosis.

Our study had a few limitations. First, the subjects were selected from a single institution, the sample size was small, and  $> 70\%$  of our subjects were healthy men. Selection bias may have affected the analysis, as the investigated cohort did not accurately represent the Japanese population. Thus, future large-scale cohort studies are required. Second, lifestyle habits were evaluated using a self-administered questionnaire, and the subjects may have stated that they had a healthier lifestyle than they actually did. Further evaluations of lifestyle habits based on a validated questionnaire are

**Table 4** Univariate and multivariate logistic regression analysis for variables associated with an maximum carotid plaque thickness of  $\geq 2$  mm

Variables	Univariate		Multivariate <sup>1</sup>	
	Odds ratio	95%CI	Odds ratio	95%CI
Cystatin C	5.31	2.27-12.39	2.92	1.13-7.99
Diabetes mellitus	3.13	1.33-7.37	1.82	0.70-4.86

Dyslipidemia	0.97	0.48-1.97		
Current smoking	0.91	0.36-2.30		
Alcohol consumers	0.61	0.29-1.25		
Exercise habits	0.67	0.31-1.45		
Visceral fat area $\geq 100$ cm <sup>2</sup>	1.31	0.62-2.78		
$\Delta$ AICc <sup>2</sup>			158	
<sup>3</sup> R <sup>2</sup>			0.16	

<sup>1</sup>Adjusted for age and sex; <sup>2</sup>Akaike's Information Criterion; <sup>3</sup>Coefficient of determination.

necessary. Third, causal inferences cannot be made because of the cross-sectional nature of the study design. A prospective study is required for determining whether higher CysC levels are associated with the development of atherosclerosis-related diseases or death.

In conclusion, higher CysC levels were correlated with carotid atherosclerosis as defined by an MCPT of  $\geq 2$  mm among middle-aged and elderly Japanese subjects. Higher CysC levels have a low specificity but a high sensitivity and can therefore help exclude atherosclerosis. The CysC cut-off value of 0.73 mg/L appears to aid in the diagnosis of atherosclerosis. Our data indicate that CysC could be a useful laboratory tool for predicting atherosclerosis during health checkups.

## COMMENTS

### Background

Atherosclerosis is a leading worldwide cause of morbidity and mortality. Carotid plaque may be a powerful predictor of vascular outcomes. Maximum carotid plaque thickness (MCPT), widely used for assessing atherosclerotic change, is associated with an increased risk of vascular morbidity.

### Research frontiers

Serum cystatin C (CysC) has recently been proposed as a reliable biomarker for atherosclerosis and chronic renal disease. However, the association between CysC and atherosclerotic disorders remains controversial, the cut-off values of CysC for atherosclerosis are unknown, and previous reports on this association as well as the association between CysC and MCPT are limited. A diagnostic CysC cut-off value has not been determined.

### Innovations and breakthroughs

Higher CysC levels were associated with an MCPT of  $\geq 2$  mm. The CysC cut-off value of 0.73 mg/L appears to aid in the diagnosis of atherosclerosis.

### Applications

It may be difficult for an institution to practice imaging assessment because of the lack of sonographers or appropriate devices. Therefore, it is potentially

important that atherosclerosis can be evaluated using a blood test, such as CysC levels. The CysC cut-off value of 0.73 mg/L could contribute to the diagnosis of atherosclerosis.

### Terminology

CysC is a 13-kD protease inhibitor which is produced by all nucleated cells. It is mainly used as a biomarker of kidney function. Recently, it has been studied for its role in predicting new-onset or deteriorating cardiovascular disease.

### Peer-review

This is a well-written article investigating the association between CysC and carotid atherosclerosis.

### Abstract

#### AIM

To perform a systematic-review and meta-analysis to compare outcomes of ivabradine combined with beta-blocker to beta-blocker alone in heart failure with reduced ejection fraction (HFrEF).

#### METHODS

We searched PubMed, Cochrane, EMBASE, CINAHL and Web of Science for trials comparing ivabradine + beta-blocker to beta-blocker alone in HFrEF. We performed a systematic-review and meta-analysis of published literature. Primary end-point was combined end point of cardiac death and hospitalization for heart failure.

#### RESULTS

Six studies with 17671 patients were included. Mean follow-up was  $8.7 \pm 7.9$  mo. Combined end-point of heart failure readmission and cardiovascular death was better in ivabradine + beta-blocker group compared to beta-blocker alone (RR: 0.93, 95%CI: 0.79-1.09,  $P = 0.354$ ). Mean difference (MD) in heart rate was higher in the ivabradine + beta-blocker group (MD: 6.14, 95%CI: 3.80-8.48,  $P < 0.001$ ). There was no difference in all cause mortality (RR: 0.98, 95%CI: 0.89-1.07,  $P = 0.609$ ), cardiovascular mortality (RR: 0.99, 95%CI: 0.86-1.15,  $P = 0.908$ ) or heart failure hospitalization (RR: 0.87, 95%CI: 0.68-1.11,  $P = 0.271$ ).

#### CONCLUSION

From the available clinical trials, ivabradine + beta-blocker resulted in a significantly greater reduction in HR

coupled with improvement in combined end-point of heart failure readmission and cardiovascular death but with no improvement in all cause or cardiovascular mortality. Given the limited evidence, further randomized controlled trials are essential before widespread clinical application of ivabradine + beta-blocker is advocated for HFrEF.

**Key words:** Ivabradine; Heart failure

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Ivabradine was recently given a class IIa indication in the 2016 focused update on systolic heart failure in the ACC/AHA/HFSA guidelines. But it is unclear whether ivabradine offers any additional benefit over and above that offered by beta blockers. Our analysis showed lower heart rate and combined end point of cardiac death and heart failure hospitalization at follow-up with ivabradine combined with beta blocker compared to beta blocker alone. Combined therapy did not improve cardiovascular mortality, all cause mortality or heart failure hospitalization. Further studies are essential before widespread use of combination therapy with ivabradine can be recommended.

## INTRODUCTION

Chronic congestive heart failure affects nearly 2%-3% of population and is associated with a one-year mortality of 6.4% in a recent study<sup>[1]</sup>. Standard pharmacological treatment for heart failure with reduced ejection fraction (HFrEF) includes beta-blockade which unequivocally decreases cardiovascular and heart failure related morbidity and mortality, in addition to promoting beneficial reverse remodeling<sup>[2,3]</sup>.

Elevated resting heart rates has been shown to be an independent predictor of mortality in heart failure, presumably acting through increased myocardial oxygen demand, and also serves as a marker of severity of underlying neurohormonal activation and cardiovascular disease<sup>[4-6]</sup>. In regard to the former, in patients with left ventricular dysfunction associated with ischemic cardiomyopathy, heart rates > 70 beats per minute (bpm) are associated with a 34% increase in cardiovascular mortality and 53% increase in hospitalization when compared to heart rates below 70 bpm<sup>[7]</sup>. Benefits derived from beta-blockers seem to be derived partly from their heart rate lowering properties<sup>[8]</sup>. However, their negative inotropic properties can have undesirable actions on

myocardial contractility<sup>[9]</sup>.

Ivabradine is a novel drug that inhibits the pacemaker current I(f) thereby slowing heart rates without exhibiting negative inotropic effect on the myocardium<sup>[10]</sup> or altering ventricular action potential<sup>[11]</sup>. In SHIFT<sup>[12]</sup>, ivabradine improved the composite end point of hospitalization and cardiovascular death in patients with HFrEF in sinus rhythm with heart rates  $\geq 70$ <sup>[12,13]</sup>. The 2016 American College of Cardiology/American Heart Association/Heart Failure Society of America (ACC/AHA/HFSA) Focused Update on the Management of Heart Failure<sup>[14]</sup> and the European Society of Cardiology (ESC) guidelines<sup>[15]</sup> have given a Class IIa (level of evidence B) recommendation for ivabradine use for patients with chronic HFrEF who are on guideline directed medical therapy [includes a maximum tolerated dose of beta-blocker, ACEi and mineralocorticoid receptor antagonist (MRA)] and who are in sinus rhythm with resting heart rates above 70 bpm (> 75 bpm in the European Society). It should be noted that in the SHIFT trial<sup>[12]</sup>, only 26% of the patient population were on target beta-blocker dosage. Thus the utility of ivabradine in the modern era, particularly with the recent approval of sacubitril with its dramatic improvement in mortality and heart failure outcomes<sup>[16]</sup> remains uncertain. To consolidate the available evidence regarding ivabradine in HFrEF, we performed a systematic review and meta-analysis including all the available clinical trials to date to evaluate the benefit of ivabradine therapy in combination with beta-blocker compared to beta-blocker alone in chronic HFrEF.

## MATERIALS AND METHODS

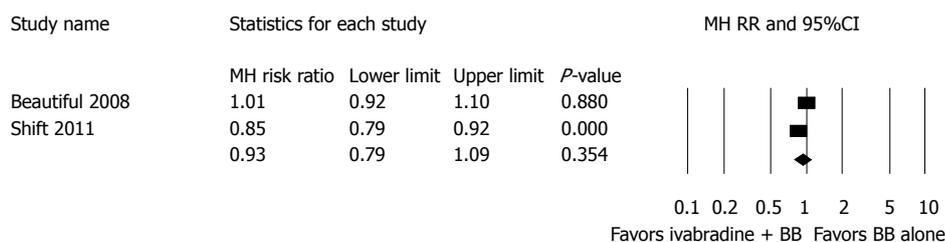

### Data search

An electronic database search was performed with the following search terms "ivabradine", "heart failure with reduced ejection fraction", "resting heart rates" and "systolic heart failure" in PubMed, EMBASE, Cochrane, CINAHL and Web of Science for studies published between January-1960 and August-2016 comparing the addition of ivabradine to beta-blocker vs beta-blocker only therapy. Supplementary appendix-1 shows PubMed search strategy.

The systematic review and meta-analysis was performed per PRISMA guidelines as shown in the Supplementary checklist<sup>[17]</sup> and Supplementary Figure 1 shows the PRISMA flowchart. We also reviewed relevant editorials, review articles and reference sections of included studies. We excluded conference abstracts with unpublished data as mentioned in the Cochrane guidelines for meta-analysis. An expert biostatistician has reviewed the paper for statistical accuracy.

### Inclusion criteria

Studies selected met the following criteria: Randomized controlled trials (RCTs), retrospective or prospective observational cohorts; included HFrEF of < 40%; compared two groups, one with ivabradine and beta-blocker and the other with beta-blocker alone; included adult patients;

**Figure 1** Comparison of Mantel-Haenszel risk ratio for combined end points of cardiovascular death and hospitalization for heart failure between ivabradine + beta-blocker vs beta-blocker alone. MH RR: Mantel-Haenszel risk ratio; BB: Beta blockers.

published in English language.

### Study definitions

We defined all cause mortality as death from any cause at follow-up. Cardiovascular mortality was defined as death from any cardiac cause including heart failure, myocardial infarction, arrhythmia, sudden cardiac death or stroke.

### Data extraction

Table 1 shows extracted patient demographics including mean age, sample size, co-morbidities, mortality data and risk estimates. Authors Mahesh Anantha Narayanan and Yogesh N Reddy reviewed the studies independently. A consensus was achieved by a third reviewer when the first two reviewers could not resolve any disagreement. We sought help from an experienced librarian when articles were not available online.

### Outcomes

The primary outcome was combined end-point of heart failure and cardiovascular death. Secondary outcomes included mean reduction in heart rate at follow up compared to baseline, all cause mortality, cardiovascular mortality, six-minute walking distance (6MWD) and ejection fraction (EF) at follow up.

### Statistical analysis

We used comprehensive meta-analysis (CMA) version 3.3.07 for statistical analysis. Categorical events were pooled using the random effects model, with pooled effect size represented by Mantel-Haenszel (MH) risk ratio (RR) with a 95% confidence interval (CI) limit. MH RR is a technique that generates an estimate of association between exposure and outcome after adjusting for confounding. Difference in Means (MD) was used for reporting outcomes with continuous variables. The combined ivabradine and beta-blocker group was the experimental group and so any MH RR (with 95%CI) that is less than 1 favors this cohort. Funnel-plots were used for assessing bias visually. Cochrane's Q-statistics were used to determine heterogeneity.  $I^2$  values of > 50%, 25%-50% and 0%-25% were considered to be high, moderate and low heterogeneity, respectively. We used an exclusion sensitivity analysis to analyze heterogeneity when required. P value of < 0.05 was considered statistically significant. A meta-regression

was performed when necessary to analyze the impact of moderator variables on outcomes of interest.

## RESULTS

### Characteristics of the included studies

A total of 696 studies were obtained using the initial search strategy as shown in Supplementary Figure 1. Initially 7 studies<sup>[12,18-23]</sup> met our inclusion criteria. We excluded the SHIFT sub group study as the sub group was not independent of the main SHIFT study population. Finally, we included 6 studies<sup>[12,18-21,23]</sup> with a total of 17671 patients. Mean follow-up was  $8.7 \pm 7.9$  mo. A total of 8845 patients received ivabradine with beta-blocker and 8826 patients received only beta-blocker. Table 1 shows characteristics of the included studies and Supplementary Table 1 summarizes the results of analyses comparing ivabradine and beta-blocker vs beta-blocker alone in patients with chronic HFrEF.

### Combined end point of cardiovascular death and hospitalization for worsening heart failure

A total of two studies reported combined end-point of cardiovascular death and hospitalization at follow up between the combined ivabradine + beta-blocker and the beta-blocker only group (Figure 1). MH RR was lower in the combined therapy group when compared to beta-blocker only group (MH RR: 0.93, 95%CI: 0.79-1.09,  $P = 0.354$ ). Heterogeneity was high ( $I^2 = 87%$ ) among the included studies.

### Heart rates at follow up

Change in heart rates at follow up from baseline was reported in all included studies. Difference in means (MD) for reduction in heart rate from baseline was greater in the ivabradine + beta-blocker group when compared to beta-blocker alone difference in means (MD): 6.14, 95%CI: 3.80-8.48,  $P < 0.001$  (Figure 2). Funnel-plot showed low risk of bias as shown in Supplementary Figure 2A and heterogeneity was high ( $I^2 = 95$ ). A sensitivity analysis performed with exclusion of the study<sup>[18]</sup> with the maximum strength did not alter the results of the analysis (MD: 6.24, 95%CI: 2.71-9.78;  $P = 0.001$ ). Analysis of only RCTs still showed that mean reduction in heart rates from baseline was greater in the combined ivabradine and beta-blocker group when compared to beta-blocker alone (MD: 6.88, 95%CI:

HR: Heart rate; RCT: Randomized controlled trial.

4.17-9.59;  $P < 0.001$  for RCTs) (Figure 3).

**All cause mortality**

Three studies that reported all cause mortality at follow-up were analyzed (Figure 4). There was no difference in all cause mortality between the combined group and the beta-blocker alone group (MH RR: 0.98, 95%CI: 0.89-1.07,  $P = 0.609$ ). Heterogeneity was low ( $I^2 = 17%$ ). When we excluded the study with maximum weight<sup>[12]</sup>, results remained unaltered (MH RR: 1.04, 95%CI: 0.89-1.07,  $P = 0.609$ ). A meta-regression of follow up time on all cause mortality was insignificant (Supplementary Figure 2B).

**Cardiovascular mortality**

Two studies reporting adverse events at follow-up were analyzed (Figure 5). There was no difference in cardiovascular mortality between the combined group and the beta-blocker alone group (MH RR: 0.99, 95%CI: 0.86-1.15,  $P = 0.908$ ). Heterogeneity was high ( $I^2 = 66%$ ).

**Hospitalization for heart failure**

Two studies reported hospitalization for heart failure (Figure 6). There was no difference in heart failure hospitalization between the combined group and the beta-blocker alone group (MH RR: 0.87, 95%CI: 0.68-1.11,  $P = 0.271$ ). Heterogeneity was high ( $I^2 = 89%$ ).

**6MWD**

Two studies reported 6MWD at follow up when compared to baseline between the combined therapy group with ivabradine plus beta-blocker and the beta-blocker alone group (Figure 7). 6MWD improved significantly from baseline in the combined therapy group (MD: 46.47, 95%CI: 14.678-3,  $P = 0.004$ ). Heterogeneity was low ( $I^2 = 0%$ ).

**Ejection fraction**

Three studies reported ejection fraction at follow up (Figure 8). Improvement in ejection fraction was better in the combined therapy group with ivabradine plus beta-

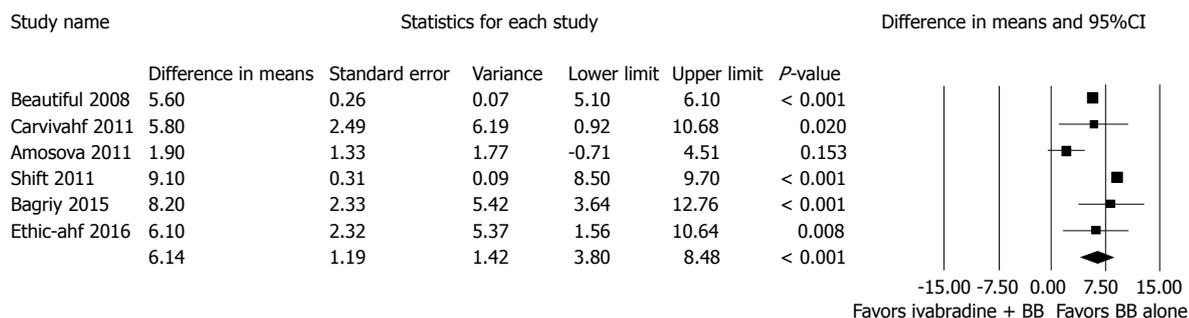

Figure 2 Comparison of mean change in heart rates from baseline between ivabradine + beta-blocker vs beta-blocker alone. BB: Beta blockers.

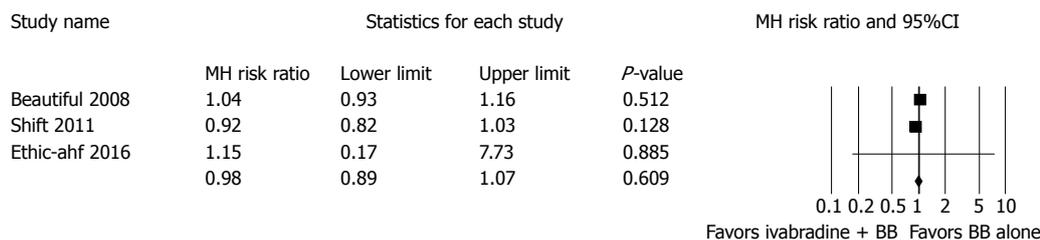

Figure 4 Comparison of Mantel-Haenszel risk ratio for all cause mortality between ivabradine + beta-blocker vs beta-blocker alone. BB: Beta blockers.

blocker when compared to the beta-blocker alone group (MD: 3.27, 95%CI: 0.42-6.13,  $P = 0.025$ ). Heterogeneity was moderate ( $I^2 = 45\%$ ).

## DISCUSSION

In this meta-analysis, ivabradine combined with beta-blockers resulted in a greater reduction of heart rates at follow up when compared to beta-blocker only group. Also, combined therapy was associated with significantly lower composite end-point of cardiovascular death or hospitalization for worsening heart failure. On the other hand, in the relatively short follow-up offered by the included studies, there was no improvement in secondary outcomes including isolated cardiovascular or all cause mortality or individual outcome of heart failure hospitalization. However surrogate markers such as 6MWD and ejection fraction appeared to improve in the ivabradine plus beta-blocker group vs beta-blocker alone. The importance of an improvement in EF with more bradycardia is difficult to determine since at

slower heart rates more complete emptying can occur and may manifest as an improvement in EF without a true increase in LV intrinsic contractility or end systolic elastance.

Ivabradine was approved by the United States Food and Drug Administration for treatment of HFrEF in 2015. It is a very specific inhibitor of hyperpolarization activated cyclic nucleotide gated channels, which decreases the diastolic  $I(f)$  current and reduces sinus rate<sup>[24]</sup>. Ivabradine has no effect on the atrio ventricular node itself<sup>[24]</sup>. In addition, it has been shown that  $I(f)$  channels may increase in chronic heart failure in ventricular myocytes, and this could be arrhythmogenic<sup>[25]</sup>, therefore inhibition of these channels by ivabradine could be beneficial in patients with HFrEF. Ivabradine has use dependency<sup>[26]</sup> and thus the reduction in heart rate is proportional to the baseline heart rate in individuals. Given all these characteristics and its effect of lowering heart rate without inducing the negative inotropic effect of beta-blockers, ivabradine was expected to not only be better tolerated than beta-blockers in HFrEF, but also to be

beneficial by minimizing the adverse cardiac structural changes associated with tachycardia<sup>[12]</sup>.

**Summary of existing trials**

In the BEAUTIFUL trial<sup>[18]</sup>, a double blind RCT, 10917 patients with coronary disease and HFrEF and an EF < 40% were randomized to either ivabradine or placebo. Both groups were on optimal conventional heart failure medications with 87% of the patient population in both groups on beta-blockers; though there was no mention of whether the subjects were on maximal tolerated beta-blocker doses. The BEAUTIFUL study<sup>[18]</sup> reported that 84% of population was in NYHA Class II or III. Four percent of subjects were lost during follow-up. At 24 mo follow up, ivabradine group had a greater improvement in Heart rate with a MD (difference in means) of 5.6

bpm when compared to the placebo group. However, although mortality benefit with heart rate reduction has been shown in multiple studies, BEAUTIFUL<sup>[18]</sup> failed to show any benefit in terms of combined cardiovascular end-point of cardiovascular death, hospital admission for myocardial infarction or new onset worsening heart failure. Also there was no improvement in individual secondary outcomes including all cause mortality, cardiac mortality, hospitalization or worsening heart failure in both the groups.

In the sub-group with heart rates of 70 bpm or more<sup>[18]</sup>, the MD in change from baseline was 6.9 bpm at 24 mo in the ivabradine arm. Although there was no difference between the groups in their primary end-points, there was a statistically significant reduction in secondary outcomes including number of follow

up hospital admissions for myocardial infarction and coronary revascularization. A borderline reduction in the composite end-point was noted in the ivabradine group when 14% of patients with activity limiting angina were analyzed separately, both in the overall group and in the sub group of HR > 70 bpm.

The SHIFT trial<sup>[12]</sup> is the next largest ivabradine RCT, and randomized 6505 patients with stable chronic ischemic and non-ischemic HFrEF of < 35% to receive either ivabradine or placebo in conjunction with optimal medical therapy for heart failure. SHIFT reported that 89% of patient population were being treated with beta-blockers at the beginning of the trial. All patients were in NYHA Class II-IV with almost 99% patient population in class II and III. The study mentioned that only 26% of the patient population was receiving optimal target dose of beta-blocker, and the most common reason for not being able to achieve the target dose was hypotension (almost 45% population in both groups). The results showed that the ivabradine group had a lower incidence of combined end-point of cardiovascular death or hospitalization for worsening of heart failure though all cause-mortality was not different between the groups. The sub-group carvedilol only study<sup>[22]</sup> still retained the benefit for combined end-point in the ivabradine plus carvedilol but cardiovascular mortality was not different between ivabradine plus carvedilol and the carvedilol only group.

In a pooled analysis of the SHIFT<sup>[12]</sup>, and the BEAUTIFUL<sup>[18]</sup> trials<sup>[27]</sup>, ivabradine achieved highest heart rate control in patients with a baseline HR of > 75 bpm when compared to patients with HR < 60 bpm; this finding is consistent with the use-dependence property of the drug. The lower heart rate at follow up in the ivabradine sub-group was associated with the lowest mortality (17.4% in < 60 bpm vs 32.4% in > 75 bpm). When the investigators did a statistical adjustment for heart rate and other prognostic factors, the benefit of ivabradine was eliminated. Consequently, it may be that ivabradine improved the combined end-point mainly by heart rate reduction, although other possible mechanisms including I(f) blockade in ventricular myocardium in chronic HFrEF cannot be eliminated. In SHIFT<sup>[12]</sup>, the MD in heart rate from baseline in the ivabradine group was greater than in BEAUTIFUL<sup>[18]</sup>; the relatively lower heart rate reduction achieved in BEAUTIFUL could be a possible explanation for absence of improvement in combined end-point of cardiovascular death or hospitalization for heart failure in the latter.

It should be noted in SHIFT<sup>[12]</sup> that patients on < 50% of the target beta-blocker dosage achieved more benefit at the combined end-point when combined with ivabradine, as compared to the overall group. One possible explanation could be patients with < 50% of target beta-blocker dosage have a higher HR and these patients tend to achieve higher benefit with ivabradine therapy than patients with a lower HR (secondary to the use-dependence property of ivabradine).

In ETHIC-AHF, a smaller recent RCT published by

Hidalgo *et al*<sup>[23]</sup>, 71 patients with acute heart failure and with EF of < 40%, sinus rhythm and HR > 70 bpm were randomized to ivabradine plus beta-blockers and beta-blockers alone. HR at 1-mo and at 4-mo follow-up were lower in the ivabradine group but the difference did not translate into improved clinical outcomes which showed no difference between the two groups in hospitalization rates for heart failure or death at follow-up.

The European Medical Agency set 75 bpm as HR cut-off<sup>[15]</sup> while the ACC/AHA guidelines<sup>[14]</sup> recommended 70 bpm as cut off for use of ivabradine in chronic HFrEF. Though the combined end-point of heart failure hospitalization or cardiac mortality was reduced along with improvement in ejection fraction and 6MWD, there was no reduction in all cause mortality, cardiovascular mortality or heart failure hospitalization alone in the current study. Also, in SHIFT<sup>[12]</sup>, the benefit was higher in patients on < 50% target dose of beta-blocker, limiting its generalizability and suggesting, that there may be only a sub group that might benefit from ivabradine therapy. Therefore, before further evidence becomes available, it is essential to follow the current guidelines and up-titrate the dosage of beta-blockers before initiating ivabradine therapy for HFrEF. Further randomized trials with long term follow-up will determine if the short-term benefit in composite end-point translates to long term mortality benefit.

### Limitations

The limitations of our meta-analysis are similar to any meta-analysis, including all limitations and biases associated with the original studies. We did not have access to patient level data and so we were not able to include outcomes of interest not reported in some articles. The meta-analysis included four RCTs and two sub-groups from RCTs along with two non-randomized trials and could be a source of bias. To diminish the bias, we analyzed RCTs separately which did not alter the outcomes. We could not adjust for confounding variables that were not adjusted for in the primary studies. The optimal dosage of beta-blockers tolerated was not reported in some trials and thus we could not analyze the correlation between baseline beta-blocker dose and ivabradine dependent outcomes. Thus, it still remains unclear if ivabradine would maintain its efficacy in patients who are on maximal tolerated doses of beta-blockers. Unavoidably, publication bias is a limitation of any meta-analysis.

In summary, the results of our systematic review and meta-analysis of the published literature supports use of ivabradine in patients with chronic HFrEF in sinus rhythm and with HR of > 70 bpm per guidelines, however the strength of evidence supporting this recommendation is weak. This approach is associated with demonstrable benefit in terms of composite end-point of cardiovascular mortality or hospitalization for heart failure. There was an improvement in ejection fraction and 6MWD at follow up but this was not reported in the majority of the published trials. More evidence is needed before ivabradine can be recommended more broadly to patients with HFrEF. The

current evidence supporting its approval is limited.

## ACKNOWLEDGMENTS

## COMMENTS

### Background

Ivabradine is a novel heart rate reducing agent by selectively inhibiting the cardiac pacemaker current if thereby slowing heart rates without exhibiting negative inotropic effect on the myocardium. It was approved by the United States Food and Drug Administration for treatment of heart failure with reduced ejection fraction (HFrEF) in 2015.

### Research frontiers

The 2016 American College of Cardiology/American Heart Association/Heart Failure Society of America (ACC/AHA/HFSA) Focused Update on the Management of Heart Failure and the European Society of Cardiology (ESC) guidelines have given a Class IIa (level of evidence B) recommendation for ivabradine use for patients with chronic HFrEF who are on guideline directed medical therapy. It is unclear, however, whether ivabradine offers any additional benefit when combined with beta-adrenergic blockade.

### Innovations and breakthroughs

Two large RCTs (BEAUTIFUL and SHIFT) and some small RCTs compared the efficacy of ivabradine with beta blockers combined with beta blocker alone in people with chronic systolic heart failure. Both BEAUTIFUL and SHIFT failed to show mortality benefit but target beta blocker dosage achieved in these studies was lower, creating bias and suggesting there may be only a sub group that might benefit from ivabradine therapy.

### Applications

The systematic review and meta-analysis supports use of ivabradine in patients with chronic HFrEF in sinus rhythm and with HR of > 70 bpm per the updated guidelines. Further randomized controlled trials are essential before ivabradine can be recommended more broadly to patients with HFrEF and the current evidence supporting its approval is limited.

### Peer-review

A useful and interesting paper that should be published after authors make some changes to ensure the article is clearer, easy to read and not too technical statistically.

### Abstract

Aberrant right subclavian artery (arteria lusoria) is the most common congenital root anomaly, remaining asymptomatic in most cases. Nevertheless, some of the 20%-40% of those affected present tracheo-esophageal symptoms. We report on a 6-year-old previously healthy girl presenting with progressive dysphagia over 4 wk. Diagnostics including barium swallow, echocardiography and magnetic resonance angiography (MRA) revealed a retro-esophageal compression by an aberrant right subclavian artery. Despite the successful, uneventful transposition of this arteria lusoria to the right common carotid *via* right-sided thoracotomy, the girl was suffering from persisting dysphagia. Another barium swallow showed the persistent compression of the esophagus on the level where the arteria lusoria had originated. As MRA showed no evidence of a significant re-obstruction by the transected vascular stump, we suspected a persisting ligamentum arteriosum. After a second surgical intervention *via* left-sided thoracotomy consisting of transecting the obviously persisting ligamentum and shortening the remaining arterial stump of the aberrant right subclavian artery, the patient recovered fully. In this case report we discuss the potential relevance of a persisting ligamentum arteriosum for patients with left

aortic arch suffering from dysphagia lusoria and rational means of diagnosing, as well as the surgical options to prevent re-do surgery.

**Key words:** Arteria lusoria dextra; Persisting ligamentum arteriosum; Dysphagia; Retroesophageal compression; Redo-surgery

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** We present a pediatric case of dysphagia caused by the common congenital root anomaly of an aberrant right subclavian artery. However, persisting symptoms after primary treatment *via* right-sided thoracotomy required redo-surgery *via* left-sided thoracotomy with transection of a persisting ligamentum arteriosum and shortening of the remaining lusorian arteries' stump. Based on this experience, we want to emphasize the potential co-existence of a compressing ligamentum arteriosum even in patients with left aortic arch.

## INTRODUCTION

Aberrant right subclavian artery is the most common congenital root anomaly in general population with a prevalence ranging from 0.5% to 1.8%<sup>[1]</sup>. The arteria lusoria was first described in 1794 by David Bayford<sup>[2]</sup>, it results from an atypical obliteration of the 4th aortic arch, whereby the right subclavian artery is formed by the persistent right dorsal aorta in connection with the 7<sup>th</sup> intersegmental artery. The resulting aberrant right subclavian artery has an atypical origin from the descending aorta and reveals a retro-esophageal course to supply the right arm with blood<sup>[1,3]</sup>.

The aberrant right subclavian artery usually remains asymptomatic<sup>[4]</sup>. Nevertheless 20%-40% of patients have tracheo-esophageal symptoms, with dysphagia being the most frequent symptom in 90% of patients with clinical symptoms<sup>[1,5]</sup>. Respiratory symptoms like cough, dyspnea, stridor, increased respiratory infections or thoracic pain are more frequent in children than in adults<sup>[6]</sup>.

Surgical treatment should be restricted to seriously symptomatic patients and is usually performed *via* right-sided thoracotomy. This operative intervention consists of mobilization and transection of the aberrant right subclavian artery from the descending aorta, and re-implantation into the right common carotid artery<sup>[7]</sup>.

## CASE REPORT

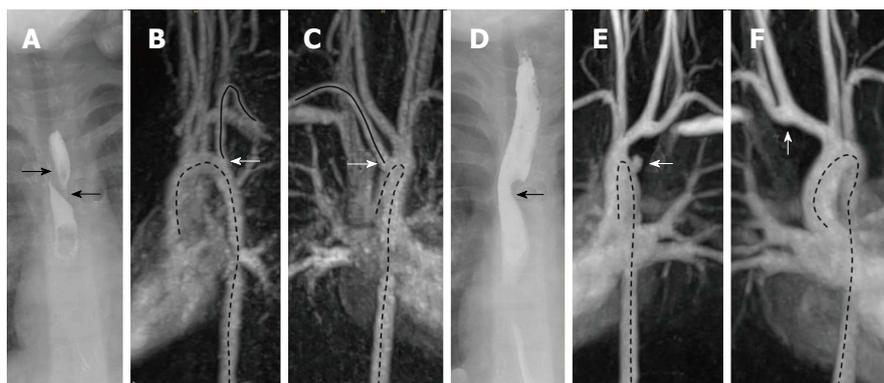

A 6-year-old girl presented with recurrent and progressive dysphagia over 4 wk. At first contact, she had lost 8 kg over 4 wk, showed severe difficulty swallowing solid foods and also suffered from recurrent thoracic pain. She underwent a barium swallow for differential diagnosis purposes which demonstrated a severe compression of the esophagus in its intermediate third, highly suspicious of vascular compression (Figure 1A). Subsequent echocardiography led to the presumptive diagnosis of an aberrant right subclavian artery with its origin in the descending aorta and a retro-esophageal course to the right side. The authors also diagnosed a truncus bicaroticus. Subsequent MRA confirmed the diagnosis of an isolated arteria lusoria (Figure 1B and C), which was considered as the proven cause for the girl's dysphagia.

Because her dysphagia had worsened so rapidly (she could only swallow liquids), her discomfort and significant weight loss, the decision for an operative intervention was made. *Via* right-sided thoracotomy over the 4<sup>th</sup> intercostal space (ICS), the aberrant right subclavian artery was mobilized, transected behind the esophagus and transposed to the right common carotid by an end-to-side-anastomosis. There were no perioperative complications. Upon her discharge on day 12 after surgery, the patient was free of symptoms such as dysphagia or thoracic pain.

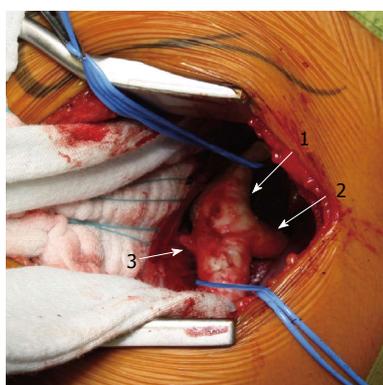

During follow-up a few weeks later, she returned suffering again from dysphagia, hypersalivation, dry cough and sore throat. Analgesics had not relieved her symptoms.

As the girl kept presenting with recurrent thoracic pain and mild symptoms of dysphagia accompanied by intermittent symptom-free periods and the lack of significant findings in clinical and diagnostic examinations, a somatoform disorder was suspected as the origin of her symptoms.

Sixteen months after corrective surgery and following a symptom-free 7-mo interval, the patient presented again with severe dysphagia (no solid food) but no thoracic pain as described before. Another barium swallow was performed (Figure 1D) which showed persistent compression of the esophagus on the level where the arteria lusoria had originated. Subsequent MRA displayed the vascular stump with a maximum length of 10 mm and diameter of 4-5 mm (Figure 1E). There were no further changes compared to the images taken 12 mo earlier. The region of the vascular anastomosis showed no abnormalities (Figure 1F). Finally, the suspicion of two factors causing the ongoing compression of the esophagus and the recurrent symptoms arose: First, compression by the persisting stump of the aberrant right subclavian artery and second, an incomplete vascular ring due to a persisting ligamentum arteriosum, which was not transected.

**Figure 1** Fluoroscopy and magnetic resonance angiography at initial presentation and at follow-up. A-C: Fluoroscopy and MRA at initial presentation; A: The arrows mark the outer boundary of the esophagus. There is a filling defect in between which runs from right side superior to left side inferior due to compression of the vessel; B and C: The arrow marks the right sided subclavian artery which originates distally to the left supraaortic vessels. The course of the artery is shown by the uninterrupted line. The dotted lines mark the course of the thoracic aorta; D-F: Fluoroscopy and MRA at follow up; D: The arrow marks a filling defect of the esophagus; E: The arrow marks the vascular stump. The dotted lines mark the course of the thoracic aorta; F: The arrow marks the anastomosis. The dotted line represents the course of the aorta. MRA: Magnetic resonance angiography.

**Figure 2** Operative findings in redo-surgery: Surgical approach over the 3<sup>rd</sup> intercostal space via left-sided thoracotomy: A structure consistent with the ligamentum arteriosum can be presented leading to the descending aorta distal the left subclavian's origin. 1: Aorta descendens; 2: Left subclavian artery; 3: Ligamentum arteriosum.

Therefore, redo-surgery was performed, this time over the 3<sup>rd</sup> ICS via left-sided thoracotomy (Figure 2) and consisted of shortening the remaining lusorians' stump and transecting the ligamentum arteriosum. The patient experienced an uneventful and complete recovery.

The barium swallow she underwent 6 wk after reoperation demonstrated no more signs of esophageal compression. At all subsequent clinical follow-ups over 6 mo after surgery, she had no more dysphagia and had regained weight.

## DISCUSSION

We report on a 6-year-old girl presenting with dysphagia attributed to an aberrant right subclavian artery that unexpectedly caused persisting symptoms after corrective surgery via right-sided thoracotomy.

As the aberrant right subclavian artery often remains asymptomatic<sup>[3]</sup>, surgical repair is restricted to highly-symptomatic patients, and it is usually very successful.

Nevertheless, a small percentage of these patients return complaining of recurrent respiratory or swallowing problems<sup>[8]</sup>.

There is a potential anatomical explanation for ongoing postoperative symptoms like dysphagia: Compared to a left-sided aortic arch, the right-sided aortic arch combined with an aberrant left subclavian artery maintains a persisting ligamentum arteriosum. In contrast, in those with a left-sided aortic arch and an aberrant right subclavian artery, a left-sided ligamentum arteriosum is much rarer but it remains a potential anatomical finding. Such a ligamentum arteriosum - a fibrous relict of the ductus arteriosus - leads from the proximal descending aorta to the left pulmonary artery. In the presence of a coexisting aberrant right subclavian artery, an incomplete vascular ring can form that compresses the esophagus<sup>[9]</sup>.

We thus maintain that, to ensure optimum recovery after a surgical intervention for arteria lusoria, it is essential to be fully aware of the patient's cardiothoracic anatomy beforehand, especially the existence of a persisting ligamentum arteriosum. In selecting the diagnostic tools, we suggest an age-dependent approach. In fetuses, newborns and infants presenting the incidental finding of an arteria lusoria, echocardiography has great potential to validate the cardiovascular system in detail, especially a vascular ring with a fibrous ductus arteriosus. Echocardiography remains highly informative even in symptomatic infants and children. Barium swallow and MRA are additional key diagnostic tools in this age group. In case of older children and adolescents, the first-line modality should be MRA. At that age, echocardiography becomes secondary because it precludes a thorough evaluation of the patient's anatomy.

Another key factor for surgical success is the choice of surgical access. Regarding the preferred approach to the aberrant right subclavian artery in children, van Son *et al.*<sup>[10]</sup> found that this vessel originates from the posteromedial side of the distal aortic arch. Therefore,

a strong argument for currently-mandated right-sided thoracotomy in children is the vessel's optimal mobilization, transection and reconnection.

However, assessing a ligamentum arteriosum is limited in this access path, thus in case of a left aortic arch with left-sided ligamentum arteriosum, the recommended surgical access to reach this usually fibrous strand is *via* left-sided thoracotomy.

In summary, we suggest considering a median thoracotomy to address both contrary structural conditions and to effectively treat a right arteria lusoria in combination with a left ligamentum arteriosum at the same time. *Via* this median access, the course of the aberrant right subclavian artery can be corrected, and the surgeon is able to explore and transect a persisting ligamentum arteriosum.

In conclusion, we suggest that our patient continued to suffer dysphagia after initial surgery of the aberrant right subclavian artery due to the persisting pathology of a ligamentum arteriosum causing further esophageal compression. Since this experience, our recommendation for other patients with a left-sided aortic arch and right arteria lusoria is first to focus on obtaining a detailed preoperative visualization of the individual's anatomy by means of diagnostic imaging, especially to watch out for a ligamentum arteriosum. In case of a potential ligamentum arteriosum, we favor a median thoracotomy because of its optimal provision of intraoperative anatomical overview and accessibility to both the aberrant artery and ligamentum arteriosum.

## COMMENTS

### Case characteristics

This is a rare pediatric case about a 6-year-old girl with an aberrant right subclavian artery unexpectedly presenting with persisting severe dysphagia after initial corrective surgery *via* right-sided thoracotomy.

### Clinical diagnosis

Apart from mild symptoms such as hypersalivation and a dry cough, there were no other significant anomalies in clinical examination.

### Differential diagnosis

Ingested foreign bodies, esophageal infection or neoplasia, disorders in esophageal innervations or secondary to cardiovascular compression or thyroid disease.

### Laboratory diagnosis

The authors' laboratory tests revealed no pathology.

### Imaging diagnosis

The initial diagnosis of an aberrant right subclavian artery was confirmed *via* barium swallow, subsequent echocardiography and magnetic resonance angiography (MRA), whereas during the persistent dysphagia after her first intervention, only the barium swallow demonstrated a dorsal esophageal compression that led us to suspect an incomplete vascular ring due to a persisting ligamentum arteriosum.

## Pathological diagnosis

Persisting esophageal compression after arteria lusoria dextra surgery caused by an incomplete vascular ring due to a persisting ligamentum arteriosum.

## Treatment

Redo-surgery *via* left-sided thoracotomy entailing the transection of a persisting ligamentum arteriosum and shortening of the remaining lusorian arteries' stump.

## Related reports

Although arteria lusoria is the most common embryologic abnormality of the aortic arch and its potential esophageal compression can result in dysphagia, a case of persisting symptoms after corrective surgery because of a co-existing ligamentum arteriosum in patients with left aortic arch has never been reported in the literature so far.

## Term explanation

Magnetic resonance angiography (MRA) is a type of magnetic resonance imaging scan to evaluate blood vessels and helps to identify vascular abnormalities by using a powerful magnetic field and pulses of radio wave energy.

## Experiences and lessons

Based on this experience, the authors wish to emphasize the potential co-existence of a compressing ligamentum arteriosum even in patients with left aortic arch; furthermore, the authors would like to inspire discussion about an age-dependent approach regarding which diagnostic tools are employed for pre-operative planning, as well as what constitutes the optimal surgical approach.

## Peer-review

This is a rare case report about a pediatric case of dysphagia attributed to an aberrant right subclavian artery that unexpectedly caused persisting symptoms after corrective surgery *via* right-sided thoracotomy. The authors suggest considering a median thoracotomy to address both contrary structural conditions and to effectively treat a right arteria lusoria in combination with a left ligamentum arteriosum at the same time. This manuscript is nicely structured and well written.

### Abstract

We describe a case of very late transcatheter heart valve (THV) thrombosis of a first-generation SAPIEN prosthesis (Edwards Lifesciences, Irvine, CA) implanted in a 64-year-old woman with severe symptomatic aortic stenosis. More than 54 mo after implantation, she presented with severe symptomatic prosthesis dysfunction (stenosis) which was successfully treated with oral anticoagulation. To our knowledge, this is the tardiest case of THV thrombosis ever reported. This case should increase clinical awareness for THV thrombosis even beyond the first two-year period following implantation.

**Key words:** Valve thrombosis; Transcatheter heart valve; Transcatheter aortic valve replacement

### INTRODUCTION

We describe a case of very late transcatheter heart valve (THV) thrombosis of a first-generation SAPIEN prosthesis (Edwards Lifesciences, Irvine, CA) implanted in a 64-year-old woman with severe symptomatic

**Figure 1** Transprosthetic gradients and effective orifice area following transcatheter aortic valve replacement (2 to 54 mo), at the time transcatheter heart valve thrombosis (54 mo) and following anticoagulation therapy (54 to 63 mo). TAVR: Transcatheter aortic valve replacement; THV: Transcatheter heart valve.

aortic stenosis. More than 54 mo after implantation, she presented with severe symptomatic prosthesis dysfunction (stenosis) which was successfully treated with oral anticoagulation. To our knowledge, this is the tardiest case of THV thrombosis ever reported. This case should increase clinical awareness for THV thrombosis even beyond the first two-year period following implantation.

## CASE REPORT

A 64-year-old woman with severe symptomatic aortic stenosis and porcelain aorta underwent transcatheter aortic valve replacement (TAVR) using a first-generation balloon-expandable Edwards SAPIEN (Edwards Lifesciences, Irvine, CA) 23 mm THV in January 2011. The patient was discharged home with aspirin and clopidogrel for three months followed by low dose aspirin.

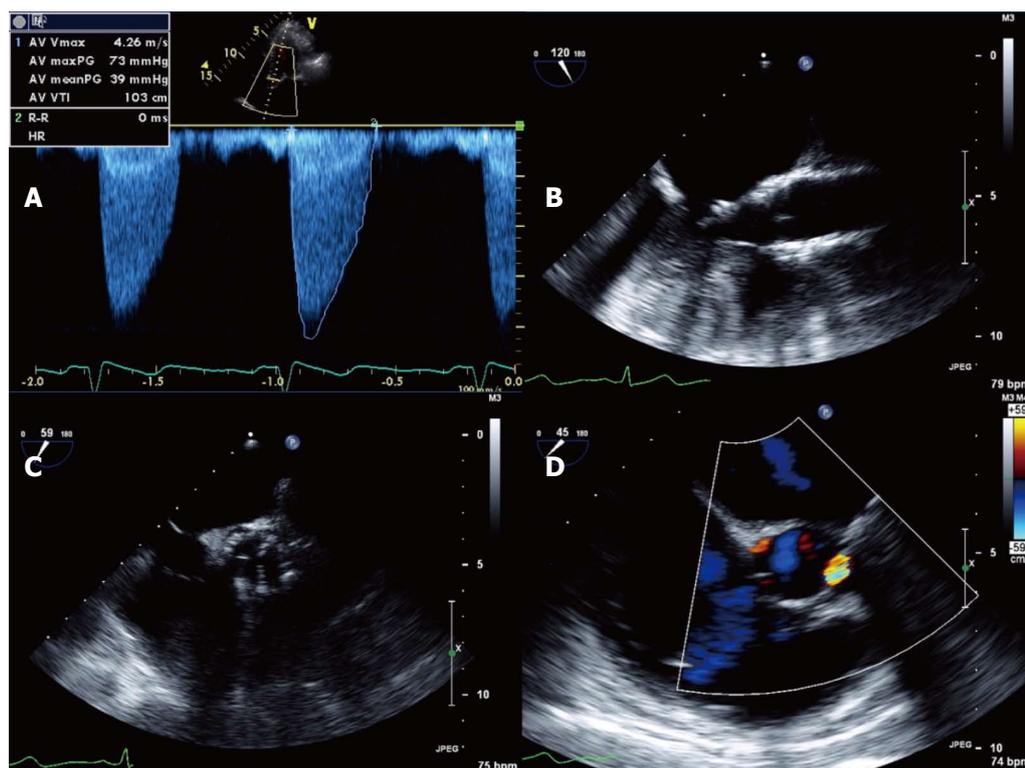

More than 54 mo following TAVR, she presented with progressive dyspnea, angina and dizziness on moderate exertion. Transthoracic echocardiogram (TTE) revealed a severe THV dysfunction with an aortic valve area (AVA) of 0.81 cm<sup>2</sup>, peak and mean trans prosthetic gradients (TPG) of 76 and 39 mmHg respectively and a preserved left ventricular ejection fraction (Figure 1). Transesophageal echocardiogram (TEE) did not demonstrate abnormal leaflet function neither THV thrombosis (Figure 2) but revealed a moderate paravalvular leak (PVL) (Figure 2D) already known from the immediate post-TAVR TEE. THV thrombosis was suspected given the absence of other explanatory findings and the abrupt progression of TPG. Therefore, anticoagulation with warfarin and unfractionated heparin was empirically started. A coronary angiogram and a cardiovascular magnetic resonance (CMR) were also performed. Angiogram revealed a severe, non-thrombotic, left main mid-shaft stenosis and percutaneous coronary intervention (PCI) with a drug-eluting stent was performed. CMR revealed an aortic regurgitation fraction of 23% consistent with the moderate PVL previously seen on the TEE. No evidence of THV thrombosis other than elevated peak velocity was detected on CMR. Nine days after initiation of anticoagulation, a repeat TTE showed mild improvement

in TPG (Figure 1). The patient was discharged home with aspirin, clopidogrel and warfarin for three months, followed by clopidogrel and warfarin. Angina was relieved immediately after PCI, but dyspnea on exertion improved over weeks. After three months, symptoms had resolved completely and TPG returned to their baseline values. They remained unchanged after nine months under chronic anticoagulation (Figure 1).

## DISCUSSION

In two series, less than 30 cases of THV thrombosis have been reported with a median presentation time of 6 mo (range, 3-735 d) with only two cases occurring beyond one year<sup>[1,2]</sup>. A case of a Direct Flow Medical THV thrombosis three years following TAVR has also been reported recently<sup>[3]</sup>. To our knowledge, never a THV thrombosis has been described so late after implant (> 54 mo) as in this case. THV thrombosis is a new entity that needs to be recognized not only by TAVR specialists. Even though estimated incidence is low (0.61%), consequences can be catastrophic if appropriate therapy is not initiated promptly<sup>[1]</sup>. Only reported cases treated with anticoagulation had favorable outcome. Therefore, a sudden increase in TPG should trigger further investigation or therapies to exclude THV thrombosis. Valve hemodynamic deterioration (VHD), defined by an increase in mean TPG of more than 10 mmHg over time, was observed more frequently in patients with smaller THV (23 mm) and those not receiving oral anticoagulation<sup>[4]</sup>. Most of these patients did not have a progressive deterioration after the first year. VHD does not seem to be part of a continuum towards THV thrombosis and this later remains unpredictable. However, the pathophysiology of VHD may include some degree of sub-clinical leaflet thrombosis.

In our case, TEE evaluation was not diagnostic. In a series of 3 pathology-proven THV thrombosis, TEE was also negative in each cases<sup>[2]</sup>. However, Makkar *et al*<sup>[5]</sup> showed that 4D-CT and TEE had a diagnostic concordance of 100% in 10 patients presenting reduced leaflets motion following TAVR. Whether 4D-CT is the optimal imaging modality remains to be proven. CMR was chosen over CT scan to assess PVL severity but

**Figure 2** Transesophageal echocardiogram. It shows transprosthetic gradients compatible with severe aortic stenosis (A); Absence of obvious mass or valve thrombosis on Transesophageal echocardiogram (B, C) but moderate paravalvular leak (D).

also failed to identify the THV thrombosis. Therefore, negative imaging should not preclude an anticoagulation trial when the diagnostic is highly suspected.

Reports have revealed subclinical leaflet thrombosis detected by TEE and 4D CT scan early after THV implantation<sup>[5]</sup>. Most of these cases were seen in patients who did not receive anticoagulation. The clinical significance of these findings remains unknown at this point. Studies are ongoing to evaluate the optimal antiplatelet/anticoagulant therapy after TAVR. The ARTE (clopidogrel; NCT01559298) and REAC-TAVI (ticagrelor vs clopidogrel; NCT02224066) trials are evaluating different antiplatelet strategies and the GALILEO (rivaroxaban; NCT02556203) and ATLANTIS (apixaban; NCT02664649) studies are looking at the effect of non-vitamin K oral anticoagulant following TAVR. Similarly, the POPular-TAVI trial (NCT02247128) is evaluating the effect of adding clopidogrel for 3 mo following implantation in patients with and without ongoing vitamin-K oral anticoagulation treatment.

This case is also particular because of the concurrent left main stenosis. Although thrombus migration in the left main could be considered an explanation, the angiographic appearance was more in favor of disease progression of a previous non-significant lesion seen on the pre-TAVR angiogram. Moderate PVL could be associated with a different flow pattern over the leaflets and in the left main that could lead to THV thrombosis as well as accelerated progression of atherosclerosis although this relationship is speculative.

This case should increase clinical awareness for THV thrombosis even beyond the first two-year period following implantation. Risk predictors for THV thrombosis and optimal antiplatelet/anticoagulant therapy post TAVR are still unknown and warrants clinical trials.

## COMMENTS

### Case characteristics

More than 54 mo following transcatheter aortic valve replacement, a 64-year-old woman presented with progressive dyspnea, angina and dizziness on moderate exertion.

### Clinical diagnosis

Prosthesis dysfunction.

### Differential diagnosis

Transcatheter heart valve (THV) degeneration; THV thrombosis; THV endocarditis.

### Imaging diagnosis

Transesophageal echocardiogram (TEE) revealed a prosthesis dysfunction with a severe stenosis. TEE failed to reveal THV thrombosis as well as vegetations.

### Treatment

Empiric treatment with unfractionated intravenous heparin followed by long-term anticoagulation with warfarin.

### Related reports

Less than 30 cases of THV thrombosis have been reported with a median presentation time of 6 mo (range, 3-735 d) with only two cases occurring beyond one year.

**Experiences and lessons**

This case should increase clinical awareness for THV thrombosis even beyond the first two-year period following implantation. Even if TEE does not reveal THV thrombosis.

**Peer-review**

The paper is well written.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Hans-Jürgen Seyfarth, MD, Doctor, Division of Respiratory Medicine, Department of Internal Medicine, Neurology and Dermatology, University Hospital of Leipzig, 04103 Leipzig, Germany

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC)*, online ISSN 1949-8462, DOI: 10.4330 is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

Aldosterone mediates many of the physiological and pathophysiological/cardio-toxic effects of angiotensin II (AngII). Its synthesis and secretion from the zona glomerulosa cells of the adrenal cortex, elevated in chronic heart failure (HF), is induced by AngII type 1 receptors (AT<sub>1</sub>Rs). The AT<sub>1</sub>R is a G protein-coupled receptor, mainly coupling to G<sub>q/11</sub> proteins. However, it can also signal through β-arrestin-1 (βarr1) or -2 (βarr2), both of which mediate G protein-independent signaling. Over the past decade, a second, G<sub>q/11</sub> protein-independent but βarr1-dependent signaling pathway emanating from the adrenocortical AT<sub>1</sub>R and leading to aldosterone production has become appreciated. Thus, it became apparent that AT<sub>1</sub>R antagonists that block both pathways equally well are warranted for fully effective aldosterone suppression in HF. This spurred the comparison of all of the currently marketed angiotensin receptor blockers (ARBs, AT<sub>1</sub>R antagonists or sartans) at blocking activation of the two signaling modes (G protein-, and βarr1-dependent) at the AngII-activated AT<sub>1</sub>R and hence, at suppression of aldosterone *in vitro* and *in vivo*. Although all agents are very potent inhibitors of G protein activation at the AT<sub>1</sub>R, candesartan and valsartan were uncovered to be the most potent ARBs at blocking βarr activation by AngII and at suppressing aldosterone *in vitro* and *in vivo* in post-myocardial infarction HF animals. In contrast, irbesartan and losartan are virtually G protein-“biased” blockers at the human AT<sub>1</sub>R, with very low efficacy for βarr inhibition and aldosterone suppression. Therefore, candesartan and valsartan (and other, structurally similar compounds) may be the most preferred ARB agents for HF pharmacotherapy, as well as for treatment of other conditions characterized by elevated aldosterone.

**Key words:** Adrenal cortex; Adrenocortical zona glomerulosa cell; Aldosterone; Angiotensin receptor blocker; Angiotensin II type 1 receptor; β-arrestin-1; Heart failure;

## Suppression efficacy

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The angiotensin II type 1 receptor (AT<sub>1</sub>R) endogenously expressed in adrenocortical cells was known for decades to induce aldosterone production *via* a well-defined G<sub>q</sub> protein-mediated signaling pathway. Over the past decade, a number of studies have elucidated another,  $\beta$ -arrestin-1 ( $\beta$ arr1)-dependent signaling cascade, which proceeds in parallel to, and independently of the G<sub>q</sub>-mediated one, and also results in aldosterone synthesis and secretion from the adrenal cortex. Importantly, although all of the Food and Drug Administration-approved angiotensin receptor blocker (ARB) drugs (AT<sub>1</sub>R antagonists) are very effective at blocking the G<sub>q</sub>-mediated pathway, as expected, since they were designed to do so (*i.e.*, to block the G protein signaling of the AT<sub>1</sub>R), they seem to display varying efficacies at blocking this new,  $\beta$ arr1-dependent pathway, which translates into significant variation at aldosterone suppression efficacies. In that context, candesartan and valsartan appear the most effective agents at blocking also the  $\beta$ arr1 pathway emanating from the adrenocortical AT<sub>1</sub>R, and thus, these two agents may be the best aldosterone suppressors within the ARB drug class.

Lymperopoulos A, Aukszi B. Angiotensin receptor blocker drugs and inhibition of adrenal beta-arrestin-1-dependent aldosterone production: Implications for heart failure therapy. *World J Cardiol* 2017; 9(3): 200-206 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/200.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.200>

## INTRODUCTION

Aldosterone is a mineralocorticoid hormone with several cardio-toxic actions, whose plasma levels are extremely high in chronic heart failure (HF) negatively affecting progression of the disease<sup>[1]</sup>. Amongst its main actions on the failing myocardium is overall promotion of adverse remodeling *via* maladaptive hypertrophy, chamber dilatation, collagen deposition and fibrosis, increased inflammation and reactive oxygen species production, *etc.* The net result of all of these effects is acceleration of cardiac functional decline<sup>[2-4]</sup>. The main source of circulating aldosterone is the adrenocortical zona glomerulosa (AZG) cells, which synthesize and secrete it in response to high serum K<sup>+</sup> levels (hyperkalemia), since its main action on the kidneys is K<sup>+</sup> excretion (along with Na<sup>+</sup> and water reabsorption)<sup>[5]</sup>. Another powerful physiological stimulus for aldosterone secretion from AZG cells is the octapeptide hormone angiotensin II (AngII), which activates its type 1 receptors (AT<sub>1</sub>Rs), endogenously expressed in AZG cells<sup>[5,6]</sup>.

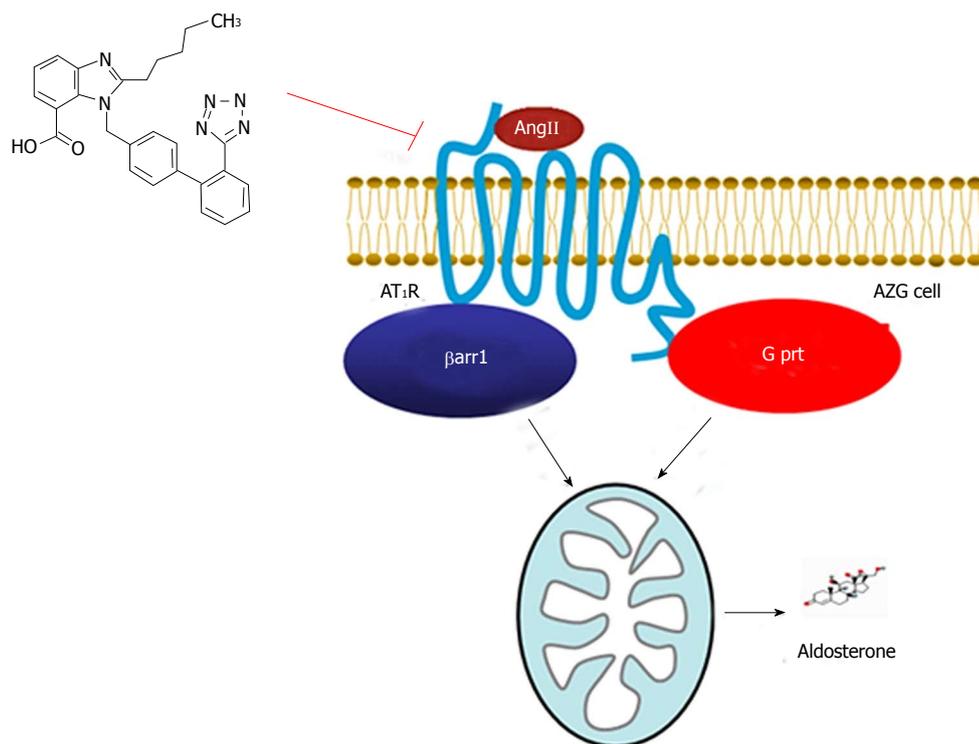

The AT<sub>1</sub>R is a 7-transmembrane-spanning or G pro-

tein-coupled receptor (GPCR); upon agonist activation, it couples primarily to the G<sub>q/11</sub> family of G proteins<sup>[6]</sup>. Nowadays however, it is known to signal also through other types of G proteins, like G<sub>i/o</sub> and G<sub>s</sub>, as well as through G protein-independent pathways mediated by the universal GPCR adapter proteins  $\beta$ -arrestin-1 ( $\beta$ arr1) and  $\beta$ arr2 (also known as arrestin-2 and -3, respectively)<sup>[7-9]</sup>. The  $\beta$ arrs bind agonist-activated and GPCR-kinase (GRK)-phosphorylated GPCRs to uncouple them from G proteins (receptor desensitization) and to target them to clathrin-coated vesicles for internalization (receptor endocytosis). At the same time, they initiate their own, "second wave" of signal transduction independently of G proteins<sup>[10-13]</sup>.

## ANGII-DEPENDENT ALDOSTERONE PRODUCTION: THE SUM OF TWO SIGNALING MODALITIES

The G<sub>q/11</sub> protein-dependent signaling pathway elicited by the AngII-activated AT<sub>1</sub>R that culminates in aldosterone synthesis and secretion in AZG cells has been well characterized (Figure 1)<sup>[14]</sup>. More specifically, diacylglycerol (DAG) and inositol trisphosphate (IP<sub>3</sub>), the two second messengers produced by this pathway, ultimately lead to: (1) aldosterone secretion, *via* elevated intracellular free Ca<sup>2+</sup> concentration, which directly stimulates exocytosis and hormonal (in the context of AZG cells, aldosterone) secretion; and (2) aldosterone synthesis, *via* extracellular signal-regulated kinase (ERK) MAPK activation, which, in turn, stimulate aldosterone biosynthesis in AZG cells by transcriptionally upregulating the StAR (steroidogenic acute regulatory) protein<sup>[14]</sup>. This protein mediates the mitochondrial uptake of the precursor of all adrenal steroids cholesterol and is the rate-limiting enzyme of aldosterone biosynthesis in AZG cells<sup>[14]</sup>.

In the chronic HF setting, adrenal GRK2 is up-regulated and, along with  $\beta$ arr1, hyperphosphorylates and severely desensitizes the sympatho-inhibitory  $\alpha_2$ -adrenergic receptors (ARs) of chromaffin cells in the adrenal medulla<sup>[15-21]</sup>. The result of this is chronic elevation of adrenal catecholamine secretion, which significantly contributes to the heightened sympathetic nervous system outflow and increased norepinephrine and epinephrine levels that further damage the failing heart<sup>[22-26]</sup>. Since aldosterone is also increased in HF and its production is stimulated by the AT<sub>1</sub>Rs of the adrenal cortex<sup>[1]</sup>, which are also GRK2 and  $\beta$ arr1 substrates, it was theorized that the upregulated (in HF) adrenal GRK2 could lead to excessive interaction of  $\beta$ arr1 also with the AT<sub>1</sub>R in the adrenal cortex, thereby modulating aldosterone secretion in the chronic HF setting, as well. Indeed, this was found to be the case<sup>[27]</sup>. *Via* a combination of *in vitro* experiments in the human AZG cell line H295R and *in vivo* experiments in experimental rats developing HF following an acute, surgically induced myocardial infarction (MI), we were

**Figure 1 Angiotensin II type 1 receptor and aldosterone production.** Schematic representation of the parallel G prt- and  $\beta$ arr1-mediated, AngII-bound AT1R signaling cascades that converge on mitochondrial aldosterone synthesis in adrenocortical zona glomerulosa (AZG) cells. The structure of the proposed AT1R antagonist (2-pentyl-1-((4-[2-(2H-1,2,3,4-tetrazol-5-yl)phenyl]phenyl)methyl)-1H-1,3-benzodiazole-7-carboxylic acid)<sup>[40]</sup>, discussed in the text, capable of suppressing both pathways equally well, is also shown (upper left corner). See text for details. G prt: G $\alpha$  protein;  $\beta$ arr1:  $\beta$ -arrestin1; AngII: Angiotensin II; AT1R: AngII type 1 receptor.

able to show that adrenal  $\beta$ arr1 actually promotes AngII-dependent aldosterone synthesis and secretion by also mediating AT1R signaling to ERK-dependent StAR upregulation independently of G proteins (Figure 1)<sup>[27,28]</sup>. This finding was somewhat surprising, given that  $\beta$ arr1 would normally be expected to reduce AngII-dependent aldosterone production thanks to desensitizing the AT1R (terminating its G protein-dependent signaling, see above). Nevertheless, it was discovered that, after abolishing the G $\alpha$ -dependent signaling by the AT1R in AZG cells, AT1R-bound  $\beta$ arr1 initiated its own signaling to aldosterone synthesis by recruiting a DAG-kinase to the activated receptor<sup>[29]</sup>, which converted the second messenger lipid DAG to phosphatidic acid (PA)<sup>[27]</sup>. PA can directly activate the small (monomeric) G protein Ras at the plasma membrane, which then initiates the cascade that results in ERK phosphorylation and activation<sup>[30]</sup>. Thus, AT1R-activated  $\beta$ arr1 elicits a "second (delayed) wave" of signaling leading to sustained ERK activation in AZG cells in its own right (*i.e.*, independently of G proteins), which, as discussed above, promotes aldosterone production *via* StAR upregulation<sup>[27]</sup>. Importantly, since StAR regulates synthesis not only of aldosterone but of all adrenal steroids throughout the three anatomical zones of the adrenal cortex<sup>[14]</sup>, adrenal  $\beta$ arr1 may also affect the synthesis of glucocorticoids and of androgens in the adrenal cortex.

Notably, adrenal  $\beta$ arr1 may not only stimulate the

AT1R-dependent aldosterone synthesis *via* its "second wave" of signaling to ERK-dependent StAR upregulation but also facilitate the acute AT1R-dependent aldosterone secretion at the plasma membrane of AZG cells and in parallel to the G protein-mediated signaling by the receptor (Figure 1). Recent evidence in transfected heterologous systems suggests such a role in the "first wave" of GPCR signaling for the  $\beta$ arrs<sup>[31,32]</sup> and a very intriguing study, done specifically in the adrenal medulla, suggested an acute stimulation of catecholamine secretion and of Ca<sup>2+</sup>-dependent exocytosis by AT1R-activated  $\beta$ arr1 (but interestingly not by  $\beta$ arr2) in adrenal chromaffin cells, thanks to its direct interaction with the plasma membrane Ca<sup>2+</sup> channel short transient receptor potential channel-3 (TRPC3)<sup>[33]</sup>. Thus, it is quite plausible that AT1R-bound  $\beta$ arr1 can directly stimulate TRPC3-dependent Ca<sup>2+</sup> currents and hence, exocytosis, also in AZG cells, thereby acutely stimulating AngII-dependent aldosterone secretion within seconds of agonist binding (and in parallel to the G $\alpha$ -mediated signaling by the AT1R). This interesting possibility of another signaling mechanism by which  $\beta$ arr1 can induce aldosterone production in AZG cells is definitely worthy of investigation in future studies.

Most importantly, adrenal  $\beta$ arr1-dependent aldosterone production has been documented to occur also *in vivo*, both under physiological (in normal, healthy animals) and pathophysiological (in the post-MI HF setting) conditions<sup>[27,28]</sup>. Specifically, adrenal-targeted

$\beta$ arr1 overexpression increased aldosterone serum levels *in vivo* in normal rats<sup>[27]</sup>, and caused severe hyperaldosteronism also in post-MI rats on top of the circulating aldosterone elevation normally occurring due to the MI injury<sup>[28]</sup>. Importantly, in the latter animals, adrenal-specific  $\beta$ arr1 blockade *in vivo* with a  $\beta$ arr1 C-terminal fragment during post-MI HF progression helped stall the decline of cardiac function and even reversed several aspects/markers of adverse cardiac remodeling courtesy of normalization of circulating aldosterone levels<sup>[28]</sup>. What's more, aldosterone levels remarkably show no increase in  $\beta$ arr1-knockout mice post-MI, which further highlights the importance of adrenal  $\beta$ arr1 in regulation of circulating aldosterone levels<sup>[34]</sup>. Together, these *in vivo* studies strongly suggest adrenal  $\beta$ arr1, in conjunction with GRK2, as an attractive therapeutic target for diseases associated with, and aggravated by hyperaldosteronism, such as post-MI HF<sup>[9,25]</sup>. Adding to its importance as a therapeutic target is also the fact that aldosterone can produce effects independently of its mineralocorticoid receptor (MR) (the so-called "non-genomic" actions of aldosterone)<sup>[4]</sup>. Obviously, these effects cannot be countered by MR antagonist drugs (*e.g.*, eplerenone, finerenone, spironolactone) and thus, suppression of aldosterone production at its source, *i.e.*, the adrenal cortex, *via* adrenal  $\beta$ arr1 blockade would be much more preferable from the therapeutic standpoint.

## WHICH ARB DRUG WINS THE ALDOSTERONE SUPPRESSION "CONTEST"?

The realization that AngII-dependent aldosterone production from the adrenal cortex proceeds through two independent signaling modalities, *i.e.*, G $\alpha$  protein- and  $\beta$ arr1-dependent (Figure 1), signaled that complete blockade of both of these modalities is needed to attain full suppression of adrenal aldosterone production and effectively lower circulating aldosterone levels in HF and in other diseases. This, coupled with the fact that some AT $_1$ R antagonist drugs (angiotensin receptor blockers, ARBs, or sartans) appear ineffective at lowering aldosterone in HF, despite their full capacity to block AT $_1$ R-G protein coupling<sup>[35-38]</sup>, prompted us to test the relative efficacy of the currently available ARBs at inhibiting the  $\beta$ arr1-dependent aldosterone production by the AT $_1$ R in an effort to identify the most effective agent(s). Indeed, the prototypic agent of this class, losartan, was found totally ineffective at preventing adrenal  $\beta$ arr1-dependent aldosterone production and combatting hyperaldosteronism post-MI due to very weak antagonism of  $\beta$ arr1 activation by the AT $_1$ R<sup>[28]</sup>. Interestingly however, the active metabolite of losartan EXP1374 was found quite effective at blocking AT $_1$ R-dependent aldosterone production and  $\beta$ arr1 activation<sup>[39,40]</sup>.

Upon subsequent head-to-head testing of all the

currently Food and Drug Administration (FDA)-approved ARB drugs, it was found that, although all ARBs (including losartan) are potent inhibitors of G protein activation by the AT $_1$ R, their potencies at preventing  $\beta$ arr1 activation by the human AT $_1$ R *in vitro* varied enormously<sup>[40]</sup>. Specifically, candesartan and valsartan appeared the most potent blockers of  $\beta$ arr1 activation and the most efficacious aldosterone suppressors *in vitro* and *in vivo*<sup>[39,40]</sup>. At the opposite end of the spectrum and in addition to losartan, was irbesartan, which was found to be a very weak  $\beta$ arr1 inhibitor and hence, a very ineffective aldosterone suppressor both *in vitro* and *in vivo*, despite its excellent G protein-blocking ability<sup>[39,40]</sup>. The rest of the class fell more or less in the middle of the  $\beta$ arr1 inhibition and AT $_1$ R-dependent aldosterone suppression scales, *i.e.*, their potency values were lower than candesartan's and valsartan's but much higher than losartan's and irbesartan's<sup>[39,40]</sup>. Importantly, their effects on cardiac function of in post-MI HF animals *in vivo* were in complete concordance with their effects on circulating aldosterone levels; candesartan and valsartan induced significant improvements in cardiac function and remodeling post-MI, whereas irbesartan and losartan were not able to alter the course of progression of post-MI animals to full-blown HF<sup>[39]</sup>.

## IMPLICATIONS FOR HF PHARMACOTHERAPY

It is widely recognized nowadays that the members of the ARB drug class display significant variation in their pharmacological and clinical properties, which has significant repercussion for their use in HF pharmacotherapy<sup>[41]</sup>. In fact, certain agents have already been shown to afford larger improvements in morbidity and mortality of chronic HF than others<sup>[42-45]</sup>. Part of the reason for these differences among these agents that belong to the same pharmacological class and share the same mechanism of action (AT $_1$ R antagonism) may be differences in their efficacies at combating the hyperaldosteronism that accompanies and burdens chronic HF<sup>[1]</sup>. In other words, agents that suppress aldosterone effectively are bound to work better for HF therapy and, since adrenal  $\beta$ arr1 plays a pivotal role in regulation of this cardio-toxic hormone's levels, the ARBs that are most effective at blocking the AT $_1$ R- $\beta$ arr1 interaction in the adrenal cortex would be expected to be preferred agents. In that vein, our aforementioned recent findings that candesartan and valsartan are the most efficacious  $\beta$ arr1 inhibitors at the AT $_1$ R, coupled with their excellent efficacy at lowering aldosterone *in vitro* and *in vivo*, point to these two ARBs as being the most preferable agents of their class to use in HF treatment (and in other hyperaldosteronic conditions, *e.g.*, salt-sensitive hypertension). In contrast, irbesartan and losartan were found very weak  $\beta$ arr1-dependent aldosterone inhibitors, a finding that may have some bearing on the lack of therapeutic benefit of these two

agents demonstrated in HF with preserved ejection fraction (HF-PEF) and on their therapeutic inferiority to candesartan in terms of HF mortality reduction<sup>[44,45]</sup>. Of course, future trials providing data on the serum aldosterone levels of the ARB-treated HF patients are needed to confirm such a link between adrenal  $\beta$ arr1-dependent aldosterone suppression efficacy and clinical benefit for this important cardiovascular drug class.

On the other hand, failure of these agents to suppress aldosterone, otherwise referred to as "aldosterone breakthrough" or "aldosterone escape", is a clinically well-documented phenomenon<sup>[46-49]</sup> and the efficacy of each agent at inhibiting  $\beta$ arr1-dependent aldosterone production may be inversely proportional to the probability of the ARB to exhibit it. In other words, the more potent  $\beta$ arr1-dependent aldosterone suppressor an ARB is, the lower the likelihood is that the treated patient will suffer from "aldosterone breakthrough". Thus, candesartan and valsartan may be the safest ARB drugs to use in HF patients in terms of the risk of "aldosterone breakthrough". However, large trials closely monitoring the circulating aldosterone levels of treated patients are again needed in order to confirm this hypothesis.

## IMPLICATIONS FOR AT<sub>1</sub>R BLOCKER MEDICINAL CHEMISTRY

The studies on the relative potencies/efficacies of the currently FDA-approved ARBs at inhibiting AT<sub>1</sub>R- $\beta$ arr1 interaction and  $\beta$ arr1-dependent aldosterone turnover provided some interesting medicinal chemistry and pharmacological insights, as well. Specifically, as far as the ARBs that are tetrazolo-biphenyl-methyl derivatives are concerned, which is a subgroup that includes losartan (and its metabolite EXP1374), irbesartan, candesartan, valsartan, and olmesartan, it was concluded that a substitution both bulky and negatively charged attached to the one side of the methylene group of the biphenyl-methyl backbone (the other end has the tetrazolo-biphenyl group attached) is needed to confer good inhibitory potency of  $\beta$ arr1 at the AT<sub>1</sub>R and consequently, effectively suppress aldosterone<sup>[40]</sup>. Indeed, both candesartan and valsartan, as well as EXP1374, have spacious, long aliphatic chain-containing and anionic (carboxylic acid) groups attached to that end of the biphenyl-methyl backbone<sup>[40]</sup>. In contrast, both losartan and irbesartan possess neutrally charged (unionizable) groups (albeit also bulky) at that biphenyl-methyl backbone end<sup>[40]</sup>. Finally, olmesartan, which also has an anionic (carboxylic acid) substitution but of intermediate bulkiness (*i.e.*, less long aliphatic chain) compared to candesartan and valsartan on that side of its backbone, displays intermediate potency at inhibiting  $\beta$ arr1 activation and suppressing aldosterone<sup>[40]</sup>. Based on these observations, we have designed the compound 2-pentyl-1-({4-[2-(2H-1,2,3,4-tetrazol-5-yl)phenyl]phenyl}methyl)-1H-1,3-benzodiazole-7-carboxylic acid (Figure 1)<sup>[40]</sup>, which carries a bulky,

carboxyl acid group with a long aliphatic chain on the other end of the tetrazolo-biphenyl-methylene backbone, and we are currently testing both its potency at blocking  $\beta$ arr1 activation by the human AT<sub>1</sub>R and its efficacy at suppressing aldosterone secretion *in vitro* and in the post-MI HF setting *in vivo*. Our hope is that it will prove to be even more efficacious than candesartan and valsartan at suppressing aldosterone levels and thus, an even better drug for HF treatment than all currently available ARBs. Of course, the above mentioned ARB structure-activity relationship inferences have to be confirmed by crystal structure resolutions of the AT<sub>1</sub>R bound to  $\beta$ arrs. The first glimpse into the human AT<sub>1</sub>R crystal structure was recently provided and it was the first step towards that goal<sup>[50]</sup>. Unfortunately however, that crystal structure lacked the intracellular C-terminal tail of the receptor, which is exactly the AT<sub>1</sub>R region that interacts with  $\beta$ arrs<sup>[51]</sup>.

## CONCLUSION

A head-to-head comparison of the ARBs currently on the United States market identified candesartan and valsartan as the most potent  $\beta$ arr1 antagonists and the most efficacious aldosterone suppressors at the human AT<sub>1</sub>R. Conversely, irbesartan and losartan were found to be largely G protein-"biased" inhibitors, with minimal efficacy towards inhibition of AngII-dependent aldosterone production. Thus, from a therapeutic standpoint, candesartan and valsartan may be the most preferable agents of this drug class, as they provide the biggest benefit for cardiac function and patient survival in post-MI HF and have the lowest propensity to cause the "aldosterone escape" adverse effect (failure to suppress aldosterone). Future studies on this class of drugs and on the effects of  $\beta$ arrs at the adrenal AT<sub>1</sub>R will help solidify these inferences and will also provide additional important information regarding AngII/AT<sub>1</sub>R pharmacology for clinicians and medicinal chemists alike.

### Abstract

In the last few decades, the recommended treatment for

coronary artery disease has been dramatically improved by percutaneous coronary intervention (PCI) and the use of balloon catheters, bare metal stents (BMSs), and drug-eluting stents (DESs). Catheter balloons were burdened by acute vessel occlusion or target-lesion restenosis. BMSs greatly reduced those problems holding up the vessel structure, but showed high rates of in-stent re-stenosis, which is characterized by neo-intimal hyperplasia and vessel remodeling leading to a re-narrowing of the vessel diameter. This challenge was overtaken by first-generation DESs, which reduced restenosis rates to nearly 5%, but demonstrated delayed arterial healing and risk for late in-stent thrombosis, with inflammatory cells playing a pivotal role. Finally, new-generation DESs, characterized by innovations in design, metal composition, surface polymers, and anti-proliferative drugs, finally reduced the risk for stent thrombosis and greatly improved revascularization outcomes. New advances include bioresorbable stents potentially changing the future of revascularization techniques as the concept bases upon the degradation of the stent scaffold to inert particles after its function expired, thus theoretically eliminating risks linked with both stent thrombosis and re-stenosis. Talking about DESs also dictates to consider dual antiplatelet therapy (DAPT), which is a fundamental moment in view of the good outcome duration, but also deals with bleeding complications. The better management of patients undergoing PCI should include the use of DESs and a DAPT finely tailored in consideration of the potentially developing bleeding risk in accordance with the indications from last updated guidelines.

**Key words:** Drug-eluting stent; Bare metal stent; In-stent re-stenosis; Stent thrombosis; Coronary artery disease

**Core tip:** Percutaneous coronary intervention (PCI) has made progress in leaps and bounds in the last 20 years. Complications occurring with catheter balloons and bare metal stents have been overwhelmed by drug-eluting

stents (DESs), especially the new-generation ones. They are characterized by innovations in design, metal composition, surface polymers, and anti-proliferative drugs, thus reducing the risk for stent thrombosis and greatly improving revascularization outcomes. DESs also need dual antiplatelet therapy (DAPT), but the latter implies bleeding complications, too. Patients undergoing PCI should be implanted with DESs and DAPT should be tailored on each patient considering the bleeding risk.

## INTRODUCTION

Since the 1990s, percutaneous coronary intervention (PCI) has brought a revolution in the field of coronary artery disease (CAD). Coronary stents have been found to efficiently halt dissection flaps and restore the round lumen in order to decrease the possibility of acute occlusion of the vessel. Bare metal stents (BMSs) have been demonstrated to limit early vessel recoil and late remodeling, justifying the lower rates of re-stenosis with respect to balloon angioplasty<sup>[1]</sup> and the favorable outcomes in terms of mortality, myocardial infarction, and stent thrombosis (ST) (Figure 1)<sup>[2]</sup>. Nonetheless, they also increased the formation of the neo-intima layer leading to re-stenosis, which was partially limited by the thinning of stent struts<sup>[3,4]</sup>. Hence, the development of drug-eluting stents (DESs) was required (Figure 1). Early DESs are characterized by a metallic structure coupled with anti-proliferative drugs, usually controlled by surface polymers demonstrating a lower risk of clinical re-stenosis compared to BMSs<sup>[2]</sup> and reduced angiographic target-vessel revascularization<sup>[5]</sup>. New-generation DESs featured durable or biodegradable polymer-coated, metallic, thin scaffold releasing anti-proliferative drugs, thus improving the post-PCI vessel injury and the healing response leading to neo-intimal hyperplasia<sup>[6]</sup>. In general, DESs naturally limiting healing processes can lead to an incomplete endothelialization, which appears as a main contributor to ST resulting in acute myocardial infarction and mortality rates ranging from 20% to 40%<sup>[6]</sup>.

According to the 2014 European Society of Cardiology (ESC)/European Association for Cardio-Thoracic Surgery (EACTS) guidelines, revascularization by either PCI or coronary artery by-pass graft (CABG) is generally indicated in coronary stenoses leading to a reduced flow in order to limit myocardial ischemia, relieve symptoms, and improve the prognosis<sup>[7]</sup>. Several studies concluded that neither PCI nor CABG alone provided a definitive solution for the entire spectrum of stable CAD needing revascularization, which should be considered as a complementary to the medical therapy. We believe that

an exhaustive discussion about PCI or CABG indications would deserve appropriate focus in systematic reviews, meta-analyses or position papers. Therefore, additional speculation appears out of the scope to the present editorial<sup>[7]</sup>.

As stated by the 2014 ESC/EACTS guidelines, no indication for BMSs over new-generation DESs is stated, irrespective of patient and lesion subset<sup>[7]</sup>. Similarly, in randomized clinical trials, BMSs and DESs did not significantly differ in long-term rates of death or myocardial infarction<sup>[2,8]</sup>. DESs have been described to better prevent coronary re-stenosis<sup>[9]</sup>. New-generation DESs have been found to reduce ST rates<sup>[10-12]</sup>, being safer and more efficient than early DESs<sup>[13,14]</sup>; finally, new-generation DESs were demonstrated to decrease the rates of death and myocardial infarction<sup>[10,11,15]</sup>.

## ST AND IN-STENT RE-STENOSIS

### ST

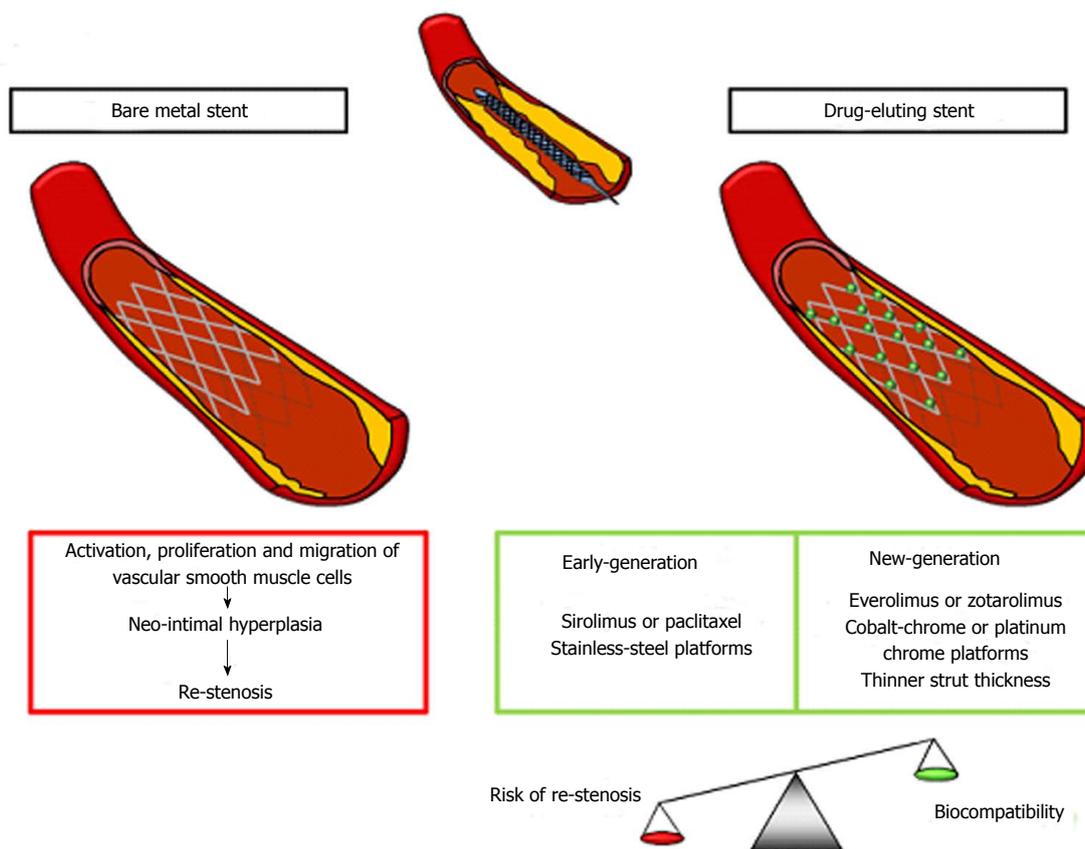

ST is a relatively rare complication (around 1% up to 3 years) characterized by angiographic or post-mortem evidence of a thrombus in a stented segment of the coronary tree<sup>[6]</sup>. The definition includes definite, probable, and possible ST according to the presence of a thrombus and the angiographic detection of an occlusion or not<sup>[16]</sup>. Moreover, ST can be divided between early (within the first 30 d from stent implantation) and late (beyond 30 d), with the former accounting for the great majority of the cases<sup>[17]</sup>. Recognized risk factors can be attributed to patient characteristics, such as diabetes, impaired left ventricular function, and premature antiplatelet disruption; stent features (BMS vs DES); and procedure-related problems, such as primary PCI, stent undersizing, and residual dissection or stenosis. The most important mean to prevent ST is represented by the prescription of an appropriate duration of a post-PCI dual antiplatelet therapy (DAPT).

### In-stent re-stenosis

Re-stenosis is defined as a re-narrowing of more than 50% of the vessel diameter when evaluated by angiography technique or as a re-narrowing of more than 75% of the reference vessel area in cross-section when measured by intravascular imaging techniques<sup>[6]</sup>. The pathophysiology starts with the vessel injury caused by BMS implantation, followed by neo-intimal hyperplasia, inflammation and remodeling of the coronary vessel<sup>[18]</sup>. Risk factors for in-stent re-stenosis can be considered as patient-dependent (such as diabetes and chronic renal disease), stent-dependent (such as BMS vs DES and early vs new-generation DESs), and procedure-related (such as small vessel, residual stenosis, longer stented segment, and bifurcation lesion)<sup>[6]</sup>.

## BMS AND DES: IS IT TIME FOR A RE-APPRAISAL?

In light of new stent design and different scaffold

**Figure 1 Bare metal stents and drug-eluting stents.** Percutaneous coronary intervention for coronary artery disease has seen important evolution in last few decades. Early bare metal stents showed a high rate of in-stent re-stenosis. Drug-eluting stents tried to overcome this complication using anti-proliferative molecules; in this sense, new-generation ones, with thinner strut thickness, showed more biocompatibility and less complications with respect to previous models.

composition, Bønaa *et al*<sup>[19]</sup> have evaluated new-generation DESs and new-generation BMSs in a randomized trial conducted in eight centers in Norway, named Norwegian Coronary Stent Trial (NORSTENT). Among more than 20000 patients undergoing PCI between 2008 and 2011, 12425 met the eligibility criteria and 9013 were randomly assigned to either DESs or BMSs. After a 5-five year follow-up period, no significant differences were found between groups for either the primary outcome (composite of death from any cause and non-fatal spontaneous myocardial infarction) or the secondary ones (death; fatal and non-fatal spontaneous and peri-procedural myocardial infarction and stroke; hospitalization for unstable angina pectoris). Interestingly, even if not considered as the primary end-point, new-generation DESs have shown better performances than BMSs in terms of rates of any revascularization (16.5% vs 19.8%, respectively,  $P < 0.001$ ), target-lesion revascularization (5.3% vs 10.3%, respectively,  $P < 0.001$ ) both for PCI and coronary artery bypass graft surgery, and definite ST (0.8% vs 1.2%,  $P = 0.0498$ ).

This trial is worth being considered not only for its results, but also because it is well-designed, correctly powered, and especially not sponsored by industry. Results are very interesting as they partly oppose to those who claimed that there is no longer a role for

BMSs in PCI because of the larger superiority of DESs; these conclusions are surely derived from studies which were underpowered, only observational or from meta-analyses pooling results<sup>[15,20,21]</sup>. Moreover, results from the NORSTENT trial are important because they are not centered on death or recurrent myocardial infarction, certainly reduced also by lifestyle modifications and appropriate drugs, but rather on reduction of need for revascularization and ST. Indeed, in the latter case, the result in absolute terms is very encouraging, but between-group difference is to be considered to the extreme limit of the statistical significance ( $P = 0.0498$ ).

As things stand at present, new-generation DESs are to be preferred in the majority of clinical situations. Recent recommendations from the American College of Cardiology/American Heart Association allow a shorter duration of DAPT to 6 mo in patients developing a high risk of bleeding<sup>[22]</sup>. If this possibility is considered, the choice of DESs with respect to BMSs becomes surely more attractive. Moreover, several trials have demonstrated that a prolonged DAPT (over 12 or 24 mo) did not add benefits in terms of major cardiovascular events, including ST, across a median 2- or 5-year follow-up period, but rather increased the frequency of bleeding complications<sup>[23,24]</sup>. These data have also been confirmed in a meta-analysis by Valgimigli *et al*<sup>[25]</sup>, who did not find any significant difference in

ischemic end-points, such as cardiac death, myocardial infarction with or without stroke, and death from any or cardiovascular causes. Indeed, in spite of the poor number of ST, prolonged DAPT duration has not been shown to provide a decrease in the definite or probable ST when compared to shorter DAPT duration. Moreover, clear evidence for prolonged DAPT for 1 year or more was found for major bleeding events and the risk of stroke<sup>[25]</sup>. Recently, Helft *et al*<sup>[26]</sup> partially confirmed the same results in the OPTimal DUAL antiplatelet therapy trial showing no reduction in adverse clinical events in the prolonged DAPT group and no apparent difference in the major bleeding rate, even if the reduced trial power has to be considered in this case; interestingly, STs were rare with no between-group differences.

Anyway, it is important to underline that BMSs might be recommended in patients with a large vessel diameter, and they show low re-stenosis rates, with poor compliance to DAPT or need for non-cardiac surgery, with reimbursement problems, and with increased risk of bleeding (such as patients with recent bleeding or under concurrent anticoagulation therapy), as indicated by Morice *et al*<sup>[27]</sup>. The latter study showed how the choice of BMSs seems to be guided mainly by the concern of bleeding or poor compliance, considering only 1 mo of DAPT for BMSs compared to 6-12 mo for DESs according to European or American guidelines, and neglecting the potential, future need for revascularization, which is accordingly an ineluctable matter to be considered in terms of costs and quality of life.

In conclusion, DESs have to be considered as the first choice in patients undergoing PCI both in stable CAD and in acute coronary syndrome as they demonstrated to reach better outcomes in terms of mortality, recurrent myocardial infarction, and revascularization. The DAPT duration is still debated depending on bleeding and ischemic risks following stent implantation both changing over time. The known rule of one-year DAPT duration cannot be applied to all patients, but rather the therapy should be tailored for each patient according to the latest guidelines. For example, those treated with new-generation DES for stable coronary disease can be administered DAPT for 6 mo or 3 mo in case of bleeding risk, while for those treated for acute coronary syndrome the choice should be at least 12 mo, which can be reduced to 6 mo in case of developing a high risk bleeding.

### Abstract

Transcatheter aortic valve replacement (TAVR) has been validated as a new therapy for patients affected by severe symptomatic aortic stenosis who are not eligible for surgical intervention because of major contraindication or high operative risk. Patient selection for TAVR should be based not only on accurate assessment of aortic stenosis morphology, but also on several clinical and functional data. Multi-Imaging modalities should be preferred for assessing the anatomy and the dimensions of the aortic valve and annulus before TAVR. Ultrasounds represent the first line tool in evaluation of this patients giving detailed anatomic description of aortic valve complex and allowing estimating with enough reliability the hemodynamic entity of valvular stenosis. Angiography should be used to assess coronary involvement and plan a revascularization strategy before the implant. Multislice computed tomography play a central role as it can give anatomical details in order to choice the best fitting prosthesis, evaluate the morphology of the access path and detect other relevant comorbidities. Cardiovascular magnetic resonance and positron emission tomography are emergent modality helpful in aortic stenosis evaluation. The aim of this review is to give an overview on

TAVR clinical and technical aspects essential for adequate selection.

## INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has been validated as a new therapy for patients affected by severe symptomatic aortic stenosis who are not eligible for surgical intervention because of major contraindication or high operative risk<sup>[1,2]</sup>. Recently this option, performed in experienced centers, using next generation devices has demonstrated to be not inferior to standard surgery also in intermediate-risk patients<sup>[3]</sup>.

The safety and efficacy of prosthesis implantation depends on a proper patient selection and procedural guidance, based on a multimodality imaging approach<sup>[4,5]</sup>. A precise measurements of annulus and aortic root allow to make a correct "sizing", that means to choose the best fitting prosthesis in native aortic seat, representing one of the most important predictor of a successful procedure<sup>[6,7]</sup>.

## CLINICAL EVALUATION

Patient selection requires a multidisciplinary team approach including interventional cardiologists, surgeons, anesthesiologists and imaging specialists in order to delineate risk profile, study the anatomy of

aortic valve, aorta and peripheral vascular structures.

First line risk evaluation is usually performed using the Logistic European System for Cardiac Operative Risk Evaluation (EuroSCORE) and/or the STS Predicted Risk of Mortality Score, defining a high risk in case of logistic EuroSCORE  $\geq 15\%$ -20% or a STS score  $\geq 10\%$ . These scores present clear limitations mostly in elderly population and have not been created for TAVR procedures but for surgery so that their suitability in percutaneous valve implantation has been questioned and a risk overestimation suspected in this context<sup>[8]</sup>.

In patient with prior cardiac surgery, including de-generation of an implanted aortic bioprosthesis (valve in valve implantation), chest radiation therapy, porcelain aorta, liver cirrhosis, pulmonary hypertension and/or right ventricular dysfunction a TAVR approach should be reasonably preferred.

On the other hand, in elderly population, frailty has been associated with worst prognosis in several pathological conditions and also after TAVR and must be considered in patient evaluation. It can be definite as a syndrome of impaired physiologic reserve with decreased resistance to stressors<sup>[9]</sup> and can be quantified using a composite of four markers: Serum albumin, dominant hand grip strength, gait speed on a 15 ft (4.57 m) walk and independence in activities in daily living. These components can be summed to derive a frailty score (ranging 0 to 12) able to identify frail patients in case of score  $\geq 5$ .

Moreover, patients with poor life expectancy (less than 1 year) or in which TAVR has not expected to significantly improve quality of life should be excluded from this selection<sup>[10]</sup>.

Relative and absolute contraindications to TAVR are listed in Table 1.

One of the main advantages of TAVR vs SAVR is the more rapid recovery from TAVR and this benefit is different according to access site and is greater for transfemoral approach. Transapical access for TAVR is an accepted approach for patients in whom vascular anatomy do not permit a transfemoral approach and if on one hand it avoids potential site complications of iliac and femoral vessels, on the other hand has some limitations including an increase in respiratory complications<sup>[11]</sup>.

## ECHOCARDIOGRAPHY

### Role of transthoracic echocardiography

Echocardiography represents the first line tool in the setting of pre- and post-interventional evaluation and planning of Transcatheter Aortic Valve Replacement procedures (Figures 1-3).

Transthoracic echocardiography (TTE) gives detailed anatomic description of aortic valve complex and allows to estimate with enough reliability the haemodynamic entity of valvular stenosis.

An adequate TTE examination in a patient presenting with aortic valve stenosis should include information

**Table 1** Contraindications for transcatheter aortic valve implantation

<b>Absolute contraindications</b>
Absence of heart team or surgery on the site
Estimated life expectancy < 1 yr
Improvement of quality of life by TAVI unlikely because of comorbidities
Severe primary associated disease of other valves with major contribution to the patient's symptoms, that can be treated only by surgery
Inadequate annulus size (< 18 mm, > 29 mm)
Thrombus in the left ventricle
Active endocarditis
Elevated risk of coronary ostium obstruction (asymmetric valve calcification, short distance between annulus and coronary ostium, small aortic sinuses)
Plaques with mobile thrombi in the ascending aorta, or arch
For transfemoral/subclavian approach: inadequate vascular access (vessel size, calcification, tortuosity)
<b>Relative contraindications</b>
Bicuspid or non-calcified valves
Untreated coronary artery disease requiring revascularization
Haemodynamic instability
LVEF < 20%
For transapical approach: severe pulmonary disease, LV apex not accessible

TAVI: Transcatheter aortic valve implantation; LVEF: Left ventricular EF.

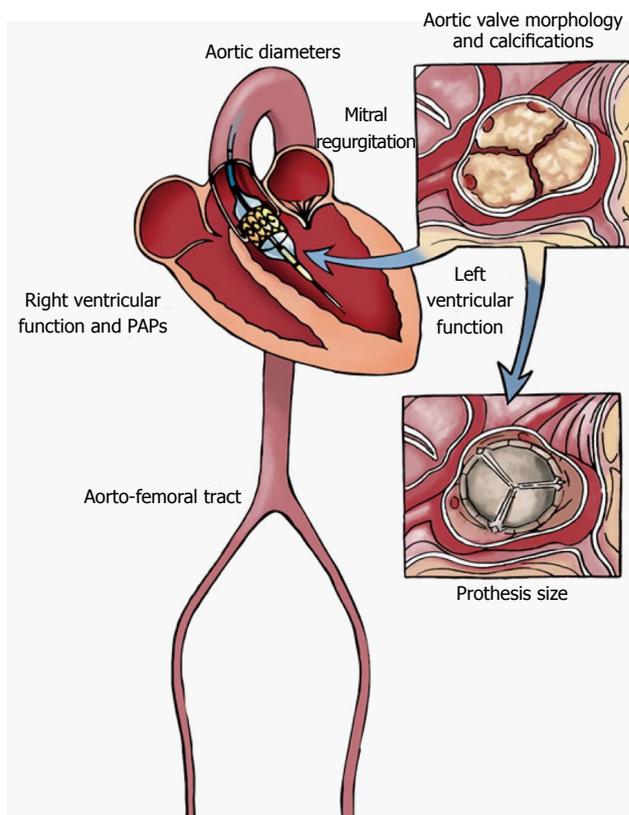

about valve anatomy (bicuspid or tricuspid valve) and severity of impairment of cusp motion. Moreover TTE provides an accurate evaluation of alterations in left and right ventricular morphology and function induced by the increase in afterload and allows to structurally and functionally investigate the other cardiac valves<sup>[12]</sup>.

Ultrasounds allow to underlie factors associated with outcome: In a longitudinal study of echo parameters in cohort A of the PARTNER trial authors showed that the TAVR and the SAVR groups had different univariate factors associated with outcome. In fact, in TAVR group, baseline low peak gradients predicted worse outcome expressing a low stroke volume status while in SAVR population the strongest determinant of mortality was mitral regurgitation<sup>[13]</sup>.

### Severity of aortic stenosis

An appropriate haemodynamic evaluation of aortic valve stenosis requires the assessment of functional aortic valve area (AVA) or indexed AVA by body surface area, derived using continuity equation, peak transvalvular gradient and velocity (Vmax), mean transvalvular pressure gradient (MPG) and Stroke Volume index (SVi). According to latest recommendations by American College of Cardiology/American Heart Association, aortic valve stenosis is considered severe when Vmax is above 4 m/s, mean pressure exceeds 40 mmHg and estimated or measured AVA is under 1 cm<sup>2</sup> (< 0.6 cm<sup>2</sup>/m<sup>2</sup> if indexed for body surface area), assuming a normal left ventricular EF (LVEF)<sup>[14]</sup>.

When performing continuity equation it should be remembered that diameter of left ventricular outflow tract (LVOT) diameter should be taken within 1 to 5 mm

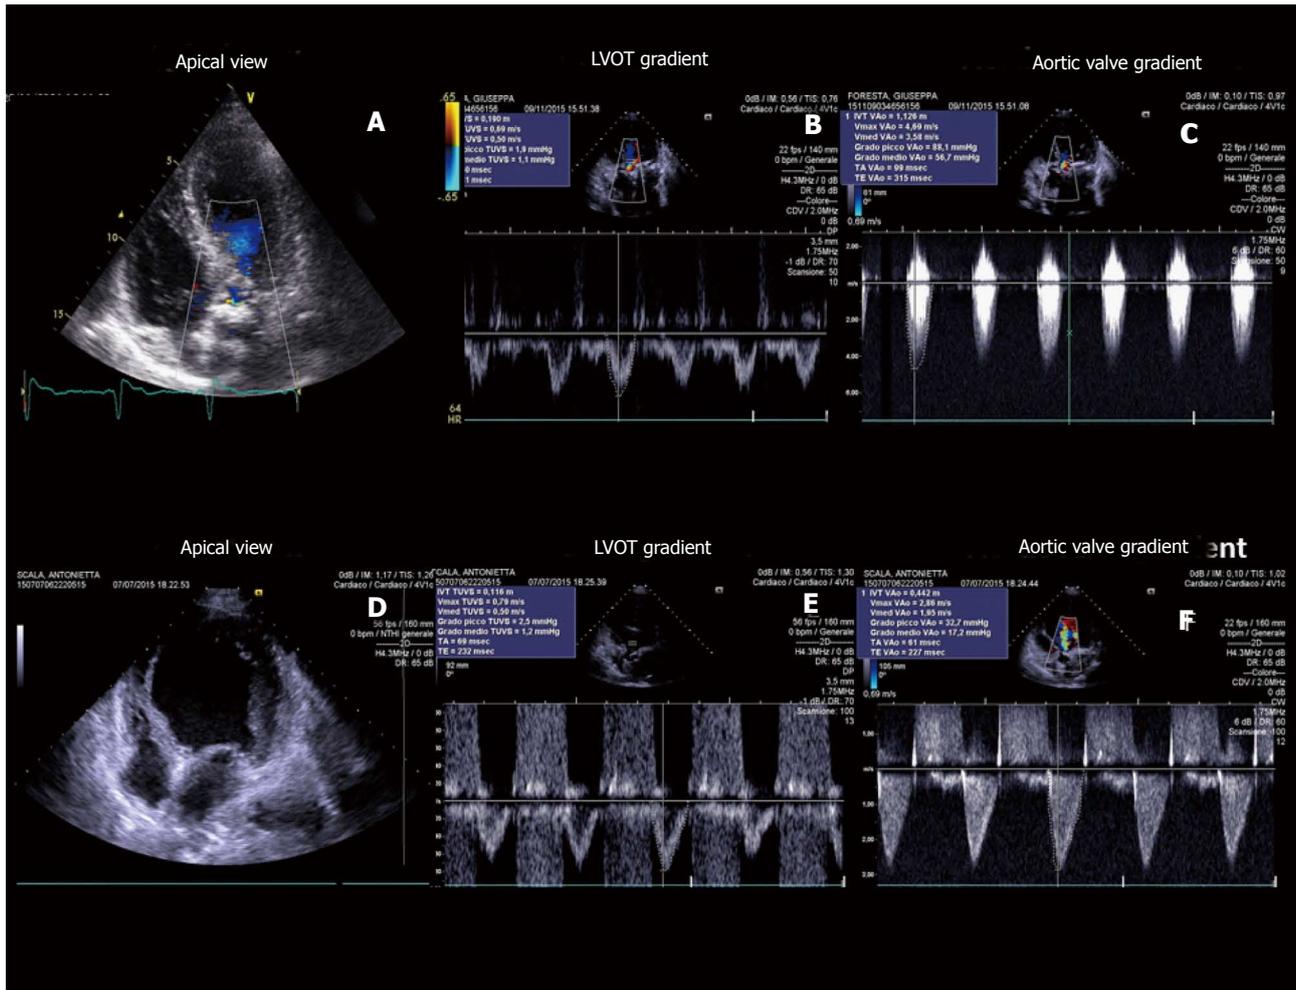

**Figure 1** Main morphologic and functional parameters to assess by Multi-Imaging approach in the setting of pre-interventional evaluation and planning of Transcatheter Aortic Valve Replacement procedures (illustrator by Germano Massenzio). PAPs: Pulmonary arterial systolic pressure.

from aortic valve annulus in order to obtain maximum diameter<sup>[15]</sup>. LVOT often is elliptical so in case of measurement of the shortest dimension the continuity equation may still under-estimate the AVA and the stroke volume.

The calculation of the valvuloarterial impedance (Zva) should be part of a routine echocardiographic examination because this parameter provide an estimate of the global hemodynamic load<sup>[16]</sup> and can be an useful parameters in the evaluation of paradoxical aortic stenosis.

In clinical practice discordance between these parameters is often encountered so that commonly a severely restricted AVA can be found concomitantly with mean and peak pressure gradients falling into the moderate or mild category. This pattern is typically observed when systolic stroke volume and consequently transvalvular flow are reduced, thus realizing a so called low-flow low-gradient (LF-LG) aortic stenosis. In this condition visual assessment of structure, calcification and mobility of aortic valve is a crucial element as it can allow suspecting the diagnosis of severe aortic stenosis regardless of Doppler values.

Two forms of LF-LG aortic stenosis have been described<sup>[17]</sup>: (1) classical LF-LG aortic stenosis defined as an AVA < 1 cm<sup>2</sup> in presence of LVEF < 50% and MPG < 40 mmHg or Vmax < 4 m/s; (2) paradoxical LF-LG aortic stenosis in presence of an AVA < 1 cm<sup>2</sup>,

**Figure 2** Transthoracic echocardiography gives detailed anatomic description of aortic valve complex and allows to estimate with enough reliability the haemodynamic entity of valvular stenosis by assessment of functional aortic valve area, derived using continuity equation. Two examples of severe aortic stenosis with normal ejection fraction and gradients (A-C), and with classical "low flow-low gradient" pattern (D-F). LVOT: Left ventricular outflow tract.

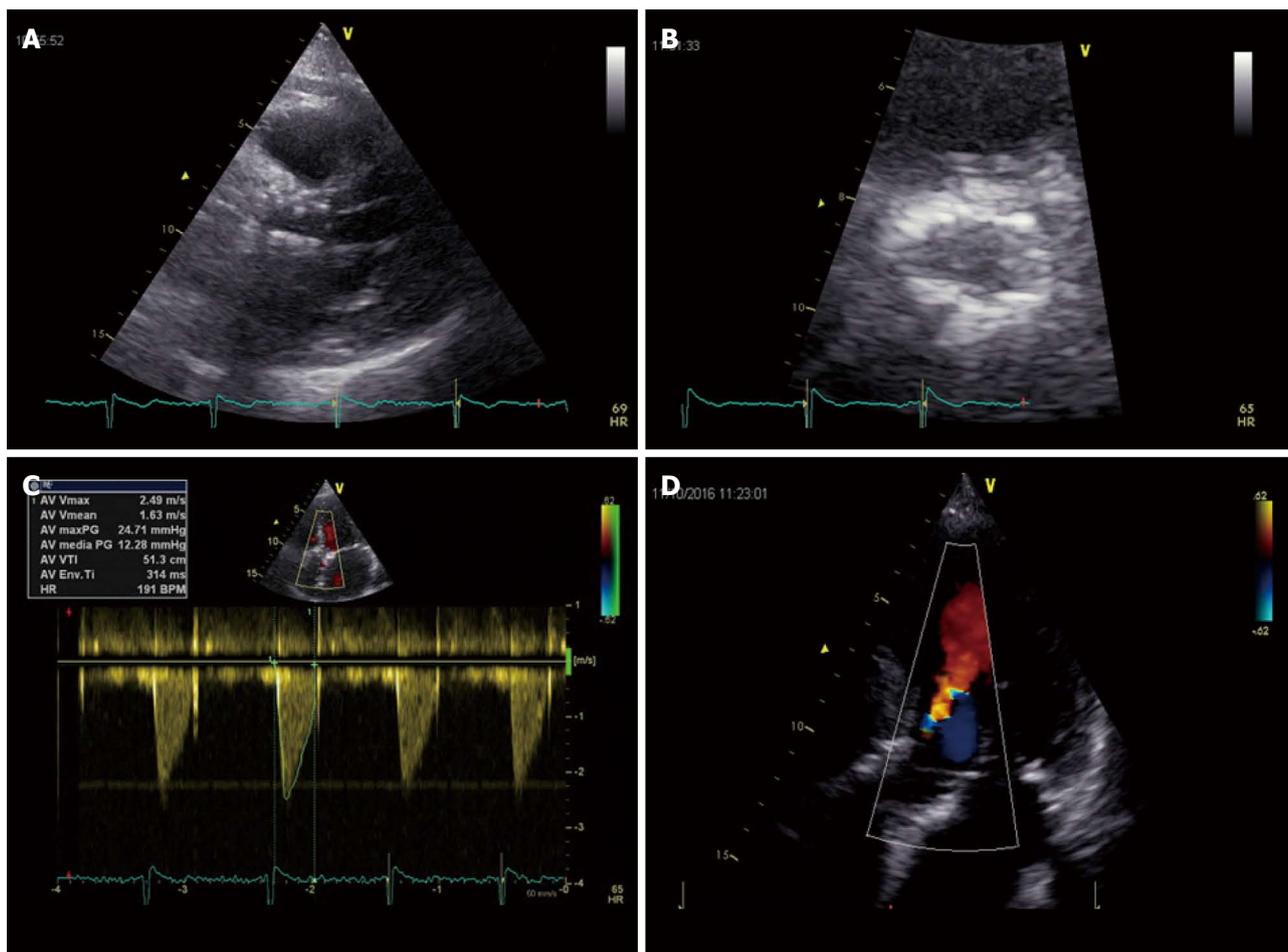

LVEF > 50%, a reduced left ventricular stroke volume (< 35 mL/m<sup>2</sup>), MPG < 40 mmHg or Vmax < 4 m/s. In this case stroke volume is low usually because of a markedly hypertrophied left ventricle with a small cavity that is unable to be filled appropriately and subsequently eject a normal stroke volume, in case of reduced volume load due to diuretic therapy<sup>[18,19]</sup> or in presence of a high valvulo-arterial impedance (ZVa > 5.5 mmHg/mL/mq)<sup>[20]</sup>. These patients seem to have a dismal prognosis, which can be improved by aortic valve replacement or TAVI, as demonstrated in a PARTNER study sub-group analysis<sup>[21]</sup>.

On the other hand, a severely reduced functional AVA associated with low transvalvular gradient may be consequent to a reduced transvalvular flow due to left ventricular dysfunction that cannot allow cusps opening, defined as "pseudo-severe" aortic stenosis. It is important to distinguish these two conditions since in this last case aortic valve intervention may not improve prognosis. In patients with reduced EF low-dose dobutamine stress echocardiography ( $\leq 20 \mu\text{g/kg}$  per minute) can be used to discriminate LF-LG severe aortic stenosis from pseudo-severe aortic stenosis as, in

the case of a severely stenotic valve, estimated AVA remains < 1 cm<sup>2</sup> and contemporarily transvalvular gradient increase<sup>[14,10]</sup>, but this variation can only be achieved in presence of a significant flow reserve (stroke volume increase > 20%).

In patients with asymptomatic severe aortic stenosis echo stress can be used, with caution and in expert centre, for unmask exercise-limiting symptoms, a drop in systolic blood pressure by > 20 mmHg, exercise increase in mean gradient  $\geq 18$  to 20 mmHg, the absence of contractile reserve (no or < 5% exercise increase in LVEF) or the presence of exercise pulmonary hypertension (> 60 mmHg) that are all strong predictors of cardiac events<sup>[22-25]</sup>.

When performing TTE evaluation of a stenotic aortic valve multiple windows should be investigated, including apical three or five chambers views and right parasternal approach, in order to obtain the best alignment of Doppler beam to transvalvular flow, thus avoiding inconsistency between estimated functional AVA and pressure gradient<sup>[26-28]</sup>. Recently in a study including 100 patients it has been shown that right parasternal window is more accurate than apical approach; in fact, when

**Figure 3** Post-implantation echocardiographic transcatheter aortic valve replacement assessment in long-axis (A) and short-axis (B) parasternal views; Normal trans-prosthesis flow gradient by Doppler analysis (C); Mild paravalvular aortic regurgitation in this apical 5-chamber view of the same patient (D).

only apical approach is used a quarter of patients was incorrectly classified, underestimating severity in two thirds of patients deemed as moderate and misjudging a third as paradoxical LF-LG<sup>[29]</sup>.

Systemic blood pressure and calibre of ascending aorta can influence severity estimation, increased left ventricular global afterload due to hypertension may cause a reduction in transvalvular flow, thus leading to stenosis underestimation<sup>[30]</sup>.

Whereas if ascending aorta diameter is smaller than 30 mm, transvalvular pressure gradient may be overestimated because of a pressure recovery phenomenon distally to the aortic valve<sup>[31]</sup>.

### **Aortic valve morphology**

Conventional 2D-TTE allows in majority of patients to determine the number and disposition of aortic valve cusps. Bicuspid aortic valve with its asymmetrical closure line tends to develop degenerative alterations earlier than normal tricuspid valves and has a markedly elliptical annulus with eccentrically disposed calcium deposition<sup>[32]</sup>.

In presence of a bicuspid aortic valve percutaneous implanted prosthesis may fail to expand completely with consequent periprosthetic regurgitation (up to 28% of

cases) and the risk of valve misplacement<sup>[33,34]</sup>. Dilation of ascending aorta, which can be a contro-indication to TAVI, is also common in bicuspid aortic valve disease, moreover TAVR could increase the risk of aortic dissection in these subjects<sup>[35]</sup>. Because of these technical conundrums PARTNER trial did not include subjects with bicuspid aortic valvular stenosis<sup>[1]</sup>. Anyway TAVR is still possible in these patients and several cases have been reported up today<sup>[36]</sup>. Phan *et al*<sup>[37]</sup> have published a meta-analysis and systematic review of literature collecting 149 patients undergone TAVR procedure there was no significant difference for patients with bicuspid aortic valves in 30-d mortality, post-procedural prosthetic haemodynamics and presence of moderate to severe perivalvular aortic regurgitation or rate of bleeding or vascular complications, indicating that TAVR can be an effective treatment also in this setting. No difference in 30-d and one year mortality between bicuspid and tricuspid stenotic valves undergoing TAVR was also found in the Poland National Registry<sup>[38]</sup>. In light of this evidence more and more centres are proposing TAVR as a valuable option for treatment patients carrying a bicuspid aortic valve, considering this condition no more an absolute but a relative contraindication to the procedure.

### **Evaluation of left ventricular function**

The presence of a left ventricle systolic dysfunction, defined as aEF < 50%, constitutes a negative prognostic marker both in symptomatic and asymptomatic severe aortic stenosis. In patients considered unsuitable for surgical aortic valve replacement enrolled in PARTNER B cohort 30-d and 1-year prognosis was not different for patients with a LVEF over 50% confronted with those with reduced LVEF<sup>[39]</sup>. Moreover in this arm of PARTNER study an increase in LVEF > 10% subsequently TAVR was found in 50% of patients considered unfit for surgery, especially for those with smaller LV chamber diameters and lower grade of mitral regurgitation before TAVR. Although LVEF improvement was not associated with improvement in survival, in those with no post-procedural increase in LVEF there was a worse prognosis at one year of follow-up.

In light of these evidences TAVR represents a valuable option in severe aortic stenosis and markedly reduced left ventricular systolic function and should be taken in consideration by the Heart Team, because in these very high risk patients for surgery TAVR may show a better outcome.

Furthermore an alteration in LV structure and function has been demonstrated in patients with severe aortic stenosis regardless a preserved LVEF and this phenomenon can be studied also with speckle tracking echocardiography, a relative new technique that provides non-Doppler evaluation of myocardial deformation as expression of systolic and diastolic dynamics<sup>[40]</sup>. In this context, in fact, a reduced GLS (global longitudinal score) has been documented with a more evident alteration in the basal LV segments and a value > -15.9% correlated with adverse prognosis<sup>[41,42]</sup>.

In patients with severe aortic stenosis undergoing TAVR, LV reverse remodelling and improvement of longitudinal myocardial function assessed by speckle tracking echocardiography have been observed together with a decrease of aorto-valvular impedance and an improvement of atrial morphology and function<sup>[43]</sup>. In fact, our group evaluated 55 patients before and 6 mo after CoreValve implantation demonstrating a significant reduction in mean transaortic gradient, LV mass, LA volume index, and an improvement of ejection fraction ( $P < 0.0001$ ). In addition, LV GLS and LA longitudinal strain significantly increased after TAVI and at the multiple logistic regression analysis, LV mass before TAVI ( $P < 0.001$ ) and peak CK MB mass after TAVI ( $P < 0.0001$ ) were powerful independent predictors of lower improvement of LV GLS. Moreover, LV mass index ( $P < 0.001$ ) and LV GLS strain ( $P < 0.001$ ) before TAVI was powerful independent predictor of LA longitudinal strain after TAVI (Figure 4).

### **Mitral regurgitation**

Haemodynamically relevant mitral regurgitation is present in a substantial amount of patients with severe valvular aortic stenosis. It may have many different underlying mechanisms, both organic and functional.

Functional mitral regurgitation may be also of ischemic nature, because of the common occurrence of coronary artery disease in these subjects. Moreover left ventricular systolic dysfunction and dilatation and concomitant aortic regurgitation may contribute to cause or aggravate mitral regurgitation<sup>[44]</sup>.

In addition high grade mitral regurgitation may result in reduced transvalvular flow and lead to incorrect classification of stenosis severity, so it has to be taken in consideration in pre-procedural TTE for a comprehensive global assessment of aortic valve disease.

Interestingly in these subset of patients improvement of mitral insufficiency is reported in around 50%, more often in the case of secondary mitral regurgitation<sup>[45,46]</sup>. This finding was consistent with the results of a recently published meta-analysis which demonstrated that MR improvement was associated with pre-procedural grade and not with causative mechanism<sup>[47]</sup>.

### **Right ventricular function and pulmonary hypertension**

Pre-procedural TTE should include a comprehensive evaluation of right ventricular dimensions and function, in addition to estimation of pulmonary arterial systolic pressure (PAPs) from tricuspid regurgitation velocity.

Registries report that after TAVR moderate or severe tricuspid regurgitation is frequent (occurring in about 15%) and in most cases it is not improved after the procedure<sup>[48]</sup>.

Pulmonary hypertension (PH) can be found in up to 25% of subjects affected by severe aortic stenosis, secondary to post-capillary increase of left ventricular filling pressure and the eventual presence of associated mitral regurgitation. PH is a predictor of worse prognosis following surgical aortic valve replacement and recently there is increasing evidence that it is a negative prognostic marker together with tricuspid regurgitation also in the setting of transcatheter aortic intervention<sup>[49]</sup>.

Evidence from TAVR registries suggests that PH (estimated PAPs over 40 mmHg on TTE) does not negatively influence success rate, amount of complications in the early phase and 30-d survival, but a negative prognostic effect is present regarding 1 year mortality, which is raised up to 22% (or higher if estimated PAPs is above 60 mmHg)<sup>[50]</sup>.

### **Role of transoesophageal echocardiography**

Transesophageal echocardiography (TEE) allows to better visualize aortic cusps, define etiology (bicuspid vs tricuspid) and directly measure aortic valve area by planimetry in doubt cases, when TTE is not conclusive. TEE can be used in association with other imaging techniques for optimal pre-procedural planning in the setting of TAVI.

### **Annulus size measurement**

Aortic valve annulus can be defined as a ring-shaped structure virtually identifiable at the level of basal attachment of aortic cusps measured in systole<sup>[46]</sup>. A correct measurement of annular size allows an appro-

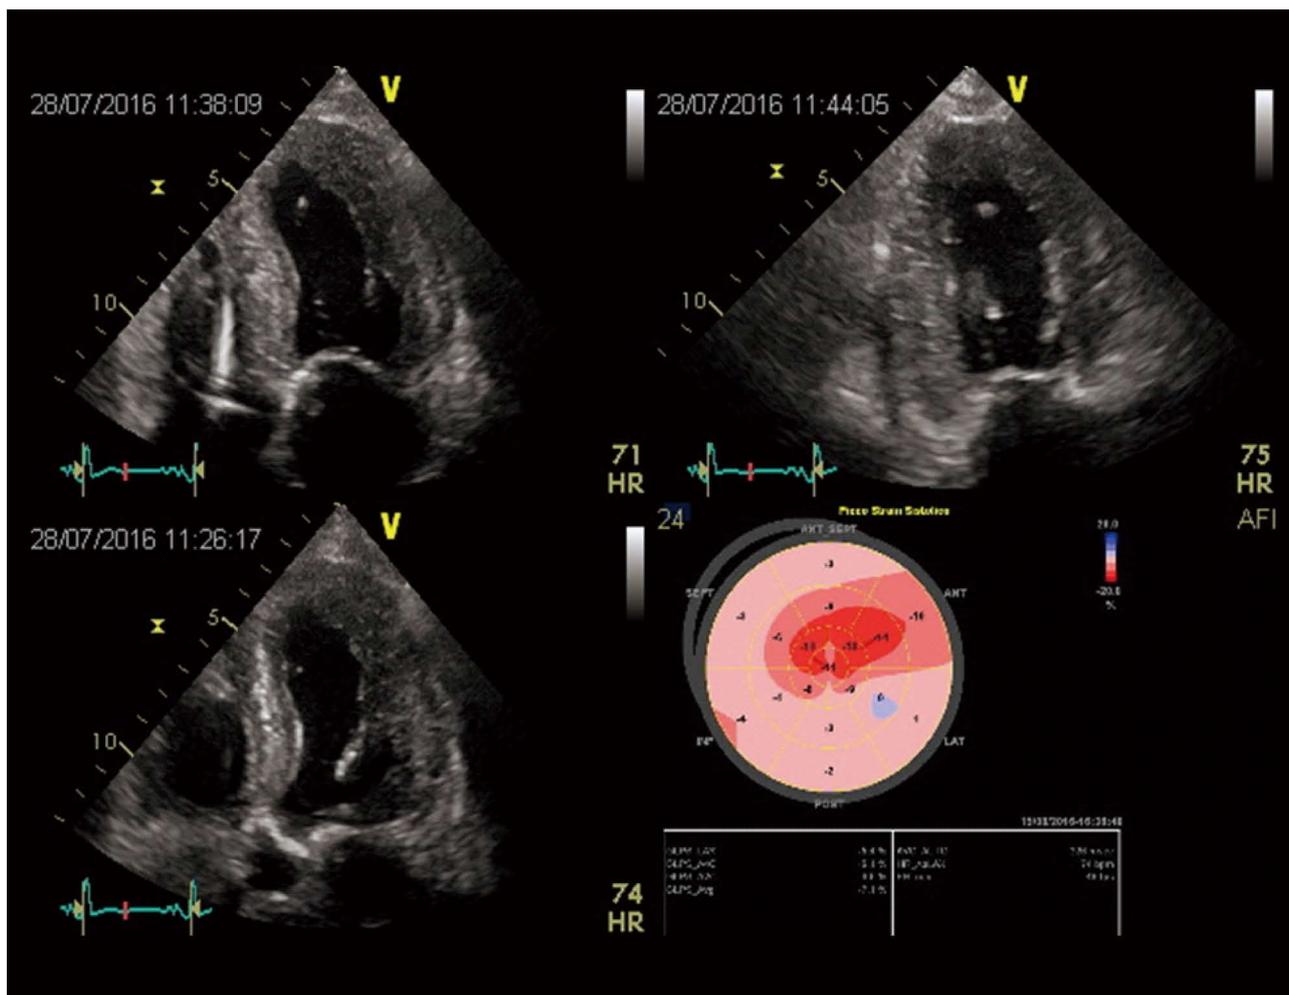

Figure 4 Two-dimensional LV strain in a patient with low flow-low gradient aortic stenosis, showing a severe and diffused impairment of myocardial deformation.

priate delivery of aortic valve prosthesis and reduce the incidence of complications<sup>[51]</sup>.

When aortic annulus is underestimated the delivery of a prosthesis too small can be followed by displacement or paraprosthetic regurgitation<sup>[4]</sup>. On the other hand prosthesis oversizing can cause insufficient expansion and valvular or paraprosthetic regurgitation or annular rupture. Optimal annular sizing aims to deliver a valve of an adequate dimension large enough to avoid paravalvular regurgitation, but not exceeding more than 20% the measured annular diameter, which increases risk of rupture.

In practice antero-posterior annular diameter is measured by TEE in mid-esophageal long axis view (120°-150°) in correspondence of basal hinge points of aortic cusps to aortic root.

Three dimensional TEE allows to visualize the real shape of LVOT, which is oval in 90% of patients<sup>[52]</sup>. 3D-TEE has proved more effective in providing optimal annular measurement and was more useful in predicting paravalvular aortic regurgitation compared to 2D-TEE<sup>[53,54]</sup> (Figure 5).

3D-TEE has been directly compared with cardiac

CT demonstrating the two imaging modalities were equally effective in predicting paraprosthetic aortic regurgitation<sup>[55]</sup>, although annulus diameter and planimetric area determined by 3D-TEE tend to result smaller than those measured by cardiac CT, except for sagittal dimensions. Considering sagittal dimensions both diagnostic techniques were equally accurate in predicting prosthetic dimensions with good post-procedural results. In conclusion before TAVI, 3D-TEE can be considered a valuable alternative to cardiac CT in pre-procedural planning, especially in patients with chronic kidney disease.

### Root anatomy

Transesophageal Echocardiography is able to evaluate the distance of coronary arterial ostia from aortic annulus and to correlate this distance with aortic cusp length, in long axis view. If cusp length is longer than coronary-annular distance there is a risk of coronary occlusion after valve delivery, when aortic valve cusps are displaced by the prosthesis expansion.

In clinical practice in order to avoid coronary occlusion, coronary-annular distance should be higher than

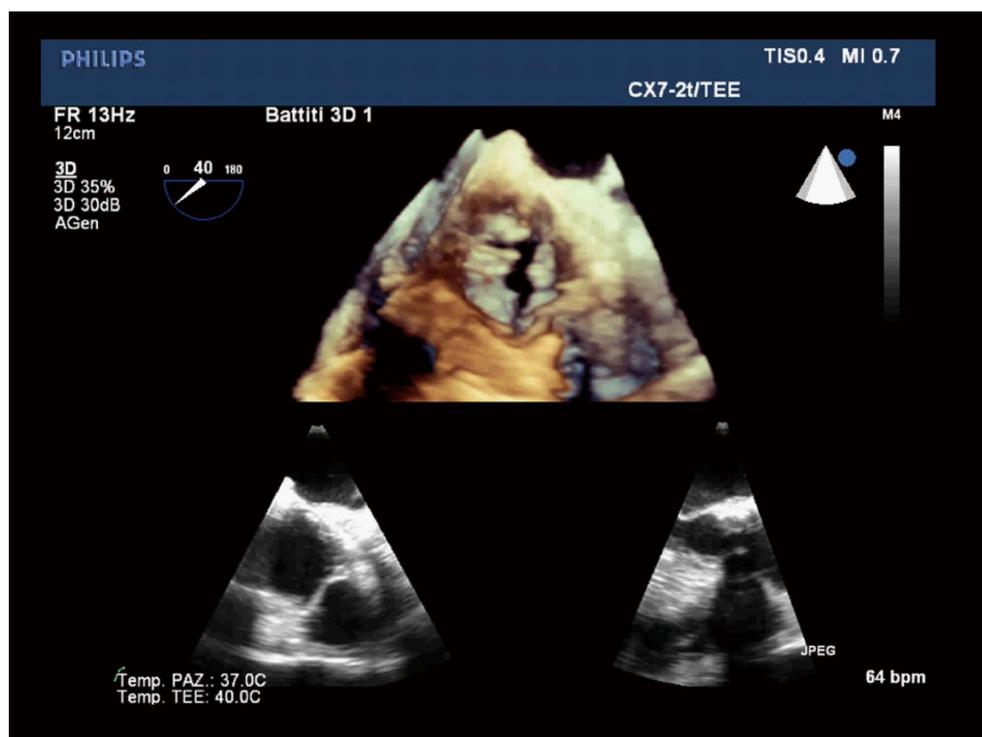

Figure 5 Three dimensional transesophageal echocardiography allows to visualize the real shape of left ventricular outflow tract, and has proved more effective in providing optimal annular measurement and was more useful in predicting paravalvular aortic regurgitation compared to 2D-transesophageal echocardiography.

10 mm<sup>[56,57]</sup>. Moreover aortic valve calcium burden should be always assessed and confronted with aortic sinus capacity. Although it is possible to measure coronary-annular distance with 2D-TEE, in the majority of patients it is necessary to use Multi Slice Computed Tomography (MSCT) or as an alternative 3D-TEE.

#### **Distribution of calcium**

TEE allows visualization of calcium deposits, which are present in almost all subjects affected by degenerative aortic stenosis, and their distribution. The presence of extensive aortic valve calcifications may cause paravalvular regurgitation due to formation of gaps between prosthetic and native valve and increase the risk of coronary ostium obstruction after TAVI delivery<sup>[58]</sup>. In addition extensively calcified sino-tubular junction may impair the expansion at the aortic end of the prosthesis eventually causing ventricular displacement of the prosthetic valve during delivery<sup>[59,60]</sup>. Great amount of calcification, particularly in subvalvular region, is also associated with increased risk of periprocedural annular rupture or sinus rupture.

#### **Characteristics of aorta and significant left ventricular septal hypertrophy**

TEE examination provides an higher spatial and temporal resolution and in pre-procedural phase allows to evaluate the ascending aorta and the descending thoracic tract in order to exclude the presence of extensive and soft atheromas which are associated with higher risk of peri-procedural ischemic stroke because they can be

mobilized and hinder the passage of delivery system<sup>[61,62]</sup>. It remains a suboptimal tool for the assessment of the distal ascending aorta and the proximal arch (TEE "blind spot" due to tracheal air shadowing) as well as for the abdominal aorta. Finally TEE may show a significant basal septal hypertrophy that may lead to prosthesis displacement in periprocedural or postprocedural phase<sup>[63,64]</sup>.

## **CORONARY ANGIOGRAPHY AND PCI**

Coronary angiography represents an essential part of patient evaluation before planning a TAVR procedure. Significant coronary artery disease is commonly found in patients with indication to TAVI, however there is no universal agreement about if and how it should be treated<sup>[61,65]</sup>. Secondary left ventricular hypertrophy may cause myocardial ischemia irrespectively of the presence of obstructive atherosclerotic lesions in major coronary arteries, in fact manifestations of angina are reported also by patients without evidence of relevant coronary artery disease (CAD) on angiographic examination<sup>[66]</sup>.

Moreover even though degenerative stenotic aortic valve disease has the same risk factors of CAD, there is substantial variability in CAD prevalence in aortic stenosis population between different studies, ranging from 34% to 75%<sup>[67,68]</sup>. A possible explanation for this inconsistency can be found in the definition adopted for significant CAD and which method is used for its diagnosis, usually angiographic examination,

which shows relevant interobserver variability. Usually angiographic cut-off for coronary obstruction is considered  $\geq 50\%$ <sup>[69-72]</sup>, but some authors use a cut off value of  $\geq 70\%$ <sup>[73-75]</sup>.

Latest recommendations about myocardial revascularization released from European Society of Cardiology suggest PTCA for patients undergoing TAVI in the presence of coronary obstructive lesions of more than 70% (class IIa, level of evidence C), despite the impact on long term survival of obstructive CAD is controversial according to different TAVI registries<sup>[76-78]</sup>. In order to definite the prognostic benefit of percutaneous revascularization of anatomically relevant CAD in patients undergoing TAVR a randomized controlled trial, the ACTIVATION study, is ongoing<sup>[79]</sup>.

In addition the burden of CAD in this setting fall in a broad spectrum going from a simple single lesion to multiple complex lesions, with different prognostic implications. Currently CAD treatment can be guided by coronary angiography and Anatomical Scoring Systems. Moreover in patients with borderline risk profile the assessment or the exclusion of coronary artery disease can induce the Heart Team to lean towards SAVR or TAVR.

### **Angiography-guided revascularization**

According to angiographic data significant obstructive CAD is found in 40%-60% of TAVR patients, evaluated through quantitative coronary angiography (QCA). Khawaja *et al*<sup>[66]</sup> in a retrospective study "Coronary artery disease in patients undergoing TAVI- why not to treat" including 271 patients evaluated through QCA, reported an incidence of obstructive CAD of 34% (defined as a 70% or more stenosis of a major coronary artery or 50% or more in left main stem or a venous graft); 26.9% of them underwent revascularization before TAVR procedure. Moreover no significant increase in mortality for patients carrying obstructive CAD was found in this study, either at 30 d or at 1 year and among them, those treated by revascularization also did not show any significant prognostic improvement.

However QCA has several pitfalls: (1) eccentric and markedly calcific plaques are difficult to assess through this technique because of calcium pools projection by X-rays; and (2) extremely tortuous epicardial coronary arteries may cause mistakes in vessel measurement and thus in stenosis evaluation<sup>[80]</sup>. Alternatively markedly calcific and contorted lesions may be more reliably evaluated through optical coherence tomography or intravascular ultrasonography, but at present the use of these techniques has not been investigated in TAVR population.

Finally according to old fashioned studies using QCA of left coronary artery in aortic valve stenosis it was demonstrated a progressive increase in coronary vessel dimensions as aortic valvular stenosis progresses, such phenomenon was reverted by SAVR, so angiographic evaluation may not reliably predict CAD extension after

TAVR procedure<sup>[81]</sup>.

### **Anatomical score system**

Anatomical scores are used to grade coronary artery disease extension in everyday clinical practice, among them the most frequently used is SYNTAX score<sup>[82]</sup>. Recently these scoring systems have been applied in small TAVR registries, taking in consideration the location and complexity of coronary lesions in order to estimate procedural risk of coronary revascularization<sup>[83,84]</sup>.

In the previously cited retrospective analysis by Khawaja *et al*<sup>[66]</sup> a SYNTAX score  $> 33$  (which defines an high risk according to SYNTAX study) had an higher rate of periprocedural complications during TAVR, whereas a SYNTAX score between 0 and 22 identified patients with a lower risk. Moreover a cut off value of 9 was a predictor of all-cause death at one month and at one year of follow-up so that revascularization may be indicated for patients with a SYNTAX score  $\geq 9$ .

Furthermore comparing surgical aortic valve replacement with TAVR in the setting of low flow-low gradient aortic stenosis, which represent an higher risk population, the extent of CAD evaluated through SYNTAX score or remaining CAD severity assessed by residual SYNTAX score after revascularization were both predictors of worse prognosis and cardiovascular death after 1 year follow-up<sup>[85]</sup>.

### **Fractional flow reserve guided revascularization**

No methods are validated to assess ischemia in patient with severe aortic stenosis and also evaluation offunctional significance of coronary artery stenosis by fractional flow reserve (FFR) is not recommended in this population. In fact the mechanism of ischemia in severe aortic stenosis is more complex and due to multiple hemodynamic factors so that aortic pressure waveform and coronary blood flow regulation is altered by left ventricular hypertrophy leading to an impaired coronary flow reserve also in absence of coronary obstruction<sup>[86]</sup>. In addition, the increased left ventricular filling pressure will rise left ventricular diastolic wall stress, this phenomenon together with reduced diastolic time may contribute to impair diastolic coronary blood flow per se.

On the other hand the administration of vasodilator drugs, necessary to asses FFR, could induce critical fall in systemic arterial pressure with potentially hemodynamic instability.

## **MULTISLICE COMPUTED TOMOGRAPHY**

Among the imaging modalities, computed tomography (CT) plays a central role in the evaluation of patients with severe aortic stenosis prior to TAVR since it allows to study anatomical details in order to choice the best fitting prosthesis, evaluate the morphology of the access path, select the best fluoroscopic projection angles and detect other relevant comorbidities (Figure 6).

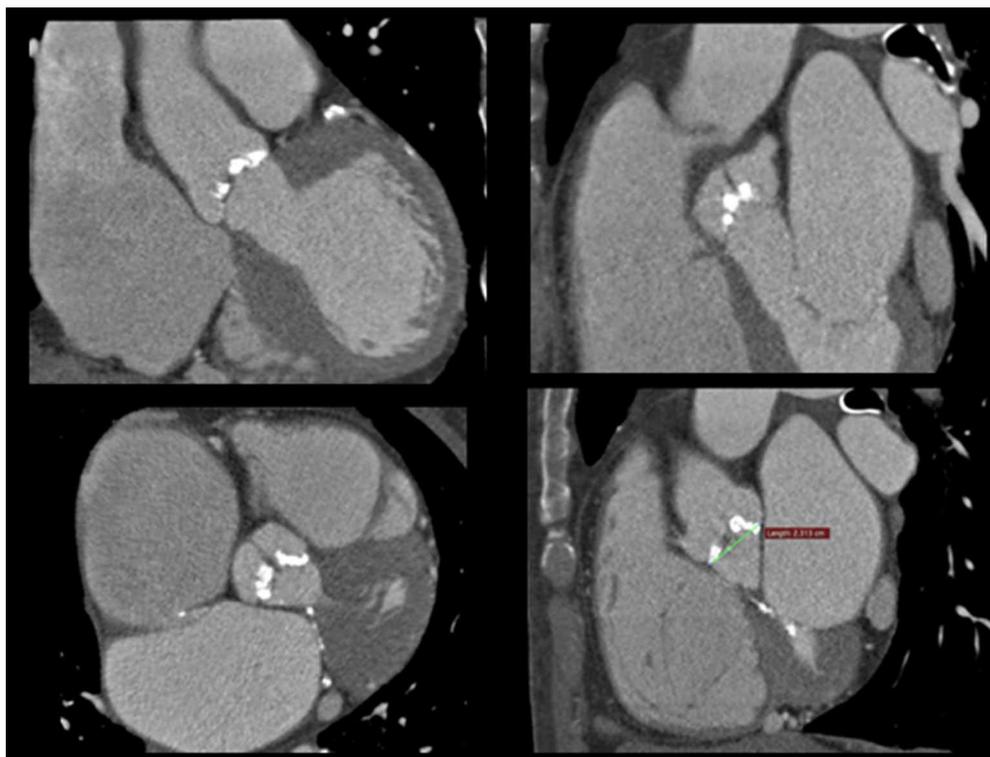

Figure 6 Multi-slice enhanced computed tomography images showing the aortic valve cusps and the first tract of the ascending aorta, with associated presence of extensive valvular calcifications.

### Measurement of aortic annulus and evaluation of aortic root

Multidetector scanners allow multiplanar reformation and 3-dimensional reconstruction of aortic root, ascending tract, arch and descending segments of aorta. Novel technological advances in CT result in higher image quality with substantially reduced scan duration, contrast volume and radiation exposure. CT provide an accurate measurement of anatomic AVA by a cross-sectional view of the aortic valve derived from left sagittal and left coronal oblique views<sup>[52]</sup>. Moreover this modality gives precise measurements diameters, expressed also as mean value between different planar reliefs, area and perimeter of aortic annulus which are essential information for a correct prosthesis choice. The annulus size is larger when measured by MSCT than by 2D transthoracic or transoesophageal echocardiography with an absolute difference  $\leq 1.52 \pm 1.1$  mm. Comparing the measurements of aortic annulus size as obtained by CT angiography and 2-dimensional transoesophageal echocardiography with direct surgical measurement in patients undergoing surgical valve replacement, CTA overestimates aortic annulus diameter in 72.2% of cases, with 46.3% > 1 TAVI valve-size (> 3 mm) overestimations, whereas TEE underestimated aortic annulus diameter in 51.1% of cases, with 16.7% > 1 valve-size underestimations<sup>[87,88]</sup>.

MSCT allows also to give precise measurements of the distance between annulus and coronary ostia and represents the gold standard for this purpose, providing a more comprehensive assessment, showing an average

annular-right coronary artery distance of  $13.6 \pm 2.8$  mm and annular-left coronary artery distance of  $13.4 \pm 3.2$  mm<sup>[89,90]</sup>. The distance between the aortic valve annular plane and the coronary ostia should be at least of  $\geq 10$ -11 mm for both type of most used prosthesis (Corevalve and Edwards). It is important also to evaluate the dimensions of ascending aorta at 45 mm above the annulus plane when the strategy foresees the implantation of a Corevalve prosthesis as this value should not exceed 40 mm for the 26-mm valve and 43 mm for the 29-mm and 31-mm.

This technique is useful to make many reconstructions with adjunctive information about calcification severity, plaque burden and prohibitive risk findings as dissections and complex atheroma of aorta<sup>[91]</sup>.

### Aortic valve calcium score

CT permits to calculate aortic valve calcium scoring. In severe aortic annular calcification the protrusion of calcium into the lumen > 4 mm can lead to an undersizing of the prosthesis valve and predict a post procedural paravalvular regurgitation<sup>[92]</sup>. Furthermore a high calcium score can help to distinguish between severe and pseudosevere aortic stenosis in patients with low left ventricle ejection fraction. Different cutoff values of calcium score in aortic stenosis have been described for men ( $\geq 2000$  AU or  $\geq 480$  AU/cm<sup>2</sup>) and women ( $\geq 1200$  AU or  $\geq 290$  AU/cm<sup>2</sup>) to identify severe AS<sup>[93]</sup>. In risk stratification, mostly in asymptomatic or paucisymptomatic patients, the aortic valve calcium load assessed by MSCT is a powerful predictor of rapid

**Table 2** Magnetic resonance sequences used for pre transcatheter aortic valve implantation evaluation<sup>[96]</sup>

Three-plane localizer	To localize aortic valve plane
Axial SSFP non ECG gated without contrast	To identify potential ascending aorta and subclavian access sites To determine size, calcification, and presence of aneurysmal dilatation of aorta
Breath held free breathing 2D ECG gated SSFP	To evaluate aortic annulus, aortic valve structure, and sinus height
Coronal aorta, LVOT and aortic root	Planimetry valve orifice area
SSFP ECG gated images: short axis stack	Calculate ejection fraction, ventricular volumes and mass
Breath held free breathing phase contrast at aortic orifice	Calculate blood flow velocity, pressure gradient, and flow volume across the aortic valve Calculate Aortic regurgitant volume
3D Navigator assisted SSFP	Coronary ostia height Aortic diameter
T2 black blood	Useful in presence of susceptibility artifacts from sternal wires or prosthetic valves

LVOT: Left ventricular outflow tract; SSFP: Steady state free procession; ECG: Electrocardiography.

stenosis progression and of cardiac events<sup>[94]</sup>.

### Detection of coronary artery disease

Invasive coronary angiography remains the gold standard diagnostic modality for the detection of significant CAD in patients with severe aortic stenosis. The role of coronary computed tomography angiography (CTA) in selection of patients for TAVR until now remains not established mainly because there are few data regarding its diagnostic accuracy in this context. In a large unselected cohort of patients with severe aortic stenosis, the identification of significant CAD has been limited by feasibility and an overall moderate accuracy (driven by the high rate of false-positive observations) so that this test cannot be used instead of invasive coronary angiography<sup>[95]</sup>. In fact, also in patients without arrhythmias, high heart rate and coronary stents up to 25% of the CTA images were found to be not fully evaluable representing coronary calcification the major confounding factor<sup>[96-98]</sup>. On the other hand, CTA has shown a good sensitivity (97%) and negative predictive value (97%) so that it can be reasonably be used as a rule-out test in some selected cases mostly in patients without prior known CAD and little calcifications<sup>[95]</sup>.

### Comorbidities detection

Computed tomography as a part of pre-TAVR diagnostic work-up is often able to detect other concomitant pathologies with important influence on outcome and sometimes questioning the indication to the procedure as in case of detection of potentially malignant diseases with poor prognosis. In fact, during CT aortography, images are acquired throughout the thorax and abdomen, and potentially significant incidental findings can be found. Until today patients candidates to TAVR tend to be elderly and it has been shown a very high overall incidence of incidental pathological findings in this population (more than 50%) and in 18.1% of cases a clinical significance has been documented<sup>[99]</sup>.

### Assessment of peripheral accesses

Appropriate approach selection is crucial for a good results of TAVR and is based on minimal aorto-femoral tract diameter detected by projection aortography or

CTA. In addition to conventional angiography (XA), CTA provides more detailed 3D images including calcification and tortuosity and allows to exclude a transfemoral access in patients with poor vessel quality or small diameter in aorto-femoral tract considering that the 18 Fr sheath requires a minimal arterial diameter of 6 mm of the aorto-femoral tract for prosthesis delivery<sup>[100,101]</sup>. It is important to know that the semi-automated CTA diameter measurement of the aortoiliac tract resulted statistically significantly smaller compared to XA-based measurements.

Patients not suitable for transfemoral TAVR should be considered for transapical implantation or conventional surgery<sup>[102]</sup>.

## MAGNETIC RESONANCE IMAGING

Cardiovascular magnetic resonance (CMR) is an emergent modality for evaluation of patients before TAVR and it is expected to gain more and more space in this setting, mostly in patients with contraindications to contrast medium. As MSCT, this technique provides precise measurements of aortic valve, annulus, aortic root, coronary ostia, definition of the thoraco-abdominal aorta and luminal caliber of the iliofemoral branches (Table 2)<sup>[103]</sup>. Moreover it is able to study LV function with the advantage of not using ionizing radiation (Figure 7).

Non contrast MR should have an important role in preoperative evaluation in selected groups of patients with aortic stenosis: (1) patients affected by severe renal function impairment with GFR < 30 mL/min/mq; (2) patients with inadequate acoustic window mostly in the context of low gradient detection and/or reduced left ventricle ejection fraction; (3) discrepancy between parameters obtained by echocardiography and symptoms; and (4) History of allergic reactions to iodinated contrast medium.

MRI technique are influenced by some limitations. In the first place multiple breath holds, claustrophobia and the presence of arrhythmias can interfere with an adequate acquisition. Aneurism clips, carotid vascular clamp, neurostimulator devices, insulin or infusion pumps, ear implant and ocular foreign bodies represent

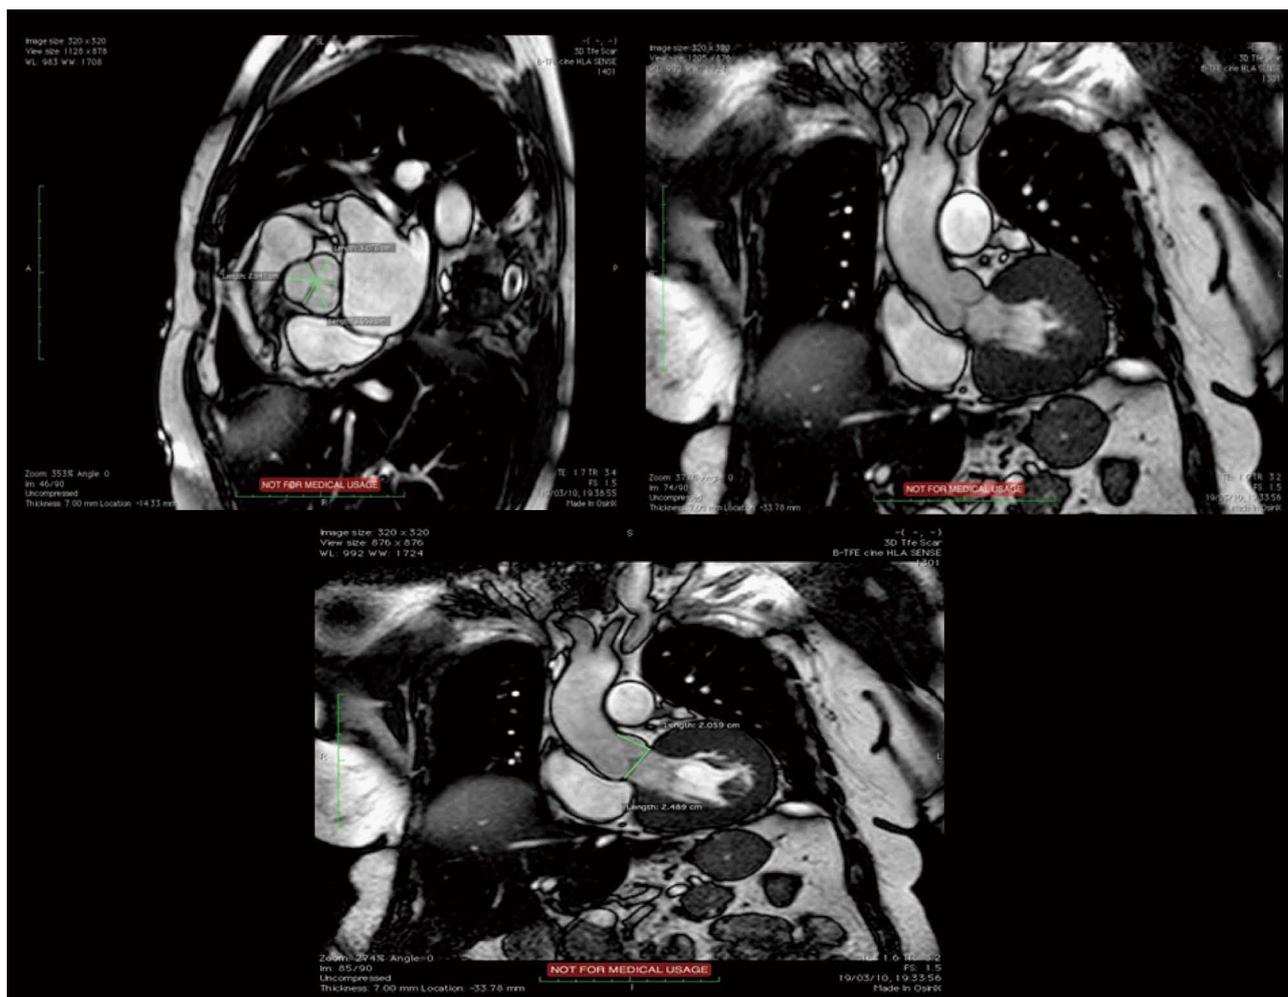

Figure 7 Balanced fast-field echo unenhanced magnetic resonance images showing the normal tricuspid aortic valve, with the typical “Mercedes-Benz Sign” and the first tract of the ascending aorta.

absolute contraindications.

### Aortic valve and root evaluation

MRI is able to provide accurate measurements of aortic annulus that in terms of capacity to predict the presence and the severity of post-implantation aortic regurgitation is similar to MSCT<sup>[104]</sup>. A good concordance between MSCT, CMR and echocardiography has been documented for aortic valve morphology definition and aortic valve area measurements<sup>[105]</sup>. In fact MRI is able to provide the planimetry of aortic valve opening area which is similar to other diagnostic modality as 3D TEE and flow-derived area calculation by catheterization using the Gorlin equation or by Doppler echocardiography using the continuity equation<sup>[106]</sup>. Although anatomic planimetry of aortic stenosis and assessment of valvular anatomy and motion is possible with MRI, this became less than optimal in patients with severe calcifications mostly in the presence of non-planar orifices. Furthermore assessment of severity of aortic stenosis can be completed by velocity-encoded cine MRI with other standard measures as peak anterograde velocity and pressure gradient but

it is necessary to know that velocities and gradients are usually underestimated if compared with Doppler echocardiography<sup>[107]</sup>.

MRI can be an alternative to 3D imaging modality for the measurement of aortic annulus (minor and major diameters, area and perimeter) having showed a good agreement with CT in this context also in presence of oval shape of the structure in which, after adequate plane orientation and 3 dimensional reconstruction, generally the coronal diameter is larger than the sagittal one<sup>[108]</sup>. As for MSCT, MRI diameters were found to be larger than those measured by 2D TEE modality.

Measurements of sinus of Valsalva diameters and definition of aortic root orientation are also possible with this approach but conversely this doesn't represent a good modality to thoracic aorta plaque burden definition as calcifications cause signal voids<sup>[103]</sup>.

The concordance with CT has been documented also for the assessment of the distance between the annulus and the ostium of the left coronary artery in relation to the length of the left coronary leaflet but at the moment more studies are needed to determine whether a strategy based on a different imaging method could

**Table 3** Multimodality imaging in pre transcatheter aortic valve replacement evaluation

Technique	Principal advantages	Disadvantages
Transthoracic echocardiography	Widespread availability First line diagnostic tool	Poor acoustic window Frequent discrepancy between different parameters
Transesophageal echocardiography 3 D reconstruction	Good spatial resolution Semi-invasive exam	Suboptimal for distal ascending aorta and arch Anatomic definition and annulus measurement
Multislice computed tomography	Multiplanar reconstruction Quantification of calcium score Evaluation of aorto-femoral tract	Potential nephrotoxicity of contrast medium Radiations exposition Controlled heart rate
Magnetic resonance imaging	Tissue characterization Multiplanar reconstruction Evaluation of aorto-femoral tract Controlled heart rate	Reduced availability Poor evaluation of calcifications Contraindicated in metallic devices wearers
Positron emission tomography	Evaluation of calcification and inflammation	Poor spatial resolution

achieve better results. A3-D SSFP free breathing stack in late diastole with a respiratory navigator allows to measure the height of coronary ostia from the annular plane.

Moreover magnetic resonance angiography can characterize aorto-ilio-femoral arteries in order to plan the more adequate access<sup>[109]</sup>.

#### Ventricular volume and function

MRI provides quantitative evaluation of left ventricle volumes and function and late gadolinium enhancement at T1-weighted sequences allows to detect myocardial fibrosis which is more often localized in mid-wall of myocardium, like in pressure-overload cardiomyopathies, and represents a predictor of poor prognosis<sup>[110]</sup>. Fibrosis represents one of the most important factors implicated in progression of hypertrophy towards heart failure and an early detection can be useful in risk profile definition mostly in asymptomatic patients or in case of borderlines parameters at conventional echocardiography evaluation. Advanced fibrosis replacement of left ventricle myocardium predicts a lack of improvement in LV systolic function after aortic valve replacement and is an independent predictor of all-cause mortality<sup>[111,112]</sup>.

#### POSITRON EMISSION TOMOGRAPHY/CT

An emergent role in pre-TAVR evaluation is attributable to positron emission tomography (PET)/CT with the advantage of combining the anatomic definition derived from CT and the functional and metabolic characterization gained from PET<sup>[15]</sup>. <sup>18</sup>F-sodium fluoride (<sup>18</sup>F-NaF) is a tracer used to detect calcification and in aortic stenosis the amount of uptake correlates with disease severity and is able to predict the progression of the disease<sup>[113-115]</sup>. On the other hand <sup>18</sup>F-fluorodeoxyglucose uptake, representing the burden of inflammation, is higher in patients with mild or moderate aortic stenosis and decrease with stenosis progression.

#### CONCLUSION

Patient selection for TAVR should be based not only on

accurate assessment of aortic stenosis morphology, but also on several clinical and functional data. The Heart Team is key in the overall risk evaluation of this population. Multi-Imaging modalities are preferred for assessing the anatomy and the dimensions of the aortic annulus before TAVI (Table 3). In any case, we should tailor our patient selection and prosthesis selection on a case-to-case basis.

### Abstract

Pulmonary vein isolation by point-by-point radiofre-

quency catheter ablation constitutes the cornerstone of catheter ablation strategies for the treatment of atrial fibrillation. However, despite advances in pulmonary vein isolation ablation strategies, long-term success rates after ablation remain suboptimal, which highlights the need to develop techniques to achieve more durable lesions. Strategies proposed to improve the durability of pulmonary vein isolation can be divided into two groups: Those addressed to improving the quality of the lesion and those that optimize the detection of acute PV reconnection during the ablation procedure. This manuscript reviews the role and potential benefits of these techniques according to current clinical evidence.

**Key words:** Atrial fibrillation; Pulmonary vein isolation; Lesion durability; Contact force; Pulmonary vein reconnection

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Results of pulmonary vein isolation remains suboptimal in terms of long-term outcomes. Improving lesion durability could reduce atrial fibrillation recurrence rate after pulmonary vein isolation. This manuscript reviews current techniques proposed in order to achieve more durable pulmonary vein isolation by point-by-point radiofrequency ablation. The role and potential benefits of these techniques are discussed according to current clinical evidence. Furthermore a stepwise approach to achieve permanent pulmonary vein isolation is proposed.

## INTRODUCTION

Atrial fibrillation (AF) is one of the major causes of stroke, heart failure, and cardiovascular morbidity worldwide<sup>[1]</sup>. Since Haïssaguerre *et al*<sup>[2]</sup> identified the pulmonary veins (PVs) as triggers capable of initiating AF paroxysms, radiofrequency (RF) catheter ablation through pulmonary vein isolation (PVI) has been developed and now constitutes the cornerstone of catheter ablation strategies for the treatment of AF<sup>[3]</sup>. Current indications for PVI include symptomatic paroxysmal or persistent AF, in general as second-line treatment after failure of or intolerance to antiarrhythmic drug therapy, but also as first-line therapy in selected cases<sup>[4]</sup>.

According to the most recent consensus statement on catheter ablation of AF<sup>[3]</sup>, the technique for achieving PVI should target a wide area around the PVs, called the antrum, with complete electrical isolation as the endpoint of the procedure. However, despite advances in PVI ablation strategies, long-term success rates after ablation remain suboptimal, which has led to the development of new techniques to achieve more durable lesions.

## PV RECONNECTION AS THE MAIN CAUSE OF AF RECURRENCE AFTER PVI

In the majority of patients with AF recurrence, an electrical reconnection between the PV and LA can be observed<sup>[5-7]</sup>. The probability of AF recurrence during follow-up after a PVI procedure has been linked with the presence of gaps, defined as poor isolation areas between the PV and LA, due to suboptimal RF lesions<sup>[8]</sup>. A recent meta-analysis of 11 studies<sup>[9]</sup> including 683 patients showed that 85.5% of patients with AF recurrence had at least one PV reconnected, opposed to 58.6% of those without AF recurrence. Although not fully established, it has been suggested that the biological mechanism underlying PV reconnection may be related to the recovery of tissue conduction after a transient phase of reversible tissue injury with inflammation and edema<sup>[10]</sup>. Therefore, achievement of permanent PV isolation should be considered the main goal of current AF ablation approaches in order to avoid recurrences.

## PERMANENT PV ISOLATION AS THE ENDPOINT OF AF ABLATION: HOW TO ACHIEVE IT?

The reasons for long-term failure of AF ablation are largely based on a suboptimal ability to effectuate a durable transmural lesion using the contemporary ablation toolset. While electrical PVI may be achieved acutely, the combination of inadequate electrode-tissue contact, insufficient power delivery, and tissue edema

may prevent RF-induced heating of myocardium to lethal temperatures. With time, as the acute effects of RF energy resolve, the transient injury induced at the time of index ablation recovers, revealing gaps in the initial line of ablation and allowing PV triggers to excite the adjacent LA and induce AF<sup>[6,10]</sup>. Several techniques to improve the durability of PVI have been proposed, and can be divided into two groups: Those addressed to improving the quality of the lesion and those that optimize the detection of acute PV reconnection during the ablation procedure.

## TECHNIQUES TO IMPROVE LESION DURABILITY

The use of irrigated catheters for PVI was associated with a dramatic decrease in PV reconnection rate<sup>[11]</sup>. However, even when irrigated catheters are used, the recurrence rate after a single PVI procedure remains high (30%-35%)<sup>[12]</sup>. Further strategies are required in order to improve long-term durability of the lesions obtained with this type of catheters.

### Use of sheaths

Efficient catheter contact can be facilitated through the use of non-steerable and steerable sheaths that allow easy maneuverability, access, and contact to target sites. Piorkowski *et al*<sup>[13]</sup> compared the use of steerable sheaths with the use of non-steerable sheaths during AF ablations in a prospective randomized trial. Although the rate of acute PVI and total RF application time did not differ between the study groups, single procedure success was significantly higher in patients treated with a steerable sheath (76% vs 53% at 6 mo). The difference persisted at 12 mo (75.7% success) after a single AF catheter ablation procedure using steerable sheath<sup>[14]</sup>. Therefore, use of a steerable sheath may help to improve the maneuverability of the ablation catheter, catheter stability, and tissue contact. This could potentially reduce recurrence through the enhancement of lesion continuity and transmurality.

### General anesthesia

In a multicenter trial, Di Biase *et al*<sup>[15]</sup> randomized 257 consecutive patients undergoing a first AF ablation procedure to general anesthesia or conscious sedation. During follow-up (mean 17 ± 8 mo), fewer patients randomized to conscious sedation were free of atrial arrhythmias while off antiarrhythmic drugs (69% vs 88% of patients randomized to general anesthesia). In their study, all patients with recurrence had a second procedure. Interestingly, 42% of PVs in the conscious sedation arm at the repeat procedure had recovered PV conduction, compared with 19% in the general anesthesia group<sup>[15]</sup>. Better and more stable tissue-catheter contact due to controlled breathing patterns and elimination of patient movements may explain this finding.

### Contact force sensing catheters

Contact force (CF) sensing is a novel technology used to assess the degree of catheter-tissue contact through a sensor at the distal tip of the ablation catheter. Studies based on animal models have shown that catheter-tissue CF is directly correlated with lesion size, and that excessive CF (> 50 g) could even provoke steam pops<sup>[16,17]</sup>. The concept of force-time integral (FTI) has also been proposed as a major factor in RF lesion size<sup>[18]</sup>. Shah *et al*<sup>[18]</sup> calculated the FTI by measuring the area under the CF curve beyond 60 s and found a linear correlation with lesion size during RF ablation. Despite similar power and peak CF values, lesions were larger with constant contact and smaller with intermittent contact.

### CF and lesion transmuralty

Several studies have assessed the relationship between CF and lesion transmuralty by means of electrogram analysis, cardiac imaging, and histopathology. Squara *et al* assessed the CF and FTI needed to create effective transmural lesions during AF ablation by analyzing bipolar electrograms before, during, and after RF application. Based on post-ablation changes in electrogram characteristics, they identified a cutoff FTI of > 392 gs to predict transmuralty with 89% sensitivity and 93% specificity<sup>[19]</sup>. Two cardiac MRI studies have demonstrated a direct correlation of CF and FTI with lesion transmuralty. In the first study, Sohns *et al*<sup>[20]</sup> performed contrast-enhanced cardiac MRI in patients treated with AF ablation using CF catheters. They found a correlation between regions where higher FTI (> 1200 g) was maintained during ablation and those showing increased late gadolinium enhancement on MRI at 3 mo after ablation<sup>[20]</sup>. In the second study, Andreu *et al* performed cardiac MRI at 3 mo after PVI ablation to assess CF thresholds required to create permanent lesions using a dragging catheter (as opposed to a point-by-point lesion delivery) technique<sup>[21]</sup>. They reported that PV segments where MRI gaps were seen had lower maximal CF values, compared to segments without gaps, and a CF threshold of > 12 g predicted the formation of a complete PV lesion with 94% specificity and 91% positive predictive value.

Results from a recent study question the correlation between CF and chronic lesion formation. Williams *et al*<sup>[22]</sup> placed linear intercaval right atrial lesions in eight pigs using high (> 20 g) or low (< 10 g) CF, intentionally leaving a gap between segments. Voltage maps and cardiac MRI were performed before, immediately after, and 2 mo after ablation. The authors found that tissue edema was greater in the acute post-ablation setting with high CF, but there was no difference in chronic lesion size or volume by voltage mapping or cardiac MRI between high vs low CF regions at 2 mo. Their results suggest that a transmural lesion can be created whenever continuous tissue-catheter contact is achieved (independently of the CF value) and adequate power is delivered with a stable catheter position throughout the

lesion.

### CF variability according to left atrium anatomy

Obtaining adequate CF can be difficult in certain portions of the LA, and certain LA regions may require less CF to achieve transmuralty with RF ablation. This may explain the observation that PV reconnection tends to recur at specific regions in the LA. For example, Schluermann *et al*<sup>[23]</sup> reported lower CF obtained in left PVs than in right PVs and found the lowest values in the anterior segments, where the ridge between the left upper PV and the LA appendage represents an especially challenging region for obtaining appropriate CF. Consistently with these data, our group observed that when operators were blinded to CF, the lowest CF values were recorded at the anterior segments of left PVs<sup>[24]</sup> (Figure 1).

On the other hand, given the differences in LA wall thickness, the amount of CF needed to achieve transmural lesions may vary in different portions of the LA. Sotomi *et al*<sup>[25]</sup> showed that higher CF may be necessary in certain regions such as the inferior right PV and posterior-superior right PV regions (22 g CF), while other areas such as the posterior-inferior right PV region may require only 10 g CF to assure acute PVI. Knowledge of CF requirements in various regions of the LA can improve safety during ablation by allowing the operator to control RF power based on CF to prevent steam pops without compromising lesion durability.

### Impact of CF on ablation outcomes-clinical studies

Several studies (Table 1) have assessed the role of CF technology in short and long-term ablation outcomes.

The TOCCATA study was the first multicenter, prospective study to demonstrate the safety of CF-sensing catheters (Tactiath, Endosense) for ablation of cardiac arrhythmias<sup>[26]</sup>. The study included 34 patients undergoing PVI for paroxysmal AF and showed that low CF was associated with higher rates of AF recurrence<sup>[26]</sup>. Specifically, all patients treated with a CF < 10 g experienced AF recurrences, whereas 80% of the patients treated with an average CF > 20 g remained free from AF recurrence at 12 mo<sup>[26]</sup>.

In order to demonstrate the correlation between CF parameters during initial procedure and PV reconnection, the EFFICAS-I study of PVI using CF-sensing catheters assessed the incidence of isolation gaps at 3-mo follow-up (Tactiath, Endosense)<sup>[27]</sup>. Interestingly, operators were blinded to CF information during the initial procedure. Isolation gap sites correlated with lower minimum CF and FTI during the initial ablation, and the authors proposed an optimal CF target of 20 g with minimum FTI of 400 gs. These cut-off values were prospectively tested in the EFFICAS-II study, which showed that 85% of PVs treated within the proposed CF guidelines were chronically isolated, suggesting a more durable PVI<sup>[28]</sup>.

The SMART-AF trial, a prospective, multicenter, non-randomized single-arm study, examined the efficacy

**Table 1** Clinical studies on contact force monitoring and mid/long-term outcomes

Study	n	Type of study	CF catheter	Control catheter	Follow-up (mo)	Findings
Andrade <i>et al</i> <sup>[55]</sup> , 2014	75	Prospective observational	Thermocool SmarTouch	Navistar Thermocool	13.3	CF reduced dormant conduction (16% vs 52%) and improved long-term arrhythmia-free survival (88% vs 66%)
Kimura <i>et al</i> <sup>[31]</sup> , 2014	38	Randomized controlled trial	Thermocool SmarTouch	Thermocool SmarTouch (blinded operator)	6	CF reduced procedure time and additional touch-up ablation
Marijon <i>et al</i> <sup>[61]</sup> , 2014	60	Prospective observational	Thermocool SmarTouch	EZ Steer Thermocool	12	CF reduced AF recurrence at 12 mo (10.5% vs 35.9%)
Shurrab <i>et al</i> <sup>[33]</sup> , 2015	42	Observational	Thermocool SmarTouch	Navistar Thermocool	2.5	CF reduced reconnection rate at 30 min postablation
TOCCASTAR, 2015	300	Randomized controlled trial	Tacticath	Thermocool Navistar	12	No differences in arrhythmia-free survival
Pedrote <i>et al</i> <sup>[24]</sup> , 2016	50	Randomized controlled trial	Thermocool SmarTouch	Thermocool SmarTouch (blinded operator)	12	CF reduced PV gaps (20% vs 68%). No benefits in arrhythmia-free survival
Ullah <i>et al</i> <sup>[34]</sup> , 2016	117	Randomized controlled trial	Thermocool SmarTouch	Thermocool SmarTouch (blinded operator)	12	CF reduced acute reconnections (22% vs 32%). No benefits in arrhythmia-free survival

CF: Contact force.

and safety of AF ablation using a SmartTouch CF-sensing catheter<sup>[29]</sup>. Only 2.5% of the 172 patients included had severe complications, suggesting that safety was not inferior to non-CF-sensing catheters. On the other hand, CF-sensing ablation that remained within target range > 80% of the time resulted in superior 1-year ablation success (81% of patients free from AF recurrence vs 66%,  $P = 0.005$ )<sup>[29]</sup>.

The TOCCASTAR study was a prospective, multi-center, randomized clinical trial that compared AF ablation with CF (TactiCath) vs non-CF (ThermoCool Navistar) catheters in 300 patients<sup>[30]</sup>. Achieving optimal CF resulted in higher rates of acute PVI and no differences were observed in long-term success (freedom from AF or atrial tachycardia recurrence at 12 mo, excluding 3-mo blanking period).

Kimura *et al*<sup>[31]</sup> compared acute bidirectional block after PVI in 38 patients randomized to non-CF guided vs CF-guided (target CF 10-20 g) ablation using Thermocool Smart Touch catheter. This study showed that CF-guided PVI reduces procedure time and the need for additional touch-up ablation. Furthermore, a nonsignificant trend towards lower AF recurrence rate at 6 mo post-PVI was observed in the CF-guided group.

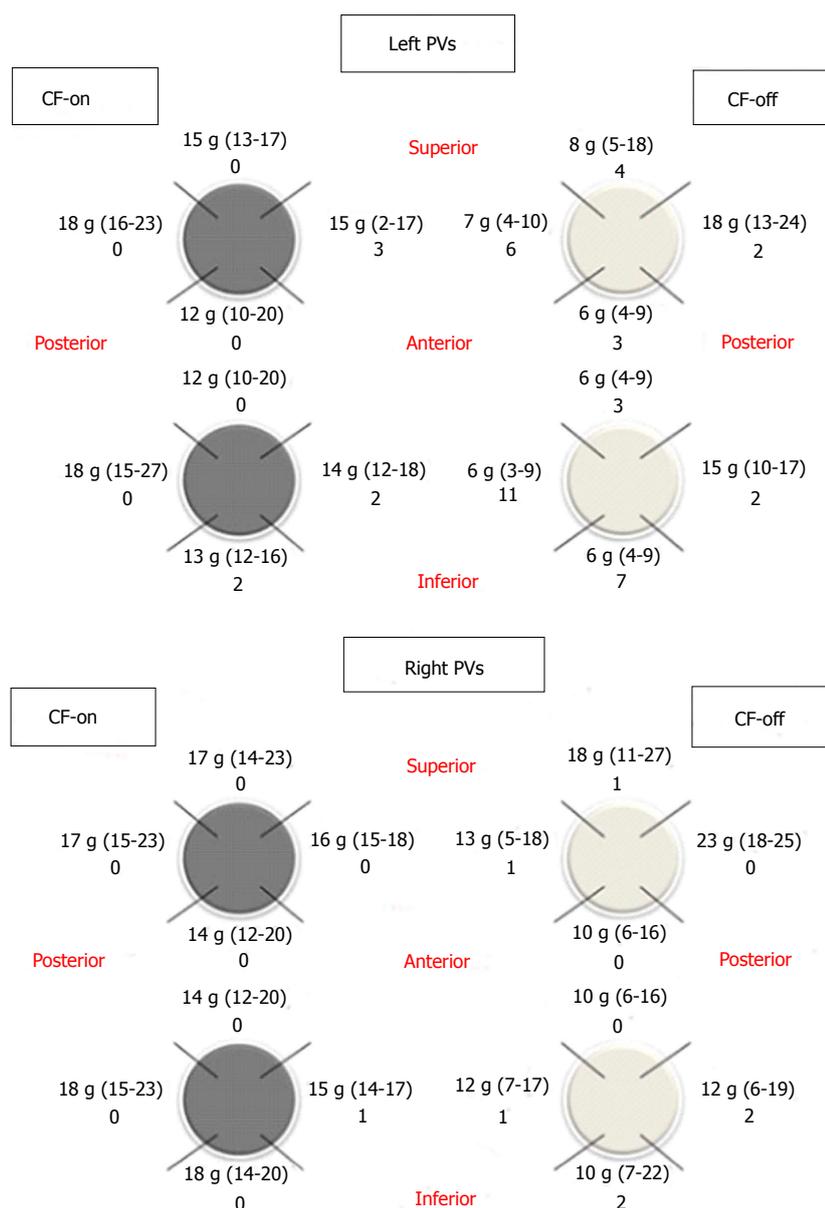

Two large meta-analyses have compared AF ablation with CF vs non-CF catheters. Afzal *et al*<sup>[32]</sup> examined data on 1148 patients in 9 studies and found that the use of CF-sensing technology reduced AF recurrence 37% overall at a median 12 mo of follow-up. Those treated with CF catheters also had reduced RF ablation duration, although no significant difference was seen in total procedure length or fluoroscopic exposure, compared to non-CF catheters. Shurrab *et al*<sup>[33]</sup> subsequently published another meta-analysis, which included 1428 patients from 11 studies (an overlap of 6 studies from the previous meta-analysis). They found a similar 38% overall reduction in AF recurrence at long-

term follow-up. However, in addition to reduced RF ablation time, overall procedure length and fluoroscopic exposure duration were significantly lower in patients treated with CF technology. This meta-analysis also demonstrated a non-significant trend toward lower complication rates in the CF group.

It should be noted that the studies mentioned above assessed the impact of CF parameters in PVI performed with a circular catheter inside the PV. The use of circular catheters allows continuous recording of the electrical signal inside the PV, which can condition the endpoint of the procedure and prevents "naïve" assessment of the potential benefit of CF monitoring. In order to test the benefits of CF monitoring in PVI with an exclusively anatomic approach (blinded to the PV catheter), our group conducted a randomized, controlled study in which 50 patients with paroxysmal atrial fibrillation were randomized into CF-on (CF > 10 g) or CF-off (CF blinded;  $n = 25$ ) groups. In the CF-on group, there was a reduction in the PV gaps at the expense of the left PVs and shortening of the procedure and radioscopy times. This confirms the benefits of operator monitoring and control of a mean CF > 10 g during PVI<sup>[24]</sup>. However, at 12 mo the AF recurrence rate was similar in both groups<sup>[24]</sup>. Consistent with these data, a larger study by Ullah *et al*<sup>[34]</sup> using the same methodology showed that access to CF data during the procedure was associated with reduced acute PV reconnection, although no benefit was observed in terms of 1-year success rate. These results suggest that CF monitoring during PVI may not impact long-term clinical outcome because it is only one of multiple factors that determine lesion durability.

### Ablation index

As has been explained, previously described endpoints (CF and FTI) do not take the power used during RF

**Figure 1 Contact force variability according to left atrium anatomy.** Contact force (CF) is expressed in grams (g; median and 25<sup>th</sup>-75<sup>th</sup> percentile) and the number of pulmonary veins segments with conduction gaps (bold) in the CF-on group (dark gray) and the CF-off group (light gray). Reproduced with permission from Pedrote *et al*<sup>[24]</sup>.

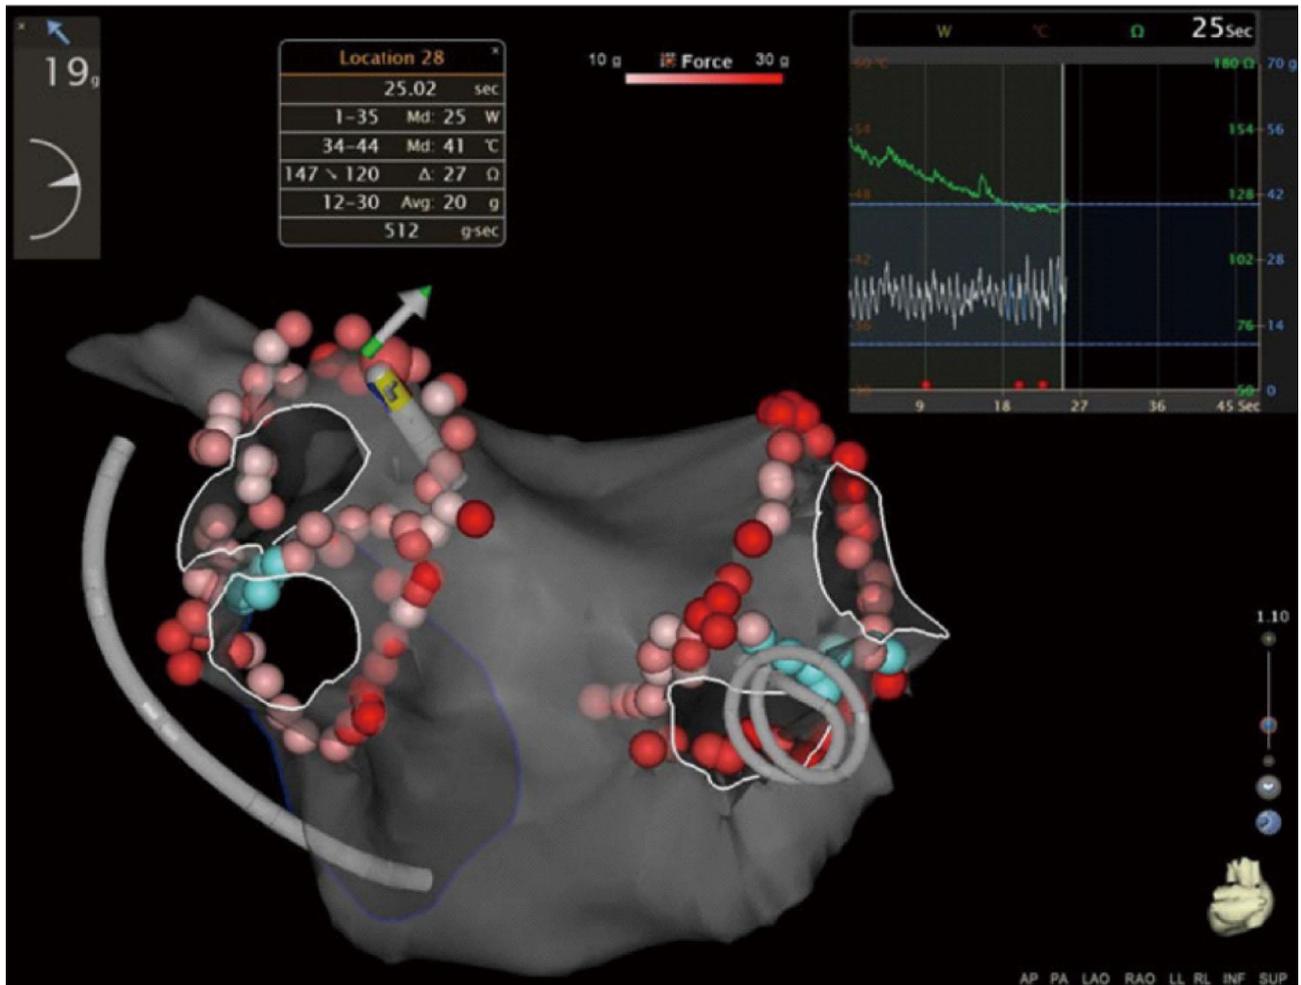

application into account. In order to resolve this limitation, the ablation index has been proposed as a marker of ablation lesion quality that incorporates CF, ablation time, and RF power in a weighted formula (the greater the impact of power over CF, the greater the impact on the initial phase of ablation). A recent study by Das *et al*<sup>[35]</sup> showed that the minimum ablation index was an independent predictor of conduction recovery after PVI. Furthermore, in this study, higher ablation index values were required to prevent reconnection of anterior/roof segments, compared to posterior/inferior segments<sup>[35]</sup>.

### Lesion contiguity

The EFFICAS-II study demonstrated that lesion contiguity is an essential component of effective PVI. The analysis

of the contiguity index revealed that even with effective use of optimized CF, 15% of PVs were reconnected after ablation due to non-contiguity between point-by-point lesions along ablation line<sup>[28]</sup>. Consistent with these data, Park *et al*<sup>[36]</sup> showed that acutely durable PVI can be achieved in CF-guided ablation when RF lesions are delivered with a mean CF > 10 g and an inter-lesion distance < 5 mm.

A novel automated technology for tagging ablation lesions (VisiTag module) allows real-time assessment of catheter stability, contact force, power, and impedance drop during radiofrequency applications (Figure 2). This technology improves lesion efficiency and reduces the number of ineffective applications<sup>[37]</sup>. Catheter stability tracking during PVI is essential in order to achieve appropriate lesion contiguity. Okumura *et al*<sup>[38]</sup> reported

**Figure 2 Automatic tagging of radiofrequency lesions.** The contact force (CF) of each application is color-coded (color bar). The manually acquired RF applications are displayed in green. The central box shows the information collected by the VisiTag™ module on each point, including average CF, time, force-time integral, temperature, power, and delta impedance. The force and impedance graphs from this RF point are shown on the right, and the real-time CF and direction dashboard are shown on the left. Reproduced with permission from Pedrote *et al.*<sup>[24]</sup>. RF: Radiofrequency.

that a strict stability setting (3-mm distance limit for at least 10 s) for VisiTag reduced acute PV reconnection, although no benefit was observed in mid-term outcomes.

## HOW TO OPTIMIZE THE DETECTION OF ACUTE PV RECONNECTION DURING THE ABLATION PROCEDURE

### **Circular mapping catheters**

Circumferential PVI guided by nonfluoroscopic electroanatomic mapping systems, without confirmation of electrical isolation with a circular mapping catheter, has been shown to be ineffective in achieving long-term arrhythmia control<sup>[39]</sup>. Additionally, a randomized study comparing PVI guided by circular mapping catheter vs PVI using only RF catheter showed that the use of circular mapping catheter is associated with better acute results and lower recurrence rates<sup>[40]</sup>. Therefore, electroanatomic mapping-guided circumferential PV ablation without use of the circular mapping catheter

has been demonstrated to be less reliable to achieve PVI and significantly less effective than circular mapping catheter-guided PVI in terms of arrhythmia-free survival.

### **Identification of dormant conduction**

The identification of dormant tissue that has been rendered unexcitable by “stunning” or edema is a significant challenge that may potentially increase risk of AF recurrence. The detection of such “dormant conduction” during the initial ablation procedure may therefore help identify PVs with the potential to reconnect after the index procedure, and targeted ablation at these sites may reduce the risk of recurrent AF. Adenosine has been shown to effectively uncover dormant conduction. Following ablation, adenosine selectively hyperpolarizes PV cells by increasing inward rectifier potassium current, thereby restoring excitability of inactivated voltage-dependent Na<sup>+</sup> (INa) and reestablishing conduction in dormant PVs<sup>[41]</sup>. Multiple studies have shown that adenosine is clinically useful in identifying PV reconnection, as well as cavotricuspid isthmus reconnection<sup>[42]</sup>. An early study reported that

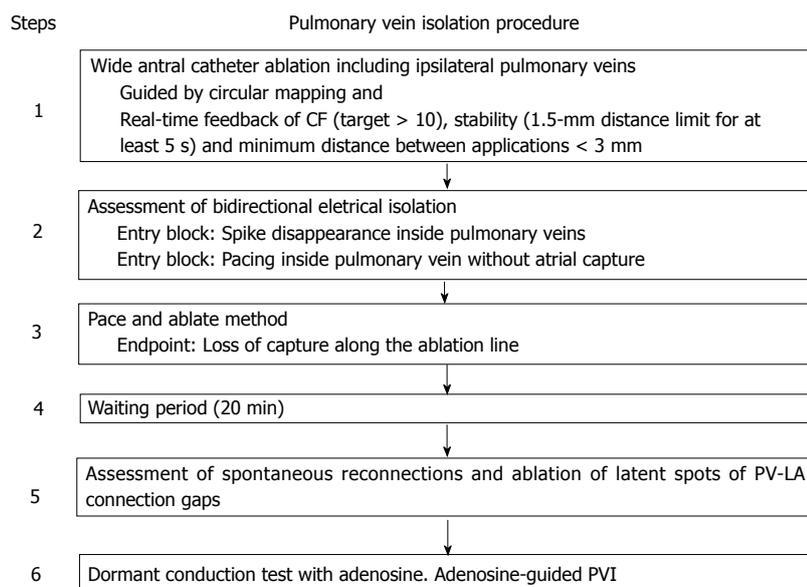

Figure 3 Stepwise approach for permanent pulmonary vein isolation. CF: Contact force; PVI: Pulmonary vein isolation.

adenosine induced reconnection in 25% of PVs immediately after successful isolation<sup>[43]</sup>. Tritto *et al.*<sup>[44]</sup> further demonstrated that delivering additional RF lesions at electrical gap sites elicited by adenosine definitively eliminated recovery of PV reconnection in all cases. Subsequent studies have shown that AF recurrence after PV isolation could be reduced by delivering additional ablation lesions to eliminate adenosine-induced dormant PV conduction<sup>[45-47]</sup>. Other studies<sup>[48,49]</sup> did not confirm the usefulness of adenosine in AF recurrence after PVI, fueling a need for randomized trials.

Two randomized trials (ADVICE and UNDER-ATP) have assessed whether elimination of dormant PV conduction after PVI is better than conventional PVI in terms of arrhythmia-free survival. The ADVICE study showed that the use of adenosine to identify and target areas of dormant conduction significantly improved long-term arrhythmia-free survival, compared to PVI alone<sup>[50]</sup>. In contrast, the UNDER-ATP trial found no significant reduction in arrhythmia-free survival by ATP-guided PVI, compared with conventional PVI<sup>[51]</sup>. The discrepancy between ADVICE and UNDER-ATP trials may be due to differences in the rate of dormant conduction, around 50% in the ADVICE trial and 28% in UNDER-ATP. This suggests that the benefit of using adenosine after PVI depends on how frequently dormant conduction is observed; which is highly affected by the ablation procedural method.

### Pace and ablate

Entrance and exit block confirmed by the absence of PV potentials and by pacing inside the PVs is a common procedural endpoint of encircling PVI. However, it has been suggested that pacing along the ablation line may identify latent spots of PV-LA antrum connection gaps not detected by circular mapping catheters. Steven *et al.*<sup>[52]</sup> showed that more RF ablation energy

was required to achieve loss of pace capture along the ablation line than for entrance block into the PVs, suggesting that reaching the endpoint of loss of capture along the ablation line may be associated with more durable lesions. Consistent with this hypothesis, a randomized study confirmed that the use of pacing to ensure an unexcitable gap along the ablation line improved success rates at 12 mo post-PVI, compared to reliance on bidirectional block alone (83% vs 52%, respectively)<sup>[53]</sup>. However, it should be noted that adenosine was not used to identify dormant conduction after PVI in this study. In contrast to these findings, two recent studies showed that although PVI followed by the pace and ablate method reduced dormant PV conduction unmasked by adenosine, there was no difference in 1-year AF recurrence, compared to adenosine-guided ablation<sup>[54,55]</sup>.

Although the available results suggest that both techniques achieve similar long-term outcomes, the potential effect on recurrence rates of combining pace and ablate with adenosine-guided PVI remains unknown. A recent study by Kogawa *et al.*<sup>[56]</sup> showed that sites with adenosine-induced dormant PV reconnection did not match the excitable gaps identified by pacing, suggesting a difference in the underlying mechanism to elucidate potential PV-antrum gaps. Thus, the authors proposed that an adenosine provocation test followed by pace and ablate method could be useful in reducing AF recurrence. Further prospective and randomized studies are required to confirm this hypothesis.

### NON-PV SOURCES OF AF RECURRENCE

It should be noted that a variable proportion of patients may have AF recurrence despite persistent PVI. This could be due to the existence of non-PV triggers<sup>[57]</sup>. Typically, these non-PV triggers are located in specific

regions such as the crista terminalis, the superior vena cava, the Eustachian ridge, the fossa ovalis, the left atrial appendage, the inferior mitral annulus and the coronary sinus. Empirical ablation of these common origins of triggers is not recommended. However, once a trigger is identified, it should be eliminated in order to achieve better outcomes<sup>[58]</sup>.

## EXPERT RECOMMENDATIONS

Based on our own experience, we propose the following step-wise approach to achieve permanent PVI (Figure 3). Our unit adopted this strategy two years ago, with good arrhythmia-free survival at 12 mo (84%), a very low complication rate (1%), and no increase in procedure time<sup>[24,59]</sup>.

## FUTURE PERSPECTIVES

The implementation of non-fluoroscopic navigation systems in the electrophysiology laboratory has improved anatomic definition of cardiac structures. However, the increased complexity of ablation procedures demands better intra-procedural anatomic definition and improved accuracy in catheter positioning. Novel non-fluoroscopic systems have been proposed for catheter guidance during PVI procedures. In animal studies, Ranjan *et al*<sup>[60]</sup> showed the feasibility of catheter tracking, electrogram recording, and RF energy delivery in a real-time MRI environment. Intra-procedural MRI allowed real-time visualization of lesion formation and tissue characterization, which could permit the assessment of lesion depth and transmural. Furthermore, their work demonstrates the utility of MRI-guided PVI to identify gaps intra-procedurally and guide catheter positioning to target them. However, this proof-of-concept has not been tested in humans. In order to use this technology in clinical settings, several technical challenges must be overcome to obtain better signals and develop more maneuverable and easily visible catheters. However, this promising technology will provide considerable benefits by delivering accurate anatomic definition and monitoring of RF lesions.

## CONCLUSION

PVI is the cornerstone of catheter-based therapies for AF. PV reconnection after PVI represents the main limitation of AF ablation techniques. Efforts should be made to develop strategies that achieve more durable lesions. Current techniques associated with better acute (and probably long-term) outcomes include antral PVI guided by circular mapping catheters, the use of CF catheters, lesion contiguity, and the assessment of dormant PV conduction by adenosine and/or pace and ablate. Finally, a subset of patients may still have AF recurrences despite persistent PVI, due to the presence of non-PV triggers. Efforts should be made in order to individualize the treatment according to each patient's

specific mechanism of recurrence (drivers, rotors, focal activity...).

### Abstract

#### AIM

To test accuracy and reproducibility of gestalt to predict

obstructive coronary artery disease (CAD) in patients with acute chest pain.

#### **METHODS**

We studied individuals who were consecutively admitted to our Chest Pain Unit. At admission, investigators performed a standardized interview and recorded 14 chest pain features. Based on these features, a cardiologist who was blind to other clinical characteristics made unstructured judgment of CAD probability, both numerically and categorically. As the reference standard for testing the accuracy of gestalt, angiography was required to rule-in CAD, while either angiography or non-invasive test could be used to rule-out. In order to assess reproducibility, a second cardiologist did the same procedure.

#### **RESULTS**

In a sample of 330 patients, the prevalence of obstructive CAD was 48%. Gestalt's numerical probability was associated with CAD, but the area under the curve of 0.61 (95%CI: 0.55-0.67) indicated low level of accuracy. Accordingly, categorical definition of typical chest pain had a sensitivity of 48% (95%CI: 40%-55%) and specificity of 66% (95%CI: 59%-73%), yielding a negligible positive likelihood ratio of 1.4 (95%CI: 0.65-2.0) and negative likelihood ratio of 0.79 (95%CI: 0.62-1.02). Agreement between the two cardiologists was poor in the numerical classification (95% limits of agreement = -71% to 51%) and categorical definition of typical pain (Kappa = 0.29; 95%CI: 0.21-0.37).

#### **CONCLUSION**

Clinical judgment based on a combination of chest pain features is neither accurate nor reproducible in predicting obstructive CAD in the acute setting.

**Key words:** Acute chest pain; Clinical judgment; Gestalt; Coronary artery disease; Acute coronary syndrome

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** In the scenario of acute chest pain, individual features of chest pain presentation are intuitively combined to form physician's impression, by a process called "gestalt". Physicians commonly assess probability of disease by unstructured clinical judgment. Although commonly used and presumed to be accurate, diagnostic assessment by gestalt of acute chest pain lacks validation. In the present manuscript, we investigated the accuracy of gestalt in the prediction of coronary artery disease (CAD). Our results indicate that clinical judgment (gestalt) of acute chest pain characteristics has low diagnostic accuracy for obstructive CAD. Thus, physicians should be cautious when relying on chest pain characteristics and investigators should redirect their focus to identify validated predictors.

Accuracy of gestalt perception of acute chest pain in predicting coronary artery disease. *World J Cardiol* 2017; 9(3): 241-247 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/241.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.241>

## **INTRODUCTION**

In the scenario of acute chest pain, specific features of symptoms have either null or weak association with coronary artery disease (CAD) etiology<sup>[1-3]</sup>. However, in clinical practice, these characteristics are not analyzed separately. Individual features of chest pain presentation are intuitively combined to form the physician's impression by a process called "gestalt". Although presumed to be accurate, diagnostic assessment by gestalt of acute chest pain lacks validation<sup>[4,5]</sup>. In fact, it remains uncertain how much physicians should rely on acute chest pain characteristics to estimate pretest probability of CAD.

Our aim was to test the hypothesis that physicians' gestalt accurately estimates probability of CAD. Since gestalt accuracy depends on chest pain characteristics, and knowing that these findings have a broad and variable spectrum, we focused our analysis exclusively on clarifying the reliability of this component. In order to isolate chest pain characteristics variables, we invited an experienced cardiologist, blind to patient's demographic and clinical features, to estimate probability of CAD based on 14 symptom characteristics obtained by remote standardized interview. The accuracy of unstructured clinical judgment was tested against non-invasive or invasive tests that were used as reference standards. Additionally, a second cardiologist performed the same evaluation in order to test for reproducibility of clinical judgment.

## **MATERIALS AND METHODS**

### **Sample selection**

During a period of 24 consecutive months, all patients admitted in the Chest Pain Unit of our Hospital due to chest discomfort were included in the study, regardless of electrocardiogram or troponin results. The study was approved by an institutional review committee and all subjects gave informed consent.

### **Clinical judgment of chest pain**

Data collection was planned a priori and performed prospectively. At admission, chest pain characteristics were collected by standardized interview performed by 3 investigators (MC, NS, FL), trained to diminish bias and improve reproducibility of data collection. Fourteen standardized questions were recorded on a specific form: Precordial location (lower left side), compressive

nature, radiation to left arm, radiation to neck, severe intensity, similarity to previous infarction (if applicable), presence of vagal symptoms, worsening with body movement, worsening with palpation, worsening with arms movement, worsening with deep breath, and relief by nitrate. Characteristics were considered positive if patient's answer was clearly affirmative. Dubious answers ("maybe", "sometimes", "not sure") were taken as negative. In addition, 3 numeric variables were recorded: Intensity of chest pain from 0 to 10 (defined by the patient according to a visual scale), number of pain episodes at rest and duration of the longest episode in minutes. No additional information regarding demographic or clinical characteristics was recorded on this form.

Subsequently, a cardiology faculty member (CV, with 23 years of experience in the field of acute chest pain) assessed the forms and classified chest pain according to the 14 characteristics. This investigator did not have any contact with the patients, and was completely blind to additional information such as name, gender, age, previous history or additional tests. This method guaranteed that medical judgment was based exclusively on chest pain characteristics. In order to assess reproducibility of medical judgment, the same procedure was independently performed by a second faculty member (LLJ) in all patients and his classification was compared with the first.

Chest pain was classified in four ways: (1) typical or atypical; (2) Non-anginal, Undefined or Anginal Chest Pain; (3) definitely angina, probably angina, probably not or definitely not; and (4) numeric probability of coronary etiology from 0 to 100. No objective predefinition of these classifications was provided to the evaluators of chest pain, enabling the definition to be a result of the physician's unstructured discretion. This method guaranteed that answers reflected authentic clinical judgment.

### **Obstructive CAD**

Outcome data was collected by 3 other independent investigators (MC, FK, FF) and adjudicated by a fourth investigator (LC). Obstructive CAD was defined by a stenosis  $\geq 70\%$  on angiography. For diagnostic evaluation, patients underwent invasive coronary angiography or a non-invasive test (perfusion magnetic resonance imaging or nuclear single-photon emission computed tomography), at the discretion of the assistant cardiologist. In case of a positive non-invasive test, patients underwent angiography for confirmation. A negative non-invasive test indicated absence of obstructive CAD and no further test was required. In case of a dominant alternative diagnosis as confirmed by imaging (such as pericarditis, pulmonary embolism, aortic dissection or pneumonia), the etiology was defined as non CAD.

### **Statistical analysis**

Frequencies were compared by Pearson's  $\chi^2$  test and

means by Student's *t* test. The accuracy of clinical judgment in predicting CAD was described by point-estimate and 95%CI of sensitivity, specificity, likelihood ratios and predictive values. The accuracy of numerical estimative of CAD probability was described by the area under the ROC curve with 95%CI.

For analysis of reproducibility, the Kappa test was utilized to assess agreement between two observers regarding the different forms of categorical classification. For numeric estimation of CAD probability, the Bland-Altman analysis was used: mean absolute error between the two observers (mean of differences without the signal), mean signed difference (bias) and 95% limits of agreement.

Sample size was calculated based on an expected CAD prevalence of 50%. Thus, a sample size of 300 would provide 150 patients with and 150 patients without CAD. Considering assumptions of 70% sensitivity and specificity, 150 patients would yield a  $\pm 8\%$  precision for the 95%CI.

## **RESULTS**

### **Sample characteristics**

From 2011 to 2013, a sample of 330 patients was studied,  $59 \pm 15$  years old, 58% males, 54% presented ischemic electrocardiographic changes and 48% had positive troponin. All individuals had gestalt evaluation and reference standard performed during the same admission. Obstructive CAD was identified according to study protocol in 48% of the individuals. Baseline characteristics are depicted on Table 1.

### **Accuracy of clinical judgment**

**Typical vs atypical chest discomfort:** Chest discomfort was classified as typical in 41% of patients. Obstructive CAD was present in 56% of individuals with typical symptoms, compared with 42% of those with atypical symptoms ( $P = 0.02$ ). Among 158 individuals with obstructive CAD, the discomfort was defined as typical in 75, yielding a sensitivity of 48% (95%CI: 40%-55%). Conversely, in 172 individuals free of CAD, 113 had symptoms defined as atypical, leading to a specificity of 66% (95%CI: 59%-73%). Consequently, typical pain had a negligible positive likelihood ratio of 1.4 (95%CI: 0.65-2.0), as well as a negative likelihood ratio of 0.79 (95%CI: 0.62-1.02). The positive predictive value of typical chest pain was only 56% (95%CI: 48%-64%), while the negative predictive value was 58% (95%CI: 51%-65%), Table 2.

### **Non-anginal, undefined or anginal chest pain:**

Patients were equally distributed among the 3 classifications, 36% defined as non-anginal, 34% as undefined and 30% as anginal. Prevalence of CAD was respectively 38%, 49% and 55% ( $P = 0.04$ ). Among 158 individuals with CAD, only 66 had anginal pain, leading to a sensitivity of 42% (95%CI: 34%-50%), positive likelihood ratio of 1.35 (95%CI: 0.89-2.1) and

**Table 1 Clinical characteristic n (%)**

Variable	Description
Sample size	330
Age (yr)	59 ± 15
Male gender	192 (58)
History of coronary disease	112 (34)
Diabetes	104 (32)
Ischemia on EKG	179 (54)
Positive troponin	157 (48)
Signs of left ventricular failure	28 (8.5)
Final diagnosis	
Unstable angina	52 (16)
Myocardial infarction	142 (43)
No CAD, but undefined diagnosis	103 (31)
Gastrointestinal disorder	5 (1.5)
Osteo-muscular disorder	1 (0.3)
Pericarditis	12 (3.6)
Pulmonary embolism	2 (0.6)
Aortic dissection	2 (0.6)
Pneumonia	2 (0.6)
Other	9 (2.7)

CAD: Coronary artery disease.

positive predictive value of 56% (95%CI: 47%-65%). Conversely, in 172 individuals free of CAD, 62 had symptoms defined as non-anginal, leading to a specificity of 36% (95%CI: 29%-43%), negative likelihood ratio of 0.67 (95%CI: 0.40-1.1) and negative predictive value of 62% (95%CI: 53%-62%) (Table 2).

**Definitely angina, probably angina, probably not and definitely not:** Patients were equally distributed among the 4 categories, with 25% classified as definitely angina, 32% as probably angina, 23% as probably not and 20% as definitely not. Prevalence of CAD was similar among the first 3 groups, respectively 49%, 56% and 51%, while patients classified as definitive no-angina had a lower prevalence of 30%, which was responsible for the statistical difference among the 4 groups ( $P = 0.008$ ). Thus, the threshold of definitely not was utilized for accuracy. Among 158 individuals with CAD, 138 were not classified as definitely not, leading to sensitivity of 83% (95%CI: 77%-89%). Among the 172 patients free of disease, only 47 were definitely not, yielding 27% specificity (95%CI: 20%-34%). Thus, the negative likelihood ratio of definitely not was a negligible 0.63 (95%CI: 0.32-1.15), with a negative predictive value of 70% (95%CI: 59%-81%) (Table 2).

**Subjective estimation of CAD probability:** Probability of CAD had a mean of 59% ± 34%, with a median of 70% (interquartile range = 30%-90%). Individuals with CAD had a median probability of 80% (interquartile range = 50%-95%), compared with 60% in patients free of disease (interquartile range = 10%-90%) -  $P < 0.001$ . The diagnostic area under the ROC for numeric probability was 0.61 (95%CI: 0.55-0.67) (Figure 1).

### Reproducibility of clinical judgment

The two observers agreed in 62% of the patients regarding typical vs atypical chest pain, yielding a weak Kappa of 0.29 (95%CI: 0.21-0.37;  $P < 0.001$ ). For non-anginal, undefined or anginal chest pain, agreement was 53% (Kappa = 0.28; 95%CI: 0.20-0.36;  $P < 0.001$ ). For definitely angina, probably angina, probably not and definitely not, agreement was 42%, leading to a weak Kappa of 0.21 (95%CI: 0.14-0.28;  $P < 0.001$ ).

Regarding numeric estimation of probability, mean absolute error was 23% ± 23%, with a mean signed difference (bias) of - 9.7% ± 31%, with 95% limits of agreement from - 71% to + 51%. The Bland-Altman plot showed a diamond pattern with reasonable agreement in very low (< 20%) or very high (> 80%) ranges of probability, with increasing disagreement as probability becomes more intermediate (Figure 2).

## DISCUSSION

The present study indicates that clinical judgment (gestalt) of acute chest pain has low diagnostic accuracy for obstructive CAD. In addition, there was poor agreement between the gestalt of two physicians, indicating low precision of intuitive interpretation of chest pain features. These findings confront the common belief that physicians should take into account the typicality of symptoms when evaluating patients with acute chest pain.

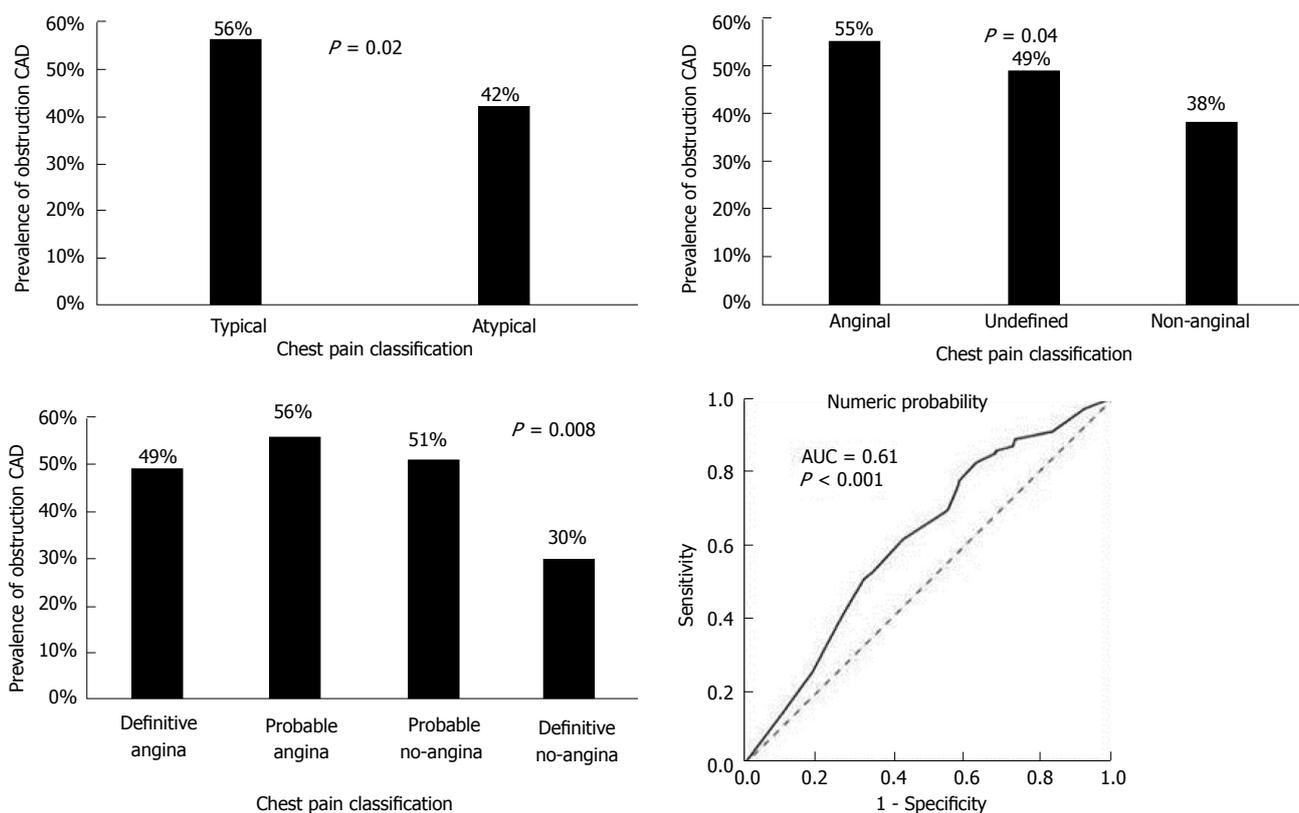

Our primary interest was to assess the role of chest pain features on clinical evaluation. Thus, our methods were designed to evaluate accuracy of clinical judgment that comes specifically from chest pain characteristics, as opposed to the entire clinical presentation. In order to do this, we blinded the physician to demographics, clinical characteristics or patient's appearance. Secondly, we tested physician's intuitive judgment that comes from the combination of all features, instead of the accuracy of specific symptom characteristics. Thus, there was not an a priori criterion for classifying chest pain, allowing the physician to use his own intuition (unstructured clinical judgment).

Physicians commonly assess probability of disease by unstructured clinical judgment. Although medical doctors normally put confidence into this type of judgment, it tends to be inaccurate. As described by Nobel Prize laureates and psychologists Kahneman and Tversky, judgment under uncertainty is vulnerable to cognitive bias, due to heuristics utilized in the process of intuitive thinking<sup>[6]</sup>. A common example of heuristics is "representativeness": If A resembles B, when A is present we think B is highly probable to be present. Oppressive chest pain resembles angina. Hence, a physician may jump to conclude that a patient with oppressive chest pain has a high probability of CAD. However, the likelihood ratio of oppressive chest pain is very low. These cognitive biases that are present in intuitive thinking explain why mechanical models are

**Table 2 Accuracy of the 3 classifications of chest pain according to medical judgment**

	Sensitivity	Specificity	Positive LR	Negative LR	Positive PV	Negative PV
Classification 1 (2-level)						
Typical ( <i>vs</i> atypical)	48% (40%-55%)	66% (59%-73%)	1.4 (0.65-2.0)	0.79 (0.62-1.02)	56% (48%-64%)	58% (51%-65%)
Classification 2 (3-level) <sup>1</sup>						
Angina ( <i>vs</i> undefined/ <i>no</i> -angina)	42% (34%-50%)	69% (62%-76%)	1.35 (0.89-2.1)		56% (47%-65%)	
No-angina ( <i>vs</i> undefined/ <i>angina</i> )	76% (69%-83%)	36% (29%-43%)		0.67 (0.40-1.1)		62% (53%-72%)
Classification 3 (4-level) <sup>1</sup>						
Definitely no-angina ( <i>vs</i> the other 3 groups)		27% (20%-34%)		0.63 (0.32-1.15)		70% (59%-81%)

Numbers in parenthesis are 95%CI. <sup>1</sup>Because only no-angina distinguished itself from the other 3 classifications, only specificity, negative LR and negative PV were calculated. LR: Likelihood ratio; PV: Predictive value.

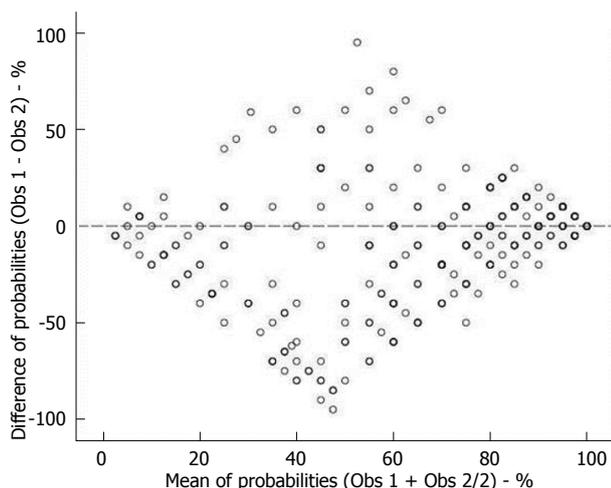

**Figure 1 Categorical and numerical accuracy of gestalt, regarding the prediction of obstructive coronary artery disease. CAD: Coronary artery disease.**

usually better predictors than medical judgment. For instance, a systematic review of several medical and non-medical situations consistently showed better predictability of probabilistic models, in comparison with specialist' decision<sup>[7]</sup>. Therefore, in order to avoid heuristics when evaluating a chest pain scenario, physicians should increase awareness of the low diagnostic value of chest pain characteristics or invest in probabilistic models able to predict obstructive disease more precisely.

The lack of reproducibility between two independent cardiologists also deserves attention. While lack of accuracy promotes diagnostic errors, lack of agreement impairs consensus regarding medical management. Thus, relying too much on chest pain characteristics does not only promote probabilistic errors, but also promote differences in clinical impressions, leading to

confusion and discordance among the medical team.

Although an experienced physician made clinical judgment, we cannot guarantee that his analysis is similar to most physicians. In fact, this would be unlikely, considering the low level of reproducibility found in our head-to-head comparisons. Nevertheless, the concept of accuracy is somewhat independent of agreement. Accuracy depends on the proportion of correct predictions. Two models can have the same proportion of correct predictions and not be related to the same patients. Indeed, we should not expect different people to have the same intuition regarding diagnosis. This rationale is the basis for testing the concept of accuracy of physician judgment by using one specific professional as a proxy of the average physician. Nevertheless, we recognize that further studies are needed to validate our findings, extending it to different populations of

**Figure 2** Bland-Altman plot of agreement between two observers regarding gestalt's numerical probability of coronary disease.

physicians and patients.

Usually, accuracy studies of acute chest pain utilize myocardial infarction as the outcome of interest. Differently, we opted to use obstructive CAD as the outcome to be predicted by clinical judgment, because it has a more objective definition than myocardial infarction. This objectiveness was important because we were evaluating physician's cognitive judgment based on clinical data, and definition of myocardial infarction as an outcome is also influenced by clinical judgment. Therefore, to avoid this redundancy, we used obstructive CAD defined by angiography or functional tests.

A sense of surprise regarding our results may arise from the traditional belief that a careful history is important. Firstly, our findings do not undermine the value of the history as a whole, because our analysis only refers to chest pain characteristics. Secondly, our data is in line with chest pain characteristics being consistently demonstrated to be inaccurate. The novelty of our study is the gestalt evaluation of these characteristics taken together. And the main application of our results prompts us to reconsider how much value we should assign to classifications such as typical or atypical chest pain, as these have little or no influence on probability of CAD. The fact that typicality of pain did not show significant differences on predicting CAD probability has important practical implications, since decision-making during the clinical management of patients can be initially guided by these subjective classifications. The overvaluing of the current categorization may be misleading, resulting in under or overdiagnosis of CAD and mismanagement of cases. Therefore, the use of probabilistic models is supposed to be a more effective way to avoid representativeness heuristics.

In conclusion, our findings indicate that physician's gestalt based on acute chest pain features lacks accuracy and reproducibility in estimating the probability of CAD. Physicians should be cautious when relying on chest pain characteristics and investigators should

redirect their focus to identify validated predictors.

## COMMENTS

### Background

Traditionally, physicians tend to strongly rely on chest pain characteristics to define whether a patient has low or high probability of having coronary artery disease, through a process called gestalt. This kind of clinical judgment, however, does not seem to have good diagnostic accuracy in predicting coronary artery disease (CAD) etiology.

### Research frontiers

Many authors have compared the accuracy of scores vs medical judgment in acute coronary syndromes. However, the study intends to clarify a current non-scientific trend of the physician community to make cardiovascular inferences directly from chest pain characteristics. This research establishes a new perspective for chest pain analysis, and reinforces the need to identify strong diagnostic clinical predictors of obstructive disease and then develop a multivariate model to help the emergency physician to assess this condition, instead of intuitive univariate diagnostic association currently applied.

### Innovations and breakthroughs

The main idea presented was the evaluation of the diagnostic accuracy of chest pain characteristics in predicting the probability of CAD. This was performed by using only pain characteristics and with no further information. The novelty of the study is the gestalt evaluation of these characteristics taken together, while previous others had analyzed the diagnostic probability of each symptom separately. Additionally, previous literature has tested medical gestalt vs probabilistic scores, while the authors have tested medical gestalt vs real diagnosis.

### Applications

The main application of the results relies on avoiding putting too much value of classifications such as typical or atypical chest pain. These classifications merely refer to chest pain characteristic and this isolated aspect has little or no influence on probability of CAD.

### Terminology

Clinical gestalt refers to the theory that physicians and healthcare professionals organize clinical perceptions into "unified wholes". This means that physicians can make clinical decisions without necessarily having complete information, posteriorly using this information to create solutions that can be generalized from one situation to another. Clinical gestalt represents an overall analysis, cultivated mainly by personal experience, history and examination.

### Peer-review

The present study essentially supports that the elements of the chest pain history are only a little bit associated with increasing accuracy of diagnosis with CAD. Furthermore, it is very interesting that there were poor agreement between the two cardiologists. The methods are sound, and the used statistics seem also sound.

### Abstract

#### AIM

To investigate validity of electrocardiographic (ECG) criteria for left ventricular hypertrophy (LVH) in young adults.

#### METHODS

Retrospectively, echocardiograms showing LVH and concomitant electrocardiograms were collected in patients 18 to 39 years old. A control group of patients without LVH was collected. Using echocardiogram as the gold standard, electrocardiograms were analyzed using common voltage criteria.

#### RESULTS

Study included 100 subjects (52% male, mean age = 28 ± 6.8 years, 96% Hispanic or African-American) with 50% LVH prevalence. Sensitivity and specificity for Sokolow-Lyon criteria were 24% (95%CI: 13.5%-38.4%) and 88% (95%CI: 74.9%-95%). For Cornell criteria, sensitivity was 32% (95%CI: 19.9%-46.8%) and specificity 98% (95%CI: 87.9%-99.8%). For R in aVL criteria, sensitivity was 12% (95%CI: 4.9%-25%) and specificity 100% (95%CI: 91.1%-100%).

#### CONCLUSION

In young adults common ECG voltage criteria have low sensitivities and high specificities similar to other age groups. Low sensitivities preclude these ECG criteria from serving as effective screening tests.

**Key words:** Electrocardiographic; Left ventricular hypertrophy criteria; Young adults

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The electrocardiographic (ECG) has been used for years to diagnose left ventricular hypertrophy (LVH). However, to the best of our knowledge, there were no prior studies validating most common ECG criteria for LVH in young adults. The authors believe that this is important group of population, as athletes screening for pre participation to professional sport falls into this category. ECG is one of the proposed screening tools and we think that it should be validated for diagnosis of LVH. This study showed that common ECG criteria for LVH can be used in young adults with similar sensitivity and specificity to other age groups.

Validity of electrocardiographic criteria for increased left ventricular mass in young patients in the general population. *World J Cardiol* 2017; 9(3): 248-254 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/248.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.248>

## INTRODUCTION

Epidemiologic studies have demonstrated that increased left ventricular mass (LVM) is a risk factor for cardiovascular disease and death<sup>[1-4]</sup>. Left ventricular hypertrophy (LVH) has a significant prevalence in the general population with some estimates approaching 16%-20% in population based samples<sup>[5,6]</sup>, and up to 50% in those with hypertension<sup>[7-9]</sup>. As a result of the obesity epidemic, even the adolescent population has had a higher incidence of hypertension and LVH<sup>[10]</sup>, with some estimates showing LVH in nearly 30% of younger hypertensive<sup>[11]</sup>. Thus, with the high prevalence of LVH that extends even into the young population and the increased cardiovascular risk it confers, it is important to identify patients with increased LVM so that they may receive appropriate care.

Another important indication for detecting LVH, specifically in younger individuals in the general population, is in the setting of pre-participation screening prior to partaking in athletic activities. Current screening methods often involve looking for evidence of LVH on electrocardiogram (ECG) and transthoracic echocardiogram (TTE) to help identify those who may be at risk for sudden cardiac death<sup>[12]</sup>. Unfortunately, LVH is often misdiagnosed during these pre-participation screenings which can lead to unwanted outcomes<sup>[13]</sup>. Due to the immense importance of detecting increased LVM in the screening process of this younger population, a reliable screening tool is vital for this age group.

The ECG is the simplest and most commonly used

method to detect LVH, but to date there has been no study evaluating the correlation between the established ECG criteria and increased LVM detected by TTE in adults from the general population with a mean age of 18 to 39 years old. Although numerous investigations have been conducted to validate the ECG criteria for LVH in individuals of the pediatric and older populations, the data for younger adults have been limited. Thus, with the growing number of young individuals with hypertension and LVH, along with the need for effective pre-participation screening, the quick and simple electrocardiographic methods for detecting increased LVM and obtaining prognostic information need to be validated for use in the younger members of the general population. Therefore, the aim of this study is to examine this particular subset of the population in order to determine the efficacy of this potentially valuable tool for identifying patients at increased risk for cardiovascular morbidity and mortality.

## MATERIALS AND METHODS

This was a single-center, retrospective study involving ECG and TTE data conducted in the Cardiology Division of the Department of Medicine at Bronx Lebanon Hospital Center, a large teaching medical center in Bronx, New York. After receiving approval from the Institutional Review Board, the hospital's electronic database was used to collect all consecutive TTEs with the finding of LVH performed between January 2010 and July 2011 on male and female patients aged 18-39 years old who were referred or admitted to the hospital. A control group of age-matched patients without LVH on TTE was also collected in the same manner from the database. Subjects were also required to have a standard 12-lead ECG within 30 d before or after the reference TTE. Excluded were patients with ECGs showing myocardial infarction, bundle branch block, paced rhythm, pre-excitation, or any intraventricular conduction delay, as these ECG findings can interfere with voltage measurements and were not included in the original studies from which the ECG criteria for detecting increased LVM were derived<sup>[14,15]</sup>. After creating the study and control groups based on the presence or absence of increased LVM using TTE as the gold standard for diagnosis, the subjects' ECGs were analyzed using several ECG criteria for detecting LVH in order to determine their efficacy in this cohort of patients.

Study subjects had previously completed the pre-requisite two-dimensional (2-D) rest echocardiogram using a standard, commercially available ultrasound transducer and machine (M3S probe, Vivid 7, GE Medical Systems). In each patient, standard parasternal views (long and short axis) and apical views (4- and 2-chamber) were obtained. TTE images were saved digitally in raw data format for off-line analysis using GE Medical Systems' EchoPAC PC software. These TTEs

were previously read by board-certified cardiologists on the day of acquisition, and it was these interpretations that were used to extract the study population from the hospital database. In order to ensure uniformity of the echocardiographic data used in this study, all subjects' TTEs were reread by a single board-certified noninvasive cardiologist who was blinded to the study arm in which the TTE's belonged. This reader remeasured left-ventricular end-diastolic dimension (LVEDd), end-diastolic posterior wall thickness (PWTd), and end-diastolic septal wall thickness (SWTd) in the standard 2-D parasternal long axis view as detailed by the American Society of Echocardiography (ASE)<sup>[16]</sup>. These measurements were then used to calculate LVM using the ASE recommended formula for estimation of LVM from left ventricular linear dimensions<sup>[16]</sup>:  $LVM = 0.8 \times \{1.04[(LVEDd + PWTd + SWTd)^3 - (LVEDd)^3]\} + 0.6$  grams. The LVM was then indexed to body surface area (BSA) which was obtained from the original reference TTE reports. The ASE gender specific cut-off values for LVM<sup>[16]</sup> were used to classify patients as having increased LVM if the LVM indexed to BSA was greater than 88 g/m<sup>2</sup> for women and greater than 102 g/m<sup>2</sup> for men.

All subjects had previously undergone a standard 12-lead rest ECG at 25 mm/s speed, 10 mm/mV sensitivity, and 0.05 Hz to 150 Hz frequency within 30 d of the index TTE. Of the various ECG criteria for LVH including, Sokolow-Lyon voltage<sup>[14]</sup>, Sokolow-Lyon product<sup>[17]</sup>, R in aVL voltage<sup>[14]</sup>, Cornell voltage<sup>[15]</sup>, Cornell product<sup>[17]</sup>, and Gubner voltage<sup>[18]</sup>, three of the most commonly used criteria in many clinical trials<sup>[19-21]</sup>, Sokolow-Lyon voltage, Cornell voltage, and R in aVL voltage, were then selected to analyze the ECGs. For Sokolow-Lyon voltage, the amplitude of the S wave in lead V1 was added to the largest amplitude of the R wave in either lead V5 or V6, with a value greater than or equal to 35 mm meeting criteria for LVH. For Cornell voltage, the amplitude of the S wave in lead V3 was added to the amplitude of the R wave in lead aVL, with a value greater than 28 mm for men and greater than 20 mm for women signifying LVH. For R in aVL voltage, an amplitude of the R wave in lead aVL greater than or equal to 11 mm was indicative of LVH. All study ECGs were evaluated for these three criteria using manual calipers by each of two trained readers who were blinded to the study group in which the ECGs belonged. Any discrepancies in measurements between the two readers were evaluated by a board-certified electrophysiologist who made the final decision on the ECG findings.

### Statistical analysis

Data management and descriptive analysis were performed with IBM SPSS 20 (Statistical Packages for the Social Sciences). Data are presented as mean (SD) for continuous variables and proportions for categorical variables. For measurements of sensitivity and specificity, increased LVM as detected by TTE was

used as the reference standard against which the performance of the ECG criteria was compared. Mean values of continuous variables were compared by using an independent sample t-test. Linear correlations were evaluated with the Pearson's r correlation. Receiver operating characteristic (ROC) curves were constructed for each ECG criteria to evaluate test performance over a wide range of possible partition values. A two-tailed value of  $P < 0.05$  was considered statistically significant.

## RESULTS

The initial database query revealed 1107 subjects who had a TTE performed during the search period. Of these 1107 patients, 239 had LVH documented in their TTE report. Using the aforementioned inclusion and exclusion criteria, 84 subjects were then found for the increased LVM group. After left ventricular dimensions were re-measured by our expert reader, there were 50 remaining subjects with increased LVM by ASE criteria. Fifty subjects without increased LVM were found for the control group, resulting in a prevalence of increased LVM by TTE of 50%. The total study population had a mean age of  $28 \pm 6.8$  years and consisted of 52 men and 48 women, of which 96% were either Hispanic or African-American. The 1007 excluded subjects had similar demographics with a mean age of  $29 \pm 6.2$  years, 38% men, and 96% Hispanic or African-American. There were no significant differences noted in age, gender, or BSA between the increased LVM and control arms (Table 1). As expected, the increased LVM group had a mean LVM indexed to BSA of  $130.35 \pm 36.76$  g/m<sup>2</sup> which was significantly higher ( $P < 0.001$ ) than the control group's value of  $63.61$  g/m<sup>2</sup>  $\pm 11.73$  (Table 1). The increased LVM group also had significantly higher values ( $P < 0.001$ ) for SWTd, PWTd, and LVEDd as compared to the control group (Table 1).

Sensitivities and specificities for detecting increased LVM with each ECG criteria are displayed in Table 2. Sensitivity and specificity for the Sokolow-Lyon criteria were 24% (95%CI: 14%-38%) and 88% (95%CI: 75%-95%), respectively. For the Cornell voltage criteria, sensitivity was 32% (95%CI: 19%-47%) and specificity was 98% (95%CI: 88%-99%). For the R in aVL criteria, sensitivity was 12% (95%CI: 5%-25%) and specificity was 100% (95%CI: 91%-100%). Positive predictive values (PPV) and negative predictive values (NPV) are also shown in Table 2. PPVs were 67% (95%CI: 41%-86%) for Sokolow-Lyon, 94% (95%CI: 69%-99%) for Cornell, and 100% (95%CI: 52%-100%) for R in aVL. NPVs were 54% (95%CI: 42%-65%) for Sokolow-Lyon, 59% (95%CI: 48%-69%) for Cornell, and 53% (95%CI: 43%-63%) for R in aVL.

ROC curves illustrating the performance of each ECG criteria in detecting increased LVM are shown in Figures 1-3. Areas under the ROC curve were 0.560 for Sokolow-Lyon, 0.650 for Cornell, and 0.560 for R in aVL. All three ECG criteria also demonstrated good statistical correlation with increased LVM by TTE (Table 3).

**Table 1 Clinical characteristics of the study population**

Parameter	Increased LVM (n = 50)	Controls (n = 50)	P value
Age (yr)	29.7 ± 5.9	26.9 ± 7.4	0.05
Male/female	27/23	25/25	0.69
BSA (m <sup>2</sup> )	1.95 ± 0.34	1.88 ± 0.32	0.30
SWTd (cm)	1.09 ± 0.16	0.79 ± 0.08	< 0.001
LVEDd (cm)	5.70 ± 0.68	4.69 ± 0.43	< 0.001
PWTd (cm)	1.05 ± 0.11	0.76 ± 0.09	< 0.001
LVM/BSA (g/m <sup>2</sup> )	130.35 ± 36.76	63.61 ± 11.73	< 0.001

LVM: Left ventricular mass; BSA: Body surface area; SWTd: Septal wall thickness at end diastole; LVEDd: Left ventricular end-diastolic dimension; PWTd: Posterior wall thickness at end diastole.

**Table 2 Sensitivity, specificity, positive and negative predictive values for electrocardiographic criteria for left ventricular hypertrophy**

ECG criteria	Sensitivity (95%CI)	Specificity (95%CI)	PPV (95%CI)	NPV (95%CI)
Sokolow-lyon	0.24 (0.14-0.38)	0.88 (0.75-0.95)	0.67 (0.41-0.86)	0.54 (0.42-0.65)
Cornell	0.32 (0.19-0.47)	0.98 (0.88-0.99)	0.94 (0.69-0.99)	0.59 (0.48-0.69)
R in aVL	0.12 (0.05-0.25)	1 (0.91-1)	1 (0.52-1)	0.53 (0.43-0.63)

PPV: Positive predictive value; NPV: Negative predictive value.

**Table 3 Correlation between left ventricular mass index and electrocardiographic criteria for left ventricular hypertrophy**

ECG criteria	Pearson's r correlation	P value <sup>a</sup>
Sokolow-lyon	0.28	0.005
Cornell	0.51	< 0.001
R in aVL	0.26	0.01

<sup>a</sup>Correlation is significant when P < 0.05. ECG: Electrocardiographic.

## DISCUSSION

This investigation found that three frequently used ECG voltage criteria are effective in identifying increased LVM in the subset of the general population aged 18 to 39 years old. Sensitivity was highest with the Cornell criteria at 32%, as compared to 24% with the Sokolow-Lyon criteria and 12% with the R in aVL criteria. The highest specificity was found with the R in aVL criteria at 100%, while the Cornell and Sokolow-Lyon criteria had somewhat lower specificities of 98% and 88%, respectively. Although there is some minor variation among these values, all three criteria demonstrated a low sensitivity but high specificity for detecting increased LVM in this young adult population. These findings are similar to those previously published for other age groups and populations.

Prior studies examining the accuracy of these ECG criteria in older individuals of the general population encompassing mean ages from 45 to 70 years old<sup>[21-24]</sup>

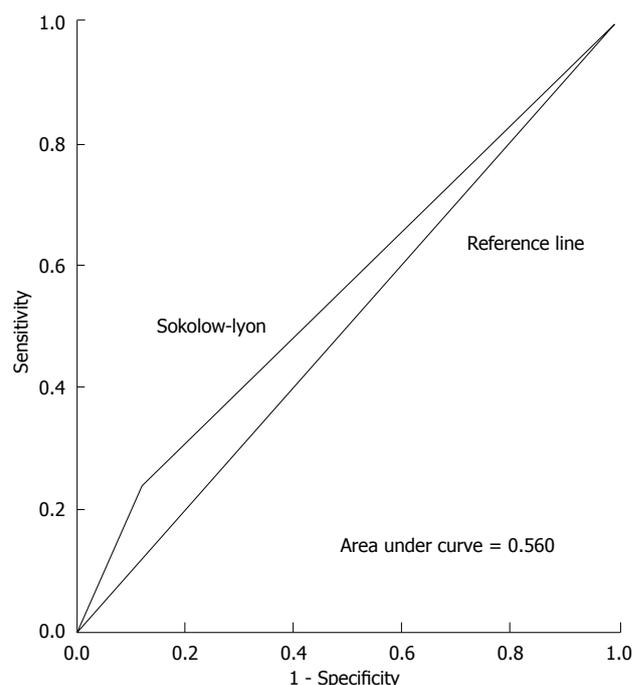

Figure 1 Receiver operating characteristic curve for Sokolow-lyon criteria.

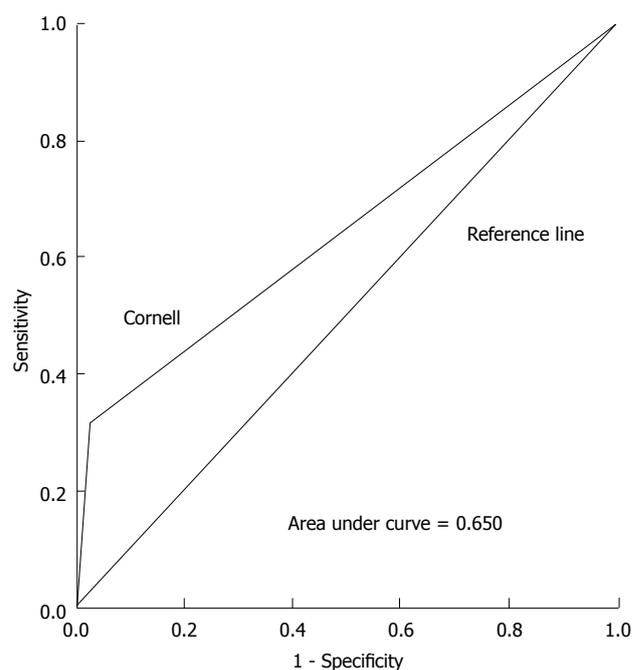

Figure 2 Receiver operating characteristic curve for Cornell criteria.

have shown similar findings with values for sensitivity ranging from 4% to 52% for the Sokolow-Lyon criteria and 2% to 41% for the Cornell criteria, and specificities ranging from 53% to 100% for the Sokolow-Lyon criteria and 89% to 100% for the Cornell criteria, as reported in a large meta-analysis<sup>[21]</sup>. In another large study in patients with mean age of 65 years old, the Sokolow-Lyon criteria had a sensitivity of 17% and

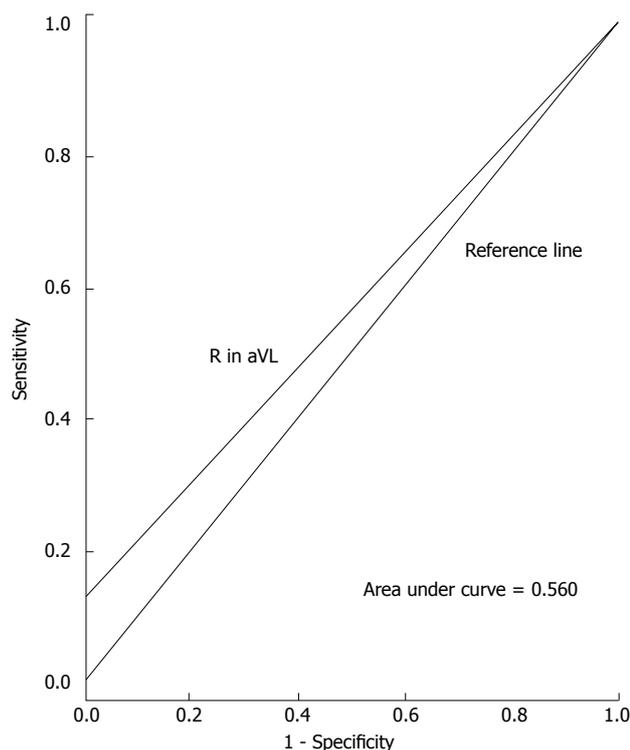

Figure 3 Receiver operating characteristic curve for r in aVL criteria.

specificity of 90%, the Cornell criteria had a sensitivity of 5.9% and a specificity of 99%, and the R in aVL criteria had a sensitivity of 8% and specificity of 94%<sup>[25]</sup>. The original Cornell criteria study<sup>[15]</sup> and a follow-up paper<sup>[26]</sup> by the same authors also found similarly low sensitivities and high specificities in the older population. Evaluation of the Sokolow-Lyon criteria in a pediatric population encompassing infants to 15 year olds also yielded a low sensitivity of 25% and high specificity of 95%<sup>[27]</sup>.

In young adults from the general population there have been no data for ECG voltage criteria until the present study was conducted and demonstrated that these commonly used criteria perform equally well as in other age groups. Prior studies involving young adults were conducted in very distinct subsets of the population. In a recent study of healthy male Air Force candidates, the Sokolow-Lyon and Cornell criteria were found to have a sensitivity of 55% and specificity of 87%<sup>[28]</sup>. Another study involving healthy young male military recruits found the Sokolow-Lyon criteria to have a sensitivity of 50% and specificity of 71%, and the Cornell criteria to have a sensitivity of 25% and specificity of 88%<sup>[29]</sup>. Other studies in the young adult population involved highly trained athletes and found poor correlation between the Sokolow-Lyon criteria and increased LVM<sup>[30,31]</sup>.

Hypertension has become more prevalent in the young adult population<sup>[10]</sup>, and has been shown to cause increased LVM and even heart failure if left untreated<sup>[32]</sup>. With proper antihypertensive therapy LVH can regress

and left ventricular dysfunction can improve<sup>[33,34]</sup>. Thus, with our findings that ECG voltage criteria are highly specific for increased LVM in young adults, it is reasonable to conclude that such a patient meeting ECG criteria for LVH may benefit from further testing, including TTE, to identify and treat increased LVM, a known and modifiable risk factor for cardiovascular disease and death<sup>[1-4]</sup>. Our results also suggest that ECG voltage criteria may not be suitable for pre-participation screening prior to partaking in athletic activities. Some screening methods often involve looking for evidence of LVH on ECG to identify those who may be at risk for sudden cardiac death<sup>[12]</sup>, but with this study demonstrating such low sensitivities for detecting increased LVM, ECG voltage criteria may not perform adequately as screening tools. This finding is in agreement with the current United States guidelines for pre-participation screening, as laid forth by the American Heart Association, which do not recommend performing an ECG as part of pre-athletic screening<sup>[35]</sup>. Despite their low sensitivities, the ECG voltage criteria showed rather high specificity for detecting increased LVM in young adults. This result brings into question the notion that the presence of ECG voltage criteria in young adults is merely a normal variant<sup>[36]</sup>. Regardless of the initial indication, if an ECG performed in a young adult meets voltage criteria for LVH, the finding should not be assumed normal until completing further investigation with an imaging modality such as TTE.

In conducting a retrospective analysis it was necessary to accept certain limitations inherent with this type of design, the most significant being the lack of randomization. In analyzing the study and control groups, however, there were no significant differences in baseline characteristics as shown in Table 1. Although this was a study of the general population, the majority of subjects were Hispanic or African-American, with few Caucasian individuals. It is likely that the ECG voltage criteria tested would also show efficacy in other races, but this cannot be concluded from this study alone. This study examined only three of the numerous ECG criteria that have been developed for detecting LVH, but this was done intentionally as those chosen are among the most commonly used and simplest to perform, with no difficult calculations or point systems.

In conclusion, three commonly used ECG voltage criteria, Sokolow-Lyon, Cornell, and R in aVL, show efficacy in detecting increased LVM in young adults of the general population and have sensitivities and specificities that are similar to those found in other age groups. Although their low sensitivities preclude these ECG criteria from serving as effective screening tests, their relatively high specificities would necessitate further evaluation if the criteria were present in a young individual. Our results provide evidence that these simple diagnostic tools can be utilized in a population subset that may benefit from the valuable prognostic information that they provide.

## COMMENTS

### Background

Electrocardiographic (ECG) is a very common test to evaluate for structural heart disease, including left ventricular hypertrophy (LVH). The ECG criteria for LVH are widely studied in older patients; its utility in young adults is unknown. ECG was proposed to be a screening test for detection of structural abnormality of the heart, however in order to be a screening test it should have high sensitivity for detection of pathology. Thus, it's important to evaluate sensitivity and specificity of ECG criteria for LVH in young adults.

### Research frontiers

ECG has been used for years to diagnose LVH. However, to the best of the authors' knowledge, there were no prior studies validating most common ECG criteria for LVH in young adults.

### Innovations and breakthroughs

The results of this study contribute to clarifying the ECG diagnostic criteria for LVH in young adults in comparison to older patients and its sensitivity and specificity.

### Applications

In young adults common ECG voltage criteria have low sensitivities and high specificities similar to other age groups. Although their low sensitivities preclude these ECG criteria from serving as effective screening tests, their relatively high specificities would necessitate further evaluation if the criteria were present in a young individual. The results provide evidence that these simple diagnostic tools can be utilized in a population subset that may benefit from the valuable prognostic information that they provide.

### Peer-review

The authors have done a good job analyzing retrospectively common electrocardiographic criteria for LVH in young adults.

### Abstract

#### AIM

To investigate the occurrence of cardiomyopathy (CMP) in a cohort of patients with histologically proven pheochromocytoma (pheo), and to determine if catecholamine excess was causative of the left ventricular (LV) dysfunction.

#### METHODS

A retrospective chart review spanning years 1998 through 2014 was undertaken and patients with a diagnosis of pheo confirmed with histopathologic examination were included. Presenting electrocardiograms and cardiac imaging studies were reviewed. Transthoracic echocardiography (TTE), ventriculography or single positron emission computed tomography imaging was evaluated and if significant abnormalities [left ventricular hypertrophy (LVH) or LV dysfunction] were noted in the pre operative period a follow up post-operative study was also analyzed. Multivariate analysis using logistic regression was used to investigate independent predictors for outcomes of interest, LV dysfunction and LVH.

#### RESULTS

We identified 18 patients with diagnosis of pheo confirmed on pathology. Mean age was  $54.3 \pm 19.3$  years and 11 (61.1%) patients were females. 50% of such patients had either resistant hypertension or labile blood pressures during hospitalization, which had raised suspicion for a pheo. Cardiac imaging studies were available for 12 (66.7%) patients at the time of inclusion into study and preceding the adrenalectomy.

7 (58.3%) patients with a TTE available for review had mild or more severe LVH while 3 (25%) patients had LV dysfunction of presumably acute onset. In a multivariate analysis, elevated catecholamine levels as assessed by urinary excretion of metabolites was not an independent predictor of development of LV systolic dysfunction or of presence of LVH on TTE. Two female patients with a preceding history of hypertension had marked LV hypertrophy and systolic anterior motion of the mitral valve. Prolongation of the QTc interval was noted in 5 (27.8%) patients but no acute arrhythmias were observed in any patient.

### CONCLUSION

This study adds to the growing body of literature on the predilection of patients with pheochromocytomas to develop non-ischemic CMP. Degree of catecholamine excess as measured by urinary secretion of metabolites did not predict the development of CMP but 2 of 3 patients developed CMP in the setting of significant acute physiologic stress. Our findings provide support to the proposed etiologic role of elevated catecholamines in TC and other stress induced forms of CMP, however, activation of a brain-neural-cardiac axis from acute stress and local release of catecholamines but not chronic catecholamine elevations are likely to be responsible in pheo related CMP.

**Core tip:** A non-ischemic cardiomyopathy (CMP) may be observed in patients with pheochromocytoma and shares several features with takotsubo cardiomyopathy. Although it is believed that pheochromocytoma related CMP is due to the catecholamine excess, the exact pathogenesis is unclear. CMP in pheochromocytoma patients often follows acute stress and while clinical course maybe complicated by acute hemodynamic compromise, prognosis is good. On the basis of our findings, where 3 of 18 pheochromocytoma patients developed an acute CMP, we suggest that activation of a brain-neural-cardiac axis from acute stress and local release of catecholamines but not chronic catecholamine elevations may likely be responsible for pheo related CMP.

### INTRODUCTION

Pheochromocytomas (pheo) are rare tumors of chrom-

affin cells originating most frequently in the adrenal medulla<sup>[1]</sup>. Catecholamines are secreted by these tumors in varying amounts and proportions<sup>[1]</sup> accounting for the various associated clinical symptoms. Cardiovascular manifestations of this catecholamine excess are several. Hypertension (both sustained and paroxysmal), ventricular hypertrophy, myocardial infarction, and arrhythmias (supraventricular and ventricular) are reported to occur in relation to this hormonal excess<sup>[2]</sup>. Left ventricular (LV) dysfunction may develop in patients with pheo and is termed catecholamine cardiomyopathy (CC)<sup>[2]</sup>. Although thought to arise from the incident catecholamine excess, the exact mechanism of such cardiac dysfunction remains elusive<sup>[3]</sup>. "Stress" or takotsubo cardiomyopathy (TC) is a syndrome characterized by transient acute LV systolic dysfunction encompassing multiple vascular territories in the absence of flow-limiting epicardial coronary artery disease (CAD)<sup>[4,5]</sup> and is purported to be caused by myocardial stunning resulting from exaggerated adrenergic signaling<sup>[6]</sup>. A similar morphologic pattern of LV dysfunction characterized by apical akinesis with preservation of contractility of more basal LV segments and described classically as apical ballooning has been described for both TC and CC<sup>[3,7]</sup>. It is therefore plausible that a common etiologic link exists between these two entities. We sought to investigate the occurrence of cardiomyopathy (CMP) in a cohort of patients with histologically proven pheo and to determine if catecholamine excess was causative of this LV dysfunction.

### MATERIALS AND METHODS

#### Patient characteristics

A retrospective chart review spanning years 1998 through 2014 was undertaken to search for patients with a diagnosis of pheo. Medical records of patients with a probable diagnosis of pheo were perused and patients were included in this study only if such diagnosis had been confirmed with histopathologic examination. The institutional review board approved the study protocol. Data on patient demographics, clinical characteristics, radiologic imaging, laboratory investigations (specifically plasma and urine catecholamine levels); and surgical and pathologic findings were collected. Presenting electrocardiograms (ECG) and cardiac imaging study results were reviewed. Transthoracic echocardiography (TTE), ventriculography and single positron emission computed tomography (SPECT) imaging was evaluated and if significant abnormalities [LV hypertrophy (LVH) or LV dysfunction] were noted in the pre-operative period a follow up post-operative study was also analyzed if available. Two physicians unaware of the knowledge of the diagnoses independently interpreted the ECG and imaging studies. LVH on ECG was diagnosed if any of the accepted voltage criteria was judged to be satisfied<sup>[8]</sup>. Echocardiograms were obtained according to a standardized institutional protocol [parasternal, apical, subcostal and suprasternal imaging planes were

scanned using Vivid 7 machine (GE® medical systems, Waukesha, Wisconsin, United States)]. Two dimensional (2D), M-mode and Doppler modalities were utilized. LVEF was calculated using the Simpson's method of disc summation and adjudicated independently by two reviewers. Our primary outcome of interest was the incidence of LV dysfunction, which was defined as an LVEF ≤ 50%, with or without regional wall motion abnormalities. LVH was defined as an increase in LV mass indexed for body surface area per guideline recommendations of the American Society of Echocardiography<sup>[9]</sup>. Disagreements in ECG or TTE interpretation were resolved by a consensus meeting or after consultation with a third author. Plasma and urine catecholamine levels were measured by a method of liquid chromatography according to current diagnostic guidelines<sup>[10]</sup>.

### Statistical analysis

Results are expressed as numbers (frequencies) for categorical variables and mean ± standard deviation (SD) for continuous variables. Differences between groups were analyzed with the use of the Student's *t* test for continuous variables and the chi-square test for categorical variables respectively. Multivariate logistic regression analysis was used to investigate predictors for outcomes of interest. A two sided *P*-value less than 0.05 was considered statistically significant. Statistical analyses were performed using IBM SPSS, Statistics version 20.0 (IBM Corp., Armonk, New York).

## RESULTS

We identified 18 patients with pathologically confirmed pheo. The demographics, clinical presentations and comorbidities for these patients are described in Table 1. Mean age was 54.3 ± 19.3 years (range 17-83 years) and 11 (61.1%) patients were females; 9 (50%) tumors were localized to the left adrenal gland while 5 (27.8%) tumors were bilateral, extra-adrenal or metastatic (Table 2). Two (11.1%) patients presented with a recurrence and both had metastatic disease. One patient, a young male had an extra-adrenal paraganglioma in close proximity to the urinary bladder. All except for one patient who had diffuse metastatic disease

underwent surgical removal of pheo. Open (52.9%) and laparoscopic approaches were utilized for tumor removal. A history of hypertension was present in 12/18 (66.7%) patients of which 50% was either resistant or labile. Prior history of CAD was uncommon; one patient had known history of obstructive CAD and another was found to have non-flow limiting atherosclerosis. Two patients were admitted for acute cardiovascular events. The first was a 37-year-old woman with a large ischemic stroke in the middle cerebral artery territory. She had experienced a self-resolving episode of LV dysfunction presumed to be secondary to a viral myocarditis 5 years before this event. Bilateral adrenal cystic tumors were found on CT and she subsequently underwent successful bilateral adrenalectomy. No LV dysfunction was noted during this time or subsequently. The other patient was a 77-year-old woman who was admitted originally with complaint of chest pain accompanied by headache and nausea suspicious for an acute coronary syndrome. Coronary angiography was negative and systolic blood pressure (BP) elevation of more than 200 mmHg had initiated a search for pheo. Overall, 14 (77.8%) patients had incidentally noted adrenal masses. One of these patients had an existing diagnosis of multiple endocrine neoplasia syndrome type 2b and was undergoing serial biochemical testing to rule out hormonal production for a known history of an enlarging adrenal mass. Plasma catecholamine secretion and 24-h urine catecholamine excretion were elevated to varying degrees in most patients (Tables 3 and 4). All patients survived to discharge after adrenalectomy.

LV function was evaluated in 12 (66.7%) patients at the time of inclusion into study and preceding the adrenalectomy (Table 5) and, thus, no assessment of LVEF was available for 6 patients and these patients were excluded from statistical comparisons. Seven (58.3%) patients with a TTE available for review had mild or more severe LVH while 3 (25%) patients had LV dysfunction of presumably acute onset. LVH and LV dysfunction patients were serially compared with patients without these findings serving as controls. Clinical characteristics, catecholamine secretion, TTE and ECG findings were compared using multivariate analysis, and elevated catecholamine levels as assessed by urinary excretion of metabolites was not found to be an independent predictor of development of LV systolic dysfunction or of presence of LVH on TTE.

Two of the 3 patients with LV dysfunction had global

hypokinesia. The first patient was an apparently healthy 47-year-old male who had a precipitous decline in BP after an initial malignant elevation shortly after elective endotracheal intubation and induction of anesthesia. Acute ST-segment elevation was noted on an ECG and warranted an emergent coronary angiography. No significant CAD or spasm was reported but severe diffuse hypokinesia was observed on TTE. Peak cardiac troponin I level was 6.8 ng/mL. Elevated 24-h urine catecholamine levels prompted a CT scan at which time a large left adrenal tumor was identified and subsequently excised. The second patient was a 64-year-old man who was admitted for severe anaphylactic reaction following multiple Hymenoptera stings. Clinical course was complicated by acute pulmonary edema and BP was labile. Acute severe diffuse LV hypokinesia and elevated cardiac troponins suggested an acute coronary syndrome, which was subsequently ruled out with a normal coronary angiogram. Pheo was detected and the tumor was excised. A follow up TTE (10 d) showed resolution of LV dysfunction and mild LVH. The third patient was a 67-year-old woman who was undergoing evaluation for severe systemic hypertension. No obstructive CAD was found on coronary angiography done previously when she was noted to have an abnormal ECG in the setting of dyspnea and chest pressure. A diagnosis of "classic" TC was made at that time in view of mid to distal wall segment hypokinesia consistent with "apical ballooning". An adrenal mass and elevated catecholamine levels were noted on a second presentation and a right adrenalectomy was performed for a moderate sized pheo.

Two women with preceding history of hypertension had marked LV hypertrophy. One such patient with septal and posterior wall thickness of 18 mm had systolic anterior motion of the mitral valve but no

resting gradient across the LV outflow tract (LVOT). The LVH resolved post adrenalectomy in this patient. The second patient had asymmetric septal hypertrophy and a resting LVOT gradient of 23 mmHg. LVH was present on admission ECG in 11.1% patients, which resolved after tumor removal in 1 patient. Prolongation of the QTc interval (> 440 ms in males and > 460 ms in females) was noted in 5 (27.8%) patients. A univariate analysis for predictors of QTc prolongation was attempted, three of those patients were females, 4 had LVH by echo criteria and 2 had acute LV dysfunction. No acute arrhythmias were observed in any patient.

## DISCUSSION

In our study, 3 out of 18 patients with histologically proven pheochromocytoma were found to have de novo non-ischemic CMP which was defined as acute onset of systolic dysfunction with LVEF ≤ 50% in the absence of flow limiting CAD on coronary angiogram. The prevalence of this "idiopathic" pheo-related CMP was therefore 17% in the overall cohort, and 25% for patients who underwent any imaging for assessment of LV function. Previous studies have reported that the incidence of such pheo-related CMP is approximately 11%<sup>[11,12]</sup>. Overall, 7.5% of patients with TC have been found to have a pheo subsequently<sup>[13]</sup> and therefore it is recommend that pheo be excluded in patients with TC<sup>[14]</sup>. Elevation of circulating catecholamine levels in TC<sup>[6]</sup> and with pheo suggests excess catecholaminergic activity may be a shared pathogenic mechanism. Catecholamines cause myocardial toxicity by enhancing lipid mobility, calcium overloading, oxygen derived free radical production, increased sarcolemmal permeability as well as by provoking a state of oxygen supply-demand mismatch<sup>[15]</sup>. Further, recurrence of CMP in patients with unresected pheo<sup>[3]</sup> and resolution of CMP after treatment of adrenergic excess also suggest a causal relationship between catecholamine excess from pheo and CMP.

Provocation of a brain-heart-neural axis by various emotional and physical "stressors" has been theorized to result in massive releases of catecholamines locally into cardiac tissue while only a small leak occurs into

the systemic circulation<sup>[16,17]</sup>. In 2 of 3 patients that developed acute LV dysfunction in our study such events followed acute stress, suggesting that increases in catecholamine levels over and above the background elevation precipitated by “stress” may provoke acute LV dysfunction in pheo patients in a manner similar to TC. No independent predictors of LV dysfunction were found in this study including degree of adrenergic excess as assessed by urinary catecholamine excretion. In a study of 5 patients with TC like LV dysfunction, catecholamines levels were elevated in coronary sinus but not peripheral blood suggesting local norepinephrine release<sup>[18]</sup>. Endogenous release of catecholamines from myocardial sympathetic nerve terminals rather than circulating catecholamines may therefore mediate neurocardiogenic injury explaining the noted lack of higher catecholamine levels in pheo patients with acute LV dysfunction despite an attendant “acute stress”<sup>[19]</sup>. The absence of universal LV dysfunction despite the chronic adrenergic excess in all pheo patients is also intriguing. Persistent elevation of plasma catecholamine levels might induce adrenergic receptor desensitization *via* mechanisms that include receptor modulation and uncoupling from down-stream effectors<sup>[20,21]</sup>. Genetic susceptibility mediated through adrenergic receptor<sup>[22,23]</sup> and G protein coupled receptor kinase polymorphisms (GRK5)<sup>[24]</sup> may also account for differences in predisposition to cardiac dysfunction in pheo and TC related LV dysfunction despite similar catecholamine elevations.

Despite sharing a common morphology and possibly a shared etiology, pheo related CMP tends to differ from “idiopathic” TC in terms of patient demographics and clinical features. A study based on a population of 38 cases assimilated from published case reports of pheo related TC found such patients to be younger; and although the majority was still females, the sexual inequality was less skewed compared to TC patients without pheo<sup>[3]</sup>. Such patients experienced an inciting event less often but experienced more recurrent episodes (13.2% vs 3.5%).

Our study has some limitations. First, the sample size is small. However, this is related to the rare incidence of the disease process being studied. Second is the utilization of a retrospective design, again necessitated by the infrequent occurrence of the disease.

In conclusion, this study adds to the growing body of literature on the predilection of patients with pheo to develop non-ischemic CMP. In doing so it provides support for the proposed etiologic role of elevated catecholamines in TC and other stress induced forms of CMP. Degree of catecholamine excess as measured by urinary secretion of metabolites did not predict the development of CMP but 2 of 3 patients developed CMP in the setting of significant acute physiologic stress. Thereby acute stress mediated activation of a brain-neural-cardiac axis and local release of catecholamines as has been described previously but not chronic catecholamine elevations are likely to be responsible in pheo related CMP.

## COMMENTS

### Background

Pheochromocytomas are adrenal medullary tumors associated with a chronic elevation in catecholamine levels. They can rarely be associated with a non-ischemic cardiomyopathy.

### Research frontiers

Acute cardiomyopathy which may develop in patients with a pheochromocytoma is similar to “stress” or “takotsubo” cardiomyopathy in several ways including an elevated levels of catecholamines in both conditions. This suggests that the two forms of cardiac dysfunction might share a common etiologic link.

### Innovations and breakthroughs

Pheochromocytoma related cardiomyopathy developed in 3 of 18 patients. Two of these patients experienced an acute stressful event in a manner similar to classic takotsubo cardiomyopathy. The authors did not find an association between urinary excretion of catecholamines and development of cardiac dysfunction.

### Applications

The findings of this study need to be confirmed in a larger multicenter international registry.

### Terminology

Pheochromocytoma: Adrenal medulla tumors that may secrete varying amounts and combinations of catecholamines; Takotsubo cardiomyopathy: A form of acute cardiac dysfunction that develops classically after an acute stressful events and without obstruction of epicardial coronary arteries.

### Peer-review

This paper is interesting review concerning association pheochromocytoma and cardiomyopathy. Therefore, this article should be published.

**Abstract****AIM**

To investigate the relationship of inferior wall ischemia on myocardial perfusion imaging in patients with non-dominant right coronary artery anatomy.

**METHODS**

This was a retrospective observational analysis of consecutive patients who presented to the emergency department with primary complaint of chest pain. Only patients who underwent single photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI) were included. Patients who showed a reversible defect on SPECT MPI and had coronary angiography during the same hospitalization was analyzed. Patients with prior history of coronary artery disease (CAD) including history of percutaneous coronary intervention and coronary artery bypass graft surgeries were excluded. True positive and false positive results were identified on the basis of hemodynamically significant CAD on coronary angiography, in the same territory as identified on SPECT MPI. Coronary artery dominance was determined on coronary angiography. Patients were divided into group 1 and group 2. Group 1 included patients with non-dominant right coronary artery (RCA) (left dominant and codominant). Group 2 included patients with dominant RCA anatomy. Demographics, baseline characteristics and positive predictive value (PPV) were analyzed for the two

groups.

## RESULTS

The mean age of the study cohort was 57.6 years. Sixty-one point seven percent of the patients were males. The prevalence of self-reported diabetes mellitus, hypertension and dyslipidemia was 36%, 71.9% and 53.9% respectively. A comparison of baseline characteristics between the two groups showed that patients with a non-dominant RCA were more likely to be men. For inferior wall ischemia on SPECT MPI, patients in study group 2 had a significantly higher PPV, 32/42 (76.1%), compared to patients in group 1, in which only 3 out of the 29 patients (10.3%) had true positive results ( $P$  value  $< 0.001$   $Z$  test). The difference remained statistically significant even when only patients with left dominant coronary system (without co-dominant) were compared to patients with right dominant system (32/40, 76.1% in right dominant group, 3/19, 15.8% in left dominant group,  $P$  value  $< 0.001$   $Z$  test). There was no significant difference in mean hospital stay, re-hospitalization, and in-hospital mortality between the two groups.

## CONCLUSION

The positive predictive value of SPECT MPI for inferior wall ischemia is affected by coronary artery dominance. More studies are needed to explain this phenomenon.

**Key words:** Myocardial perfusion imaging; Single photon emission computed tomography; False positive results; Coronary artery dominance; Inferior wall ischemia

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** A positive test for ischemia on single photon emission computed tomography (SPECT), myocardial perfusion imaging (MPI) is often followed up with coronary angiography. The aim of our study was to assess the relationship of inferior wall ischemia on SPECT MPI with non-dominant right coronary artery (RCA) anatomy. We found that positive predictive value of inferior wall ischemia on SPECT MPI was significantly lower in patients with non-dominant RCA anatomy. We postulate that in non-dominant RCA anatomy flow tracer may show relatively decreased uptake in the inferior wall that might not be indicative of flow limiting stenosis.

Significance of inferior wall ischemia in non-dominant right coronary artery anatomy. *World J Cardiol* 2017; 9(3): 261-267 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/261.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.261>

## INTRODUCTION

Single photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI) is most often used to assess the likelihood of obstructive coronary artery

disease (CAD), presence of ischemia in a patient with known CAD, and evaluating the extent of ischemia for prognostic value<sup>[1]</sup>. In essence SPECT MPI accomplishes this by measuring relative changes in perfusion of myocardial territories before and after augmenting coronary blood flow<sup>[1]</sup>. SPECT MPI has enjoyed widespread clinical use because of its well documented diagnostic and prognostic utility in CAD<sup>[2]</sup>.

Coronary artery dominance is determined by the artery supplying the posterior portion of interventricular (IV) septum<sup>[3]</sup>. In a right dominant system, the right coronary artery (RCA) supplies this territory and feeds the posterior descending artery, in contrast to left dominant system in which the left circumflex artery (LCX) accomplishes this role<sup>[3]</sup>. In a co-dominant system, the supply of posterior IV septum is shared by both RCA and LCX<sup>[3]</sup>. Right dominant system is the more prevalent variant occurring in approximately 70% of people, followed by left dominant and co-dominant system<sup>[4]</sup>.

The prognostic significance of coronary artery dominance in patients with CAD has been studied. Left dominant system has been shown to be an independent risk factor of morbidity and mortality in patients undergoing both surgical and percutaneous revascularization, especially in patients with ST segment elevated myocardial infarction (STEMI)<sup>[4-7]</sup>.

The effect of coronary anatomy on diagnostic accuracy of cardiac magnetic resonance imaging (CMR) has been studied<sup>[8]</sup>. However, no study to our knowledge has evaluated the effect of coronary artery dominance on diagnostic accuracy of SPECT (MPI studies). We present the first report showing the effect of coronary artery dominance on positive predictive value of SPECT MPI.

## MATERIALS AND METHODS

### Study design

The study was a single center retrospective analysis conducted at a tertiary care center.

### Inclusion and exclusion criteria

All patients who underwent rest and stress SPECT MPI from January 1<sup>st</sup> 2013 to June 30<sup>th</sup> 2014, for diagnostic purposes were included in our study. All patients who did not undergo a coronary angiogram during the same hospital stay were excluded. Furthermore, all patients who did not have evidence of reversible ischemia on SPECT MPI were excluded.

These patients presented with chest pain that were deemed to be of intermediate pre-test probability for ischemia. The images were initially read by an experienced radiologist and results verified by the cardiologist.

### Institute review board approval

The study was approved by the Institute Review Board at University Medical Center of Southern Nevada. This study was performed in accordance with the ethical standards as laid down in the 1964 Declaration of

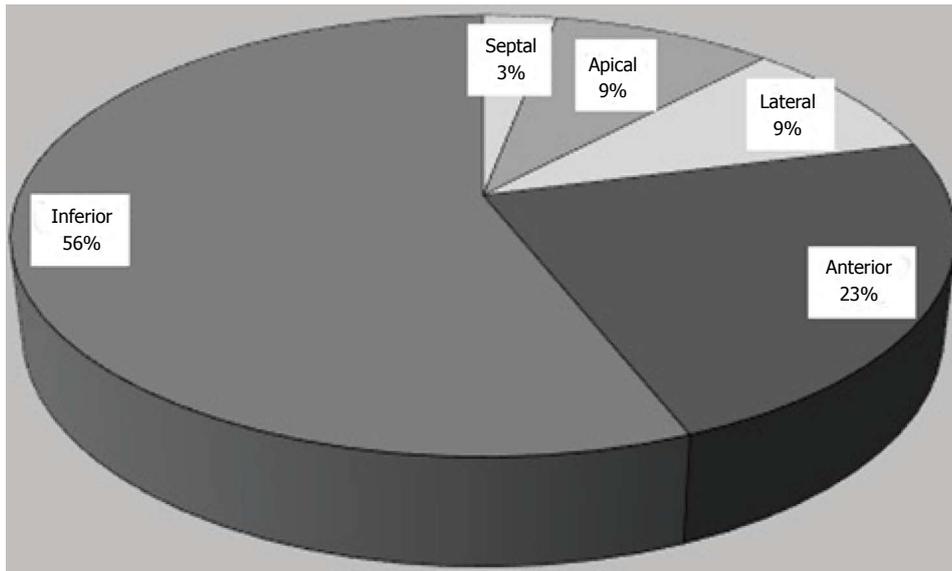

Figure 1 Defect location on single photon emission computed tomography myocardial perfusion imaging.

Helsinki and its later amendments or comparable ethical standards.

#### Coronary angiography and defining obstructive CAD

All of the patients subsequently underwent a coronary angiogram during the same hospital stay after the SPECT MPI. Patients were divided into two groups on the basis of coronary artery dominance. Group 1 included patients with a non-dominant RCA (left dominant and co-dominant). Group 2 included patients with right dominant coronary artery system.

The coronary angiogram was performed by an experienced interventional cardiologist. It was noted if there was obstructive CAD, in the same distribution as shown by the SPECT MPI the study was deemed to be true positive. Obstructive CAD was defined as maximal coronary artery stenosis of more than 70%.

#### SPECT MPI and determination of reversible ischemia

SPECT MPI was performed using standard protocols approved by the American Society of Nuclear Cardiology<sup>[9]</sup>. An experienced radiologist initially read the images and the presence of any reversible ischemia was verified by the cardiology team. Figure 1 shows representative images of SPECT MPI, showing inferior wall ischemia and normal scan respectively.

#### Study outcome

The primary study outcome was determining diagnostic accuracy of the SPECT MPI, with the coronary angiogram as gold standard. The positive predictive value of SPECT MPI was compared in both groups.

#### Statistical analysis

Data for each study variable were summarized initially for the whole cohort and then by dominant coronary artery group, using means for continuous variables

and frequencies/percentages for categorical variables. Means for the non-dominant RCA and dominant RCA groups were compared using independent-samples *t*-tests (or Mann Whitney *U* tests, for variables with non-normally distributed data). Frequencies/percentages were compared using  $\chi^2$  tests. Positive predictive values for were compared *via* *Z* tests of proportions. The significance level (alpha) was set at 0.05, and all analyses were completed *via* SPSS, version 22 (IBM).

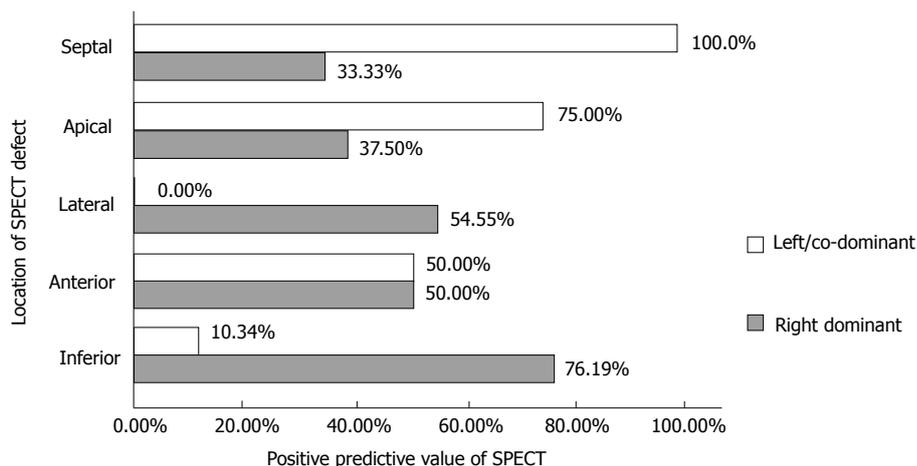

## RESULTS

The mean age of the study cohort was 57.6 years. Sixty-one point seven percent of the patients were males. The prevalence of self-reported diabetes mellitus, hypertension and dyslipidemia was 36%, 71.9% and 53.9% respectively. A comparison of baseline characteristics between the two groups showed that patients with a non-dominant RCA were more likely to be men. Table 1 shows comparison of other baseline characteristics.

The most common location for the reversible defect was seen the inferior wall (Figure 2).

The positive predictive value (PPV) was analyzed and compared between the two study groups. Sub-group analysis showed that for inferior wall ischemia on SPECT MPI, patients in study group 2 had a significantly higher PPV, 32/42 (76.1%), compared to patients in group 1, in which PPV was 10.3% (3/29) (*P* value < 0.001 *Z* test) Figure 2 illustrates the results. The difference remained statistically significant even when only patients with left dominant coronary system (without co-dominant) were compared to patients with right dominant system. (32/40, 76.1% in right dominant group, 3/19, 15.8% in left dominant group, *P* value < 0.001 *Z* test).

There was no significant difference in mean hospital stay, re-hospitalization, and in-hospital mortality between the two groups as shown in Table 2.

Significant difference between left/co-dominant and right dominant,  $P < 0.001$ .

## DISCUSSION

Around 15 million patients seek medical attention for symptoms concerning for CAD<sup>[10]</sup>. In stable patients, not having acute coronary syndrome non-invasive testing like SPECT MPI, act as gatekeepers to coronary angiography because of risks and costs associated with coronary angiography<sup>[11,12]</sup>. Despite the use of conventional non-invasive testing such as SPECT MPI an analysis of almost 400000 coronary angiograms in patients with no prior history of CAD disease revealed no obstructive disease in more than 60% of the cases, resulting in unnecessary risks and costs<sup>[13,14]</sup>. Hence, from a public health standpoint, it is imperative that we

study the reasons for false positive diagnoses associated with non-invasive tests such as SPECT MPI.

SPECT MPI is widely used for diagnostic purposes in patients presenting with chest pain when acute coronary syndrome (ACS) has been ruled out<sup>[2]</sup>. A recent study showed that SPECT MPI is widely used for diagnostic and risk stratification purposes in the United States and patient's socio-economic status did not significantly affect the use of SPECT MPI by physicians<sup>[15]</sup>. In the developing world several studies have shown the widespread use of SPECT MPI by physicians to aid in diagnosis in management<sup>[16,17]</sup>. One such report from Iran regarding SPECT MPI referral practices showed that 72.5% (211/291) of the referrals found to be appropriate per ASNC recommendations<sup>[16]</sup>.

The utilization of SPECT MPI is often on the physician's assessment of pre-test probability. The American College of Physicians pre-test probability assessment and Duke chest pain score are two common objective tools used for this assessment<sup>[18]</sup>. In our retrospective analysis, SPECT MPI was done, on the physician's assessment of the patient's pre-test probability.

Our study shows that SPECT MPI in patients with non-dominant RCA has significantly high false positive results for inferior wall ischemia. In a study using positron emission tomography measuring absolute myocardial blood flow (MBF) in low risk normal patients' authors found baseline MBF in the inferior region was significantly ( $P < 0.0001$ ) lower than either the anterior or lateral regions<sup>[19]</sup>. However, coronary anatomy was not available in this study population. Nonetheless this finding may contribute to our observation as well. One study using stress CMR also showed a statistically significant difference in false positive rate correlating with dominance<sup>[8]</sup>. They also showed a correlation with the vessel size, postulating that the smaller vessel size that usually comes with non-dominant vessels was the factor leading to false positive readings<sup>[8]</sup>.

**Table 2 Comparison of outcomes between study groups**

	<b>Dominant RCA n = 87</b>	<b>Non-dominant RCA n = 41</b>	<b>P value (test)</b>
Mean hospital stay (d)	4.33	4.29	0.713 (Mann-Whitney)
In-hospital mortality	0/87	0/41	-
30-d re-hospitalization for chest pain	10/87 (11.49%)	2/41 (4.88%)	0.231 ( $\chi^2$ )

RCA: Right coronary artery.

Gender differences in vessel caliber and coronary artery dominance could also play a role. As shown in our results patients with non-dominant RCA were more likely to be men. This is consistent with the report by Gebhard *et al*<sup>[5]</sup> in which patients with left dominant coronary artery anatomy were more likely to be males. In contrast in a cohort of patients with STEMI, lower percentage of patients with left dominant circulation were men compared to patients with right dominant circulation<sup>[7]</sup>. This was not statistically significant. Vessel caliber was not available in either of these studies. Whether gender differences affect coronary artery, dominance is not clear at this time.

Regardless our study finding has important consequences. First, it has been shown that patients with left dominant system are at high risk in terms of cardiovascular events<sup>[6]</sup>; hence, it is important that significant CAD is promptly addressed in these patients. If the diagnostic accuracy of SPECT MPI is particularly low in this sub group of patients, then it is important that more studies are done to evaluate the negative predictive value (NPV) in this subset to reach a better understanding about role of SPECT MPI in excluding significant CAD in these patients. In our retrospective analysis patients with negative SPECT MPI imaging did not have a coronary angiogram, hence analysis of NPV was not possible.

Second, if the diagnostic accuracy of inferior wall ischemia on SPECT MPI is affected by coronary artery dominance and it has a significantly lower PPV in patients with non-dominant RCA, it would mean that many patients in this sub-group are exposed to unnecessary invasive procedures. This is in addition to utilizing the resources when it will not help the patient.

In conclusion, based on our findings we hypothesize that the flow tracer in a non-dominant RCA may show relatively decreased uptake in the inferior wall that might not be indicative of flow limiting stenosis. More multi-center studies to explore the relationship of coronary artery dominance on SPECT MPI are needed to reach a better understanding regarding positive or negative results in patients in the context of non-dominant RCA anatomy.

### Study limitations

This study was done only at a single center and the

SPECT MPI results were only read by one group of physicians. Prone imaging was not done. Also some patients could have had inferior wall abnormality and coronary computed tomography angiogram was not utilized. Coronary angiograms were not done on patients with normal SPECT MPI results. Hence we could not analyze the effect of coronary dominance on NPV. We did not strictly use objective validated models to quantify SPECT MPI defect so some measurement bias may be present.

## COMMENTS

### Background

Single photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI) is most often used to assess the likelihood of obstructive coronary artery disease (CAD), presence of ischemia in a patient with known CAD, and evaluating the ex-tent of ischemia for prognostic value. SPECT MPI has enjoyed widespread clinical use because of its well documented diagnostic and prognostic utility in CAD. The authors' study aims to understand the effect of coronary artery dominance on the positive predictive value (PPV) of SPECT MPI.

### Research frontiers

The effect of coronary anatomy on diagnostic accuracy of cardiac magnetic resonance imaging (CMR) has been studied. However, no study to our knowledge has evaluated the effect of coronary artery dominance on diagnostic accuracy of SPECT MPI studies. The authors' present the first report showing the effect of coronary artery dominance on PPV of SPECT MPI.

### Innovations and breakthroughs

They studied the effect of coronary artery dominance on the PPV of SPECT MPI. The effect of coronary anatomy on diagnostic accuracy of cardiac magnetic resonance imaging (CMR) has been studied. In a study using positron emission tomography measuring absolute myocardial blood flow (MBF) in low risk normal patients' authors found baseline MBF in the inferior region was significantly lower than either the anterior or lateral regions. However, coronary anatomy was not available in this study population. They studied the effect of coronary artery dominance on the PPV of SPECT MPI.

### Applications

In stable patients, not having acute coronary syndrome non-invasive testing like SPECT MPI, act as gatekeepers to coronary angiography because of risks and costs associated with coronary angiography. Despite the use of conventional non-invasive testing such as SPECT MPI an analysis of almost 400000 coronary angiograms in patients with no prior history of CAD disease revealed no obstructive disease in more than 60% of the cases, resulting in unnecessary risks and costs. Hence, from a public health standpoint, it is imperative that the study the reasons for false positive diagnoses associated with non-invasive tests such as SPECT MPI. They show in the study that the PPV of SPECT MPI for inferior wall ischemia in stable patients not having ACS, is affected by coronary artery dominance. Although more studies are needed to explain this phenomenon, maybe this subset of patients should undergo further non-invasive testing before proceeding to invasive coronary angiography.

### Terminology

SPECT MPI: SPECT MPI is most often used to assess the likelihood of obstructive CAD, presence of ischemia in a patient with known CAD, and evaluating the ex-tent of ischemia for prognostic value. In essence SPECT MPI accomplishes this by measuring relative changes in perfusion of myocardial territories before and after augmenting coronary blood flow; coronary artery dominance: Coronary artery dominance is determined by the artery supplying the posterior portion of interventricular (IV) septum. In a right dominant system, the right coronary artery (RCA) supplies this territory and feeds the posterior descending artery, in contrast to left dominant system in which the left circumflex artery (LCX) accomplishes this role. In a co-dominant system, the supply of

posterior IV septum is shared by both RCA and LCX.

**Peer-review**

This is an interesting manuscript about the association of a positive test for inferior wall ischemia on MPI with non-dominant RCA anatomy.

**Abstract****AIM**

To assess the arrhythmic determinants and prognosis of patients presenting with myocardial infarction and non-obstructive coronary arteries (MINOCA) with normal ejection fraction (EF).

**METHODS**

This is an observational analysis of 131 MINOCA patients with normal EF. Three cardiac magnetic resonance (CMR) diagnosis classes were recognized according to the late gadolinium enhancement (LGE) pattern: Myocardial infarction (MI) ( $n = 34$ ), myocarditis ( $n = 47$ ), and "no LGE" ( $n = 50$ ). Ventricular events occurring during hospitalization were recorded and the entire population

was followed-up at 1 year.

## RESULTS

Ventricular arrhythmia was observed in 18 (13.8%) patients during hospitalization. The “no LGE” patients experienced fewer ventricular events than the MI and myocarditis patients [4.0% *vs* 26.5% and 14.9%, respectively ( $P = 0.013$ )]. There was no significant difference between the MI and myocarditis groups. On multivariate analysis, LGE transmural extent [OR = 1.52 (1.08-2.15),  $P = 0.017$ ] and ST-segment elevation [OR = 4.65 (1.61-13.40),  $P = 0.004$ ] were independent predictors of ventricular arrhythmic events, irrespective of the diagnosis class. Finally, no patient experienced sudden cardiac death or ventricular arrhythmia recurrence at 1-year.

## CONCLUSION

MINOCA patients with normal EF presented no 1-year cardiovascular events, irrespective of the CMR diagnosis class. LGE transmural extent and ST segment elevation at admission are risk markers of ventricular arrhythmia during hospitalization.

**Key words:** Ventricular tachycardia; Myocarditis; Myocardial infarction; Late gadolinium enhancement; Cardiac magnetic resonance; Myocardial infarction and non-obstructive coronary arteries

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Out of 131 myocardial infarction and non-obstructive coronary arteries patients, 18 experienced a ventricular arrhythmic event during hospitalization, consisting of 17 ventricular tachycardia and one ventricular fibrillation. No patient died during the 1-year follow-up. Cardiac magnetic resonance classified the underlying diagnosis in 61.8% of the cases, as a myocarditis or a myocardial infarction. Rather than the diagnosis itself, late gadolinium enhancement and ST-segment elevation were found as valuable tools to stratify the risk for arrhythmia of these patients. These findings may be useful to select patients who might be eligible for either arrhythmia prevention or secondary prevention therapy.

Risk of ventricular arrhythmia in patients with myocardial infarction and non-obstructive coronary arteries and normal ejection fraction. *World J Cardiol* 2017; 9(3): 268-276 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/268.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.268>

## INTRODUCTION

Sudden cardiac death is still the most common cause of death worldwide, accounting for over 50% of all deaths

from cardiovascular disease. Coronary artery disease represents approximately 80% of all cases<sup>[1]</sup>. However, 1%-12% of patients with chest pain and cardiac troponin elevation present with normal coronary arteries on angiography analysis<sup>[2]</sup>. This pathological entity is called myocardial infarction and non-obstructive coronary arteries (MINOCA) and encompasses myocarditis, transient apical ballooning syndrome, and authentic ischemic injuries<sup>[2]</sup>. Cardiac magnetic resonance (CMR) imaging is helpful for providing detailed information on myocardial tissue characteristics, and has become the gold standard for *in vivo* detection of necrosis, notably in acute myocardial infarction (MI) and myocarditis<sup>[3]</sup>.

Early-sustained ventricular arrhythmias complicate 2%-20% of acute MIs and are associated with increased hospital mortality rates<sup>[4,5]</sup>. While the arrhythmic prognosis of MI with abnormal coronary angiography is well known, there is little data concerning MINOCA, even when the arrhythmic prognosis seems to be relatively good<sup>[6,7]</sup>. As a result of the lack of data concerning this entity, there are no specific guidelines concerning hospitalization duration, follow-up, or treatment for this specific setting.

Our study sought to evaluate the risk of ventricular arrhythmias of presumed low-risk MINOCA patients at both early-stage consultation and 1-year follow-up, based on the diagnosis class established by CMR imaging.

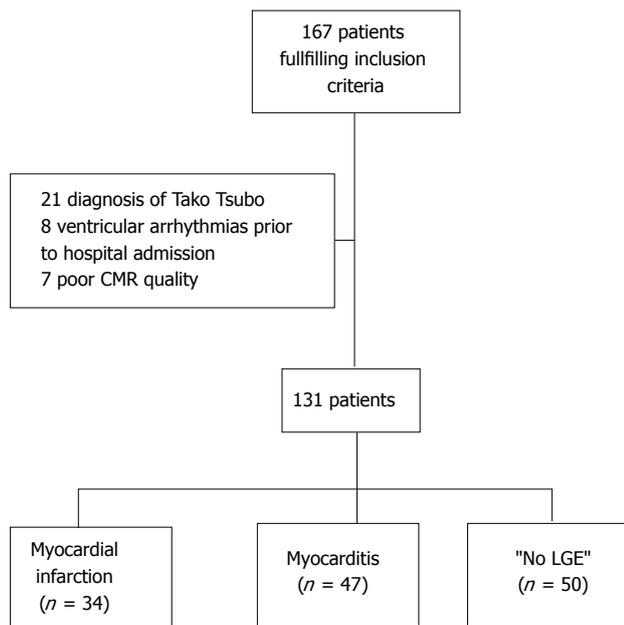

## MATERIALS AND METHODS

One hundred and sixty-seven patients were retrospectively enrolled between 2007 and 2012 in the French university hospitals of Nantes and Angers. The inclusion criteria were: (1) hospitalization for acute anginal chest pain; (2) increase in troponin rates superior to the normal range; (3) left ventricular ejection fraction (LVEF)  $\geq 45\%$ ; and (4) absence of coronary artery stenosis or thrombosis (stenosis  $< 50\%$  of the diameter of the epicardial vessel).

All patients underwent CMR and the arrhythmic evaluation included at least 48 h of electrocardiography (ECG) monitoring after admission.

In order to avoid overestimating the arrhythmic risk in this population, patients hospitalized for sustained ventricular tachycardia ( $n = 8$ ) or cardiopulmonary arrest were not included in the study. Patients presenting with Tako-Tsubo ( $n = 21$ ) were therefore also from the study due to this syndrome's specific pathophysiology. Seven more patients could not be included due to poor CMR quality so that the study was performed on 131 patients (Figure 1). The study complies with the Declaration of Helsinki and local ethics committee has approved the research protocol.

Ventricular tachycardia (VT) was defined as at least three consecutive ventricular beats with a rate  $> 100$  bpm<sup>[8]</sup>. Prolonged VT was defined as at least eight consecutive ventricular beats<sup>[9]</sup>. Ventricular fibrillation

**Figure 1** Flow chart of the study population. CMR: Cardiac magnetic resonance; LGE: Late gadolinium enhancement.

was defined as an irregular ventricular rhythm with marked variability in the QRS cycle length, morphology, and rapid amplitude, usually over 300 bpm/200 ms (cycle length: 180 ms or less)<sup>[8]</sup>.

All data concerning the initial hospitalization were recorded from the patient medical files. Repolarization abnormalities were defined as ST-segment depression  $\geq 0.1$  mV at 0.08 s from the junction (J point) (STD), asymmetrical T wave inversion  $\geq 0.1$  mV deep in two or more leads except lead aVR, and ST-segment elevation  $\geq 0.2$  mV (STE). Q waves  $> 0.3$  mV in depth or  $> 0.04$  s in duration in at least two leads, except lead aVR, were considered abnormal.

At the 1-year follow-up, the following outcomes were collected: Ventricular arrhythmia, death from any cause, cardiovascular (CV) death, and particularly sudden cardiac death. The chosen treatments were evaluated on hospital discharge and at 1 year. If necessary, the referring cardiologists or general practitioners were contacted to obtain information concerning the patients at 1-year follow-up. Data on 1-year survival was completed for every patient.

CMR was performed using 1.5T scanners (Avanto, Siemens, Erlangen, Germany) with 8-element phased-array cardiac receiver coils. The median time from presentation of MINOCA to CMR was 7 d (interquartile range: 4; 13).

LV function was determined by means of cine imaging, in multiple short-axis views covering the entire LV. The typical in-plane resolution was 1.6 mm  $\times$  1.9 mm and 7.0-mm thickness sections were used. Temporal resolution was around 35-45 ms.

Late gadolinium enhancement (LGE) was performed 10 min after administering the gadolinium-based contrast agent, at a cumulative dose of 0.2 mmol/kg,

by means of a two-dimensional segmented inversion recovery gradient-echo pulse sequence. The inversion time was set to null the signal of the viable myocardium, typically ranging from 240 to 300 ms.

A post-hoc core analysis was specifically performed for this study, using a dedicated software package (Medis 7.1, Mass, Leiden, The Netherlands). For all qualitative assessments, the recommended 17-segment system was applied, requiring the consensus of two blinded observers.

On all the short-axis cine slices, the endocardial and epicardial borders were outlined manually on the end-diastolic and end-systolic images, with the exclusion of the trabeculae and papillary muscles. The reproducibility of the LVEF and LV volumes assessments was good, the details of which are published elsewhere<sup>[10]</sup>.

The cine imaging was assessed visually by analyzing the LV wall thickening using a three-grade scale: 0 = normal, 1 = hypokinesia, 2 = akinesia. We counted the number of segments affected in order to determine the extent of hypokinesia. Furthermore, pericardial effusion was noted when considered exceeding trivial effusion<sup>[3]</sup>.

LGE was evaluated by means of visual analysis. We estimated the maximal transmural extent of LGE within each segment as a percentage of the LV using a five-grade scale: 0% = 0, 0%-25% = 1, 25%-50% = 2, 50%-75% = 3, and  $> 75\%$  = 4 (Figure 2). The number of segments with LGE defined the LGE transversal extent.

Following analysis by means of CMR, the patients were classified according to LGE pattern, as described: Subendocardial LGE was revealed in the MI group, subepicardial or medioventricular LGE in the myocarditis group, and absence of LGE in the "no LGE" group<sup>[11]</sup>.

When the extent of LGE was transmural ( $> 75\%$ ), the border zones were analyzed to more precisely determine the CMR diagnosis, for example, if the signal of LGE borders was subendocardial, myocardial infarction was diagnosed.

### Statistical analysis

Statistical analyses were performed using SPSS Version 15.0 software for Windows (SPSS Inc., Chicago, Illinois, United States). The data was presented as mean  $\pm$  standard deviation (SD) or median (25<sup>th</sup>; 75<sup>th</sup> percentiles) in cases of non-normal distribution, with categorical data expressed as frequencies and percentages. Continuous variables were compared by means of the unpaired *t* test or Wilcoxon rank-sum test, when necessary. Non-continuous variables were compared using the  $\chi^2$  test. Differences were considered significant with a *P* < 0.05. For the multivariate analysis of ventricular events during hospitalization, clinical and CMR data were tested by means of an ascending step-by-step binomial logistic regression analysis, including variables with *P* values < 0.05 in univariate analysis. The Hosmer-Lemeshow goodness-of-fit test was used to assess the applied models.

## RESULTS

A total of 131 patients (87 men, median age: 48.5 ± 16 years) fulfilled our criteria. LGE was present in 81 of the 131 patients (61.8%). There were 34 (25.9%) patients classified in the MI group, 47 (35.9%) in the myocarditis group, and 50 (38.2%) in the "no LGE" group (Table 1). The myocarditis group exhibited a specific pattern of myocarditic lesions, located predominantly in the free lateral wall (42/47 cases) and in the subepicardial layers (45/47 cases). The ischemic lesions were distributed homogeneously (Figure 2).

Patients classed in the myocarditis group were younger ( $P < 0.001$ ) and more frequently male ( $P < 0.005$ ) than the others. No differences in cardiovascular risk factor were noted.

The median time between symptom onset and hospital admission was 9 h (2; 24). Patients from the MI group were admitted to the hospital more quickly than those in the myocarditis group ( $P = 0.002$ ).

The prevalence of ECG abnormalities was 69.5%, predominantly consisting of STE (35.7%) and T-wave inversion (23.1%). There were no differences in the frequency of ECG abnormalities between the groups.

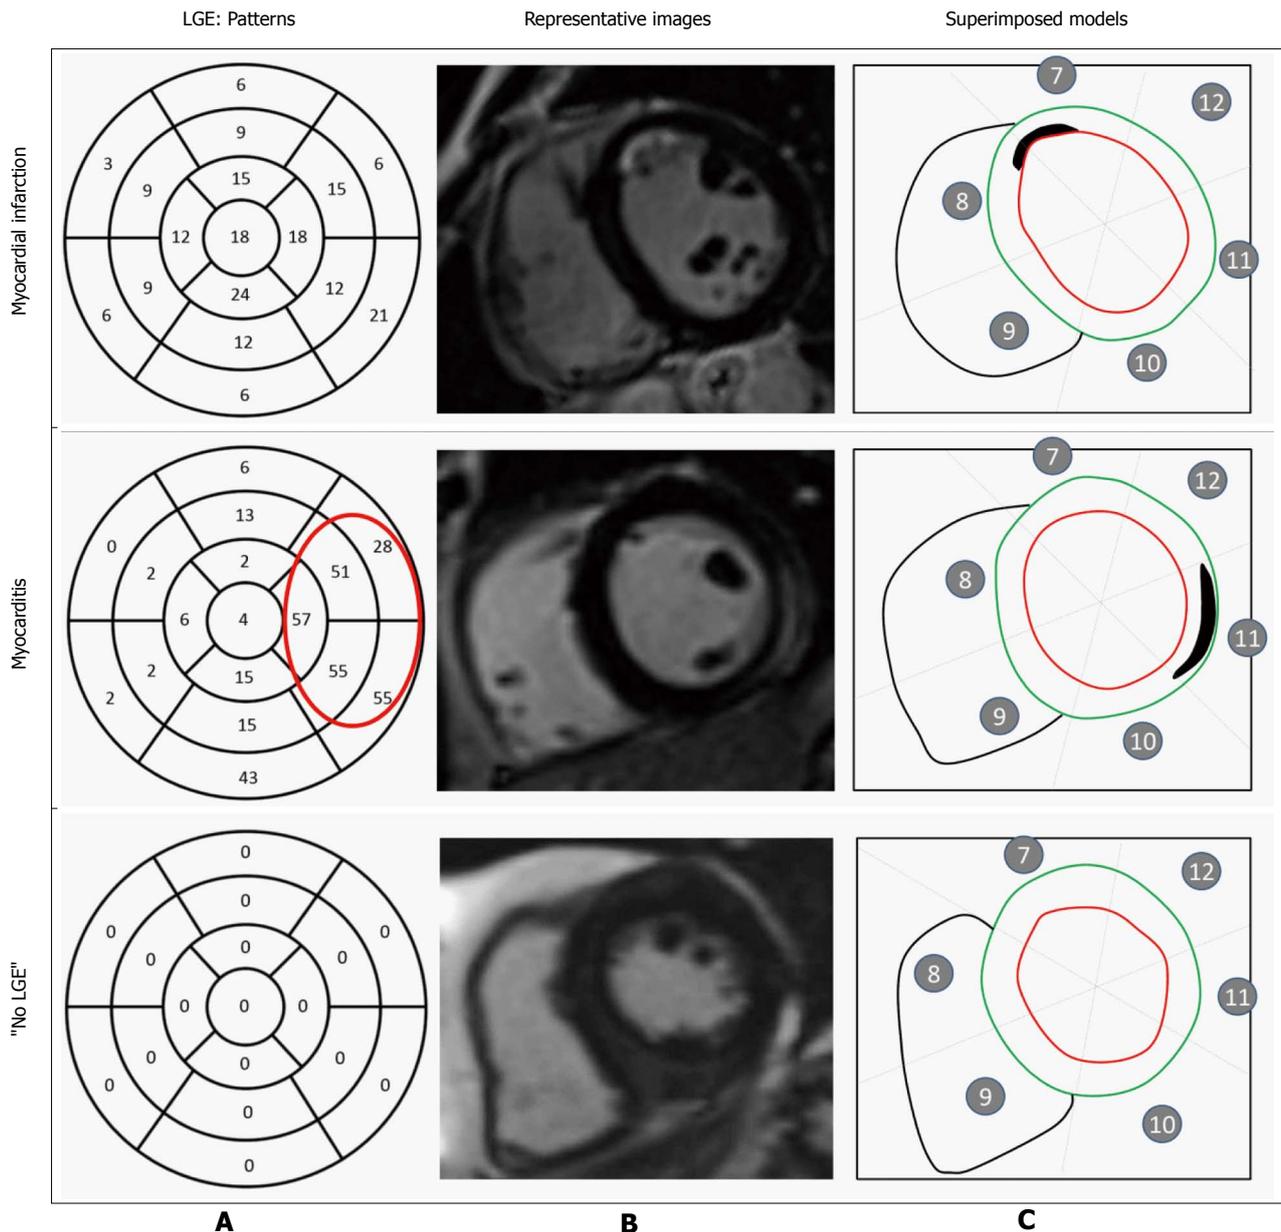

Troponin rates were lower in the "no LGE" group compared to those of the MI and myocarditis groups ( $P = 0.001$  and  $P = 0.013$ , respectively).

The MI patients presented with lower C-reactive protein (CRP) rates than the myocarditis and "no LGE" patients ( $P < 0.001$  and  $P = 0.020$ , respectively). Elevated CRP was observed in 42 (93.3%), 22 (66.7%), and 37 (82.2%) patients from the myocarditis, MI, and "no LGE" groups, respectively.

During hospitalization, 69% of patients were treated with β-blockers and 43% received angiotensin-converting enzyme inhibitors (ACEIs), with no difference observed between the different groups. At 1 year, only 13% of the patients were receiving either β-blockers or ACEIs, with a trend for higher rates of treatment seen in the MI group, though this difference was not statistically significant. Notably, no other antiarrhythmic drug than β-blockers was given at any time of the study.

The mean LVEF was 58.6% ± 8.2%. No significant differences were observed in either LVEF or LV end-diastolic volume between the groups. The "no LGE" group exhibited smaller LV end-systolic volumes than those of the MI and myocarditis patients. LV wall thickening was more often altered in the MI group. Moreover, the MI patients presented with higher rates of akinesia compared to the myocarditis and "no LGE" patients (58.8% vs 4.3% and 2.0%,  $P < 0.001$ ). Pericardial effusion was detected nonspecifically in 20 patients (15.4%) (Table 2).

During hospitalization, 18 patients experienced

**Figure 2** Pattern of late gadolinium enhancement. A: Incidence of late gadolinium enhancement (LGE) within each segment (percentage) of all patients, including those with and without LGE. In myocarditis cases, LGE was predominantly on the lateral wall. In myocardial infarction, no specific pattern of LGE could be identified; B: Representative short-axis slice images showing LGE location; C: Superimposed segmental models showing location and spatial extent of LGE (outlined).

a ventricular arrhythmic event, consisting of 17 VTs and one ventricular fibrillation (Tables 3 and 4). No differences were observed between the MI and the myocarditis groups ( $n = 9$ , 26.5% vs  $n = 6$ , 12.8%,  $P = 0.10$ ), whereas the MI patients exhibited higher rates of VT than the "no LGE" group ( $n = 2$ , 4.0%,  $P = 0.001$ ). All these events occurred in the early stages of hospitalization, with a median onset of 1 (0-1) d. One episode of ventricular fibrillation occurred in a myocarditis patient on day 3, who was successfully defibrillated. We found no differences in cardiovascular risk factor, CRP, coronary atheroma, or use of  $\beta$ -blockers and ACEIs in correlation with the ventricular events.

The transmural extent of LGE was more marked in the MI group ( $P < 0.001$ ). An LGE transmural extent  $> 50\%$  was observed in 32 patients (94.1%)

in the MI group, in contrast to 16 patients (34.0%) in the myocarditis group ( $P < 0.001$ ). LGE was more contained in the MI group, exhibiting lower transversal extents than the myocarditis group. Only eight patients (23.5%) were found to have more than two segments with LGE presence in the MI group, vs 27 (57.4%) in the myocarditis group ( $P = 0.002$ ).

Of note, the concordance among Cine and LGE data was higher in the MI group compared to the myocarditis group (88.2% vs 41.3%,  $P < 0.001$ ).

The multivariate analysis demonstrated that STE [OR = 5.72 (1.77-18.46),  $P = 0.004$ ] and LGE transmural extent [OR = 1.50 (1.02-2.20),  $P = 0.039$ ] were both independently related to ventricular events during hospitalization (Table 5). STE presented high sensitivity for the diagnosis of prolonged VT (83%), achieving a

specificity of 77% and negative predictive value of 92%. At 1 year, no patients presented with sudden cardiac death or recurrence of symptomatic ventricular event. One patient died of cancer.

## DISCUSSION

The key point of the study is to demonstrate that none of the patients presenting with MINOCA and normal LVEF died of cardiovascular death or sudden cardiac death following the initial phase of hospitalization. ST segment elevation and LGE extent were the best predictors of in-hospital ventricular arrhythmic events, irrespective of the etiology.

During hospitalization, 13.8% of the patients experienced a ventricular arrhythmic event, primarily consisting of VT, with one case of ventricular fibrillation. Most of these events occurred during the first 48 h following symptom onset. These results are consistent with the literature, with previous reports of similar rates of early arrhythmic outcomes among patients with MINOCA<sup>[7,12-14]</sup> or in cases of myocarditis<sup>[15]</sup>. Our study demonstrated that, in the absence of decreased LVEF, MI and myocarditis patients are affected by the same arrhythmic risks. Following the initial phase of the disease, where the risk of ventricular arrhythmia is

present, the arrhythmic risk appears very low.

The initial arrhythmic risk of myocarditis is well known and studies have shown that in patients < 35 years, myocarditis was the second most common identified cause of sudden cardiac death after coronary artery disease<sup>[16]</sup>.

Our study demonstrated that STE is an independent predictor of ventricular arrhythmia at early-stage disease, achieving a good negative predictive value of 92% for prolonged VT. Data on the prognostic role of ECG abnormalities are currently scarce. This finding was assumed to be in relation to the transient character of the ST changes in myocarditis<sup>[17]</sup>, as well as the weak relationship between STE and LGE localization<sup>[17,18]</sup>.

The adverse prognostic value of LGE-CMR in ischemic and non-ischemic cardiomyopathy has been proven in patients with reduced LVEF<sup>[19]</sup>. Conversely, Grün *et al.*<sup>[20]</sup> demonstrated a relevant cardiac mortality of 15% in 203 patients with myocarditis, which was primarily driven by the presence of LGE. Nevertheless, a large proportion of their patients presented with heart failure and decreased LVEF. In another report of fewer selected patients with suspected myocarditis, LGE was found in only 28% of cases, and LGE and LVEF were defined as predictors for a composite of cardiac death and heart failure<sup>[15]</sup>. In our study, considering the

excellent prognosis of the population, we have found that LGE is not useful for evaluating cardiac outcomes.

Despite this, however, the transmural extent of LGE was identified as an independent predictor for ventricular arrhythmia during the acute phase of the disease. This could therefore be of great value, if performed very early after the hospitalization, to identify at-risk patients requiring special attention and perhaps more prolonged rhythmic monitoring.

In our study, CMR imaging provided etiological diagnosis in 81 patients (61.8%), which is consistent with previous reports<sup>[21,22]</sup>. Clinical evaluations including

biopsy have demonstrated that myocarditis could be present in patients with normal CMR results in 32% to 47% of cases<sup>[20,23]</sup>. It is likely that the frequency of myocarditis was underestimated in our study, especially in the “no LGE” group, as suggested by the CRP levels that were similar to those with myocarditis. It has been suggested that global LV involvement in myocarditis may be the cause of LGE absence<sup>[24]</sup>.

The choice of medical management strategy for these patients remains controversial. There is little data, which is also conflicted, on the use of a secondary prevention treatment involving at least β-blockers in patients affected by myocarditis mimicking acute MI<sup>[25]</sup>. In our cohort, 69.5% of the patients received β-blockers during hospitalization, reflecting the management of a recent MI. Regarding the relatively-high percentage of patients who experienced ventricular arrhythmia, there is no doubt that this treatment is of interest during this period of time.

In our study, the absence of sudden cardiac death at 1 year suggests that β-blockers should not be continued over the long term, even if the β-blocker treatment had already been stopped in most of the population, with only one myocarditis patient still undergoing treatment. The need to prolong the treatment immediately after the hospital discharge is, however, a more controversial topic. LGE and ST segment elevation may represent valuable tools to stratify the risk of these patients and select those eligible for secondary prevention therapy.

The first limitation of our study was the sample size, which was too small to detect any statistical difference between the myocarditis group and the MI group. Secondly, the retrospective study design also, evidently, posed a limit. Finally, no systematic rhythm

monitoring was organized to screen the last recurrence of ventricular events after discharge. Similarly, the therapeutic management that may be chosen based on such preclinical events was left to the discretion of the referring cardiologist, and the use of  $\beta$ -blockers or ACEIs was extremely low at follow-up (12.2% and 13.0%, respectively). Nevertheless, none of our patients presented with sudden cardiac death or severe arrhythmia during follow-up. We must also admit that prognosis may differ by ethnicity but are not stressed in our study.

In conclusion, our study indicated that patients with MINOCA and normal LVEF did not present any 1-year CV events, particularly no sudden cardiac death, after hospital discharge. Most of them had even stopped treatment at 1-year follow-up.

STE on admission and LGE transmural extent appear to be good markers for identifying patients at risk of ventricular events in the early stages of disease.

## COMMENTS

### Background

About 1%-12% of patients with chest pain and cardiac troponin elevation present with normal coronary arteries on angiography analysis. While the arrhythmic prognosis of myocardial infarction with abnormal coronary angiography is well known, there is little data concerning myocardial infarction with non-obstructive coronary arteries (MINOCA). This study sought to evaluate the risk of ventricular arrhythmias of presumed low-risk MINOCA patients, based on the diagnosis class established by cardiac magnetic resonance (CMR) imaging.

### Research frontiers

Numerous patients are affected by MINOCA, and yet prognosis is expected to be favorable as soon as left-ventricular ejection fraction (LVEF) is good. Nevertheless, the mere presence of a myocardial injury/scar/fibrosis, let us empirically dare for the occurrence of ventricular arrhythmia.

### Innovations and breakthroughs

CMR was used systematically to identify MINOCA's aetiology, but also to assess myocardial injury and its extent. Continuous electrocardiography was also systematically performed to solve the question of arrhythmic risk during the first days after symptoms onset. It was continued by a one-year clinical follow-up. Nevertheless, this study does not focus on medical therapy, including the effect of  $\beta$ -blockers on ventricular arrhythmia.

### Applications

This study provides evidence on the good prognosis (including arrhythmic events) presented by patients with MINOCA and preserved LVEF. When ventricular arrhythmias occurred, they correlated with myocardial injury, as assessed by transmural late gadolinium enhancement (LGE) by CMR. Therefore, this study provides reassuring data about survival but also point out the need to stress the effect of antiarrhythmic therapies on the newly-identified risk markers that are LGE and ST segment elevation.

### Terminology

MINOCA is a recent terminology that relates to ischemic injuries, myocarditis, tako-tsubo cardiomyopathy, hypertrophic cardiomyopathy, dilated cardiomyopathy, and other causes such as pericarditis and amyloidosis.

### Peer-review

This paper is interesting, novel, and an overall well-conducted study. It provides a timely study on this field.

### Abstract

#### AIM

To describe the clinical and echocardiographic features of Nigerian children with transposition of the great arteries and emphasize the need for collaboration with cardiac centres in the developed countries to be able to salvage the children.

#### METHODS

Prospective and cross sectional involving consecutive patients diagnosed with transposition of the great arteries using clinical evaluation and echocardiography at the Paediatric Department of Lagos State University

Teaching Hospital, Lagos Nigeria as part of a large study between January 2007 and December 2015.

### RESULTS

There were 51 cases of transposition of the great arteries within the study period with a male to female ratio of 2:1 and a prevalence of 1.55 per 10000 among population of children who presented to centre during the study. Its proportion amongst children with congenital heart disease was 4.9%, while it was 15.4% among those with cyanotic congenital heart disease. The mean age  $\pm$  SD of the subjects was 10.3  $\pm$  21.8 mo. Up to 70% of the patients were less than 6 mo of age at initial presentation. The most common mode of presentation was cyanosis. The most common associated intracardiac anomaly was ventricular septal defect which occurred in 56% of the patients.

### CONCLUSION

Transposition of the great arteries is as common in Nigeria as in the other parts of the world. The most common mode of presentation was cyanosis. There is an urgent need to establish paediatric cardiac centres in Nigeria if these children are to be salvaged.

**Key words:** Transposition; Cyanosis; Children; Salvage; Nigeria

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Transposition of the great arteries is as common in Nigeria as in the other parts of the world. The most common mode of presentation in our subjects was cyanosis. Palliative and definitive interventions are currently not available for them in Nigeria. A lot of lives are being wasted yearly because of unavailable and inaccessible surgical care.

Animasahun BA, Madise-Wobo AD, Gbelee HO, Omokhodion SI. Children with transposition of the great arteries: Should they actually be born in Nigeria? *World J Cardiol* 2017; 9(3): 277-282 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/277.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.277>

### INTRODUCTION

Transposition of the great arteries (TGA) affects children of all races as documented earlier<sup>[1,2]</sup> and African children are no exception<sup>[3,4]</sup>. Advance surgical techniques to manage children with congenital heart lesions is still in infancy stage in Nigeria<sup>[5,6]</sup>. That notwithstanding, cases of TGA are seen and managed within the available limitations. There are only very few reports on TGA in Africa especially from sub-Saharan Africa. At best TGA is only mentioned as part of other congenital heart disease or as case reports. There has been no report on cohorts of children with

TGA in West Africa. This article will describe the pattern and presentation of children diagnosed with TGA and the management and outcome of such patients in a tertiary hospital in sub-Saharan Africa. This is to make data available on these group of subjects for reference purpose for future research in the region, create awareness on TGA among health professionals in the region and for advocacy on the urgent need to establish paediatric cardiac centres in Nigeria so that these children can be salvaged, especially the need for collaboration with established paediatric cardiac centres in the developed countries in order to improve the outcome of children born with TGA in the West Africa region through early diagnosis and prompt intervention.

### MATERIALS AND METHODS

This was a review of prospectively collected data of all patients less than 13 years of age diagnosed with TGA using echocardiography at the Paediatric Department of Lagos State University Teaching Hospital Lagos Nigeria between January 2007 and December 2015.

The hospital is a tertiary institution in Southwestern Nigeria and receives referral from the region. Patients with suspected cardiac lesion are referred to the department for evaluation from within the state and sub-region. A paediatric cardiologist is in charge of the cardiology unit. Patients referred to the cardiology unit of the department are evaluated with chest radiograph, electrocardiography other ancillary investigations as required including echocardiography.

One echocardiography machine was used on all the subjects throughout the study period, a GE Vivid Q echocardiography machine reference number 14502 WP SN 2084. It has facility for two dimensional, M-mode and color flow Doppler imaging. The paediatric cardiologist performed the echocardiography on all the subjects.

Definitive diagnosis is based on echocardiography which demonstrates the characteristic bifurcation of the pulmonary artery arising posteriorly from the left ventricle in the parasternal long axis view and the aorta anterior and to the right of the pulmonary artery. Other associated cardiac anomalies such as the atrial septal defect (ASD), ventricular septal defect (VSD), patent ductus arteriosus, double outlet right ventricle (DORV), pulmonary stenosis (PS) and abnormal coronary arteries were documented for all the patients. A diagnosis of TGA was made based on the combination of clinical signs and symptoms, with or without a chest radiograph features described above with the characteristic echocardiographic features<sup>[7,8]</sup>.

All the patients were followed up at the paediatric cardiology clinic. Surgical correction was required by all the subjects but this is not available in Nigeria and thus the patients were referred outside Nigeria for the correction. The patients who had surgical correction were referred back to the unit after the correction and they were followed up in the unit.

The data were imputed in a personal laptop and

**Table 1** Yearly incidence and percentage of transposition of the great arteries amongst the congenital heart disease

TGA: Transposition of the great arteries; CHD: Congenital heart disease.

analysed using Statistical Package for Social Sciences version 20. The children's age, sex, indication for echocardiograph, echocardiographic findings and outcome and were documented. Tables and charts were used to depict those variables. Means of continuous variables were compared using the Student *t* test, and proportions using  $\chi^2$  test. Level of significance set at  $P < 0.05$ .

## RESULTS

### Prevalence of TGA

Prevalence rates were based on 51 cases of TGA diagnosed between January 2007 and December 2015. A total of 326662 children were seen at the department during the study period and 1693 had echocardiography done. Of the 1693 who had echocardiography done, 1123 had congenital heart diseases (772 and 351 for acyanotic and cyanotic congenital heart defects respectively).

Table 1 shows the yearly distribution, prevalence of TGA and proportion of subjects with TGA amongst the cases of congenital heart disease. The prevalence of TGA within the study period was 1.55 per 10000 populations of children who present to the hospital. The percentage of TGA amongst children with congenital heart disease was 4.5% and 14.5% amongst those with cyanotic congenital heart disease.

### Clinical presentation

There were 51 cases of TGA within the study period. They comprised 34 males and 17 females with a male to female ratio of 2:1. The mean age of the children at initial presentation in month was  $10.3 \pm 21.8$  with a median age of 4 mo and a bimodal age of 1 and 4 mo. The mean age of the males was  $9.3 \pm 24.3$  while that of the females was  $12.2 \pm 16.8$  ( $P = 0.28$ ). The distribution of the age of the patients was the same across both sexes. The median age for the males and females was 3.5 and 5.5 mo respectively. The modal age for the males was 4 mo while that of the females was bimodal, 2 and

**Table 2** Ages at echocardiography and sex distribution of the patients

Age (mo)	Male	Female	$\chi^2$	<i>P</i>
0-6	25	11	2.0	0.36
6.1-12	4	2		
$\geq 12.1$	5	4		
Total	34	17		

$\chi^2 = 2.0$ ,  $P = 0.36$ .

6 mo. Up to 70% of the patients were less than 6 mo of age at initial presentation. The youngest patient was 14 d old while the oldest patient was 11 years old. Table 2 depicts the age distribution of the children at diagnosis.

All the children were ill at presentation. Forty-seven children were cyanosed while 4 were acyanosed at presentation. The indications for echocardiography are depicted in Table 3. In most cases there were more than one reasons/indication for echocardiography. All the study subjects had d-TGA. Other associated intracardiac anomaly are as highlighted in Table 4. The most common associated intracardiac anomaly was ventricular septal defect which occurred in 56% of the patients and this co-existed alone or in combination with other intracardiac connections.

### Treatment and outcome

The patients received anti-congestive agents and angiotensin converting enzyme inhibitors. Five patients had surgical intervention done outside the study centre. One patient had atrial switch and is doing well on follow up three years post surgery. The other four had arterial switch surgeries. One patient succumbed at the immediate post up period. Another died about two months' post surgery in a secondary centre. Another died about one-year post surgery secondary to a non-cardiac illness. The remaining patient is on followed up in the department eight-year post-surgery and is stable. The other patients who could not afford treatment succumbed while sourcing for funds to do surgery. More than 90% of the patients died at infancy, a few at about 14 mo of age. All the patients who had surgery were operated in India.

## DISCUSSION

TGA is the most common cyanotic congenital heart lesion in the newborn<sup>[9]</sup>. The Center for Disease Control (CDC) estimated that each year, 1901 babies in the United States are born with TGA or an approximate of 5 in 10000 babies born yearly with it<sup>[10]</sup>. It is present in 5%-7% of all patients with congenital heart disease<sup>[11]</sup>. There is a male predominance with a male to female ratio of 1.5:1 to 3:2<sup>[12-14]</sup>. The mortality in untreated patients is up to 50% in the first month and 90% by the end of the first year<sup>[7]</sup>. Maron *et al*<sup>[1]</sup> in the United States over four decades ago, documented that there was no racial difference in the frequency of TGA.

**Table 3** Indication for cardiac evaluation of the subjects

Indication	Frequency	% of all patients
Cyanosis	47	92
ACHD	4	7.8
Breathlessness	10	19.6
CCF	1	1.9
Stroke	1	1.9
Murmur	1	1.9
Failure to thrive	1	1.9
Suspected TGA	1	1.9
Dextro Cardia	1	1.9
Down syndrome	2	3.9

Some patients had more than one indication. ACHD: Acyanotic congenital heart disease; CCF: Congestive cardiac failure.

However, a more recent study by Botto *et al.*<sup>[2]</sup> in the same country documented a higher occurrence of TGA in whites compared to negroes. In 10% of cases of TGA association with noncardiac malformations have been documented<sup>[15]</sup>.

The aetiology is largely unknown. Associated risk factors include gestational diabetes mellitus<sup>[16,17]</sup>, maternal exposure to rodenticides and herbicides<sup>[18]</sup> and maternal use of antiepileptic<sup>[19]</sup>. Genetic mechanisms have been implicated and some genetic mutations have been implicated<sup>[20,21]</sup>.

The prevalence of TGA in this study was 1.55 per 10000 populations of children who presented to the hospital. This result is less than the CDC report of 5 in 10000 live births in the United States<sup>[12]</sup>. However the CDC report is a study on the proportions of live birth which is a different denominator compared to the present study. We have also documented the yearly prevalence of TGA. It was highest in 2010, 3.84 per 10000 children and lowest in 2007, 0.21 per 10000 children per year. Reasons why it may have been low in the first year is because the echocardiography machine was just made available and there was little awareness of its availability for evaluation of children with structural heart disease within the region. Thus there were little referral for cardiac evaluation at that time. The prevalence rate documented in this study may be a far cry from the actual prevalence rate because a lot of cases may have been missed in the neonatal period and early infancy for a number reasons. Firstly, prenatal cardiac evaluations are rarely done in Nigeria thus a sizeable number may have been missed at birth. Secondly, the clinical presentation of TGA is non-specific and thus a number of cases may have been ill and in the absence of proper evaluation with a high index of suspicion of a congenital heart disease some babies may have be managed for other morbidities and died without a cardiac evaluation. Thirdly, because of cultural practices prevalent in the region, infants who died before a proper evaluation was done may not have autopsy done to confirm a suspicion of a congenital heart disease and TGA to be specific<sup>[22]</sup>.

TGA was documented in 4.5% of all congenital

**Table 4** Associated intracardiac connections in subjects

Cardiac anomaly	Frequency	% of all TGA
ASD	19	37.3
AVCD	3	5.9
DORV	10	19.6
HLH	1	1.9
PDA	15	29.4
PFO	2	3.9
PS	6	11.8
TAPVC	1	1.9
TOF	1	1.9
TR	3	5.9
VSD	27	52.9

Most patients had more than one intracardiac connections. TGA: Transposition of the great arteries; ASD: Atrial septal defect; AVCD: Atrioventricular canal defect; DORV: Double outlet right ventricle; HLH: Hypoplastic left heart; PDA: Patent ductus arteriosus; PFO: Patent foramen ovale; TAPVC: Total anomalous pulmonary venous connections; TOF: Tetralogy of fallot; TR: Tricuspid regurgitation; VSD: Ventricular septal defect.

heart disease within the study period. Two decades ago, Jaiyesimi *et al.*<sup>[23]</sup> in UCH Ibadan documented a prevalence rate of 4.8% in cardiac lesions which is similar to findings in the present study. International rate of TGA amongst all congenital heart lesion is 5%-7%<sup>[14]</sup> and this is also similar to the value documented in the present study. We also documented a male predominance in TGA with a male to female ratio of 2:1. This is consistent with international ratio of 1.5:1-3.2:1<sup>[12-14]</sup>.

The mean age of the children with TGA was 9.3 ± 24.3. The mean age was not different in both sex. The youngest child was 2 wk and the oldest was 11 years old. Although 70% of the patients were ≤ 6 mo old there were three patients who were three, six and eleven years old and those values significantly affected the mean age and resulted in a large standard deviation. In an earlier study by Adegboye *et al.*<sup>[4]</sup> in Ibadan, southwestern Nigeria, the mean age of the children with TGA who underwent palliative surgery was 6.8 ± 2.4. The mean age recorded in Ibadan was not significantly different from that documented in this study although the subjects were fewer in the later study. In contrast, in advanced countries, diagnosis of TGA is made in neonatal period.

Patients with TGA present with central cyanosis from the first month of life with varying clinical manifestation based on the degree of mixing between the two circulations<sup>[17]</sup>. Patients with a large ventricular septal defect and or a patent ductus arteriosus (PDA) may present early with congestive cardiac failure. Long term complications are secondary to cyanosis. A definitive diagnosis of TGA is made with an echocardiogram<sup>[8]</sup>.

The most common mode of presentation in our subjects was cyanosis and some patients presented with more than one presentation. This is not an unusual finding as the signs and symptoms of TGA varies depending on the associated intracardiac lesion<sup>[8]</sup>.

Cyanosis may go unnoticed in some patients with large ventricular septal defects without right outflow. Similarly, 8% of our study subjects were not cyanosed at presentation and one had congestive cardiac failure.

Complications from cyanosis and polycythemia may occur especially in untreated cases. One of the subjects was a 3.25-year-old male who had been cyanosed from infancy, he presented to the hospital for the first time with cerebrovascular accident and cardiac evaluation revealed a TGA.

D-TGA is the common form of TGA worldwide and all our study subjects had d-TGA. Simple TGA is not compatible with extra-uterine life except there are intracardiac connections for admixture of blood<sup>[24,25]</sup>. All our subjects had intracardiac connections and not surprisingly the most common was a VSD which occurred either alone or in combination with other intracardiac lesions. ASD was the second most common closely followed by a PDA in 37.3% and 29.4% respectively. Left ventricular outflow obstruction may occur in one eighth to a third of patients with TGA. We report in this study 12.5% of cases of pulmonary stenosis and all but one of those subjects had an associated VSD while the other patient had an atrioventricular canal defect. Other complex lesions documented in this study are TOF, hypoplastic left heart, TAPVC, DORV and tricuspid atresia.

TGA is known to be associated with other congenital disorder in 10% of cases<sup>[6]</sup>. Sporadic association of TGA with trisomy 8, 18, VACTERL and CHARGE syndrome have been documented<sup>[26,27]</sup>. Two (3.9%) of our subjects had Down syndrome and the others had no dysmorphologies.

Treatment of patients with TGA is both medical and surgical. Initial palliative care is instituted to achieve optimal intercirculatory mixing and optimize the clinical condition<sup>[7,18]</sup>. Mechanical ventilation and oxygen may be needed for unstable infants, correction of metabolic acidosis and administration of prostaglandin E<sub>1</sub> to maintain arterial duct patency<sup>[7]</sup>. Balloon atrial septostomy may be done to maintain admixture of blood at atrial level. Surgery provides the definitive treatment. It may be offered within the first month of life depending on the clinical setting. The arterial switch procedure can be done. Others include the Rastelli operation and Nikaidoh's procedure<sup>[8]</sup>.

In the current study, all our patients required definitive surgical corrections which is currently not available in Nigeria. Only three (5.9%) could afford to do corrective surgery outside Nigeria. Three patients presented within the first two weeks of life and all three had a PDA with either a VSD or an ASD. They required palliative surgery but could not afford one. Almost 90% of the patients could not access the much needed surgical care and succumbed before help could be provided. This was not surprising because the case fatality rate for TGA is as high as 50% by the end of the first month and 90% at one year for untreated cases. These are largely preventable deaths if diagnosis can be made on time

and appropriate treatment instituted timely.

In conclusion, transposition of the great arteries is as common Nigeria as in the other parts of the world. The most common mode of presentation in our subjects was cyanosis. Palliative and definitive interventions are currently not available for them in Nigeria. A lot of lives are being wasted yearly because of unavailable and inaccessible surgical care. There is an urgent need to establish paediatric cardiac centres in Nigeria so that these children can be salvaged. Collaboration is needed from established paediatric cardiac centres from developing and developed world if this is to be achieved.

## ACKNOWLEDGMENTS

The patients, parents and caregivers involved in this study are acknowledged including all the health professionals involved in their care.

## COMMENTS

### Background

Transposition of the great arteries (TGA) affects children of all races as documented earlier including African children. Prompt and advance surgical intervention needed to salvage these children is currently not available in Nigeria.

### Research frontiers

Arterial switch is one of the surgical option for correction of TGA is preferable done during the neonatal period.

### Innovations and breakthroughs

This article described pattern and presentation of children diagnosed with TGA and the management and outcome of such patients in a tertiary hospital in sub-Saharan Africa. Data on these group of subjects has been provided by this study for reference purpose.

### Applications

The data provided in this study is useful for, future research in the region on the subject, awareness creation on TGA among health professionals in the region, for advocacy on the urgent need to establish paediatric cardiac centres in Nigeria if these children can be salvaged, especially the need for collaboration with established paediatric cardiac centres in the developed countries in order to improve the outcome of children born with TGA in the West Africa region through early diagnosis and prompt intervention.

### Terminology

TGA is a congenital heart anomaly that occurs when the two main arteries of the heart, aorta and pulmonary arteries, are switched in position so that the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Other names or synonyms used to describe TGA are: Physiologically uncorrected transposition, complete transposition and atrioventricular concordance with ventriculoarterial discordance. TGA is classified based on the spatial relationship between the great arteries to each other and or the infundibular morphology. dextro-TGA (D-TGA) is when the aorta is anterior and to the right of the pulmonary artery and it is the most common form. levo-TGA (L-TGA) describes the aorta that is anterior and to the left of the pulmonary artery. Furthermore, irrespective of either the L- or D-TGA, the patients may still have a subaortic infundibulum, absence of a subpulmonary infundibulum and a fibrous continuity between the mitral and pulmonary valves. Aside the above classifications, different presentations and exceptions have been described. However, the unifying hallmark is the ventriculoarterial discordance. In TGA, the pulmonary and systemic circulations run in parallel rather than in series. Oxygenated blood flows through a closed circuit that involves the lungs and left

cardiac chambers, while deoxygenated blood also flows in a closed circuit that starts from the systemic circulation and ends in the right heart chambers. This parallel circulation is incompatible with prolonged survival, so there is usually admixture of blood through the atrial or ventricular septum and or a patent ductus arteriosus.

### Peer-review

The paper is well-written and provides an appropriate view about the current situation and future interventions.

### Abstract

Kounis syndrome is the concurrence of coronary spasm, acute myocardial infarction or stent thrombosis, with allergic reactions in the setting of mast-cell and platelet activation. In this report Kounis syndrome manifesting as stent thrombosis with left ventricular thrombus formation was triggered by a food-induced allergic reaction. The allergic reaction to food was confirmed by oral rice pudding ingredients challenge test while skin tests were inconclusive. To our knowledge, this is first report of early stent thrombosis secondary to food allergic reaction in a 70-year-old man patient who was found to have left ventricular thrombus and undiagnosed hypertrophic cardiomyopathy.

**Key words:** Allergic myocardial infarction; Allergic reaction; Kounis syndrome; Stent thrombosis

**Core tip:** Kounis syndrome highlights, the role of anaphylactic mediated acute coronary syndromes complicating stent thrombosis in the era of invasive treatment of coronary artery disease. Drugs, stings,

bites, contrast material, atopic diathesis and even food ingestion could be the culprits. Managing the complex pathophysiology of this condition is a challenging issue, especially in the emergency setting, that requires rapid treatment decisions. The role of detailed past history and of preventive anti-allergic medication in high risk patients with anaphylactic reactions should be considered in randomized studies.

Tzani G, Bonou M, Mikos N, Biliou S, Koniari I, Kounis NG, Barbetseas J. Early stent thrombosis secondary to food allergic reaction: Kounis syndrome following rice pudding ingestion. *World J Cardiol* 2017; 9(3): 283-288 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i3/283.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i3.283>

## INTRODUCTION

Kounis syndrome is a variety of acute coronary syndromes triggered by the release of inflammatory mediators following an allergic insult<sup>[1]</sup>. Stent thrombosis is a rare, but serious, complication that is strongly associated with severe morbidity and mortality. Stent thrombosis associated with allergic mediated inflammatory reaction has been described as a serious manifestation of Kounis syndrome<sup>[2-4]</sup>. Several reports exist in the medical literature on patients with coronary stent implantation who developed stent thrombosis, concurrently with an allergic reaction manifesting as Kounis syndrome. Such reactions had been triggered by non anionic contrast material iopromide, flavonate-propylphenazone, non steroidal anti-inflammatory agent acemetacine, insect stings, snake bite and clopidogrel, the drug that is given itself to prevent stent thrombosis<sup>[5-10]</sup>. In the following report we describe a patient who suffered early stent thrombosis with left ventricular thrombus formation triggered by an allergic reaction following food consumption. To the best of our knowledge, this is the first case of early stent thrombosis associated with food-induced allergy reaction.

## CASE REPORT

A 70-year-old man smoker with a previous history of a transient ischemic attack, was referred to the emergency department of our hospital because of a pain to the left shoulder and arm that had started 4 d ago and was unresponsive to analgesics.

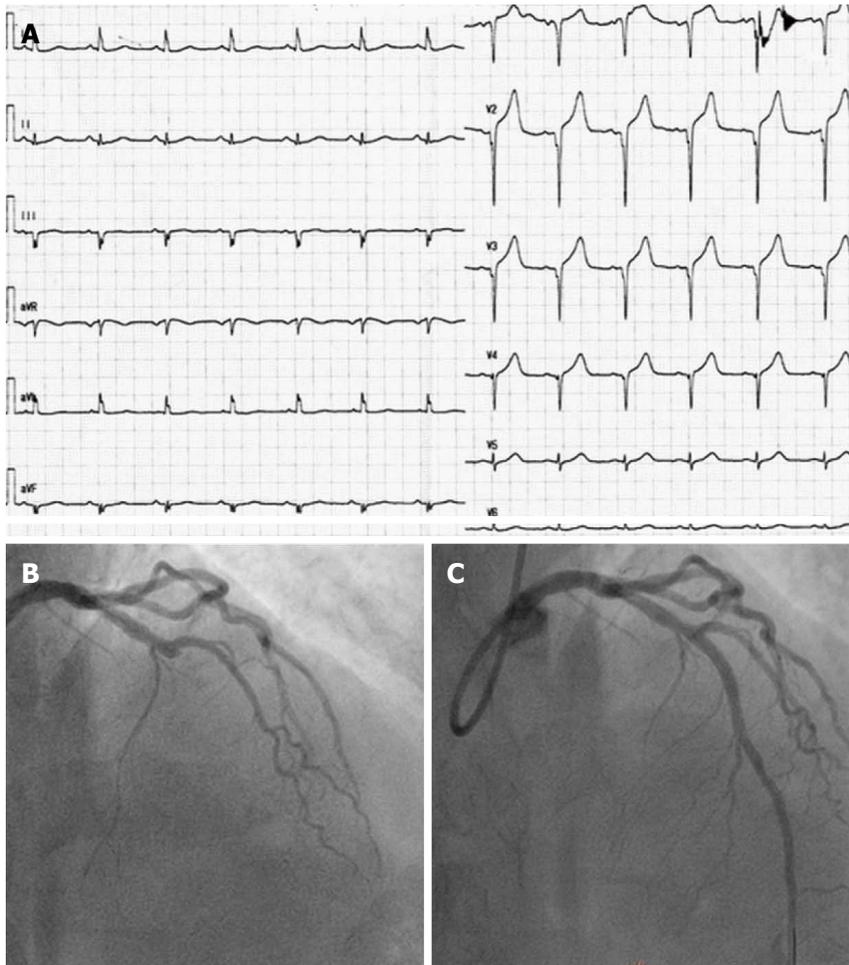

Upon admission, the electrocardiogram showed anteroseptal ST elevation myocardial infarction (Figure 1A) and transthoracic echocardiography revealed left ventricular hypertrophy, that was more pronounced at the interventricular septum, compatible with hypertrophic cardiomyopathy. Additional findings were an apical aneurysm, and moderate attenuation of systolic function. High sensitivity troponin I was elevated to

11037 ng/L. The patient was transferred to the coronary care unit and the next day coronary angiography revealed left anterior descending artery occlusion at the mid-level (Figure 1B). Subsequently, he was submitted to balloon angioplasty with placement of a drug-eluting stent (Resolute Integrity, 3 mm × 18 mm, Figure 1C). The patient remained asymptomatic and was discharged under optimal medical treatment including aspirin, clopidogrel, simvastatin, metoprolol, furosemide, lisinopril and eplerenone.

Four days later and about 20 min after taking his evening medication that was metoprolol and simvastatin and during ingestion of Greek rice pudding made of sheep milk, rice and sugar, the patient started gradually to develop lip swelling and itching followed by erythematous rash in all over his body. Within, approximately, 15 min he complained of chest pain and discomfort spreading to the left shoulder and arm. He was immediately transferred to the emergency department of our hospital. On arrival, the patient was covered in all his body with rash accompanied by itching and angioedema of the lips. The electrocardiogram showed ST elevation in V1-V4 leads (Figure 2A). Hydrocortisone and dimetindene maleate was given intravenously together with oral desloratadine and he was transferred to the catheterization laboratory, where coronary angiography revealed stent thrombosis with left anterior descending coronary artery occlusion (Figure 2B). The patient underwent thrombus aspiration that was followed by an additional stent placement (stent in stent procedure, drug eluting stent 3 mm × 16 mm, Figure 2C). However, mild chest pain remained for about 2 h and was attributed to "no reflow" phenomenon. Transthoracic echocardiography revealed, apart from hypertrophic cardiomyopathy with asymmetrical septal hypertrophy, also thrombus formation in an apical aneurysm (Figure 2E and F) necessitating heparin infusion. Contrast-echocardiography with SonoVue-Sulfur hexafluoride microbubbles revealed sessile apical thrombus (Figure 2F). Tryptase was elevated confirming an allergic reaction. The patient had an uneventful recovery and was scheduled for discharge after an allergology investigation.

### Oral food challenge test

In order to identify what had triggered the allergic reaction, skin prick tests were performed, under strict hemodynamic monitoring, for simvastatin and metoprolol that were the drugs the patient was taking after the first episode, and were inconclusive. Subsequently, it was decided to proceed to an oral food challenge test, again under strict hemodynamic monitoring, using the rice pudding ingredients that were sheep milk, rice and sugar according to the protocol described previously<sup>[11]</sup>. Following an initial amount of 0.6 g of sheep milk given slowly and 15 min after swallowing of 5 g of sheep milk the patient suddenly felt unwell, dizzy, started sweating, developed urticarial rash and complained of severe dyspnea. Soon after, he became

**Figure 1** First presentation with acute coronary syndrome. A: Electrocardiograph upon admission; B: Coronary angiography showing critical stenosis in left anterior descending; C: After implantation of resolute integrity drug-eluting stent.

disorientated and sleepy. On examination, he was pale with bronchospasm accompanied by hypoxemia (SpO<sub>2</sub> 82%), and sinus tachycardia (110/60 mmHg, 125 bpm), feeling itchy but without electrocardiographic changes. He was immediately treated with 250 mg hydrocortisone intravenously, 4 mg dimetindene maleate intravenously and 5 mg desloratadine orally with improvement in signs and symptoms. He gradually became stable and asymptomatic. Blood examinations, 10 min after onset of symptoms were performed for troponin, IgE antibodies and tryptase. Troponin was not increased, eosinophils were 70/ $\mu$ L, but IgE levels were increased to > 1000 IU/mL (normal values: 1-183 IU/mL). We did not proceed to challenge the patient with rice or sugar on ethical grounds, while the patient recalled that he was apprehended to sheep milk in the past.

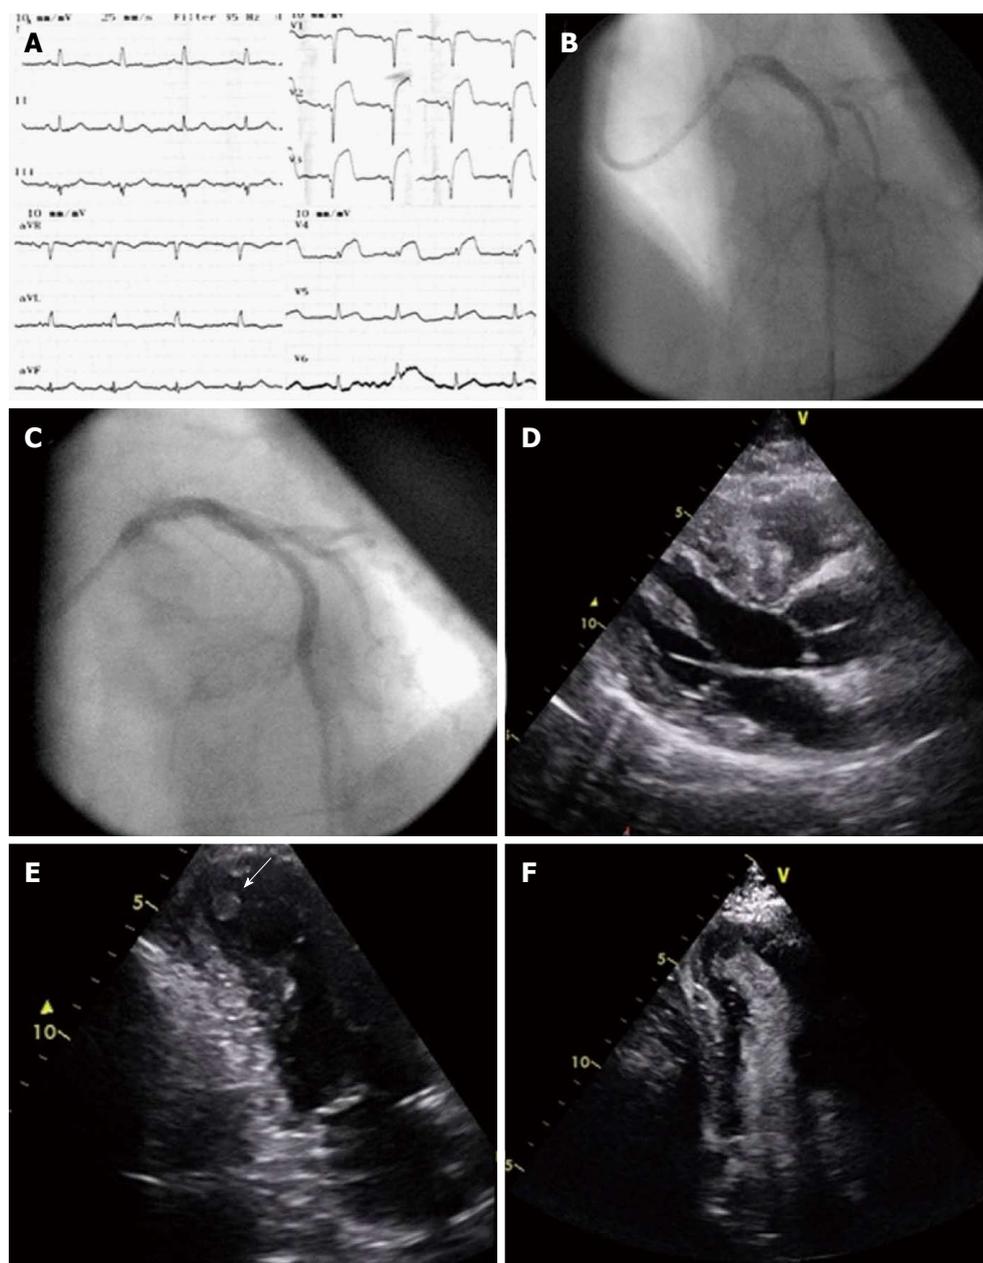

He had an uncomplicated hospital follow-up and was discharged with the advice neither to eat rice pudding nor to drink sheep's milk again.

## DISCUSSION

Acute myocardial infarction after a prolonged allergic reaction was firstly described in 1950<sup>[12]</sup>. However, a

detailed description of the allergic angina syndrome progressing to acute myocardial infarction was described in 1991 by Kounis *et al.*<sup>[13]</sup>. Three variants of Kounis syndrome have been described so far<sup>[14]</sup>: Type I that includes patients with normal coronary arteries in whom the acute release of inflammatory mediators can induce coronary artery spasm that could progress to acute myocardial infarction. Type II that includes patients with culprit and quiescent atheromatous disease in whom the acute release of inflammatory mediators may induce plaque erosion or rupture manifesting as acute myocardial infarction. The type III variant includes coronary artery stent thrombosis in the setting of allergic or hypersensitivity and anaphylactic or anaphylactoid insults. In this type, the thrombus is infiltrated by eosinophils and/or mast cells.

The patient was found to have a previously undiagnosed hypertrophic cardiomyopathy with septal hypertrophy and apical thrombus formation. Coexisting of hypertrophic cardiomyopathy with coronary spasm is not frequent and clinical characteristics in patients with both diseases have not been clarified yet. However, in a study of 36 patients with hypertrophic cardiomyopathy challenged with acetylcholine provocation test coronary

**Figure 2** Kounis syndrome following rice pudding consumption. A: Electrocardiograph upon admission; B: Coronary angiography showing stent thrombosis; C: After implantation of drug-eluting stent (stent in stent); D: Parasternal long axis view showing excessive hypertrophy of the septum; E: Thrombus in aneurysmatic apex, apical 2-chamber view; F: Contrast derived image, with thrombus in the apex, apical 2-chamber view.

vasospasm was induced in 10 (28%). The conclusion was that coronary vasospasm appears to play a significant role in the etiology of myocardial ischemia in patients with hypertrophic cardiomyopathy and smoking, as in our patient, might be a major risk factor for coexistence of coronary vasospasm<sup>[15]</sup>.

The apical thrombus formation could be attributed to pre-existing ischemic disease with aneurysmal dilatation of the apex. However, the activation of the thrombotic path during Kounis syndrome may have played an additional role. Indeed, platelet surface membrane contains, not only the well known receptors for thromboxane, adenosine diphosphate, IIb/IIIa but additional receptors for multiple exogenous agonists which contribute to platelet activation. These include

receptors for thrombin, serotonin, epinephrine collagen, platelet activating factor and histamine<sup>[16]</sup>. Additionally, a subset of platelets bear in their surface high and low affinity FC $\gamma$ RI, FC $\gamma$ RII, FC $\epsilon$ RI and FR $\epsilon$ RII IgE receptors<sup>[17]</sup> that are activated during hypersensitivity responses.

The anaphylactic reaction was confirmed during hospitalization with oral food consumption test and it was found that the patient was allergic to sheep milk. Tryptase levels were not elevated and this might be due to blood sample collection soon after the onset of symptoms, and according to tryptase kinetics these levels are found to elevate later<sup>[18]</sup>. Immunoglobulin E antibodies were highly elevated that explains the IgE-mediated allergic reaction. In a study comparing cow milk allergy with sheep and goat milk allergy, it was

found that the latter affects older children and appears at a later age. In sheep or goat milk allergic patients, the IgE antibodies recognize the caseins but not the whey proteins. Moreover, IgE specificity and affinity was high to sheep-goat milk and lower to cow milk caseins despite their marked sequence homology<sup>[19]</sup>.

Both physicians and susceptible individuals should be aware that high risk patients and patients with predisposition to allergies, especially allergy to sheep or goat milk require strict avoidance of such milk and milk derived products as reactions could be severe and life threatening. Vigorous anti-allergic medication and standardized treatment protocol is mandatory in order to prevent allergic insults and catastrophic cardiovascular adverse events.

## COMMENTS

### Case characteristics

A 70-year-old man with coronary artery disease who suffered early stent thrombosis with left ventricular thrombus formation triggered by a food-induced (sheep milk in rice pudding) allergic reaction and was found by oral food challenge test to be sensitized to sheep milk.

### Clinical diagnosis

Clinical diagnosis Kounis syndrome, complicating early stent thrombosis following Greek rice pudding consumption, in a patient with coronary artery disease and hypertrophic cardiomyopathy.

### Differential diagnosis

Acute coronary syndrome and anaphylactic shock. Both of them are the two sides of the same coin when investigating the complex pathophysiology of Kounis syndrome.

### Laboratory diagnosis

Increased cardiac enzymes, IgE antibodies and tryptase levels.

### Imaging diagnosis

Coronary angiography revealed stent thrombosis completely occluding left anterior descending artery. Echocardiography demonstrated left ventricular hypertrophy compatible with hypertrophic cardiomyopathy, an apical aneurysm and moderate attenuation of systolic function with thrombus formation in the apical aneurysm.

### Pathological diagnosis

In the acute setting of the coronary syndrome, no thrombus was kept for pathological analysis.

### Treatment

The patient underwent balloon angioplasty with placement of a drug-eluting stent in the acute setting of the stent thrombosis. In the second allergic reaction, during the allergic skin tests and the oral food challenge test, he was treated with hydrocortisone, dimetindene maleate and desloratadine with improvement in signs and symptoms of the allergic reaction.

### Related reports

To our knowledge, this is the first report of Kounis syndrome with the clinical manifestation of early stent thrombosis after food allergic reaction.

### Experience and lessons

Kounis syndrome is "a new twist on an old disease", which is frequently misdiagnosed. The early diagnosis could improve patients' outcome and prognosis, while original randomized studies could investigate the role of

preventive anti-allergic medication in high risk patients with anaphylactic reactions.

### Peer-review

This manuscript is well-written and an interesting case report with addressing type III Kounis syndrome (anaphylactic reaction) induced by food allergy.

### Abstract

The spasm provocation test (SPT) is an important test in the diagnosis of vasospastic angina (VSA). In many cases, this test is performed as the gold standard test, and VSA is considered not present if the SPT is negative. However, some patients continue to experience chest symptoms despite a negative SPT. In this study, we report four cases in which SPT was repeated to evaluate chest symptoms despite the negative results of the first SPT. Two men in their 70s, one woman in her 60s, and one woman in her 70s, all with chest symptoms, underwent a second SPT at 4, 3, 2, and 3 years, respectively, after the first SPT, which was negative. Three patients had positive results in the second SPT (75%). In conclusion, even when SPT is negative, the diagnosis of VSA should be made with clinical symptoms in consideration. In some cases, a second SPT may be required to confirm the diagnosis of VSA.

**Core tip:** The spasm provocation test (SPT) is an important examination when diagnosing vasospastic angina (VSA). In general, if the SPT is negative, VSA is considered not present. However, we encountered four patients who underwent a second SPT although the first SPT was negative. In these patients, some show a positive second SPT result. SPT is not a perfect examination, and in the clinical setting, the diagnosis of VSA should be made with the consideration of their clinical symptoms and examinations.

## INTRODUCTION

Coronary spasm is characterized by transient vasoconstriction of the epicardial coronary artery, leading to myocardial ischemia. Coronary spasm is the cause of not only typical rest angina but also exertional angina, acute myocardial infarction, and sudden cardiac death<sup>[1,2]</sup>. Therefore, the diagnosis of vasospastic angina (VSA) should be made with certainty. VSA is diagnosed by the presence of chest symptoms accompanied by transient ST deviation on the electrocardiogram (ECG)<sup>[3,4]</sup>. This can, however, be difficult in the clinical setting because angina attacks do not necessarily occur during the one day of ECG monitoring or because ST changes are not always documented by ECG even in the presence of chest symptoms. In such cases, the spasm provocation test (SPT) can be used<sup>[3-5]</sup>. In the clinical setting, SPT is the gold standard examination to diagnose VSA. However, we observed some cases in which chest symptoms continued despite a negative SPT. Here, we report four such cases in which a second SPT was performed to evaluate chest symptoms despite negative results in the first SPT.

## CASE REPORT

At our institution, SPT is performed in the afternoon. Vasodilators are stopped 2 d before SPT. For SPT, acetylcholine (ACh) is usually used as the provocation drug, with 30 and 50  $\mu\text{g}$  for the right coronary artery (RCA) and 50 and 100  $\mu\text{g}$  for the left coronary artery (LCA). If the SPT results are negative with these doses, additional doses of ACh (80  $\mu\text{g}$  for the RCA and 200  $\mu\text{g}$  for the LCA) and/or ergonovine maleate (EM; 20, 40, and 60  $\mu\text{g}$  for the LCA) are sometimes added. A positive SPT is defined as the presence of transient vasoconstriction > 90% in response to intracoronary infusions of provocative drugs on coronary angiograms. The positive result is accompanied by the usual chest symptoms and/or ischemic ST deviations in the patient's ECG<sup>[3]</sup>.

### Case 1

A man in his 70s underwent an SPT because of chest pain at rest. His coronary risk factors were smoking (30 cigarettes per day for 30 years) and hypertension. The SPT showed negative results after intracoronary infusions of ACh with 50  $\mu\text{g}$  for the RCA and 100  $\mu\text{g}$  for the LCA (Figure 1A). Thereafter, he continued to experience chest pain at rest but did not seek further help for his chest symptoms. Four years later, he felt severe chest pain at rest in the early morning, which was relieved by sublingual nitroglycerin (NTG).

Therefore, he underwent a second SPT, which was positive for the RCA with an intracoronary infusion of 30  $\mu\text{g}$  ACh. The result was accompanied by the usual chest symptoms and ECG changes, despite negative LCA results after an intracoronary infusion of NTG (Figure 1B). At that time, we used a pressure wire inserted into the distal RCA. The distal intracoronary pressure /aortic pressure (Pd/Pa) decreased from 0.99 at baseline to 0.73 after the ACh infusion. He was diagnosed with VSA and discharged with a prescription for a calcium channel blocker (CCB).

### Case 2

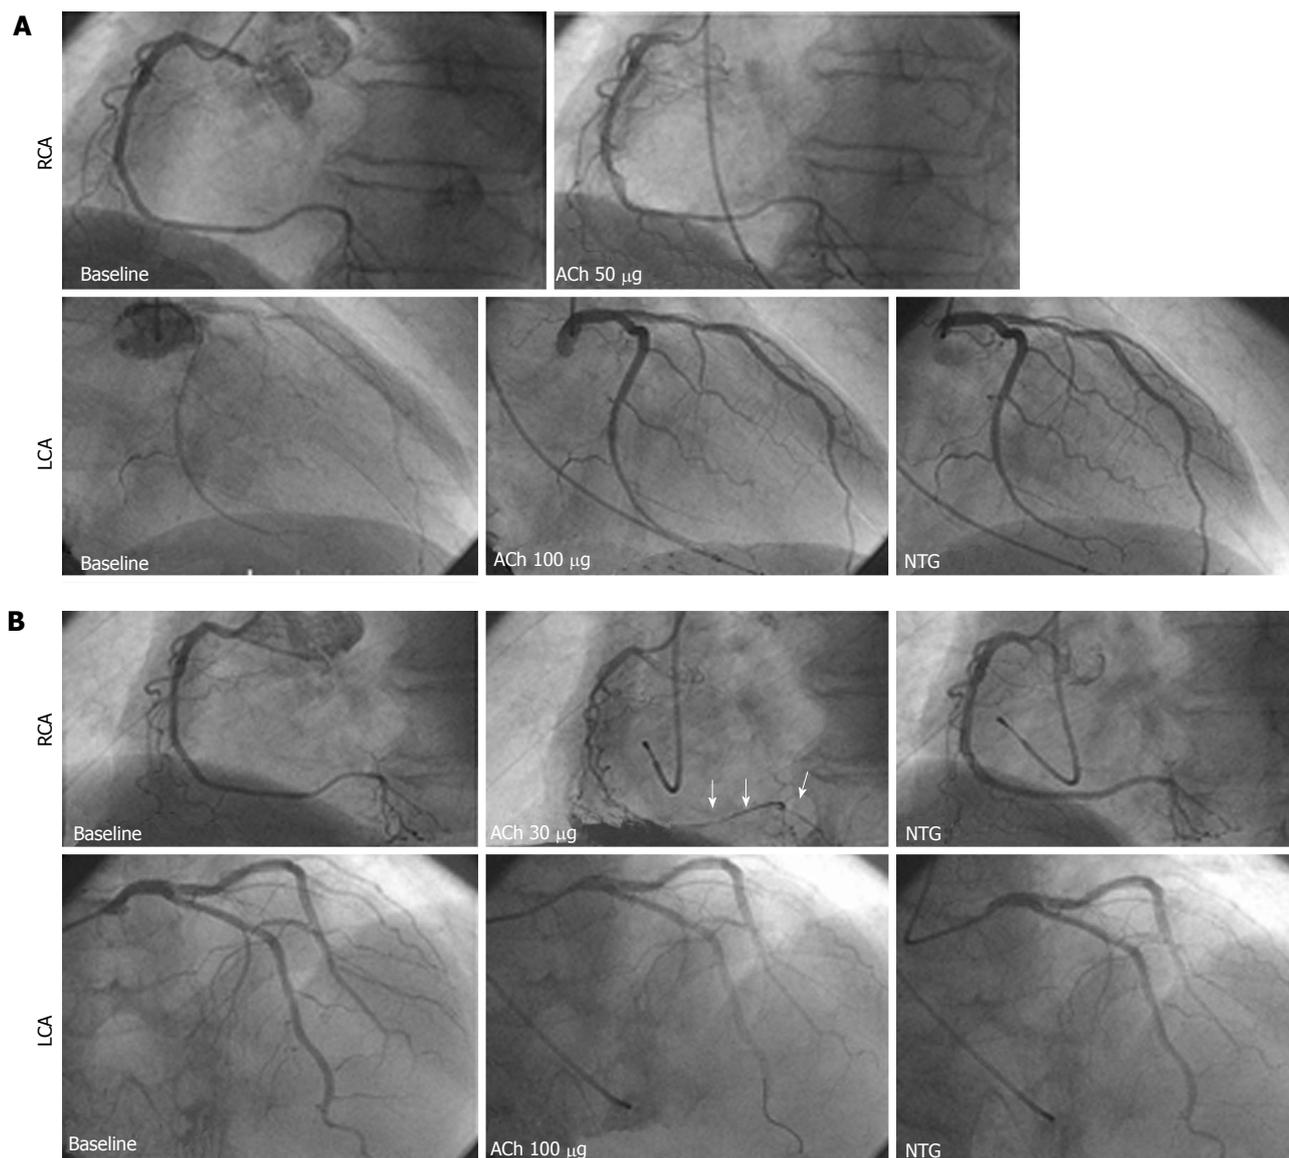

A male in his 70s underwent an SPT because of chest pain at rest, which occurred for 1-2 min and frequently 3-4 times/wk. He had no coronary risk factors. The SPT showed moderate vasoconstriction of the RCA after 50  $\mu\text{g}$  ACh and moderate vasoconstriction of the LCA after 100  $\mu\text{g}$  ACh (Figure 2A). However, he did not experience chest symptoms or ST deviation on ECG during the SPT. Hence, the SPT result was judged as negative. His chest symptoms continued thereafter, and he had severe chest pain at midnight 3 years later; therefore, he underwent a second SPT 3 years after the first SPT. The second SPT showed positive results for both the RCA after intracoronary infusions of 50  $\mu\text{g}$  ACh and the LCA after infusions of 100  $\mu\text{g}$  ACh (Figure 2B). The test was accompanied by the usual chest symptoms. The Pd/Pa decreased from 0.96 at baseline to 0.75 during the RCA spasm and from 0.93 at baseline to 0.74 during the left anterior descending coronary artery (LAD) spasm. He was diagnosed with VSA and was discharged with CCB medication.

### Case 3

A female in her 60s underwent an SPT due to 1-2-min chest pain at rest during the night. She had no coronary risk factors. The SPT showed negative RCA results after 50  $\mu\text{g}$  ACh and for the LCA after an intracoronary infusion of 100  $\mu\text{g}$  ACh (Figure 3A). Nevertheless, her symptoms continued. CCB did not help, and she underwent the second SPT 3 years after the first SPT. The second SPT showed negative RCA results after 80  $\mu\text{g}$  ACh and for the LCA after 200  $\mu\text{g}$  ACh (Figure 3B). The Pd/Pa did not change significantly, from 1.00 at baseline to 0.92 with 80  $\mu\text{g}$  ACh in the RCA and from 0.95 at baseline to 0.93 with 200  $\mu\text{g}$  ACh in the LAD. She was discharged with analgesic and anti-depressive medication.

### Case 4

A female in her 70s underwent an SPT to evaluate chest pain in the evening lasting for 1 min. Her coronary risk factors were hypertension and lipid disorder. The SPT showed negative RCA results after 50  $\mu\text{g}$  ACh and for the LCA after 100  $\mu\text{g}$  ACh (Figure 4A). Thereafter, her chest symptoms were infrequent, but she felt severe

**Figure 1** Coronary angiograms during the first and second spasm provocation test in case 1. A: The first spasm provocation test (SPT) showed negative results after intracoronary infusions of acetylcholine (ACh) with 50 µg for the right coronary artery (RCA) and 100 µg for the left coronary artery (LCA); B: The second SPT showed positive RCA results with an infusion of 30 µg ACh, accompanied by the usual chest symptoms and electrocardiogram changes, despite negative LCA results after an intracoronary infusion of nitroglycerin (NTG). Arrows indicate coronary spasm.

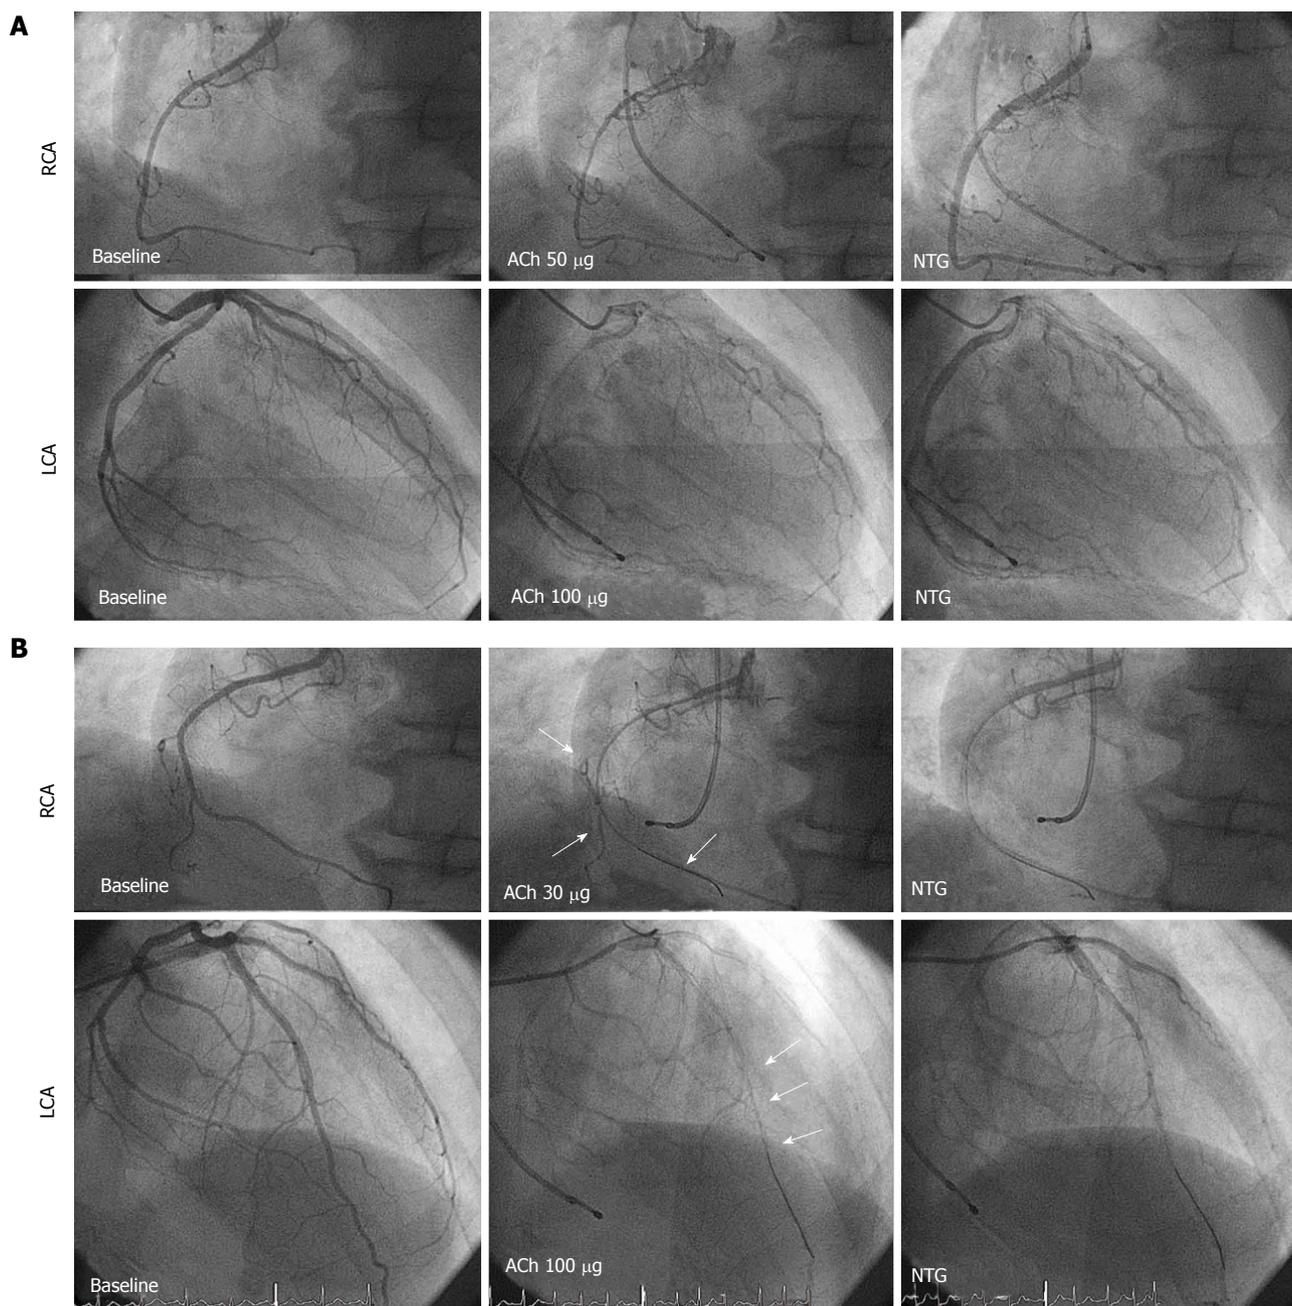

chest pain at rest 3 years later, when she presented at our institution for the second SPT. The second SPT showed negative RCA results after an intracoronary infusion of 50 µg ACh, and severe vasoconstriction at the distal LAD without chest symptoms and ECG changes after an intracoronary infusion of 100 µg ACh (Figure 4B). At the time, the Pa/Pa decreased from 0.90 at baseline to 0.73 after the ACh infusion. Based on the angiograms and pressure wire findings, she was diagnosed with VSA. She was discharged with CCB medication and has not experienced chest symptoms since.

In summary, there were three positive results from a second SPT (75%) of four cases that experienced chest symptoms and had negative results for the first SPT.

## DISCUSSION

In the present report, we present four patients who underwent a second SPT for the evaluation of chest symptoms, despite negative results from the first SPT. Of the four cases, there were three positive cases (75%). From these cases, we learned that SPT is not an absolute and final examination for diagnosing VSA.

SPT has been widely adopted as the final examination for the diagnosis of VSA. However, several factors may affect a positive SPT finding, such as VSA activity, time of day when the SPT is performed, and the duration of the withdrawal of vasodilators. VSA activity is variable, not only daily but also seasonally or yearly<sup>[3]</sup>, and this may contribute to the difference in SPT results. According to the time spent performing the SPT, it may

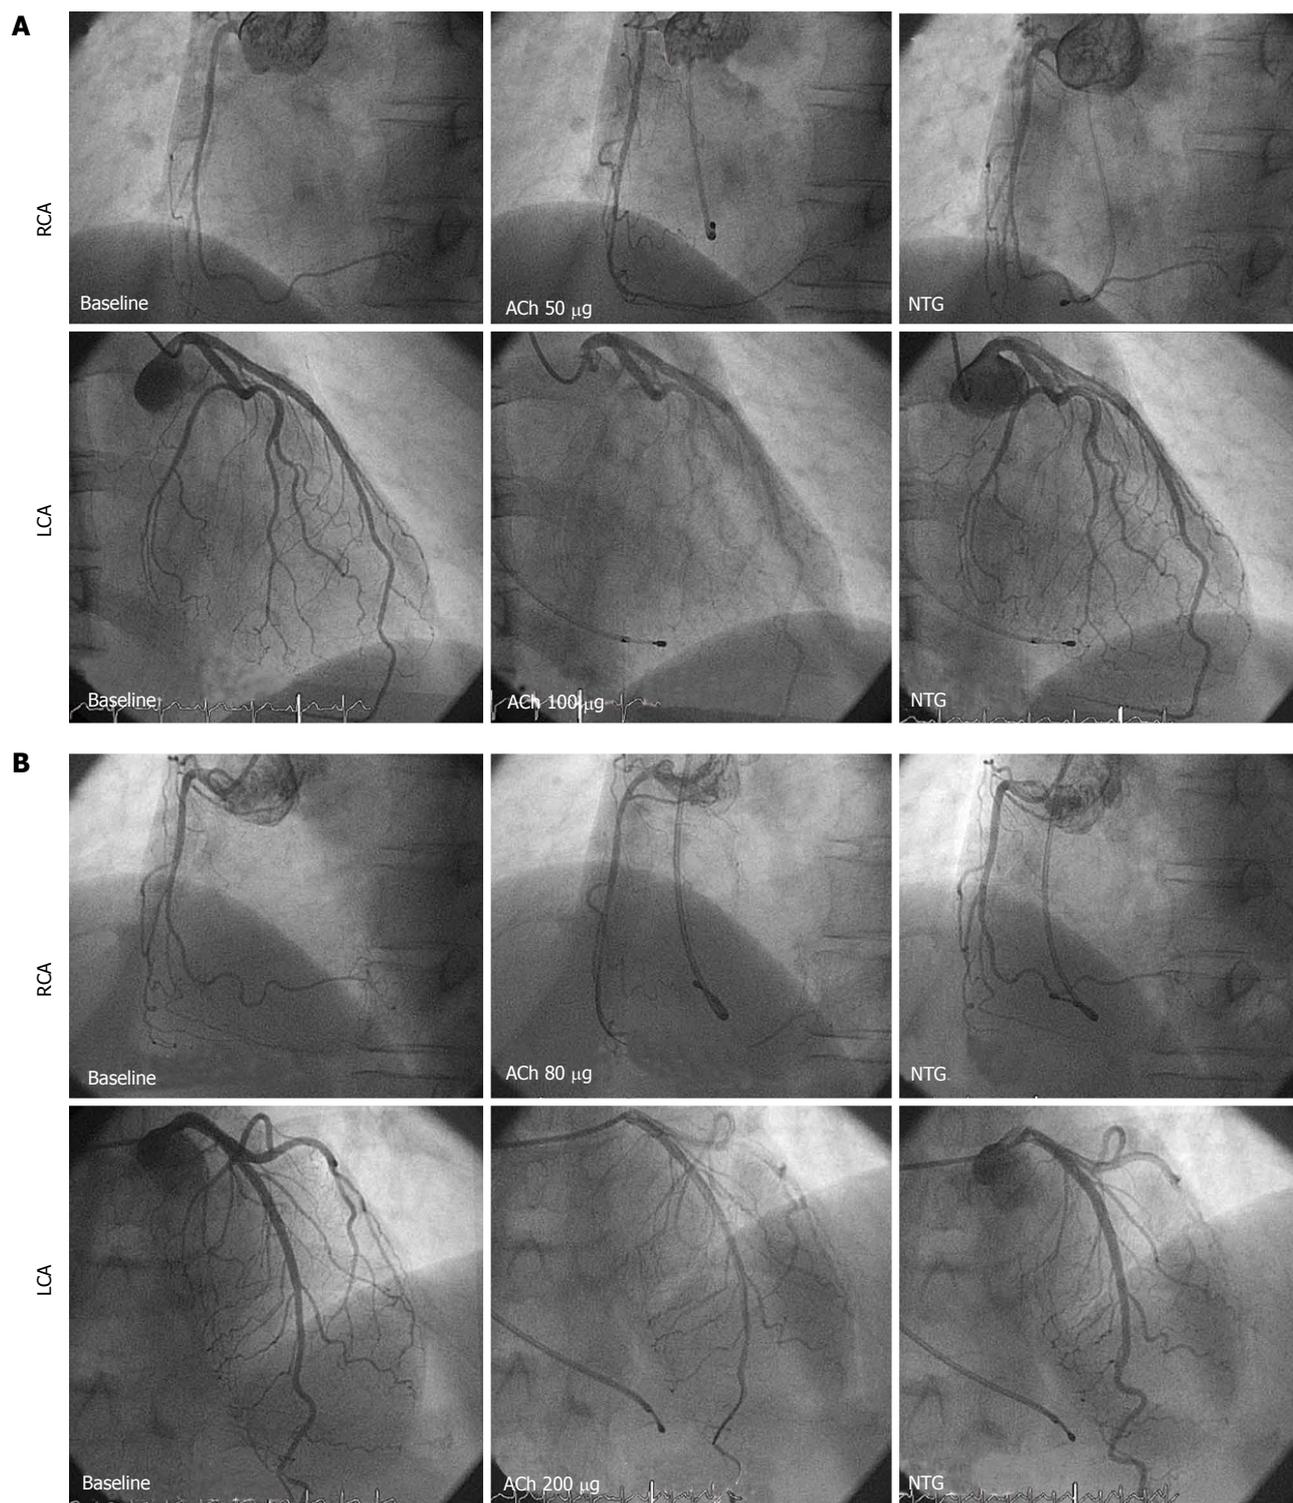

**Figure 2** Coronary angiograms during the first and second spasm provocation test in case 2. A: The first spasm provocation test (SPT) showed moderate vasoconstriction of the right coronary artery (RCA) after infusions of 50 µg acetylcholine (ACh) and moderate left coronary artery (LCA) vasoconstriction after infusions of 100 µg ACh. However, neither chest symptoms nor ST deviation of the electrocardiogram occurred during the SPT; B: The second SPT showed positive results with both the RCA after intracoronary infusions of 50 µg ACh and the LCA after infusions of 100 µg ACh, accompanied by the usual chest symptoms. Arrows indicate coronary spasms.

be ideal to perform the SPT when VSA angina attacks occur easily, particularly in the morning. However, at our institution, SPTs are performed only in the afternoon. In these four cases presented here, both the first and second SPTs were performed at the same time in the afternoon. For the withdrawal of vasodilators before SPT, vasodilators were withheld at least 48 h before SPT<sup>[3,6]</sup>; however, 2 d may be insufficient for the withdrawal of long-acting CCBs. This factor may contribute to the discrepancy of SPT results.

The SPT procedure is another important problem.

The maximal doses of 50 µg ACh for the RCA and 100 µg for the LCA, in general, are recommended<sup>[3]</sup>. However, SPT using higher ACh doses of 80 µg for the RCA and 200 µg for the LCA<sup>[7,8]</sup> and/or using a combination of ACh and EM<sup>[6,8]</sup>, have recently been recommended. The use of higher ACh doses and/or a combination of ACh and EM may decrease the number of incomplete SPTs. In case 3, we judged the results as negative after higher ACh intracoronary infusion doses for the second SPT. To deny the possibility of VSA, it may be ideal to perform the SPT using higher

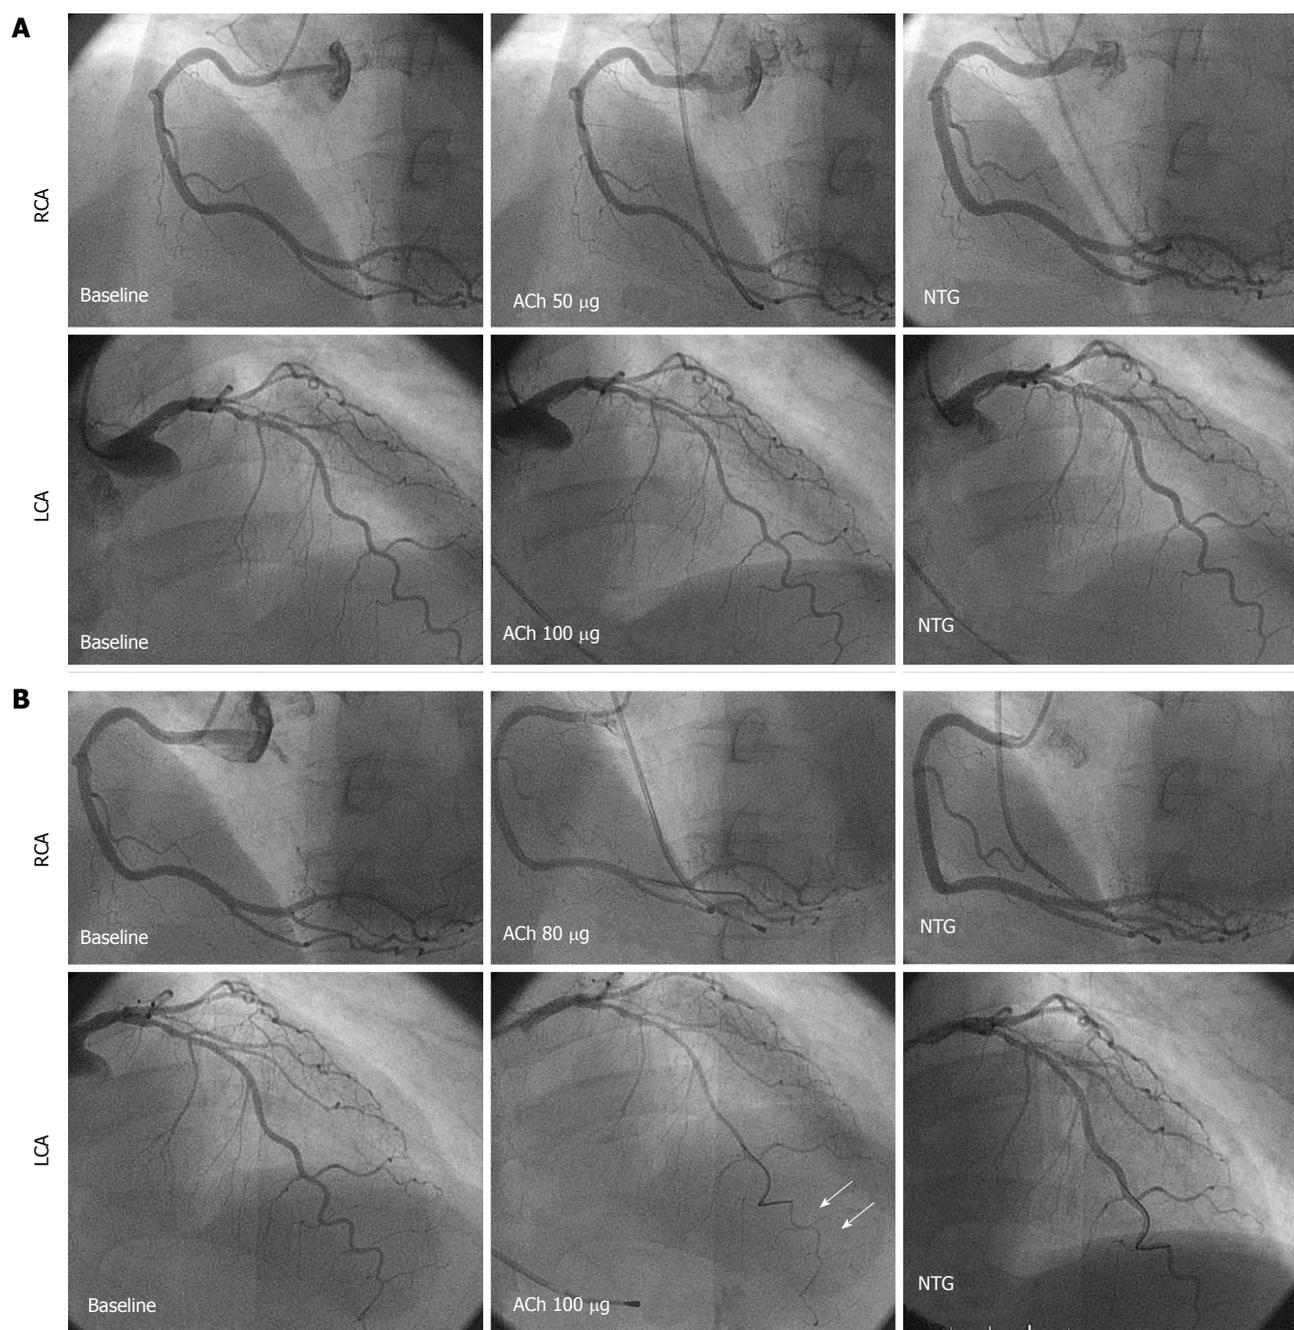

**Figure 3** Coronary angiograms during the first and second spasm provocation test in case 3. A: The first spasm provocation test (SPT) showed negative right coronary artery (RCA) results after an intracoronary infusion of 50 µg acetylcholine (ACh) and of the left coronary artery (LCA) after an intracoronary infusion of 100 µg ACh; B: The second SPT also showed negative RCA results after an intracoronary infusion of 80 µg ACh and of the LCA after an intracoronary infusion of 200 µg ACh.

concentrations of ACh. In addition, we used a pressure wire in all four cases. Using a pressure wire in SPT may be useful for diagnosing VSA<sup>[9]</sup> because the presence of myocardial ischemia can be detected promptly when the Pd/Pa is continuously monitored. Although an SPT

using a pressure wire is not always recommended in all patients, this technique may provide additional information for VSA diagnosis and may, therefore, be useful for the second SPT.

In our cases shown here, there were the gaps of 3 to

**Figure 4** Coronary angiograms during the first and second spasm provocation test in case 4. A: The first spasm provocation test (SPT) showed negative right coronary artery (RCA) results after an intracoronary infusion of 50 µg acetylcholine (ACh) and of the left coronary artery (LCA) after an intracoronary infusion of 100 µg ACh; B: The second SPT showed negative RCA results after an intracoronary infusion with 50 µg ACh, and severe vasoconstriction at the distal left anterior descending coronary artery, after an intracoronary infusion of 100 µg ACh. Arrows indicate coronary spasms.

4 years between the first and second SPT. During these periods, vascular dysfunction and/or atherosclerotic changes were newly developed. Thus, we cannot deny the possibility that coronary spasticity emerges during such periods, leading to a positive result for second SPT despite a negative result of the first SPT.

Even when the SPT is negative, the diagnosis of VSA should be with clinical symptoms in consideration. In some cases, a second SPT may be needed to confirm the diagnosis of VSA. Cardiologists should keep these concepts in mind.

## COMMENTS

### Case characteristics

There are four patients who underwent a spasm provocation test (SPT) for a second time to evaluate chest symptoms despite negative results for the first SPT.

### Clinical diagnosis

Vasospastic angina, which was diagnosed with the second SPT.

### Differential diagnosis

Microvascular angina, chest pain syndrome and gastroesophageal reflux

disease.

### Laboratory diagnosis

All labs were within normal limits.

### Imaging diagnosis

In 3 of 4 patients, the second SPT showed positive results with the angiographical coronary vasoconstriction, accompanied by usual chest symptoms and reduced intracoronary pressure measured with a pressure wire and/or ischemic changes of the electrocardiogram (ECG).

### Treatment

Vasodilators, including calcium-channel blockers, were administered in 3 patients who had positive results in the second spasm SPT, and analgesics and anti-depressive medication were administered in 1 patient with a negative result for the second SPT.

### Related reports

There are many case reports and studies of the spasm provocation test; however, this is the first report showing positive results for the second SPT despite negative results for the first SPT.

### Term explanation

Vasospastic angina (VSA) is characterized by the transient vasoconstriction of the epicardial coronary artery, leading to myocardial ischemia. It is the cause of not only rest angina but also exertional angina, acute coronary syndrome and ischemic cardiac arrest. VSA is diagnosed with chest symptoms and transient ischemic changes of the ECG, mainly at rest, but there are many cases in which the diagnosis is difficult when only based on chest symptoms and ECG monitoring. In such cases, an SPT using acetylcholine and/or ergonovine are performed and the results of the SPT are considered the final decision.

### Experience and lessons

Even when SPT is negative, the diagnosis of VSA should be made with the consideration of clinical symptoms. In some cases, a second SPT may be needed to confirm the diagnosis of VSA.

### Peer-review

This paper is interesting.

**ABOUT COVER**

Editorial Board Member of *World Journal of Cardiology*, Peter E Ong, MD, Senior Scientist, Department of Cardiology, Robert Bosch Krankenhaus, 70376 Stuttgart, Germany

**AIM AND SCOPE**

*World Journal of Cardiology (World J Cardiol, WJC*, online ISSN 1949-8462, DOI: 10.4330) is a peer-reviewed open access journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJC* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of cardiology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Cardiology* is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

### Abstract

The purpose of this paper is to summarize the need, feasibility, safety, legality, and ethical perspectives of pacemaker reutilization in low- and middle-income countries (LMICs). It will also describe, in-depth, Project My Heart Your Heart (PMHYH) as a model for pacemaker reuse in LMICs. The primary source of the discussion points in this paper is a collection of 14 publications produced by the research team at the University of Michigan and its collaborative partners. The need for pacemaker reutilization in LMICs is evident. Numerous studies show that the concept of pacemaker reutilization in LMICs is feasible. Infection and device malfunction are the main concerns in regard to pacemaker reutilization, yet many studies have shown that pacemaker reuse is not associated with increased infection risk or higher mortality compared with new device implantation. Under the right circumstances, the ethical and legal bases for pacemaker reutilization are supported. PMHYH is a proof of concept pacemaker donation initiative that has allowed funeral home and crematory directors to send explanted devices to an academic center for evaluation and re-sterilization before donation to underserved patients in LMICs. The time is now to pursue large-scale studies and trials of pacemaker reuse for the betterment of society. PMHYH is leading the way in the effort and is poised to conduct a prospective randomized, non-inferiority, multicenter study to confirm the clinical efficacy and safety of pacemaker

reuse, for clinical and legal support.

**Key words:** Pacing and clinical electrophysiology; Bradyarrhythmia; Disparity; Project My Heart Your Heart; Cardiovascular disease

## INTRODUCTION

The purpose of this paper is to summarize the need for, feasibility, safety, legality, and ethical perspectives of pacemaker reutilization in low- and middle-income countries (LMICs). It will also show Project My Heart Your Heart (PMHYH) as a model for pacemaker reuse in LMICs. The source of the discussion points in this paper is a collection of 14 publications<sup>[1-14]</sup> produced by experts at the University of Michigan and their collaborative partners.

## NEED

Cardiovascular disease (CVD) comprises about 30% of all deaths in the world, more than any other singular disease or condition<sup>[15]</sup>. CVD causes twice as many deaths as the major contemporary infectious diseases-human immunodeficiency virus/acquired immune deficiency syndrome, malaria, and tuberculosis<sup>[16]</sup>. Major advances in the science of medicine, and a greater emphasis on primary prevention have improved the morbidity and mortality attributed to CVD in the industrialized world<sup>[17]</sup>. A similar improvement has not taken place in LMICs. Of the 17.5 million deaths worldwide in 2012, which were due to CVD, over 75% occurred in LMICs<sup>[15]</sup>.

The disparity in CVD care between developed nations and LMICs is especially evident in the field of heart rhythm disorders. It is estimated that 1 million individuals die every year because they cannot access bradyarrhythmia therapy<sup>[18]</sup>. Pacemaker implantation, a common treatment for bradyarrhythmia, is strikingly uncommon where it is most needed - in LMICs. In 2005, 752 pacemakers were

implanted per million individuals residing in the United States and an average of 475 per million were implanted in European countries<sup>[19]</sup>. In the same year there were only 22, 14, and 4 pacemaker implantations per million in Thailand, Peru, and Bangladesh, respectively<sup>[19]</sup>. This disparity remained unchanged in a 2009 survey showing that while 767 pacemakers were implanted per million individuals in the United States and 782 per million in France, only 30, 5, and 4 per million were placed in patients in Peru, Bangladesh, and Pakistan, respectively<sup>[20]</sup>.

The World Bank defines LMICs as any nation, whose gross per capita national product is under United States \$12736<sup>[21]</sup>. Thus, not surprisingly, a major hurdle for patients in LMICs in need of a pacemaker is its prohibitive cost. A pacemaker generally costs between \$2500 and \$3000, with leads priced as high as \$800 and \$1000<sup>[5]</sup>. Implantable cardioverter-defibrillator (ICD) generators, used to treat life threatening ventricular tachy-arrhythmias, may cost between \$20000 and \$40000, with leads priced sometimes over \$10000<sup>[5]</sup>. It is often the case that the cost of a pacemaker or an ICD far exceeds the per capita annual economic output of individuals in LMICs<sup>[19]</sup>.

Founded in 1984, Heartbeat International is a charity, which aims to distribute pacemakers and ICDs approaching the use-by-date to a dozen or more recipient implantation centers in LMICs. Device manufacturers such as Medtronic, St Jude Medical, Boston Scientific, and more recently BIOTRONIK have supported this work. Since its beginnings, Heartbeat International has distributed over 14000 near-expired devices to needy patients<sup>[18]</sup>. Nonetheless, this supply of near-expired devices cannot possibly satisfy the enormous unmet need for pacemakers and ICDs in LMICs.

In the developed world, pacemaker implantation commonly results from sinus node dysfunction<sup>[22]</sup>. In LMICs however, the most common reason patients undergo pacemaker implantation is complete heart block<sup>[23,24]</sup>. This difference is in part due to greater prevalence of infectious diseases in LMICs vs developed nations. Chagas disease, for example, is caused by an infection with *Trypanosomiasis cruzi*, and is particularly common in Latin America<sup>[25]</sup>. Seventy-two percent of pacemaker recipients in a Brazilian study by Oliveira *et al.*<sup>[26]</sup> were seropositive for *Trypanosomiasis cruzi*. Also contributing to the great need in LMICs for cardiac implantable electronic devices - pacemakers and ICDs - is coronary artery disease, owing to increased tobacco use and an increased prevalence of hypertension and diabetes worldwide<sup>[14]</sup>.

## FEASIBILITY

Pacemaker reuse is a feasible and efficacious method to reduce the health disparity between developed economies and LMICs. The concept of pacemaker reuse has been considered for decades. For example, in the early 1990s, 5% of pacemakers implanted in Sweden were reused devices<sup>[27]</sup>. However, as Sweden joined the European Union, this practice ended. Due to the high demand for devices in LMICs, lack of sufficient supply

of expired devices, and financial constraints of LMIC citizens to afford new devices, pacemaker and ICD reutilization must be re-considered.

Postmortem pacemaker donation from the funeral industry is a potential source of devices harvested for the purpose of reutilization<sup>[1]</sup>. In the United States alone 225000 pacemakers are implanted each year<sup>[19]</sup>. And while in a recent pacemaker recipient registry the mean longevity of pacemakers was  $11.2 \pm 2.6$  years, patients receiving the devices often do not live that long<sup>[28]</sup>. Brunner *et al*<sup>[29]</sup> found that only 66% of pacemaker recipients are still alive at 5 years after implantation.

According to funeral directors, 85% of the deceased with pacemakers and ICDs are buried with their device<sup>[8]</sup>. Of those devices removed prior to burial, some are donated to charity to be reused, though many, indeed the majority, are treated as waste or abandoned<sup>[30]</sup>. Pacemakers must be extracted before the deceased are cremated due to the risk of device explosion, and according to The Cremation Association of North America, the rate of cremation in the United States is projected to rise from 39% in 2010 to 59% in 2025<sup>[31]</sup>. The vast majority (over 90%) of patients with pacemakers, when surveyed, were positively inclined to advance directives to donate their devices postmortem to poor patients in LMICs<sup>[32]</sup>.

In 2008, Detroit area funeral homes rendered 50 pacemakers to World Medical Relief<sup>[12]</sup>. Eighteen of these devices met the threshold of at least 70% of battery life remaining<sup>[12]</sup>. In a 2012 study, flyers were mailed to the Michigan Funeral Directors Association regarding device collection - and of the 3176 devices returned, 21% had acceptable battery life ( $\geq 75\%$  or  $\geq 4$  years estimated longevity)<sup>[1]</sup>. Thus, funeral homes and crematories represent a useful source for pacemakers and ICDs with adequate battery life to be reused in LMICs.

An additional source of pacemakers for reutilization is devices explanted in hospitals due to changing clinical indications. A study at The University of Michigan found that 52% of pacemakers, 54% of ICDs, and 48% of cardiac resynchronization therapy defibrillators explanted for clinical indications, other than elective replacement indicator, had sufficient battery life ( $\geq 48$  mo or  $> 75\%$  battery life) and appeared to function well<sup>[11]</sup>. According to the National Cardiovascular Data Registry, between 2010 and 2012, over 63500 devices were explanted annually in the United States<sup>[11]</sup>. If the yield nationwide were similar to that of The University of Michigan, perhaps as many as 13000 pacemakers and ICDs with sufficient battery could be harvested from this pool each year for donation<sup>[11]</sup>.

While supplying pacemakers from the funeral homes, crematories, and hospitals appears viable, obtaining leads from these sources is less so. Leads are generally not reusable for at least three reasons: (1) lead extraction would add a great deal of complexity to the donation process; (2) the integrity of most extracted leads would be inadequate for repurposing; and (3) cleaning and sterilization of the leads would be fraught

with significant technical challenges<sup>[5]</sup>. Thus, a patient in a LMIC would either have to receive a donated new lead or purchase a new lead himself or herself. Both of these are plausible options, especially because the cost of the leads is much less than the pacemakers or defibrillators. This might be possible with charitable donations from companies<sup>[5]</sup>. Also, given that at government-run facilities in LMICs, patients would not be required to pay for the implantation procedure, if lead donations were to fall short of the demand, a patient and his or her family could potentially pool resources to pay for a new pacemaker or ICD lead. This is especially true given that manufacturers in India currently produce a low-cost lead priced near \$200<sup>[3]</sup>.

## SAFETY

With regards to safety, there are two prime concerns that must be considered in regard to pacemaker and ICD reutilization: Infection and device malfunction. Adequate sterilization requires removal of all organic material. This task is made difficult by the composition and geometry of the epoxy header<sup>[5]</sup>. Nonetheless, several studies have shown that pacemaker reuse does not result in higher rates of infection or mortality when compared with new pacemaker surgery. Romero *et al*<sup>[33]</sup> described four trials enrolling a total of 603 subjects, in whom reuse did not result in greater infection risk. Similarly, Nava *et al*<sup>[34]</sup> reported comparable infection rates between new and refurbished pacemakers. Panja *et al*<sup>[35]</sup> found comparable mortality and infection rates for new and used pacemakers. In a meta-analysis of studies with hard outcomes of pacemaker reuse<sup>[4]</sup>, pooled patient data ( $n = 2270$ ) from 18 trials indicated that there was no significant difference in infection rate between new and reused pacemakers. This analysis did find that in 0.68% of cases, device malfunction became apparent at the time of pacemaker surgery or shortly thereafter, which admittedly is far higher than the risk of malfunction for a new pacemaker. While the studies comprised in the analysis were heterogeneous, and some important information may not have been universally reported, none of the papers indicated that the malfunction lead to patient death.

To minimize the risk of infection and device malfunction, comprehensive protocols for device cleaning, sterilization, and functionality testing must be developed. One such sterilization process, used successfully for pacemaker reutilization in previous studies<sup>[36,37]</sup>, is shown in Figure 1. Key areas of any proposed cleaning protocol must be the treatment of set-screws and header connections<sup>[6]</sup>. In prior reports, set-screw abnormalities developed during extraction led to most malfunctions in refurbished devices<sup>[8,34]</sup>. The complex process of device handling at the funeral home and shipment to a collection center exposes the pacemakers to an additional risk of damage, which may not be grossly evident. Thus it is imperative to assess the major pacemaker functions, so that no patient experiences critical device failure<sup>[30]</sup>.

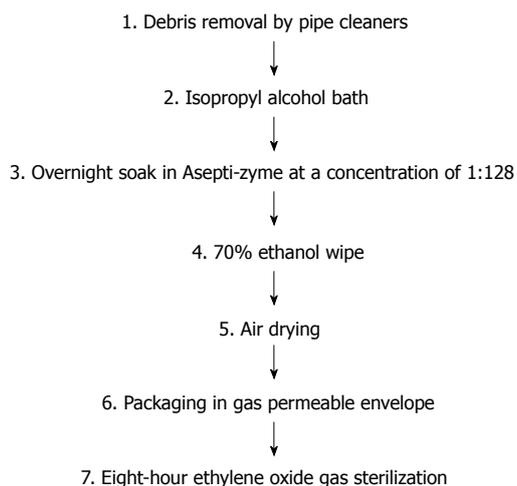

Figure 1 Pacemaker sterilization process.

Aspects of proper pacemaker interrogation are shown in Figure 2.

Anecdotal evidence of safety in pacemaker reutilization is strong. Twelve of the 50 devices donated to World Medical Relief from Detroit Metropolitan funeral homes, mentioned above, were offered to impoverished patients at the Philippine General Hospital (PGH) in Manila. The patients were screened by the local social services, which determined that these individuals were not in a position to pay the local market price for the pacemaker. There were no acute complications at the time of implantation, and a 2-mo follow-up showed that none of the pacemakers malfunctioned or became infected.

One powerful example of successful pacemaker reutilization is a patient at PGH. In a 2010 publication, Romero *et al*<sup>[2]</sup> detailed implantation of a pacemaker, which had been procured post-mortem, into a 65-year-old Filipino woman. This woman, a widow with two adult children, experienced third-degree heart block and was recommended to have a temporary pacemaker but ultimately refused a permanent pacemaker implantation due to lack of financial resources. She requested to be discharged, but returned one week later to the hospital with another syncopal episode. With her family unable to afford a new pacemaker, World Medical Relief donated a pacemaker obtained post-mortem with battery life of about 85%, and this reused pacemaker was implanted without complication. She showed no signs or symptoms of infection and her pacemaker had normal function 6-mo after the implantation.

## LEGALITY

The prime legal hurdle for pacemaker reprocessing in the United States is that the Food and Drug Administration (FDA) considers cardiac implantable electronic devices to be single-use devices (SUDs)<sup>[5]</sup>. Reuse of SUDs is highly regulated and while pacemaker reuse is technically possible, the United States FDA currently

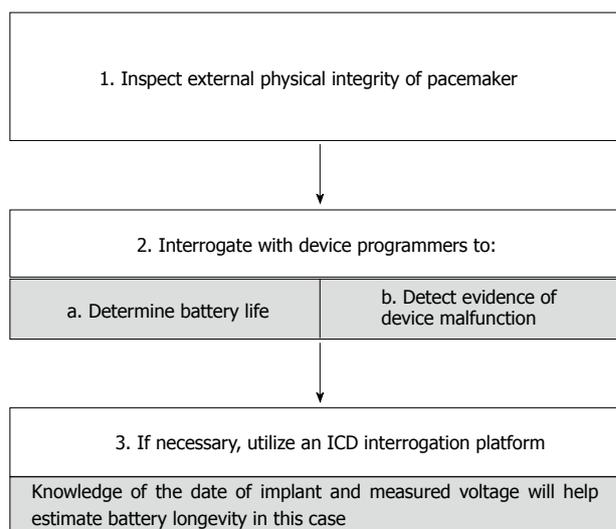

Figure 2 Aspects of pacemaker interrogation. ICD: Implantable cardioverter-defibrillator.

views it as “an objectionable practice”<sup>[38]</sup>. It is important to note that reuse of dialysis filters is commonplace in the United States and falls under stringent regulation<sup>[5]</sup>. For pacemaker reuse though, there exist other legal concerns to consider.

One is a concern among device manufacturers regarding a potential for legal action as a consequence of reused device failure. This sort of action is unlikely for two reasons. First, there are very few laws regarding SUDs in LMICs<sup>[5]</sup>. The United States is a highly litigious country, but the legal environment in countries where pacemakers would be reused is generally less susceptible to civil litigation<sup>[5]</sup>. Second, there is little tying device manufacturers to reuse of their products. Pacemakers are labeled as SUDs, warranties do not cover reuse, and none of the manufacturers sanctions pacemaker reuse. These two points notwithstanding, patients in LMICs receiving these devices must be made fully aware of the pacemaker origin, that the pacemaker no longer adheres to the original equipment manufacturer specifications, and that there may be rare risks of which we are not aware<sup>[5]</sup>.

Ownership of explanted devices, post-mortem or after an extraction due to new clinical circumstances, presents an additional legal obstacle. There are no United States federal statutes addressing the ownership of medical devices after the patient’s death or a generator replacement procedure<sup>[5]</sup>. So theoretically patients, physicians, device manufacturers, and insurers could all lay claim to explanted devices. In Sweden in the 1990s, when pacemaker reuse was frequent, ownership of an explanted device was understood to belong to the medical center, which had placed the device<sup>[5]</sup>. In Holland and Canada, devices have traditionally been property of the patients or their heirs<sup>[39]</sup>. Alternatively, the medical professional who implants pacemakers could insist that the devices be returned to him/her for analysis<sup>[5]</sup>. An agency within the United States Department of Health

and Human Services provides payment for the cost of the pacemakers and ICDs and associated implantation costs for a lion share of the elderly and the disabled, and it is conceivable that the payer might legally seek to own the product<sup>[5]</sup>. Device manufacturers may also lay claim through a contractual agreement that states the devices must be returned to the company after explantation for quality improvement<sup>[5]</sup>. Heart Rhythm Society endorses the return of devices to manufacturers for assessment and quality improvement<sup>[40]</sup>.

Ultimately, under the precept of patient autonomy, which is deeply embedded in the medical ethics, device removal from a deceased patient without express patient or next of kin authorization is probably objectionable<sup>[5]</sup>. While insurers may wish to lay claim, premiums and/or taxes paid by the patient fund these entities. Any other claims for the device would do not prevail over patient's property rights. In fact, the National Institutes of Health has embraced the notion of patient ownership<sup>[41]</sup>. An advance directive/pacemaker living will would officially outline patient wishes and authorize the funeral and crematory directors to retrieve pacemakers for donation or send them back to the manufacturer<sup>[5]</sup>.

## ETHICS

Health can be viewed through a prism of both private (individual) and societal (collective) good<sup>[13]</sup>, and as such must be considered from many ethical and moral perspectives. In considering pacemaker reuse, the first question to ask is "does donating a device not approved for use in the donor country create a double standard too great to be morally acceptable<sup>[13]</sup>?" The World Health Organization (WHO) maintains that the donated device quality should be high enough so that the donor would find it acceptable<sup>[42]</sup>. Refurbished pacemakers would certainly be deemed unacceptable by the WHO given that their use in the United States is not approved<sup>[13]</sup>.

Under egalitarian principles the ethics regarding pacemaker reuse is less clear. The most basic provision of health care to all is justified under most egalitarianism conceptions<sup>[13]</sup>. However, under egalitarian conceptions one would assert that there must be equal quality of healthcare resources available to all patients. This stance comports with the WHO and argues against pacemaker reutilization<sup>[13]</sup>.

Utilitarian theories in the health care domain emphasize the utility of being healthy<sup>[13]</sup>. Much like how food banks acquire donated food and deliver it for those in need despite the fact that some items may not be "readily marketable", pacemaker reutilization is consistent with the utilitarian concept given that the recipient benefit exceeds any harm to device donor<sup>[13]</sup>. Utilitarian theories often follow the rule of the greatest good for the greatest number of people<sup>[13]</sup>. In the context of pacemaker reutilization, the good that can be provided through device return for quality improvement must be considered and weighed against the good of reutilization. It can be argued however, that after a certain number

of devices are returned to the manufacturer, the devices remaining will provide the most benefit through pacemaker reutilization<sup>[5]</sup>.

According to the Difference Principle, proposed by Rawls<sup>[43]</sup>, inequalities should be arranged "to the greatest benefit of the least advantaged". In a 2010 WHO World Health Report<sup>[44]</sup>, authors noted that 100 million people are impoverished every year due to their inability to meet the costs of the health care they need. Whether the recipients of reutilized pacemakers are the least advantaged is debatable. However, if pacemaker reuse improves patient physical condition and well-being, it may likely be considered tolerable under the Difference Principle<sup>[13]</sup>. As with many of the other theories discussed, a thorough exploration of the benefits and detriments of pacemaker reutilization is needed for a complete reconciliation with the Difference Principle<sup>[13]</sup>.

The burdens, risks, and acceptable criteria of pacemaker reutilization must be considered as well. While the use of reprocessed pacemakers appears to be beneficial, measures need be in place to ensure that if a device malfunction or infection occurs, the implanting institution is capable of handling an emergency immediately and the patient is still able to receive a functioning device<sup>[13]</sup>. Nonmaleficence must be considered, as some patients may not be able to adhere to the recommended and important follow up with the implanting institution<sup>[5]</sup>. There is a potential of causing more harm than good with pacemaker reutilization if the patient is not able to access regular follow-up, and this risk requires careful examination<sup>[5]</sup>. Decisions on acceptable pacemaker condition, battery life, and resource distribution should be made collaboratively by all stakeholders - including members of the medical field and the lay public - to ensure equitable distribution of donated devices<sup>[13]</sup>. The risk of a "black market" for refurbished pacemakers is real and proper procedural strategies must be implemented to avoid foul play<sup>[5]</sup>. It is essential that there is a robust tracking system of the devices from the point of donation, through reprocessing, shipment, distribution to local implanting centers, and ultimately to the recipient patients. Careful patient screening for clinical and financial need can help ensure that the right resources get to the right recipient in the right place at the right time<sup>[5]</sup>.

Voltaire is often quoted "the best is the enemy of the good"<sup>[45]</sup>. In the face of no reasonable alternative, as is the case for many in the target population for pacemaker reutilization, the benefit provided through a donated refurbished device significantly outweighs the possible risks<sup>[7]</sup>. A re-sterilized pacemaker can enhance the quality of life or even preserve life with no loss of equivalent moral value; thus it is a practice that ought to be pursued<sup>[7]</sup>.

## PMHYH

PMHYH shows that pacemaker donation involving funeral homes and crematories and an academic medical center

**Table 1 Project My Heart Your Heart framework for device acquisition and performance measures**

1. ID device for potential reuse
2. Obtain signed consent from family
3. Train funeral directors in device explanation
4. Send device to center of excellence for investigation
  - a. Center does interrogation to assure adequate battery life and other performance-testing specifications
  - b. Use cutoff of  $\geq 70\%$  battery life
5. Devices that pass all quality-control measures undergo process to erase all patient identifiers
6. Sterilize and package
7. Send device to nonprofit charitable organization that specializes in delivering medical equipment for distribution to low- and middle-income countries
8. Device implanted with new unused leads

is a viable means of providing underserved patients in LMICs with much needed device therapy<sup>[6]</sup>. PMHYH was founded in 2010 by physicians within The University of Michigan Frankel Cardiovascular Center in collaboration with World Medical Relief, the Michigan Funeral Directors Association, and a company that recycles the metallic by-products of the cremation process (Implant Recycling, LLC)<sup>[14]</sup>. The goal of PMHYH is to create a blueprint for treating those with severe bradyarrhythmia in LMICs<sup>[9]</sup>.

Device acquisition is a key aspect of PMHYH. Specifically, funeral home industry is afforded access to an infrastructure of resources for obtaining consent from families of the deceased for pacemaker removal and an easy charge-free shipment of pacemaker after its removal<sup>[6]</sup>. As of 2013, PMHYH had collected over 10000 devices from funeral directors in the state of Michigan and 21% of the devices had  $\geq 75\%$  battery life or  $\geq 4$  years expected longevity<sup>[8]</sup>.

Any pacemakers acquired will be subject to stringent interrogation to inspect for evidence of damage, to ensure sufficient battery life, and to check other important performance measures. To satisfy device manufacturers, interrogation printouts, necessary for reuse, can be provided after PMHYH interrogation<sup>[5]</sup>. For manufacturers, this is certainly more information than when devices are buried with the deceased or discarded as medical waste<sup>[5]</sup>. Devices with sufficient battery life that pass interrogation will then undergo a validated cleansing and sterilization protocol.

Once sterilized, devices can be packaged and made ready for shipment. Device storage prior to shipment, interrogation, cleaning, and sterilization would all occur at a centralized center of excellence. Project MHYH estimates the cost of the entire collection, reprocessing, and distribution to be roughly \$75-\$100 per device. Assuming implanting physicians and hospitals are willing to provide their services free of charge or at an acceptably low rate, individual and corporate donations would allow the pacemakers and ICDs to be provided to patients without charge<sup>[6]</sup>.

In order for an institution to become a recipient of donated refurbished pacemaker or ICD, implanting hospitals will be required to provide some evidence of the existing infrastructure, where the implantation may take place, as well as physician and staff expertise in pacemaker and ICD implantation and related care<sup>[6]</sup>. This

may include a visit from physicians in the United States and other nations who are affiliated with PMHYH. Upon approval of the institution and arrival of the devices, local physicians will implant the refurbished devices with new leads into patients with the greatest need based on recipients' financial status and degree of conduction disease<sup>[9]</sup>. These same local physicians will then provide necessary follow-up services. This course of action taken by local physicians will aid in implantation success and patient health, and will reduce even further the risk for manufacturers of liability and potential legal action. The established relationships between PMHYH and UP-PGH in the Philippines and Indus Hospital in Karachi, Pakistan are good examples of the cross-institutional coordination necessary for pacemaker reuse and may prove valuable for future, large-scale implementation.

A web-based database would be created, allowing physicians to monitor patients with refurbished pacemakers<sup>[6]</sup>. This hopefully would restrain any inappropriate sale of refurbished pacemakers as well as provide a means (beyond routine follow-up) for communication between implanting physicians and patients in the case of device recall, or other emergent issues<sup>[6]</sup>.

A brief summary of the PMHYH model, from collection to implantation, is shown in Table 1<sup>[8]</sup>.

## CONCLUSION

Numerous studies show that the concept of pacemaker reutilization in LMICs is feasible. Most ethical concepts support pacemaker reuse. Rates of malfunction for reused devices have been found in prior studies to be no higher than that for new devices. The increased rate of malfunction found in the recent meta-analysis while concerning, is a risk believed to be acceptable for patients in dire need of bradyarrhythmia therapy in LMICs<sup>[10]</sup>. PMHYH is poised to conduct a prospective randomized, non-inferiority, multicenter study to confirm the clinical efficacy and safety of pacemaker reuse, for clinical and legal support.

There exists now a wonderful opportunity to positively affect countless lives in impoverished countries through pacemaker reutilization. A resource, which is currently not used, could enhance quality of life and extend life in LMICs and the time is now to pursue trials of pacemaker reuse for the betterment of society.

### Abstract

Incidental diagnosis of left ventricular systolic dysfunction

(LVD) is common in clinical practice. The prevalence of asymptomatic LVD (Ejection Fraction, EF < 50%) is 6.0% in men and 0.8% in women and is twice as common as symptomatic LVD. The timely and definitive exclusion of an ischemic etiology is central to optimizing care and reducing mortality in LVD. Advances in cardiovascular imaging provide many options for imaging of patients with left ventricular dysfunction. Clinician experience, patient endurance, imaging modality characteristics, cost and safety determine the choice of testing. In this review, we have compared the diagnostic utility of established tests - nuclear and echocardiographic stress testing with newer techniques like coronary computerized tomography and cardiac magnetic resonance imaging and highlight their inherent limitations in patients with underlying left ventricular dysfunction.

**Key words:** Coronary artery disease; Stress testing; Left ventricular dysfunction; Myocardial perfusion imaging; Dobutamine stress echocardiography

**Core tip:** Left ventricular systolic dysfunction is common in clinical practice and may be detected in asymptomatic patients. The timely and definitive exclusion of an ischemic etiology is central to optimizing care and reducing mortality. Clinician experience, imaging modality characteristics, cost and safety determine the choice of testing. We compare the diagnostic utility of established tests like nuclear and echocardiographic stress testing with newer techniques like coronary computerized tomography and cardiac magnetic resonance imaging. Due to limitations inherent to each non-invasive modality, oftentimes cardiac catheterization remains the definitive method to exclude coronary artery disease in patients with underlying left ventricular dysfunction.

## INTRODUCTION

Incidental diagnosis of left ventricular systolic dysfunction (LVD) is common in clinical practice. The prevalence of asymptomatic LVD (ejection fraction, EF < 50%) is 6.0% in men and 0.8% in women<sup>[1]</sup>. Asymptomatic LVD is at least twice as common as symptomatic LVD<sup>[2]</sup>. The diagnosis of LVD is usually made by demonstration of reduced systolic contractility and low EF by echocardiography. To determine whether LVD is due to coronary artery disease (CAD) is critical in the management of these patients as coronary revascularization has been shown to substantially reduce mortality in ischemic LVD. Modalities available for CAD diagnosis are either invasive coronary angiography (CA) or various non-invasive techniques such as dobutamine stress echocardiography (DSE), myocardial perfusion imaging (MPI) or single photon emission computerized tomography (SPECT), positron emission tomography (PET), cardiac magnetic resonance imaging (CMR) and coronary computerized tomography (CCT). Clinician experience, patient endurance, imaging modality characteristics, cost, safety and local availability determine the choice of testing.

ACC/AHA in 2005 recommended CA for patients with heart failure who have angina or significant ischemia; CA was felt to be reasonable in patients with chest pain that may or may not be cardiac in origin in whom coronary anatomy is not known, those with known or suspected CAD as well as patients with myocardial viability on noninvasive tests<sup>[3]</sup>. The 2013 revised guidelines finds it reasonable (class II a) to pursue either non-invasive imaging or CA in revascularization eligible patients<sup>[4]</sup>. CA is an invasive procedure with potentially serious complications such as atheroembolism, bleeding, renal failure, myocardial infarction, ventricular tachyarrhythmias, stroke and death. The low yield of CA in the setting of LVD further highlights the unfavorable risk benefit ratio. Therefore, a noninvasive method that can identify ischemic myocardial scarring or coronary luminal narrowing would be ideal in this setting. This would reduce the number of unwanted CA in patients with a truly non-ischemic cardiomyopathy. On the other hand, importantly, an ischemic etiology for cardiomyopathy can be missed when relying solely on non-invasive tests. In patients undergoing cardiac transplantation, severe CAD was found in all patients with a pretransplant diagnosis of ischemic cardiomyopathy (57 percent of a total 112 patients); unexpectedly at the time of transplant, severe CAD was also found in 9 of 38 patients previously thought to have idiopathic dilated cardiomyopathy (DCM) and 3 of 4 with presumptive alcoholic cardiomyopathy<sup>[5]</sup>.

DSE and MPI are commonly used modalities for evaluation of CAD. Both have proven to be clinically useful in large series, are widely available and provide prognostic information as well. Despite the high sen-

sitivity and specificity reported with these tests over the last 2 decades, clinicians still have to deal with ambiguous test results when evaluating systolic heart failure patients. Available literature suggests that the sensitivity and specificity of non-invasive methods ranges between 80%-95%; this implies that the etiology of cardiomyopathy may be misdiagnosed in approximately 1 out of every 10 patients. Myocardial perfusion using newer imaging modalities like CMR and PET provide physiological data similar to DSE and SPECT while CCT predominantly provides anatomical information along the lines of invasive angiography. In this review, we will focus specifically on CAD detection in patients with LVD; role of imaging in LVD associated with myocarditis or specific cardiomyopathies like tachycardia induced cardiomyopathy, peripartum cardiomyopathy and stress cardiomyopathy are beyond the scope of this review.

## LITERATURE SEARCH

We performed a search of MEDLINE, PUBMED, SCOPUS, Clinical trials.gov and The Cochrane Library from January 1975 through Dec 2015. We set no geographic or language restrictions. To increase yield, we also searched the references of all the retrieved manuscripts and review article. MeSH terms used were Coronary Artery Disease; Ventricular Dysfunction, Left; Magnetic Resonance ImagingCine; Computerized Tomogram, Echocardiography, Stress; Dobutamine; Positron-Emission Tomography; Tomography, X-Ray Computed; and Tomography, Emission-Computed, Single-Photon.

After extensive review it was noted that though modalities like DSE, SPECT, PET and magnetic resonance imaging (MRI) have been extensively studied and written about as regards to assessment of viability in patients with cardiomyopathy, recent published literature is scant specifically with diagnosis of CAD in these patients. A few recent reviews extensively discuss specific technical aspects<sup>[6,7]</sup>. We present our review highlighting the limited literature specifically pertaining to diagnostic accuracy of various cardiac imaging modalities in left ventricular (LV) systolic dysfunction.

## DISCUSSION

### SPECT

SPECT allows direct assessment of myocardial perfusion. Parameters that factor into SPECT reporting are myocardial perfusion, wall motion abnormalities and LV ejection fraction. An inducible perfusion abnormality indicates impaired perfusion reserve which in turn corresponds to epicardial coronary obstruction.

Various studies have evaluated the utility of SPECT in detection of CAD. Bulkley *et al*<sup>[8]</sup> in 1977 reported that SPECT could reliably differentiate between ischemic and idiopathic cardiomyopathy obviating the need for cardiac catheterization. A similar conclusion was made by Tauberg *et al*<sup>[9]</sup> in 1993; based on the size of perfusion

deficit, they showed that large defects have 97% predictive value for ischemic cardiomyopathy and 94% predictive value for idiopathic cardiomyopathy, and could reliably differentiate the two entities<sup>[9]</sup>. In contrast, Dunn *et al.*<sup>[10]</sup> in 1982 reported lower accuracy (80%) for SPECT in differentiating between the two entities. Moreover, only complete perfusion defects indicated CAD in this study; partial perfusion defects as well as reversible defects were seen both in CAD as well as DCM. A study by Wu *et al.*<sup>[11]</sup> in 2003 reported that SPECT was only of modest value to distinguish between ischemic and idiopathic cardiomyopathy and concluded that SPECT cannot be relied upon in an individual patient to differentiate the two entities. Overall, the existing literature points to a high sensitivity for SPECT in CAD detection (nearly 100% in some published studies) while specificity on average is only about 40%-50% in LVD patients<sup>[12-15]</sup>.

### Limitations of SPECT

Although individual studies report high diagnostic accuracy for detecting CAD, SPECT has limitations specific to prior LVD that impact reliability. Regional wall motion abnormalities may point to CAD if located in particular coronary distributions. However, in a study of 50 DCM patients, 64% had regional wall motion abnormalities<sup>[16]</sup>; other studies report the presence of regional wall motion abnormalities in 30%-50% of patients with DCM<sup>[17-19]</sup>. Thus, regional wall motion abnormalities do not automatically imply an ischemic etiology for the cardiomyopathy.

Reversible myocardial perfusion defects are traditionally considered specific for ischemia. However reversible perfusion defects can occur in dilated cardiomyopathy as well. In one study, complete perfusion defects in thallium redistribution studies appeared to imply an ischemic etiology but was seen in only a few patients<sup>[11]</sup>; the key finding in this study was that partially reversible defects occur in both DCM and ischemic cardiomyopathy when the LVD is severe (EF in the 25% range). In most instances, there is overlap of perfusion abnormalities between DCM and ischemic cardiomyopathy (even when large or reversible perfusion defects are present), thereby limiting the role of SPECT in the setting of LVD.

There are several possible reasons for the presence of perfusion defects in DCM. Structural changes in the myocardium of DCM patients like fibrosis and scarring could account for fixed perfusion defects<sup>[19]</sup>. Dilatation of ventricle and abnormal cell membrane permeability could lead to variable radioactive tracer uptake and redistribution. Stress testing induced LV geometry changes are also known to cause reversible defects in DCM<sup>[20]</sup>. Exercise induced coronary spasm<sup>[21]</sup>, mitral valve prolapse<sup>[22]</sup>, and aortic stenosis<sup>[23]</sup> have been associated with SPECT abnormalities. Clinicians should consider the role of these confounders while interpreting SPECT results.

In a given patient with LVD, DCM is likely if SPECT shows normal perfusion and global (*i.e.*, non-regional)

systolic dysfunction. However, if reversible defects are detected, especially in coronary territories, possibility of CAD remains high<sup>[24]</sup>. Another important concern in patients with severe LVD is balanced ischemia. Severe left main or triple vessel disease could cause equal reduction in tracer uptake in all major segments. As SPECT does not involve absolute quantification of tracer uptake, this matched perfusion defect in multiple territories appears as "normal" in this qualitative comparison of segments relative to each other<sup>[25]</sup>. In patients with balanced ischemia, diffuse ST depression during stress, subtle perfusion defects and transient cavity dilatation (TID) may be the only clues for underlying severe CAD.

### DSE

In contemporary clinical practice, DSE and exercise stress echocardiography play a major role in detection of CAD and risk stratification. A graded dobutamine infusion starting at 5 mg/kg per minute and increasing at 3-min intervals to 10, 20, 30 and 40 mg/kg per minute is the standard for dobutamine stress testing<sup>[26]</sup>. If LVD is known to be of ischemic etiology, presence of myocardial viability and the probability of recovery after revascularization can be reliably predicted based on demonstrating contractile reserve with low dose dobutamine stress testing. There is a paucity of literature for exercise stress echocardiography in LVD.

Geleijnse *et al.*<sup>[27]</sup> reported the sensitivity, specificity and accuracy of DSE for detection of CAD to be 80%, 84% and 81% respectively. In a study by Marcovitz *et al.*<sup>[28]</sup>, DSE had 96% sensitivity and 66% specificity for detection of CAD based on resting or inducible wall motion abnormalities. Similarly, in a study evaluating chest pain, Hennesse *et al.*<sup>[29]</sup> showed that the overall sensitivity and specificity of DSE were 82% and 65% respectively: Positive and negative predictive values were 89% and 51% respectively. In a recent meta-analysis of 32 studies, DSE had a higher sensitivity (94% vs 75%,  $P < 0.001$ ) and lower negative likelihood ratio (0.21 vs 0.47,  $P < 0.001$ ) compared to SPECT for detection of left main or triple vessel disease<sup>[30]</sup>. These studies were performed predominantly in patients with preserved cardiac function.

Few DSE studies have been specifically performed in patients with LVD. One study by Jong *et al.*<sup>[31]</sup> showed that most of the patients with DCM were found to have an abnormal regional myocardial contractile response to dobutamine. Cohen *et al.*<sup>[32]</sup> reported in a study that although dobutamine had a reasonable specificity and positive predictive value, it lacked sensitivity in diagnosis of CAD in DCM patients. Sharp *et al.*<sup>[33]</sup> reported that using the change in global wall motion score index from low to peak dose, DSE had a sensitivity of 83% and a specificity of 71% for detection of CAD. In one study, changes in left ventricular geometry as seen in patients with DCM can lead to false positive and false negative results in approximately 22% patients, hence reducing the accuracy of DSE<sup>[34]</sup>. Vigna *et al.*<sup>[35]</sup> showed that

although DSE has a specificity of 96% it has a lower sensitivity of 80% in diagnosis of CAD in patients with DCM.

### **Limitations of DSE**

Similar to SPECT, the reliability of DSE for CAD detection remains a challenge in the setting of LVD. Coronary territory specific hypokinesia, characteristic thinning and scar related hyperechoic signals would help confirm an ischemic etiology. When baseline LVD is significant with predominantly global hypokinesia, lack of response to dobutamine could mean a poor contractile reserve and not necessarily ischemia. On the other hand, some regional variability in improved contractility may be due to endothelial dysfunction, microvascular abnormalities or focal fibrosis. These factors together with increased wall stress may lead to a reduced myocardial perfusion reserve and wall motion abnormalities in the absence of CAD. Segmental wall motion abnormalities and abnormal contractile response that could be interpreted as ischemia or hibernation are common in patients with DCM despite the absence of CAD<sup>[36]</sup>. Finally, DSE is an observer and patient dependent procedure, the accuracy of which depends on the experience of the interpreter as well the acoustic windows available during stress testing.

Not much data is available comparing the accuracy of SPECT and DSE in detection of ischemia in patients with prior LVD. There are multiple studies comparing these modalities in patients with preserved cardiac function and a pooled analysis concluded that MPI was more sensitive compared to DSE (84% vs 80%) but DSE was more specific (86% vs 77%)<sup>[37]</sup>. The accuracy for both modalities is likely to be significantly lower in patients with LVD and dilated hearts.

### **CCT**

Many new techniques are clinically useful in LVD providing information about etiology, ischemia and prognosis. Prominent among them are coronary computed tomography (CT) and cardiac magnetic resonance imaging (MRI). Currently 64-slice CT is considered the minimum standard for evaluation of coronary stenosis. In a study using 64-slice CT, the accuracy, sensitivity, specificity, positive and negative predictive value were found to be 95%, 90%, 97%, 93% and 95% respectively for identifying ischemic cardiomyopathy<sup>[38]</sup>. Another new study also using 64-slice CT showed sensitivity, specificity, positive and negative predictive values of 96%, 99%, 94%, and 100% respectively for detection of > 70% coronary stenosis in patients with cardiomyopathy of unknown etiology<sup>[39]</sup>. Compared to CA, CT technology has advanced rapidly with 256- and 320-slice CT becoming available in many centers; it is likely that these newer scanners will provide better results. Thus, CCT is a non-invasive alternative to CA in patients with LVD for detection of CAD; however, CCT in its current state cannot overcome the inherent limitation of luminography, *i.e.*, ability to provide only coronary anatomic

information. Detection of atherosclerosis or stenotic lesions may not prove causality in LVD. Active research is underway to test the feasibility of ischemia detection simultaneously using myocardial perfusion CT.

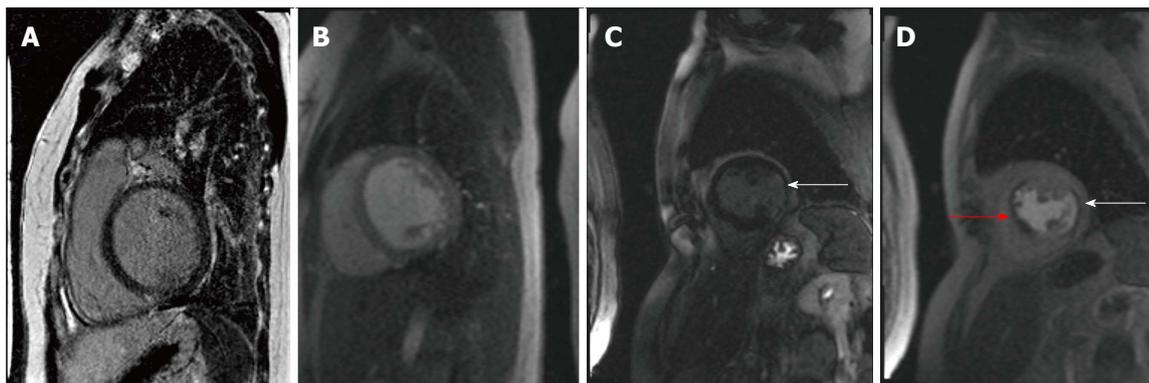

### **CMR**

In evaluation of patients with LVD, CMR has distinct advantages over other modalities. Delayed enhancement CMR is the only technique that is able to directly visualize myocardial infarction *in vivo*. Subendocardial and transmural hyperenhancement corresponding to coronary perfusion territories is observed in CAD compared to mid-myocardial and epicardial hyperenhancement that may be found in non-ischemic cardiomyopathies<sup>[40]</sup>. Delayed enhancement CMR has 40 times higher spatial resolution compared to nuclear imaging<sup>[41]</sup>; it can detect small subendocardial infarcts that are likely to be missed by nuclear imaging<sup>[42]</sup>. CMR can also help in identifying the specific etiology of DCM<sup>[40]</sup>.

CMR is now considered as an effective alternative to CA for CAD diagnosis in patients with heart failure (Figure 1, illustrative images). In one study, delayed enhancement CMR was shown to have sensitivity and specificity comparable to CA in differentiation between ischemic and non-ischemic cardiomyopathy<sup>[43]</sup>. In a recent study, it was named as a noninvasive gatekeeper to CA due to its accuracy and cost-effectiveness; delayed enhancement CMR had a sensitivity of 100%, specificity of 96%, and diagnostic accuracy of 97% for CAD detection, which were equivalent to CA<sup>[44,45]</sup>. One study clearly showed that the absence of CAD type hyperenhancement can reliably exclude myocardial infarction or severe CAD in patients with LVD and may obviate the need for CA<sup>[46]</sup>. With high sensitivity and specificity, CMR is now considered the gold standard for differentiation of ischemic and non-ischemic cardiomyopathy<sup>[47]</sup>.

### **PET**

PET imaging can help determine if CAD is the etiology of LVD based on sequential Perfusion-Metabolic scan using flow tracer N-13 Ammonia (N-13 NH<sub>3</sub>) followed by metabolic tracer F-18 2 fluorodeoxyglucose (FDG). Two techniques have traditionally been used for reading PET scans: Visual analysis and Circumferential Profile Analysis<sup>[48]</sup>. On Visual analysis it was observed that patients with DCM had a homogenous distribution of blood flow on the N-13 NH<sub>3</sub> and glucose metabolism on FDG in contrast to patients with CAD who exhibited LV segments with discrete blood flow reduction and enhanced or concordantly reduced glucose utilization. On Circumferential Profile Analysis ICMP patients had a regional reduction in N-13 NH<sub>3</sub> Myocardial uptake<sup>[49]</sup>. DCM patients with left bundle branch block demonstrate selective uptake of FDG in the septum resulting in false positive results. PET imaging has limitations, including assumption of uniformity of myocardial thickness and decreased spatial resolution. Patchy fibrosis in DCM can falsely resemble a CAD pattern. The most important

**Figure 1** Two patients underwent cardiac stress magnetic resonance imaging for evaluation of significant left ventricular dysfunction systolic dysfunction. Patient 1 with Idiopathic dilated cardiomyopathy, EF 30%: Panel A shows post gadolinium contrast images with absence of delayed enhancement in the left ventricular myocardium and Panel B shows lack of perfusion defect with adenosine stress imaging. Patient 2 with Ischemic cardiomyopathy, EF 15%: Panel C shows subendocardial delayed enhancement in the inferolateral wall (arrow) and Panel D shows stress perfusion defect in the anteroseptum (red arrow) consistent with ischemia and another matched perfusion defect caused by the inferolateral infarction (arrow).

**Table 1** Comparative analysis of the sensitivity, specificity and diagnostic accuracy for coronary artery disease detection using various imaging modalities<sup>1</sup>

Modality	Sensitivity	Specificity	Positive predictive value	Negative predictive value	Diagnostic accuracy
SPECT	80%-100%	40%-50%	90%-95%	90%-95%	75%-80%
DSE	80%-85%	60%-80%	80%-90%	45%-60%	75%-80%
PET	85%-90%	80%-85%	85%-90%	80%-95%	80%-85%
CCT	70%-90%	85%-90%	90%-95%	90%-95%	90%-95%
CMR	95%-100%	90%-95%	90%-95%	90%-95%	95%-100%

<sup>1</sup>This data is limited as it includes both patients with and without left ventricular dysfunction. DSE: Dobutamine stress echocardiography; SPECT: Single photon emission computerized tomography; PET: Positron emission tomography; CCT: Coronary computerized tomography; CMR: Cardiac magnetic resonance imaging.

limiting factor is cost and availability. In most centers, PET is thus used for viability assessment in LVD patients to determine revascularization suitability after CA quantifies CAD burden. Combined PET-CT imaging has shown promise in low risk patients<sup>[50]</sup> and in the future may provide the combined functional and anatomic information to obviate the need for invasive CA.

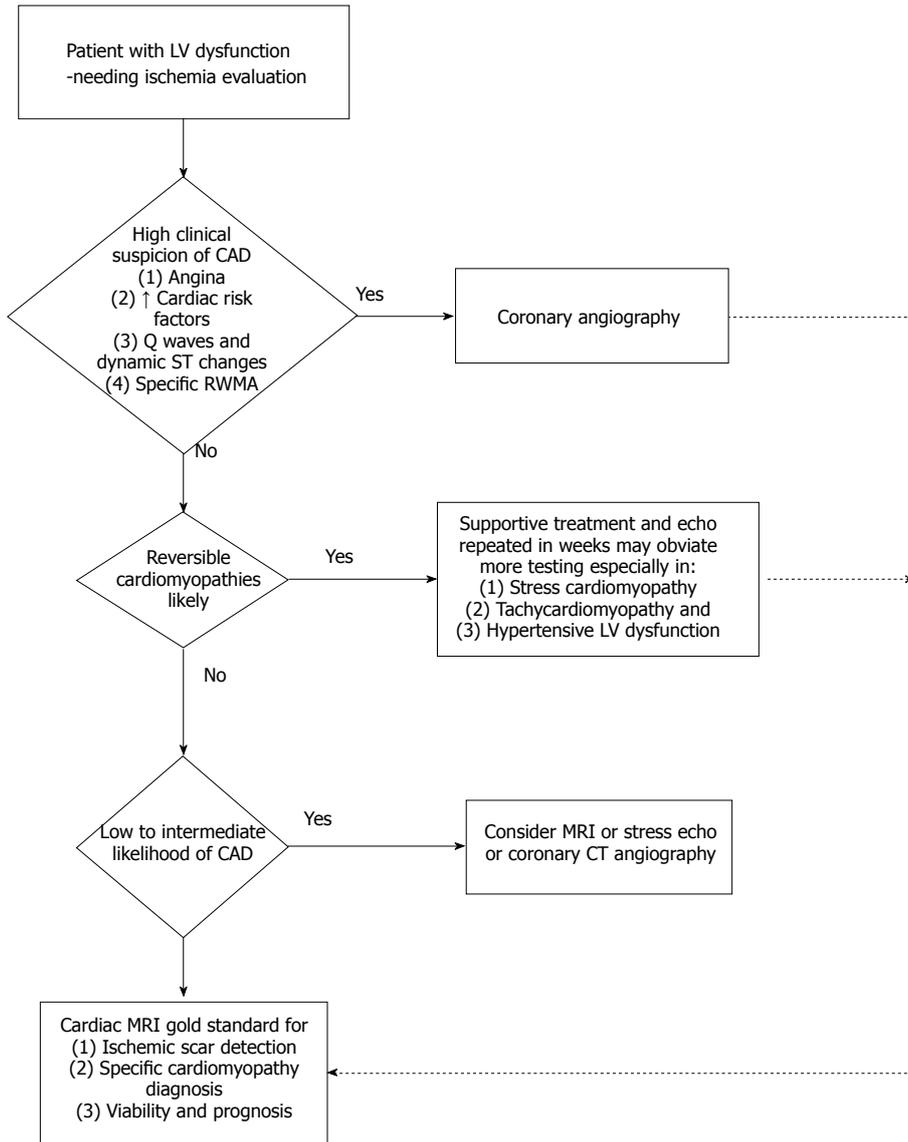

**Recommendations**

Identifying the etiology in patients with LVD is critical. The imaging modalities differ in their accuracy for CAD detection (Table 1). In patients with ischemic cardiomyopathy, adequate revascularization, especially if done early, significantly improves outcome. To achieve favorable risk-benefit ratio as well as cost effectiveness, we suggest a stepwise algorithm that incorporates patient demographics, clinical presentation and probability of CAD to determine the imaging approach for CAD detection. In patients with LVD and high index of suspicion for CAD, proceeding directly to CA would be prudent (Figure 2). When a reversible etiology such as stress cardiomyopathy or tachycardiomyopathy is likely, supportive treatment and repeat imaging in few weeks may obviate the need for invasive CA<sup>[51,52]</sup>. A sizeable proportion of patients with cardiomyopathy

of undetermined etiology have a low to intermediate probability of CAD; here various imaging modalities may serve as the gatekeeper for CA. In our opinion, the wide availability of DSE or SPECT makes these modalities reasonable in those with low likelihood of CAD. CCT is also appropriate in low to intermediate risk groups<sup>[53]</sup>. Our algorithm for evaluation of LVD patients is outlined in Figure 2. CMR, if available, would arguably be the ideal test in the setting of LVD to identify CAD scar pattern; at the same time, CMR may establish the specific etiology in several non-ischemic cardiomyopathies (Table 2). Finally, even in patients with CA proven CAD, the CMR scar pattern will help differentiate true ischemic cardiomyopathy (embolic or recanalized coronary lesions) from coincidental CAD.

**CONCLUSION**

Incidental LVD is not uncommon in clinical practice. Numerous imaging modalities are available to help establish the etiology and guide management in this population. When the suspicion of CAD is high, proceeding directly to CA would be of highest clinical value eliminating the need for noninvasive testing. In other settings where noninvasive testing would be appropriate, an algorithmic

**Figure 2** Algorithm for management of left ventricular dysfunction based on clinical presentation to optimize outcomes with cost-effective cardiac testing. LV: Left ventricular; CAD: Coronary artery disease; MRI: Magnetic resonance imaging; CT: Computerized tomography; RWMA: Regional wall motion abnormality.

**Table 2** Key advantages and limitations of various imaging modalities in detection of coronary artery disease in patients with left ventricular dysfunction

Modality	Advantages	Limitations
SPECT	Wide availability	Radiation May miss left main and triple vessel disease
DSE	Wide availability Evaluates valves and pericardium	Inter-observer variability Nonspecific response to inotrope in LVD
PET	Viability evaluation Quantifies myocardial blood flow	Radiation
CCT	Anatomic information like invasive angiogram	Radiation Iodinated contrast in renal dysfunction
CMR	Evaluates valves and pericardium Viability evaluation Determine etiology of DCM	Gadolinium in renal dysfunction

DSE: Dobutamine stress echocardiography; SPECT: Single photon emission computerized tomography; PET: Positron emission tomography; CCT: Coronary computerized tomography; CMR: Cardiac magnetic resonance imaging; LVD: Left ventricular systolic dysfunction.

imaging approach would optimize patient care.

### Abstract

Cardiovascular disease is a leading cause of morbidity and mortality globally. Early diagnostic markers are gaining popularity for better patient care disease outcomes. There is an increasing interest in noninvasive cardiac imaging biomarkers to diagnose subclinical cardiac disease. Feature tracking cardiac magnetic resonance imaging is a novel post-processing technique that is increasingly being employed to assess global and regional myocardial function. This technique has numerous applications in structural and functional diagnostics. It has been validated in multiple studies, although there is still a long way to go for it to become routine standard of care.

**Key words:** Feature tracking cardiac magnetic resonance imaging; Feature tracking; Myocardial tagging

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Feature tracking cardiac magnetic resonance imaging (FT-CMR) is novel non-invasive imaging technique that is being used commonly in assessment of different cardiac disorders. FT-CMR utilizes standard steady-state free precession sequences and is simpler, more practical and easily available. It has been validated in multiple studies. The objective of our literature review is to look at the current literature regarding validation, normal and abnormal values, advantages and limitations of FT-CMR in

research and clinical trials.

## INTRODUCTION

Cardiovascular diseases constitute a major global public health burden. It accounts for about one third (30.9%) of patient mortality worldwide<sup>[1]</sup>. Due to increasing economic burden and shrinking resources, there is a major shift in strategy towards prevention and early detection of cardiac disease worldwide.

Among non-invasive diagnostic techniques, cardiac magnetic resonance imaging (MRI) is a gold standard. Strain imaging on cardiac magnetic resonance imaging (CMR) through myocardial tagging was in vogue since the ground-breaking work of Zerhouni in 1988. Since then many imaging sequences have been designed to measure the global and regional function of myocardium. However, most of these sequences are fraught with fading of tag lines in diastole, long the breath-hold time which are cumbersome in acutely ill and advanced cardiac failure and those with coexistent pulmonary diseases.

Strain imaging using Echocardiographic measurements obtained using tissue Doppler is limited by noise interference and angle dependency. While speckle tracking has largely overcome these issues, it is often limited by image quality CMR with feature tracking is a novel technique which uses myocardial deformation for global and segmental functional analysis. Feature tracking uses different myocardial strain patterns including longitudinal, radial and circumferential strain measurements for global and segmental functional assessment<sup>[2]</sup>. Strain on feature tracking is not dependent on loading conditions, unlike ejection fraction, and it is actually a ratio of initial and final myocardial lengths during different portions of myocardial cycle. Strain is equal to  $L - L_0/L_0$ , where L is final length and  $L_0$  is initial length.

Strain is a measure of myocardial deformation, longitudinal strain is measured in long axis while circumferential and radial strains are measured in short-axis. As cardiac magnetic resonance feature tracking (CMR-FT) is less time consuming due to no prolonged post processing times involved, it may have a better future value in quick assessment of myocardial mechanics<sup>[2]</sup>. It has been well studied in last few years and it has shown to play a great role in the diagnosis of multiple cardiac conditions as detailed below. The purpose of our literature review was to assess its integration in routine clinical care for the assessment of myocardial function to avoid unnecessary invasive diagnostic, e.g., intravascular ultrasound and cardiac catheterization.

## VALIDATION OF CMR AS NOVEL IMAGING MODALITY

Feature-tracking (FT) is a novel technology which is used to calculate strain for the assessment of cardiovascular disease, is not a validated technique at the moment, against a standard myocardial tagging analysis for any strain parameter. It needs to be validated before incorporating it into routine clinical practice. We will compare CMR-FT with other diagnostic modalities such as echocardiogram to assess its equivalence vs superiority or inferiority. Echocardiographic measurements obtained using tissue Doppler imaging are limited by noise interference and angle dependency. While speckle tracking has largely overcome these issues, it is often limited by image quality. In order to label it as standard of care, we also need to look for inter study, inter and intra observer reproducibility of CMR feature tracking (Table 1).

Taylor *et al*<sup>[3]</sup> studied 20 healthy volunteers and measured myocardial strain using FT. They found FT highly reproducible within operators and needed a short analysis time of  $3 \pm 1$  min.

Augustine *et al*<sup>[4]</sup> used feature tracking in 145 healthy individuals to measure different myocardial deformation parameters including radial, circumferential and longitudinal strain, and segmental levels based on age and gender and recorded the normal values. They found these values to be similar when compared to prior studies based on age and gender. They also used myocardial tagging in 20 of these subjects to measure these same values and compared them with those obtained by feature tracking. Feature tracking measurements of circumferential but not longitudinal or radially directed global strain showed reasonable agreement with myocardial tagging and acceptable inter-observer reproducibility. Similarly, Schuster *et al*<sup>[2]</sup> studied feature tracking measurements in 20 healthy subjects with 2 sets of measurements, one at baseline and other after 4 wk. They found that FT-CMR had reasonable intra observer reproducibility in different groups of individuals. It was most reproducible for left ventricular circumferential strain measurements while it was least reproducible for right ventricular longitudinal strain.

Use of Feature tracking was not only studied in primary cardiovascular disease patients but was also used to study left ventricular radial and circumferential strain to assess anthracycline induced cardiotoxicity. Both circumferential and radial strain detected subclinical cardiac dysfunction in this cohort. Feature tracking was compared with harmonic phase imaging analysis (HAARP). Circumferential strain was found to be a robust and reproducible index in this study while radial strain did not show much promise<sup>[5]</sup>.

To assess the reproducibility of myocardial strain, FT was compared with tagging in a small patient cohort of left bundle branch block (LBBB) and hypertensive cardiomyopathy. It concluded that peak circumferential strain and time to peak circumferential strain are not good

Table 1 Validation studies at glance

Ref.	Technique compared	Cardiac disease	Population studied (n)	Results of validation
Taylor <i>et al</i> <sup>[10]</sup>	-	Healthy individuals	55	FT is highly reproducible within operators, requiring a short analysis time
Augustine <i>et al</i> <sup>[4]</sup>	Myocardial tagging	Healthy individuals	145	FT measurements of circumferential strain showed reasonable agreement with myocardial tagging
Schuster <i>et al</i> <sup>[2]</sup>	-	Healthy individuals	20	FT showing reasonable intra-observer reproducibility in different groups of individuals
Lu <i>et al</i> <sup>[5]</sup>	HAARP	Anthracycline induced cardiomyopathy	26	Circumferential strain was found to be a robust and reproducible index of myocardial deformation
Hor <i>et al</i> <sup>[7]</sup>	HAARP	Duchenne muscular dystrophy	233	Good correlation between CMR-FT and HAARP for the mean circumferential strain values
Morton <i>et al</i> <sup>[8]</sup>	-	Healthy individuals	16	FT had good inter-study reproducibility for global strain analysis
Kempny <i>et al</i> <sup>[9]</sup>	STE and simple EBD	ToF	25	Feature tracking showed better inter observer reproducibility for circumferential or radial left ventricular and longitudinal right ventricular global strain when compared to STE
Padiyath <i>et al</i> <sup>[10]</sup>	2D echocardiography	20 patients with ToF and 20 healthy controls	40	Reasonable agreement between FT and 2D echo in measurement of global circumferential strain and global longitudinal strain for the left ventricle
Harrild <i>et al</i> <sup>[12]</sup>	Myocardial tagging	HCM	24	Closer agreement between 2 modalities in measuring time to peak strain
Orwat <i>et al</i> <sup>[13]</sup>	Trans-thoracic echocardiogram with speckle tracking	HCM	40	Trans-thoracic echocardiogram with speckle tracking. They found decent agreement between left ventricular longitudinal strain measurements between the 2 modalities while the agreement for circumferential strain not encouraging

HCM: Hypertrophic cardiomyopathy; EBD: Endocardial border delineation; STE: Speckle tracking echocardiography; ToF: Teratology of Fallot; HAARP: Harmonic phase imaging analysis; CMR-FT: Cardiac magnetic resonance feature tracking; FT: Feature tracking; 2D: 2-Dimensional.

indices in this patient population. Although it was well designed study, but due to small sample size ( $n = 20$ ) it would be far from conclusive<sup>[6]</sup>.

Another well designed study on large cohort ( $n = 233$ ) Duchene Muscular Dystrophy (DMD) patients stratified into various groups based on EF and late gadolinium enhancement (LGE) after age and gender matching. There was a good correlation between CMR-FT and HAARP for the mean circumferential strain values ( $-13.3\% \pm 3.8\%$  for CMR-FT vs  $13.6\% \pm 3.4\%$  for HAARP) with an  $r = 0.899$ <sup>[7]</sup>.

Morton *et al*<sup>[8]</sup> imaged 16 healthy individuals with CMR feature tracking 3 times in a single day and different time points to look for inter-study reproducibility. They concluded that CMR-FT had good inter-study reproducibility for global strain analysis while it was poor for segmental strain. Though, they did not find any diurnal variation in strain measurements<sup>[8]</sup>.

Kempny *et al*<sup>[9]</sup> used feature tracking for biventricular myocardial function assessment in 28 patients of repaired Teratology of Fallot (ToF) and healthy 25 controls and compared it with speckle tracking echocardiography (STE) and simple endocardial border delineation (EBD). They found close agreement between right and left ventricular global strain. Inter observer agreement for features tracking and STE was moderate for longitudinal left ventricular global strain while feature tracking showed better inter observer reproducibility for circumferential or radial left ventricular and longitudinal right ventricular global strain when compared to STE. Feature tracking

showed poor reproducibility for regional strain. The relative systolic length change of endocardial border as measured by EBD was similar to feature tracking global strain<sup>[9]</sup>. Similarly studying similar population and comparing this novel technique with 2D echocardiography, Padiyath *et al*<sup>[10]</sup> studied myocardial mechanics in 20 patients with Teratology of Fallot and 20 healthy controls using 2D STE echocardiography and FT-CMR. They found reasonable agreement between the 2 modalities in measurement of global circumferential strain and global longitudinal strain for the left ventricle ( $9.5\%$  and  $16.4\%$  inter modality variability, respectively) while right ventricular global longitudinal strain had an inter modality variability of  $25.7\%$ . Also, the global radial strain measurements had high inter modality and inter observer variability<sup>[10]</sup>. When compared with 2D echocardiography for right ventricular strain assessment, CMR-FT showed reasonable agreement with 2D echo in these assessments<sup>[11]</sup>.

In hypertrophic cardiomyopathy (HCM) patients, feature tracking was compared with myocardial tagging in 13 normal subjects and 11 patients of HCM patients, showing closer agreement between 2 modalities in measuring time to peak strain while agreement was more modest in measuring magnitude of the peak strain<sup>[12]</sup>. Orwat *et al*<sup>[13]</sup> studied feature tracking myocardial measurements in 20 healthy volunteers (10 male, mean age  $24 \pm 3$  years) and 20 patients with HCM (12 male, mean age  $47 \pm 19$  years) and compared them with trans-thoracic echocardiogram with speckle tracking. They found decent agreement between left ventricular longitudinal

strain measurements between the 2 modalities while the agreement for circumferential strain and strain rate was not encouraging. There was high reproducibility for left ventricular peak global strain measurements as compared to strain rate<sup>[13]</sup>.

Validity of FT-CMR was also studied in patients with recent or past myocardial infarction patients. Gao *et al.*<sup>[14]</sup> examined 3 healthy controls and 41 patients with either recent or past MI to assess left ventricular strain and compared with DENSE [displacement encoding with stimulated echoes in cardiac functional magnetic resonance imaging (MRI)]. He found good agreement in peak circumferential and peak radial strain values in patient population although peak radial strain measurements in healthy patients was overestimated in healthy controls when using cine CMR as compared to DENSE<sup>[14]</sup>. Also in aortic stenosis patients ( $n = 30$ ), a reasonable agreement was found in deformation measurements as measured from myocardial strain using FT as compared to tagging technique<sup>[15]</sup>. In another study, Schneeweis *et al.*<sup>[16]</sup> measured circumferential strain by using speckle tracking echocardiography (STE), FT and myocardial tagging and compared these three modalities. They found that FT and Tagging had moderate agreement in global circumferential strain analysis while agreement was poor for segmental analysis. No agreement was found between CMR (FT and MT) based global and segmental circumferential strain measurements and ST based values<sup>[16]</sup>.

Anwar *et al.*<sup>[17]</sup> studied 15 single ventricle Fontan ("Fontan" is a procedure done in pediatric patients who have 1 functional ventricle when born) patients with FT and compared it with tagging. They found moderate agreement between these 2 modalities in the assessment of circumferential strain<sup>[17]</sup>.

## REFERENCE VALUES OF FT-CMR FOR NORMAL AND DISEASED PATIENTS

Feature tracking imaging could reliably be used to assess myocardial function in patients with early dysfunction. Multiple parameter datasets are available for radial systolic strain values, circumferential strain values, circumferential strain, longitudinal endocardial systolic strain, longitudinal strain and segmental reproducibility for systolic strain measurements<sup>[18]</sup>. Similarly, Taylor *et al.*<sup>[19]</sup> studied the values for feature tracking in a cohort of 108 cardiomyopathy patients and 55 normal healthy controls. Healthy controls ( $n = 55$ , age:  $42.9 \pm 13$  years, LVEF:  $70\% \pm 5\%$ , QRS:  $88 \pm 9$  ms) and patients with cardiomyopathy ( $n = 108$ , age:  $64.7 \pm 12$  years, LVEF:  $29\% \pm 6\%$ , QRS:  $147 \pm 29$  ms) underwent FT-CMR for the assessment of the circumferential uniformity ratio estimate (CURE) and radial uniformity estimate ratio (RURE) based on myocardial strain (both CURE and RURE: 0 to 1; 1 = perfect synchrony). CURE ( $0.79 \pm 0.14$  vs  $0.97 \pm 0.02$ ) and RURE ( $0.71 \pm 0.14$  vs  $0.91 \pm 0.04$ ) were lower in patients with cardiomyopathy than in healthy controls (both  $P < 0.0001$ ). CURE [area under the receiver-operator

characteristic curve (AUC): 0.96], RURE (AUC: 0.96) and an average of these [CURE: RURE atrioventricular groove (AVG), AUC: 0.98]. They concluded that measures like CURE and RURE provide absolute differentiation between patients with cardiomyopathy and normal healthy controls with a sensitivity of 90%, specificity of 98% at a cut-off of 0.89<sup>[19]</sup>. Buss *et al.*<sup>[20]</sup> and Shang *et al.*<sup>[21]</sup> measured reference values in 110 healthy adult patients and 115 healthy pediatric patients. Their work was based on the fact that some observational studies of left ventricular function in adults suggest that global longitudinal strain correlate with EF, and is superior to EF as a predictor of outcome. Also, Kadiyala *et al.*<sup>[22]</sup> measured values of myocardial strain in 60 normal subjects and tabulated them for reference.

### Features tracking algorithm

Proto-type software is TomTec (Diogenes Medical, Germany). Different algorithms are available for strain measurement. Elnakib *et al.*<sup>[23]</sup> suggested the algorithm shown in Table 2.

### Clinical applications of feature tracking

Assessment of left ventricular function is a key application of CMR. Feature tracking imaging is a fast and rapid method that provides an objective and reliable measurement of left ventricular function. CMR-FT is a novel promising technique to diagnose structural and functional heart disease. It provides a rapid a method to diagnose these conditions without long and watchful waiting processing times<sup>[3]</sup>. In 1 study<sup>[7]</sup>, analysis of a complete data set using Feature Tracking was quicker than by tagging ( $8.8 \pm 4.7$  min vs  $15.4 \pm 4.9$  min,  $P < 0.05$ ). It does not require any extra imaging sequences and can be applied to any imaging sequence.

**Structural heart disease:** In single ventricular patients, feature tracking could help to identify ventricular dysfunction based on specific type of defect present. Moore *et al.*<sup>[24]</sup> collected the data from 25 control subjects and 30 patients with single ventricle (right or left) and used feature tracking for mechanical dyssynchrony and strain analysis in these patients. They concluded that analysis of circumferential strain is abnormal in single ventricle patients despite normal ejection fraction<sup>[24]</sup>. In patients after repair of coarctation of aorta, FT can detect early systolic dysfunction. Kutty *et al.*<sup>[25]</sup> used FT to identify abnormal strain patterns as indication of early systolic dysfunction despite normal ejection fraction in 81 patients 10-13 years after repair for coarctation of aorta. It was noted that global longitudinal strain measurements were worse in the presence of left ventricular hypertrophy<sup>[25]</sup>. FT was found to be better, fast and reliable method in quantification of wall mechanics and strain after 10 healthy subjects were examined with CMR-FT to for quantitative wall motion assessment during intermediate dose dobutamine stress CMR<sup>[26]</sup>. In addition to diagnosing early cardiac dysfunction in structural heart disease patients, FT allows quantitative elaboration of myocardial tissue and blood flow<sup>[27]</sup>. Fifteen patients with

**Table 2 Feature tracking algorithm**

Algorithm	Strain estimation algorithm
Step 1	Wall borders segmentation Segment the LV wall from cine CMR
Step 2	For each image, find the centerline of the LV wall as follows Start with the inner border of the LV wall Solve the Laplace equation between the inner and outer wall borders to find the corresponding outer points to the defined inner points in step 2(a) Pick the points located equidistant from the corresponding point-pairs Form the centerline ( <i>i.e.</i> , mid-wall border) using a closed spline fit for the selected points
Step 3	Tracking For each two successive images, solve the Laplace equation between their respective inner borders, mid-walls, and outer borders Track the co-allocated points at the inner, mid-wall, and outer edges of the first image frame (defined in step 2) throughout the cardiac cycle
Step 4	Strain estimation Estimate the circumferential strains by tracking the change in distance between tracked points on the same border ( <i>i.e.</i> , inner, mid-wall, and outer borders) Estimate the radial strains by tracking the change in distance between radially oriented tracked points

CMR: Cardiac magnetic resonance imaging; LV: Left ventricle.

ischemic cardiomyopathy were enrolled in 1 study for viability assessment *via* feature tracking measurements. FT imaging was done both at rest and during low-dose dobutamine stress. Feature tracking was found to be a reliable method for quantitative assessment of myocardial viability in patients with ischemic cardiomyopathy<sup>[28]</sup>. Feature tracking was also useful in identifying higher indexes of left ventricular dyssynchrony which were associated with ventricular tachycardia and death in patients with repaired tetralogy of Fallot<sup>[29]</sup>. This technique was also used to study the impact of transcatheter pulmonary valve placement on biventricular strain and synchrony in patients with right ventricular outflow tract conduit dysfunction which showed improved right and left ventricular global strain and left ventricular synchrony, showing the value of feature tracking in this patient population<sup>[30]</sup>. Role of feature tracking in the diagnosis of muscular dystrophy associated cardiomyopathy has been evaluated in some studies. Rosales *et al.*<sup>[31]</sup> found the role of FT in diagnosis of Limb Girdle Dystrophy associated cardiac dysfunction including cardiomyopathy with systolic dysfunction, myocardial fibrosis and diastolic dysfunction.

**Ischemic cardiomyopathy:** Usefulness of FT is not only limited to structural heart diseases, it has been studied extensively in patients with ischemic cardiomyopathy secondary to coronary artery disease. In a study by Buss *et al.*<sup>[32]</sup>, FT was used in 74 patients with first STEMI 2-4 d after reperfusion. Circumferential strain analysis provided an objective method in the assessment of infarct size<sup>[32]</sup>. They found similar utility of FTI in another study of 54 patients with first time STEMI<sup>[33]</sup>.

**Non-ischemic cardiomyopathies:** FT doesn't limit its usefulness in ischemic and structural heart disease patients, non-ischemic cardiomyopathies can also be managed early in the course if FT is used. Breuninger *et al.*<sup>[34]</sup> used FT to assess myocardial strain in 88 patients with

dilated cardiomyopathy and 30 healthy controls and found it to be reliable in analyzing global myocardial function. Steinmetz *et al.*<sup>[35]</sup> studied 26 patients with uncorrected Ebstein's anomaly and 10 healthy controls with FT to measure right and left ventricular deformation and dyssynchrony which showed RV intraventricular dyssynchrony and reduced RV global strain in patients with Ebstein's Anomaly as compared to healthy controls. Buss *et al.*<sup>[33]</sup> studied 210 patients with dilated cardiomyopathy with FT and noted that LV longitudinal strain assessment *via* FT was an independent predictor of patient survival and thus a helpful diagnostic tool for risk stratification in this patient population beyond clinical parameter and standard CMR<sup>[32]</sup>. Similarly, in hypertrophic cardiomyopathy (HCM) patients, Smith *et al.*<sup>[36]</sup> used FT to follow 30 HCM pediatric patients (14.1 ± 3.2 years) and the relationship of LGE (present in 17 of those patients) to adverse clinical outcome (defined as cardiac death non sustained Ventricular tachycardia, ventricular fibrillation and appropriate AICD discharge) over a period of 26.9 mo. They found LGE presence in these pediatric patients comparable to adult population in terms of decreased myocardial strain and adverse clinical outcome<sup>[36]</sup>. Thavendiranathan *et al.*<sup>[37]</sup> studied 30 patients with myocarditis and takotsubo cardiomyopathy with CMR and feature tracking and they found it a rapid and reliable method to diagnose myocardial injury in these conditions<sup>[37]</sup>. Petryka *et al.*<sup>[38]</sup> used FT in 137 children with known or suspected HCM, DCM or LV non compaction to measure strain and its prognostic significance. Circumferential Strain measurements in these patients were thought to be valuable in predicting adverse outcome.

**Advanced heart failure:** Cardiac resynchronization therapy (CRT) provides both morbidity and mortality benefit in advanced heart failure patients. Measurement of left ventricular mechanical dyssynchrony in these patients might provide prognostic information along with QRS duration. Onitsha *et al.*<sup>[39]</sup> studied 72 patients

to assess left ventricular dyssynchrony using CMR-FT and speckle tracking echocardiography with promising results concluding FT as a reasonable technique for patients with more marked dyssynchrony.

**Cardio-oncology:** Use of feature tracking for the diagnosis of chemotherapy-induced cardiomyopathy has been established in multiple studies<sup>[5,40]</sup>. In another study, Kowallick *et al.*<sup>[41]</sup> used this technique to measure left atrial mechanics in 10 healthy controls, 10 patients with HCM and 10 patients with heart failure with preserved LVEF (HFpEF). They concluded that FT reliably differentiated between healthy controls and patients with impaired left ventricular relaxation based on LA longitudinal strain and strain rate measurements<sup>[41]</sup>.

**Other diseases:** A small study identified the role of feature tracking in diagnosing myocardial abnormalities in patients with Churg-Strauss syndrome and Wegener's Granulomatosis and in clinical remission with normal EKG and transthoracic echocardiogram<sup>[30]</sup>. Feature tracking could also be useful in the diagnostic workup of left ventricular hypertrophy and the detection of early cardiac involvement in Anderson Fabry's disease which is an X-linked lipid storage disorder (characterized by multi organ involvement and premature death due to cardiac failure, renal failure, stroke and arrhythmias), with potential for therapy monitoring<sup>[42]</sup>. Strain measurements using feature tracking should play a major role in instituting early therapy for cardiomyopathy in patients with Duchenne Muscular Dystrophy associated cardiomyopathy and other similar cardiomyopathies where abnormal strain patterns precede the systolic dysfunction<sup>[43,44]</sup>. These measurements could also be helpful in following paroxysmal atrial fibrillation patients after ablation therapy to look for the presence and reversibility of cardiac dysfunction<sup>[29]</sup>. Bratis *et al.*<sup>[45]</sup> found FT to be helpful in differentiating between normal controls and Kawasaki Disease patients in a study of 29 KD convalescent patients and 10 healthy controls.

## FUTURE DIRECTION

Despite recent surge in the number of studies looking at this diagnostic modality, we still need large randomized trials. More studies are needed to assess the role of feature tracking in the assessment of right ventricular/right and left atrial dysfunction<sup>[11]</sup>. Further refinements are needed to overcome poor reproducibility in left ventricular segmental strain measurements and right ventricular strain measurements<sup>[27]</sup>.

## CONCLUSION

CMR-FT is a new and potentially useful noninvasive technique for measuring myocardial strain from routine cine CMR images using feature-tracking algorithms that were initially designed for echocardiographic strain analysis. FT-CMR tracks tissue voxel motion using standard steady-state

free precession sequences and is simpler, more practical and easily available and less time consuming than other CMR-based strain techniques for global and segmental myocardial function analysis. It needs to be further studied and validated for routine use in current clinical practice.

**Data sharing statement:** Resources: Principles and Guidelines for Recipients of NIH Grants and Contracts" issued in December, 1999. Dr. Lu Lu is responsible for coordinating data sharing through GeneNetwork (GN) at the: <http://www.genenetwork.org/webqtl/main.py>. GN is a group of linked data sets and tools used to study complex networks of genes, molecules, and higher order gene function and phenotypes. GN combines more than 25 years of legacy data generated by hundreds of scientists together with sequence data (SNPs) and massive transcriptome data sets (expression genetic or quantitative trait locus data sets). GN connected to numerous links to the UCSC and Ensembl Genome Browsers, PubMed, Entrez Gene, GNF Expression Atlas, ABI Panther, and WebGestalt provide users with rapid interpretive information about genomic regions, published phenotypes and genes.

## Abstract

### AIM

To investigate the regulation of Myopalladin (*Mypn*) and identify its gene network involved in restrictive cardiomyopathy (RCM).

### METHODS

Gene expression values were measured in the heart of a large family of BXD recombinant inbred (RI) mice derived from C57BL/6J and DBA/2J. The proteomics data were collected from *Mypn* knock-in and knock-out mice. Expression quantitative trait locus (eQTL) mapping methods and gene enrichment analysis were used to identify *Mypn* regulation, gene pathway and co-expression networks.

### RESULTS

A wide range of variation was found in expression of *Mypn* among BXD strains. We identified upstream genetic loci at chromosome 1 and 5 that modulate the expression of *Mypn*. Candidate genes within these loci include *Ncoa2*, *Vcpip1*, *Sgk3*, and *Lgi2*. We also identified 15 sarcomeric genes interacting with *Mypn* and constructed the gene network. Two novel members of this network (*Syme1* and *Myom1*) have been confirmed at the protein level. Several members in this network are already known to relate to cardiomyopathy with some novel genes candidates that could be involved in RCM.

### CONCLUSION

Using systematic genetics approach, we constructed *Mypn* co-expression networks that define the biological process categories within which similarly regulated genes function. Through this strategy we have found several novel genes that interact with *Mypn* that may play an important role in the development of RCM.

**Key words:** System genetics; Myopalladin; System proteomics; Cardiomyopathy; Mutation

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Myopalladin (*Mypn*) is one of genes associated with many types of familial cardiomyopathies including dilated, hypertrophic and restrictive cardiomyopathy (RCM). Using systematic genetics approach, we constructed *Mypn* co-expression networks of similarly regulated genes that function within defined biological

processes. Several novel *Mypn*-interacting genes with potential important role in the development of RCM were discovered.

Dissection of Z-disc myopalladin gene network involved in the development of restrictive cardiomyopathy using system genetics approach. *World J Cardiol* 2017; 9(4): 320-331 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/320.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.320>

## INTRODUCTION

Cardiomyopathies are heterogeneous diseases of heart muscle with unknown etiologies in 60%-70% of cases<sup>[1]</sup>. Outcomes such as heart failure, transplant or death in children and adults due to lack of definite effective treatment make cardiomyopathies one of the most devastating diseases<sup>[2]</sup>. Familial restrictive cardiomyopathy (RCM), a rare form of cardiomyopathy, is characterized by diastolic dysfunction with restrictive physiology due to fibrosis and stiffness of the myocardium. Familial RCM has high incidence of sudden cardiac death, particularly in children with 2-year survival of 50% which drops up to 25% in 5-year survival period<sup>[3]</sup>. History of familial RCM is documented in 30% of cases with possible presence of dilated or hypertrophic cardiomyopathies (DCM and HCM, respectively)<sup>[4]</sup>. Only a few genes, troponins (*cTnI* and *cTnT*), myosin-binding protein C (*MyBP-C*) - myosin heavy chain (*MYH7*), myosin light chain2 and 3 (*MYL2*, *MYL3*), desmin (*DES*) and myopalladin (*MYPN*), have been reported to be associated with familial RCM.

The *MYPN* gene, located at chromosome 10q21.3, encodes a 147-kDa protein containing five immunoglobulin (Ig) domains<sup>[5]</sup>. *MYPN* localizes to the Z-discs and nucleus in striated muscle and functions in sarcomere assembly and regulation of gene expression. To date, twenty-three monoallelic heterozygous mutations in *MYPN* associated with DCM, HCM and RCM have been reported<sup>[6-8]</sup>. Clinical presentation of cardiomyopathy and heart failure typically exhibits in adulthood. Interestingly, different phenotypes were observed in family members and unrelated individuals carrying the same mutation. For instance, teenage siblings carrying the heterozygous c.1585C>T (p.Q529X-MYPN) nonsense mutation exhibited signs of overlapping phenotypes of DCM, HCM and RCM. The c.1585C>T mutation escapes a nonsense-mediated mRNA decay and produces a truncated 65-kDa MYPN protein, acting as a "poison peptide"<sup>[7,9]</sup>. The phenotype of knock-in mutant mice carrying heterozygous *Mypn*-Q526X mutation (KI), equivalent to human MYPN-Q529X, resembles RCM<sup>[9]</sup>. On the other hand, the homozygous mutants with biallelic *Mypn*-Q526X acted as the *Mypn*-null model due to ablation/knock-out (KO) of *Mypn* protein as a result of nonsense-mediated mRNA decay.

Over the last decade, it has become clear that genes do not work in isolation but in a complex combination with other genes and the environment. Thus, it is critical to identify gene networks rather than individual gene for complex traits or many diseases, including cardiomyopathies. We hypothesized that *Myfn* as a cardiomyopathy causal gene interacts with many other genes in a gene network to cause cardiomyopathy symptoms. The purpose of this investigation is to define novel cardiomyopathy causative genes through *Myfn* network using combined approaches of systems genetics and proteomics. To explore the *Myfn* gene network, we used BXD mice, a recombinant inbred (RI) strains derived from C57BL/6J strain (B6) and DBA/2J (D2) mouse cross. The *Myfn* gene is highly expressed and highly variable in the myocardium of BXD RI mouse strains. We identified an upstream modulator of *Myfn* and defined both pathway and gene network. Proteomics studies in *Myfn* KI and KO mice defined potential mechanisms through which Q526X-*Myfn* mutation induced RCM and familial cardiomyopathies in general.

## MATERIALS AND METHODS

### Animal care and use statement

BXD and *Myfn* KI and KO mice described earlier were used<sup>[9-11]</sup>. Mice were maintained in micro-isolator cages at 25 °C under a 14/10 h light/dark cycle with free access to water and food. PCR analysis of tail genomic DNA was used for genotyping of knock-in and knock-out mice. Genotyping of BXD mice was generated using GigaMUGA genotyping array that typed approximately 150000 SNPs. All animal studies were approved by institutional IACUC of the University of Tennessee Health Science Center (UTHSC).

### Tissue harvest, RNA extraction and microarray

The animals were sacrificed under isoflurane anesthesia. Cardiac perfusion were performed after an overnight fast. Hearts were taken immediately after perfusion, and then frozen in liquid nitrogen no more than a minute after sacrifice. The pieces of tissue were taken from frozen heart (most of them from ventricles) randomly. The hearts were harvested from 40 strains of the BXD family (BXD43 - BXD103) and both parental strains (C57BL/6 and DBA/2). Five animals per strain were used for this study.

RNA was extracted using QIAGEN RNA extraction kits (<https://www.qiagen.com>) as per the manufacturer's instructions. In order to reduce the inhomogeneous nature of tissues due to the presence of different segments of the heart, the individual RNA sample from 5 mice at same strain were pooled evenly (by microgram of RNA) into a single RNA sample. The pooled RNA samples were then purified using RNeasy kit. The Agilent 2100 Bioanalyzer was used to evaluate RNA integrity and quality. The RNA integrity values had to be greater than 1.8 to pass quality control. The RIN of most samples were greater than 2. The Affymetrix Mouse Gene 2.0 ST arrays were used for

gene expression measurement and were run in a single batch.

### Data processing

Raw microarray data were normalized using the Robust Multichip Array (RMA) method. The expression data were then re-normalized using a modified z-score described previously<sup>[12-15]</sup>. We calculated the log base 2 of normalized values above, computed Z scores for each array, multiplied the Z scores by 2, and added an offset of 8 units to each value. The reason for this transformation is to produce a set of Z-like scores for each array that have a mean of 8 and standard deviation of 2. The advantage of this modified Z score is that a two-fold difference in expression corresponds approximately to a 1-unit change.

### Expression QTL mapping

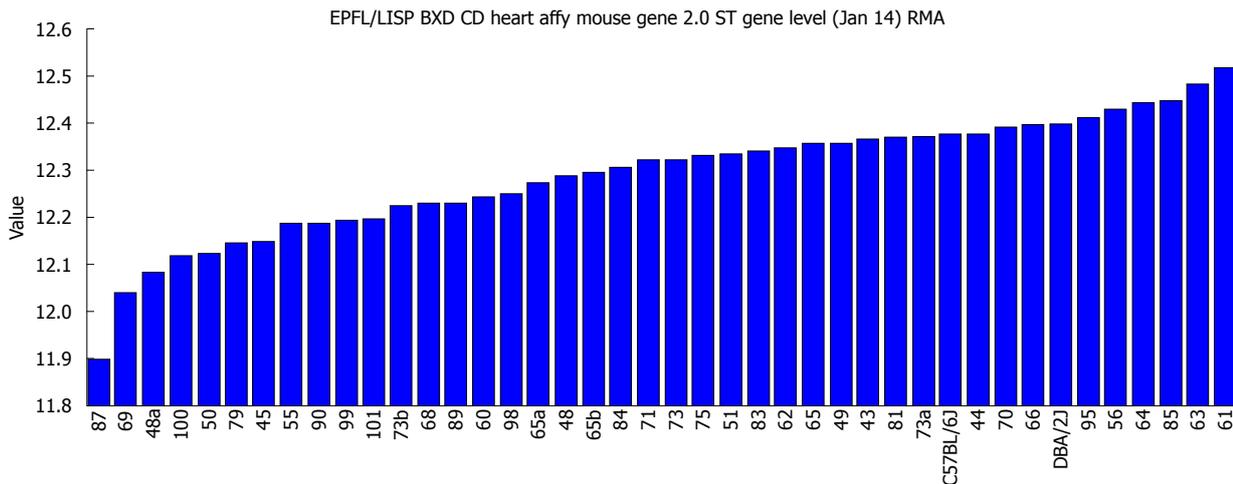

Expression QTL (eQTL) mapping was performed at gene and exon levels through the WebQTL module on GeneNetwork as published previously<sup>[12-14]</sup>. This methodology uses regression analysis to determine the association between variability in a trait vs variability in alleles at markers across the genome. Simple interval mapping was performed to identify potential eQTLs that regulate *Myfn* expression levels and estimate the significance at each location consistent to known genotype data for those sites. Composite interval mapping was also performed to control for genetic variance associated with major eQTLs as well as any potentially masked secondary eQTLs. A quantitative measure of confidence of linkage between the observed phenotype, known genetic markers and expression level of *Myfn* was provided by creating a likelihood ratio statistic (LRS). Then, we established genome-wide significance for each eQTL using a permutation test that compared the LRS of our novel site with the LRS values for 1000-10000 genetic permutations<sup>[16]</sup>.

### Identification of upstream candidate genes

To identify upstream gene of *Myfn*, we determined the 1.5-LOD location of the significant eQTL of *Myfn*. All genes in this eQTL region were used for candidate gene analysis. The following criteria were used to identify the most likely candidates: (1) the gene is highly expressed in the heart; (2) the gene is significant ( $P < 0.05$ ) correlated with *Myfn* expression in the heart; and (3) the gene has non-synonymous SNP, missense SNP or indel in coding regions of the gene, or the gene has significant *cis*-eQTL<sup>[14]</sup>.

### Genetic correlation and partial correlation analysis

We calculated Pearson product-moment correlations between expression of *Myfn* and expression of all other probe sets across the genome and produced sets of genetically correlated genes. After that, in order to identify biologically relevant correlates of *Myfn*, we also performed partial correlation analyses to remove linkage disequilibrium by controlling for *cis*-regulated

**Figure 1** Rank-ordered expression of *Mypn* in the heart across the 40 BXD strains and their parental strains. The X-axis denotes the strain name while the Y-axis denotes the mean expression given in a LOG2 scale.

genes near *Mypn*<sup>[14]</sup>. Both genetic correlation and partial correlation can be computed using the tools on GeneNetwork.

#### Gene set enrichment analysis

The genes that have both significant genetic correlation and partial correlation with *Mypn* were selected for gene set enrichment analysis. After removing Riken clones, intergenic sequences, predicted genes, and probes not associated with functional mouse genes, the remaining list of correlates with mean expression levels above baseline in the heart were uploaded to Webgestalt (<http://bioinfo.vanderbilt.edu/webgestalt/>) for gene enrichment analysis<sup>[17]</sup>. The *P* values generated from the hypergeometric test were automatically adjusted to account for multiple comparisons using the Benjamini and Hochberg correction<sup>[18]</sup>. The categories with an adjusted *P* value (adjp) of < 0.05 indicated that the set of submitted genes are significantly over-represented in that categories.

#### Gene network construction

The gene network was constructed and visualized using Cytoscape utility through "Gene-set Cohesion Analysis Tool (GCAT)" (<http://binf1.memphis.edu/gcat/index.py>). The nodes in the network represent genes and the edge between two nodes represent cosine score of Latent Semantic Indexing (LSI) that determines the functional coherence of gene sets is larger than 0.6. The significance of the functional cohesion is evaluated by the observed number of gene relationships above a cosine threshold of 0.6 in the LSI model. The literature *P*-value (LP) is calculated using Fisher's exact test by comparing the cohesion of the given gene set to a random one<sup>[19]</sup>.

#### Protein isolation and 2D-DIGE analysis in *Mypn* KO and KI mice

To investigate genetic and proteomics correlations and

to discover possible posttranslational alterations at the onset of restrictive phenotype, 3-mo-old wild-type (WT), mutant heterozygous *Mypn*<sup>WT/Q526X</sup> (KI) and homozygous *Mypn*<sup>Q526X</sup> (KO) male littermate mice were used<sup>[9]</sup>. The total protein from left ventricular (LV) myocardium was isolated, aliquoted, snap-frozen in liquid nitrogen and kept at 80 °C until further analysis. Two-dimensional gel electrophoresis (2D-DIGE) including protein labeling, 2D-electrophoreses, gel analysis and identification of proteins of interests using tandem mass spectrometry (MS) were performed by Applied Biomics (Hayward, CA) using established protocols as described previously<sup>[20]</sup>.

#### MALDI-TOF (MS) and TOF/TOF (tandem MS/MS)

Tandem MS/MS were performed on a 5800 mass spectrometer (AB Sciex) as described previously<sup>[20]</sup>. Candidates with either protein score CI% or Ion CI% greater than 95 were considered significant.

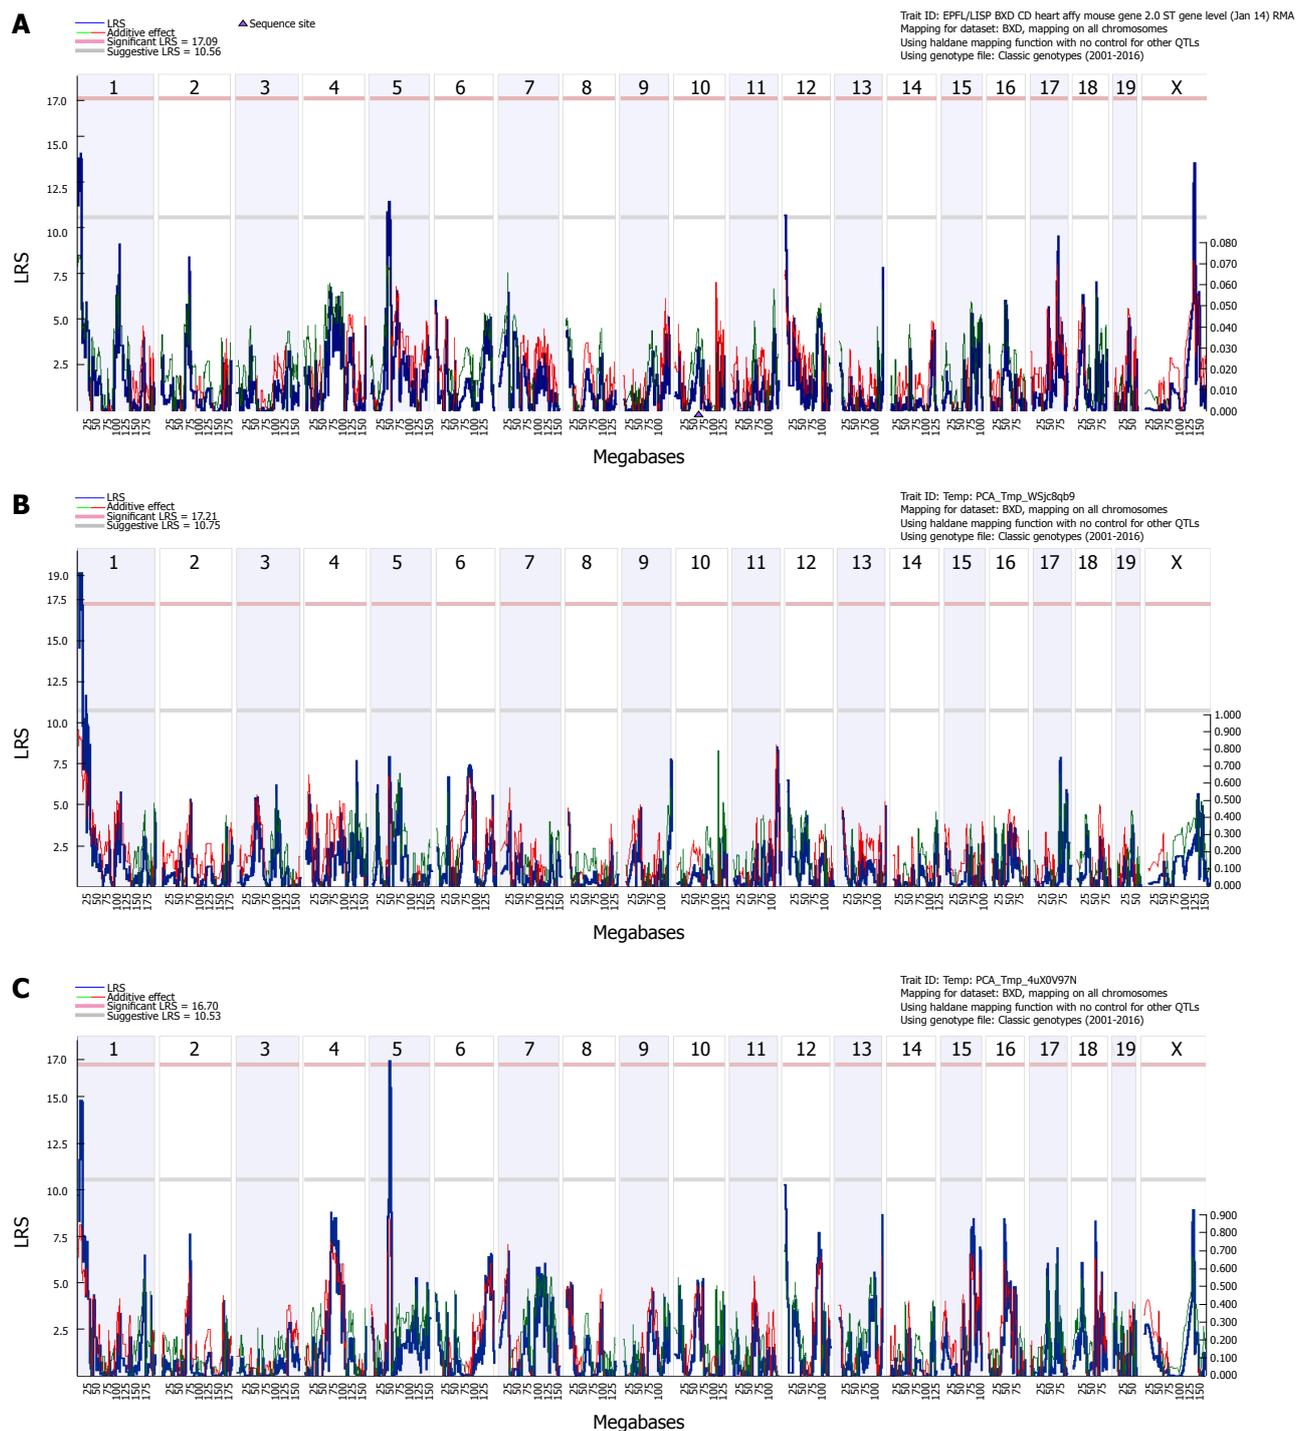

## RESULTS

#### *Mypn* expression levels in heart of BXD mice

*Mypn* which is highly expressed in the heart shows broad variability in expression among the BXD strains. The average expression of *Mypn* in all BXD strains was  $12.29 \pm 0.02$  (log<sub>2</sub> scale, mean  $\pm$  SEM). The highest expression levels of 12.52 was found in BXD61 strain and the lowest of 11.89 was found in BXD87 strain (Figure 1), a difference more than 1.5 fold.

#### eQTL mapping and candidate regulator of *Mypn*

By performing simple interval mapping for *Mypn* at the transcript level, we found four suggestive eQTLs that are located on chromosome (Chr) 1, 5, 12 and X, respectively (Figure 2A). Simple interval mapping at exon level showed the expression of exons 6, 12 and 17 map to the same locus on Chr 1; and the expression of exons 7, 14, 18 and 19 map to the same locus at Chr 5. Principal component analyses were then performed

**Figure 2 Genetic mapping of *Mypn* expression in the heart of BXD mice.** The interval mapping at the transcript level identified 4 suggestive eQTLs at chromosome 1, 5, 12, and X respectively (A). The interval mapping for the first principal component of exon 6, 12, and 17 showed a significant eQTL (genome-wide  $P < 0.05$ ) at Chr 1 (B). The interval mapping for the first principal component of exons 7, 14, 18, and 19 showed a suggestive eQTL at Chr 1 and a significant eQTL (genome-wide  $P < 0.05$ ) at Chr 5 (Figure 2C). The left Y-axis provides LRS score in blue and right Y-axis provides the additive effect in green. The red and green lines show the effect of the D or B allele on trait values, respectively. The upper X-axis shows location by chromosome and the lower X-axis shows location in megabases. The two horizontal lines across the plot make the threshold for genome-wide significant ( $P < 0.05$ , red or upper line) and suggestive ( $P < 0.63$ , grey or lower line) thresholds. eQTL: Expression quantitative trait locus; LRS: Likelihood ratio statistic.

to identify the main factor contributing to the variable expression of those exons. The first principal component (PC1) captured 67% of the expression variance for exons 6, 12 and 17. Simple interval mapping for this PC1 identified a significant eQTL with LRS of 19 (genome-wide  $P < 0.05$ ) at Chr 1 whose location is the same as

for gene level (Figure 2B). The first principal component captured 49% of the expression variance for exons 7, 14, 18 and 19. Simple interval mapping for this PC1 identified a suggestive eQTL with LRS of 14.7 at Chr 1 and a significant eQTL with LRS of 17.2 (genome-wide  $P < 0.05$ ) at Chr 5 whose locations are the same as for

gene level (Figure 2C). The first principal component for any other exons did not show any significant eQTLs by performing simple interval mapping. Composite interval mapping at both gene and exon levels revealed no other loci that modulate *Mypn* expression levels; so, *Mypn* expression in heart is regulated by two trans-eQTLs. The 1.5 LOD intervals of trans-eQTLs are located from 3 to 13.2 Mb of Chr 1 and 47 to 53 Mb of Chr 5 respectively.

There are more than 70 genes/probesets in eQTL 1.5 LOD interval at Chr 1 and there are 22 genes/probesets whose expression is significantly correlated with *Mypn* expression ( $P < 0.05$ ). After further filtering by expression value, sequence polymorphism, and eQTL type, there are only 3 genes that match the criteria for candidate genes. They are nuclear receptor coactivator 2 (*Ncoa2*), valosin containing protein (*Vcpi1*), and serum (*Sgk3*). *Ncoa2* and *Vcpi1* have nonsynonymous SNP between B6 and D2, while *Sgk3* is *cis*-regulated. All three genes are highly expressed in the heart and considered as candidate genes that regulate *Mypn* expression.

There are more than 30 genes/probesets in eQTL 1.5 LOD interval on Chr 5. The expression of four of them is significantly correlated with *Mypn* expression ( $P < 0.05$ ), but only leucine-rich repeat LGI family member 2 (*Lgi2*) is *cis*-regulated and is highly expressed in the heart. Accordingly, this gene is considered as the candidate gene at Chr 5 locus that regulates *Mypn* expression.

### Gene function enrichment

The expression of 2843 transcripts/probesets has been

found to correlate significantly with that of *Mypn* ( $P < 0.05$ ). There are 1704 transcripts/probesets left after partial correction analysis. Among them, 1593 transcripts have unique Entrez gene IDs and were submitted for enrichment analysis. The most significant enrichments in the biological function category are "cellular process" (1026 genes,  $\text{adjp} = 0.000000000001$ ) and "development process" (369 genes,  $\text{adjp} = 0.000000036$ ) including "anatomical structure development" (321 genes,  $\text{adjp} = 0.0000009$ ), "muscle structure development" (64 genes,  $\text{adjp} = 0.0000084$ ) and "muscle cell differentiation" (47 genes,  $\text{adjp} = 0.0000031$ ). The most relevant enrichments in the molecular function category are "cytoskeletal protein binding" (63 genes,  $\text{adjp} < 0.006$ ), "SH3 domain binding" (19 genes,  $\text{adjp} < 0.01$ ), "growth factor binding" (19 genes,  $\text{adjp} < 0.003$ ), and "Protein serine/threonine kinase activity" (47 genes,  $\text{adjp} < 0.01$ ). The most significant enrichments in the cellular component category that is relative to muscle function are "contractile fiber" (24 genes,  $\text{adjp} < 0.009$ ), "myofibril" (21 genes,  $\text{adjp} < 0.03$ ), "sarcomere" (19 genes,  $\text{adjp} < 0.03$ ), "Z disc" (13 genes,  $\text{adjp} < 0.05$ ), "Phosphorylase kinase complex" (3 genes,  $\text{adjp} < 0.02$ ), and "AMP-activated protein kinase complex" (4 genes,  $\text{adjp} < 0.02$ ).

The disease enrichment analysis showed that those genes are significantly involved in 29 diseases ( $\text{adjp} < 0.05$ , Table 1). Almost all of diseases shown in Table 1 are cardiovascular related diseases, including cardiac arrhythmias, ventricular dysfunction and cardiovascular abnormalities. Diseases such myocardial ischemia, Romano-Ward syndrome, congenital heart defects, congenital long QT syndrome, atrial fibrillation (AF), atrioventricular block, nitrous oxide system (NOS) and coronary disease are the novel diseases that could be an interest.

The gene pathway analysis showed that those genes are significantly enriched in 10 pathways. Table 2 demonstrates top seven pathways, including "Insulin signaling pathway", "Hypertrophic cardiomyopathy", "Arrhythmogenic right ventricular cardiomyopathy", "ECM-receptor interactions", and "Focal adhesion" that are known mechanisms involved in the development of cardiomyopathy.

### Genetic network

The strength of correlation among genes with which *Mypn* is involved can be evaluated by co-expression network. In order to identify known biological relations among co-expressed genes, we selected genes that statistically significantly enriched in sarcomere (19 genes,  $\text{adjp} < 0.03$ ), and uploaded them to GCAT (<http://binf1.memphis.edu/gcat/index.py>) for the functional coherence analysis and gene network construction. Three genes out of these 19 are not found in the database or have no functional relationship with other genes. The remaining 16 genes showed significant functional cohesion with literature  $P$  value of  $1.15e-10$  (Figure 3). Multiple resources including Chilibot, GeneCard, and PubMed were used to determine whether members of the *Mypn* co-expression network had been previously associated

**Table 2 The significantly enriched gene pathways**

with cardiomyopathy. In addition to *Mypn*, another 6 genes in this network (*Ldb3*, *Des*, *Actn2*, *Fhod3*, *Tpm2*, *Syne1*) are already known to relate to cardiomyopathy. Furthermore, 6 genes (*Myo18b*, *Fhod3*, *Myom1*, *Bmp10*, *Myl4*, *Obscn*, *Pdim5*) in the network have missense SNP that could change their protein function.

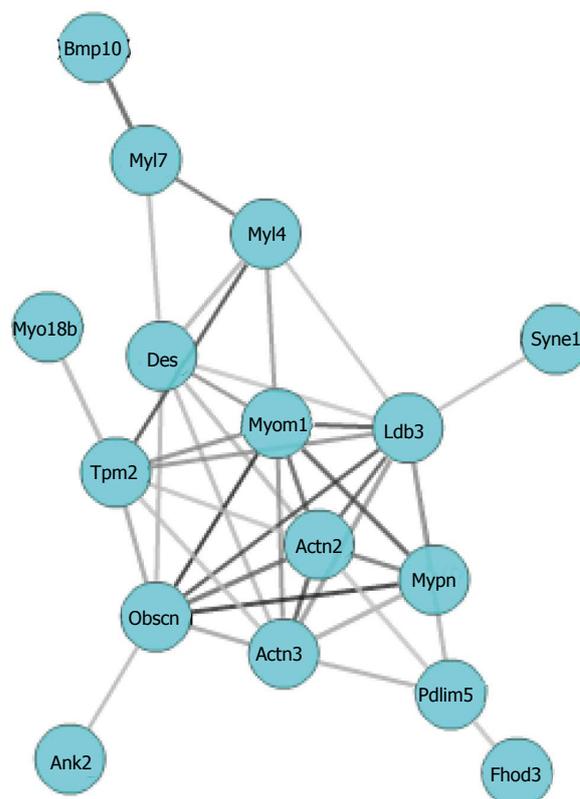

**Myocardial proteomics in *Mypn*-KI and *Mypn*-KO mouse hearts**

In order to confirm if the selected transcriptional networks are reproduced on a protein level, the proteomic profile of the myocardium from KI and KO *Mypn* mice were compared to the myocardial protein profile from WT littermates (*n* = 3). In 2D-DIGE analysis, about 2100 matched spots on each 2D gel were detected by DeCyder software, among of which a relative abundance of 65 polypeptides were altered between WT vs KI (Figure 4A), WT vs KO (Figure 4B) and KI vs KO (Figure 4C). Out of these 65 peptides, 27 are significantly changed ( $\geq 1.5$  fold and  $P \leq 0.05$ ) between WT and both of KO and KI mice. Table 3 demonstrates differential protein profiling in mutant mice vs control WT littermates and strong association of these 27 proteins with RCM phenotype. For example, proteins involved in regulation of focal adhesion, sarcomere, actin-cytoskeleton, microtubule organization and Ca-signaling are upregulated in KI mice compared to control WT mice, while KO hearts display downregulation of these proteins compared to WT.

Out of these 27 proteins, 12 were also significantly correlated with *Mypn* in mouse hearts at the transcriptional level (Table 4). Further, two of them (*Syne1* and *Myom1*, Tables 3 and 4, asterisks) have the closest connection with *Mypn* representing as potential members of *Mypn* gene network described above.

**DISCUSSION**

Cardiomyopathies are devastating heart muscle diseases with lack of definite, effective treatment, ultimately resulting in heart failure, transplant or death in children and adults<sup>[2]</sup>. Clinically, cardiomyopathies are heterogeneous diseases and classified into 5 distinctive groups characterized by changes in chamber size, thickness of myocardial walls,

**Figure 3 *Mypn* gene network graph created using Gene-set Cohesion Analysis Tool described in the methods. Gene symbols are located at nodes in circles and lines interconnecting the nodes are based on literature correlation.**

and function<sup>[1]</sup>. Although many studies have identified disease-causative mutations in all forms of cardiomyopathy, etiology remains unknown in 60%-70% of cases<sup>[21,22]</sup>. Most of genetic studies consider individual genes and mutations rather than co-regulated genes networks. The systems genetics approach is a powerful tool in identifying candidate genes and constructing genetic networks that regulate complex traits and phenotypes of mono- and poly-genetic diseases<sup>[12]</sup>. Thus, we used the system biology methodology in BXD RI strains and genetically engineered KI and KO *Mypn* mice to reveal the gene network that is co-regulated with *Mypn*, a gene that contributes to the development of cardiomyopathies.

The MYPN protein, a nodal messenger molecule, transmits stretch-signaling from Z-discs to the nucleus in cardiac myocytes<sup>[5]</sup>. It has been reported that mutations in *Mypn* cause autosomal dominant cardiomyopathies in humans with variable penetrance<sup>[6-8]</sup>. Murine models used in this study are well-characterized model of human RCM, which carries a Q526X-*Mypn* mutation<sup>[9]</sup>. Characteristic features of RCM phenotype in heterozygous mutant (KI) model include diastolic dysfunction with abnormal relaxation or impaired ventricular filling during diastole without systolic dysfunction due to "poison (mutant) peptide" effect. Homozygous mutants considered as a *Mypn*-null (KO) models due to ablation of *Mypn* gene did not manifest RCM phenotypes. Upon this functional knowledge, we sought to

expand identifying loci that regulate expressions of *Myfn* and other genes whose expression levels are co-regulated along with *Myfn*. We have identified two loci of interest that regulate *Myfn* expression in the heart. The first locus located at proximal Chr 1 is associated with *Myfn* exon 6, 12 and 17 (Figure 5). Three genes at this locus, *Ncoa2* (nuclear receptor coactivator 2, also known as *Grip1*), *Vcpip1* (valosin containing protein interacting protein 1), and *Sgk3* (serum/glucocorticoid regulated kinase family member 3), match criteria of candidate genes. Interestingly, *Ncoa2* is shown to be required in regulation of muscle-specific gene expression for expression of *MYOG* (OMIM169980), *CDKN1A* (OMIM116899) and *MEF2C* (OMIM600662) in both proliferating and confluent myoblasts<sup>[23]</sup>. Second locus located at the middle of Chr 5 is associated with *Myfn* exons 7, 14, 18 and 19. Only one gene, *Lgi2* (leucine-rich repeat LGI family, member 2), at this locus matches the criteria of candidate genes.

To reveal the possible mechanisms by which *Myfn* variants affect individuals with RCM, we further performed gene enrichment analysis for genes that significantly co-vary with *Myfn* in the heart. The gene ontology analysis found multiple significant biological processes for *Myfn* and its correlated genes. It includes "cytoskeletal protein binding", "SH3 binding domains", "growth factor binding", "muscle structure development", and "muscle cell differentiation". For example, genes such as *Des*, *Plec*, *Fln*, *Actn2*, *Actn3*, *Tpm2*, *Obscn* and *Ank2* from "cytoskeletal protein binding" are known cytoskeletal

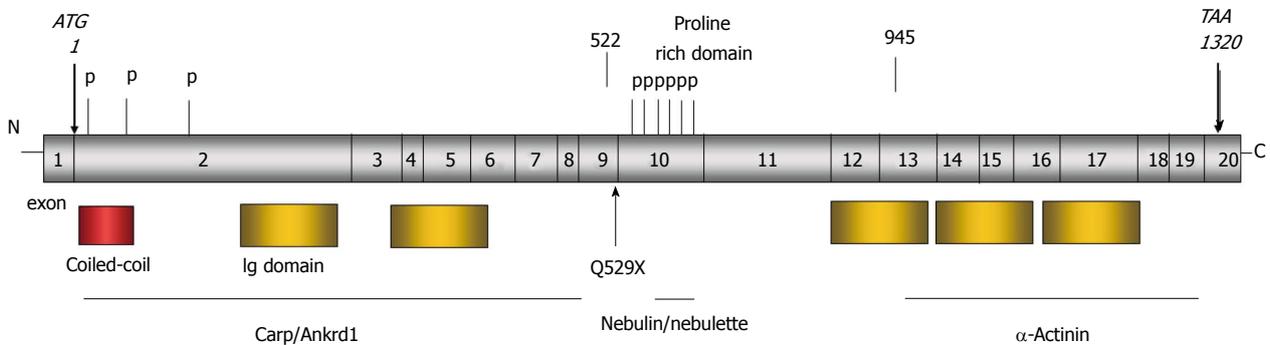

genes associated with cardiomyopathies. Interestingly, many genes from those categories could be candidates for further investigation as possible disease-causative genes for RCM. As shown in Figure 5, *Myfn* has several phosphorylation sites in the N-terminal Carp/Ankrd1 binding domain. The rod domain of *Myfn* responsive for the SH3-nebulin/nebulette binding has also several phosphorylation sites at the proline rich domain. Related to this, we found 47 genes involved in the "protein serine/threonine kinase activity", suggesting possibly novel biological processes in which *Myfn* may be involved.

The gene ontology analysis also revealed several significant cellular component categories. They are especially enriched at "contractile fiber", "myofibril", "sarcomere", and "Z-disc". All these cytoskeletal genes encode a protein network team with distinct function of each that play key roles in the orchestrated contractile function of myocytes. We discovered posttranslational changes in *Myom2* and *MSN/moesin* (Table 3) directing our attention to the genes from "phosphorylase kinase complex" and "AMP-activated protein kinase complex". These findings support the idea that *Myfn* mutations may alter phosphorylation of other cytoskeletal proteins.

The disease enrichment analysis showed that those genes are considerably involved in 29 diseases. Almost all of those 29 diseases are cardiovascular related, which support the involvement of *Myfn* and its networked genes in the development and progression of cardiovascular diseases including RCM.

**Figure 4** Two-dimensional gel electrophoresis of heart lysates from 12-wk-old mice. Comparative proteomics analysis revealed 10 non-redundant proteins in KI (heterozygote mutant) vs WT controls (A), 8 non-redundant proteins in KO (homozygote mutant) vs WT mouse hearts (B); 19 non-redundant protein changes in KO vs KI (C). Arrows indicate differential phosphorylation of proteins in WT vs KO and KI vs KO mice hearts (B and C, respectively).

**Figure 5** Structure of *Mypn* gene and functional domain of the protein. The N-terminal domain containing two immunoglobulin (Ig) and coiled-coil domains binds to cardiac ankyrin repeat protein (Carp/Ankrd1), the negative regulator of muscle gene expression. The rod domain contains proline rich domain with phosphorylation residues and binds to the SH3-domain of nebulin/nebulette at the Z-discs. The C-terminal domain containing 3 Ig domains binds to  $\alpha$ -actinin at the Z-discs.

The KEGG database was queried to identify pathways correlated to *Mypn* expression. We identified 10 significant pathways, most of which are involved in known mechanisms of cardiomyopathy including for instance insulin signaling, HCM, focal adhesion and MARK signaling. We found novel pathways as well, such as ARVC and EMC-receptor interactions that can be of high importance during development of cardiomyopathy.

Further, we used 16 genes that are significantly enriched in the sarcomere to create a gene network. All genes from the "sarcomere" network are highly expressed in the heart and significantly correlated with *Mypn* expression. We found well-known cardiomyopathy-associated genes

such as *Ldb3*, *Des*, *Actn2*, *Fhod3*, *Tpm2*, and *Syne1* in this network. Other genes in the network including *Myo18b*, *Fhod3*, *Myom1*, *Bmp10*, *Myl4*, *Obscn*, and *Pdlim5* are likely to be modifier genes interacting with *Mypn* to induce cardiomyopathy, especially genes that have missense SNPs. For example, the Z-discs *Myo18b* (OMIM607295), a potential *Mypn*-partner gene with nonsynonymous SNPs at exons 7, 18, 22, may alter *Mypn* protein function and lead to similar phenotypes. A human homozygous p.S2302X nonsense mutation in MYO18B was reported as causative for Klippel-Feil syndrome with nemaline myopathy and facial dysmorphism<sup>[24]</sup>. We also found that nonsynonymous SNP at exon 2 in *Myl4* (a fetal-specific myosin light chain

**Table 4** Genes whose gene expression has significant correlation with *Myfn* and gene product have significant change comparing with KI or KO mice

4 highly expressed in atrial myocardium) to be connected with *Myfn*. To support our finding, a heterozygous p.G11L mutation in *MYL4* (OMIM160770) in a family with early-onset AF was recently reported<sup>[25]</sup>. Another mutation, p.E17K in *MYL4* causes disruption of F-actin-Z-disc complex, consequently disturbing the mechano-electrical integration and calcium signaling in cardiomyocytes leading to atrial myopathy with AF. Given our findings, we highlight possible implication of *Myfn* gene network in arrhythmia disorders involving primary atrial-specific or overlapping ventricular/atrial inherited myopathies.

Two novel genes (*Syne1* and *Myom1*) in this gene network have been found to interact with *Myfn* at the protein level in *Myfn*-KO and KI mice hearts. Both genes are highly expressed the heart and have highly significant correlation with *Myfn* at the transcriptional level. Human *SYNE1* (OMIM608441) encodes the nesprin, a giant 8797-amino acid protein. The N-terminus of nesprin is localized to the sarcomeres of cardiac and skeletal muscle, while the C-terminus is localized to the nuclear envelope participating in a complex that links the nucleoskeleton to the cytoskeleton (LINC)<sup>[26]</sup>. Mutations in *SYNE1* are associated with Emery-Dreifuss muscular dystrophy and DCM<sup>[27]</sup>. Common features of MYPN and SYNE1 proteins are that both are involved in a force transmission between cytoskeleton and the nucleus. This further highlights importance of *Myfn*-*Syne1* interactions in transducing the mechanical signal into transcriptional response.

Here we report that *Myom1*, encoding protein Myomesin1/Skelemin, is a novel candidate gene for RCM due to its strong genetic correlations to known RCM networked genes. *Myom1* is *cis*-regulated gene and has non-synonymous SNPs in coding areas with strong downstream effects on cardiomyopathy phenotypes. *Myom1* is found to be significantly altered on a protein level in *Myfn* mouse disease models. Common features of MYOM1 and MYPN proteins are that both contain Ig-domains that play critical structural roles during muscle force-generation<sup>[28]</sup>. Like MYPN, MYOM1 is also detected in

the nucleus and cytoskeleton, suggesting that it may play a role in gene expression and stretch-induced signaling<sup>[29]</sup>. The only missense mutation, p.V1490I, that affects dimerization and elastic properties of MYOM1 was reported in a family with inherited HCM<sup>[30]</sup>. Important functions of MYOM1 in regulating titin, a giant molecular spring which is responsible for the passive elasticity of muscle further underscore such a possibilities<sup>[31]</sup>. We also hypothesize that posttranslational phosphorylation of MYOM1 may contribute to the development of RCM in *Myfn* mouse models.

In summary, we have discovered two genetic loci that modulate the expression of *Myfn*. We have found *Myfn* co-varies with a different sets of genes and enriched in pathways involved in the development of cardiomyopathy. Finally, we constructed a sarcomeric *Myfn* gene network containing 16 genes. Moreover, expression changes in *SYNE1* and *MYOM1* were confirmed on a protein level in RCM model *in vivo*. We emphasize that systems genetic and genomics analysis in patients may define novel candidate genes and mechanisms of cardiomyopathies.

## ACKNOWLEDGMENTS

The authors thank Drs. Evan Williams and Robert Williams for help to edit manuscript and process the gene expression data.

## COMMENTS

### Background

Genetic differences mediate individual differences in susceptibility to cardiomyopathies and severity of disease symptoms. *Myfn* gene mutations are associated with familial restrictive cardiomyopathy (RCM). Mutant mice carrying human mutations recapitulate the RCM phenotype.

### Research frontiers

Most of genetic studies consider individual genes and mutations rather than associated networks of co-regulated genes. Systems genetics and proteomics approaches have proven to be a powerful tool for identifying candidate genes and constructing genetic and protein networks that regulate complex traits and phenotypes of mono- and polygenetic diseases.

### Innovations and breakthroughs

This study is the first constructing the *Myfn*-gene network and discovering novel RCM-causative genes using systems genetics and proteomics approaches.

### Applications

The study will provide bases for discovering novel genes that are associated with the development of cardiac muscle diseases.

### Terminology

Cardiomyopathies are diseases of heart muscle that ultimately result in heart failure, transplant or death in children and adults.

### Peer-review

Very great study, methodology is well.

**Abstract****AIM**

To demonstrate the feasibility of blood conservation methods and practice across all ages and risk categories in congenital cardiac surgery.

**METHODS**

We retrospectively analyzed a collected database of 356 patients who underwent cardiac surgery using cardiopulmonary bypass (CPB) from 2010-2015. The patients were grouped into blood conservation ( $n = 138$ ) and non-conservation ( $n = 218$ ) groups and sub-grouped based on their ages and procedural complexity scores.

**RESULTS**

There were no statistical differences in gender, weight, pre-operative and pre-CPB hematocrit levels in both groups. Despite equivalent hematocrit levels during and after CPB for both groups, there was significantly less operative homologous blood utilized in blood conservation group across all ages and complexity levels.

**CONCLUSION**

Blood conservation surgery can be performed in con-

genital patients needing cardiac surgery in all age groups and complexity categories. The above findings in addition to attendant risks and side effects of blood transfusion and the rising cost of safer blood products justify blood conservation in congenital cardiac surgery.

**Key words:** Congenital heart disease; Cardiac surgery; Blood conservation

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** We evaluated the feasibility of blood conservation pediatric cardiac surgery for all age groups and complexity levels in this retrospective study. We reviewed 356 patients who underwent cardiac surgery from 2010-2015. The patients were grouped into historical non-conservation (NC = 218) and blood conservation (BC = 138) cohorts. The blood conservation was performed by miniaturizing bypass circuit, changing the trigger point for transfusion and adapting protocols and guidelines accepted and implemented by the group. We demonstrated that the blood conservation practice can be performed safely in all ages and complexity levels by reducing cardiopulmonary bypass prime volume and institutional commitment to guidelines and practice of blood conservation cardiac surgery.

## INTRODUCTION

There are accumulating evidences of the association of red blood cell (RBC) transfusion with adverse outcomes in both adult and pediatric patients undergoing cardiac surgery<sup>[1-5]</sup>. The increasing costs associated with blood transfusion and the need for preservation of limited blood supplies have mandated that RBC transfusion to be included as a quality indicator in cardiac surgery<sup>[6]</sup>.

There are many blood conservation strategies available for children undergoing cardiac surgery depending on age and type of surgery. The main goal of blood conservation is to minimize exposure to allogeneic transfusion while maximizing the use of autologous red cells. Although, the effects and costs of all these methods have not yet been completely assessed, many of these strategies have been implemented in clinical practice collectively with great efficacy.

The purpose of this single-center study is to demonstrate the feasibility of blood conservation cardiac surgery practice across different age groups and complexity scores in congenital cardiac surgery.

**Figure 1** Histogram of demographics in age and STAT categories for blood conservation and non-conservation cohorts. BC: Blood conservation; NC: Non-conservation; STAT: Society of Thoracic Surgeons-European Association for Cardio-Thoracic Surgery Congenital Heart Surgery Mortality Scores; N: Neonate; I: Infant; C: Child; A: Adolescent.

## MATERIALS AND METHODS

Retrospective analysis of 356 patients who underwent open heart surgery from 2010 to 2015 was investigated. The patients were categorized into blood conservation (BC) and non-conservation (NC) groups and subcategorized by their different age categories and the Society of Thoracic Surgeons-European Association for Cardio-Thoracic Surgery Congenital Heart Surgery Mortality scores (STAT Complexity Scores) (Figure 1). The NC group (n = 218) underwent surgical procedures between 2010 and 2014 using conventional cardiopulmonary bypass (CPB) without utilizing intra-operative blood conservation methods or protocols. The BC group (n = 138) underwent surgical procedures between 2014 and 2015 by incorporating blood conservation equipment, techniques, and intra-operative guidelines for homologous RBC transfusion.

The patients were analyzed for the amount of intraoperative RBC usage based on by their age categories and STAT complexity scores. There were no changes in clinical personnel as far as anesthesia, perfusion, intensive care, or cardiology care givers for both groups. A comprehensive database including demographics and intra-operative data was created for all the patients in the cohort using electronic and paper medical records. All the data collection was complete for the primary outcome of total intraoperative RBC usage in eligible patients undergoing cardiac surgery. The subjects requiring extracorporeal membrane oxygenator before or after surgery were excluded from the study groups. The institutional review board has exempted patients' consent and approved the study.

Intraoperative data included CPB and aortic cross-clamp (CC) times, hematocrit levels, and amount of homologous RBC transfusion. Preoperative hematocrit was measured by the preoperative work up in the core laboratory. Pre-bypass hematocrit was defined as the patient hematocrit measure by the blood gas analyzer prior to CPB. On bypass hematocrit was defined as hematocrit immediately after initiation of CPB. Post-bypass hematocrit was defined as the hematocrit prior to leaving the operating room suite. Intraoperative RBC transfusion was defined as the total amount of homologous RBC that the patient received from the time of arrival to the operating room until leaving the operating room, including prime volume for the CPB circuit. All the patients received irradiated and leukocyte depleted RBC based on the institutional blood bank protocol.

A strategic protocol by the surgeons, anesthesiology, and perfusion staff was formulated and agreed upon to achieve a reduction in hemodilution and trigger points for RBC transfusion. The formulation of the plan was divided into equipment and technique.

**Equipment**

The Terumo System One Heart Lung Machine (Terumo Cardiovascular, Ann Arbor, MI) was modified and positioned close to the operating table to reduce tubing lengths. Four different arterio-venous loops were customized specific to the weight of the patient. The Terumo FX05 (weight < 12 kg), FX15 (weight 12-75 kg), and FX25 (weight > 75 kg) oxygenators with integrated arterial filter were utilized for the CPB runs. The Terumo Capiox CP50 was configured for the administration of cold cardioplegia and modified ultrafiltration (MUF). The Hemocor HPH 400TS (Minntech Corporation, Minneapolis, MN) was used to remove excess fluid from the circuit. The Haemonetics Cell Saver 5 (Haemonetics Corporation, Braintree, MA) has allowed for successful return of shed blood during and after surgery. Continuous arterial and venous blood gas monitoring (CDI 500 Terumo Cardiovascular, Ann Arbor, MI), and cerebral saturation monitoring (Somanetics INVOS 5100 C system, Somanetics Corporation, Troy, MI) provided additional hemodynamic information regarding adequacy of patient oxygenation and perfusion in order to tailor the need for blood transfusion. Utilization of point of care testing with

i-STAT<sup>®</sup> (Abbott Point of Care, Princeton, NJ) and the Hemochron Signature Elite (ITC, Edison, NJ) allowed us for micro sampling of 0.5 mL of patient blood throughout the operative management. The differences in perfusion equipment for the two eras are depicted in Table 1.

**Perfusion technique**

The anesthesiology staff made every effort to minimize the amount of intravenous crystalloid infusion at the induction and throughout the operation to minimize hemodilution. Our current practice allows the primary perfusion staff to customize the patient circuitry with four available tubing packs and three oxygenators. These selections provided optimal circuit configuration based on patient size in order to decrease hemodilution while working safely within Food and Drug Administration (FDA) product specifications. The differences in priming volume between the two groups are demonstrated in Table 2. The circuit is positioned closed to the operating bed while avoiding crowdedness around the surgeon and assistant. Incorporating vacuum assisted drainage has made it possible to increase the height of the oxygenator to the level of the patient decreasing the arterial and venous tubing length and significantly reducing hemodilution. Retrograde arterial and venous priming have been instrumental in displacing the crystalloid priming volume of the circuit with the patients’ own blood reducing hemodilution effect at the initial stage of CPB.

We also aggressively ultrafiltrated the added crystalloid volume to the circuit to maintain an even fluid balance throughout the case. In addition, we performed arteriovenous MUF on all patients at the conclusion of the CPB. We routinely ultrafiltrated the remainder of the volume in the circuit and checked the hematocrit to ensure it was greater than or equal to the patient’s most recent hematocrit before reinfusion. This whole blood containing clotting factors and the cell saver processed blood are given to the patient prior to leaving the operating room or taken to the intensive care unit for postoperative transfusion as needed.

**Statistical analysis**

Standard descriptive statistics were used for patient demographic information. Values were calculated as mean ± SD. Continuous variables were compared between blood conservation and non-conservation groups using independent sample *t*-tests, for each of the 4 age groups (neonate, infant, child, and adolescent) and 5 STAT categories. *P* value < 0.05 was considered to be statistically significant. SPSS software (IBM, Armonk, New York) was used for statistical analysis.

**RESULTS**

There were a total of 356 patients with 218 patients in NC and 138 in BC arms. The breakdown of the patients in the ages and STAT categories for both groups are depicted in Figure 1. There were in general no statistically

Table 2 Cardiopulmonary bypass circuit prime volume			
Body weight (kg)	NC (mL)	BC (mL)	Reduction (%)
Neonate-12	400	160	60
12-35	600	445	26
35-55	800	520	35
55-75	1000	765	24
> 75	1000	880	12

BC: Blood conservation; NC: Non-conservation.

discernible differences in gender, weight, preoperative hematocrit, or pre-bypass hematocrit levels between the two groups across all ages and STAT categories. There was a trend toward longer bypass and cross clamp times in neonates, infants, and patients with STAT scores of 3 and 4 in NC cohort than BC counterpart, but did not consistently reach statistical significance (Tables 3 and 4). The neonates in NC group had higher post-bypass hematocrit ( $P = 0.001$ ) despite comparable on-bypass hematocrit due to usage of larger volume of RBC ( $P > 0.001$ ). The infants in BC group were younger ( $P = 0.001$ ) and had shorter CBP and CC times and much less RBC transfusion ( $P < 0.001$ ) despite comparable on-bypass hematocrits. The children in BC group had shorter bypass time ( $P = 0.04$ ) but comparable CC time, on-bypass, and post-bypass hematocrit, but statistically less RBC usage ( $P = 0.002$ ). Interestingly, the adolescence patients had higher on-bypass and post-bypass hematocrit ( $P < 0.001$ ) despite less RBC usage ( $P = 0.02$ ) signifying the efficacy of our circuit and protocol to conserve blood (Table 3). Overall, there was significantly less homologous RBC utilization across all age groups in BC than NC cohorts (Figure 2).

The data was also further analyzed looking at the differences in complexity of the procedures based on STAT mortality scores (1, least complex - 5, more complex) (Table 4). Patients in BC STAT 1 complexity level had higher post-bypass hematocrit ( $P = 0.02$ ) with comparable on-bypass hematocrit despite less RBC usage ( $P < 0.001$ ). Patients in BC STAT 2 group were younger ( $P = 0.001$ ) and had shorter bypass time ( $P = 0.03$ ), which was also evident in BC STAT 3 category ( $P = 0.02$ ). The BC STAT 1-4 categories in general had equivalent on-bypass hematocrit with less intraoperative RBC transfusion, which were all statistically significant. The STAT 5 groups could not be compared due to lack of sufficient subjects and power in NC group. Overall, there was significantly less homologous RBC utilization in BC group than NC group across all STAT complexity scores (Figure 3).

## DISCUSSION

Blood conservation in pediatric cardiac surgery has been a panacea and quest of cardiac surgeon due to societal and institutional push for quality care. Despite its challenges, blood conservation cardiac surgery has been practiced in all stages of cardiac surgery in adult

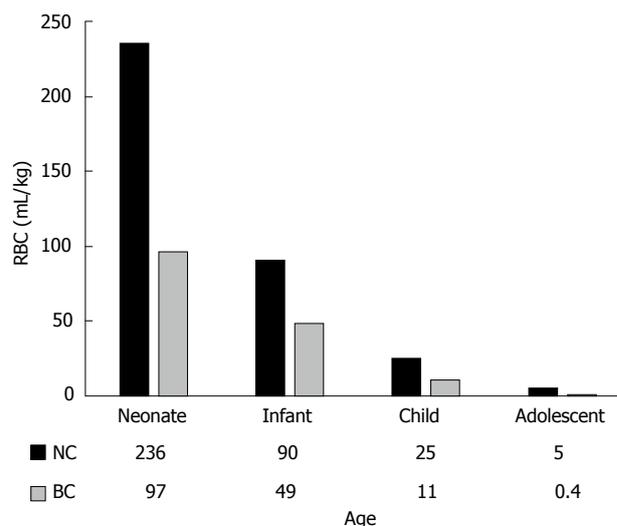

Figure 2 Bar graph for red blood cell usage in age categories for blood conservation and non-conservation cohorts. RBC: Red blood cell; BC: Blood conservation; NC: Non-conservation.

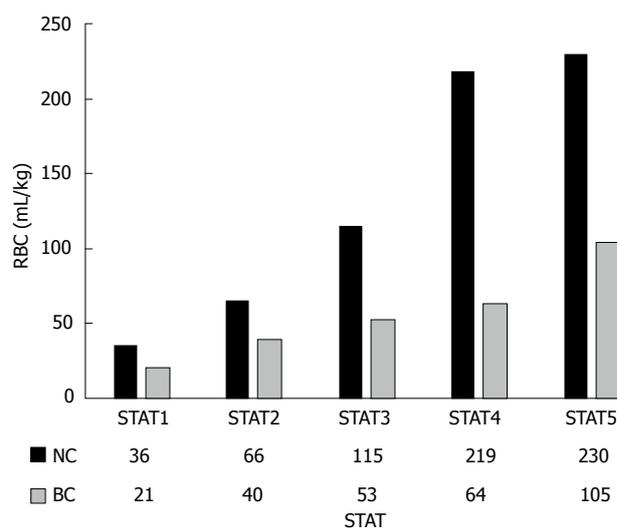

Figure 3 Bar Graph for red blood cell usage in STAT categories for blood conservation and non-conservation cohorts. and pediatric in certain circumstances with a great success<sup>[7,8]</sup>. There is a great variability in practice of blood transfusion for a given diagnostic code and complexity and pediatric population is no exception to the rule<sup>[9]</sup>. By far, pediatric patients undergoing cardiac surgery are exposed to more blood transfusion intra and post-operatively with no consensus or scientific evidence to what would be the optimal hematocrit level across different diagnosis and physiologic status<sup>[10-15]</sup>.

In this retrospective study we have looked at the effectiveness of intra-operative blood conservation practice as compared to the historical non-conservation cohort. We have adapted novel techniques in CPB by miniaturizing and customizing the circuit to the patient's weight and using parameters such as mixed venous saturation,

regional cerebral saturations, and serum lactic acid levels to tailor our decision about RBC transfusion. The bypass circuit was primed with the patients' own blood by performing retrograde arterial and venous priming once the aortic and venous cannulas were in place for majority of the operative procedures. We also performed aggressive hemofiltration during the bypass run and performed arteriovenous MUF after termination of CPB to remove excessive intravascular volume. Pediatric cell saver also was used throughout the operation and the salvaged blood was infused before leaving the operating room or immediately after arrival to the PICU. The efficacies of these conservation measures and practices have been reported by others as the result of greater emphasis that has recently been placed in performing blood conservation cardiac surgery in pediatric population<sup>[16-19]</sup>.

Our general trigger point for RBC transfusion was hematocrit of less than 21% for older age and low complexity category patients with biventricular physiology, and less than 25% for neonates, high complexity, and

cyanotic univentricular patients. This protocol was followed as long other critical parameters of adequate systemic and cerebral perfusion remained within acceptable range. There were no patients in the blood conservation group whom experienced adverse neurologic events or other complications as the result of these changes in philosophy of RBC transfusion trigger points. We consistently maintained mixed venous saturation at greater than 60% and regional cerebral saturation at greater than the baseline level by increasing flow and cerebral vasodilation using pH-stat during cooling. The trend in serum lactate level after CPB was also used to determine the need for blood transfusion prior to leaving the operating room. Implementation of intraoperative transfusion algorithms in pediatric cardiac operations has also been shown to significantly reduce perioperative blood product use and morbidity<sup>[20]</sup>. Similarly, a comprehensive intraoperative blood-sparing approach that resulted in no transfusion in 25% of children undergoing cardiac operations compared with children who received a transfusion during the

surgery demonstrated a shorter length of postoperative mechanical ventilation and a shorter PICU stay<sup>[21]</sup>. This has also been demonstrated that blood conservation in pediatric cardiac surgery was associated with a decrease in post-operative inotropic needs, days on ventilator, and length of stay in patients with biventricular physiology<sup>[22]</sup>.

Historically, hemodilution during CPB was introduced to decrease homologous blood use and has been thought to improve microcirculatory flow<sup>[23,24]</sup>. Hemodilution also potentially could reduce perfusion pressure, which increases the risk of an adverse neurologic outcome after CPB, increases cerebral blood flow and thereby increases the microembolic load to the brain, and reduces the oxygen carrying capacity of blood which might critically limit oxygen delivery to neurons and other cells<sup>[25]</sup>. Intraoperative implementation of hemodilution restriction prior to CPB to maintain the hematocrit close to preoperative hematocrit is paramount to a successful blood conservation cardiac surgery practice. By limiting crystalloid infusion during and after anesthesia induction, we significantly reduced the additional hemodilution that the patient will invariably face upon initiation of CPB. Having higher hematocrit prior to CPB will allow for retrograde priming of the bypass circuit and higher hematocrit during and after bypass. This was consistently achieved with our protocol and circuit modification throughout the operation despite lower RBC utilization signifying the efficacy of our conservation strategies across all ages and complexity levels.

This study carries some of the known limitations of a retrospective study design. It precludes accurate assessment of practice pattern and trigger points for RBC transfusion in the non-conservation group. There were also differences in surgeons as well as perfusion techniques and equipment that collectively could affect the variability in RBC transfusion trigger point and practices. Also, because of the lack of electronic charting and the absence of specific intraoperative measurements (*i.e.*, cerebral and somatic saturation, serum lactic acid level) for non-conservation cohorts, we could not perform any statistical comparison for some variables between the two groups.

This study has shown that blood conservation in pediatric cardiac surgery is reproducible across different ages and complexity categories. Miniaturization of the CPB circuit, contemporary techniques and equipment, and institutional commitments and protocols were paramount in establishing a successful blood conservation program. Future improvements in perfusion technology and blood conservation protocols in association with additional prospective randomized trials will further capitalize our understanding of the benefit of blood conservation in pediatric cardiac surgery.

surgical patients are at high risk of receiving blood transfusion as the result of cardiopulmonary bypass. Blood conservation surgery practice has been encouraged to reduced or eliminate related risks.

### Research frontiers

The principle author has demonstrated previously that blood conservation in pediatric cardiac operations is associated with fewer ventilator days, lower inotropic scores, and shorter lengths of stay in patients with biventricular physiology. This study has expanded the safety and applicability of blood conservation cardiac surgery practice to all ages and complexity levels in patients with biventricular and univentricular hearts.

### Innovations and breakthroughs

Blood conservation cardiac surgery has been a quest of surgeons for a long time due to associated risks inherent to homologous blood transfusion. There are sporadic successful reports of blood conservation surgery in pediatric population with no concrete methodology or guidelines accepted by most practices to adapt and implement it in their practices. In most part, there are no accepted guidelines in what would be a safe hematocrit range during circulatory support in order to avoid cerebral and end organ ischemic injuries. This single-intuition retrospective study is the only study that has demonstrated blood conservation pediatric cardiac surgery can safely be performed in all ages and complexity categories in a wide spectrum of structural congenital cardiac defects.

### Peer-review

The authors present their experience with implementing a blood conservation strategy for pediatric cardiac surgery at their institution. Overall, the manuscript is best categorized as a quality improvement evaluation.

### Abstract

#### AIM

To investigate the survival benefit of bilateral internal mammary artery (BIMA) grafts in patients with left ventricular dysfunction.

#### METHODS

Between 1996 and 2009, we performed elective, isolated, primary, multiple cardiac arterial bypass grafting in 430 consecutive patients with left ventricular ejection fraction  $\leq 40\%$ . The early and long-term results were compared between 167 patients undergoing BIMA grafting and 263 patients using left internal mammary artery (LIMA)-saphenous venous grafting (SVG).

#### RESULTS

The mean age of the overall population was  $60.1 \pm 15$  years. In-hospital mortality was not different between the two groups (7.8% *vs* 10.3%,  $P = 0.49$ ). Early postoperative morbidity included myocardial infarction (4.2% *vs* 3.8%,  $P = 0.80$ ), stroke (1.2% *vs* 3.8%,  $P = 0.14$ ), and mediastinitis (5.3% *vs* 2.3%,  $P = 0.11$ ). At 8-year follow-up, Kaplan-Meier-estimated survival (74.2% *vs* 58.9%,  $P = 0.02$ ) and Kaplan-Meier-estimated event-

free survival (all cause deaths, myocardial infarction, stroke, target vessel revascularization, heart failure) (61.7% and 41.1%,  $P < 0.01$ ) were significantly higher in the BIMA group compared with the LIMA-SVG group in univariate analysis. The propensity score matching analysis confirmed that BIMA grafting is a safe revascularization procedure but there was no long term survival ( $P = 0.40$ ) and event-free survival ( $P = 0.13$ ) in comparison with LIMA-SVG use.

### CONCLUSION

Our longitudinal analysis suggests that BIMA grafting can be performed with acceptable perioperative mortality in patients with left ventricular dysfunction.

**Key words:** Bilateral internal mammary artery grafting; Heart failure; Coronary artery disease

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This study reports a daily practice observation of patients with multivessel coronary artery disease and left ventricular (LV) dysfunction undergoing surgical revascularization. We evaluate the periprocedural safety of bilateral internal mammary artery grafting (BIMA) in this high risk population and its long-term survival benefit compared with the left internal mammary artery grafting (LIMA) to left anterior descending artery with additional saphenous venous grafting (SVG). Our longitudinal analysis suggests that BIMA grafting can be performed with acceptable perioperative mortality in patients with LV dysfunction but there was no survival difference in our follow up in comparison with LIMA-SVG use.

Bilateral vs unilateral internal mammary revascularization in patients with left ventricular dysfunction. *World J Cardiol* 2017; 9(4): 339-346 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/339.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.339>

## INTRODUCTION

Coronary artery disease is an important contributor to the rise in the prevalence of heart failure and its associated morbidity and mortality<sup>[1,2]</sup>. Severe left ventricular (LV) dysfunction caused by extensive coronary artery disease usually carries a poor prognosis, although surgical revascularization is thought to be the most effective treatment strategy<sup>[2-4]</sup>. Myocardial revascularization in patients with severe LV dysfunction preserves the remaining myocardium, prevents further myocardial damage, and induces the recovery of systolic function in ischemic LV myocardial segments. However, although advances in surgical techniques and myocardial protection have improved outcomes, cardiac arterial bypass grafting (CABG) in patients with LV impairment is still associated

with high perioperative risk and the long-term survival remains unsatisfactory overall.

The use of a single internal mammary artery rather than vein graft to the left anterior descending coronary artery has become the standard operation, largely due to excellent long-term graft patency into the first and second postoperative decade<sup>[5]</sup>. The superior outcome associated with left internal mammary artery (LIMA) grafting has quickly encouraged the use of bilateral internal mammary artery (BIMA)<sup>[6,7]</sup>. However, the widespread adoption of BIMA grafting is hindered because it might be associated with increased early morbidity.

We report here our experience in patients with multivessel coronary artery disease and LV dysfunction undergoing surgical revascularization. We evaluate the periprocedural safety of BIMA grafting in this high risk population and its long-term survival benefit compared with the conventional standard-of-care CABG using the LIMA to left anterior descending artery with additional saphenous venous grafting (SVG).

## MATERIALS AND METHODS

### Patients

From April 1996 to December 2009, 4210 patients underwent isolated CABG at our university center. From this group, we identified 430 patients with left ventricular ejection fraction (LVEF) of  $\leq 40\%$  who underwent primary isolated multivessel CABG with a least 2 grafts. Among them, 167 procedures were performed using BIMA grafting  $\pm$  SVG and 263 procedures were performed with LIMA and SVG. Exclusion criteria were patients older than 80 years, surgical myocardial revascularization of only one coronary artery, concomitant repair/replacement of valve, cardiac rupture, ventricular aneurysm or ascending aortic aneurysm.

Coronary artery disease was defined as a reduction of the vessel diameter by  $\geq 70\%$  in 1 view on coronary angiography. The presence of stenosis  $\geq 70\%$  in the left anterior descending, circumflex, or right coronary system was used as the criterion for single, double, or triple-vessel disease.

The preoperative measurement of LV chamber size at end-diastole and end-systole as well as the assessment of mitral regurgitation were performed by transthoracic two-dimensional echocardiographic images in the parasternal long-axis view (including M-mode) and by apical four-chamber view. LVEF was measured using Simpson's method with two views. LV chamber dilatation was defined by LV diastolic diameter  $> 54$  mm and  $> 60$  mm in women and men respectively<sup>[8]</sup>. Mitral regurgitation was quantified according to the prevailing guidelines at the time of the study and was taken into account as reported by the expert cardiologist who performed the examination. Before myocardial revascularization, the heart team, including cardiologists and surgeons, systematically identified the target vessels according to myocardial viability. Revascularization was considered complete if every significant target vessel was grafted.

### Surgical technique

Our selection of patients for LIMA-SVG and BIMA grafting was not random but was influenced by the heart team decision and was decided from the *in situ* graft size. CABG was performed using standard on-pump or off-pump bypass techniques at the discretion of the operating surgeon. Myocardial preservation during cardiopulmonary bypass involves normothermic, intermittent, antegrade and retrograde blood cardioplegia.

The LIMA was harvested as a pedicle and grafted exclusively to the left coronary system. The right internal mammary artery (RIMA) was mostly harvested as a pedicle and grafted to the left coronary system or the right coronary artery, and in a minority of cases, used as a free graft. A free RIMA was used when the length of the conduit was too short, or if the distal anastomotic site was unreachable with a pedicled RIMA. The composite graft included an end-to-side anastomosis of the free RIMA onto an *in situ* LIMA. The right gastroepiploic artery or radial artery was not used as a third arterial conduit in our study.

### Definitions of terms and data collection

The in-hospital course was studied in terms of procedural characteristics, vital status, renal status, peri- and post-operative red blood cell transfusions, infectious complications, myocardial infarction, cerebrovascular events, mesenteric ischemia, emergency repeat coronary and/or peripheral revascularization procedures and arrhythmias.

Patients did not undergo systematic control angiography during the follow-up period. Perioperative myocardial infarction (*i.e.*, within 7 d after intervention) was defined as a creatine kinase-MB  $\geq 5$  times the upper limit of normal, with new Q waves in 2 contiguous leads on the postoperative electrocardiogram or the new development of bundle branch block. In the case of elevated creatine kinase levels at baseline, myocardial infarction was defined as an increase of  $> 50\%$  over baseline values after intervention. After this postoperative period, myocardial infarction was defined as the presence of new pathologic Q waves or the new development of left bundle branch block with increased cardiac marker levels (*i.e.*, creatine kinase-MB  $\geq 3$  times the upper limit of normal). Cardiovascular death included death resulting from an acute myocardial infarction, sudden cardiac death, hospitalization for heart failure, stroke, pulmonary embolism or digestive ischemia.

Event free survival is a composite end point of all cause deaths, myocardial infarction, stroke, target vessel revascularization and first hospitalization for heart failure.

Follow up was obtained through comprehensive questionnaires and by telephone with the patient's personal physician. If subsequent hospitalization, death, or other events had occurred, the patient's physician or appropriate hospital record department were interviewed to document the events.

This study was conducted according the principles

of the Helsinki declaration. The retrospective study of patients' files was approved by the Commission Nationale Informatique et Libertés (CNIL), in keeping with French law for single-center usual care observational studies.

### Statistical analysis

Continuous variables are presented as means  $\pm$  standard deviation (SD), categorical variables as frequencies (percentages). Comparison of patients characteristics between groups were carried out using Student's *t* tests, Wilcoxon tests or Pearson's  $\chi^2$  tests as required. Kaplan-Meier survival curves were compared using the log-rank test.

The associations between mortality and age, sex, risk factors, previous history, clinical presentation and LV ejection fraction were performed using Cox regression models. Assumptions of log-linearity, absence of interaction between surgical strategy and adjustment covariate mentioned above, absence of collinearity and proportionality of hazards were thoroughly verified. Cox proportionality assumption was verified using interaction between time and each covariate. A propensity score was developed to control the selection bias potentially related to surgery strategy. Propensity scores were constructed using logistic model with surgery strategy as predicted event and independent covariates which were selected a priori on the basis of their known or suspected association with both surgery strategies and mortality and cardiovascular events. A value of  $P < 0.05$  was used to determine the statistical significance of all tests.

## RESULTS

The patients' baseline and operative characteristics are presented in Tables 1 and 2.

From April 1996 to December 2009, we identified 430 patients with LVEF  $\leq 0.4$  who underwent isolated CABG including patients with LVEF  $\leq 30\%$  in 34% of cases.

Patients who received LIMA-SVG grafting were significantly older than BIMA group ( $64 \pm 9$  years vs  $58.5 \pm 10$  years,  $P = 0.01$ ), with more frequent dyslipidemia ( $59.6\%$  vs  $69.6\%$ ,  $P = 0.04$ ) and trend for a more frequent peripheral artery disease ( $42.2\%$  vs  $33.1\%$ ,  $P = 0.07$ ).

Patients who received BIMA grafting were significantly younger than LIMA-SVG ( $58.5 \pm 10$  years vs  $64 \pm 9$  years,  $P = 0.01$ ) with less frequent dyslipidemia ( $59.6\%$  vs  $69.6\%$ ,  $P = 0.04$ ). Although acute coronary syndrome and ambulatory myocardial infarction were the most common clinical presentations in both groups, NYHA class 3 and 4 in the preoperative period was more frequent in group 2 ( $P = 0.03$ ).

The analysis of echocardiographic parameters showed that mean LVEF, LV chamber dilatation and the presence of mitral insufficiency  $\geq 2$  were not significantly different between two groups.

The number of grafts per patient was similar in both

groups, most surgeries were performed on-pump, and complete revascularization was obtained in 70% of group 1 compared with 66.5% of group 2 (*P* = 0.50).

In group 1, the LIMA was harvested almost exclusively as a pedicle and grafted onto the left coronary system. The LIMA was grafted onto the circumflex as a free graft in 4 patients. A sequential anastomosis technique for the left anterior descending artery and diagonal branch was used in 30 patients. The RIMA graft was anastomosed to the left coronary system in 141 (82%) patients and the

right coronary artery in 31 (18%) patients. The RIMA was harvested as a pedicle in most cases and was grafted onto the circumflex artery as a free graft or on an *in situ* LIMA in 39 patients (23% of cases).

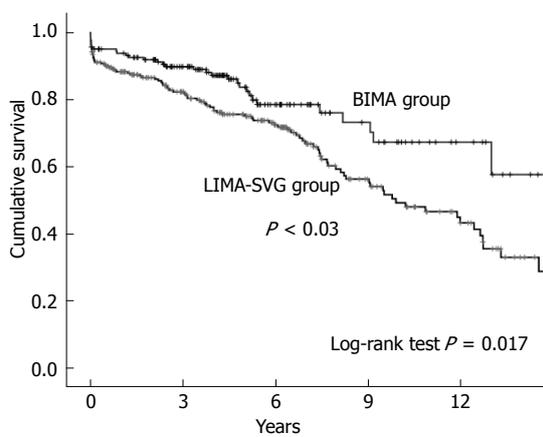

**Early results**

The older age of patients and worse initial clinical status in LIMA group influenced the post-operative period with longer ventilation time, higher vasopressor use and transfusion.

**Table 3** In-hospital course

Characteristics [n (%)]	BIMA group (n = 167)	LIMA-SVG group (n = 263)	P

LIMA-SVG group	263	168	109	49	26

**Figure 1** Kaplan-Meier estimated overall survival in unmatched cohorts. BIMA: Bilateral internal mammary artery; LIMA: Left internal mammary artery; SVG: Saphenous venous graft.

The overall in-hospital mortality rate in our study was 9.5%, and cardiovascular mortality represented 75% of deaths. The analysis of in-hospital course showed that all-cause mortality (7.8% vs 10.3%,  $P = 0.49$ ) and early postoperative morbidity including myocardial infarction (4.2% vs 3.8%,  $P = 0.80$ ), stroke (1.2% vs 3.8%,  $P = 0.14$ ), and digestive ischemia (1.8% vs 1.9%,  $P = 0.94$ ) were not significantly different between two groups (Table 3).

Mediastinitis requiring sternal re-opening and antibiotics occurred in 15 patients without significant difference between two groups group (5.3% vs 2.3%,  $P = 0.11$ ). Among patients who experienced mediastinitis, 8 (53.3%) patients were diabetic and 7 (43%) were obese.

**Long-term results**

The long-term follow-up (mean follow up: 6.2 ± 3.8 years; median follow up: 5.6 years) revealed 135 deaths, including 75 cardiovascular deaths.

The evidence-based medical postoperative treatment didn't significantly differ between LIMA-SVG group and BIMA group: Statin therapy (88.3% vs 94.7%,  $P = 0.4$ ),

beta blockers (77.1% vs 82.0%,  $P = 0.4$ ), angiotensin-converting enzyme inhibitor (84.3% vs 88.6%,  $P = 0.6$ ) and aspirin (90.5% vs 94.7%,  $P = 0.7$ ). During the follow up, 18 patients received an implantable cardiac defibrillator without significant difference between two groups.

At 1-year follow-up, LVEF value was obtained in 93.0% of cases, and mean LVEF in the overall population was 43.1% ± 6.2%. In comparison with the preoperative LVEF estimation, 1-year LVEF was improved in 72.5% of cases (in LIMA-SVG and BIMA groups: 71.3% and 74.9%, respectively,  $P = 0.32$ ) and unchanged or worsened in 27.5% of cases. A LVEF of > 50% was achieved in 49.1% of cases.

Figure 1 show Kaplan-Meier estimated overall survival in unmatched cohorts. The Kaplan-Meier 8-year estimated overall survival for patients in the BIMA group compared with patients in the LIMA-SVG group were 74.2% and 58.9%, respectively ( $P = 0.02$ ) but this significant difference became insignificant after multivariate adjustment hazard ratio (HR) [95% confidence interval (CI)] 1.02 (0.68-1.56),  $P = 0.8$ .

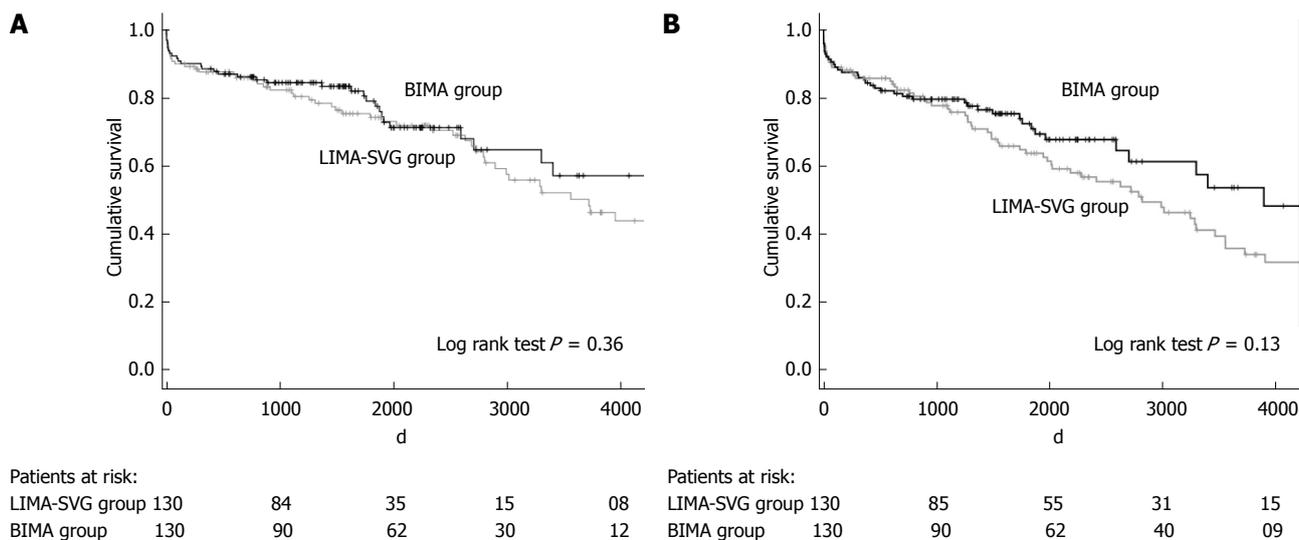

We performed 1:1 propensity score matching to select patients receiving BIMA or LIMA SVG group with comparable preoperative characteristics (Figure 2).

The propensity score matching analysis revealed that BIMA grafting is a safe revascularization procedure without on long term survival ( $P = 0.40$ ) or event free survival ( $P = 0.13$ ) difference in comparison with LIMA-SVG use.

**DISCUSSION**

We present a large, single-center observational study of surgical coronary revascularization in patients with reduced LVEF, which represent a sizeable proportion of all procedures performed at our hospital during this period (11% of cases).

Our analysis of the overall postoperative course is consistent with large contemporary reports on the topic, which indicate an in-hospital mortality ranging from about 4% to greater than 20% according to the comorbid conditions and the degree of LV dysfunction<sup>[4,9,10]</sup>.

**Figure 2** Kaplan-Meier estimated overall survival curves. A: Event-free survival; B: Comparing BIMA and LIMA-SVG in a propensity score-matched cohorts. BIMA: Bilateral internal mammary artery; LIMA: Left internal mammary artery; SVG: Saphenous vein graft.

One of the most interesting points of our study is to confirm that BIMA grafting does not modify the postoperative mortality in patients with LV impairment compared to LIMA-SVG grafting. Furthermore, although BIMA grafting appears to be the technically more challenging of the two techniques, the duration of surgical procedures did not differ between the two groups. This similarity may explain the relatively good postoperative outcome. The safety of BIMA grafting was also demonstrated by relatively low rates of periprocedural stroke, myocardial infarction and mesenteric ischemia, with no significant differences from the control group.

Sternal deep wound infection is a major complication after cardiac surgery with high in-hospital mortality (30% in our study). This complication concerned 3.5% of our overall population without significant difference between both surgical revascularization strategies. Among patients who experienced mediastinitis in our report, diabetes and obese patients represent well known high-risk subgroups (54% and 43% respectively)<sup>[11,12]</sup>. There is now good evidence in the contemporary literature that the use of both internal mammary arteries doesn't significantly increase the rate of sternal deep wound complication, especially with the skeletonized technique<sup>[13,14]</sup>. Moreover, high-risk subgroups as diabetic patients have the most to gain from this technique thereby preserving collaterals and sternal blood supply<sup>[14,15]</sup>. Galbut *et al*<sup>[16]</sup> also confirms that BIMA grafting doesn't significantly increase the rate of sternal wound infection whatever the preoperative LV function.

Late survival, although reduced when compared with patients with no decrease in LVEF, remains relatively high with estimated 5- and 8-year overall survival rates of 77% and 64%, respectively, in our study. This prognosis is largely influenced by the reduction of ischemia and the preservation of the remaining myocardium leading to the improvement of postoperative LVEF. In our study, we noted that LVEF was improved by surgical

revascularization in 72.5% of cases at 1 year follow-up, and LVEF was > 50% in 49.1% of cases. This benefit on LVEF is especially shown in patients with ischemic but viable myocardium who subsequently underwent revascularization<sup>[17,18]</sup>. However, the lack of interaction between myocardial viability status and benefit from CABG in the Stich trial indicates that assessment of myocardial viability alone should not be the deciding factor in selecting the best therapy for these patients<sup>[8]</sup>. Other structural predictive parameters such as LV volumes and ischemic mitral regurgitation should be taken into account for intervention planning.

Long-term survival after CABG is presumed to be directly correlated with late patency of the selected conduits and grafts. The internal mammary artery upregulates eNOS and therefore has higher concentration of NO than other conduits, which not only explain its improved patency but also likely has a significant impact on vascular endothelium and resistance to atherosclerosis in the grafted coronaries or in the coronaries that were not bypassed<sup>[19]</sup>.

However, the benefit of arterial conduits seems to concern internal mammary artery conduits in a majority of cases. Ruttman *et al*<sup>[20]</sup> demonstrated the superiority of the internal mammary artery graft over the radial artery as a second graft, and the benefit of all-arterial revascularization using additional radial artery is still debated.

Several large studies recently added to the growing literature that confirms the superiority of BIMA grafting over LIMA use, particularly in terms of improved long-term mortality with no significant increase in perioperative complications<sup>[7,13,21]</sup>. Recently, Locker *et al*<sup>[7]</sup> showed that multi-artery grafting compared with LIMA-SVG improved long-term survival in almost all comorbid conditions, including impaired LV function.

In our analysis, the difference between the BIMA group and the LIMA-SVG group concerning long-term

survival and event-free survival was significant in a univariate analysis. The older age of patients in LIMA-SVG group and the difference in baseline characteristics between the two groups may explain in part these results. However, the propensity score matching analysis revealed that BIMA grafting is a safe revascularization procedure but no significant difference on long term survival in comparison with LIMA-SVG was noted. These results reflect possibly the small size of two groups after propensity score matching analysis and therefore a type II error. It also suggests that the difference between these surgical strategies remains small in patients with low to moderate LVEF ( $\leq 40\%$ ) despite a long term follow up.

Galbut *et al.*<sup>[16]</sup> recently confirmed also that the benefit of BIMA grafting on long term survival concerned especially patients with normal LV function and moderate LV dysfunction (LVEF from 30% to 50%). However, this revascularization strategy should be considered with more caution in patients with low LV dysfunction.

It seems that the advantage of BIMA grafting compared with LIMA-SVG grafting in patients with reduced ejection fraction increases over time and the real benefit depends on survival probability determined by age and comorbidities. Comorbid factors, especially postoperative atrial fibrillation also increase the risk of long-term mortality and should be given important consideration when evaluating the benefits of the surgical revascularization strategy<sup>[22]</sup>. Therefore, further stratified analyses with larger number of patients and a follow up of one or two decades should be encouraged to identify the exact benefit from BIMA grafting in this situation.

### Limitations

Our study was a non-randomised, retrospective, and observational study with inherent bias.

There was a definite patient selection bias, demonstrated by a younger population in BIMA group that led to overestimate the benefits of this procedure in univariate analyses. The cut-off value of ejection fraction  $\leq 40\%$  has also influenced the results of our study. Further stratified analysis with larger number of patients should identify the exact benefit of BIMA grafting according to different level of LV dysfunction. Other variables not included in the multivariate models, however, may also influence the results of surgical revascularization as the quality of coronary vessels requiring bypass grafting and the location of both grafts. Likewise, we cannot exclude that the degree of viability or extent of fibrosis/necrosis might have led to the preferred choice of one or the other operative technique.

Medications including beta blockers, statins or ACE inhibitors at the time of discharge but also LV remodelling<sup>[23]</sup> and mitral regurgitation<sup>[24]</sup> might have affected the long term results. However, multiple adjustments using many factors could not be performed because of limited number of events.

Patients with severe coronary artery disease and markedly reduced LVEF represent a high-risk group

that can undergo CABG safely. Our longitudinal analysis suggests that BIMA grafting can be performed with acceptable perioperative mortality in patients with LV dysfunction but there was no survival difference in our follow up in comparison with LIMA-SVG use. Further studies, assessing the long-term impact hybrid approaches using BIMA and elective PCI using drug eluting stents will determine whether these new approaches constitute a true improvement in the field of myocardial revascularization<sup>[25]</sup>.

## COMMENTS

### Background

Patients with severe coronary artery disease and markedly reduced left ventricular ejection fraction represent a high-risk group that can undergo cardiac arterial bypass grafting (CABG) safely. The excellent outcome associated with left internal mammary artery (LIMA) grafting has quickly encouraged the use of bilateral internal mammary artery (BIMA). However, the widespread adoption of BIMA grafting is hindered because it might be associated with increased early morbidity. The aim of this study was to review the authors' institutional experience over 13 years with 430 patients with left ventricular (LV) dysfunction who underwent surgical revascularization.

### Research frontiers

To our knowledge, this is the largest single center observational report on patients with LV dysfunction who underwent myocardial surgical revascularization.

### Innovations and breakthroughs

This longitudinal analysis demonstrates that BIMA grafting can be performed with acceptable perioperative mortality in patients with LV dysfunction but there was no survival difference in our follow up in comparison with LIMA-SVG use.

### Applications

Appropriate patient selection.

### Terminology

BIMA grafting (bilateral internal mammary artery grafting) and LIMA-SVG (left internal mammary artery with saphenous venous) grafting: Two surgical strategies used to revascularize heart with impaired function.

### Peer-review

The manuscript is well written and addresses interesting and important facts regarding the revascularisation in left ventricular dysfunction.

## Abstract

### AIM

To determine the prevalence of QT prolongation in a large series of end stage liver disease (ESLD) patients and its association to clinical variables and mortality.

### METHODS

The QT interval was measured and corrected for heart rate for each patient, with a prolonged QT cutoff defined as QT > 450 ms for males and QT > 470 ms for females.

Multiple clinical variables were evaluated including sex, age, serum sodium, international normalized ratio, creatinine, total bilirubin, beta-blocker use, Model for End-Stage Liver Disease (MELD), MELD-Na, and etiology of liver disease.

### RESULTS

Among 406 ESLD patients analyzed, 207 (51.0%) had QT prolongation. The only clinical variable associated with QT prolongation was male gender (OR = 3.04, 95%CI: 2.01-4.60,  $P < 0.001$ ). During the study period, 187 patients (46.1%) died. QT prolongation was a significant independent predictor of mortality (OR = 1.69, 95%CI: 1.03-2.77,  $P = 0.039$ ). In addition, mortality was also associated with viral etiology of ESLD, elevated MELD score and its components ( $P < 0.05$  for all). No significant reversibility in the QT interval was seen after liver transplantation.

### CONCLUSION

QT prolongation was commonly encountered in an ESLD population, especially in males, and served as a strong independent marker for increased mortality in ESLD patients.

**Core tip:** We performed a case-control retrospective study in a large cohort of patients with end stage liver disease (ESLD) to determine the prevalence of QT prolongation and its association to clinical variables and mortality. Our results showed a high prevalence of QT prolongation in ESLD patients (51%), especially in males, and QT prolongation was a significant independent predictor of mortality. Based on our findings, we recommend close monitoring of the QT interval in ESLD patients with increased attention to any modifiable causes for QT prolongation.

## INTRODUCTION

The QT interval on an electrocardiogram (ECG) is a measure of ventricular depolarization and repolarization. Prolongation of the QT interval is associated with ventricular arrhythmias as well as sudden cardiac death in both congenital and acquired conditions. Multiple factors are thought to be responsible for the prolongation

of the QT interval in both congenital and acquired conditions, including electrolyte abnormalities, ventricular channelopathies, myocardial ischemia, medications, alcohol toxicity, and autonomic imbalance with sympathetic nervous system hyperactivity<sup>[1-11]</sup>. Recent studies have shown that end stage liver disease (ESLD) is associated with several electrophysiological changes; specifically, an increased prevalence of QT prolongation is seen in this population<sup>[12-30]</sup>. While the exact mechanism for QT prolongation is unknown, both improvement in liver function and liver transplantation have been associated with significant shortening in the QT interval in studies with small sample sizes<sup>[25-31]</sup>. Likewise, previous studies demonstrate reduction in the QT interval for cirrhotic patients who receive beta-adrenergic blockade in both the acute and chronic settings<sup>[32-34]</sup>. Thus, this may be a modifiable condition and amenable to therapy. Although some studies suggest a prolonged QT interval is related to severity of liver disease, etiology of liver disease, and increased mortality, conflicting results exist regarding these important clinical questions<sup>[14,19,24-30,35,36]</sup>.

We aimed to determine the prevalence and variables associated with QT prolongation in ESLD patients. Furthermore, we assessed whether QT prolongation was associated with increased mortality in these patients.

## MATERIALS AND METHODS

The research study was conducted in accordance to the ethical guidelines of the 1975 Declaration of Helsinki as reflected by approval by the institutional review board. After institutional review board approval was obtained, we performed a case-control retrospective study estimating the prevalence of QT prolongation in a cohort of cirrhotic patients with ESLD being evaluated for liver transplant. We then quantified the associations of QT prolongation with multiple clinical variables including etiology of liver disease, sex, age, Model for End-Stage Liver Disease (MELD) score, MELD-Na (MELD with incorporation of serum sodium) score, sodium level, international normalized ratio (INR), creatinine, total bilirubin, beta-blocker use, liver transplantation, and mortality. Variables were collected from the most recent labs collected (within 90 d of baseline ECG) as part of routine outpatient care. We utilized the Organ Transplant Tracking Record (OTTR) database and hospital records to identify our cohort and track their survival.

Patients included men and women above age of 18 with ESLD who were undergoing a liver transplant evaluation for any indication and had ECGs available for visual analysis. For patients who did not undergo a liver transplant, the most recent ECGs were used as baseline. For transplanted patients, the ECG prior to transplant was used as the baseline ECG while the average QT interval from the post-transplant ECGs was used to determine the effects of transplant on QT prolongation. This was done to eliminate artifacts due to the unstable or immediate post transplantation recovery period when the

patients' ECGs are vulnerable to medication changes or electrolyte imbalances. Patients without an interpretable ECG, or with conduction abnormalities, recent myocardial infarction (within the last 30 d by history), or pacemaker use, were excluded from the study.

### QT determination

For all 12 lead ECGs, the QT interval based on Bazett's principle (QT<sub>c</sub>) was obtained automatically using a computerized ECG machine (General Electronics MAC 5500 HD) to avoid interobserver variability. With Bazett's principle, the QT interval is measured from the beginning of the QRS complex to the termination of the T-wave and divided by the square root of the R-R interval in seconds<sup>[37]</sup>. A QT<sub>c</sub> > 450 ms for males and a QT<sub>c</sub> > 470 ms for females was considered abnormal or prolonged, as defined by European regulatory guidelines<sup>[38]</sup> and Goldenburg *et al.*<sup>[39]</sup> to account for gender differences. Patients with QT<sub>c</sub> prolongation were subdivided into three categories for analytic purposes: mild (451-470 ms in males; 471-490 ms in females), moderate (471-490 ms in males; 491-510 ms in females), and severe (> 490 ms in males; > 510 ms in females).

### Statistical analysis

Patients with ( $n = 207$ ) and without QT<sub>c</sub> prolongation ( $n = 199$ ) were compared on various clinical characteristics by *T* tests (for continuous variables and after log transformation for INR, creatinine, and bilirubin) and Fisher's exact tests (for dichotomous variables). Logistic regressions with QT<sub>c</sub> prolongation as the outcome were performed to identify significant unadjusted and adjusted associations with clinical characteristics identified in the next sentence. The first of three multivariate models included beta blocker use, etiology (viral, ethanol, non-alcohol steatohepatitis), MELD components (sodium, log INR, log creatinine, and log bilirubin), gender, and age as predictors; the second and third multivariate models replaced MELD components by total MELD score and total MELD-Na score respectively. Four logistic regressions with mortality as the outcome were also performed. The first related mortality to degree (mild, moderate, severe) of QT<sub>c</sub> prolongation. The second through fourth analyses related mortality to QT<sub>c</sub> prolongation and the aforementioned clinical characteristics, in parallel with the three multivariate models for QT<sub>c</sub> prolongation. A paired signed rank test was used to examine the change in QT<sub>c</sub> before and after surgery in a subset of patients ( $n = 74$ ) receiving liver transplantations. Approximately 25% of the patients did not have routine outpatient labs within the 90 d of their baseline ECG. Therefore, the analyses involving the MELD components and MELD totals were performed using multiple imputation. Microsoft Excel, SAS, and R were used for data analysis and visualization. Statistical significance was declared when  $P < 0.05$ .

## RESULTS

### Patient characteristics

The OTTR database revealed that 729 patients were

evaluated for a liver transplant at the University of Kentucky over a recent 12-year period. Of the 729 patients, 406 met the inclusion criteria for this study. In addition, approximately 25% of the patients (102 out of 406) did not have routine outpatient labs within the 90 d of their baseline ECG. The effective sample size for comparison of QT interval pre- and post-transplantation was 74. The estimated prevalence of QT prolongation was 51.0% (207 out of 406).

Table 1 shows that the 207 patients with QT prolongation (QT<sub>c</sub> by Bazett's  $\geq 450$  for males and  $\geq 470$  ms for females) were generally similar to the 199 patients without QT prolongation based on clinical variables. However, males with QT prolongation had higher creatinine, MELD, and MELD-NA scores than males without QT prolongation. Beta-blocker use was more common in females without QT prolongation.

In logistic regression analysis with QT<sub>c</sub> prolongation as an outcome variable, there was a significant association with male sex [estimated odds ratio (OR) 3.04, 95%CI: 2.01-4.60,  $P < 0.001$ ]. The association persisted in all three multivariate models, with adjusted OR between 3.05 and 3.09 ( $P < 0.001$  in all cases); there were no other significant predictors of QT<sub>c</sub> prolongation in these models.

Of the 406 patients, 187 (46.1%) died during the study period. Any level (mild, moderate, or severe) of QT<sub>c</sub> prolongation was associated with significantly increased mortality (Table 2). However, the risk of mortality did not exhibit an increasing pattern with respect to the level of prolongation.

Figure 1 shows that QT<sub>c</sub> prolongation is a significant predictor of mortality (OR 1.69, 95%CI: 1.03-2.77,  $P = 0.039$ ) in a multivariate model which adjusts for the components of MELD and other clinical variables. This model also reveals significant associations with mortality for viral etiology, ethanol etiology, combined viral and ethanol etiology, INR, creatinine, and bilirubin. Figure 2 depicts findings for an additional multivariate model in which MELD replaces its components, while Figure 3 pertains to a model with MELD-Na. In all the models, QT<sub>c</sub> prolongation and the aforementioned etiologies remain significant predictors of mortality.

Effective sample size for comparison of QT<sub>c</sub> interval pre- and post-transplantation was 74. Median pre-transplant QT<sub>c</sub> was 457 with interquartile range of 435-472 ms. Median post-transplant QT<sub>c</sub> was 450 with interquartile range of 429-468. Our study showed no significant change in the QT<sub>c</sub> interval after liver transplantation ( $P = 0.24$ ).

## DISCUSSION

Electrophysiologic cardiac abnormalities are well documented in patients with ESLD. As noted in our study, QT prolongation is a common finding within this population. Although the exact mechanism for QT prolongation in ESLD remains to be established, previous studies have suggested QT prolongation in ESLD may be multifactorial

**Table 1 Patient characteristics n (%)**

Variable	QTc prolongation			No QTc prolongation		
	All (n = 207)	Male (n = 150)	Female (n = 57)	All (n = 199)	Male (n = 92)	Female (n = 107)
Beta-blocker use <sup>1</sup>	161 (77.8)	122 (81.3)	39 (68.4)	153 (77.7)	66 (71.7)	87 (82.9) <sup>3</sup>
Viral etiology	80 (38.7)	65 (43.3)	15 (26.3)	69 (34.7)	42 (45.7)	27 (25.2)

Entries are number (percent) or mean + SD. <sup>1</sup>Excluded for two subjects; <sup>2</sup>Excluded for 102 subjects; <sup>3</sup>Significantly different (*P* < 0.05) *vs* patients of same gender with QTc prolongation.

**Table 2 Estimated odds ratios for mortality based on levels of QTc prolongation**

	OR	P	95%CI
Mild QTc prolongation <i>vs</i> none	1.67	0.045	1.01-2.76
Moderate QTc prolongation <i>vs</i> none	2.11	0.013	1.17-3.81
Severe QTc prolongation <i>vs</i> none	1.83	0.044	1.02-3.31

Mild QTc prolongation: 451-470 ms in males and 471-490 ms in females; Moderate QTc prolongation: 471-490 ms in males and 491-510 ms in females; Severe QTc prolongation: > 490 ms in males and > 510 ms in females.

and related to abnormalities in potassium channels involved in repolarization, high plasma concentrations of bile salts, and autonomic dysfunction<sup>[12-19,40]</sup>.

In our study, the majority of patients (51.0%) demonstrated QT prolongation when calculated using Bazett’s formula. Of the 406 patients evaluated, 187 (46.1%) died between years 2000 to 2013, confirming the high mortality in ESLD. An increase in mortality was seen at all levels of prolonged QT. Moreover, some etiologies and MELD components, as well as total MELD and MELD-Na scores, were predictive of mortality. These findings suggest worse outcomes in patients with viral hepatitis or combined viral and ethanol etiology, and they further validate the utility of MELD, MELD-Na, and its components for predicting survival in ESLD<sup>[41,42]</sup>. Importantly, QT prolongation predicts mortality above and beyond the aforementioned factors.

A number of studies have evaluated the association between QT prolongation and severity of ESLD as measured by Child-Pugh scores<sup>[14,19,24,25,28,36]</sup>. The majority of such studies have shown an increase in QT prolongation in association with higher Child-Pugh scores with the exception of studies done by Carey *et al.*<sup>[27]</sup> and Adigun *et al.*<sup>[30]</sup>. Due to the interobserver variability and use of subjective parameters in Child-Pugh classifications, MELD and MELD-Na scores are now widely viewed as superior indices for predicting mortality and allocating

transplants<sup>[41,42]</sup>. In our study, no significant associations were seen between QT prolongation and these superior indices of ESLD, in accord with the smaller studies by Zurick *et al.*<sup>[29]</sup> and Day *et al.*<sup>[35]</sup>.

Our study is unique in that we used validated thresholds for QT prolongation. While other studies used a cutoff of 440 msec, our study uses gender specific cutoffs as suggested by Goldenberg *et al.*<sup>[39]</sup>, to account for gender differences in QT prolongation that are typically longer for females<sup>[7,38,39,43]</sup>. Given our use of higher thresholds (> 450 ms for males and > 470 for females), which allowed higher selectivity for more severe QT prolongation, we may have underestimated the prevalence of QT prolongation while overestimating its association with other variables. Although Adigun *et al.*<sup>[30]</sup> demonstrated that a physiologic gender difference in the QTc interval is abolished in cirrhosis and that gender hormone concentrations have no effect on the QTc interval, our study reports a much higher prevalence of QT prolongation among males. When QTc prolongation was a dependent variable in our logistic regression models, both unadjusted and adjusted results showed statistically significant associations between QTc prolongation and male sex, while no other variables considered were significantly associated with QTc prolongation. A potential limitation to our study and explanation for these findings may be the use of gender specific thresholds and the corresponding assumption that gender differences in QT interval exist among ESLD patients. In particular, the higher cutoff for females may tend to understate QT prolongation prevalence within that gender.

Due to their utility and wide use in portal hypertension, the effects of acute and chronic beta-blockers on QT prolongation have been evaluated, with results showing a reduced QT interval<sup>[32-34]</sup>. In addition, partial or full reversal of QT prolongation following liver transplantation has also been noted<sup>[14,26-31]</sup>. Contrary to these findings, in our study, QTc prolongation was not significantly influenced by etiology, age, beta-blocker use, or transplantation. Although beta-blocker use had a trend towards lower

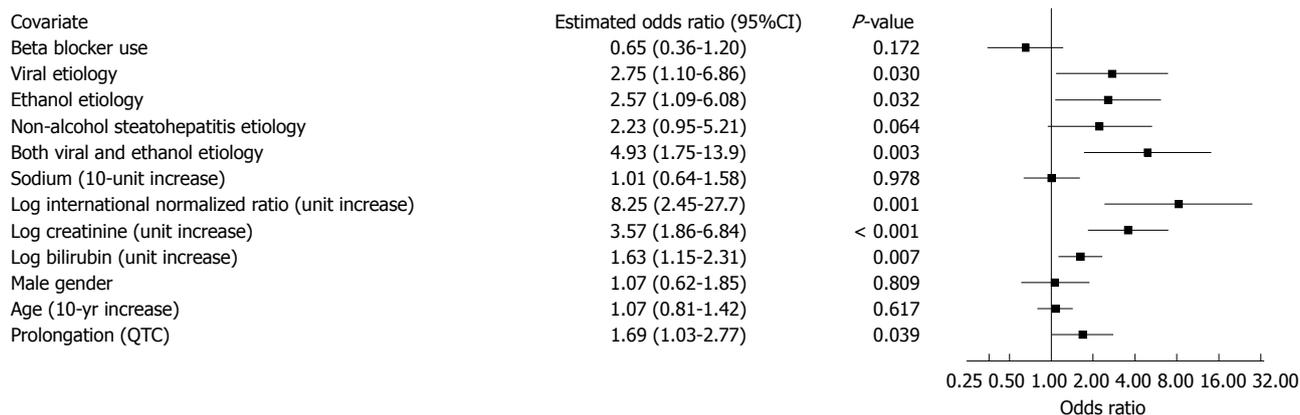

Figure 1 Association of mortality with Model for End-Stage Liver Disease components and clinical variables.

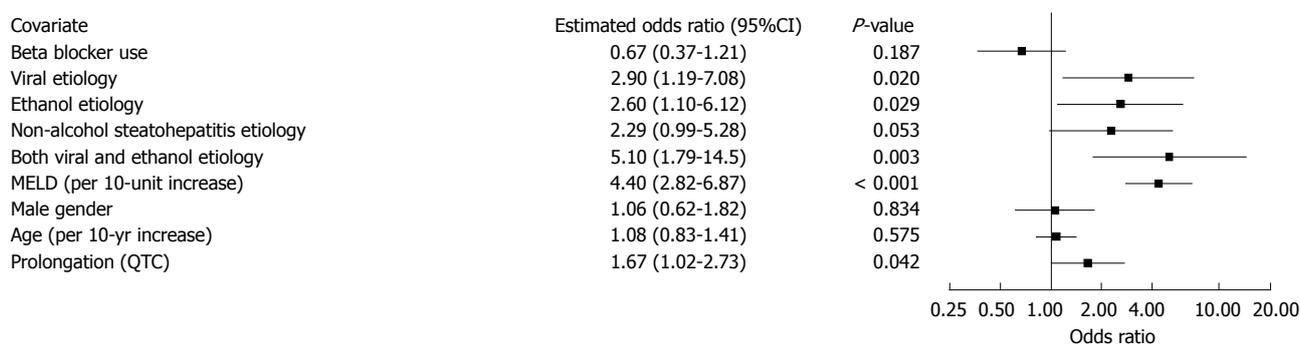

Figure 2 Association of mortality with total Model for End-Stage Liver Disease score and clinical variables.

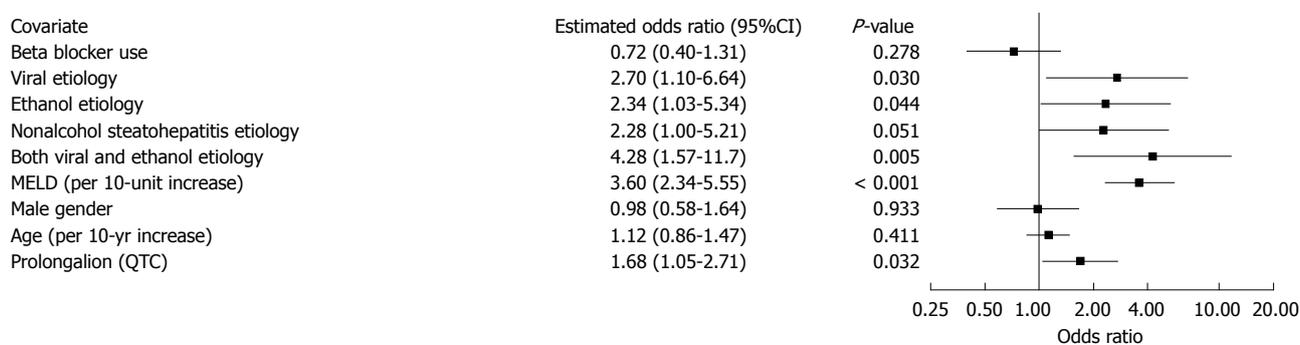

Figure 3 Association of mortality with total Model for End-Stage Liver Disease with incorporation of serum sodium score and clinical variables.

mortality, this did not meet statistical significance. The lack of reversibility in the QT interval following liver transplantation in our study may be due to our small effective sample size.

Several additional limitations need to be considered in our present investigation. As a retrospective study, our results have the potential for unintentional selection bias. Patients from our study were mostly Caucasian residing in rural areas from the state of Kentucky, which may not generalize geographically to the entire country. Our preoperative and postoperative ECGs were obtained during unspecified hospital or clinic visits, exposing our study to sampling bias related to factors such as electrolyte imbalance or concomitant use of QT

prolonging drugs. As noted above, MELD variables were unavailable from 102 out of 406 patients (25%) due to lack of outpatient labs within 90 d of their baseline ECG. Although MELD scores are frequently calculated for cirrhotics as part of their routine assessment, acute biochemical changes are often observed during inpatient hospitalizations, while labs performed outside 90 d of the baseline ECG may not accurately reflect the 90-d mortality rate assessed by MELD score in association to the observed ECG changes. Despite unavailable MELD scores on 102 patients, our analyses re-confirmed what is already well established in current literature that higher MELD scores are associated with higher mortality in ESLD patients. When the MELD components and

total score were evaluated in relation to the presence of QT prolongation, our results did show that males with QT prolongation had higher creatinine, MELD, and MELD-NA scores than males without QT prolongation (Table 1). Although males with worse MELD scores (*i.e.*, sicker patients) may have had a higher prevalence of QT prolongation, the retrospective nature of this study does not establish a cause and effect relationship, and the findings do not directly impact the main conclusion of our study where QT prolongation was an independent risk factor for mortality in ESLD.

When examining the severity of QT prolongation and its association with mortality, we defined mild, moderate, and severe levels of prolongation to categorize our patients. However, this categorization may not yield the best discriminatory power. Although the vast majority of heart rates in our study were within an acceptable range, calculation of QT intervals using Bazett's formula is thought to be less accurate with particularly low or high heart rates<sup>[44]</sup>. Furthermore, our study relies on the implicit assumptions of accurate data gathering and correct QT interval readings from our ECG machine, which may be prone to systematic error; however, the ECG machine does eliminate interobserver variability. Finally, although QT prolongation has been associated with increased mortality secondary to ventricular arrhythmias, our study did not differentiate specific causes of death.

Our study showed that QT prolongation was common, especially for male patients, in ESLD. Although an association between mortality and QT<sub>c</sub> prolongation was evident, a greater degree of QT<sub>c</sub> prolongation did not clearly portend worse outcomes. Finally, while QT<sub>c</sub> interval may be an independent risk factor for mortality in ESLD patients, the exact mechanism for the increase in mortality remains to be established. Based on our findings, it is reasonable to recommend close monitoring of the QT interval in ESLD patients with attention to any modifiable causes for QT prolongation, such as electrolyte imbalances or medications.

## COMMENTS

### Background

The QT interval on an electrocardiogram (ECG) is a measure of ventricular depolarization and repolarization. Prolongation of the QT interval is associated with ventricular arrhythmias as well as sudden cardiac death in both congenital and acquired conditions. Multiple factors are thought to be responsible for the prolongation of the QT interval in both congenital and acquired conditions, including electrolyte abnormalities, ventricular channelopathies, myocardial ischemia, medications, alcohol toxicity, and autonomic imbalance with sympathetic nervous system hyperactivity.

### Research frontiers

Recent studies have shown that end stage liver disease (ESLD) is associated with several electrophysiological changes; specifically, an increased prevalence of QT prolongation is seen in this population. While the exact mechanism for QT prolongation is unknown, improvement in liver function, beta-blocker use, and liver transplantation have been associated with shortening in the QT interval in studies with small sample sizes. Although some studies suggest a prolonged QT interval is related to severity of liver disease, etiology of liver disease, and

increased mortality, conflicting results exist regarding this important clinical question.

### Innovations and breakthroughs

The authors aimed to determine the prevalence of QT prolongation in a large series of ESLD patients and its association to clinical variables and mortality. The QT interval was measured and corrected for heart rate (QT<sub>c</sub>) for each patient, with prolongation defined as QT<sub>c</sub> > 450 ms for males and QT<sub>c</sub> > 470 ms for females. Multiple clinical variables were evaluated including sex, age, serum sodium, international normalized ratio, creatinine, total bilirubin, beta-blocker use, Model for End-Stage Liver Disease (MELD), MELD-Na, and etiology of liver disease. Among 406 ESLD patients analyzed, 207 (51.0%) had QT prolongation. The only clinical variable associated with QT prolongation was male gender (OR = 3.04, 95%CI: 2.01-4.60, *P* < 0.001). During the study period, 187 patients (46.1%) died. QT prolongation was a significant independent predictor of mortality (OR = 1.69, 95%CI: 1.03-2.77, *P* = 0.039). In addition, mortality was also associated with viral etiology of ESLD, elevated MELD score and its components (*P* < 0.05 for all). No significant reversibility in the QT<sub>c</sub> interval was seen after liver transplantation.

### Applications

QT<sub>c</sub> interval may be an independent risk factor for mortality in ESLD patients and thus the authors recommend close monitoring of the QT interval in ESLD patients and increased attention to any modifiable causes for QT prolongation such as electrolyte imbalances or medications.

### Terminology

ESLD: End stage liver disease; MELD: Model for End-Stage Liver Disease; MELD-Na: Model for End-Stage Liver Disease score with serum sodium; OTTR: Organ Transplant Tracking Record; QT<sub>c</sub>: QT interval corrected for heart rate.

### Peer-review

This is an interesting and important finding, as QT measurement is not formally considered in liver transplant clinics. The results of this study are interesting and relevant.

### Abstract

#### AIM

To investigate the rates and determinants of success of repeat percutaneous coronary intervention (PCI) following an initial failed attempt at recanalising the chronic total occlusions (CTO) percutaneously.

#### METHODS

In 445 consecutive first attempt CTO-PCI procedures in our institution, procedural failure occurred in 149 (33.5%). Sixty-four re-PCI procedures were performed in 58 patients (39%) all had a single CTO. Procedural and outcome data in the re-PCI population was entered into the institutional database. A retrospective analysis of clinical, angiographic and procedural data was performed.

#### RESULTS

Procedural success was achieved in 41 (64%) procedures. Univariate analysis of clinical and angiographic characteristics showed that re-PCI success was associated with intravascular ultrasound (IVUS) guidance (19.5% vs 0%,  $P = 0.042$ ), while failure was associated with severe

calcification (30.4% *vs* 9.7%,  $P = 0.047$ ) and a JCTO score  $> 3$  (56.5% *vs* 17.1%  $P = 0.003$ ). Following multiple regression analysis the degree of lesion complexity (J-CTO score  $> 3$ ), IVUS use, involvement of an experienced CTO operator and LAD CTO location were significant predictors of successful re-PCI. Overall the complication rate was low, with the only MACCE two periprocedural MI's neither of which required intervention.

### CONCLUSION

Re-PCI substantially increases the overall success rate of CTO revascularization. Predictors of re-PCI success included the use of IVUS, the involvement of an experienced CTO operator in the repeat attempt and the location of the CTO.

**Key words:** Repeat percutaneous coronary intervention; Chronic total occlusion

**Core tip:** Failed percutaneous recanalization of chronic total occlusions (CTO) constitutes a clinical conundrum. While percutaneous treatment is often abandoned in favour of medical therapy, CTO-percutaneous coronary intervention (PCI) expertise and alternative techniques may contribute to improve procedural success. This study shows that with careful pre-procedural planning reattempt PCI in CTO's is both safe and efficacious.

Determinants of percutaneous coronary intervention success in repeat chronic total occlusion procedures following an initial failed attempt. *World J Cardiol* 2017; 9(4): 355-362 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/355.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.355>

## INTRODUCTION

Revascularization of chronic total occlusions (CTO) is a well accepted technique, albeit one of the most challenging procedures in interventional cardiology with the presence of a CTO a strong predictor against percutaneous recanalisation<sup>[1,2]</sup>. There is growing evidence that CTO recanalization confers benefit to patients<sup>[3-11]</sup>, however the success rate of CTO percutaneous coronary intervention (PCI) is significantly lower than in non-CTO lesions, ranging from 51% to  $> 80\%$  in different series<sup>[3,8,12,13]</sup>. Several attempts have been made to rate procedural difficulty in CTOs, with the JCTO score<sup>[14]</sup>, the most commonly used score, identifying prior CTO failure as one of the five key determinants of PCI success. The introduction of novel techniques including parallel wiring, CART/reverse CART, hybrid procedures and bilateral injections have increased the success of the procedure<sup>[15-17]</sup>, with several studies promoting the use of intravascular ultrasound (IVUS)

in guiding wiring of the true lumen and optimizing CTO-PCI outcomes<sup>[17-19]</sup>. Despite the potential benefits of CTO recanalization a significant proportion of patients are managed medically rather than reattempting CTO-PCI<sup>[5]</sup>, perhaps because, when compared to initial attempts at CTO-PCI, the predictors of and success rates in re-PCI are largely unknown. The purpose of this study was to evaluate the success rate of re-PCI, as well as to identify predictors of success.

## MATERIALS AND METHODS

Between January 2008 and September 2012, 445 patients had first time native vessel CTO PCI procedures in our institution. In 149 patients the initial procedure was unsuccessful with re-PCI planned in 58 patients (39%) who underwent 64 further procedures, four patients had two re-PCI attempts while one patient had three re-PCI attempts (Figure 1). Procedural and outcomes data in this re-PCI population was entered into the institutional database.

Data was collected in relation to factors that may affect procedural success, including fluoroscopy time, use of stiffer polymer coated CTO guide-wires and *ad-hoc* PCIs. Re-PCI data collected including change of strategy, IVUS guidance and involvement of an experienced operator. The patients were divided into subgroups according to procedural outcome (successful/failure) for analysis. Post-procedural data including evidence of periprocedural MI, renal impairment and death was obtained from the institutional database.

CTO was defined as a TIMI (thrombolysis in myocardial infarction) grade 0 flow in the target segment, with a duration  $> 3$  mo, determined based on clinical symptoms or prior angiography when available<sup>[12]</sup>. Angiographic success was defined as a residual stenosis  $< 30\%$  with TIMI grade flow  $\geq 2$ . The EuroCTO club definition of an operator with a success rate of at least 80% in CTO PCI was used to identify experienced operators<sup>[1]</sup>, all other operators were considered non-experienced operators. IVUS guidance included two techniques (IVUS-guided wiring of the CTO stump, and IVUS-guided penetration from the subintimal space). The lesion complexity was classified using the J-CTO score with lesions scored as 0-5 dependent on the presence of one or more of the following features: Blunt stump, length  $> 20$  mm, severe calcification,  $> 45^\circ$  tortuosity and previous failed attempt<sup>[14]</sup>.

### Statistical analysis

Categorical and continuous variables are expressed as counts (%) and mean  $\pm$  SD, respectively. The angiographic, clinical and procedural factors were analyzed as possible determinants of success in a new attempt at recanalization and were compared between patient groups.

Categorical variables were compared with the Fisher's exact test and continuous variables were compared with a *t* test. All indices with a *P*-value  $< 0.1$  in the

univariate analysis were included in a multiple logistic regression analysis and the final model was selected by Akaike's Information Criterion<sup>[20]</sup>. Fitting a classical logistic regression model with this dataset leads to a non-identifiable problem, as some variables induce a separation. In order to obtain stable logistic regression coefficients, we use Bayesian inference<sup>[21]</sup>. The computations required to estimate the coefficients of the model are implemented in the arm package for applied regression and multilevel modelling in R v.3.2.2 software.

## RESULTS

The success rate for CTO re-PCI was 64.1%. The baseline clinical characteristics of the patients are shown in Table 1. The mean age was 59.5 ± 11.5 years, and 86.2% were male. There were no significant differences between the successful and failed re-PCI groups. Baseline angiographic and procedural characteristics are shown in Tables 2 and 3. The left anterior descending artery (LAD) and the right coronary artery (RCA) were the most commonly affected vessel in the successful and failed groups respectively. Of the individual components of the JCTO score only calcification was significant with

more severely calcified lesions in the failed group (30.4% vs 9.7%,  $P < 0.047$ ). The successful group had a lower average J-CTO score ( $2.73 \pm 0.84$  vs  $3.2 \pm 0.99$ ,  $P < 0.010$ ), with fewer lesions with a J-CTO score  $\geq 4$ .

Inability to cross the lesion with a guidewire is the most common reason for failure in CTO-PCI. We analyzed factors associated with the initial failed attempt that may reflect the effort invested in the initial attempt and therefore could have an indirectly proportional relationship with success in re-PCI. These included fluoroscopy time, use of dedicated guidewires and a planned initial attempt vs *ad-hoc* CTO-PCI. There were no significant differences in any of these variables. In the patients who underwent a reattempt 30% of the initial failed procedures were *ad-hoc* CTO PCI attempts at the time of diagnostic angiography. The group who underwent initial *ad-hoc* PCI had a higher success rate than those who underwent an initial planned attempt (89% vs 48.8%,  $P = 1$ ) however this did not reach statistical significance.

All IVUS guided procedures were successful ( $P = 0.020$ ). There were no significant differences observed with the use of individual pieces of equipment such as guide catheters, guidewire type or microcatheters; or

implementation of new strategies such as retrograde access, contralateral injection or parallel wiring.

Multiple logistic regression analysis identified the degree of lesion complexity (J-CTO score ≤ 3 and >3), IVUS use, involvement of an experienced CTO operator in the repeat PCI attempt, and LAD location of the CTO as independent predictors of procedural success/failure (Table 4). A model for predicting probability of procedural success was developed with logistic regression analysis that combined these angiographic and technical variables (Figures 2 and 3). As seen in Figures 2 and 3, IVUS use in combination with an experienced CTO operator increases the probability of success particularly when the J-CTO score is > 3.

Overall, the complication rate was low with 2 peri-procedural MI's one occurring in a successful procedure and one in a failed procedure, both were characterized by minimal elevation in cardiac enzymes post procedure and

neither required further intervention. There were no deaths in the population and no contrast induced nephropathy.

## DISCUSSION

The main conclusion of our study is that re-PCI in CTO after a failed attempt is associated with a good success rate. Adequate pre procedural evaluation and planning is crucial. In complex lesions factors such as IVUS-guidance and experienced CTO operators increase the chances of success. Less complex lesions, particularly those in the LAD, may be attempted by non-experienced CTO operators with a good success rate.

In our study population, the success rate for CTO-re-PCI was 64.1%, this compares favorably with the Japanese CTO registry where re-PCI attempts had a procedural success rate of 68.5%<sup>[11]</sup>. Involvement of experienced operators and used of IVUS is associated

Table 4 Predictors of procedural success/failure					
Variable	Coefficient (b)	SD (b)	95%CI	P (b ≠ 0   data)	P value
J-CTO ≤ 3	0.26	0.52	-2.04	0.69	0.31
J-CTO > 3	-1.67	0.67	-3.34	0.99	0.01
LAD	0.9	0.6	-2.36	0.93	0.07
IVUS use	2.96	1.58	-6.2	0.97	0.03
Experienced operator	0.78	0.58	-2.28	0.91	0.09

LAD: Left anterior descending, J-CTO: Japanese chronic total occlusion; IVUS: Intravascular ultrasound.

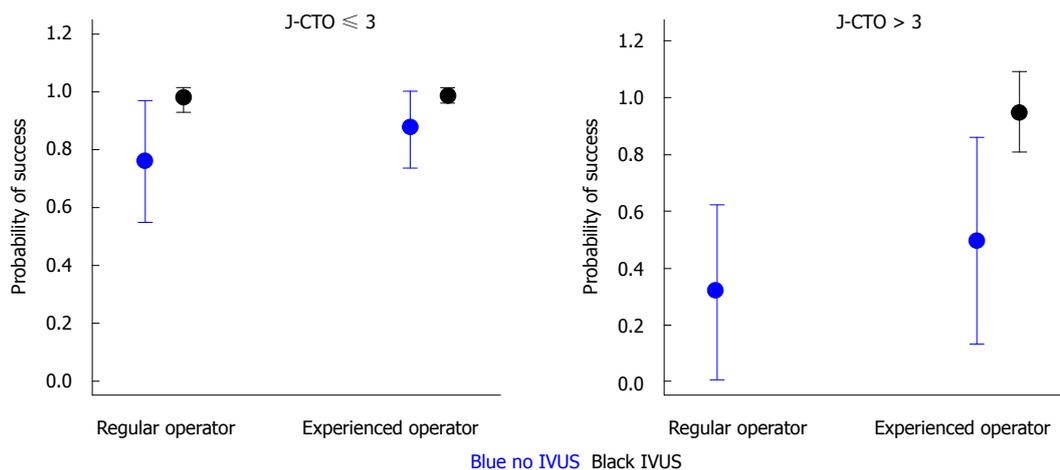

Figure 2 Mean probability of success with 95%CI dependent on angiographic and procedural variables in left anterior descending chronic total occlusion. LAD: Left anterior descending; JCTO: Japanese chronic total occlusion; IVUS: Intravascular ultrasound.

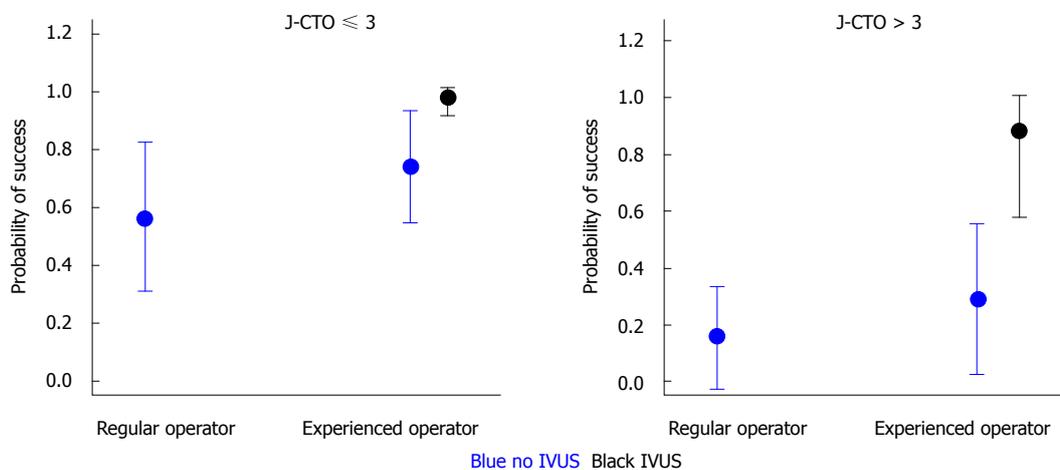

Figure 3 Mean probability of success with 95%CI dependent on angiographic and procedural variables in non left anterior descending chronic total occlusion. LAD: Left anterior descending; JCTO: Japanese chronic total occlusion; IVUS: Intravascular ultrasound.

with improved success, particularly in CTOs in the LAD location. Compared to the Japanese CTO data where success rates in re-PCI cases were significantly lower than initial attempts (68.5% vs 86.6% respectively), in our group, we found a similar overall success rate in the re-PCI group (64.1% vs 66.5%). This is likely explained by a less aggressive initial approach to CTO-PCI in our population during the study period. Patients who underwent initial *ad-hoc* PCI had a higher re-PCI success rates than those who underwent an initial planned

attempt (89% vs 48.8%,  $P = 1$ ), probably reflecting a less dedicated attempt, with difficulties easily overcome in a second, more aggressive procedure. The success rate in re-PCI contributes to a significant increase in per patient success of PCI in this complex anatomical scenario.

There have been several attempts to rate CTO procedural difficulty. The J-CTO score, the most popular of the CTO procedural difficulty scores, was developed by Morino *et al*<sup>[14]</sup> in their large multicenter registry to

classify the difficulty of antegrade lesion crossing, and identified prior CTO failure as a one of the five key determinants of PCI success. In our population, we found only one of the traditional predictors of procedural difficulty in initial attempt CTO-PCI, severe calcification to be significantly associated with procedural success re-PCI. Nombela-Franco *et al.*<sup>[22]</sup> validated the predictive value of the J-CTO score in successful antegrade crossing of the lesion within thirty minutes however they failed to show an ability to predict procedural success. Although not validated for predicting success the J-CTO score remains a useful tool in stratifying lesion complexity with significantly more patients with a J-CTO score > 4 in the failed group. Similar to data from Thompson *et al.*<sup>[23]</sup> showing a significantly higher PCI success rate with experienced operators (75.2% vs 58.9%;  $P < 0.001$ ), we found an experienced operator an important predictor of success in re-PCI attempts.

Data from the EuroCTO club puts IVUS use at 1.5% amongst its members in 2010. This is likely due to economic constraints and differs from Japan and the US where imaging techniques play a much larger role in CTO revascularization<sup>[24]</sup>. In our population, IVUS was used in 20% of all successful re-PCIs, in 6 (15%) cases a second wire was introduced into the true lumen *via* IVUS guidance after visualizing the first wire in false lumen and in 2 (5%) cases IVUS was used for ostial wiring. Furthermore, in these cases IVUS aided vessel sizing prior to stent implantation suggesting IVUS can be used to enhance the safety of CTO-PCI and optimize final results.

The CTO PCI reattempt rate remains relatively low, approximately 38% in this study, perhaps due to lack of large randomized clinical trials demonstrating benefit with CTO revascularisation. A large meta-analysis from Joyal *et al.*<sup>[25]</sup> in 2010 comparing successful to failed CTO recanalization showed a 44% reduction in mortality, 78% reduction in subsequent CABG and a 55% reduction in residual angina in successfully recanalised CTO's. However there was significant heterogeneity amongst the clinical outcomes and successful recanalization did not impact on MI or MACE. Other studies have shown successful percutaneous coronary intervention in a chronic total occlusion (CTO-PCI) to be beneficial in terms of recurrent myocardial, infarction, all-cause death, recurrent angina pectoris, subsequent CABG and cumulative survival rate compared to conservative management after failed PCI attempts however these are small heterogeneous populations<sup>[3-8]</sup>. In the context of acute myocardial infarctions it has been shown that the presence of a CTO increases long term mortality<sup>[9]</sup>, with CTO an independent predictor of mortality in STEMI with cardiogenic shock<sup>[10]</sup>. The high success rate, low procedural complication and in-hospital MACE rates observed in this study suggest that after failed attempt a reattempt a CTO-PCI should be considered.

Finally, combination of the angiographic and procedural factors identified by multiple regression analysis as predictive of success or failure (degree of lesion complexity,

IVUS use and an experienced CTO operator) yielded anticipated success rates ranging from 16% to 99%. It was observed that the implementation of procedural factors such as IVUS-guidance and experienced CTO operators are crucial when it comes to complex lesions (J-CTO score > 3), increasing in the probability of success from 16% to 99%. In comparison in less complex lesions (J-CTO score < 3), technical factors play a lesser role and these lesions even when attempted by non-experienced operators using IVUS have a high probability of success. These factors should be considered when planning a CTO-PCI strategy.

### Limitations

There are a number of limitations to our study. First, it is a descriptive and retrospective study designed only to look at the angiographic success rates and immediate in hospital outcomes of reattempt PCI. Long-term clinical and angiographic outcomes require evaluation in large-scale prospective clinical trials. Second, the angiographic characteristics of the CTOs were evaluated retrospectively. Third, this is a small sample from a single centre therefore one must be cautious when interpreting these results.

In conclusion, our findings suggest that re-PCI increased substantially the overall success rate of CTO revascularization. Predictors of re-PCI success included the use of IVUS, the involvement of an experienced CTO operator in the repeat attempt and the location of the CTO. The high success rate, low procedural complication and in-hospital MACE rates observed in this study suggest that after failed attempt a carefully planned reattempt at CTO-PCI should be considered.

## COMMENTS

### Background

Failed percutaneous recanalization of chronic total occlusions (CTO) constitutes a clinical conundrum. While percutaneous treatment is often abandoned in favour of medical therapy, CTO PCI expertise and alternative techniques may contribute to improve procedural success. There is growing evidence that CTO recanalization confers benefit to patients, however the success rate of CTO PCI is significantly lower than in non-CTO lesions, ranging from 51% to > 80% in different series. In this study the authors evaluated the success rates and predictors of success in reattempt PCI in CTO's.

### Research frontiers

Recanalising CTO's with viable myocardium appears to be beneficial to patients. Few prior studies have evaluated the benefit of reattempting PCI after an initial failed attempt.

### Innovations and breakthrough

Re-PCI in CTO after a failed attempt is associated with a good success rate. Adequate pre procedural evaluation and planning is crucial. In complex lesions factors such as IVUS-guidance and experienced CTO operators increase the chances of success. Less complex lesions, particularly those in the LAD, may be attempted by non-experienced CTO operators with a good success rate.

### Applications

The results of this study can assist operators in adequate pre-procedural planning in CTO's.

## Terminology

CTO: Chronic total occlusion an artery that has been occluded for longer than three months. IVUS: Intra-vascular ultrasound a technique that can be used to assist in visualizing the stump of a CTO, identifying wire position periprocedurally and optimizing stenting. PCI: Percutaneous coronary intervention a transcatheter technique used to revascularise a coronary territory.

## Peer-review

This study has value as it emphasizes the need for pre-procedural evaluation of lesion complexity and therefore complex lesions must be faced by experienced operators through an IVUS guided CTO-PCI approach.

**Abstract****AIM**

To explore regional systolic strain of midwall and endocardial segments using speckle tracking echocardiography in patients with apical hypertrophic cardiomyopathy (HCM).

**METHODS**

We prospectively assessed 20 patients (mean age 53 ± 16 years, range: 18-81 years, 10 were male), with apical HCM. We measured global longitudinal peak systolic strain (GLPSS) in the midwall and endocardium of the left ventricle.

**RESULTS**

The diastolic thickness of the 4 apical segments was 16.25 ± 2.75 mm. All patients had a normal global systolic

function with a fractional shortening of  $50\% \pm 8\%$ . In spite of supernormal left ventricular (LV) systolic function, midwall GLPSS was decreased in all patients, more in the apical ( $-7.3\% \pm -8.8\%$ ) than in basal segments ( $-15.5\% \pm -6.93\%$ ), while endocardial GLPPS was significantly greater and reached normal values (apical:  $-22.8\% \pm -7.8\%$ , basal:  $-17.9\% \pm -7.5\%$ ).

### CONCLUSION

This study shows that two-dimensional strain was decreased mainly confined to the mesocardium, while endocardium myocardial deformation was preserved in HCM and allowed to identify subclinical LV dysfunction. This transmural heterogeneity in systolic strain had not been previously described in HCM and could be explained by the distribution of myofibrillar disarray in deep myocardial areas. The clinical application of this novel finding may help further understanding of the pathophysiology of HCM.

**Key words:** Apical hypertrophic cardiomyopathy; Two-dimensional strain; Speckle tracking; Endocardium; Mid-wall; Regional myocardial systolic function

## INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a genetic disease transmitted with an autosomal dominant pattern, whereby the direct relatives of affected subjects carry 50% chances of having the disease<sup>[1]</sup>. Its prevalence in the general population is 0.2% and it is frequent cause of sudden cardiac death in patients younger than age 30,

including athletes. The annual mortality rate is 1%, but may be as high as 6% during childhood and adolescence; of note, sudden death may be the first symptom of disease<sup>[2]</sup>. It is a heterogeneous disease in its clinical as well as genetic aspects, characterized by the presence of primary left ventricular hypertrophy (LVH), with variable clinical expression and outcome<sup>[3]</sup>, and caused by genetic mutations that lead to abnormal sarcomeric proteins<sup>[4]</sup>.

In patients with complete phenotypic expression, characteristic findings are: Hypertrophy, myofibrillar disarray, interstitial fibrosis and microvascular dysfunction, all of which contribute to the progression to heart failure, ventricular arrhythmias and sudden death. Recent studies with MRI have shown that many patients with HCM have multiple areas of myocardial fibrosis, even with normal LV ejection fraction<sup>[5]</sup>.

Epicardial coronary arteries in patients with HCM are usually normal, but coronary flow reserve is diminished due to narrowing of the small intramyocardial arteries<sup>[6]</sup>. This microvascular ischemia is one of the factors resulting in LV diastolic dysfunction, which in turn is the main functional consequence of this disease.

Although patients with HCM have a normal ejection fraction, studies with Doppler tissue imaging have documented a regional systolic dysfunction in the longitudinal fibers of the LV<sup>[7-10]</sup>.

Regional LV function may be assessed non-invasively by measuring strain or systolic deformation. Initially, strain calculated with colour tissue Doppler proved to be a useful and sensitive tool to detect early systolic function abnormalities in patients with HCM<sup>[11]</sup>. However, its clinical application proved to be hindered by the complexity of data collection and limited reproducibility.

Recently, a method derived from the two-dimensional (2-D) echocardiogram, called "speckle tracking" of 2-D strain, has been developed to measure systolic strain<sup>[12]</sup>. The goal of this study was to assess the abnormalities of global and regional systolic LV function using 2-D strain in patients with apical HCM.

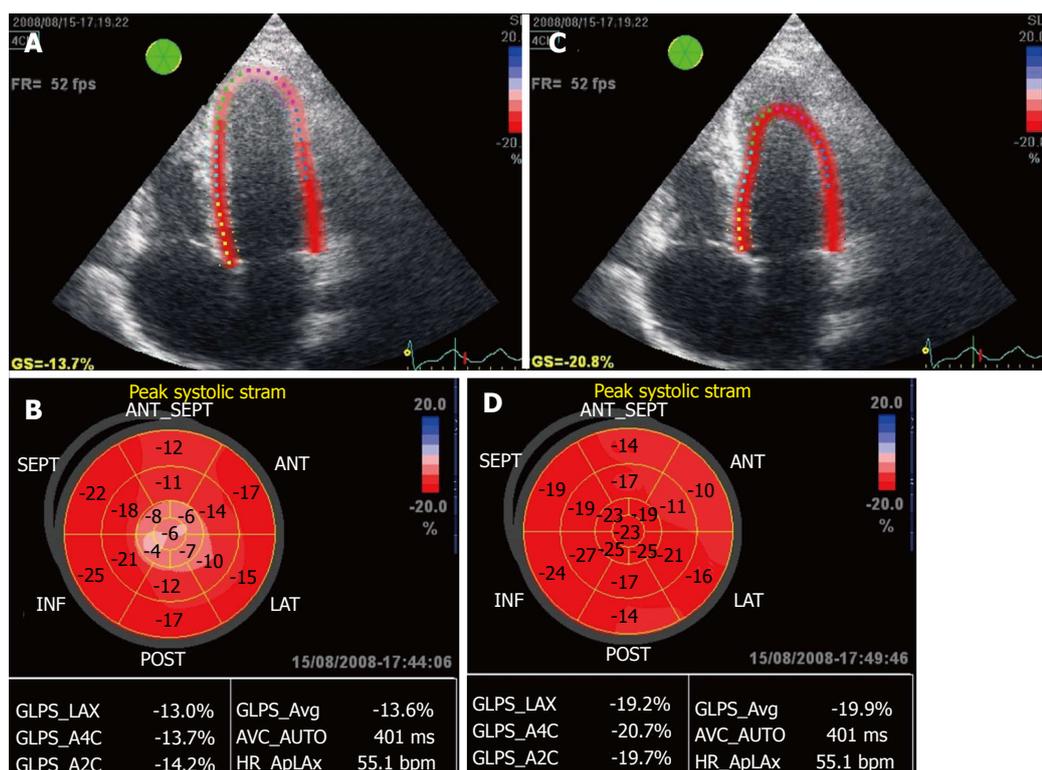

## MATERIALS AND METHODS

### Population

The study has a cross-sectional design and included 20 patients with apical HCM who were being followed at our tertiary referral center. Using a retrospective methodology, 2-D strain was measured in 340 myocardial segments.

The diagnostic criteria for apical HCM included demonstration of asymmetric left ventricular hypertrophy (LVH), confined predominantly to the LV apex with an apical wall thickness  $> 15$  mm, a ratio of maximal apical to posterior wall thickness  $> 1.5$ <sup>[13]</sup>, and a "spade shape" deformity of the left ventricle with apical cavity obliteration in end-systole based on 2-D echocardiography.

Inclusion criteria were: HCM with apical involvement, non-dilated LV, normal global and regional systolic LV function, normal blood pressure, sinus rhythm, absence of comorbidities and without history of hypertension.

**Figure 1** Apical 4-chamber view of a patient with apical hypertrophic cardiomyopathy. A: Midwall parametric image; B: Midwall bull's eye with a mean global longitudinal peak systolic strain (GLPS\_Avg) of -13.6%; C: Endocardial parametric image; D: Endocardial bull's eye with a GLPS\_Avg of -19.9%. Red: Normal strain; Pink: Reduced strain; Light pink: Severely reduced strain.

Noninvasive evaluation of global and regional systolic LV function was done by calculation of LV ejection fraction and visual judgement of segmental function from 2-D echocardiographic images.

Exclusion criteria were obesity, poor echocardiographic window, concomitant diseases that could cause ventricular hypertrophy or abnormal systolic or diastolic function (hypertension, diabetes, coronary heart disease, valve disease, cardiomyopathy, pericardial disease, congenital heart disease or systemic disease).

The study was approved by the Education and Research Committee and the Ethics Committee of the "Dr. Cosme Argerich" Hospital. All patients signed the informed consent form, including the authorization to use the data collected for future studies.

### Echocardiographic measurements

Standard echocardiographic examinations were performed in all patients using a Vivid Seven digital ultrasound system (GE Medical System, Hotern, Norway). Cardiac cycles were stored in digital, cine-loop format for off-line analysis performed by two independent observers (TFC and JAL) with a dedicated software package (EchoPAC PC, version 108.1.5).

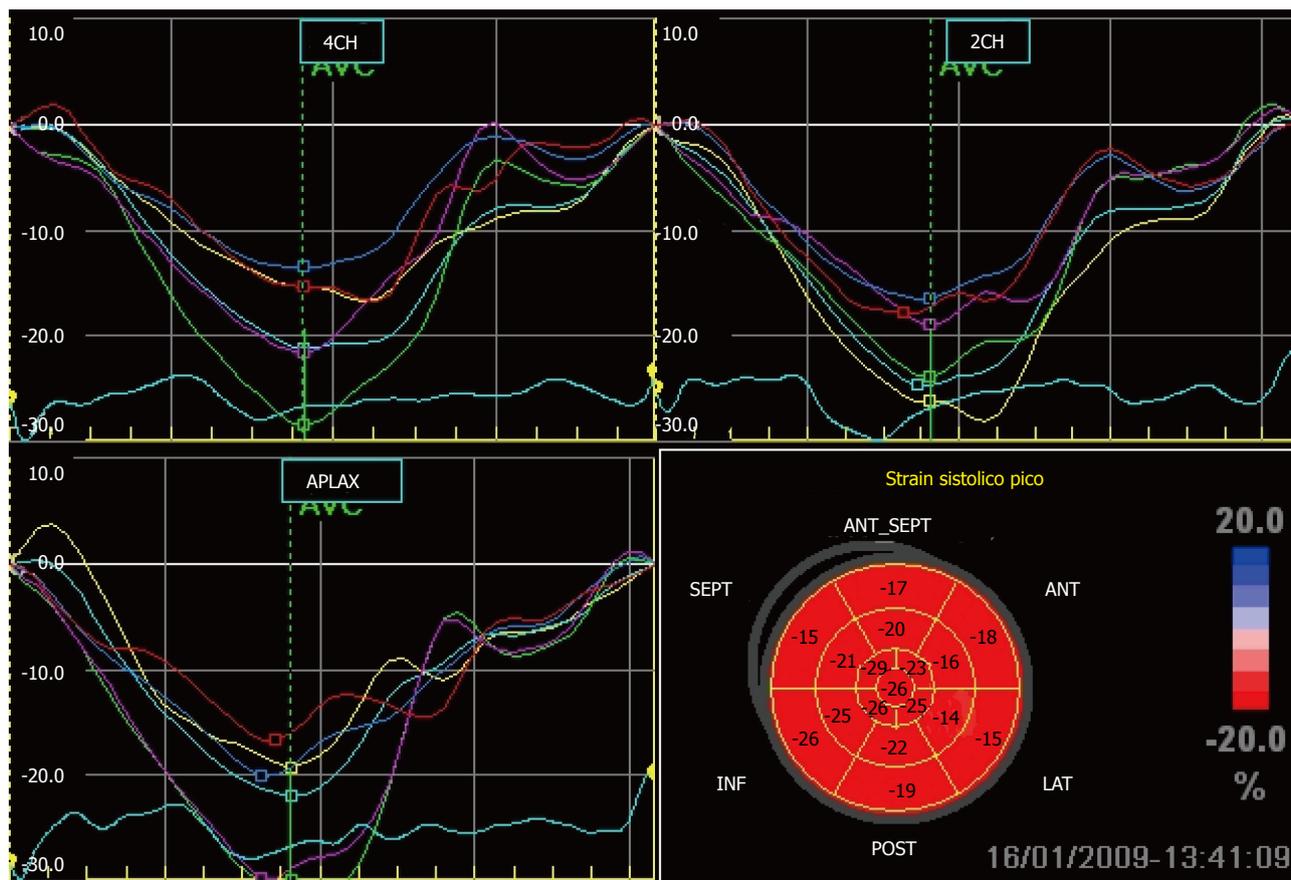

Both parasternal long- and short-axis views were analyzed. The M-mode echo was derived from the parasternal short-axis at the papillary muscle level, and the following measurements were obtained according to the American and European Societies of Echocardiography<sup>[14]</sup>:

LV end-diastolic diameter (EDD), LV end-systolic diameter (ESD), interventricular septum and posterior LV wall thickness, and end-systolic left atrial diameter. Ejection fraction was measured by Simpson method. Continuous Doppler from the apical 5-chamber view was used to rule out the presence of a dynamic subaortic gradient.

### Measurement of 2-D strain

2-D strain is a novel non-Doppler-based method to evaluate strain from standard 2-D acquisitions<sup>[15]</sup>. By tracing the endocardial contour on an end-systolic frame, the software will automatically track the contour on subsequent frames. Adequate tracking can be verified in real-time and corrected by adjusting the region of interest (ROI) or manually correcting the contour to ensure optimal tracking. A minimum frame rate of 30 Hz was required for reliable operation of this program and frame rates of 30 to 80 Hz were used for routine gray scale imaging. 2-D longitudinal strains were assessed in 2 orthogonal apical views (4- 3 and 2-chambers, 17 segments) starting from the septal, posterior and the inferior atrioventricular wall junction, respectively. The 2-D strain software adequately tracked > 85% of the attempted segments.

The ROI was reduced and shifted to the meso-cardium to obtain the parametric image, which allowed quantifying strain in each of the 17 segments of the LV as a "bull's eye" (Figure 1A and B), the mean value of peak global systolic strain and strain in the 3 apical views. Later, the ROI was shifted to the endocardium to obtain

**Figure 2** Curves of global longitudinal peak systolic strain from each apical view in a normal subject. Note that in most segments, peak strain occurs during aortic closure. 4CH: Apical 4-chamber; 2CH: Apical 2-chamber; APLAX: Apical long-axis (apical 3-chamber).

the endocardial strain of the 17 segments represented as a bull's eye (Figure 1C and D).

In the present study we only used global longitudinal peak systolic strain (GLPSS), which was plotted as a negative curve with a peak close to the aortic closure (Figure 2). These GLPSS curves represent the maximum myocardial longitudinal shortening during contraction in each of the 17 segments. In a normal subject (Figure 3) GLPSS varies between -15% and -20%<sup>[15]</sup>.

**Reproducibility**

The first 10 studies were analyzed blindly by a second operator who measured longitudinal 2-D strain in 170 myocardial segments. Intraobserver variability was calculated from the mean of the differences obtained in the 170 segments. Interobserver variability was calculated as the absolute difference divided by the mean of the 2 observations for all segments measured<sup>[16]</sup>.

**Statistical analysis**

Quantitative data with a normal distribution were expressed as the mean ± SD and data without a Gaussian distribution were expressed as medians (interquartile interval).

For the comparison of quantitative variables with a normal distribution we used the Student's *t* test for paired data; for variables without a normal distribution

we used the *Wilcoxon or Signed Rank Test*.

All *P* values < 0.05 were considered statistically significant. Statistical analyses were performed with Statistix 7.0 software for Windows.

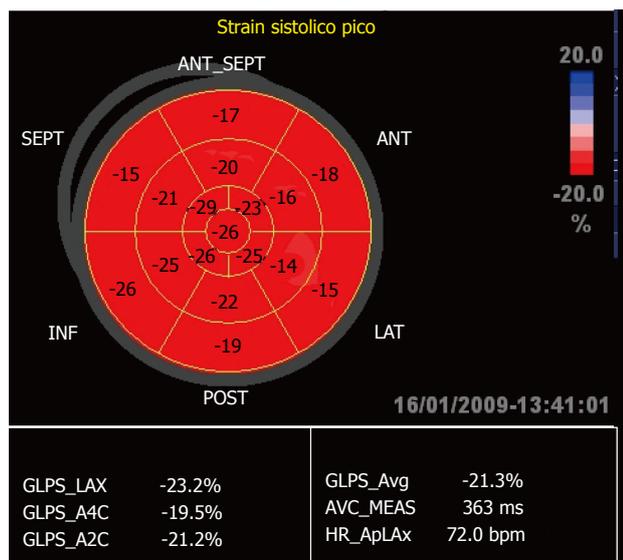

**RESULTS**

The clinical and echocardiographic characteristics of patients with apical HCM are summarized in Table 1. No patient was receiving medication at the time of inclusion in this study.

All patients exhibited apical hypertrophy, (the diastolic thickness of the 4 apical segments is described in Table 1). All patients had a normal ejection fraction (69% ± 5%).

A total of 20 patients with apical HCM were assessed and 340 myocardial segments were analyzed; midwall longitudinal peak systolic strain (LPSS) was measured and compared to endocardial LPSS (Table 2 and Figure 4). We confirmed that, in spite of a supernormal systolic LV function, midwall GLPSS exhibited a diminished percent of strain, which was more marked in the apical than in basal segments. By contrast, endocardial GLPSS was significantly higher and reached normal values.

Midwall GLPSS in the basal segments (Table 3) was lower than the endocardial GLPSS, but without significant differences (-15.5% ± -6.93% vs -17.9% ± -7.5%, *P*

**Figure 3** Bull's eye image of the same normal subject shown in Figure 2, showing percent strain value in the 17 segments analyzed. Mean value of the peak overall systolic strain is also reported (GLPS\_Avg: -21.8%) as well as that of each of the 3 apical views (GLPS\_LAX: -20.1%, GLPS\_A4C: -23.3% and GLPS\_A2C: -22%).

= NS). Midwall GLPSS was significantly decreased in the medial segments (-12.4% ± -7.3% vs -19.7% ± -7.6%, *P* < 0.001), with a 52% increase in endocardium strain. But the largest difference between midwall and endocardial strain was found in the apical segments, with a 168% increase in endocardial strain (-7.3% ± -8.8% vs -22.8% ± -7.8%, *P* < 0.001). The increase of the GLPSS from basal to apex segments can be seen in the dotted line (Figure 4).

Using 2D-based method for myocardial velocity strain (XStrain) that allows analyse the endocardial and epicardial border, this transmural gradient between the midwall and endocardial of global longitudinal peak systolic strain were seen in normal subjects, but without significant differences.

**Reproducibility**

In our laboratory, intraobserver and interobserver variability of 2-D strain was low and varied between 3.6% and 5.3% and 7% and 11.8% respectively.

**DISCUSSION**

To our knowledge, this is the first study to show that in a selected population of patients with apical HCM and normal LV ejection fraction, the regional systolic strain is decreased in the mesocardium, with a compensatory effect in the endocardium. The clinical application of this new finding may help to further understanding the pathophysiology of apical HCM.

Mutations of genes that code for contractile proteins of the sarcomere are responsible for the structural and functional changes seen in patients with HCM, and cause ventricular hypertrophy, myofibrillar disarray and interstitial fibrosis. In spite of the hyperdynamic systolic

function seen by echo, midwall 2-D strain detected a decrease in myocardial strain in all of our patients.

All patients had hypertrophy of the LV apex with normal apical wall motion, but they exhibited a decreased midwall 2-D strain, predominantly in the apex. One might postulate that this finding expresses myofibrillar disarray with microvascular ischemia, which contributes to increased myocardial fibrosis in those segments with greater hypertrophy.

In patients with HCM, Popović *et al*<sup>[17]</sup> have shown that 2-D strain was lower in patients whose MRI showed myocardial fibrosis than in patients without fibrosis, but they did not analyze whether longitudinal strain had

**Figure 4** The dotted line shows the mean global longitudinal peak systolic strain in the 20 patients. Midwall strain is shown in blue and endocardial strain is shown in red. In both lines, each point illustrates the strain value in each of the 17 segments (Basal segments: segments 1-6; Medial segments: segments 7-12; Apical segments: segments 13-17).

Segments	Mesocardial GLPSS (%)	Endocardial GLPSS (%)	Media of increment	CI	Increase of GLPSS	P value
Basal	-15.5 ± -6.93	-17.9 ± -7.5	-2.4	-3/-1.3	18%	NS
Medial	-12.4 ± -7.3	-19.7 ± -7.6	-7.2	-8.4/-6	52%	< 0.001
Apical	-7.3 ± -8.8	-22.8 ± -7.8	-15.5	-17/-13	168%	< 0.001

Values are expressed as mean ± standard deviation. GLPSS: Global longitudinal peak systolic strain; CI: Confidence intervals; NS: No significance.

transmural heterogeneity, as shown in our study.

The normal LV contracts longitudinally in systole and also radially. The array of myocardial fibers in the ventricular wall is quite unique; endocardial and subepicardial fibers align longitudinally, in a spiral shape, and midwall fibers are aligned circumferentially. This latter group is responsible for the radial contraction in the minor axis of the LV (similar to the movement of the bellows of an accordion), while the former cause longitudinal contraction similar to the movement of a piston. This fiber orientation is so efficient that a 15%-20% reduction in the myocyte's length can result in a 40%-60% radial wall thickening, thus allowing the LV to achieve an ejection fraction of 60%.

In patients with apical HCM, longitudinal midwall strain allowed to identify subclinical global systolic dysfunction, with a lower intra and interobserver variability than for strain derived from colour tissue Doppler<sup>[18]</sup>.

In our study of 20 patients with apical HCM, we analyzed 340 myocardial segments with midwall LPSS and compared it to endocardial LPSS. We confirmed that although systolic ventricular function was supernormal, midwall GLPSS exhibited a decrease in the percent of strain, more evident in apical than in medial segments, whereas endocardial GLPSS was significantly greater, and reached normal values<sup>[19]</sup>. These findings indicate that in spite of the apical ventricular hypertrophy with excellent ejection fraction parameters, there is subclinical abnormality in midwall strain, while endocardial function

is preserved. An explanation for this phenomenon could be that myofiber disarray<sup>[5,20]</sup> and interstitial fibrosis<sup>[21-23]</sup> are mostly located in the mid third of the ventricular wall. This particular distribution of histological abnormalities in apical HCM also explains why endomyocardial biopsy is not useful in the diagnosis of HCM, since the biotome does not reach the myocardium with fiber disarray and interstitial fibrosis<sup>[24]</sup>.

**Study limitations**

One limitation of this study is that we only measured longitudinal strain. It is possible that measurement of radial and circumferential strain will add useful information to the data obtained in this work. 2-D strain is a sensitive method to measure myocardial strain, but it is very much dependent on echo image quality, and in patients with necrotic scars strain may be measured in 80% of segments analyzed<sup>[12]</sup>. Such limitation is not applicable to our population, since the presence of LVH helped in obtaining a good quality image.

Another limitation is that the ROI of speckle tracking method cannot be diminished more than 10 mm. The most patients did not exhibit hypertrophy of the basal segments; hence, further midwall strain overlapped with endocardial strain, which might explain the smaller difference between them.

In conclusion, this study shows that 2-D strain assessed by "speckle tracking" is a sensitive method to detect subclinical systolic LV dysfunction. When

midwall and endocardial strain values were compared, we confirmed that the decrease in strain was confined to the midwall, while endocardial myocardial function was preserved. This transmural heterogeneity of systolic deformity in apical HCM has not been previously described. A possible explanation could be that myofibrillar disarray and interstitial fibrosis are distributed in deeper areas of the myocardium. The clinical application of this new finding may help in the pathophysiological interpretation of HCM.

Future studies, with more subjects, will allow assessing whether patients with greater change in midwall strain may be at higher risk for ventricular arrhythmias, sudden death or progression to heart failure due to systolic dysfunction. Additionally, the method could help in evaluating the benefit of conventional treatment and new therapeutic strategies.

We would like to thank Ing. Ariel Desseno (General Electric) for his technical assistance.

## COMMENTS

### Background

Hypertrophic cardiomyopathy (HCM) is associated with normal left ventricular (LV) ejection fraction and impaired LV strain, but there are no studies so far comparing midwall and endocardial strain.

### Research frontiers

The diagnostic criteria for apical HCM included demonstration of asymmetric left ventricular hypertrophy (LVH), confined predominantly to the LV apex with an apical wall thickness > 15 mm, a ratio of maximal apical to posterior wall thickness > 1.5, and a "spade shape" deformity of the left ventricle with apical cavity obliteration in end-systole based on 2-D echocardiography.

### Innovations and breakthroughs

This study shows that two-dimensional strain assessed by "speckle tracking" is a sensitive method to detect subclinical systolic LV dysfunction. When midwall and endocardial strain values were compared, the authors confirmed that the decrease in strain was confined to the midwall, while endocardial myocardial function was preserved. This transmural heterogeneity of systolic deformity in apical HCM has not been previously described. A possible explanation could be that myofibrillar disarray and interstitial fibrosis are distributed in deeper areas of the myocardium. The clinical application of this new finding may help in the pathophysiological interpretation of HCM.

### Applications

Two-dimensional strain is a novel non-Doppler-based method to evaluate strain from standard two-dimensional acquisitions. By tracing the endocardial contour on an end-systolic frame, the software will automatically track the contour on subsequent frames. Two-dimensional longitudinal strains were assessed in 2 orthogonal apical views (4- 3 and 2-chambers, 17 segments). The region of interest (ROI) was reduced and shifted to the mesocardium to obtain the parametric image, which allowed quantifying strain in each of the 17 segments of the LV. Later, the ROI was shifted to the endocardium to obtain the endocardial strain of the 17 segments.

### Peer-review

The study by Saccheri *et al* reports the data obtained by speckle tracking echocardiography in patients with apical hypertrophic cardiomyopathy. The authors show that two-dimensional strain is able to identify subclinical systolic

left ventricular dysfunction in this patient population. The manuscript is interesting and well written.

## Abstract

### AIM

To assess the association of inter-ethnic vs intra-ethnic marriage with severity of coronary artery disease (CAD) in men undergoing angiography.

### METHODS

We conducted a prospective multicenter, multi-ethnic, cross sectional observational study at five hospitals in Saudi Arabia and the United Arab Emirates, in which we used logistic regression analysis with and without adjustment for baseline differences.

### RESULTS

Data were collected for 1068 enrolled patients undergoing coronary angiography for clinical indications during the period of April 1<sup>st</sup>, 2013 to March 30<sup>th</sup>, 2014. Ethnicities of spouses were available only for male patients. Of those enrolled, 687 were married men and constituted the cohort for the present analysis. Intra-ethnic marriages were reported in 70% and inter-ethnic marriages in 30%. After adjusting for baseline differences, inter-ethnic marriage was associated with lower odds of having significant CAD [adjusted odds ratio 0.52 (95%CI: 0.33, 0.81)] or multi-vessel disease (MVD) [adjusted odds ratio 0.57 (95%CI: 0.37, 0.86)]. The adjusted association with left main disease showed a similar trend, but was not statistically significant [adjusted odds ratio 0.74 (95%CI: 0.41, 1.32)]. The association between inter-ethnic marriage and the presence of significant CAD and MVD was not modified by number of concurrent wives (*P* interaction > 0.05 for both).

### CONCLUSION

Among married men undergoing coronary angiography, inter-ethnic, as compared to intra-ethnic, marriage is associated with lower odds of significant CAD and MVD.

**Key words:** Arabian Gulf; Inter-ethnic marriage; Coronary artery disease; Cardiac epidemiology; Coronary angiography

**Core tip:** One thousand and sixty-eight enrolled patients underwent coronary angiography for clinical indications. Ethnicities of spouses were available for only male patients. Of the 771 males, 687 were married. Seventy percent of them were in intra-ethnic marriages and 30% in inter-ethnic marriages. After adjusting for baseline differences, inter-ethnic marriage was associated with lower odds of having significant coronary artery disease (CAD) or multi-vessel disease (MVD). The adjusted association with left main disease showed a similar trend, but was not statistically significant. The association between inter-ethnic marriage and the presence of significant CAD and MVD was not modified by number of concurrent wives.

## INTRODUCTION

Coronary artery disease (CAD) is a major cause of death throughout the world. The high prevalence and mortality have led to great importance in understanding the risk factors associated with CAD<sup>[1-3]</sup>. Traditional risk factors comprise the majority of the increase for cardiovascular events<sup>[4]</sup>. Additional factors such as physiological, psychological, emotional, social, and stress, both acute and chronic, have been studied<sup>[5-23]</sup>. The interactions between risk factors also have great consequences<sup>[24]</sup>. Studies investigating the association between marital status and CAD have predominantly been performed in developed countries, and none examined the role of spousal ethnicities and CAD<sup>[25-32]</sup>. Selecting a spouse is often influenced by social norms, and cultural practices typically prefer marriages between persons of the same ethnic background. However, inter-ethnic marriages are increasingly common as societal attitudes and demographic patterns change. Studies from Western societies demonstrated that such marriages are associated with increased stress and lower relationship quality<sup>[33-35]</sup>. Due to these findings, we examined the relationship between inter-ethnic marriages and severity of CAD in two Gulf States.

## MATERIALS AND METHODS

### Study population and data collection

The details regarding the design, methods, and end-points of this multicenter, observational study came from the Polygamy and Risk of Coronary Artery Disease

in Men Undergoing Angiography<sup>[36]</sup>. In the current study the data were collected prospectively from five hospitals in two Gulf Regions (the Kingdom of Saudi Arabia and the United Arab Emirates), during the period of April 1<sup>st</sup>, 2013 to March 30<sup>th</sup>, 2014. The study was approved by King Faisal Specialist Hospital and Research Center Institutional Review Board, and an invitation letter was given to all participants who affirmed verbal consent prior to their enrollment. For each patient undergoing coronary angiography for clinical indication, two separate data forms, one general and one angiographic, were filled out by the research assistant and assigned cardiologist, respectively. Both forms were completed before the patients were discharged from hospital. All data forms were reviewed by the assigned cardiologist then sent online to the principle investigator, who also checked the forms prior to submission for analysis. All patients undergoing coronary angiography were recruited for the study. There was no exclusion criteria.

#### **Contents of personal data form**

Demographic data: Age, ethnic background; Physiologic status: Hypertension, diabetes, dyslipidemia, BMI; Life style: Smoking history; Past medical history: CAD, percutaneous coronary intervention, coronary artery bypass surgery, cerebral vascular disease, peripheral arterial disease, congestive heart failure, atrial fibrillation, chronic kidney disease. Socioeconomic data: Occupation (unemployed, private sector, government sector, self-employed), living in rural or urban area, highest level of education completed (illiterate, secondary school, university, masters, PhD), monthly income (< 1300, 1300 to 2600, 2600 to 5300, 5300 to 7900, 7900 to 10600, > 10600 USD); Number of wives: Single or multiple concurrent wives; Ethnicity of spouse (Arabic Gulf region, Arabs non-Gulf region, non-Arabic).

#### **Contents of angiographic data form**

Reason for coronary angiography: Elective or urgent/emergent; Number of vessels involved (severity); Treatment: Medical or revascularization.

#### **Definitions**

Significant CAD was defined as  $\geq 70\%$  luminal stenosis in a major epicardial vessel or  $\geq 50\%$  stenosis in the left main coronary artery. Multi-vessel disease (MVD) was defined as having more than one significant CAD; Inter-ethnic marriage was defined as Arab men from the Gulf region marrying Arab women from a non-Gulf region or non-Arab women; Intra-ethnic marriage was defined as Arab men from the Gulf region marrying Arab women from the same region.

#### **Statistical analysis**

Standard summary statistics were used to describe the cohort. Continuous variables are presented as mean  $\pm$  SD and were compared across multiple groups using the analysis of variance test. Categorical variables are

presented as percentages and compared using the  $\chi^2$  test. The associations between inter-ethnic or intra-ethnic marriage and CAD, MVD and left main disease (LMD) were assessed using logistic regression models and quantified with odds ratios. Adjusted regression models included the following explanatory variables: Age, community setting (urban vs rural), employment, income level, education level, number of concurrent wives, and additional variables that differed by ethnicity of spouse in univariate comparisons ( $P < 0.1$ ). All statistical tests were two-tailed and significance was defined as  $P < 0.05$ . No adjustments for multiple comparisons were made.

## **RESULTS**

### **Overall characteristics of patients and coronary angiogram findings**

A detailed description can be found in Polygamy and Risk of Coronary Artery Disease in Men Undergoing Angiography<sup>[36]</sup>.

### **Patients characteristics stratified by ethnicity of spouse**

We enrolled 1068 patients in the current study. Ethnicities of spouses were available for only male patients, so the analysis excludes female patients. Of the 771 males, 685 were married; however, spouse ethnicity was not available for two of these men. Married men were categorized according to number of wives: The majority had one wife (68%), while some had a history of two wives (19%), three wives (10%) or four wives (3%). Most were in intra-ethnic marriages 481 (70%), as opposed to inter-ethnic marriages 204 (30%), Table 1. The majority of inter-ethnic marriages were between Gulf nationals and non-Gulf Arab women (65%). Men in inter-ethnic marriages were more likely to have a history of hypertension and CABG, to live in rural communities, and to be in polygamous marriages. In univariate analyses, there was a significant association between inter-ethnic marriage and presence of LMD therefore the rate of CABG was higher in these subjects when compared with those in intra-ethnic marriages, who had undergone more PCI (Table 1). In multivariate logistic regressions adjusting for baseline differences, inter-ethnic marriage was associated with lower odds of having significant CAD [adjusted odds ratio 0.52 (95%CI: 0.33, 0.81)] or MVD [adjusted odds ratio 0.57 (95%CI: 0.37, 0.86)]. The adjusted association with LMD showed a similar trend, but was not statistically significant [adjusted odds ratio 0.74 (95%CI: 0.41, 1.32)] (Figure 1). The association between inter-ethnic marriage and the presence of significant CAD or MVD was not modified by number of concurrent wives ( $P$  interaction  $> 0.05$  for both) (Figure 2).

## **DISCUSSION**

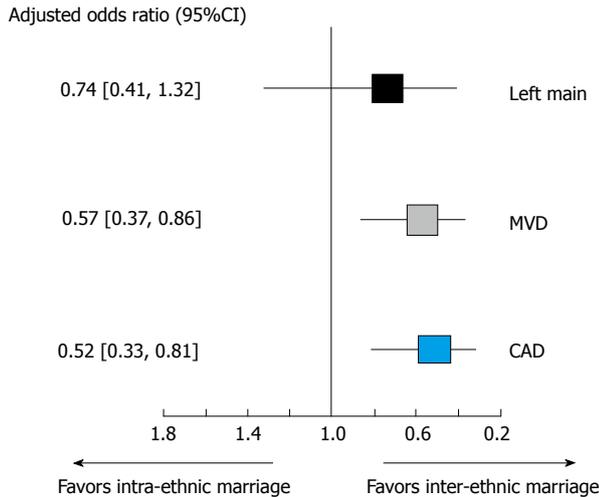

Previous literature from non-Gulf regions demonstrated that inter-ethnic marriages were found to have lower income and education level and poor level of family

**Table 1 Overall patient characteristic stratified by ethnicity of spouse**

	All (n = 685)	Intra-ethnic (n = 481)	Inter-ethnic (n = 204)	P value

acceptance and support when compared to intra-ethnic marriages. In addition, inter-ethnic couples reported lower

**Figure 1** Adjusted association between type of marriage (inter-ethnic vs intra ethnic) and presence of any coronary artery disease, multi-vessel disease and left main disease. CAD: Coronary artery disease; MVD: Multi-vessel disease.

relationship satisfaction, and increased conflict within the relationship over such issues as money and spending time together. These factors are associated with increased stress and lower relationship quality<sup>[33-35]</sup>. Furthermore, it is known that acute and chronic stress is associated with the development of CAD<sup>[17,18]</sup>. However, the impact of inter-ethnic marriage on the severity of CAD is unknown. Our study is the first to analyze the association between inter-ethnic vs intra-ethnic marriage and severity of CAD among men using coronary angiography, the gold standard for identifying CAD. After adjusting for baseline characteristics, we observed that inter-ethnic marriage was associated with lower odds of having significant CAD or MVD. The adjusted association with LMD showed a similar trend, but was not statistically significant. Studies from western societies reported an increase in stress within inter-ethnic marriages; however, our study found lower odds of CAD in inter-ethnic vs intra-ethnic marriage, which may suggest lower levels of stress in these marriages. A number of factors may contribute to our results. First, in the current study, 80% of the patients reported income levels of 32000 USD or less annually. Although there is family and societal pressure to marry within the same region, the overall cost of getting married and maintaining the relationship within the Gulf region is high, which may impact men from this region leading them to select a spouse from elsewhere. The high cost of marriage in the Gulf is associated with complex family interactions, which possibly creates unrealistic expectations when anticipating a marital lifestyle. This may be a source of significant stress in and of itself. Second, almost 80% of the patients in our study had low level of education. In the Gulf region, there are increased opportunities for educated men to marry, which may necessitate less educated men to select a spouse from outside the region. Additionally, the conservative social and cultural practices in the Gulf region may play a role in stress levels when compared to non-Gulf regions. Men from Gulf region who marry women

**Figure 2** The proportion of patients with any coronary artery disease, multi-vessel disease or left main disease stratified by type of marriage (inter- or intra-ethnic and polygamous vs monogamous). CAD: Coronary artery disease; MVD: Multi-vessel disease; LMD: Left main disease.

from outside the region may be more health conscious than men who marry women from inside the Gulf. Classically, women from the Gulf region tend to prepare dishes rich in fat, which are atherogenic, whereas wives from elsewhere may favor dishes that are more healthy, notably those from the Arab Mediterranean region<sup>[37-39]</sup>. Non-Gulf wives may encourage their husbands to be healthy and maintain fitness, as their literacy and health awareness may be superior to that of Gulf-native women.

**Strengths of this study**

This study is the first to look at the association between inter-ethnic vs intra-ethnic marriages and severity of CAD using coronary angiography in men from Arabian Gulf States.

**Contributions of the study**

The study provides additional knowledge on the risks associated with inter-ethnic vs intra-ethnic marriages. This information will be useful for personalizing care and preventing CAD. Not only will it provide patients information concerning social risk factors, it will also help providers identify and treat adults who are at increased risk of CAD. Further studies are required to confirm our findings and to investigate the mechanism underlying these findings in order to identify possible interventions to reduce these risks. In future studies, assessment of the local culture, social and medical practices, and attitudes toward inter-ethnic marriage should be performed.

**Study limitations**

Limitations of the study include a small sample size and the lack of documentation of the length of marriages prior to cardiac catheterization; this interval may influence the findings. Our study population was selected to undergo coronary angiography if clinically indicated, and as such, cannot be generalized to all married men in the Gulf region. Additionally, 42% of the patients were illiterate and 80% reported income levels of 32000 USD or less

annually; indicating that the results may not be applicable to those with higher incomes or higher levels of education. We did not look at unmeasured confounding variables such as dietary habits, physical activity, inflammatory or stress markers, or additional variables that may have played a role.

## ACKNOWLEDGMENTS

We would like to sincerely thank all patients who agreed to participate in this study.

## COMMENTS

### Background

Selecting a spouse is often influenced by social norms, and societies typically prefer marriages of the same ethnic background. However, inter-ethnic marriages are increasingly common as societal attitudes and demographic patterns change. Studies from Western societies have demonstrated that inter-ethnic marriages are associated with increased stress and lower relationship quality. The majority of these studies examine the association between marital status and coronary artery disease (CAD), but none have examined the role of spousal ethnicity and CAD.

### Research frontiers

It is unknown whether such marriages have an impact on the severity of CAD.

### Innovations and breakthroughs

This study is the first to look at the association between inter-ethnic vs intra-ethnic marriages and severity of CAD using coronary angiography in men from Arabian Gulf States.

### Applications

The data in this study suggest that among married men undergoing coronary angiography, inter-ethnic marriage is associated with lower odds of significant CAD and multi-vessel disease (MVD). Further studies are required to confirm these findings and to investigate the mechanism underlying these findings in order to identify possible interventions to reduce these risks. In future studies, assessment of the local culture, social and medical practices, and attitudes toward inter-ethnic marriage should be performed.

### Terminology

Significant coronary artery disease (CAD) was defined as  $\geq 70\%$  luminal stenosis in a major epicardial vessel or  $\geq 50\%$  stenosis in the left main coronary artery. MVD was defined as having more than one significant CAD. Inter-ethnic marriage was defined as Arab men from the Gulf region marrying Arab women from a non-Gulf region or non-Arab women. Intra-ethnic marriage was defined as Arab men from the Gulf region marrying Arab women from the same region.

### Peer-review

The data is interesting.

### Abstract

#### AIM

To compare the amount of contrast used during percutaneous coronary intervention (PCI) *via trans*-radial access (TRA) *vs trans*-femoral access (TFA).

#### METHODS

Scientific databases and websites were searched for: randomizedcontrolledtrials (RCTs). Data were extracted by two independent reviewers and was summarized as the weighted mean difference (WMD) of contrast used with a 95%CI using a random-effects model.

#### RESULTS

The meta-analysis included 13 RCTs with a total of 3165 patients. There was no difference between the two strategies in the amount of contrast used (WMD = - 0.65 mL, 95%CI: -10.94-9.46 mL;  $P = 0.901$ ).

#### CONCLUSION

This meta-analysis shows that in patients undergoing PCI, the amount of contrast volume used was not different between TRA and TFA.

**Key words:** Femoral; Contrast; Percutaneous coronary interventions; Radial

© **The Author(s) 2017.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Adaptation of radial access for percutaneous coronary interventions in patients with chronic kidney disease is slower because of concern about contrast-induced nephropathy from the greater contrast load. Data from individual studies vary; therefore we performed a comprehensive meta-analysis of randomized controlled trials comparing the amount of contrast used between radial access and femoral access.

Shah R, Mattox A, Khan MR, Berzingi C, Rashid A. Contrast use in relation to the arterial access site for percutaneous coronary intervention: A comprehensive meta-analysis of randomized trials. *World J Cardiol* 2017; 9(4): 378-383 Available from: URL: <http://www.wjgnet.com/1949-8462/full/v9/i4/378.htm> DOI: <http://dx.doi.org/10.4330/wjc.v9.i4.378>

## INTRODUCTION

Trans-radial access (TRA) for percutaneous coronary interventions (PCIs) results in a lower risk for bleeding and vascular complications than trans-femoral access (TFA)<sup>[1-5]</sup>. However, CathPCI registry data suggest that adaptation of TRA-PCI in patients with lower glomerular filtration rates (GFRs) is lower compared to patients with higher GFRs; one wonders if this could be the result of concern over the larger amount of contrast used in TRA compared to TFA<sup>[6]</sup>. Data from individual studies have been variable: Some show larger contrast volume is used with TRA<sup>[2,7]</sup>, others show equal amounts used in both strategies<sup>[5,8]</sup>, and yet others show less contrast used with TRA<sup>[3,9]</sup>. Therefore, we performed an updated comprehensive meta-analysis of randomized controlled trials (RCTs) comparing the amounts of contrast used in TRA and TFA during PCI.

## MATERIALS AND METHODS

This meta-analysis was performed according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines for systematic reviews and meta-analyses<sup>[10]</sup>. We performed a systematic search of PubMed, Embase, and the Cochrane Library and cross-referenced relevant articles using various combinations of keywords such as "radial", "femoral", "cardiac catheterization", and "coronary intervention" for eligible published studies. Data were collected by two independent investigators, and disagreements were resolved by consensus. Trials were included if they enrolled patients undergoing PCI and randomly assigned them to TRA or TFA. We recorded mean contrast volume used. We also contacted corresponding authors for those articles not reporting

contrast volume or reporting the median contrast used. We were able to obtain the mean contrast used for only one additional trial<sup>[11]</sup>.

We summarized the data as the weighted mean difference (WMD) of contrast used with a 95%CI using Comprehensive Meta-Analysis (CMA) system version 3 (Comprehensive Meta-Analysis; Biostat Inc., Englewood, NJ, United States). A random-effects model was used to analyze data. The presence of heterogeneity across trials was evaluated using the Cochran Q test and the Higgins  $I^2$  test<sup>[12]</sup>. The measure of  $I^2$  can be interpreted as the percentage of variability resulting from heterogeneity between studies rather than sampling error<sup>[12]</sup>. Finally, an additional sensitivity analysis was performed where one study at a time was excluded, and the impact on the summary results of removing each was evaluated.

## RESULTS

Among 26 identified RCTs, only 15 trials reported the amount of contrast used. However, data for the mean contrast used was available for only 13 RCTs, which used 3165 patients, and these were used for final analysis<sup>[4,5,7,11,13-20]</sup>. Figure 1 shows the search flow diagram. The bias assessment for each RCT is shown in Figure 2.

The characteristics of the individual trials included in the meta-analysis are shown in Table 1. Most studies were single-center studies with broad spectra of patient populations, including patients with stable angina, acute coronary syndrome, or ST-elevation myocardial infarction. The majority of the procedures were performed by radial experts.

There was no difference in the amount of contrast used during either TRA or TFA (WMD = - 0.65 mL, 95%CI: -10.94 to 9.46 mL;  $P = 0.901$ ; Figure 3). We found significant between-trial heterogeneity ( $Q = 260.8$ ,  $df = 12$ ;  $P < 0.001$ ;  $I^2 = 95.4$ ). However, during sensitivity analysis, removal of any single study did not affect summary results (Figure 4).

## DISCUSSION

In this study, we compared a broad spectrum of 3165 patients enrolled in 13 RCTs in terms of the contrast volume used during TRA or TFA during PCI. Overall, there was no difference in contrast volume use between the two access strategies. However, most trials were single-centered, and the majority of procedures were performed by radial experts.

Acute kidney injury (AKI) is a well-recognized complication of PCI that is associated with greater risk of in-hospital mortality and poor long-term outcomes<sup>[21]</sup>. The two major causes of post-PCI AKI are contrast-induced nephropathy (CIN) and renal atheroembolus<sup>[22,23]</sup>. The reported incidence of CIN post-PCI varies widely depending on numerous clinical, demographic, and procedural

factors<sup>[22]</sup>. Among these, contrast volume is a well-established, dose-dependent, and potentially modifiable risk factor for CIN<sup>[22]</sup>. Although there have been reports of greater contrast use with TRA and concerns about possible subsequent CIN from this more extensive dye load<sup>[2,7,24]</sup>, our meta-analysis shows that the volume of contrast used is not higher among patients undergoing PCI with TRA compared to TFA.

In contrast, a report from the British Columbia Cardiac and Renal Registries that included 69214 patients after coronary catheterization and PCI showed that chronic kidney disease (CKD) onset within 6 mo was significantly lower with TRA compared to TFA (0.5% vs 2.2%,  $P < 0.001$ ) even after adjusting for baseline variables<sup>[9]</sup>. Similarly, another propensity-matched study showed that TRA, compared to TFA, was associated with a lower risk of AKI<sup>[25]</sup>. Finally, a recent meta-analysis of observational studies (adjusted by propensity score matching) showed that TRA, compared to TFA, was associated with lower risk of AKI<sup>[26]</sup>. The primary mechanism by which TRA was associated with a lower risk of kidney injury is thought to be through a reduced likelihood of renal atheroembolization because it offers the additional advantage of avoiding passage through potential atheromatous aortae and renal vessels<sup>[9,23]</sup>. The other mechanism by which TRA leads to less kidney injury is through a reduced risk of bleeding and the subsequent need for a blood transfusion. Post procedure bleeding and blood transfusion are independently associated with the development of AKI<sup>[27,28]</sup>.

The potential benefits of TRA in CRD patients is in paradox to the CathPCI registry data, which show a slow adaption of TRA-PCI in patients with lower GFRs compared to patients with higher GFRs<sup>[6]</sup>. It is not clear if this is a result of misconceptions about potential increases in contrast use with radial access<sup>[24]</sup> or due to

**Figure 3** Forest plot showing weighted mean difference of contrast use. The size of the square represents the weight that the corresponding study exerts in the meta-analysis. The larger the square, the more the study contributes to the overall estimate. Diamonds indicate the overall summary estimate for the analysis, its width representing the 95%CI. TRA: *Trans*-radial access; TFA: *Trans*-femoral access.

pressure from nephrologists who routinely recommend against using TRA in patient with CKD<sup>[29]</sup>. Even the Fistula First Initiative Coalition, sponsored by the Centers for Medicare and Medicaid Services, discourages use of the radial artery for access of the arterial vasculature in patients at risk for, or with known Stage 4 or 5 CKD<sup>[30]</sup>. This needs further investigation to assure we are not withholding beneficial intervention in these patient populations because of the theoretical possibility that dialysis access will be lost in the future.

This meta-analysis has several limitations. First, as with all meta-analyses, it is subject to various biases because data were combined from many studies with varying protocols. Second, most of the studies were single-centered, and the majority of procedures were performed by radial experts. Furthermore, in a majority of the trials, patients with coronary artery bypass grafts (CABG) were excluded. Therefore, the generalizability

of this study may be limited, particularly to operators less-skilled in radial access and to patients with CABG. Finally, apart from the AKI-MATRIX sub-study, none of the randomized studies comparing TRA and TFA has ever systematically explored the issue of renal complications<sup>[31]</sup>. Therefore, we were not able perform the meta-analysis using AKI as one of the outcomes.

In conclusion, this meta-analysis of RCTs showed that in patients undergoing PCI, the amount of contrast volume used was not different between the TRA and TFA arms.

## COMMENTS

### Background

Trans-radial access (TRA) for percutaneous coronary interventions (PCIs) results in lower bleeding and vascular complications than trans-femoral access (TFA). A recent randomized controlled trial (RCT) and several updated meta-

analyses of RCTs have also shown that TRA also improves mortality compared to TFA in patients with acute coronary syndrome.

**Research frontiers**

Despite the proven benefits of TRA for PCI, its adaptation for patients with chronic kidney disease has been slow because of concern about contrast-induced nephropathy from greater contrast use. Data from individual studies have been variable: Some show larger contrast volumes with TRA, but others show equal amounts of contrast use in both strategies.

**Innovations and breakthroughs**

In this study, the authors investigated the amounts of contrast used in TRA compared to TFA during PCI. This is the most comprehensive meta-analysis of RCTs in this field.

**Applications**

This study shows that the amount of contrast used does not differ between TRA-PCI and TFA-PCI. Therefore, TRA-PCI should not be avoided in patients with chronic kidney disease solely because of concern for increased contrast use.

**Peer-review**

The authors investigated the dose of contrast volume in patients who underwent trans-radial percutaneous coronary intervention (PCI) or trans-femoral PCI, using the meta-analysis method. They showed no difference in contrast medium between the two arms. This meta-analysis seems to be interesting.
