AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α, β, δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Over the past few decades, food fortification and infant formula supplementation with high levels of vitamins have led to a sharp increase in vitamin intake among infants, children and adults. This is followed by a sharp increase in the prevalence of obesity and related diseases, with significant disparities among countries and different groups within a country. It has long been known that B vitamins at doses below their toxicity threshold strongly promote body fat gain. Studies have demonstrated that formulas, which have very high levels of vitamins, significantly promote infant weight gain, especially fat mass gain, a known risk factor for children developing obesity. Furthermore, ecological studies have shown that increased B vitamin consumption is strongly correlated with the prevalence of obesity and diabetes. We therefore hypothesize that excess vitamins may play a causal role in the increased prevalence of obesity. This review will discuss: (1) the causes of increased vitamin intake; (2) the non-monotonic effect of excess vitamin intake on weight and fat gain; and (3) the role of vitamin fortification in obesity disparities among countries and different groups within a country.

Key words: Vitamin fortification; Refined grain; Infant formula; Obesity; Diabetes; Insulin resistance; Oxidative stress; Glycemic index; Formula feeding; Epigenetic

Core tip: B vitamins are a known fat gain promoting factor. Food fortification-induced high vitamin consumption is followed by a rapid increase in obesity prevalence. Why is the fat gain effect of B vitamins neglected in obesity studies? Why does obesity prevalence vary from country to country? Why are the poor in developed countries but the rich in developing countries at high risk of obesity? Why is obesity prevalence higher in blacks than whites in the United States? Why does formula feeding (which is associated with high energy expenditure) increase the risk for obesity? Why is physical inactivity associated with increased obesity risk? This paper reviews the role of excess vitamins in obesity and proposes a unified answer to these questions.

INTRODUCTION

Obesity, a state of excessive accumulation of fat in the body, is a major risk factor for many diseases, such as type 2 diabetes and cardiovascular disease[1,2]. In the 1970s and 1980s, a rapid increase in the prevalence of obesity occurred almost simultaneously in many developed countries. Since then, developing countries have also experienced a rapid increase in obesity rates[3,4]. Nowadays, obesity has become a global epidemic[5]. It is worth noting that the prevalence of obesity differs greatly among

countries[3,4,6,7] as well as groups within a country[8-12]. It is more prevalent among those with low socioeconomic status (SES) in developed countries[6,8-10] but with high SES in developing countries, especially at their early stage of development[10-12]. Interestingly, compared with breast-fed infants, formula-fed infants have higher rather than lower levels of energy expenditure[13,14] and are more at risk for obesity in later life[15-17]. Therefore, the rapidly increased prevalence of obesity cannot be simply explained by genetic factors or decreased energy expenditure.

Recently, it has been suggested that changes in the global food system may play a role in the increased prevalence of obesity[4]. If this is the case, the global food system must have sharply changed in the 1970s-1980s. Notably, in the 1970s and 1980s, the contents of vitamins (organic chemicals affecting the body's functioning) in the food system of many developed countries were sharply increased due to modifications or changes in their rules, laws and regulations regarding food fortification[18-20]. This led to a nationwide increase in the consumption of many vitamins, especially fat synthesis-promoting B vitamins[21-24], including B_1 (thiamin), B_2 (riboflavin), B_3 (niacin) and B_6, in many countries[18-20]. Thus, there is a possibility that the food fortification-induced high vitamin intake may be related to the sudden increase in the prevalence of obesity in the 1970s-1980s. Indeed, emerging evidence suggests that this food fortification-induced excess vitamin intake might play a major role in the increased prevalence of obesity[25,26]. In this review, we will discuss the cause of increased vitamin intake and its possible role in obesity, as well as the obesity disparities among countries and groups within countries.

CAUSES OF EXCESS VITAMIN INTAKE

Until the mid 1930s when the first commercial yeast extract vitamin B complex and semi-synthetic vitamin C supplement tablets were sold, vitamins were obtained solely through natural foods and seasonal changes in diet usually greatly altered the types and amounts of vitamins ingested. For example, the intake of fresh vegetable-derived vitamins might be high in summer but low in winter. However, through evolution, humans have adapted to this seasonal variations in vitamin intake by developing mechanisms to maintain the vitamin homeostasis. While the intake of vitamins is higher in summer, their elimination through sweat and sebum[27-30] may also increase because the secretion of sweat and sebum is higher in summer than in winter[28,31,32]. Moreover, the body can store a certain amount of vitamins when the supply is adequate, which can be used for some time when the intake is inadequate. For example, it will take several months before the first symptoms of vitamin C deficiency appear in a vitamin C deprivation condition[33]. From this point of view, it seems unnecessary to take vitamins everyday, although estimated daily average requirements (EARs) and the recommended dietary allowances are given (Table 1). Yet over the past several decades, the actual intake of vitamins has been significantly higher than the EARs due to the following causes.

Increased vitamin intake from vegetable/fruit sources

Over the past several decades, many fresh vegetables and fruits with better quality can be obtained year round due to widespread out-of-season cultivation. This has not only led to an increase in the intake of vegetable/fruit-derived vitamins (*e.g.*, vitamin C), but also abolished the seasonal vitamin intake variations. Taking the United States as an example, the per capita consumption of vegetables and fruits showed an increasing trend in the 1970s through the 1990s (Figure 1A), leading to an increase in vitamin C intake since the mid-1960s[34].

Increased vitamin intake from animal sources

The consumption of animal-based foods significantly increased in developed countries in the second half of the last century. Dietary patterns in developing countries have been shifting to a more meat-centric diet over the past few decades[5,35]. Such a nutrition transition has increased the intake of vitamins (especially nicotinamide, a form of niacin) from animal-based foods. For example, United States per capita consumption of total meat showed an increasing trend between the 1930s and 2000 (Figure 1B), which increased the daily intake of meat-derived nicotinamide from 6.8 mg in the 1930s to 11.4 mg in 2000, according to the data on meat contribution to daily niacin intake[34].

Increased vitamin intake from artificial sources

Besides increased natural vitamin sources, vitamins may be obtained from artificial sources, which involves food fortification, infant formula fortification, and vitamin-enriched drinks. Fortification is the process of adding synthetic vitamins to foods and infant milk (including breast milk or formula) to increase its overall vitamin content[34]. Some staple foods (such as flour and maize) are used as a vehicle for fortification. Wheat flour fortification with synthetic vitamins (B_1, B_2 and niacin) was started first in the United States in the late 1930s, which was soon adopted by many developed countries and then introduced

to developing countries[19,20]. Notably, ready-to-eat cereals are a major vehicle of fortification of B vitamins (B_1, B_2, B_6 and niacin). Especially since 1974 when the food fortification standards for cereals were updated, ready-to-eat cereals have become the top food source of many vitamins[20,34]. The levels of vitamins in fortified ready-to-eat cereals are so high (Table 2) that consumption of less than a quarter pound of them (because foods *per se* also contain some amount of vitamins) meets the daily need for these vitamins in an adult. Many sugar-sweetened beverages are also supplemented with vitamins[36,37], which is also an important cause of increased vitamin intake. Since the 1950s, synthetic vitamins have been added to infant formulas[38]. In the 1980s, the governments of most countries established minimum nutrient requirements for commercial infant formulas[39], resulting in a significant increase in the content of vitamins in formulas. The levels of vitamins in some formulas for premature infants are more than 20 times higher than that of human milk (*i.e.*, about the minimum limit for nutrients) (Table 3). This leads to a high vitamin intake in infancy.

As a result of the combination of the above factors, the intake of vitamins has been significantly increased

over the past few decades. As shown in Figure 2, United States per capita daily consumption of vitamin B_1, B_2 and niacin has doubled from the 1930s to 2000, which is significantly higher than the EARs.

FOOD FORTIFICATION-RELATED DISPARITIES

Food fortification may lead to differential exposure to

synthetic vitamins. The major differences include: (1) Different vitamin exposure among countries. Food fortification has caused significant differences in daily synthetic-vitamin consumption among countries due to different fortification policies and fortification standards[19], as shown in Table 4. Nationwide exposure to fortified foods in developing countries occurs much later than in developed countries[19], *e.g.*, it was not until 1994 that China began mandatory fortification[41]; (2) Different vitamin exposure among groups within countries. Wheat flour is fortified with B vitamins. Thus, those who use wheat flour products as staple foods possibly consume a higher amount of synthetic B vitamins. Vitamin-fortified foods are cheaper than fresh and natural foods in developed countries[34,47], which may lead to a higher intake of synthetic vitamins in low SES groups than in high SES groups in these countries[47,48]. In contrast, in developing countries, those who live in urban areas may consume more fortified foods than those who live in rural areas[49,50]. Infant formula milk (Table 3) and children foods (*e.g.*, ready-to-eat cereals[34]) are highly fortified with vitamins. Thus, infants fed formula milk and children are likely to have excess vitamin intake, as reported in the literature[51-54]; and (3) Different tolerance to fortified foods among population groups. Water-soluble vitamins can be eliminated through sweat[27,28]. Thus, under the same conditions of high vitamin intake, people who often sweat (*e.g.*, doing physical work and/or living in hot regions) may have a lower risk of excess accumulation of water-soluble vitamins in the body than those who rarely sweat (*e.g.*, living a sedentary life and/or in cold regions).

VITAMIN FORTIFICATION AND OBESITY PREVALENCE

Although there are few studies linking the increased prevalence of obesity to vitamin fortification, existing evidence suggests that high-risk populations are those who are most likely to have an increased intake of synthetic vitamins and decreased vitamin elimination, *e.g.*, populations in fortified countries[6], individuals with low SES in developed countries[6-10] or with high SES in developing countries[11,12,55], formula-fed infants[15-17], and those who live in fortified countries with less rigorous physical activity[56-59].

The prevalence of obesity varies from country to country. It seems that this variation may be related to dif-

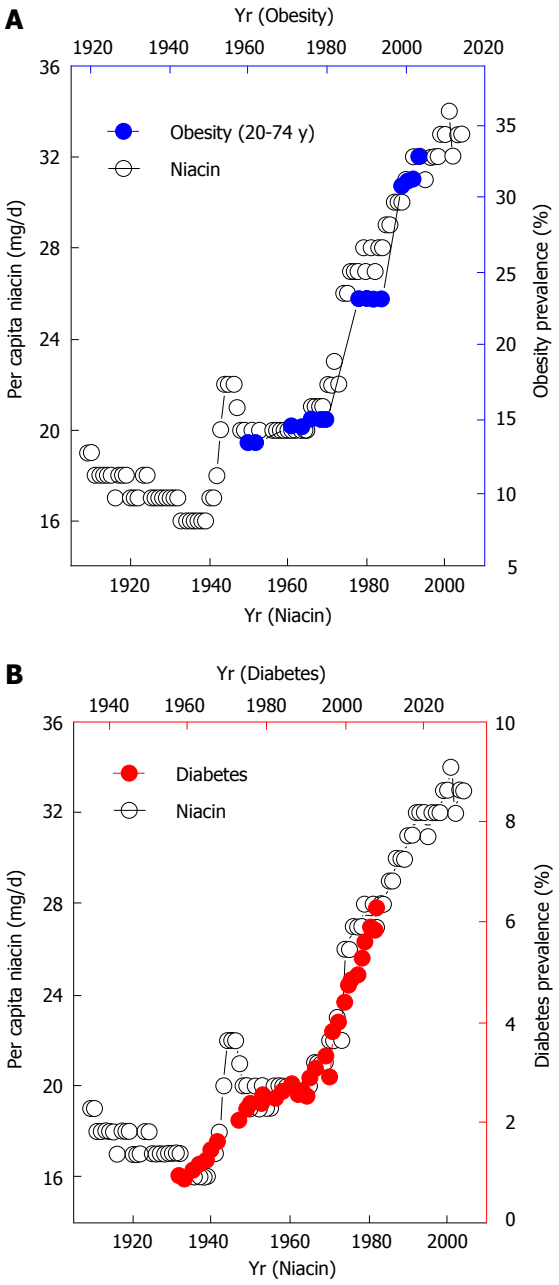

Figure 3 Lagged correlations between United States per capita niacin consumption and the prevalence of obesity and diabetes. The lag time between per capita niacin consumption and the prevalence of obesity and diabetes is 10 (A) and 26 years (B), respectively[25,26].

ferent food fortification policies and standards among countries. As shown in Table 4, the ranking of countries according to their prevalence of child obesity is similar to the ranking by the fortification standards of B vitamins. Evidently, flour fortification prohibited countries have a low prevalence of obesity, while countries with high flour fortification standard have high rates of obesity. Over the past few decades, food fortification has spread from developed countries to developing countries[19]. Therefore, it is possible that the spread of obesity from developed countries to developing countries may reflect the time sequence of implementing food fortification with vitamins.

Implementation of a vitamin fortification policy in a country will surely cause a sudden nationwide increase in vitamin intake in a short period. The initiation of food fortification with B vitamins in the late 1930s-1940s and the update of fortification standards in the 1970s in developed countries led to three phases in the consumption of vitamin B_1, B_2 and niacin: a rapid increase in the 1940s, followed by a plateau period between the 1950s and the 1960s and a steep increase thereafter, as shown in Figure 2. Available evidence has suggested an association between these food events and the prevalence of obesity. Two birth cohort studies conducted in Switzerland[60] and Denmark[61] showed that there was a significant increase in the prevalence of being overweight and obesity which occurred mainly in the cohorts born in the 1930s and the 1940s and in the cohorts born in the late 1960s to the 1970s. A Fels longitudinal study also showed that the child obesity epidemic in the United States is a sudden event that started in the 1970s and the 1980s[62]. A similar phenomenon is also seen in Saudi Arabia. Saudi Arabia started wheat flour fortification in the 1970s[63]. Following its food system change, Saudi Arabia experienced a rapid increase in obesity rates in the 1980s and the 1990s, and its obesity rate in schoolboys sharply increased from 3.4% in 1988 to 24.5% in 2005[64]. Our ecological studies clearly showed that there are strong lagged correlations between United States per capita consumption of B vitamins (B_1, B_2 and niacin) and the prevalence of obesity and diabetes[25,26]. Figure 3 clearly shows that both the initiation of food fortification in the 1940s and the update of fortification standards in 1974 are followed by a sharp increase in diabetes prevalence. The update of fortification standards followed a sharp rise in obesity prevalence.

As mentioned above, low SES groups in developed countries but high SES groups in developing counties may have a high synthetic vitamin intake from fortified foods. This may explain the findings that obesity is more prevalent in low SES groups in developed countries[6-10] but in high SES groups in developing countries[10-12,55]. Formula-fed infants have a high vitamin intake. Studies have demonstrated that formula-fed infants have a higher plasma level of vitamins compared with human milk-fed infants[51-53]. It is known that formula feeding[65-67] and micronutrient-fortified human milk feeding[68,69] can lead to rapid infant weight gain, a known major risk factor for children developing obesity[70-72]. Therefore, excess vitamin intake may mediate the link between formula feeding and childhood obesity.

In most developed countries, the energy expenditure needed for daily life has decreased since the beginning of the 20th century because of increasing mechanization, urbanization, motorization and computerization[4]. However, it is only since the 1970s, when food fortification standards were dramatically increased, that obesity prevalence has risen substantially. Moreover, although formula feeding is associated with an increased risk for obesity[15-17], there is no evidence indicating that there is a decrease in energy expenditure in formula-fed infants compared with breast-fed infants[73,74]. Instead, evidence shows that formula-fed infants may have higher total

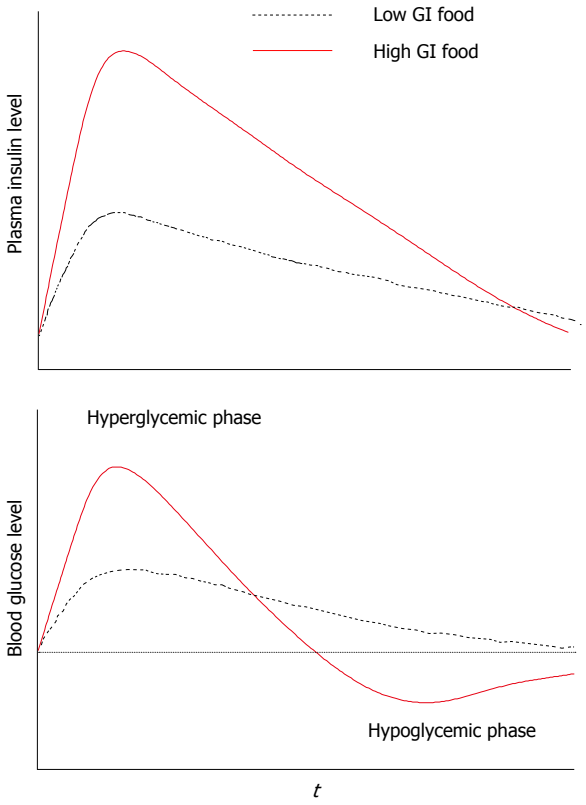

Figure 4 Typical glycemic responses to ingestion of a high glycemic index food and a low glycemic index I food. This figure is based on literature data[85-87]. GI: Glycemic index.

daily energy expenditure[13,14]. These data suggest that increased B vitamin intake rather than decreased energy expenditure may play a major role in the development of obesity. On the other hand, many studies, especially those conducted in highly B vitamin fortified countries, such as the United States[56], Canada[57], Saudi Arabia[58] and Kuwait[59], found that moderate to vigorous physical activity is associated with a reduced risk of obesity. It is proposed that this association may involve increased elimination of vitamins through sweat because moderate to vigorous physical activity can increase the sweat rate[28]. We have demonstrated that excess nicotinamide can be rapidly removed through sweating[75]. Sweat-mediated elimination of nicotinamide may be a crucial factor in preventing nicotinamide toxicity because human kidneys hardly excrete nicotinamide due to the reabsorption of renal tubules[76]. Therefore, it is conceivable that under the same conditions of high vitamin intake, those individuals who live a life that inhibits the activity of sweat glands (*e.g.*, physical inactivity) may be at greater risk of obesity. From this point of view, black people should be more sensitive to excess vitamins than whites, because the activity of sweat glands of blacks is lower than that of whites in the same temperature environment[77]. There is evidence showing that black women may have lower levels of physical activity than black men[78]. This may explain why obesity prevalence is greater in blacks, especially black women, than in whites in the United States[79,80]. Taken together, it may be concluded that food fortification-induced high intake of vitamins, especially B vitamins, may be responsible for the increased global prevalence of obesity.

MECHANISM OF EXCESS VITAMINS-INDUCED OBESITY

Many vitamins are known to act as coenzymes or as parts of enzymes responsible for essential chemical reactions, *e.g.*, the synthesis of fat and neurotransmitters. Excess vitamins may also affect the degradation of neurotransmitters and one-carbon metabolism. Therefore, excess vitamins may trigger obesity through multiple ways, including increasing fat synthesis, causing insulin resistance, disturbing neurotransmitter metabolism and inducing epigenetic changes.

B vitamins enhance fat synthesis

Obesity involves an accumulation of excess body fat. Early studies have already demonstrated that B vitamins play a crucial role in fat synthesis and there is a synergistic effect of B vitamins on fat synthesis. Vitamin B_1 and B_6 are required for the synthesis of fat from carbohydrate and protein[21-23] and their effects on fat synthesis are enhanced by the presence of other B vitamins. Vitamin B_6 administered together with B_1, B_2 and B_5 (pantothenic acid) resulted in a significant increase in body fat in rats[22]. Niacin has been found to increase daily feed intake, weight gain and percentage of abdominal fat in chicken when increasing supplementation from 0 to 60 mg nicotinic acid per kilogram diet[24]. It has been found that formula feeding leads to more fat gain, which may account for increased risk of later obesity[81,82]. Considering that formulas contain high levels of B vitamins (Table 3) that are a known factor increasing fat synthesis, we therefore propose that formula feeding-induced fat gain may be due to excess vitamins. Taken together, existing evidence suggests that excess vitamins, especially B vitamins, may play a role in the development of obesity.

Excess vitamins cause insulin resistance

Insulin resistance, a characteristic of obesity and type 2 diabetes[83], is a condition in which the tissues of the body do not respond appropriately to normal levels of insulin. It is known that glycemic and insulin responses are related to food. Foods can be classified by their glycemic index (GI, a relative measure of the incremental glucose response per gram of carbohydrate)[84]. Figure 4 shows the different glycemic and insulin responses to low GI food and high GI food. The typical glycemic response to high GI foods is a biphasic response, with an initial significantly higher blood glucose and insulin level (hyperglycemic phase) followed by significantly lower blood glucose level (postprandial reactive hypoglycemic phase)[85-87]. Postprandial reactive hypoglycemia stimulates appetite and may lead to increased caloric intake[86,88,89]. Therefore, it may be particularly important to understand how high GI foods induce a biphasic glycemic response.

Grain foods are a major source of carbohydrates.

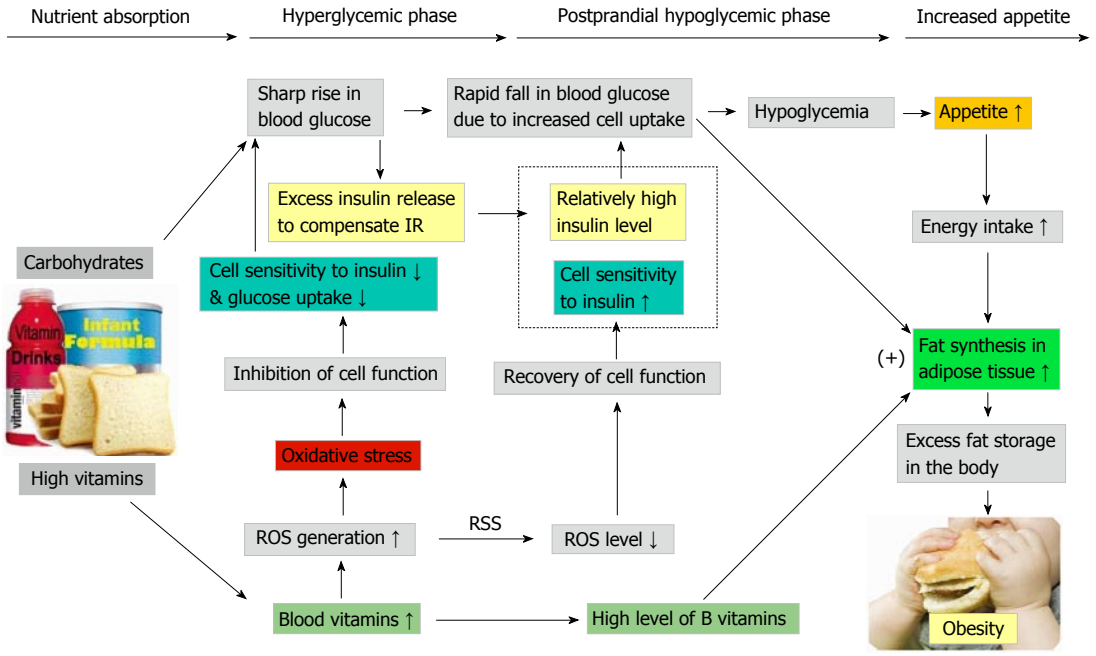

Figure 5 Proposed mechanism of excess vitamins-induced obesity. The absorption of sugar stimulates the release of insulin, while absorbed excess vitamins (from vitamin-fortified foods and drinks) generate ROS, leading to a decrease in the sensitivity of peripheral tissues to insulin (*i.e.,* insulin resistance). To compensate the insulin resistance, additional insulin has to be secreted, resulting in a high blood insulin level. Then, the sensitivity of peripheral tissues recovered with the rapid clearance of ROS, consequently, relatively high insulin level causes a rapid decrease in blood glucose due to increased glucose uptake, which may trigger excess energy intake. The conversion of glucose to fat in adipose tissue is promoted by high levels of B vitamins. Therefore, long-term consumption of vitamin fortified foods (including formulas) and drinks may cause fat accumulation in the body and subsequent obesity. ROS: Reactive oxygen species; RSS: ROS scavenging system.

Historically, high grain intake was associated with a low incidence of obesity. However, over the past few decades, refined (processed) grains became high GI foods[86,90,91]. Many processed grains (*e.g.,* white bread) produce even higher glycemic responses than simple sugars[86]. It seems that the effect of refined grains is not merely a matter of increased rate of digestion and absorption of carbohydrate, but a matter of increased insulin resistance. Grain foods are used as a vehicle of B vitamin fortification. Therefore, it is possible that the increased GI of processed grains may be due to their increased levels of B vitamins. Among the B vitamins fortified in foods, niacin is known to induce insulin resistance and glucose intolerance[92-95]. Nicotinamide is the most common form of niacin used in food fortification and infant formula supplementation (*e.g.,* Table 3). A study compared the glycemic and insulin responses of healthy subjects to glucose alone and glucose plus nicotinamide. The result showed that glucose plus nicotinamide significantly increased the levels of plasma insulin and hydrogen peroxide [a major component of reactive oxygen species (ROS)], followed by reactive hypoglycemia and hunger[26]. This study suggested for the first time that drinking nicotinamide-containing sugar-sweetened beverages may induce insulin resistance and nicotinamide fortification may contribute to the increased GI of refined grains.

It is known that increased ROS levels (*i.e.*, oxidative stress) may play a causal role in insulin resistance[96,97]. We therefore hypothesize that oxidative stress may mediate the effect of nicotinamide. The mechanism may be as follows. After glucose and nicotinamide are absorbed into the circulation, increased blood glucose level stimulates insulin secretion, while increased nicotinamide level may induce oxidative stress due to increased ROS generation (as found in Ref 26), leading to a decrease in cell functions, including insulin signaling (*i.e.*, insulin resistance). This results in a sharp increase in the level of blood glucose, which stimulates more insulin release (hyperglycemic phase). The clearance of ROS is more rapid than that of insulin. With the rapid clearance of ROS, cell response to insulin recovers quickly and as a result, the uptake of glucose by tissues (including adipose tissue) increases rapidly in response to relatively high insulin, which thus leads to a rapid fall in the level of blood glucose (hypoglycemic phase). Hypoglycemia initiates the feeling of hunger and subsequent feeding behavior. As mentioned above, B vitamins promote fat synthesis from carbohydrates. Thus, the cooperation of increased glucose uptake in the hypoglycemic phase and increased fat synthesis by high levels of B vitamins may induce excess fat storage and subsequent obesity (Figure 5). Unfortunately, the insulin resistance-inducing and obesity-promoting effects of B vitamins might have long been underestimated because traditional laboratory tests (*e.g.,* glucose tolerance test) are usually performed under fasting conditions, in which most, if not all, of increased ROS produced in the degradation of excess vitamins must have been cleared up after overnight fasting. For example, we found that oral nicotinamide (300 mg) induced increase in circulating hydrogen peroxide had returned to normal at 3 h[26].

It has been demonstrated in rats that the weight/fat gain-promoting effect of B vitamins is more efficient

when given in successive doses (added to the diet, like human food fortification) than in periodic doses[98]. This may explain why obesity prevalence significantly increased after the implementation of grain fortification with B vitamins. Because consumption of B vitamins-fortified foods may increase the burden of pancreatic islet B-cells, it is conceivable that obesity is closely associated with type 2 diabetes. In addition, other vitamins, even those that have antioxidant function (*e.g.,* vitamin C and E[99]), when used in large doses can increase ROS generation. Thus, high consumption of other vitamins may also contribute to the development of obesity. The relationship between dietary carbohydrates, excess vitamins, oxidative stress, insulin resistance, postprandial hypoglycemia, increased appetite and the development of obesity is proposed in Figure 5.

From the excess vitamin point of view, it may be easy to understand why the price of fast food, which determines the consumption of synthetic vitamins from fast food, may affect the body mass index of teens with low SES[100] and why vitamin-rich formulas[15-17] and sugar-sweetened beverages may increase the risk for obesity and type 2 diabetes[17,37,101,102]. It is interesting that some overweight children become overweight adults, while others do not[103]. One possible explanation for this may be a changing vitamin intake during the lifetime. Whether obese infants become obese children and then obese adults may to a large degree depends on the intake of vitamins after weaning. In theory, infants, even with normal body weight, may become obese adults if they always consume high vitamin-fortified foods (*e.g.,* refined grains) after weaning. We therefore recommend that the role of vitamin intake be taken into consideration in the study of the relationship between infant obesity and later obesity.

Excess vitamins may disturb neurotransmitter metabolism

Food intake is regulated by many neurotransmitters, including monoamine neurotransmitters (*e.g.,* dopamine and serotonin[104,105]) in the central nervous system. Therefore, factors that affect monoamine neurotransmitters may affect feeding behavior. Some vitamins are known to play an important role in the synthesis of monoamine neurotransmitters (serotonin and catecholamines). For example, vitamin B_6 is a cofactor for aromatic L-amino acid decarboxylase that catalyzes the formation of serotonin and dopamine[106]. Vitamin C enhances norepinephrine synthesis from dopamine by neuronal cells[107]. L-methylfolate, a derivate of the vitamin folate, also regulates the synthesis of the monoamine neurotransmitters serotonin, dopamine and norepinephrine[108].

Although small amount of vitamins can be directly eliminated through the urine, sweat[27,28,75] and sebum (such as vitamin E[29,30]), most of them usually undergo a series of phase I (oxidation, reduction and hydrolysis) and phase Ⅱ (conjugation, including glutathione conjugation, sulfation, methylation and glucuronidation) biotransformation before elimination from the body. As a result, vitamin degradation produces many metabolites. For example, at least 18 metabolites of vitamin B_1 are identified in the urine, of which six are major[109]. Niacin is degraded mainly to a number of methylated metabolites[110]. Vitamin C is degraded through sulfation[111] and glutathione conjugation[112]. Vitamin E also undergoes extensive metabolism and its conjugated metabolites (including sulfated) are also identified[113]. Because vitamins and neurotransmitters share the same biotransformation and detoxification system in the body[106,114], excess vitamins may affect the degradation of neurotransmitters by competing for the detoxification resources. For example, vitamin C has been known to inhibit the sulfation of other chemicals by competing for limited sulfate[111]. Although there are no systematic studies on the effect of vitamin fortification on the degradation of neurotransmitters, evidence has shown that excess vitamin C[115,116] and nicotinamide[117] can inhibit the degradation of catecholamines by depletion of sulfate and methyl groups, respectively. Thus, in theory, the effect of vitamins on the metabolism of monoamine neurotransmitters may affect the function of the nervous system. It is known that niacin can stimulate appetite. Niacin deficiency (*i.e.*, pellagra) is associated with a loss of appetite[118], which might involve changes in neurotransmitter metabolism in the brain.

Excess vitamins-induced obesity may involve epigenetic changes

Epigenetic changes are biochemical modifications that affect gene expression without changing the sequence of DNA. Emerging evidence suggests that epigenetic mechanisms may play a role in the development of obesity[119]. Epigenetic mechanisms involve an environment-gene interaction[120,121]. Nutrition is a crucial environmental factor which affects health and disease. Both maternal undernutrition and overnutrition can induce persistent changes in gene expression and metabolism[120]. Over the past few decades, one of the biggest changes in our food system has been the extensive use of synthetic vitamins. Therefore, it is possible that excess vitamin intake may contribute to epigenetic changes.

DNA methylation, which occurs at cytosine residues in CpG dinucleotides in gene promoters, is one of several epigenetic modifications[122]. The primary function of DNA methylation is to suppress gene expression. Global DNA hypomethylation increases genomic instability[122]. Although the mechanism of global DNA hypomethylation is not well understood, a lack of methyl groups may play a role in abnormal DNA methylation, because an adequate supply of methyl groups is a prerequisite for DNA methylation[123]. The biotransformation of some vitamins, especially niacin[117], may increase the demand for labile methyl groups and therefore, an excess intake of these vitamins may disturb DNA methylation by competing methyl groups. Recently, we tested this possibility by investigating the effect of nicotinamide supplementation on DNA methylation in rats and found that long-term high nicotinamide exposure led to a decrease in the methyl pool and in the levels of hepatic DNA methylation associated with alteration of gene expression[123]. Moreover,

maternal nicotinamide supplementation is also found to disturb fetal one-carbon metabolism in rats, including decreased global DNA methylation and decreased DNA uracil content in the brain and liver[124]. These data indicate that excess vitamins may be an important factor leading to epigenetic changes. The role of vitamin fortification in the development of methylation-related diseases is an open question.

NON-MONOTONIC EFFECT OF VITAMINS ON WEIGHT GAIN

Although it is known that B vitamins promote fat synthesis and vitamin-fortified foods and formulas increase the risk for obesity, why is there so little attention to the relationship between excess vitamin intake and obesity prevalence? A possible reason may be due to ignorance of the fact that the effect of vitamins on weight gain is non-monotonic. While vitamins are an important weight gain-promoting factor, at toxic levels they are no longer associated with weight gain or even cause weight loss.

It has long been known that many micronutrients (vitamins and minerals) are essential for life at low concentrations but become toxic at high concentrations. This phenomenon is termed Bertrand's rule[125]. The effect of vitamins on weight gain also follows this Bertrand's rule. We may take the weight-gain effect of niacin as an example. Jiang and colleagues[24] investigated the effects of dietary supplemental nicotinic acid at different doses (0, 30, 60 and 120 mg/kg diet) on the growth performance of chicken. They found that increasing supplementation from 0 to 60 mg nicotinic acid/kg tended to increase the average daily feed intake, weight gain and fat gain, *i.e.,* the maximum weight and fat gain was achieved at 60 mg/kg diet. Ivers and Veum found that among the doses used (6, 10, 14, 18, 22 and 44 mg/kg diet with adequate Trp), 14 mg of niacin/kg produced maximum weight gain in growing pigs[126]. Shibata *et al*[127] studied the effect of nicotinamide at doses of 0, 60, 1000 and 5000 mg/kg diet on rat weight gain. Their result showed that nicotinamide increased the food intake of rats, especially in the groups fed diet containing 60 and 1000 mg/kg of nicotinamide. The highest weight gain was observed at 60 mg/kg, while high-dose nicotinamide (5000 mg/kg diet) led to an inhibition of weight gain at the early stage of exposure due to its toxicity. These animal studies suggest that the supplemental dose for niacin to achieve maximum weight-gain effect may be around or less than 60 mg/kg diet. This dose is similar to that used in wheat flour fortification in some countries, *e.g.,* the United States, Canada, Saudi Arabia and Kuwait (Table 4). Thus, food fortification with niacin in these countries might have induced a maximum weight gain effect. In this case, further supplementation with niacin or niacin-containing multivitamin may offset the weight gain effect due to increased toxic effects, such as hepatotoxicity[128-131] and oxidative tissue damage[123]. This may account for the observations that further multivitamin supplementation in the United States[132] and Canada[133] or large-dose niacin treatment for dyslipidemia (1-3 g/d)[134,135] does not show weight gain.

Some other vitamins at high doses may also have toxic effects, including death. Davis *et al*[136] found that sudden infant death syndrome (a sudden and unexplained infant death) was association with high serum thiamin levels. A randomized controlled trial on vitamin C supplementation in very preterm infants showed that the infants who died in the trial were those who had significantly higher level of plasma vitamin C before randomization than surviving infants[137]. A systematic review and meta-analysis showed that long-term supplementation with beta carotene, vitamin A and vitamin E may increase mortality[138]. Therefore, it is not surprising that multivitamin supplementation in those who live in high-dose vitamin-fortified countries, *e.g.,* the United States[132] and Canada[133], may be associated with a slight weight loss. A similar phenomenon has been also observed in formula-fed infants. It has been found that formula feeding can lead to a more rapid weight gain, especially fat gain[81,82], compared to human milk feeding[17,65,67]. However, when formulas were further enriched with vitamins, their weight-gain effect was decreased rather than increased, compared with the standard formulas[139]. It seems clear that the weight-gain effect of vitamins has already been saturated at fortification doses used in infant formulas, children and adult foods, while further increasing the doses (*i.e.*, fortification plus additional supplementation) may induce a weight-loss effect due to the toxic effect. Considering that high vitamin intake which may cause hepatotoxicity (*e.g.,* niacin, as mentioned above) is very popular nowadays, we suggest that high vitamin intake may contribute to non-alcoholic fatty liver disease, the most frequent chronic liver disease in developed countries[140].

CONCLUSION

Since the late 1930s, when synthetic vitamins were first used, the human being has experienced the largest growth in vitamin intake in human history. It is possible that excess vitamins, especially B vitamins, may contribute to the development of obesity. Vitamin-rich formulas and food fortification with vitamins may, to a large extent, be responsible for the increased prevalence of obesity over the past several decades. Different fortification policies and standards may account for the differences in the prevalence between countries, while disparities in the consumption of fortified foods may contribute to the disparities in obesity between population groups within a country. Staple food fortification may be of great harm because it leads to a sustained high vitamin intake. Therefore, given that there has been a significant increase in vitamin supply from natural sources, it is necessary and urgent to review and modify the standards of vitamin fortification.

Abstract

While insulin-like growth factor I is a well-known anabolic agent in bone evidence is beginning to accumulate that its homologue, insulin, also has some anabolic properties for bone. There is specific evidence that insulin may work to stimulate osteoblast differentiation, which in turn would enhance production of osteocalcin, the osteoblast-produced peptide that can stimulate pancreatic β cell proliferation and skeletal muscle insulin sensitivity. It is uncertain whether insulin stimulates bone directly or indirectly by increasing muscle work and therefore skeletal loading. We raise the question of the sequence of events that occurs with insulin resistance, such as type 2 diabetes. Evidence to date suggests that these patients have lower serum concentrations of osteocalcin, perhaps reduced skeletal loading, and reduced bone strength as evidenced by microindentation studies.

Key words: Type 2 diabetes; Insulin; Bone; Osteoblasts; Insulin resistance

Core tip: This is a review of recent publications that suggest an anabolic loop among bone, pancreas, and skeletal muscle.

INTRODUCTION

The interactions between insulin and bone would on the surface appear to be an unlikely subject for an article, let alone a review article, but with the advent of the knockout mouse model many relationships that would not have been obvious now require investigation. The aim of this paper is to provide evidence supporting an anabolic loop including the pancreas, skeletal muscle, and bone.

GROWTH FACTOR

We do not want to confound the anabolic effects of insulin with those of insulin-like growth factor (IGF)-1, although the homology of molecular structure of both molecules may in fact account for some of the anabolic effects of insulin on bone. It should be emphasized at this point that insulin is synthesized in the pancreatic β cells while endocrine IGF-1 is synthesized in the liver. The stimuli for insulin production include glucose and, as we will see, osteocalcin, while endocrine IGF-1 is synthesized by liver in response to growth hormone and the paracrine IGF-1 produced by bone cells, including preosteoblasts and osteoblasts, osteocytes and osteoclasts[1,2] is synthesized in response to stimuli that have not yet been clarified.

While there are copious reports of the anabolic effects of IGF-1 on bone there is a growing amount of data suggesting that insulin itself has an anabolic effect on bone. Suggestions of this effect came from studies involving burned children in which a hyperinsulinemic, euglycemic clamp was employed resulting in an increase in both lean body mass, often indicative of muscle mass, and bone mass at time of hospital discharge compared

to controls, usually between 6 wk to 3 mo post-burn[3]. Moreover, both pre-osteoblasts and osteoblasts manifest different isoforms of the insulin receptor (IR), with IRA being expressed in pre-osteoblasts and IRB being expressed in mature osteoblasts[4]. This specificity suggests that insulin is a critical element in osteoblast differentiation from marrow stromal cells. This may have significance in the generation of the osteoblast peptide osteocalcin, which, as we shall see, has major implications for glucose metabolism. Whether the direct effect of insulin on osteoblasts has clinical significance, however, is not entirely clear. This is in part because the abovementioned report on hyperinsulinemia demonstrated increases in both lean body mass and bone mass[3].

INSULIN

The other side of this proposed loop is the effect of bone on insulin. The stimulus for the work that produced these findings is the knockout mouse model. In this model a significant contribution has been made by Wei *et al*[5] who have most recently reported that osteocalcin stimulates β cell replication in the pancreas *via* a cyclin D1-dependent mechanism utilizing the G-protein coupled receptor family C group 6 member A receptor expressed by these cells. This stimulation occurs during both peak β cell proliferation, which occurs in the perinatal period and in adult mice[5]. Moreover, they described the effects of daily osteocalcin injections in obese type 2 diabetic mice reporting an increase in the number of mitochondria in skeletal muscle as well as an increase in energy expenditure[6], indicating that osteocalcin can also increase muscle work by increasing insulin sensitivity.

Thus these recent data would suggest that under normal conditions insulin may stimulate osteoblast differentiation in order to produce more osteocalcin, which would then stimulate more insulin production by the pancreas and greater insulin sensitivity of skeletal muscle. There are also some recent clinical correlates of these studies in adults. In a recent study Díaz-López *et al*[7] performed a case-control study of 153 diabetic subjects and 306 individually matched controls and found that both the carboxylated and undercarboxylated forms of osteocalcin were lower than matched controls and that carboxylated osteocalcin concentrations were inversely associated with a model assessment of insulin resistance and fasting glucose concentrations. Another report by Gower *et al*[8] indicated that in obese individuals total osteocalcin was directly associated with skeletal muscle but not hepatic insulin sensitivity while undercarboxylated osteocalcin was associated with β cell function in those with abnormal fasting glucose concentrations.

BONE

A major unanswered question is exactly what happens to bone in cases of peripheral insulin resistance? Are the IRs in pre-osteoblasts and osteoblasts down-regulated? We know that osteocalcin levels are lower in type 2 diabetics[7,8]. In addition, we know that insulin resistance is also caused by factors that cause bone resorption, such as the interleukin-6-mediated chronic low grade inflammation that contributes to non-alcoholic fatty liver disease (NAFLD)[9] and excessive glucocorticoid production, another significant contributor to NAFLD[10]. However, we do not at this point know precisely how peripheral insulin resistance affects bone. One conjecture would be that if muscles expend less energy due to their inability to take up glucose then muscle strength may be reduced and skeletal loading may also be consequently decreased. This scenario could explain abnormalities in bone with type 2 diabetes. Were this to be so then bone loss would result in reduced production of osteocalcin and a perpetuation of the problem of peripheral insulin resistance.

So, why has bone loss with type 2 diabetes been so difficult to determine up to now? As summarized by Ferrari[11] in a review article on diabetes and osteoporosis, bone mineral density (BMD) may not be reduced in this condition inasmuch as weight and fat mass must be factored into the BMD determinations. The probability of fracture as assessed by use of the on-line FRAX tool developed by the World Health Organization may also underestimate fracture risk in this condition. As evidence that this may indeed be the case a recent report by Hothersall *et al*[12] examined the files of all hip fractures in Scotland from 2005-2007 and the prevalence of both type 1 and type 2 diabetes in this population. While there was a significant correlation between hip fractures and type 1 diabetes, in which insulin deficiency is the issue, there was no overall increased risk of hip fracture in type 2 diabetes, according to this review. The investigators do, however, state that these findings do not rule out increased risk in sub-groups of type 2 diabetics. While we have demonstrated that osteocalcin, also a marker of bone formation, is lower in patients with type 2 diabetes, not all markers of bone formation or resorption are consistent. For example, Chen *et al*[13] found that while osteocalcin was lower in diabetics *vs* controls, there was no difference in bone specific alkaline phosphatase. Similarly while Bhattoa *et al*[14] found that urinary cross-laps, a resorption marker, was lower in type 2 diabetics *vs* controls while Chen *et al*[13] found that urinary hydroxyproline was elevated.

A new development, however, has shed some light on this problem. In a study that has been Epublished ahead of print, Farr *et al*[15] have reported the use of *in vivo* microindentation of the tibia as an index of bone strength. In this study of 60 post-menopausal women, half of whom had type 2 diabetes, this technique demonstrated decreased bone strength in the diabetic women.

Much more work needs to be done to follow up on these findings but clearly the greater chance of microcracks in the bones of insulin-resistant diabetics may not be detected by bone density determinations.

Therefore, for those who care for diabetic patients, the complications involving bone have been subtle and difficult to detect but as more attention is being paid to this area the pathogenesis of the bone problem should

be more clearly elucidated and new therapeutic targets identified.

Abstract

Cardiac autonomic neuropathy (CAN) is an often overlooked and common complication of diabetes mellitus. CAN is associated with increased cardiovascular morbidity and mortality. The pathogenesis of CAN is complex and involves a cascade of pathways activated by hyperglycaemia resulting in neuronal ischaemia and cellular death. In addition, autoimmune and genetic factors are involved in the development of CAN. CAN might be subclinical for several years until the patient develops resting tachycardia, exercise intolerance, postural hypotension, cardiac dysfunction and diabetic cardiomyopathy. During its sub-clinical phase, heart rate variability that is influenced by the balance between parasympathetic and sympathetic tones can help in detecting CAN before the disease is symptomatic. Newer imaging techniques (such as scintigraphy) have allowed earlier detection of CAN in the pre-clinical phase and allowed better assessment of the sympathetic nervous system. One of the main difficulties in CAN research is the lack of a universally accepted definition of CAN; however, the Toronto Consensus Panel on Diabetic Neuropathy has recently issued guidance for the diagnosis and staging of CAN, and also proposed screening for CAN in patients with diabetes mellitus. A major challenge, however, is the lack of specific treatment to slow the progression or prevent the development of CAN. Lifestyle changes, improved metabolic control might prevent or slow the progression of CAN. Reversal will require combination of these treatments with new targeted therapeutic approaches. The aim of this article is to review the latest evidence regarding the epidemiology, pathogenesis, manifestations, diagnosis and treatment for CAN.

Key words: Diabetes mellitus; Cardiac; Cardiovascular; Autonomic; Neuropathy; Dysfunction; Cardiac autonomic neuropathy; Sympathetic; Parasympathetic; Heart rate variability; Spectral analysis; Diabetic cardiomyopathy; Postural hypotension

Core tip: Cardiac autonomic neuropathy (CAN) is a complication of diabetes mellitus that is often underdiagnosed but can lead to severe morbidity and mortality, due to the associated cardiovascular burden. New evidence has emerged surrounding its complex pathways, but its full pathogenesis is yet to be understood. CAN manifests in a spectrum of subclinical and clinical presentations, ranging from resting tachycardia to cardiomyopathy. Heart rate variability and scintigraphy have enabled the diagnosis at a subclinical stage, thus providing the opportunity for better prevention and treatment. However, no definite therapeutic approaches have been adopted to date, emphasizing the need for newer targeted treatments.

INTRODUCTION

Diabetes mellitus (DM) is a global epidemic affecting at least 8.3% of the global population and 371 million people worldwide with a significant proportion (50%) remaining undiagnosed. It is estimated that almost one in six people are currently at risk of developing diabetes-related complications[1]. Cardiovascular disease (CVD) is the leading cause of mortality and morbidity in patients with diabetes and subsequently the primary goal of diabetes treatment is to reduce the burden of CVD as well as the vascular complications associated with diabetes[2,3]. Much of the CVD prevention strategies in patients with DM are based on lowering blood pressure and LDL-cholesterol levels and improving glycaemic control[4-7]. Despite that, CVD remains very common and a major cause of mortality and morbidity in patients with DM. Hence, better understanding of pathogenesis of CVD is crucial to develop new therapeutic targets.

Cardiac autonomic neuropathy (CAN) is a very common and often overlooked diabetes-related complication that has a major impact on CVD, mortality and morbidity in patients with DM[8,9]. Improving our understanding of the pathogenesis of CAN and its role in CVD, offers the potential of new treatment targets that might reduce the burden of CVD in patients with diabetes. This review aims to provide an overview of the epidemiology, pathogenesis, cardiovascular consequence, diagnosis, and treatments of CAN, with particular emphasis on the latest developments in the field.

LITERATURE SEARCH STRATEGY

We conducted a review of the original papers and review articles indexed in PubMed, Medline and Google Scholar between 1975 and 2013. We have used several terms individually or in combination including: diabetes, autonomic neuropathy, CAN, cardiovascular, cardiac, autonomic, neuropathy, dysfunction. Only articles in English and in adult population were reviewed.

DEFINITIONS AND EPIDEMIOLOGY

Based on the CAN Subcommittee of the Toronto Consensus Panel on Diabetic Neuropathy[10], CAN is defined as the impairment of cardiovascular autonomic control in patients with established DM following the exclusion of other causes. CAN, especially at the early stages, can be sub-clinical and thus as the disease progresses, it becomes clinically evident.

The prevalence of CAN varies between 1%-90% in patients with type 1 DM (T1DM) and 20%-73% in patients with T2DM (Table 1). This huge variation in CAN prevalence is due to the inconsistency in the criteria used to diagnose CAN and significant differences in the study populations, particularly in relation to CAN risk factors (such as age, gender and DM duration amongst others).

CAN has been detected at time of diagnosis of diabetes in patients with either T1DM or T2DM irrespective of age, suggesting that CAN presentation is not limited by age or type of diabetes and can occur before DM is evident clinically[11-15]. However, the duration of diabetes is an independent factor for developing CAN irrespective to diabetes type[10,16]. CAN is detected in about 7% of both T1DM and T2DM at the time of initial diagnosis[17], and it is estimated that the risk for developing CAN increases annually by approximately 6% and 2% in patients with T1DM and T2DM respectively[17-19].

Poor glycaemic control is a major risk factor for CAN progression[14,19-21]. In the Diabetes Control and Complications Trial (DCCT), intensive glycaemic control resulted in a 50% decrease in CAN incidence over the 6.5 years follow-up period[19]. This protective effect persisted 14 years after the end of the study despite the disappearance of HbA1c differences that were achieved between the groups during the randomised phase of trial[18]. Similarly, CAN has been shown to be associated with conventional CVD risk factors, such as hypertension, smoking, hyperlipidaemia and obesity[22-24]. In the Steno-2 trial of patients with T2DM and microalbuminuria, intensive pharmacological intervention targeting hypertension, hyperlipidaemia and microalbuminuria combined with behavioural treatment (exercise, diet and smoking cessation) reduced the risk of autonomic neuropathy over the course of a 7.8 years follow-up (HR = 0.37, 95%CI: 0.18-0.79)[5]. After a mean of 5.5 years following the end of the study, the same protective effect against the development of autonomic neuropathy persisted (RR = 0.53, 95%CI: 0.34-0.81, P = 0.004). There was also reduction in the risk for developing CVD (RR = 0.43, 95%CI: 0.19-0.94, P = 0.04) and overall mortality (RR = 0.54, 95%CI: 0.32-0.89, P = 0.02) in this study[25].

Moreover, in a large cohort of more than 1000 patients with T2DM the incidence of CAN over a 7.5 years follow-up correlated with age (P < 0.001) and microvascular disease (P = 0.035)[26]. Diabetic nephropathy (including microalbuminura), diabetic retinopathy and diabetic polyneuropathy have been widely identified as clinical predictors of CAN[23,24,27], which is not surprising as diabetic microvascular complications share common mechanisms and risk factors. The impact of gender on CAN is controversial. In a multi-centre, cross sectional study of 3250 patients with DM, CAN prevalence was no different between men and women (35% male *vs* 37% female)[28]. However, in the action to control cardiovascular risk in diabetes trial including more than 8000 patients with T2DM CAN was more prevalent in women (2.6% in men *vs* 4.7% in women for moderate severity CAN and 1.4% in men *vs* 2.2% in women for severe CAN, P < 0.01 for all three definitions of CAN in the study)[29].

Table 1 Prevalence of cardiac autonomic neuropathy as reported in major studies

Ref.	Year	Country	*N* of subjects	Type of DM	Population characteristics	Diagnostic test	Criteria applied	Prevalence (%)	Comments
O'Brien *et al*[111]	1991	United Kingdom	506	IDDM	Mean age 45 yr, mean DM duration 15 yr, female 42%	HRV in response to (1) rest (2) single deep breath (3) Valsalva manoeuvre or (4) standing	At least two positive of the tests mentioned in the previous column	17	Prevalence of CAN was associated with the presence of other DM complications
Ziegler *et al*[223]	1992	Germany Austria Switzerland	130 647 524	Newly diagnosed IDDM Total IDDM Non-IDDM		CV of HRV, low- and mid-frequency bands of spectral analysis, MCR, Valsalva manoeuvre or lying-to standing	At least three positive of the tests mentioned in the previous column	7.7 25.3 34.3	
Kennedy *et al*[11]	1995	United States	290	IDDM	Listed pancreas transplantation recipients	HRV Valsalva manoeuvre		90 88	
DCCT research group[19]	1998	United States	1441	IDDM (1) primary prevention cohort (absence of end–organ damage such as retinopathy and microalbuminuria) (2) secondary intervention cohort (mild/moderate retinopathy +/- microalbuminuria)	Mean age 27 yr, female 47% duration of DM 1-5 yr (mean 2.6) primary prevention cohort 1-15 yr (mean 8.8) secondary intervention cohort	HRV Valsalva manoeuvre Postural BP	R-R variation < 15 Valsalva ratio < 1.5 Diastolic BP drop > 10 mmHg	1.6-6.2 5.5-6.3 0	These figures represent baseline characteristics
Kempler *et al*[28] (EURODIAB IDDM)	2002	16 European countries	3250	T1DM	Mean age 32 yr, mean DM duration 14 yr, female 49%	(1) R-R response to standing (2) Postural BP	R-R ratio < 1.04 or drop > 20 mmHg in systolic BP	36	Correlation with age, DM duration and HbA1c
Gaede *et al*[5,224] (the Steno type 2 study)	2003	Denmark	160	T2DM	Mean age 55 yr, female 27%, HbA1C 8.8% at baseline	(1) R-R response to breathing (2)Postural BP	R-R variation < 6 or drop > 25 mmHg in systolic BP	27.5	This figure represents baseline findings
Valensi *et al*[27]	2003	France	245 151	T1DM T2DM	Mean age 39.6 yr, mean DM duration 8.6 yr, female 43%	R-R response to (1) deep breathing (2) Valsalva and (3) standing	Criteria for abnormal tests were based on Armstrong *et al*[225] At least two positive tests (classed as moderate CAN)	21.2 20.7 33.5 20	Rate of moderate/severe CAN was higher in T1DM (18.2% and 4.8%) than in T2DM (12.3% and 2.3%) (P = 0.031)
Low *et al*[23]	2004	United States	83 148	T1DM T2DM	Mean age 59 yr, white 99%, female 48%	(1) Sudomotor axon-reflex test (2) Valsalva manoeuvre (3) BP and HR response to standing (4) R-R response to deep breathing	CASS ⩾ 1 in two domains or ⩾ 2 in one domain (sudomotor, cardiovagal, adrenergic)	54 73	This study focuses on DAN but encompasses several cardiac autonomic tests
Pop-Busui *et al*[18] (DCCT/EDIC study)	2009	United States	620 591	IDDM-former intensive Tx group IDDM-former conventional Tx group	Mean age 47 yr in both groups, mean DM duration 26 yr, female 49% and 46% respectively	R-R response to (1) deep breathing (2) Valsalva manoeuvre (3) postural BP	R-R < 15 or R-R 15-19.9 and Valsalva ratio < 1.5 or drop > 15 mmHg in diastolic BP	29 35	13/14 yr post closeout of DCCT

DM: Diabetes mellitus; IDDM: Insulin dependent diabetes mellitus; CV: Coefficient of variation; MCR: Mean circular resultant; HRV: Heart rate variability; BP: Blood pressure; CAN: Cardiac autonomic neuropathy; CASS: Composite Autonomic Severity Score; DCCT: Diabetes Control and Complications Trial; T1DM: Type 1 diabetes mellitus.

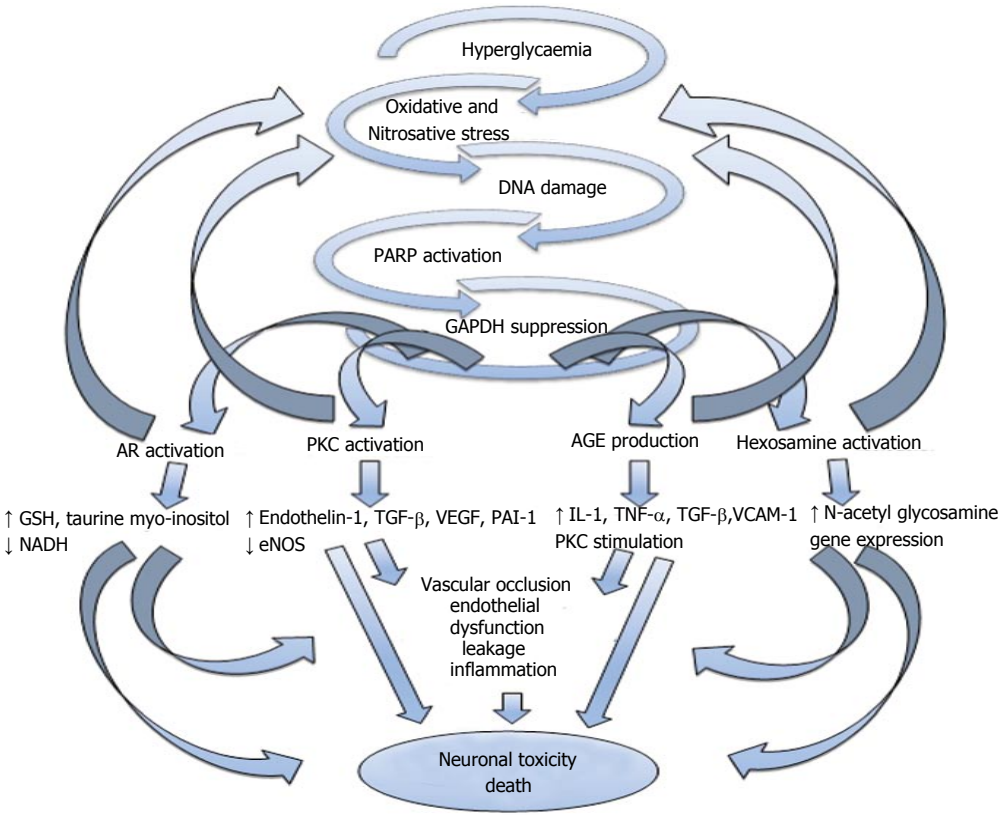

Figure 1 Summary of the mechanisms that relate hyperglycaemia to microvascular complications in patients with diabetes. PKC: Protein kinase C; AGE: Advanced glycation end-products; PARP: Poly ADP-ribose polymerase; GAPDH: Glyceraldehyde-3 phosphate dehydrogenase; GSH: Glutathione; NADH: Nicotinamide adenine dinucleotide; TGF-β: Transforming growth factor; VEGF: Vascular endothelial growth factor; PAI-1: Plasminogen activator inhibitor-1; eNOS: Endothelial nitric oxide synthase; IL-1: Interleukin 1; TNF-α: Tumour necrosis factor-α; VCAM-1: Vascular cell adhesion molecule 1.

Ethnicity has also been postulated to be a risk factor for CAN as South Asians seem to have lower rates of peripheral neuropathy than White Europeans with DM[30]. More specifically, the prevalence of small fibre neuropathy was significantly lower in Indian Asians than in Europeans (32% *vs* 43% respectively, $P = 0.03$) and mean nerve conduction velocity Z scores (measuring large fibre neuropathy) were superior in Asians compared to Europeans (mean ± SD 0.07 ± -0.62 *vs* -0.11 ± 0.60, $P = 0.007$). However, using heart rate variability (HRV) spectral analysis as well as frequency and time domain analysis showed no difference in CAN prevalence between South Asians and white Europeans (Tahrani *et al*, unpublished data).

PATHOGENESIS OF CAN

The exact pathogenesis of CAN is complex and remains unclear. Most of the proposed mechanisms of neuronal injury are based on models of somatic rather than autonomic neuropathy. Although many of these mechanisms might be shared between autonomic and somatic neuropathies, differences do exist as shown by the Steno-2 trial (described above) in which the multi-factorial intervention (including intensive metabolic control and lifestyle changes) slowed down the progression of autonomic but not somatic neuropathy.

Hyperglycaemia induced neuronal injury and ischaemia

The pathogenesis of CAN is likely to be multi-factorial[31] and to involve several mechanisms and pathways that lead to neuronal ischaemia or direct neuronal death/dysfunction (Figure 1). Hyperglycaemia and the adverse metabolic environment in patients with DM result in increased oxidative and nitrosative stress[17], which can cause direct neuronal damage/dysfunction as well as endothelial dysfunction resulting in neuronal ischaemia. Neuronal axons are rich in mitochondria which makes them particularly susceptible to the direct and indirect effects on oxidative and nitrosative stress[32].

Increased oxidative stress results in poly ADP-ribose polymerase activation which when coupled with other activated downstream pathways including the polyol pathway, advanced glycation endproducts production, protein kinase C and the hexosamine pathway are thought to contribute to glucose toxicity[33-36]. These different pathways can in return exacerbate oxidative stress and can induce changes in gene expression, transcription factors, diverse cellular products disrupting several cellular functions and the communication between the cell and the surrounding matrix all of which leads to neuronal dysfunction and death[37-39]. These pathways also result in impaired microvascular-- regulation and endothelial dysfunction by different mechanisms, including increase in plasminogen activator inhibitor-1 and endothelin-1 production and impairment of endothelial nitric oxide (NO) synthase and NO actions[40,41]. This can lead to reduction of neurovascular perfusion, dysfunction and cellular apoptosis[42].

Autoimmunity

The role of autoimmunity has also been explored particularly in patients with T1DM. The presence of complement-fixing antibodies against sympathetic and para-

sympathetic tissues in patients with insulin-dependent diabetes and their correlation with CAN was described in the early 90s[43,44]. In a study of 78 patients with DM, the prevalence of phospholipid autoantibodies (PLA) in the patient's serum was significantly higher in those tested positive for autonomic neuropathy (88% of the patients with autonomic neuropathy *vs* 32% of those without, $P < 0.001$) and there was a strong correlation between the PLA titre and total neuropathy score ($r^2 = 0.58$, $P = 0.0002$)[45]. Granberg *et al*[46] demonstrated in a group of patients with T1DM that patients positive for complement-fixing antibodies to the sympathetic ganglion, vagus nerve and adrenal medulla had a significant higher risk to develop cardiac autonomic dysfunction (measured by the E/I ratio during deep inspiration and HRV to postural change) over a 6-year follow-up (RR = 7.5, 95%CI: 1.72-32.80). There are, however, conflicting reports whether these auto-antibodies contribute to the pathogenesis of autonomic neuropathy or represent rather incidental findings and can be attributed to autoimmunity against concurrent conditions, such as thyroid disease[47]. A recent study of mixed T1DM and T2DM patients concluded that neither peripheral nor CAN was associated with the presence or the levels of Neuropeptide Y Autoantibodies[48].

Residual β-cell function

Several studies have shown a protective effect of residual β-cell function (*i.e.,* C-peptide levels) on the development and incidence of microvascular complications (including CAN) in patients with T1DM[49,50]. The exact mechanisms for these associations are not clear but it is thought that the C-peptide activates Na/K channels, lowers inflammation and improves NO bioavailability and endothelial function[51,52]. Small RCTs have shown beneficial effect of C-peptide treatment on CAN parameters[53].

Genetic factors

More recently data suggesting genetic predisposition to CAN have emerged. In a study of 154 patients with T2DM, TCF7L2 gene was found to be strongly associated with the presence of CAN, as assessed by deep breathing, lying to standing, Valsalva manoeuvre and postural hypotension tests (OR = 8.28, $P = 0.022$ for the rs7903146 allele)[54]. Another study on healthy Japanese individuals showed that the T393C polymorphism of the gene encoding the Gs-protein-α-subunit (GNAS1) is significantly associated with cardiovascular autonomic dysfunction, detected with power spectral analysis ($P < 0.05$ for TT + TC *vs* CC polymorphism)[55]. Twins studies, however, failed to show an association between CAN and genetic factors[56].

Obstructive sleep apnoea

Obstructive sleep apnoea (OSA) is emerging as another possible factor in the development of CAN. OSA is very common in patients with diabetes and has been associated with increased sympathetic tone in patients without diabetes[57,58]. The interrelationship between OSA and CAN in patients with DM requires further investigation and is likely to be bidirectional. While the intermittent hypoxia that occurs in OSA could lead to increased oxidative stress, nitrosative stress, and impaired microvascular complications which could lead to CAN[59], CAN on the other hand could lead to changes in upper airways tone and changes in respiratory drive which could predispose the patient to OSA. One recent study presented in the Diabetic Neuropathy Study Group of the European Association for the Study of Diabetes 2012 meeting showed that the prevalence of CAN was similar in patients with T2DM with and without OSA, but CAN severity was worse in the OSA group (Tahrani *et al*[59], unpublished data). Furthermore, the presence of CAN was associated with more severe apnoea/hypopnea episodes (Tahrani *et al*[59], unpublished data).

NATURAL HISTORY OF CAN

DM affects the autonomic (as well as the peripheral) nervous system in an ascending length-dependent manner. The vagus nerve, which anatomically is the longest autonomic nerve and physiologically mediates 75% of the overall parasympathetic activity, tends to be involved early in the course of CAN development. The early stages of CAN therefore involve reduction in parasympathetic activity, which results in sympathetic predominance. This increase in sympathetic tone continues until the latest stage of CAN when sympathetic denervation ensues, which spreads gradually from the apex to the base of the heart[60,61].

CAN is divided into a sub-clinical and a clinical stage. During the initial sub-clinical stage, CAN is detected through abnormalities in frequency and time domains of the spectral analysis of HRV and the Baroreflex Sensitivity (BRS) tests, as well as an increased torsion of the left ventricle (LV) on cardiac imaging before the development of abnormalities in standard cardiac autonomic reflex testing (CART) (please see below for details)[62-67]. Studies have shown that these abnormalities can even be present at the time of diagnosis of DM[63]. CAN progresses and parasympathetic denervation is followed by compensatory sympathetic overdrive, resulting in abnormal CARTs followed by symptomatic CAN in which the clinical manifestations become apparent (please see below). At the stage of sympathetic denervation, autonomic dysfunction correlates clinically with postural hypotension[63] (Figure 2). The time scale for the progression of subclinical CAN to the development of abnormal CART is unclear; similarly the natural history of the development of early cardiac abnormalities (such as torsion or deficits in myocardial perfusion or cardiac energetic) and its relationship to subclinical CAN is also unclear. But we estimate that many patients with sub-clinical CAN will develop abnormal CART and early features of cardiac involvement within 5 years of developing abnormal frequency and time domain parameters.

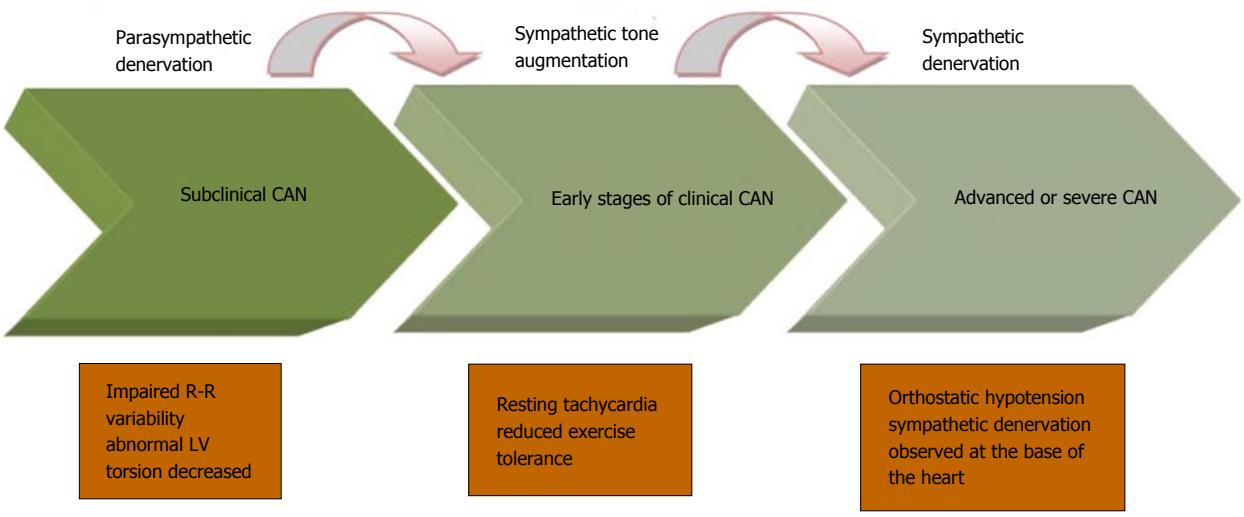

Figure 2 Natural progression of CAN and correlation with clinical signs and symptoms. CAN: Cardiac autonomic neuropathy; LV: Left ventricle.

CLINICAL MANIFESTATIONS OF CAN

Resting tachycardia

Resting tachycardia is a common manifestation of CAN that occurs at a relatively early stage of the disease. A HR of 90-130 beats per minute (bpm) can be observed and is associated with a reduction in parasympathetic tone followed by increased sympathetic activity as CAN progresses[68]. A fixed HR which does not change during sleep, exercise or stress is a sign of complete cardiac denervation[69]. Moreover, poor HR response to adenosine is associated with higher risk for adverse cardiac events[70], including all-cause and CVD mortality[71]. Hence, resting HR can be used as a diagnostic and prognostic tool in patients with DM after excluding other causes of tachycardia[10].

Exercise intolerance

Impaired blood pressure, HR and cardiac stroke volume in response to exercise in the absence of structural or coronary cardiac disease are all features of CAN[69]. As disease progresses, the parasympathetic-sympathetic imbalance can lead to further impairment of the above parameters[68] which limits the diagnostic utility of exercise tolerance testing in these patients due to increased false-negative outcomes caused by blunted HR response[72]. In addition, patients with CAN should be tested using stress cardiac imaging (usually echocardiography) prior to starting an exercise program, especially those with high-risk profile[69].

Orthostatic hypotension

Orthostatic hypotension is a manifestation of advanced CAN. Orthostatic hypotension is defined as the reduction in systolic blood pressure by > 20 mmHg or in diastolic blood pressure by > 10 mmHg 2 min following postural change from supine to standing[17,19,69]. Orthostatic hypotension occurs as a result of the impairment of the sympathetic response to postural change secondary to poor norepinephrine response and abnormalities in the baro-receptor sensitivity, resulting in inadequate HR response and peripheral vasoconstriction[23,69]. Orthostatic hypotension can be aggravated by many medications that are commonly used in patients with DM such as diuretics, vasodilators, tricyclic antidepressants and insulin[63]. Similar to resting tachycardia, assessing the presence of orthostatic hypotension is of prognostic value as a marker of advanced CAN[10]. In the middle-aged general population, orthostatic hypotension has been shown to be an independent prognostic factor for CVD and all-cause mortality[73].

Silent ischaemia

CAN is associated with a prolonged subjective angina threshold (which is defined as the time between the observation of 1 mm ST depression on the electrocardiogram and the development of symptoms of angina pectoris); thus rendering patients with CAN susceptible for experiencing silent myocardial ischaemia and potentially infarction, despite being asymptomatic[74]. A meta-analysis of 12 cross-sectional studies showed that CAN is associated with silent ischaemia in patients with DM (the Mantel-Haenszel estimate for prevalence rate risk was 1.96, 95%CI: 1.53-2.51)[17]. A study of 120 patients with DM and no previous CVD found evidence that CAN (detected using the Valsalva manoeuvre, the deep breath test and lying-to-standing HRV) was a better predictor of major cardiac events [*i.e.,* myocardial infarction or myocardial infarction (MI)] than the presence of silent ischaemia (OR = 4.16, 95%CI: 1.01-17.19) but when CAN was combined with silent ischaemia the risk was even higher (5 out of 10 had a major event)[75]. A study from Spain that included 217 patients with T1DM and T2DM, found that the presence of autonomic neuropathy is independently associated with increased risk for developing silent ischaemia (as demonstrated by positive exercise test) (OR = 6.5, 95%CI: 1.3-7.9) especially when combined with other cardiovascular risk factors such as microalbuminuria[76]. In the Detection of Ischaemia in Asymptomatic Diabetic subjects study which included 1123 patients with T2DM,

CAN (defined as abnormal Valsalva manoeuvre) was also a predictor of silent ischaemia (defined using stress cardiac perfusion imaging) (OR = 5.6, 95%CI: 2.6-12.4, P = 0.0001)[77].

It is evident that patients with DM and CAN are at high risk of sustaining a major cardiovascular event during exercise, due to the limited perception of ischaemic pain which could delay the appropriate and timely response to ischaemia. A recent statement from the Toronto Consensus Panel on Diabetic Neuropathy has emphasised the importance of integration of cardiac autonomic function testing into the current risk stratification pathways for patients with DM and established CVD risk factors[10].

The mechanisms underpinning relationship between CAN and silent ischaemia are not clear. Several mechanisms have been proposed including altered pain threshold, impaired afferent myocardial autonomic pathways and ischaemic processes not detected by routine electrocardiography. There has also been debate over whether the relationship between them is indeed a causative one, or both CAN and silent ischaemia are a product of coronary artery disease observed in diabetes[78,79].

Diabetic cardiomyopathy and LV dysfunction

Diabetic cardiomyopathy is a clinical entity that is characterised by changes in the biochemical signalling in the presence of a sympathetic-vagal imbalance resulting ultimately in left ventricular hypertrophy and remodelling, and therefore cardiac dysfunction in patients with DM in the absence of coronary artery disease[63]. Diabetic cardiomyopathy results in variable degrees of systolic and predominantly diastolic dysfunction in the absence of structural or valvular cardiac disease, coronary vessel disease, or hypertension[80,81]. Changes in the diastolic and/or systolic function can be identified on various diagnostic imaging modalities in otherwise asymptomatic patients and can precede the occurrence of macrovascular diabetic complications[82]. Frequently, the only detectable abnormality in the early stages of CAN is an isolated diastolic dysfunction with a normal LV ejection fraction[83] associated with high CVD morbidity[84,85].

Conventional echocardiography studies, with or without Doppler technique, showed that CAN is associated with significant reduction in the peak diastolic filling and an increase in the atrial component of diastole[69]. The introduction of new diagnostic modalities, such as the cardiac magnetic resonance imaging has allowed even more sensitive means of diagnosing and classifying diabetic cardiomyopathy even in the early stages by examining myocardial twist, torsion and strain[86]. Torsion is a measure of the apical rotation along the long axis of the heart and is followed by a rapid untwisting, occurring during the isovolumic relaxation phase[87]. Both torsion and maximal torsion rate have been found to be increased in patients with T2DM and preserved systolic function[86]. In patients with T1DM, increased torsion appears to be independent of energetic deficits but related to microvascular perfusion deficits and correlates with changes in sympathetic denervation[88,89]. Myocardial Perfusion Reserve (another diagnostic tool used for the detection of microvascular abnormalities) has been shown to detect the early stages of CAN in asymptomatic patients and to assess CAN severity[90].

There are several proposed mechanisms for the development of diabetic cardiomyopathy. The parasympathetic denervation observed in the early stages of the disease leads to a dominant sympathetic tone[91], which promotes a cascade of intrinsic metabolic changes, including the release of high myocardial catecholamine levels and catecholamine toxicity[92,93]. This catecholamine rise has been shown to induce mitochondrial uncoupling[94,95], switching energy generation on a cardiac level from myocardial glucose to free fatty acids, which is considered an inefficient energy source[96] and therefore increases the oxygen demand[94,95]. These alterations on the cardiac biochemical and cellular level, lead ultimately to programmed cell death and fibrosis[97,98], elevated oxygen consumption relevant to the cardiac work[99,100] and finally hypertrophy and remodelling of the LV[101]. Crucial mediators in the above process are the mitochondrial reactive oxygen species[102,103], insulin resistance[104] and calcium dependent apoptosis[102,105,106].

On a macroscopic level, diastolic dysfunction in CAN is associated with delayed relaxation, impaired filling and increased stiffness of the LV[107]. The previously described sympathetic predominance is a stimulator of the rennin-angiotensin-aldosterone axis, resulting in increased HR, cardiac output and peripheral vasoconstriction[108]. Studies have shown that this alteration on the cardiac profile can lead to reduction of coronary blood perfusion and diastolic dysfunction in patients with evidence of early microangiopathy[60]. Sympathetic overdrive may also lead LV wall stress and LV hypertrophy. Pop-Busui et al have recently shown in a large cohort of the DCCT/EDIC study, that CAN is associated with a mass increase as well as a concentric remodelling of the LV, independent of other risk factors[109].

Mortality/sudden death

CAN is associated with an increased mortality risk (Table 2). This was described in longitudinal studies in the early 1990s showing a 50% increase in 5 year-mortality risk in patients with DM and autonomic neuropathy compared to those without[110-113]. In a meta-analysis of 15 studies on the basis that they included patients with DM who had baseline assessment of HRV using one or more tests described by Maser *et al*[114] showed that the pooled estimated relative mortality risk was 2.14, (95%CI: 1.83-2.51, P < 0.0001), for those who had CAN. CAN was also found to have the strongest association with mortality amongst other risk factors in the EURODIAB IDDM Complications Study[115].

Even in patients with high CVD risk profile such as the population of the ACCORD trial, CAN was an independent predictor of all-cause mortality (HR = 2.14, 95%CI: 1.37-3.37) as well as CVD mortality (HR = 2.62, 95%CI: 1.4-4.91) after a mean follow-up of 3.5 years[29].

Table 2 Observed mortality in significant studies in the last two decades

Ref.	Country	*N* of subjects	Type of DM	FUp (yr)	Diagnostic test for CAN	Criteria applied	Mortality figures (expressed in HR, RR and incidence)	Comments
Veglio *et al*[226]	Italy	316	T1DM	5	(1) Resting heart rate (2) HRV during deep breathing (3) BP response to standing	⩾ 2 abnormal tests	Relative risk: 3.55 (1.4-8.9) and 2.21 (0.62-7.84, $P = 0.22$) after multivariate analysis for all-cause mortality	The mortality rates were 13% and 4% in the presence and absence of CAN respectively
Gerritsen *et al*[164] the Hoorn Study	Nether-lands	446	Non-DM	9	Seven parameters assessing HRV and BP response to: (1) 3-min breathing and (2) six deep breaths	Cut–off set as the lowest 25th percentile of non-diabetic group	Only E/I had a statistically significant association with mortality- Relative Risk: 2.25 (1.13–4.45) for all cause and 2.04 (0.74–5.65) for CVD mortality	An additional four parameters showed a tendency ($P < 0.10$) for association with acc-cause mortality: mean NN, LF power, HF power, and BRS
Chen *et al*[227]	Taiwan	159 612	T2DM T2DM	7.7	HRV response to: (1) single deep breath (2) six consecutive breaths (3) standing, (4) Valsalva manoeuvre	⩾ 3 abnormal tests	All cause mortality: 29% *vs* 12% with and without CAN respectively CVD mortality: 9% *vs* 2% in pts with and without CAN	The 8-yr survival rate for pts with abnormal CAN tests was 63.6% in males and 76.4% in females, compared with 80.9% and 93.3% for patients with normal CAN tests
Wheeler *et al*[228]	United States	843	T1DM and T2DM		HRV response to deep breathing and postural BP	Drop in BP ⩾ 30 mmHg and HRV divided into 5 quintiles	Hazard Ratio: 1.49 (1.01-2.19) for all-cause mortality and 1.08 (0.69-1.70) for CVD mortality	Of the 142 patients for whom cause of death was available, 75 deaths (49.7%) were due to CVD. The lowest quintile of HRV was associated with a 50% increase in mortality after adjusting for other risk factors
Astrup *et al*[229]	Denmark	388	T1DM (197 with macro-, 191 normo-albuminuria)	10.1	HRV to deep breathing	HRV < 10 bpm at baseline abnormal E/I	in the lowest quintile of HRV. Relative Risk for orthostatic hypotension: 0.65 (0.69-1.70) Relative risk: 4.9 (2.1-11.5, $P < 0.0001$) after adjustment for traditional CVD risk factors	During follow-up, 33 Patients died from cardiovascular causes, During follow-up 54 of 104 patients died: 41 patients (80.4%) with diabetic nephropathy and 13 patients (24.5%) with normoalbuminuria. Thirty patients (55%) died from cardio-vascular causes
Astrup *et al*[230]	Denmark	104	T2DM (51 with nephropathy, 52 with normal albuminuria)	9.2	HRV to deep breathing		Hazard Ratio: 0.92 (0.87–0.98, $P = 0.005$) for HRV (1 beat/min increase)	
Soedamah-Muthu *et al*[115] the EURODIAB PCS	16 European countries	2787	T1DM	7	HRV response to standing and postural BP	R-R ratio of < 1.04 and drop in systolic BP ⩾ 20 mmHg	Hazard Ratio: 3.61 (1.49–8.76) for CVD mortality and 2.83 (1.82–4.38) for all-cause mortality.	Autonomic neuropathy and microalbuminuria were the most important independent predictors of mortality
Lykke *et al*[231]	Denmark	391	T1DM	10	HRV and QTc		All cause mortality Hazard Ratio: 2.5 (0.9–6.8, $P = 0.071$) in pts with abnormal HRV and 2.3 (1.3-4.0, $P = 0.005$) in those with abnormal QT combined hazard ratio 6.7 (1.8-25, $P = 0.005$)	Out of 34 patients with both tests abnormal, 15 died in the 10 yr period (14 from cardiovascular causes)
Ziegler *et al*[232] MONICA/ KORA Augsburg Cohort study	Germany	1560 160	Non-DM DM	9	HRV, QTc interval and QTD	Group (1) Lowest quartile for SDNN, CV and max-min R-R intervals Group (2) QTc > 440, Group (3) QTD > 60 ms	All-cause mortality Relative Risk: 0.93 (0.65-1.34)/2.02 (1.29-3.17)/0.98 (0.60-1.60) in patients without DM and 1.74 (0.95-3.18)/3.00 (1.34-6.71)/0.42 (0.06-3.16) in patients with DM for group 1/2/3 respectively	Prolonged QTc interval was an independent predictor of mortality both in patients with and without DM, Low HRV trended towards an increased risk of mortality by 73% in patients with DM but not the population without DM
Beijers *et al*[233] the Hoorn Study	Nether-lands	376 114	Non-DM T2DM	13.6	HRV and BP response to: (1) 3-min breathing, (2) six deep breaths (3) standing	Calculated z-score for each parameter and averaged into a total CAD score	Relative risk: 2.54 (1.60–4.04) for CVD mortality and 2.11 (1.58–2.81) for all cause mortality,	CAN was associated with all-cause and CVD mortality independent to other CVD risk factors and microalbuminuria
Pop-Busui *et al*[29]	United States and Canada	8135	T2DM	3.5	HRV and QTI computed from 10-s resting electrocardiograms	CAN1: lowest quartile of SDNN and highest QTI quartile, CAN2: CAN1 and resting heart rate, CAN3: CAN1 and peripheral neuropathy	Hazard ratios: 1.55 (1.09-2.21)/2.14 (1.37-2.37)/2.07 (1.14-3.76) for all-cause and 1.94 (1.20-3.12)/2.62 (1.40-4.91)/2.95 (1.33-6.53) for CVD mortality in CAN1/CAN2/CAN3 respectively	CAN was independently associated with overall and CVD mortality after adjusting for baseline CVD, DM duration, traditional CVD risk factors and medications

FUP: Follow up; HR: Hazard ratio; RR: Relative risk; HRV: Heart rate variability; BP: Blood pressure; E/I: Expiration/inspiration; SDNN: Standard deviation of normally conducted R-R intervals; NN: Normal to normal R-R intervals; LF: Low frequency; HF: High frequency; BRS: Baroreflex sensitivity; CV: Coefficient of variation; QTD: QT dispersion; QTI: QT index; DM: Diabetes mellitus; T1DM: Type 1 diabetes mellitus; CAN: Cardiac autonomic neuropathy; CVD: Cardiovascular disease.

Interestingly the relationship between CAN and mortality was similar regardless of treatment allocation to the intensive or standard glycaemic control groups[29].

CAN was also found to be associated with a higher mortality risk in patients who had myocardial infarction[116], suggesting that screening for CAN in patients with DM who suffered a myocardial infarction can be used for risk stratification[117].

CAN is also associated with increased risk of sudden cardiac death[112,113,118]. This can be explained by the increased rate of fatal cardiac arrhythmias due to the imbalance between the sympathetic and parasympathetic autonomic function[119], as well as cardiac sympathetic denervation[67]. QT prolongation which has been associated with autonomic neuropathy in several studies[120-122], can also provide an alternative mechanism, rendering patients with CAN more susceptible to suffer life-threatening cardiac arrhythmias, including Torsades de Pointes[69]. The exact relationship between CAN and sudden cardiac death remains, however, under question. As shown by the Rochester Diabetic Neuropathy Study, sudden death cases are also related to severe coronary artery disease or LV dysfunction rather than CAN itself[123]. Nonetheless, as we discussed above, CAN seems to contribute to cardiovascular mortality even in those with established coronary artery disease.

Several mechanisms have been implicated in explaining the relationship between CAN and mortality in patients with DM. Autonomic neuropathy can lead to impaired response to hypoxic state[124], reduced hypoglycaemia awareness and prolonged hypoglycaemic episodes[111]. The observed mortality can also be attributed to a direct effect of autonomic neuropathy and its microvascular complications[125] as well as to an indirect association with end-organ complications, such as nephropathy, left ventricular hypertrophy and diastolic dysfunction[100]. In addition, the lack of the physiological nocturnal parasympathetic dominance in patients with CAN can lead to nocturnal hypertension, causing LV hypertrophy[126,127] and increasing the CVD burden[93,128].

Perioperative and intraoperative complications

Patients with CAN exhibit 2- to 3-times fold increase in perioperative morbidity (perioperative complications, impaired wound healing, impaired drug metabolism) and mortality[129,130]. Patients with CAN are more likely to require vasopressor support in the theatre setting[130]. They are also prone to experience a blood pressure and HR reduction during the induction of anaesthesia, as well as severe intraoperative hypothermia[131]. The above findings can be explained by an impairment or absence of the normal vasoconstrictive response to vasodilating anaesthesia in patients with CAN[130].

Cerebrovascular disease

Unlike the strong links between CAN and CVD, there is only limited data regarding the impact of CAN on cerebrovascular disease. In a study conducted by Töyry *et al*[132] that included 133 patients with T2DM, CAN was found to be an independent risk factor for developing stroke after 10 years of follow-up (OR = 6.7, 95%CI: 1.5-29.9 for HRV response to deep breathing and OR = 1.1, 95%CI: 1.01-1.2 for lying-standing BP). In a subanalysis of the Appropriate Blood Pressure Control in Diabetes population, including 950 patients with T2DM over a 5-year period, CAN was significantly associated with the occurrence of stroke, independent to other risk factors[133]. The later was also confirmed by a recent study including 1458 patients with T2DM who were followed up for 7 years[134].

Diabetic nephropathy

Several authors have hypothesized that CAN is involved in the pathogenesis of diabetic nephropathy, although causation has not been proven[135]. Sympathetic overactivity has been shown to cause glomerular and tubular dysfunction in diabetic animal models *via* indirect (hypertension and angiotensin Ⅱ) and direct (vascular smooth muscles proliferation, vasoconstriction, podocytes injury) insults[136]. CAN is associated with increased CVD morbidity and mortality[63,135] and with haemodynamic changes such as lack of nocturnal BP dipping (causing increased intra-glomerular pressure resulting in albuminuria)[137] and diurnal postural falls in BP (resulting in lower intra-glomerular pressure)[138] and endothelial dysfunction in humans. In addition, CAN is associated with deficits in erythropoietin production and, as a result, erythropoietin-deficiency anaemia[137]. Subsequently, CAN patients are deprived from the direct nephroprotective action of erythropoietin and thus, anaemia becomes a strong predictor of nephropathy and progression of chronic kidney disease[68]. In streptozotocin-diabetic rats, sympathetic overactivation has been shown to be involved in the pathogenesis of diabetic nephropathy[139] and renal denervation was shown to prevent glomerular hyperfiltration[140]. Hence it is plausible that CAN is involved in the development and progression of diabetic nephropathy. Several studies examined the association between CAN and either albuminuria and/or glomerular filtration rate[141-145], but all these studies had a cross-sectional design, hence causation cannot be proven, particularly that the pathogenesis of CAN is similar to other microvascular complications including diabetic nephropathy. Longitudinal studies are scarce and limited to a small number of patients with T1DM[138,146]. Hence, data regarding the longitudinal impact of CAN on diabetic nephropathy in patients with T2DM is lacking.

Lower limb complications

CAN has been proposed as a contributing factor in the development of lower limb vascular and neurological complications. Autonomic neuropathy can cause alterations in microvascular blood flow (MBF), which predispose to changes in skin structure and quality and impairment of sweat glands' innervation resulting in dry skin and increased risk of oedema and foot deformity which increases pressure on certain areas causing ulceration[147]. It is also believed that CAN, through the sympathetic

denervation of the lower limb vasculature, can induce lower extremity hyperaemia, increase inflammation and erosion into the joints/bones and therefore contribute in Charcot's neuroarthropathy. As a result, the patient with Charcot will typically present with prominent peripheral pulses due to vasodilatation and autonomic neuropathy. Power Spectral Analysis and HRV has been employed in trials for the detection of autonomic neuropathy in patients with Charcot's disease[148]. Similarly to Charcot's arthropathy, patients with recurrent vascular neuropathic ulcers appear to share analogous cardiac autonomic dysfunction, as shown by the use of HRV, Valsalva ratio and orthostatic hypotension[149].

THE DIAGNOSIS OF CAN

CARTs

Ewing *et al*[150] proposed in early 1970s five simple non-invasive tests to measure cardiac autonomic function based on the HR and blood pressure response to certain physiological manoeuvres. These tests include: (1) the HR response to deep breathing, which assesses beat to beat HR variation (R-R variation) during paced deep breathing [expiration-to-inspiration ratio (E:I)]; (2) the HR response to standing, which is expressed as the 30:15 ratio which is the ratio of the longest R-R interval (between the 20th and 40th beat) to the shortest R-R interval (between beats 5-25) elicited by a change from horizontal to vertical position; (3) the Valsalva manoeuvre which evaluates the HR response during and after a provoked increase in the intra-thoracic and intra-abdominal pressures (the patient normally exhales for a period of 15 seconds against a fixed resistance); (4) the blood pressure response to standing, which assesses the baro-reflex mediated blood pressure change following postural change; and finally; and (5) the blood pressure response to sustained handgrip, as defined by the diastolic blood pressure increase caused by the sustained muscle contraction with the use of a handgrip dynamometer[17]. The first two tests reflect defects in the parasympathetic activity (*i.e.,* the ability of the vagal nerve to slow the HR during the procedures which increases the R-R interval and hence increases the ratios), while the last two also describe changes in the sympathetic function (*i.e.*, the ability to provide appropriate BP and HR response to the activity involved)[151,152]. The autonomic changes that occur during the Valsalva manoeuvre are complex and involve both the sympathetic and parasympathetic systems[153], although the Valsalva ratio mostly represents parasympathetic activity. For more details about the autonomic changes during Valsalva please see[17].

While the above described CARTs have been widely used since their introduction, there is no evidence on the superiority of one test over another when it comes to assessing CAN[10]. However, the HR response to deep breathing is the most commonly utilised, because of its high reproducibility and specificity[154] and its ease of use[10,155]. All the tests are considered to be valid markers of autonomic dysfunction, given that end organ failure is excluded and parameters such as concomitant illness, use of over the counter medications and lifestyle factors (exercise, smoking, exercise) are taken into consideration[156].

HRV

A reduction in HRV has been associated with the early stages of clinical CAN. In healthy individuals, the beat-to-beat variability with aspiration is predominantly affected by the direct sympathetic and parasympathetic activity[62,157], as well as various other stimuli, including certain neurohumoral factors (catecholamines, thyroid hormones), temperature changes and mechanical and ionic changes in the sinus node[158]. The efferent sympathetic and vagal stimulation is characterised by synchronised discharges, modulated by central and peripheral oscillators, with the former referring to vasomotor and respiratory centres and the later to respiratory movements and arterial pressure. These synchronous neural discharges can manifest as short and long -term oscillations in the HR[63].

The R-R intervals recorded under paced breathing are transformed to generate the time and frequency domains. Conceptually, if the faster respiratory sinus arrhythmia signal and the slower mean HR changes could each be separated from the patient's cardiogram and analyzed independently, the result would yield a measure of Vagal outflow from the respiratory sinus arrhythmia and a measure of sympathetic activity from the changes in mean HR. Effectively this is what is accomplished in the frequency- or spectral-domain. Spectral analysis of respiratory sinus arrhythmia provides the indication of where in the frequency domain the Vagus is influencing the heart. The frequency domains are generated using continuous wavelet transform method (Fourier transform) and separated to three basic components: very-low-frequency, low-frequency (LF) and high-frequency (HF)[61,159]. HF represents vagal activity, whereas LF is attributed to the combined effect of sympathetic and parasympathetic influence[62,160]. Modern software (such as ANSAR technology) adjusts for the respiratory rate, hence simplifying the process. Parameters generated include: respiratory frequency (Rfa, 0.15 to 0.4 Hz, represents parasympathetic function), and LF (Lfa, 0.04 to 0.15 Hz, represents sympathetic function). The HRV and BP are recorded with the patient in sitting position during resting, deep breathing, Valsalva manoeuvre and standing position.

The electrocardiogram (ECG) recordings were initially longer in duration, usually over a period of 24 h but recent data has demonstrated that recording of shorter duration can provide equally reliable information[16,158,161]. Time domain analysis is a useful tool in the assessment of parasympathetic activity by measuring the normal R-R intervals, whereas the frequency domain is based on the spectral analysis of R-R interval and other cardiovascular and respiratory signals based on short-term ECG recordings (2-5 min)[69,158].

The key element in the accurate use and interpretation of HRV models is the standardisation of the conditions under which the test is carried, including age, blood pres-

sure, HR, tobacco smoking or caffeine use and, above all, respiration control[69].

Baro-reflex sensitivity

The BRS measures the cardiac vagal and sympathetic baro-reflex function. The idea behind its function is that an increase in the BP normally induces a reflective increase in the vagal cardiac efferents and a reduction to the efferent sympathetic activity, resulting in bradycardia and hypotension, due to the reduction in cardiac output as well as the peripheral vasodilation[158]. A reduction in BP induces opposite responses. Thus, to correctly measure the baro-reflex function, both the vagal efferent activity (evidenced by changes in HR in response to changes in BP), and the sympathetic efferent activity (affecting the arterial vessels) should be taken into account.

In practice, the term "baro-reflex sensitivity" normally applies to the cardiac-vagal arm, and to methods measuring changes in HR in response to changes in (systolic) BP. The test can be performed either with the use of pharmacological methods (intravenous bolus injection of epinephrine)[162] or non-pharmacological techniques (physical manoeuvres such as postural change). Although the former is considered the gold standard to date for evaluating BRS, both of them correlate well clinically with each other[163]. Both techniques require a continuous measure of BP and a continuous and synchronised measure of HR (R-R interval)[158].

BRS can be used for detecting sub-clinical CAN[63], since BRS can be abnormal in diabetes, before the demonstration of any clinical signs of CAN or other conventional autonomic function tests detect any abnormalities[64,65]. Several studies on patients with diabetes have concluded that BRS is a strong independent risk factor for mortality[164], especially in cohorts suffering from heart failure or following a myocardial infarction[162,165].

Scintigraphy

The use of Single-photon emission computed tomography (SPECT) and/or positron emission tomography (PET) and sympathetic neurotransmitter analogues, such as the ^{123}I-metaiodobenylguanide (^{123}I-MIBG) (SPECT), the ^{11}C-metahydroxyephedrine (^{11}C-HED) (PET) and ^{11}C-epinephrine has enabled the quantitative scintigraphic evaluation of cardiac sympathetic innervation[63].

^{123}I-MIBG undergoes rapid uptake in the myocardium but as it is semi-quantitative is not a precise indicator of neuronal uptake[158]. Metabolically stable ^{11}C-HED demonstrates a highly specific uptake by the sympathetic nerves mediated by norepinephrine transporters[166]. It is important, however, to take myocardial perfusion (which affects the delivery of the tracer of interest) into consideration before interpreting the results of these imaging techniques. Retention defects of both ^{123}I-MIBG and ^{11}C-HED have been reported in patients with T1DM and T2DM and have been variably correlated with abnormal but also normal CARTs[60,67,167]. The consistent pattern of sympathetic denervation in patients with T1DM supports the notion that ^{11}C-HED can be used to monitor the population of sympathetic nerves and evaluate the regional autonomic deficits of sympathetic innervations[66,166,167]. In patients with CAN and T1DM, the wash rates of ^{11}C-epinephrine have been shown to correlate well with those of ^{11}C-HED[158]. The development of microvascular complications has been associated with the augmentation in sympathetic tone and adrenergic hyperresponsiveness, by the use of ^{11}C-HED[63]. As CAN reaches an advanced stage, a heterogenous pattern of ^{11}C-HED retention is observed, with a reduced ^{11}C-HED retention in the distal LV and a persistent or increased ^{11}C-HED retention seen proximally, indicating a proximal to distal pattern of sympathetic denervation of the LV[63].

Increases in the sympathetic nervous tone and elevated epinephrine levels can affect the retention of sympathetic neurotransmitter analogues, making the interpretation of the above scintigraphic models rather challenging. Furthermore, the lack of standardisation, the high cost and the demand on highly skilled operators, restricts the role of scintigraphy as a valuable research tool and not a part of daily clinical routine[68].

When it comes to radiation exposure, ^{123}I-MIBG lacks a β-particle emission and has a half-life of 13.2 h, whereas its energy of the primary imaging photon is calculated at 159 keV (kiloelectron volt)[168]. When compared to ^{131}I, ^{123}I-labelled agent is to be considered the radiopharmaceutical of choice as it has a more favourable dosimetry and better radiation profile. Whole-body radiation is markedly lower using ^{11}C-HED PET [effective dose equivalent in adults, 1.2 milliSieverts (mSv)] compared with ^{123}I-MIBG scintigraphy (effective dose equivalent in adults, 6.0 mSv)[169]. The radiation dose to the whole body from 20 milliCuri (mCi) ^{11}C-HED is 0.186 rad, less than that from 0.5 mCi ^{131}I-MIBG IBG (0.45 rad) or 10 mCi ^{123}I-MIBG (0.53 rad)[170].

Muscle nerve sympathetic nerve activity

Muscle sympathetic nerve activity (MSNA) is based on the ability to record efferent sympathetic nerve signals in the skeletal muscles either at rest or in response to physiological perturbations with the use of microelectrodes into a fascicle or a distal sympathetic nerve of the skin or muscle (microneurography)-usually the peroneal nerve[171].

MSNA is the most direct measure of peripheral sympathetic activity and therefore a useful research tool. However, its invasiveness, cost and time-consuming nature is not recommended for routine autonomic assessment[158].

Other tests

Occasionally, various tests have been proposed for the assessment, diagnosis and monitoring of CAN. A recent study on 167 patients with type I diabetes conducted by the University of Liege, found the use of pulsatile stress, which measures the arterial stiffness, correlates well with baro-reflex sensitivity, suggesting therefore that arterial stiffness can be used as a marker of CAN[172]. The association between arterial stiffness (expressed as carotid-femoral wave velocity (PWV)) had already been explored

Significance of CAN

According to the Toronto Consensus Panel on Diabetic Neuropathy statement, *screening for CAN* in the patients with DM should be considered good clinical practice, due to the following:

(1) It enables the accurate and clinical relevant diagnosis of various CAN forms

(2) It assists in the appropriate detection and subsequently the tailored treatment of CAN multiple clinical manifestations as described in the previous section

(3) It provides a clinical tool for the risk stratification for diabetic complications as well as the cardiovascular morbidity and mortality

(4) It can be used for the modulation of targets of diabetes treatment

Figure 3 Current recommendations on screening for cardiac autonomic neuropathy. CAN: Cardiac autonomic neuropathy; DM: Diabetes mellitus.

by another study. After multivariable linear regression, the association between CAN (E/I index in particular) and PWV not only remained significant but E/I index was the strongest predictor of PWV in the model (β coefficient: -0.326, 95%CI: (-3.110)-(-0.750), $P = 0.002$)[173]. Catecholamine kinetics, most specifically epinephrine and norepinephrine plasma clearance have been labelled as the biochemical equivalent of MSNA but they have failed to date to produce reliable diagnostic data[158].

Another aspect of autonomic function is the assessment of cutaneous MBF. The skin offer an accessible organ to asses MBF and endothelial function, which is often involved in the development of micro and macrovascular diabetes, correlates with systematic endothelial function measures and myocardial microcirculation[174]. Several methods are available to assess skin MBF[175]. Laser Doppler (LD) allows the determination of blood flow under basal conditions or following physical (*e.g.,* heating) or pharmacological (*e.g.,* acetylcholine and/or sodium nitroprusside) stimulation; allowing the differentiation between endothelial-dependant and independent responses[174]. Furthermore, LD allows the measurement of nerve axon reflex-related vasodilation following acetylcholine iontophoresis which is the result of C-fibre stimulation[176]. LD techniques include LD flowmetry, LD perfusion imaging and laser speckle contrast imaging[158,174].

Another assessment of the peripheral autonomic system is intra epidermal nerve fibre density (IENFD) using immuno staining[177]. IENFD is highly sensitive and specific to diagnose small fibre neuropathy (88%-98% and 88.8%-95% respectively)[178]. IENFD correlates also inversely with thermal thresholds[178]. In addition, IENFD innervates the sweat glands. Reduction in sweat production in the feet contributes to the development of dry skin/callus and hence predispose to the development of foot ulceration. This function can be assessed by several methods such as Neuropad[147] and Sudoscan[179].

CRITERIA FOR DIAGNOSIS AND STAGING

HR responses to deep breathing, standing and Valsalva manoeuvre, as well as blood pressure response to standing (CART) are considered as the gold standard in clinical testing for autonomic neuropathy[10]. Their applicability in bedside clinical practice is based on their sensitivity, specificity, reproducibility, ease and safety of use and standardisation.

According to the CAN Subcommittee of the Toronto Consensus Panel statement following the 8th international symposium on diabetic neuropathy in 2010[10], the criteria for diagnosis and staging of CAN are as follows: (1) A single abnormal CART result suffices for the diagnosis of possible or early CAN; (2) The presence of two or three abnormal test among the seven autonomic cardiovascular indices (5 CARTS, time-domain and frequency-domain HRV tests) are required for the diagnosis of definite or confirmed CAN; and (3) The presence of orthostatic hypotension in addition to the above criteria signifies the presence of severe of advanced CAN.

SCREENING FOR CAN

The majority of diabetes patients with CAN have subclinical or asymptomatic disease, rendering the diagnosis and appreciation of CAN in clinical practice rather difficult[63]. Once CAN reaches the stage that becomes clinically evident, the disease might have reached an advanced level and management becomes more difficult. Screening for early CAN is therefore considered good clinical practice several reasons as summarised in Figure 3[10].

The Toronto Diabetic Neuropathy Expert Group in a recent statement have recommended that screening should be considered for patients at time of diagnosis of T2DM and within 5 years of diagnosis of T1DM, particularly in patients with other macro- and/or microvascular complications[180]. Patients with a history of poor glycaemic control are especially at risk for developing CAN, as demonstrated in several studies, suggesting that this clinical group may benefit from screening[17]. Due to its impact on exercise tolerance, testing for CAN should be a part of the screening in patients that are about to begin a new exercise programme that involves more intense physical activity than brisk walking[69,181]. Evidence also suggests that screening for CAN could be incorporated into the perioperative assessment of patients with poor glycaemic control and coronary artery disease, due to the association between CAN and haemodynamic instability peri- and intra-operatively[182]. Finally, testing for CAN could potentially be of benefit in patients with DM that have suffered MI, as this would serve in the risk stratifica-

tion of this subgroup and assist into adapting a more aggressive therapeutic approach for those at risk of sudden cardiac death or life threatening arrhythmias.

THERAPEUTIC APPROACHES FOR CAN

CAN treatment can either be symptomatic or aimed at slowing or reversing CAN progression. However, effective therapies to slow or reverse CAN progression are rather limited as the complete underlying pathogenesis remains unclear. However, based on our current understanding of CAN pathogenesis and risk factors, several potential treatments have been examined.

Lifestyle modification

Lifestyle changes have been shown to have a beneficial impact on the prevention of CAN progression in the Steno-2 trial[5] and the Diabetes Prevention Program (DPP)[183]. In the Steno-2 study, patients with T2DM and microalbuminuria were randomised to a multi-factorial cardiovascular risk factor intervention that included behavioural therapy (diet, physical exercise and smoking cessation) and pharmacological intervention (to control BP, lipids and hyperglycaemia) or conventional treatment in accordance to the national guidelines. After an average of 7.8 years of follow-up, the risk for developing CAN was significantly lower on the intervention arm (49% in the intensive group *vs* 65% in the conventional group, HR = 0.37, 95%CI: 0.18-0.79, $P = 0.002$). In the DPP, lifestyle modification demonstrated superior results in the improvement of autonomic dysfunction (assessed with HRV and QT indexes) as compared to the use of metformin or placebo.

Weight loss and dietary intervention accompanied[69] or not[184] by supervised training was associated with improvement on CAN indices. Aerobic training has also been shown to improve CAN, with some indication that mild physical exercise is recommended in less severe CAN cases. A recent review summarising the evidence for the impact of life style interventions on CAN has concluded that moderate endurance and aerobic exercise in both T1DM and T2DM, improve HRV and cardiac autonomic function significantly, in favour of parasympathetic dominance, independent of BMI, glycaemic or BP control and duration of diabetes[185].

Intensive glycaemic control

Hyperglycaemia is a major risk factor for CAN development and progression. Intensive glycaemic control has been shown to slow the progression and prevent/delay the development of CAN[18,66,186,187]. In the DCCT trial, intensive glycaemic control in a group of patients with T1DM reduced the CAN incidence by 50% over 6.5 years follow-up compared with conventional therapy (7% *vs* 14% respectively)[19]. These beneficial effects persisted 13-14 years after close-out of the trial[18]. Although both former treatment arms exhibited deterioration in CAN during follow-up after the end of the DCCT, the former intensive treatment group continued to demonstrate a statistically significant slower decline in CAN.

PET cardiac imaging with the use of 11C-HED showed similar beneficial effects in a 3-year prospective trial. Good glycaemic control (defined as mean HbA1c < 8%) was associated with reduction of sympathetic denervation as opposed to the group of poor diabetes control (HbA1c $\geqslant$ 8%)[167]. In the SEARCH CVD study, 354 young patients with T1DM were assessed for the presence of sub-clinical autonomic dysfunction, as demonstrated by the use of HRV parameters and the presence parasympathetic loss with sympathetic override. Poor glycaemic control, as defined by HbA1C > 7.5%, was independently associated with the presence of subclinical CAN as compared to a frequency-matched control group without DM[188].

The effects of glycaemic control in T2DM are not similarly encouraging. Data from recent studies have failed to demonstrate differences in the incidence of CAN based on the application of intensive therapy in T2DM patients[189,190]. The sensitivity of tests utilised for the diagnosis of CAN in those trials, however have been questioned, suggesting that more research is needed to investigate the relationship between metabolic control and CAN in patients with T2DM.

Therapies based on CAN pathogenesis

There is limited but increasing data on the use of pharmacotherapy targeting specific pathogenic pathways. The use of the specific antioxidant α-lipoic acid improved CAN in patients with T2DM in a 4-mo controlled randomised trial[191]. In animal models, the pharmacological agents FP15 and FeTMPS, which act by catalysing the decomposition of peroxynitrite, have shown promising results in improving neuronal function[192-194]. The use of glucagon-like peptide 1 analogues or the dipeptidyl peptidase 4 inhibitors have demonstrated cardioprotective[195] and neuroprotective properties[196], raising the possibility of their use for treatment not only for peripheral neuropathy, but autonomic neuropathy as well. In small scale studies, aldose reductase inhibitors have been shown to improve LV function in patients with DAN without any alteration on CAN indices[197]. There is also evidence suggesting the vitamin E and C-peptide can both improve HRV indices[10]. In a randomised controlled trial, vitamin E when compared to placebo managed to increase the R-R interval ($P < 0.05$) and the HF component of HRV (HF; $P < 0.05$) in 50 patients with T2DM over a period of 4 mo[198]. Small RCTs have shown beneficial effect of C-peptide treatment on CAN parameters[53]. In a recent randomised placebo-controlled trial of 44 patients with T1DM, treatment with a triple antioxidant regime (allopurinol, α-lipoic acid and nicotinamide) over the course of 2 years failed to prevent progression of CAN and had no benefit on myocardial perfusion as demonstrated with scintigraphic imaging modalities[199]. Further research is required to confirm these findings and explore other potential pathogenetic therapies.

The renin-angiotensin-aldosterone axis

There is substantial data to support the use of certain pharmacological agents in the improvement of the left ventricular dysfunction associated with autonomic neuropathy in diabetes. In patients with heart failure, the use of bisoprolol[200] or the addition of spironolactone to enalapril, furosemide and digoxin[201], demonstrated a beneficial effect on autonomic function, as shown by HRV testing and sympatho-vagal balance respectively. The use of angiotensin-converting enzyme (ACE) inhibitors could potentially improve the parasympathetic/sympathetic balance[202] and improve prognosis in cardiac failure[203]. The addition of angiotensin receptor blockers to ACE inhibitors may be superior to monotherapy[204-206], due to the enhanced blockade on the renin-angiotensin-aldosterone axis[207]. In a small study by Didangelos *et al*[208], including 62 patients with type I and type II DM, the use of ACE inhibitors or ARBs, as well their combination, managed to improve both diabetic autonomic neuropathy and LV diastolic dysfunction.

Symptomatic treatment of orthostatic hypotension

Treatment of orthostatic hypotension is required in symptomatic patients with autonomic neuropathy. There are several strategies available, including lifestyle and behavioural measures as well as pharmacological options. The former include advice provided to the patients to avoid sudden changes in body posture, eat smaller and more frequent meals, avoid drugs-precipitants of postural hypotension (diuretics, tricyclic antidepressants, α-adrenoreceptor antagonists), perform physical countermanoeuvres (leg crossing, stooping and squatting), increase fluid and salt intake, avoid physical activity that leads to straining and finally use garments over legs and abdomen[69,209].

If the above measures fail to improve symptoms, pharmacological intervention may be considered. A risk-benefit consideration should take place for each individual before starting a medication, especially weighing up the risk of developing marked supine hypertension against the benefit of preserving the erect blood pressure. Should a pharmacological agent be considered appropriate by the clinician, there are several options available[210-212].

Midodrine, a peripheral selective α_1-adrenergic agonist, is considered a first line agent that acts through peripheral vasoconstriction of arterioles and veins. It remains to date the only drug approved by the food and drug administration (FDA) for the treatment of orthostatic hypotension[213,214]. However, post-market trials to prove drug's efficacy are still ongoing and the final results on midodrine's benefits are scheduled to be published in 2014, 18 years after the drug was given FDA approval[215].

9-α-fluorohydrocortisone, a synthetic mineralocorticoid, is another first line option that acts through sodium retention and plasma expansion[216]. In a double-blinded crossover study, 9-α-fluorohydrocortisone treated successfully the orthostatic hypotension of patients with diabetes and autonomic neuropathy[216]. 9-α-fluorohydrocortisone doses between 100 and 400 micrograms decreased significantly the orthostatic hypotension in 14 symptomatic patients with DM over a mean period of 12 mo ($P < 0.001$)[217]. Extra care should be taken when prescribed in patients with cardiac failure, as it can lead to fluid overload. There is usually a period of 10-14 d before its effects can become clinically evident[212].

Somatostatin and somatostatin analogues (octreotide) inhibit the release of vasoactive peptides from the GI tract and thus increase splanchnic vasoconstriction, leading to increase in mean blood pressure[218]. The use of long acting octreotide in patients with autonomic neuropathy increased the mean systolic BP from 83.8 ± 7.1 mmHg to 104.1 ± 3.1 mmHg ($P < 0.025$) within eight weeks, improving orthostatic dizziness and fatigue[219]. In a study of 18 patients with idiopathic orthostatic hypotension, octreotide reduced postural, postprandial and exertion-induced hypotension, as demonstrated by 24-h ambulatory blood pressure profiles and cusum analyses[220].

Other available pharmacological strategies include the use of erythropoietin which can increase the erect BP through the increase of red cell mass and circulating volume, the improvement of anaemia and its regulatory effect on vascular tone[221] and desmopressin acetate whose efficacy is mainly observed in morning time hypotension[212]. Finally, caffeine and acarbose can potentially be used in the management of post-prandial hypotension[212]. In a case report of 58 years old patient with DM and severe postprandial hypotension refractory to the use of midodrine and octreotide, acarbose (an alpha-glucosidase inhibitor) reduced the postural drop from 50 mmHg to 18 mmHg, improving the patients symptoms dramatically[222].

Unfortunately, despite the different options available, postural hypotension remains a difficult condition to treat and many patients require multiple therapies and develop severe intractable disabling symptoms. Beta blockers might help controlling the tachycardia in some patients[69].

CONCLUSION -SYNOPSIS AND FUTURE CONSIDERATIONS

CAN is very common and is an underdiagnosed complication of DM. CAN is associated with significant increase in morbidity and mortality and plays an important role in the development of diabetic cardiomyopathy and silent ischaemia. Clinicians interpreting exercise tolerance testing should be aware of the reduced accuracy of this test in patients with CAN. In addition, CAN might play a role in the pathogenesis of diabetes-related microvascular complications and the development of lower limb complications. However, before CAN is symptomatic and evident clinically, patients might have sub-clinical CAN for several years. The time scale for the progression from sub-clinical to clinically evident CAN is unknown. In addition, the time scale for the progression from early abnormalities (such as increased LV torsion) to clini-

cally detectable cardiac disease is also unknown. Recent guidelines have recommended screening for CAN in patients with diabetes and issued guidance regarding the criteria used to diagnose CAN. CAN is assessed using several methods including CARTs, HRV, and imaging amongst others. The use of HRV and spectral analysis has simplified CAN testing which nonetheless remains time consuming. Despite our improved understanding of the pathogenesis of CAN, disease modifying treatment is lacking. Improving glycaemic control, life style changes and CVD risk factors management are the mainstay of treatment, which generally slow the progression of CAN rather than reversing it.

Further research exploring the natural history of CAN and the natural history of the impact of CAN on CVD is needed. Better understanding of CAN pathogenesis is also required in order to develop disease modifying treatments. OSA is increasingly recognised as an important contributor to the development of microvascular complications in DM, hence it is important to clarify the relationship between CAN and OSA as this might identify new treatment targets.

Abstract

There are many advantages of combining incretin therapy [glucagon-like peptide-1 (GLP-1) receptor agonists and dipeptidyl peptidase-4 (DPP-4) inhibitors] with insulin therapy as a glucose-lowering strategy in type 2 diabetes. One important advantage is the complementary mode of the mechanistic action of incretin and insulin therapy. Another advantage is the reduction in risk of hypoglycemia and weight gain when adding incretin therapy to insulin. Several clinical trials have studied the addition of GLP-1 receptor agonists [exenatide BID (twice daily), lixisenatide, albiglutide] or DPP-4 inhibitors (vildagliptin, sitagliptin, saxagliptin, alogliptin, linagliptin) to ongoing insulin therapy or adding insulin to ongoing therapy with a GLP-1 receptor agonist (liraglutide). These studies show improved glycemia in the presence of limited risk for hypoglycemia and weight gain with the combination of incretin therapy with insulin. This article reviews the background and clinical studies on this combination.

Key words: Type 2 diabetes; Glucose lowering; Insulin therapy; Glucagon-like peptide-1 receptor agonists; Dipeptidyl peptidase-4 inhibitors; Incretin therapy; Combination

Core tip: Incretin therapy (glucagon-like peptide-1 receptor agonists or dipeptidyl peptidase-4 inhibitors) combined with insulin therapy is a glucose-lowering strategy in type 2 diabetes. The combination allows a complementary mode of mechanistic action and, as demonstrated in several clinical trials, is glucose-lowering in association with limited risk for hypoglycemia and weight gain. The combination is a promising strategy in patients in whom metformin with either incretin therapy or basal insulin is insufficient for adequate glycemic control. This article reviews the background and clinical studies on this combination.

INSULIN IN COMBINATION WITH INCRETINS: A MORE COMMONLY USED GLUCOSE-LOWERING THERAPY

Life style changes accompanied by addition of metformin are often first line glucose reducing therapy in type 2 diabetes[1,2]. When metformin as the only pharmaceutical agent is insufficient for adequate glycemic control, several options are currently available. Of these, sulfonylureas, thiazolidinediones, dipeptidyl peptidase-4 (DPP-4) inhibitors, glucagon-like peptide-1 (GLP-1) receptor agonists and insulin were recently suggested by the joint position statement from the American Diabetes Association and the European Association of the Study of Diabetes to be potentials as an add-on to metformin[1]. They were suggested to be individualized to target the best combination for the individual patient. However, even after combination of metformin with any of these second-line thera-

pies, many patients still do not reach the glycemic target which is mainly due to the progression of the disease. At this stage, three-drug combinations are suggested to be used, involving metformin in combination with two of the other options. One such three-drug combination is the combination of insulin therapy with incretin therapy (+ metformin) as a glucose-reducing strategy of type 2 diabetes[2-6]. This article reviews the current evidence and experience for this combination.

BASIS FOR INCRETIN THERAPY

Incretin therapy is based on the anti-diabetic effects of GLP-1[7]. As an incretin hormone, GLP-1 is released from the gut after meal ingestion and augments insulin secretion in a glucose-dependent manner[7,8]. This effect on the beta cells is achieved through activating specific GLP-1 receptors, which are G protein coupled receptors[9]. GLP-1 also has an important effect to inhibit glucagon secretion[10]. These double effects on islet hormone secretion are of importance for the anti-diabetic action of incretin therapy and, furthermore, by targeting the double alpha and beta cell dysfunction, incretin therapy targets a main pathophysiological cause of the disease[11]. GLP-1 receptors are, however, also expressed in other cells and therefore GLP-1 also exhibits extra-islet effects, such as delay of gastric emptying[12] and satiety through a central effect in the hypothalamus[13]. GLP-1 also has the potential of preserving beta cell function through inhibition of apoptosis[14], although this has so far only been demonstrated in animal studies and not shown in humans.

The first study showing an anti-diabetic action of GLP-1 was published in 1992[15]. In the early development of GLP-1 as a therapy, GLP-1 had to be given as an intravenous infusion since the hormone is rapidly inactivated by DPP-4[16]. The two successful strategies for incretin therapy used this knowledge and today we have several GLP-1 receptor agonists which are not or only weakly inactivated by DPP-4 and DPP-4 inhibitors[17-20].

GLP-1 receptor agonists are injected subcutaneously once or twice daily [exenatide BID (twice daily), liraglutide, lixisenatide] or once weekly {exenatide once weekly [Quaque weekly (QW)]}. In addition, once weekly GLP-1 receptor agonists are in late clinical development (albiglutide, semaglutide, dulaglutide)[17,20]. The GLP-1 receptor agonists therefore differ in several respects, such as dosage regimen. However, GLP-1 receptor agonists also differ in other aspects, as was recently reviewed[17-20]. Thus, the different GLP-1 receptor agonists have different molecular structures and in this context, they may be derived from exendin-4, showing approximately 50% homology with native GLP-1 (exenatide, lixisenatide), or they may be true GLP-1 analogues with a structure showing a high (> 90%) homology to GLP-1 (liraglutide, albiglutide, semaglutide, dulaglutide). The GLP-1 receptor agonists also differ in molecular size since they may be similar in size to native GLP-1 (exenatide, lixisenatide, liraglutide, semaglutide) or be 15-20 times bigger because of fusion of GLP-1 with albumin (albiglutide) or immunoglobulin (dulaglutide).

DPP-4 inhibitors are oral agents given once or twice daily (sitagliptin, vildagliptin, saxagliptin, linagliptin, alogliptin, tenelagliptin, anagliptin, gemagliptin)[18,19]. They are different from each other in terms of molecular structure, although they are all small molecules, and they also differ, besides in pharmacokinetics with relevance for dosing regimen, in elimination mechanisms, as was recently reviewed[21].

Incretin therapy is today established as an add-on treatment to metformin and is also used in other conditions; it results in reduction of both fasting and postprandial glucose and it is associated with a low risk of hypoglycemia and no weight gain (weight reduction or weight neutrality)[19,20,22].

RATIONALE FOR COMBINATION INSULIN THERAPY PLUS INCRETIN THERAPY

The combination of incretin therapy and insulin therapy was initially not clearly evident during the development of incretin therapy. Instead, incretin therapy was mainly developed for combination with oral antihyperglycemic agents, in particular metformin. This is still a very important combination. However, as discussed for GLP-1 receptor agonists[4] and DPP-4 inhibitors[2,3], incretin therapy offers mechanistic advantages when used in association with insulin, which makes this combination a promising strategy for treatment.

The mechanistic complementary actions of the two approaches relate to reduction in fasting glucose, reduction in postprandial glucose, the low risk for hypoglycemia and the prevention of weight gain. More mechanistic studies are required, however, for a full appreciation of the complementary actions of insulin and incretins in combination.

Fasting glucose

Reduction of fasting glucose is a major goal for glucose-lowering therapy since fasting glucose contributes largely to hemoglobin A1c (HbA1c)[23,24]. A main effect of basal insulin is the reduction of fasting glucose, which is achieved through increased peripheral (mainly muscle and fat tissue) glucose utilization and inhibited hepatic glucose output[25,26]. Also, GLP-1-receptor agonists and DPP-4 inhibitors reduce fasting glucose but this is achieved through other mechanisms than insulin; mainly a glucose-dependent inhibition of glucagon secretion from the islet alpha cells[10,27]. In addition, direct liver effects of GLP-1 may also contribute[28]. Hence, the combination of insulin with incretin therapy would be expected to complement each other to reduce fasting glucose.

Postprandial glucose

Postprandial glucose also contributes to HbA1c and is therefore a target for glucose-lowering therapy[23,24]. Postprandial glucose is mainly regulated by gastric emptying

and the meal-induced islet hormone responses[29-31]. These effects are not appreciably affected by basal insulin. In contrast, incretin therapy reduces postprandial glucose, although the mode of action to achieve this effect differs between GLP-1 receptor agonists and DPP-4 inhibitors. GLP-1 receptor agonists reduce postprandial glucose mainly by delaying gastric emptying[29-31]. This effect of GLP-1 shows, however, tachyphylaxis, meaning that during long-term and continuous stimulation, the effect is reduced[32,33]. Consequently, intermittently acting GLP-1 receptor agonists (exenatide BID, lixisenatide) have been shown to be more potent to reduce gastric emptying than continuously acting GLP-1 receptor agonists (liraglutide, exenatide QW)[34,35]. In contrast, DPP-4 inhibitors do not inhibit gastric emptying[36] but instead reduce postprandial glucose mainly through inhibiting postprandial glucagon levels and stimulating beta cell function[27,37]. Both incretin therapy strategies therefore reduce postprandial glucose and thus complement the lack of such an effect by insulin in the combination therapy.

Hypoglycemia

Hypoglycemia is an adverse event for glucose-lowering therapy and is occasionally the limitation factor for achieving good glycemic control. Hypoglycemia is associated with negative impact, such as unpleasant and sometimes dangerous symptoms, weight gain (due to defense eating), deterioration of glycemic control (due to reduced adherence to therapy and therapeutic goals because of fear of new hypoglycemic episodes), increased cardiovascular risk and increased risk for microvascular complications[38-41]. Insulin therapy is associated with a high risk of hypoglycemia[29-31]. In contrast, incretin therapy is associated with a low risk of hypoglycemia[30,31,39-47]. This is because the islet effect of GLP-1 is glucose dependent[7,9] and the glucagon counter-regulation to hypoglycemia is preserved or augmented[48-50]. Therefore, incretin therapy has the potential to prevent the hypoglycemia induced by insulin when the two treatments are used in combination.

Body weight

Since increased body weight is associated with long-term negative effects, prevention of weight gain or weight reduction is of importance for glucose-lowering therapies. Body weight is increased by insulin therapy[51]. This is due to the anabolic action of insulin but may also be due to the self-defense eating associated with hypoglycemic events. Incretin therapy, on the other hand, prevents weight gain since its lowering of glycemia is not associated with increased risk of hypoglycemia and therefore the therapy avoid the self-defense eating[52]. GLP-1 receptor agonists also induce satiety through effects on the satiety center in the hypothalamus, thereby inducing weight reduction[13]. Therefore, the combination of incretin therapy with insulin has a great advantage of preventing the weight gain induced by insulin.

Disease modifying effects

Type 2 diabetes is a progressive disease with is mainly due to a continuous decline in beta cell function[53]. It has been discussed whether insulin therapy and incretin therapy may have complementary disease modifying effects[5]. The rationale for this suggestion is that insulin has been suggested to improve beta cell function through its normalization of fasting glucose, thereby preventing glucotoxicity and may also result in "beta cell rest"[54]. On the other hand, GLP-1 based therapies may improve beta cell function so much that beta cell function will also be improved over a long-term perspective, particularly in association with inhibited beta cell apoptosis[7,9].

ADVANTAGES OF COMBINING INSULIN WITH INCRETIN THERAPY

The complementary actions of insulin and incretin therapy, as discussed above, may result in potential advantages that may be observed by using this combination as a glucose-lowering strategy when treating people with type 2 diabetes. The main advantages are: (1) the combined reduction of fasting and postprandial glycemia which will lower HbA1c; (2) the lower risk of hypoglycemia which is due to the protection against hypoglycemia with incretin therapy in association with the often observed reduction in insulin dose when using this combination; (3) the lower risk for weight gain, which again is due to the protection against weight gain by incretin therapy in association with reduced weight gain through reduction in the insulin dose; and (4) the potential long-term disease modifying prospect of the combination.

CLINICAL STUDIES OF ADDING GLP-1 RECEPTOR AGONISTS TO INSULIN

Exenatide

The first proper clinical trial exploring the combination of incretin therapy with insulin was a study in 259 patients with type 2 diabetes who were treated with insulin glargine (± metformin and/or pioglitazone) with insufficient glycemic control (HbA1c 7.5%-10.5%; mean 8.4%). Patients were randomized to receive additional therapy with exenatide BID (n = 138) or placebo (n = 123) and the dose of insulin glargine was titrated to achieve a fasting glucose level less than 5.6 mmol/L[55]. After the study period of 30 wk, HbA1c was reduced by 1.7% in the group treated with exenatide BID as an add-on compared to 1.0% by placebo ($P < 0.001$). The daily insulin glargine dose had increased by 20 U (95%CI: 16-24) in the placebo group and by 13 U (95%CI: 9-17) in the exenatide BID-group ($P = 0.030$) (baseline insulin glargine dose was 48 U). Postprandial glucose was reduced in the exenatide BID-treated group (by 2.0 mmol/L, 95%CI: 1.5-2.5 mmol/L) but not changed in the placebo group ($P < 0.001$), whereas changes in fasting glucose did not differ between the two groups. Body weight was reduced (by 1.8 kg) in the exenatide BID group but increased (by 1.0 kg) in the placebo-treated group (baseline 94 kg). Furthermore, the number of hypoglycemic events did

Insulin glargine was used in all studies. Occurrence of hypoglycemia was reported as number of episodes per patient year[1], number of events[2] or as percentage of patients with at least one hypoglycemic episode[3]. One study also reported percentage of patients not on sulfonylurea who experienced at least one hypoglycemic episode[4]. Variation in baseline is SD, variation in effect is SE. Variation within parenthesis is the 95%CI. FPG: Fasting glucose; GLP-1: Glucagon-like peptide-1; HbA1c: Hemoglobin A1c.

not differ significantly between the groups inspite of the difference in HbA1c (1.4 episodes per patient year in the exenatide BID-treated group *vs* 1.2 episodes per patient year in the placebo group) (Table 1).

In another study, a direct comparison was performed between adding exenatide BID *vs* short-acting prandial insulin lispro to ongoing insulin glargine (+ metformin) in patients who were inadequately controlled on insulin glargine + metformin. The study used an initial 12 wk titration phase with insulin glargine [fasting glucose (FPG) glucose target < 5.6 mmol/L]. Patients who failed to reduce HbA1c below 7% during this titration period (mean 8.3%) were randomized to receive additional exenatide BID (n = 316) or insulin lispro (n = 321). The results showed that after 30 wk, HbA1c had been reduced by 1.1% ± 0.1% in both groups (not significantly different). Fasting glucose was reduced by 0.5 ± 0.2 mmol/L in the exenatide group *vs* 0.2 ± 0.2 mmol/L in the insulin lispor group (P = 0.002) and whereas postprandial glucose was similarly reduced after breakfast and evening meals, it was more pronouncedly reduced by lispro at lunch (when exenatide was not given; P < 0.001). Body weight was reduced in the exenatide BID group (by 2.4 ± 0.2 kg) and increased in the insulin lispro group (by 2.1 ± 0.2 kg). The number of hypoglycemic events was lower in the exenatide group (n = 206) than in the insulin lispro group (n = 522)[56].

Lixisenatide

The GLP-1 receptor agonist lixisenatide has been examined as an add-on to basal insulin in three studies. In the first study, patients treated with basal insulin with inadequate glycemic control (HbA1c 7%-10%, mean 7.6%) were randomized to addition of lixisenatide (n = 328) or placebo (n = 167) without any insulin titration[57]. The used basal insulins in the study were insulin glargine (50%), insulin detemir (47%), neutral protamine Hagedorn (NPH) insulin (7%) or premix insulin (2%) and 80% of the patients were additionally treated with metformin. After the study period of 24 wk, HbA1c was reduced by 0.7% by lixisenatide and by 0.4% by placebo (P < 0.001). Fasting glucose was reduced in both groups but with no significant difference. In contrast, postprandial glucose was more pronouncedly reduced in the lixisenatide group (by 5.5 ± 0.5 mmol/L) than in the placebo group (by 1.7 ± 0.5 mmol/L, P < 0.001). Body weight (from baseline of 88 kg) was reduced by 1.8 kg by lixisenatide and 0.5 kg by placebo (P < 0.001). The daily insulin dose (mean 56 U at baseline) had been reduced by 5 U in the lixisenatide group and by 2 U in the placebo group. Twenty-eight percent of patients in the lixisenatide group reported hypoglycemia *vs* 22% in the placebo group.

In the second study on add-on with lixisenatide to basal insulin, lixisenatide was added to insulin glargine in patients who initially failed to control glycemia with oral agents (HbA1c 7%-10%, mean HbA1c 8.6%)[58]. After an initial titration phase of insulin glargine alone for 12 wk targeting a fasting glucose of 4.4-5.6 mmol/L (mean HbA1c was reduced to 7.6%), patients were randomized to lixisenatide (n = 223) or placebo (n = 223) together with ongoing insulin therapy (+ metformin) for 24 wk. It was found that mean HbA1c was further reduced to 7.0% in the lixisenatide group *vs* to 7.3% in the placebo group (P < 0.001). Fasting glucose was similarly reduced in both groups, whereas postprandial glucose was reduced more in the lixisenatide group (by 3.4 ± 0.5 mmol/L) than in the placebo group (0.1 ± 0.5 mmol/L; P < 0.001). Body weight was increased by 1.2 kg in the placebo group and by 0.3 kg in the lixisenatide group (baseline 86 kg) (P = 0.0012). Confirmed hypoglycemia was reported in 0.80 episodes per patient year in the lixisenatide group *vs* 0.44 in the placebo group.

Finally, the effect of adding lixisenatide to ongoing insulin therapy has also been examined in Asian patients with inadequate glycemic control on basal insulin [with (70%) or without sulfonylurea therapy][59]. Of the patients, 60% were treated with insulin glargine, 27% with insulin detemir and 13% with NPH insulin with a mean daily insulin dose of 25 U. The patients were randomized to addition of lixisenatide (n = 154) or placebo (n = 157) together with ongoing therapy with basal insulin ± sulfonylurea. After the 24 wk study period, HbA1c was reduced by 0.8% in the lixisenatide group *vs* increased by 0.1% in the placebo group (P < 0.001). There was a reduction in fasting glucose in the lixisenatide group compared to the placebo group (P = 0.0187) and postprandial

In the studies long and medium acting insulin and premixed insulins were used. Occurrence of hypoglycemia was reported as number of events[1] or as percentage of patients with at least one hypoglycemic episode[2]. Variation in baseline is SD, variation in effect is SE. Variation within parenthesis is the 95%CI. FPG: Fasting glucose; BMI: Body mass index (kg/m^2); HbA1c: Hemoglobin A1c.

glucose was reduced by 8 mmol/L in the lixisenatide group but not changed in the placebo group ($P < 0.001$). Symptomatic hypoglycemia was more frequent with lixisenatide (42.9%) *vs* placebo (23.6%). In contrast, in patients not treated with sulfonylurea, hypoglycemia was similar between groups (32.6% *vs* 28.3%, respectively). Change in body weight was not significantly different between the groups whereas the daily insulin dose was reduced by 1.4 U in lixisenatide group *vs* by 0.1 U in the placebo group ($P = 0.0019$).

Albiglutide

A study compared the effects of the once weekly GLP-1 receptor agonist albiglutide ($n = 285$) *vs* insulin lispro ($n = 281$) to ongoing insulin glargine therapy (+ oral agents, no sulfonylurea) in patients with type 2 diabetes with inadequate glycemic control (mean HbA1c 8.5%)[60]. There was a titration algorithm for insulin glargine to achieve fasting glucose of 4.4-7.2 mmol/L. After the 26 wk study period, HbA1c was similarly reduced by albiglutide (0.8% ± 0.1%) and by insulin lispro (0.7% ± 0.2%). Fasting glucose was reduced in both groups with no significant difference. Body weight (baseline 92 kg) was reduced 0.7 ± 0.2 kg by albiglutide and increased by 0.8 ± 0.2 kg by insulin lispro ($P < 0.001$). Mean insulin glargine dose did not change during the study. Thirty-two percent of patients on albiglutide experienced hypoglycemia *vs* 50% with insulin lispro.

CLINICAL STUDIES OF ADDING DPP-4 INHIBITORS TO INSULIN

Vildagliptin

The first study examining a DPP-4 inhibitor in combination with insulin added vildagliptin (*vs* placebo) to insulin treated patients with insufficient glycemic control (HbA1c 7.5%-11%, mean HbA1c 8.4%; $n = 296$)[61]. Patients were treated with basal and prandial insulin (mean 2.8 injections per day, mean daily insulin dose 82 U). After the 24 wk study period, HbA1c was reduced by 0.5% in the vildagliptin group *vs* 0.2% in the placebo group (baseline 8.4%) ($P = 0.01$). During the course of the study, there were 113 hypoglycemic events in the vildagliptin group compared to 185 in the placebo group and whereas there were 6 episodes of severe hypoglycemia in the placebo group, no severe hypoglycemic episode was seen in the vildagliptin group. The mean daily insulin dose was reduced by 1.9 U in the vildaglitpin *vs* increased by 2.4 U in the placebo group. Change in body weight did not differ between the groups (Table 2).

Another study examined the addition of vildagliptin to ongoing insulin (+ metformin) therapy in 449 patients over 24 wk[62]. The patients were treated with long-acting insulin (22%), intermediate acting insulin (17%) and premixed insulin (60%), with a mean daily insulin dose of 40 U. They had insufficient glycemic control (HbA1c 7.5%-11%; mean HbA1c 8.8%). It was found that HbA1c was reduced by vildagliptin by 0.8% and by placebo by 0.1% ($P < 0.001$). Fasting glucose was reduced in the vildagliptin group but not in the placebo group ($P = 0.050$). Hypoglycemia was reported in 8.4% of patients in the vildagliptin group and by 7.2% in the placebo group. The daily insulin dose was 41 U at baseline and slightly reduced in both groups with no difference. There was no change in body weight in any of the groups.

Sitagliptin

The first study examining the combination of sitagliptin with insulin therapy added the DPP-4 inhibitor *vs* placebo to ongoing insulin (+ metformin) treatment over 24 wk in 641 patients with poorly controlled type 2 diabetes

(HbA1c 7.5%-11%, mean HbA1c 8.6%)[63]. Seventy-four percent of the patients were treated with long-acting or intermediate-acting insulin and 26% were treated with premixed insulin. After the 24 wk study period, HbA1c was reduced by 0.6% by sitagliptin *vs* no change by placebo ($P < 0.001$). Fasting glucose was reduced in the sitagliptin group but not in the placebo group ($P < 0.001$). Similarly, postprandial glucose was reduced in the sitagliptin group (by -1.7 mmol/L, 95%CI: -2.2, -1.2) but not changed in the placebo group (0.3 mmol/L, 95%CI: -0.2-0.7) ($P < 0.001$). Hypoglycemia was observed in 16% of the patients on sitagliptin *vs* 8% of patients on placebo. Insulin dose was reduced by 0.1 U in the sitagliptin and by 1.6 U in the placebo group (baseline 44 U for long acting insulin and 67-74 U with premixed insulin). Body weight was reduced by 0.1 kg in both groups.

Another study compared adding sitagliptin to insulin therapy *vs* increasing the insulin dose in 140 patients on insulin therapy (+ oral agents) who had inadequate glycemic control (baseline HbA1c 7.5%-11%, mean HbA1c 9.2%). Patients were treated with insulin glargine alone (48%), insulin glargine together with rapid acting insulin (23%) or NPH insulin in combination with regular insulin (29%); mean daily insulin dose was 37 U. It was found that over the 24 wk study period, sitagliptin (mean insulin dose reduced by 2 U) reduced HbA1c by 0.6%, whereas increasing the insulin dose (by 10 U) reduced HbA1c by 0.2% ($P < 0.005$)[64]. Fasting glucose was reduced by approximately 1 mmol/L in both groups with no significant difference. Hypoglycemia occurred in 7 events per patient year in the sitagliptin group *vs* 14.3 events per patient year in the insulin group. Body weight was reduced by 0.7 kg in the sitagliptin group *vs* increased by 1.1 kg in the insulin group ($P < 0.05$).

A third study examined the add-on of sitagliptin ($n = 236$) *vs* placebo ($n = 232$) to patients who were treated with insulin (long-acting, intermediate-acting or premixed insulin) in combination with metformin over 6 mo. It was found that with the addition of sitagliptin, HbA1c was reduced by 0.8% (baseline 8.5%) *vs* no change in HbA1c after addition of placebo ($P < 0.001$). Relative to the placebo group, fasting glucose was reduced by 1.0 mmol/L and postprandial glucose by 2.0 mmol/L. Hypoglycemia was observed in 18% of patients in the sitagliptin group *vs* 8% in the placebo group[65].

Alogliptin

Alogliptin (two doses) or placebo was added to ongoing insulin therapy alone (40%) or with metformin in 390 patients with inadequate glycemic control (HbA1c $\geqslant$ 8.0%; baseline HbA1c 9.3%)[66]. The insulin treatment that was used was premixed insulin or insulin combinations (64%), as well as long-acting basal insulin alone (34%) or short-acting insulin alone (2%); mean daily insulin dose was 57 U. During the course of the 26 wk study, daily insulin dose was kept constant. Alogliptin reduced HbA1c by 0.6% (12.5 mg daily; $n = 131$) and 0.7% (25 mg daily; $n = 129$) *vs* a reduction by 0.1% in the placebo group ($n = 130$) ($P < 0.001$). Fasting glucose was reduced by aloglitin in the 25 mg group (by -0.6 ± 0.3 mmol/L *vs* the placebo group (0.3 ± 0.3 mmol/L; $P = 0.030$) but not changed in the 12.5 mg group. The number of patients reporting hypoglycemia was lower in the two alogliptin groups (21% and 20%, respectively) than in the placebo group (40%; $P < 0.001$). There was no difference in hypoglycemia events (24%-27% of patients reported hypoglycemic episodes in the three groups). Body weight increased by 0.6 kg (baseline 88 kg) in all groups.

Saxagliptin

Saxagliptin or placebo was added to ongoing insulin therapy (basal insulin or premixed insulin ± metformin) in 455 patients with inadequate glycemic control (HbA1c 7.5-11). During the course of the 24 wk study, daily insulin dose was kept constant[67]. Placebo-adjusted reduction in HbA1c by saxagliptin was 0.4% ($P < 0.001$). There was no difference in hypoglycemia events (18% with saxagliptin, 20% with placebo). Body weight was increased by 0.4 kg in the saxagliptin group and by 0.2 kg in the placebo group. An extension phase of this study showed sustained effects over 52 wk[68].

Linagliptin

Linagliptin or placebo was added to ongoing basal insulin therapy (± metformin and/or pioglitazone) in 1261 patients with inadequate glycemic control (HbA1c 7-10). During the study, daily insulin dose was kept constant during the first 24 wk but could thereafter be titrated according to fasting glucose[69]. After 24 wk, HbA1c was reduced by 0.6% (baseline 8.3%) by linagliptin and by 0.1% by placebo ($P < 0.001$). Placebo-adjusted reduction in fasting glucose with linagliptin was 0.6 mmol/L (95%CI: -0.9-0.4). During the following 28 wk, insulin dose was increased by 2.6 U in the linagliptin group and by 4.2 U in the placebo group but with no further change in HbA1c. There was no difference in hypoglycemia events (23% with linagliptin, 22% with placebo after 24 wk). Body weight was reduced by 0.3 kg in the linagliptin group and by 0.04 kg in the placebo group.

COMPARING CONTROLLED TRIALS COMBINING ADDING INCRETIN THERAPY TO INSULIN

As outlined above, the reduction in HbA1c, fasting and postprandial glucose, the lower risk of hypoglycemia, the prevention of weight gain and the potential disease modification are the main advantages of combining incretin therapy with insulin. Except for any direct evidence of a disease modifying effect of the combination, the controlled trials summarized above include information on these aspects and therefore it is of interest to compare their results in this regard (Tables 1 and 2).

HbA1c

The mean reduction in HbA1c in the controlled clinical studies adding incretin therapy to stable dose for 6 mo

was -0.8% ± 0.1% compared to -0.3% ± 0.1% when placebo was added ($P < 0.001$; Tables 1 and 2). There does not seem to be a difference between the two different strategies of incretin therapy since the placebo-adjusted reduction in HbA1c was -0.6% ± 0.2% for GLP-1 receptor agonists ($n = 4$ studies) *vs* -0.5% ± 0.1% for DPP-4 inhibitors ($n = 6$ studies).

Fasting glucose

Fasting glucose is also reduced by adding incretin therapy to stable dose of insulin. It was found to be reduced by -0.7 ± 0.1 mmol/L by the incretin therapy *vs* by -0.3 ± 0.1 mmol/L in the placebo groups ($P = 0.027$; Tables 1 and 2). There does not seem to be a difference between the two different strategies of incretin therapy since fasting glucose was reduced by 0.2 ± 0.2 mmol/L by GLP-1 receptor agonists ($n = 4$ studies) *vs* by -0.6 ± 0.2 mmol/L by DPP-4 inhibitors ($n = 5$ studies).

Postprandial glucose

A few studies also examined postprandial glucose after adding incretin therapy to a stable dose of insulin. They showed that postprandial glucose was markedly reduced when adding GLP-1 receptor agonists exenatide BID[55] and lixisenatide[58], whereas after adding the DPP-4 inhibitor sitagliptin, postprandial glucose was more modestly reduced[63].

Hypoglycemia

In the studies where incretin therapy has been added to insulin compared to ongoing insulin, the occurrence of hypoglycemia was not different between the incretin treatment and placebo in most studies (Tables 1 and 2). Since in most of these studies HbA1c is lower after addition of incretin therapy compared to placebo, an increased risk of hypoglycemia would be expected after incretin therapy. Since the opposite was the case, a conclusion is that incretin therapy will reduce the risk of hypoglycemia. This conclusion is also evident in the studies in which incretin therapy as an add-on to basal insulin was compared with the active comparator of either adding short-acting insulin[56,60] or increasing the insulin dose[64]. A reason for the low risk of hypoglycemia when adding incretin therapy to insulin therapy could be the reduced dose of insulin which often accompanies the combination. It may, however, also be caused be a sustainment of the glucagon counterregulation to hypoglycemia, as was recently demonstrated for the DPP-4 inhibitor vildagliptin when added to insulin; the sustained glucagon counterregulation assures a sufficient hepatic glucose response to prevent hypoglycemia[50].

Weight gain

Body weight was significantly reduced by -0.9 ± 0.5 kg by adding GLP-1 receptor agonists to ongoing insulin therapy compared to 0.4 ± 0.4 kg in the placebo groups, corresponding to a placebo-adjusted reduction by -1.4 ± 0.5 kg (Table 1). In contrast, DPP-4 inhibitors are weight neutral when added to insulin with a placebo-adjusted change in body weight of -0.2 ± 0.1 kg (Table 2).

OTHER STUDIES COMBINING INCRETIN THERAPY WITH INSULIN

Adding insulin to a GLP-1 receptor agonist

One study has examined the addition of basal insulin to patients who are treated with a GLP-1 receptor agonist with insufficient glycemic control. The study initially examined addition of liraglutide to patients failing glycemic control on metformin (± sulfonylurea; sulfonylurea was removed at start of study) ($n = 988$)[70]. After 12 wk, patients who were still uncontrolled (HbA1c > 7%) were randomized to continue metformin plus liraglutide or addition of insulin detemir to titrate fasting glucose to 4-6 mmol/L. After another 26 wk, HbA1c had been reduced by 0.5% by the combination of insulin detemir plus liraglutide, whereas those on liraglutide alone (all with metformin) had no further change in HbA1c ($P < 0.001$). FPG decreased more in the liraglutide + insulin group than in the liraglutide control group ($P < 0.001$). Hypoglycemia rates were 9.2% in the group given insulin detemir and liraglutide *vs* 1.3% with liraglutide alone. Body weight (baseline 96 kg) decreased by 3.5 kg by liraglutide during the initial period and then by 0.16 kg with insulin detemir and liraglutide *vs* by 0.95 kg with liraglutide without insulin detemir ($P = 0.03$).

Initial combination of incretin therapy with insulin

Liraglutide has been examined in a fixed ratio combination with insulin degludec in a randomized study in subjects with type 2 diabetes[71]. It was a large trial in which patients treated with metformin ± pioglitazone and inadequate glycemic control (baseline HbA1c 8.3%) were randomized to the addition of insulin degludec ($n = 414$), liraglutide ($n = 415$) or the combination of insulin degludec and liraglutide ($n = 834$). After 26 wk of treatment, HbA1c had been reduced by 1.4% with insulin degludec alone, 1.3% with liraglutide alone and 1.9% with insulin degludec in combination with liraglutide. Body weight had increased by 2.2 kg with insulin degludec alone, was reduced by 2.4 kg by liraglutide and was neutral with the combination. Cumulative episodes of hypoglycemia were 1.3 per patient in the insulin degludec group and reduced to 0.9 per patient in the combination group (0.1 in the liraglutide alone group).

Another study randomized 217 patients who had insufficient glycemic control on metformin ± sulfonylurea to receiving sitagliptin plus sulfonylurea or sitagliptin plus insulin detemir (all on metformin). After the 26 wk study period, sitagliptin had reduced HbA1c by 0.9% (mean baseline HbA1c 8.5%), whereas sitagliptin plus insulin detemir had decreased HbA1c by 1.4%. Hypoglycemia was reported in 1.3% of patients in the insulin detemir plus sitagliptin group and 1.7% in the sitagliptin alone group. Body weight decreased in both arms with a mean decrease of -1.7 kg in the sitagliptin control group *vs* -0.8

kg with sitagliptin plus insulin detemir group[72].

Uncontrolled studies combining incretin therapy with insulin

There are also a few uncontrolled studies of combining insulin therapy and incretin therapy in patients with type 2 diabetes which arrive at similar conclusions as the previously summarized controlled trials. One retrospective report showed that addition of exenatide BID to 188 insulin-treated patients resulted in a reduction in HbA1c by 0.66% (baseline 8.1%) after 6 mo with a persistent effect throughout two years; mean insulin dose could be reduced by 15% and only 4% of patients experienced hypoglycemia[73]. Furthermore, a study in obese patients with type 2 diabetes added exenatide BID (n = 21) or liraglutide (n = 40) to ongoing insulin therapy and showed a reduction in HbA1c in these patients by 1.0% (baseline 8.9%) after 7 mo. At the same time, the daily insulin dose was reduced from 91 U to 52 U and only a few hypoglycemia episodes were reported[74]. Moreover, a study in severely insulin resistant obese subjects treated with insulin U-500 (mean daily dose 192 U) received liraglutide for twelve weeks which reduced HbA1c by 1.4% (mean baseline HbA1c 8.5%) and at the same time the insulin dose was reduced by 28%. There were no reports of hypoglycemia and body weight was reduced by 5 kg (baseline body weight 136 kg)[75].

SAFETY OF THE COMBINATION OF INSULIN AND INCRETIN THERAPY

Incretin therapy has been shown to be safe with high tolerability and the only consistent adverse event is nausea and vomiting during the initial treatment period with GLP-1 receptor agonists[17-20,76]. Local injection site reactions (nodules and/or erythema) sometimes occur in association with treatment with GLP-1 receptor agonists, although such reactions are rare and commonly transient. Antibodies may be formed against GLP-1 receptor agonists; more commonly with exendin-4-based agonists (exenatide, lixisenatide) than after GLP-1-based agonists. In contrast, adverse events are rare during treatment with DPP-4 inhibitors, as evident from pooled analysis of clinical trials[77,78]. Recently, there has been a discussion about whether there is an increased risk of acute pancreatitis in incretin therapy. However, pooled or meta-analysis analyses have not demonstrated any increased risk when compared to placebo or other comparators[76-79]. Nevertheless, it is important to follow patients on GLP-1 receptor agonists in this regard and in patients with a history of acute pancreatitis, incretin therapy should not be given. Rodent data also suggest that GLP-1 receptor agonists may be associated with medullary thyroid carcinoma[80]. This has not, however, been observed in other animal species or humans, possibly because C-cells in humans have a lower expression of GLP-1 receptors than rodent C-cells[81].

Incretin therapy has also been discussed in relationship to cardiovascular safety and meta-analyses have shown that there is no detrimental effect of GLP-1 receptor agonists[82] or DPP-4 inhibitors[83]. Furthermore, several cardiovascular safety trials with incretin therapy are at present ongoing and two such recently published studies showed no increased risk for cardiovascular disease with saxagliptin[84] or alogliptin[85].

Also, insulin therapy is safe with the only concern being the increased risk of hypoglycemia and weight gain, expected adverse events through the glucose-lowering actions of the therapy. By combining incretin therapy and insulin, there is no additional concern for safety or tolerability, as evident from the studies reported in this review[55-69]. Hence, the number of adverse events is not higher in the incretin therapy + insulin treatment groups than in placebo groups in placebo-controlled clinical trials on GLP-1 receptor agonists or DPP-4 inhibitors as an add-on to insulin therapy, except the nausea and vomiting for the GLP-1 receptor agonists. This also includes recently discussed potential adverse events such as acute pancreatitis.

Some practical aspects need to be taken into account for incretin therapy. This includes the dose reduction of sitagliptin, vildagliptin, saxagliptin and alogliptin in patients with renal impairment due to their renal excretion. Furthermore, exenatide and liraglutide should be cautiously used in patients with renal impairment due to insufficient experience in this patient group. Furthermore, in patients with hepatic impairment, vildagliptin is not recommended. As for all new treatment combinations, however, the combination of incretin therapy with insulin also needs careful follow-up for examining potential adverse events which have not yet been observed.

SUMMARY AND CLINICAL POSITIONING OF INCRETIN PLUS INSULIN COMBINATION

The combination of insulin therapy with incretin therapy is attractive due to experience that this combination improves glycemia with a low risk of increasing risk for hypoglycemia and low risk of weight gain. The combination is therefore of particular value in patients on insulin therapy in whom HbA1c is not sufficiently reduced. In some patients, insufficient improvement of glycemia may be caused by clinical inertia with reluctance to increase the insulin dose due to fear of hypoglycemia or weight gain. Addition of incretin therapy with its lower risk of hypoglycemia and low risk of weight gain may therefore prevent the clinical inertia in these patients.

Incretin addition is also of value in patients who have insufficient reduction in HbA1c by intensified basal insulin therapy due to persistent high postprandial glycemia or frequent hypoglycemia. Incretin therapy offers advantages over addition of prandial insulin in these patients. Of particular importance is the prevention of hypoglycemia, since hypoglycemia is associated with both short-

term and long-term negative impact, not least on cardiovascular outcomes. The combination of incretin therapy with insulin may therefore provide advantages both in the short-term and by reducing long-term complications to the disease.

A main indication for the combination of incretin therapy and insulin is thus in patients who are treated with basal insulin (± metformin) in whom there is insufficient glycemic control and/or an unacceptable high rate of hypoglycemia and/or unacceptable weight gain. In patients with HbA1c levels which are not very high (< 7.5%), it is advisable to reduce the basal insulin dose when starting incretin therapy. The combination of incretin therapy with insulin is also an important treatment strategy in patients who are treated with metformin and incretin therapy in combination and in whom the glycemic control is insufficient, *i.e.*, to add basal insulin therapy to incretin therapy (+ metformin). The combination with incretin therapy and insulin may thus be introduced in either way, starting with incretin therapy or starting with insulin. It is also a possibility to start immediately with initial combination with incretin therapy and insulin in patients who are treated with metformin and who are in insufficient metabolic control. Such an early introduction of the combination may be a solution to the unmet need to start aggressive therapy early on during the disease development to achieve long-term control. Further studies are required to examine the long-term effects of this initial combination. One important set of trials would be studies comparing this treatment strategy with other three-drug combinations. This would be of interest to further analyze the potential for the combination of incretin plus insulin therapy (+ metformin). What would also be of value would be to compare different incretin therapies (different GLP-1 receptor agonists and different DPP-4 inhibitors) to elucidate potential differences in effects of the different compounds when combined with insulin. More mechanistic studies would also be of value, for example to examine the relationship between insulin therapy and incretin hormones for the regulation of hepatic glucose output, glucose utilization and islet function and, furthermore, to study impact of the combination therapy on gastric emptying and satiety. Moreover, it would also be of great value to analyze the cardiovascular outcome of this three-drug combination. This would be possible in sub-group analysis on the cardiovascular outcome trials of incretin treatment in which patients on insulin therapy have also been enrolled. Finally, studies directly aiming at examining the potential disease modifying effect of the combination of incretin therapy and insulin are important; these studies need to have a long duration and include mechanistic studies on islet function.

The combination of incretin therapy with insulin (± metformin) is thus a promising glucose-lowering strategy in type 2 diabetes, allowing a more intensified treatment at an earlier stage of the disease with a lower risk for hypoglycemia and weight gain when compared to other intensifying therapies.

Abstract

Approximately 170 million people worldwide are chronically infected with hepatitis C virus (HCV). Chronic HCV infection is the leading cause for the development of liver fibrosis, cirrhosis, hepatocellular carcinoma (HCC) and is the primary cause for liver transplantation in the western world. Insulin resistance is one of the pathological features in patients with HCV infection and often leads to development of type Ⅱ diabetes. Insulin resistance plays an important role in the development of various complications associated with HCV infection. Recent evidence indicates that HCV associated insulin resistance may result in hepatic fibrosis, steatosis, HCC and resistance to anti-viral treatment. Thus, HCV associated insulin resistance is a therapeutic target at any stage of HCV infection. HCV modulates normal cellular gene expression and interferes with the insulin signaling pathway. Various mechanisms have been proposed in regard to HCV mediated insulin resistance, involving up regulation of inflammatory cytokines, like tumor necrosis factor-α, phosphorylation of insulin-receptor substrate-1, Akt, up-regulation of gluconeogenic genes like glucose 6 phosphatase, phosphoenolpyruvate carboxykinase 2, and accumulation of lipid droplets. In this review, we summarize the available information on how HCV infection interferes with insulin signaling pathways resulting in insulin resistance.

Key words: Hepatitis C virus; Insulin resistance; Insulin receptor substrate 1; Protein kinase B; mammalian target of rapamycin/S6K1; Suppressor of cytokine signaling 3; Glucose transporter-4; Lipid metabolism; Anti-viral therapy

Core tip: Insulin resistance is one of the pathological features in patients with hepatitis C virus (HCV) infection and often leads to development of type Ⅱ diabetes. Recent evidence indicates that HCV associated insulin resistance may result in hepatic fibrosis, steatosis, hepatocellular carcinoma and resistance to anti-viral treatment. In this review, we summarize the available information on how HCV infection interferes with insulin signaling pathways.

INTRODUCTION

Hepatitis C virus (HCV) contains a positive sense single stranded RNA genome and belongs to the family Flaviviridae and genus Hepacivirus[1]. HCV genome, 9.6 kb in length, is composed of a 5' non-translated region (NTR), a long open reading frame (ORF) encoding a polyprotein and a 3' NTR. The ORF encodes a polyprotein of about 3000 amino acids that is translated *via* an internal ribosome entry site at the 5' NTR. The polyprotein is then cleaved by both cellular and viral proteases into at least

10 different proteins[1]. These include three structural proteins namely, core and two envelope glycoproteins (E1 and E2). In addition, a protein called F or ARFP can be produced from a frame-shift of the core protein[2]. An ion channel protein p7 is formed by cleavage of E2[3]. Non structural proteins of HCV include NS2, NS3, NS4A, NS4B, NS5A, and NS5B.

The primary host cell for HCV is hepatocytes but replication may also occur in other cell types, such as peripheral blood mononuclear cells, as well as in B and T cell lines[4,5]. HCV is a major cause of acute and chronic liver disease worldwide. More than 170 million people are currently infected with HCV[6]. Currently HCV vaccine is not available. Acute infection is usually asymptomatic, making early diagnosis difficult. Approximately 70% of acutely infected individuals fail to clear the virus and become chronically infected[7]. Chronic HCV infection is the leading cause for the development of liver fibrosis, cirrhosis, hepatocellular carcinoma (HCC), and is the primary cause for liver transplantation in the western world. The sustained antiviral response rate in treatment of chronic HCV infection with interferon (IFN)-α with ribavirin is limited (about 30%-40%)[8,9]. Boceprevir and telaprevir protease inhibitors, have been shown to exhibit significantly higher rates of sustained virologic response (SVR) against HCV genotype 1 (about 65%-75%) as compared with peginterferon-ribavirin alone[10,11]. However, use of these antiviral agents display higher incidence of adverse events, such as rash, gastrointestinal disorders, and anemia.

Insulin resistance plays an important role in the development of various complications associated with HCV infection. Recent evidence indicates that HCV associated insulin resistance may result in hepatic fibrosis, steatosis, HCC and resistance to anti-viral treatment[12]. Thus, HCV associated insulin resistance is a therapeutic target at any stage of HCV infection. HCV modulates normal cellular gene expression and interferes with the insulin signaling pathway. The aim of this review is to summarize the currently available information on how chronic HCV infection interferes with insulin signaling pathways resulting in insulin resistance.

GLUCOSE UPTAKE AND INSULIN RESISTANCE

Glucose is a key metabolite essential for the production of energy (mostly ATP) which is required by cells. There are several mechanisms underlying increased glucose production. These include production of free glucose by increased glycogenolysis in the liver, increased gluconeogenesis, activation of forkhead box transcription factor (FoxO1) and improper insulin-glucagon hormonal balance, which stimulates increased glucose production[13]. Several factors contribute to elevated gluconeogenesis in diabetes, namely (1) increased supply of glucogenic precursors to the liver (glycerol, amino acids, free fatty acids), (2) increased lipid content, (3) increased cytokines and adipokines, and (4) decreased insulin receptor (IR) signaling in hepatocytes[13]. Glucose uptake into cells is regulated by the action of specific hormones, namely insulin and glucagon. Insulin is a peptide hormone secreted by the β-cells of the pancreatic islets of langerhans and maintains normal blood glucose levels by facilitating cellular glucose uptake, regulating carbohydrate, lipid and protein metabolism and promoting cell division and growth through its mitogenic effects[14]. The ability of insulin to stimulate glucose uptake into tissues is central to the maintenance of whole-body glucose homeostasis[15]. Type Ⅱ diabetes mellitus (T2DM), occurs when the production of insulin is not sufficient to overcome a difficulty the body has in properly using insulin. This difficulty is called insulin resistance, resulting in increased glucose levels. Both forms of diabetes can pose an increased risk of major lifelong complications. In the case of insulin resistance, this includes a fivefold increased risk of coronary vascular disease, diabetic retinopathy and neuropathy[16-19]. Fatty liver is relatively common in overweight and obese persons with T2DM and is an aspect of body composition related to severity of insulin resistance, dyslipidemia, and inflammatory markers[20].

Glucose transporter-4 (GLUT-4) was shown to be the major isoform responsible for enhanced glucose uptake into muscle and adipose tissues following the secretion of insulin into the bloodstream[21,22]. The process of glucose uptake by cells requires a series of events to take place in a timely manner. It involves the binding of insulin to the IR resulting in subsequent phosphorylation and activation of IR substrate 1 and 2 (IRS-1/IRS-2), central molecules of the insulin signaling cascade[23,24]. This in turn activates protein kinase B (AKT) by phosphorylation of Ser^{473} and Thr^{308} residues. Activated AKT causes the translocation of GLUT-4 from intracellular compartments to the cell surface where it is required for glucose uptake[25]. Any change in the signaling is likely to induce insulin resistance which is associated with a number of pathophysiological changes including glucose intolerance, obesity, dyslipidemia and hypertension. Insulin resistance is a physiological condition in which cells fail to respond to the normal actions of the hormone insulin. The body produces insulin, but the cells in the body become resistant to insulin and are unable to use it as effectively, resulting in an attenuated biological response, leading to hyperglycemia[26]. Accumulation of ectopic lipid metabolites, activation of the unfolded protein response pathway, and innate immune pathways have all been implicated in the pathogenesis of insulin resistance[27]. During the course of insulin resistance several inflammatory cytokines and lipid metabolites, like free fatty acids, interrupt with the normal insulin signaling and promote T2DM.

CHRONIC HCV INFECTION AND INSULIN RESISTANCE

Epidemiological studies suggest that patients with chron-

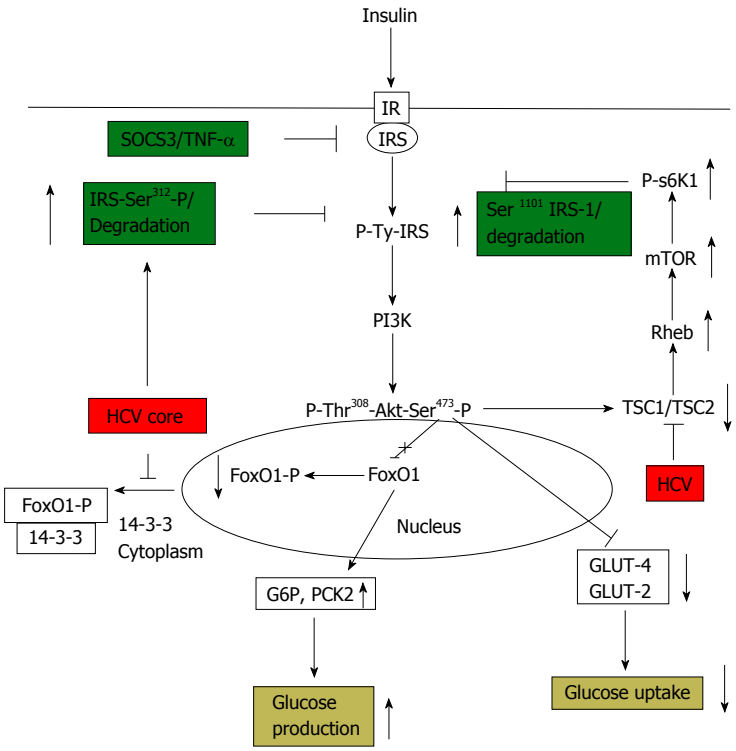

Figure 1 Schematic showing the interference of Hepatitis C virus in the insulin signaling pathway. Hepatitis C virus (HCV) core protein is known to up regulate Ser^{312} phosphorylation of insulin receptor substrate (IRS)-1 leading to degradation of IRS-1, the key molecule involved in propagation of insulin signal downstream from the insulin receptor (IR). HCV infection is also known to down regulate TSC1/TSC2 complex, resulting in subsequent upregulation of mTOR/S6K1 which leads to Ser^{1101} phosphorylation of IRS-1 and its subsequent degradation. A role of HCV mediated upregulation of SOCS3 and tumor necrosis factor-α (TNF-α) has also been proposed which leads to degradation and blocking of IRS-1 function. HCV also upregulates glucose 6 phosphatase (G6P), phosphoenolpyruvate carboxykinase 2 (PCK2) leading to increased glucose production, and down regulates glucose transporter (GLUT)-4, GLUT-2, leading to decreased glucose uptake by hepatocytes. Overall, these alterations lead to insulin resistance. mTOR: Mammalian target of rapamycin.

ic HCV infection have a significantly increased prevalence of T2DM as compared to hepatitis B virus infected patients[28-30]. Both insulin resistance and diabetes can adversely affect the course of chronic hepatitis C (CHC), leading to enhanced steatohepatitis and liver fibrosis[30-32]. Insulin resistance, associated with type 2 diabetes, can promote fatty liver, and excessive hepatic accumulation of fat may promote insulin resistance and therefore contribute to the pathogenesis of the metabolic syndrome[33]. Insulin resistance is a critical component of type 2 diabetes mellitus pathogenesis. Several mechanisms are likely to be involved in the pathogenesis of HCV-related insulin resistance[34]. Several cellular lesions have been associated with insulin resistance, but the precise mechanism by which HCV induces insulin resistance remains elusive with numerous viewpoints and opinions[30].

Impairment of IRS-1 and IRS-2 expression has been observed in the liver of patients with chronic HCV infection, as well as in HCV core transgenic mice, and from *in vitro* cell culture system[35-38]. HCV mediates dysfunction of the insulin signaling pathways *via* several distinct mechanisms, such as upregulating the expression of suppressors of cytokine signaling 3 expression[35], down regulation of peroxisome proliferator-activated receptors gamma (PPARγ)[36], activation of mammalian target of rapamycin (mTOR)/S6K1 pathway[38], and increased tumor necrosis factor-α (TNF-α) secretion[39].

MODULATION OF IR SUBSTRATE BY HCV

HCV modulates insulin signaling and IRS-1 *via* multiple mechanisms which have been presented in Figure 1. Ser/Thr phosphorylation of IRS-1 inhibits its association with the IR, which in turn inhibits tyrosine phosphorylation of IRS-1, required for its activation, and promotes degradation. Upregulation of serine phosphorylation of IRS-1 is a key negative feedback mechanism under physiological conditions to prevent the action of insulin. In an insulin-resistant state, an imbalance occurs between positive IRS-1 Tyr-phosphorylation and negative Ser-phosphorylation of IRS-1[40]. HCV core protein expression in hepatocytes upregulates Ser^{312} phosphorylation status of IRS-1 and modulates downstream Akt activity by inhibiting Thr^{308} phosphorylation[37]. Ser^{312} and Ser^{1101} phosphorylation of IRS-1 inhibits its association with the IR and stimulates degradation. HCV core protein induces insulin resistance by increasing Ser^{312} and Ser^{1101} phosphorylation, marking its for degradation *via* the activated mTOR/S6K1 pathway[38], and subsequently blocking Tyr-phosphorylation of IRS-1 and Thr^{308} phosphorylation of Akt for the inhibition of glucose uptake. Activation of mTOR signaling also plays a key role in modulating IRS-1 activity. HCV genotype 2a infection significantly down-regulates the expression of TSC1/TSC2, which in turn results in activation of downstream mTOR and S6K1[38]. Phosphorylation of IRS-1 at Ser^{1101} *via* the mTOR-S6K1 pathway may release IRS-1 from intracellular complexes, thereby enabling its degradation[41]. HCV significantly increases Ser^{1101} phosphorylation of IRS-1, which enables its degradation[38].

A decrease in expression of IRS-1 and IRS-2, in patients with HCV infection has also been reported[35]. Down-regulation of IRS-1 and IRS-2 was also seen in HCV core-transgenic mice livers and HCV core-transfected human hepatoma cells[35]. HCV core up-regulated suppressor of cytokine signaling 3 (SOCS3) and caused ubiquitination of IRS-1 and IRS-2. HCV core-induced

down-regulation of IRS-1 and IRS-2 was not seen in *SOCS3(-/-)* mouse embryonic fibroblast cells, indicating the important role played by SOCS3 in mediating down regulation of IRS-1[35]. There have been reports that HCV genotypes might play an important role in deciding the pathway by which it impairs insulin signaling. It has been shown that the core protein of HCV genotype 3a promoted IRS-1 degradation through the downregulation of PPARγ and by upregulating the SOCS7, the core protein of genotype 1b activated the mTOR[36].

TNF-α, released in an excess may promote phosphorylation of serine residues of IRS-1 eventually leading to the downregulation of downstream insulin signaling molecule Akt. HCV core protein increases the expression level of TNF-α and promotes insulin resistance[42].

IMPAIRED LIPID AND GLUCOSE METABOLISM BY HCV

Insulin resistance is strongly influenced by abnormalities in lipid metabolism. Any dysfunction of the lipid metabolism triggers lipotoxicity through the production of free fatty acids thereby promoting insulin resistance[43]. HCV core protein down-regulates microsomal triglyceride transfer protein, an enzyme that mediates lipid translocation to the endoplasmic reticulum membrane and decreases the assembly of very low density lipoproteins[44]. It has been observed that HCV promotes fatty acid synthesis by the upregulation of lipogenic gene sterol regulatory element binding protein 1c which promotes the transcriptional activation of other lipogenic genes like acetyl CoA carboxylase, ATP citrate lyase, hydroxymethylglutaryl CoA reductase[45].

HCV infection promotes the expression of gluconeogenic genes namely, glucose 6 phosphatase (G6P) and phosphoenolpyruvate carboxykinase 2 (PCK2) resulting in increased glucose production and enhanced insulin resistance[46,38]. HCV also down regulates the expression of GLUT4, which is necessary for uptake of glucose. This results in a decreased glucose uptake and increased plasma glucose, leading to development of insulin resistance[38].

A schematic showing how HCV interferes with insulin signaling pathway, leading to insulin resistance is presented in (Figure 1). HCV modulates functioning of IRS-1 *via* multiple mechanisms, including up regulation of Ser^{312} or Ser^{1101} phosphorylation which leads to degradation of IRS-1. HCV also upregulates SOCS3 and down regulates TSC1/TSC2 leading to blocking of insulin signaling. HCV infection leads to increased gluconeogenesis *via* up regulation of G6P and PCK2. GLUT-4, and GLUT-2 expression is also down regulated by HCV leading to decreased glucose uptake. Overall, all these alterations by HCV leads to development of insulin resistance.

INSULIN RESISTANCE AND LIVER DISEASE PROGRESSION

The metabolic syndrome is a constellation of problems that includes insulin resistance, obesity, hypertension, and hyperlipidemia[47]. Increasingly, components of the metabolic syndrome are being linked to various forms of cancer, including the risk of developing HCC. IR is induced by HCV-4 irrespective of severity of liver disease. IR starts early in infection and facilitates progression of hepatic fibrosis and HCC development[47]. HCC patients showed higher IR frequency, and moderate to high viral load associated with high HOMA-IR in CHC and HCC[47]. Insulin resistance associates with a higher risk of HCC in cirrhotic HIV/HCV-co-infected patients also[48]. There are many causes of HCC, and nonalcoholic fatty liver disease (NASH) is emerging as a leading risk factor owing to the epidemic of obesity and T2DM. The mechanisms leading to HCC in obesity and T2DM likely involve interactions between several signaling pathways, many of which are modulated by HCV infection, and also include oxidative stress, inflammation, oncogenes, adiponectins, and insulin resistance associated with visceral adiposity and diabetes[49].

Insulin resistance and subsequent hyperinsulinemia are highly associated with fatty liver disease and is an important risk factor for the progression of fibrosis in CHC[50,51]. From metabolic aspect, HCV infection resembles NASH in numerous features, such as the presence of steatosis, serum dyslipidemia, and oxidative stress in the liver[52]. On the other hand, there are noticeable differences between hepatitis C and NASH, in the fact that HCV modulates cellular gene expression and intracellular signal transduction pathways, while such details have not been noted for NASH. HCV core protein expression leads to the development of progressive hepatic steatosis and HCC in transgenic mice[53]. Hepatic steatosis is known to occur at a high rate (40%-86%) in chronic HCV patients, and a close relationship between steatosis and intrahepatic core protein expression has been noted[54]. Insulin resistance is a prominent mechanism linking steatosis and fibrogenesis although this link is complex and not properly understood.

CLINICAL IMPLICATIONS OF HCV-MEDIATED INSULIN RESISTANCE

Several epidemiological, clinical and experimental data show that HCV plays a direct role in perturbing glucose metabolism, leading to both insulin resistance and diabetes[28-30]. Curing HCV results in the amelioration of insulin resistance and decreased incidence of diabetes after the end of therapy[55,56]. In the only trial that used the antidiabetic metformin[57], only a marginal, nonsignificant increase of the SVR rate was observed, despite an increased virological response after 4 wk of triple therapy. The data reported in a study using different schedules containing the antiglycaemic PPAR-γ agonist pioglitazone[58] are discouraging. Overall, the administration of insulin sensitizers together with the standard of care has not only failed to improve the virological response to therapy, but has also fallen short of providing much use-

ful insight into the mechanisms linking reduced response to insulin resistance[59]. Early sulfonylureas although useful in lowering blood glucose level, were associated with significant off-target effects, and the biguanide phenformin was discontinued due to adverse events[60]. Although metformin is in the same drug class, it has a better safety profile and is now recommended as first-line treatment of diabetes during HCV infection.

THERAPEUTIC APPROACHES AND FUTURE GOALS

Treatment for HCV induced insulin resistance is highly linked with anti-viral treatment. Treatment of chronic HCV infection has 2 goals. The first is to achieve SVR (*i.e.*, sustained eradication of HCV, which is defined as the persistent absence of HCV RNA in serum 6 mo or more after completing antiviral treatment). The second goal is to prevent progression to cirrhosis, HCC, and decompensated liver disease requiring liver transplantation. The treatment of HCV has evolved over the years. Current treatment options include combination therapy consisting of ribavirin and pegylated IFN. Protease inhibitors are emerging as a third feature of combination therapy. The sustained antiviral response rate in treatment of chronic HCV infection with IFN-α and ribavirin is limited (about 30%-40%)[8,9]. Boceprevir and telaprevir protease inhibitors have been shown to exhibit significantly higher rates of SVR against HCV genotype 1 (65%-75%) as compared with peginterferon-ribavirin alone[10,11]. More recently, sofosbuvir has also been used for treatment along with ribavirin, with significant increased SVR[61]. However, use of these antiviral agents display higher incidence of adverse events, such as rash, gastrointestinal disorders, and anemia. Thus, development of therapies with less side effects is desirable.

The prevalence of HCV antibodies in the type 2 diabetic population ranges between 1.78% and 12.1%[62]. Several cross-sectional studies have found a higher prevalence of HCV antibodies in type 2 diabetic patients than expected in the general population[62,63]. Early phase and total insulin secretion are determined using oral glucose tolerance testing (OGTT), Insulin sensitivity was measured directly by steady-state plasma glucose concentration during insulin suppression test. Fasting plasma glucose $\geqslant$ 126 mg/dL or 2-h plasma glucose > 200 mg/dL during OGTT are generally used as criteria for diagnosis of diabetes[64]. Well controlled DM was defined when the HbA1c level was < 7%. Agents used in diabetic therapy include the following: sulfonylureas, biguanides, alpha-glucosidase inhibitors, thiazolidinediones, Meglitinide derivatives *etc*[60]. Although effective in reducing blood glucose levels, early sulfonylureas were associated with significant off-target effects, and the biguanide phenformin was discontinued due to adverse events[60]. Although metformin is in the same drug class, it has a better safety profile and is now recommended as first-line treatment. However, many patients require additional glucose control treatment with an agent that has a complementary mechanism of action like metformin. Some common drugs used for treatment of T2DM available in the market include metformin oral, actos oral, Byetta subQ, Janu*via* oral, *etc*.

Another possible way of reversing insulin resistance would be *via* targeting the signaling components in the insulin signaling pathway modulated by HCV. For instance, we have shown that HCV up regulates phospho-S6K1, which stimulates degradation of IRS-1[38]. Thus, targeting phospho-S6K1 would be a target against HCV induced insulin resistance. These studies have not been done yet, so at this time it will be difficult to comment on the predictive outcome on reversal of insulin resistance. Use of specific inhibitors of SOCS-3, which may become useful to correct resistance to both insulin and IFN-α, are not available for clinical use. Alternatively, one may envision inhibiting TNF-α by administering infliximab or similar agents. IR also results from uncontrolled diet and life style. Regulation of weight, diet, and life style management will also be key in managing IR.

Abstract

AIM: To minimize the expansion of pancreatic mesenchymal cells *in vitro* and confirm that β-cell progenitors reside within the pancreatic epithelium.

METHODS: Due to mesenchymal stem cell (MSC) expansion and overgrowth, progenitor cells within the pancreatic epithelium cannot be characterized *in vitro*, though β-cell dedifferentiation and expansion of MSC intermediates *via* epithelial-mesenchymal transition (EMT) may generate β-cell progenitors. Pancreatic epithelial cells from endocrine and non-endocrine tissue were expanded and differentiated in a novel pancreatic epithelial expansion medium supplemented with growth factors known to support epithelial cell growth (dexamethasone, epidermal growth factor, 3,5,3'-triiodo-l-thyronine, bovine brain extract). Cells were also infected with a single and dual lentiviral reporter prior to cell differentiation. Enhanced green fluorescent protein was controlled by the rat *Insulin 1* promoter and the monomeric red fluorescent protein was controlled by the mouse *PDX1* promoter. In combination with lentiviral tracing, cells expanded and differentiated in the pancreatic medium were characterized by flow cytometry (BD fluorescence activated cell sorting), immunostaining and real-time polymerase chain reaction (PCR) (7900HT Fast Realtime PCR System).

RESULTS: In the presence of 10% serum MSCs rapidly expand *in vitro* while the epithelial cell population declines. The percentage of vimentin$^+$ cells increased from 22% ± 5.83% to 80.43% ± 3.24% (14 d) and 99.00% ± 0.0% (21 d), and the percentage of epithelial cells decreased from 74.71% ± 8.34% to 26.57% ± 9.75% (14 d) and 4.00% ± 1.53% (21 d), $P < 0.01$ for all time points. Our novel pancreatic epithelial expansion medium preserved the epithelial cell phenotype and minimized epithelial cell dedifferentiation and EMT. Cells expanded in our epithelial medium contained significantly less mesenchymal cells (vimentin$^+$) compared to controls (44.87% ± 4.93% *vs* 95.67% ± 1.36%; $P < 0.01$). During cell differentiation lentiviral reporting demonstrated that, PDX1$^+$ and insulin$^+$ cells were localized within adherent epithelial cell aggregates compared to controls. Compared to starting islets differentiated cells had at least two fold higher gene expression of PDX1, insulin, PAX4 and RFX ($P < 0.05$).

CONCLUSION: PDX1$^+$ cells were confined to adherent epithelial cell aggregates and not vimentin$^+$ cells (mesenchymal), suggesting that EMT is not a mechanism for generating pancreatic progenitor cells.

Key words: Differentiation; Epithelial; Epithelial-mesenchymal transition; Mesenchymal; PDX1; Insulin; Pro-

genitor; Vimentin

Core tip: Previously, we demonstrated that mesenchymal stem cells could be expanded from human endocrine and non-endocrine pancreas cell fractions *in vitro*. However, we were unable to complete cell differentiation of mesenchymal cell intermediates to functional endocrine cells. In this study we utilized a novel cell culture medium to prevent epithelial cell de-differentiation and mesenchymal cell expansion. After epithelial cell expansion in this medium cells were differentiated *via* our previously described protocol and we confirmed by lineage tracing, flow cytometry, immunostaining and real-time polymerase chain reaction that islet progenitors reside in the pancreatic epithelium and are not derived *via* a mesenchymal cell intermediate.

INTRODUCTION

Islet transplantation is an attractive alternative to daily insulin injections to achieve a more physiological means for restoring glucose homeostasis[1-3]. Identifying and understanding the origin of a potential human β-cell progenitor could alleviate the current shortage of donor islets and contribute to the overall knowledge of β-cell regeneration. However, the study of β-cell progenitors is fraught with controversy, as several conflicting models and mechanisms describing the origin and existence of these progenitor cells have been proposed. Despite lineage tracing experiments utilizing transgenic mouse models[4-6] the exact origin of β-cell progenitors residing within the pancreas is yet to be elucidated. For example β-cell progenitors have been proposed to originate from: β-cell replication[4], acinar cell transdifferentiation[7,8], ductal cell transdifferentiation[9-12], pancreas derived multipotent precursors[13], pluripotent islet survivor cells[14] and β-cell dedifferentiation with expansion of mesenchymal stem cell (MSC) intermediates *via* epithelial mesenchymal transition (EMT)[15-20].

Previously we reported[21] that MSCs, also referred to as multi-potent stromal cells[22], could be expanded 12-fold from human islet depleted pancreatic tissue (IDPT) that remains following islet isolation. We demonstrated that these pancreatic MSCs could be partially differentiated into islet-like cells. However, in a follow up study[23] we could not restore an epithelial phenotype during tissue culture or generate functional endocrine cells. We hypothesized that this was due in part to our experimental culture conditions, which favored pancreatic MSC expansion and negatively selected pancreatic epithelial cells.

In this study we report that, during *in vitro* pancreatic MSC expansion, epithelial cells also proliferate and when these epithelial cells are enriched and differentiated, this cell population expresses developmental transcription factors indicative of a β-cell progenitor such as PAX4 and RFX6[24-26]. Therefore, to maintain epithelial cell phenotype and allow long-term study of this cell population *in vitro,* we utilized a pancreatic epithelial expansion medium that minimized epithelial cell dedifferentiation and MSC overgrowth in combination with our differentiation protocol[21,23]. Furthermore, by utilizing single and dual lentiviral reporters where, enhanced green fluorescent protein (EGFP) is controlled by the rat *Insulin 1* (Ins1) promoter and monomeric red fluorescent protein (mRFP) is controlled by the mouse *PDX1* promoter[26] we determined that PDX1$^+$ cells observed after 25 d post-differentiation were epithelial cells. Unlike the reversible (EMT) model first described by Gershengorn *et al*[15] and the dedifferentiation of β-cells then replication of β-cell-derived cells described by Russ *et al*[20], we propose that β-cell progenitors reside within the human pancreatic epithelium and that these cells have the potential to respond favorably to *in vitro* differentiation without dedifferentiation into a MSC intermediate *via* EMT. Overall, we report a novel cell culture media that promotes pancreatic epithelial cell survival and minimizes MSC overgrowth, and report that PDX1$^+$ cells observed 25 d post-differentiation are epithelial cells.

MATERIALS AND METHODS

Cell expansion and differentiation

Human islets (n = 9) and IDPT (n = 13) were obtained from the Edmonton Clinical Islet Transplant Program (University of Alberta and Alberta Health Services). Written, informed, consent was provided by donor relatives and all protocols were approved by the UofA Research Ethics Office. Average donor age was 54 (30-71 years) and islet purity assessed by dithizone staining ranged between 10%-40%. IDPT (< 5% insulin positive cells) was obtained following removal of islets by density gradient purification[21,23,27]. Upon receipt, IDPT was cultured in Roswell Park Memorial Institute (RPMI) 1640 medium (Invitrogen, Burlington, ON Canada) supplemented with 0.5% w/v fraction V bovine serum albumin (Sigma-Aldrich, Oakville, ON Canada), 1% insulin-transferrin-selenium (Sigma-Aldrich) and 100 U penicillin/1000 U streptomycin (Invitrogen). Islets were cultured in Connaught Medical Research Laboratories-1066 medium (Invitrogen) supplemented with 10% fetal bovine serum (FBS, Invitrogen), 2 mmol/L L-glutamine (Invitrogen), 10 mmol/L hydroxyethyl piperazineethanesulfonic acid (HEPES) and 100 U penicillin/1000 U streptomycin (Invitrogen). Both IDPT and islets were cultured in 150 mm non-tissue culture treated plates (Corning, NY, United States) and maintained for 24-48 h at 37 ℃ in 5% CO_2 and 95% air. Following culture, single cell suspensions were derived by, dissociating islets or cellular aggregates derived from the cultured IDPT with 0.05% trypsin, 0.5 mmol/L ethylenediaminetetraacetic acid (Invitrogen) in 1X PBS.

Single cell preparations were cultured and expanded in pancreatic MSC medium or pancreatic epithelial expansion medium. MSC medium is composed of RPMI-1640 supplemented with 10% FBS, 10 mmol/L HEPES, 1 mmol/L sodium pyruvate (Invitrogen), 71.5 μmol/L β-mercaptoethanol (Sigma-Aldrich), 20 ng/mL epidermal growth factor (EGF, R&D, Minneapolis, MN United States), 20 ng/mL fibroblast growth factor (Invitrogen) and 100 U pencillin/1000 U streptomycin[21,23,27]. Cell confluence was achieved in 10-14 d and cells required passaging every 7 d after that. From both islets and IDPT at the 2nd and 3rd passage we routinely generate a cell population with MSC characteristics as previously described[21,23,27]. To preserve epithelial cell phenotype, single cells derived from islets or the IDPT were also cultured and expanded in a pancreatic epithelial expansion medium either on 150 mm tissue culture treated plates (Corning) or 12 mm poly-l-lysine coated cover slips (BD Biosciences) placed in 24 well tissue culture treated plates (Corning). Pancreatic epithelial expansion medium is composed of Dulbecco's Modified Eagle's Medium/F12 (Invitrogen) supplemented with 0.5% FBS, 0.1 μg/mL EGF, 0.4 μg/mL dexamethasone (Sigma-Aldrich), 14 mg/mL bovine brain extract (Lonza, Walkersville, MD United States), 0.05 μmol/L triiodo-l-thryonine sodium salt (Sigma-Aldrich), 0.1 mg/mL soybean trypsin inhibitor (US Biological, Swampscott, MA, United States), 0.5X ITS+premix (BD Biosciences) and 100 U penicillin/1000 U streptomycin. Expanded cell populations were subsequently differentiated using a multi-step protocol previously described[21,23,27,28] and characterized by flow cytometry, immunohistochemistry and real-time polymerase chain reaction (PCR). For differentiation, the cell monolayer was treated with 20 ng/mL OncostatinM (R&D) for 72 h. In steps 2 and 3 the medium was supplemented with 10 mmol/L nicotinamide (Sigma-Aldrich) for 72 h followed by 10 mmol/L nicotinamide and 10 nmol/L exendin4 (Sigma-Aldrich) for another 72 h. In step 4, 10 ng/mL of transforming growth factor-β1 (TGFβ-1; EMD Millipore, Billerica, MA, United States) was included with nicotinamide and exendin4 for 3-10 d with media changes every 72 h. Cell monolayers were detached with trypsin and aggregated by reconstituting cells at 125000 cells/mL in medium supplemented with nicotinamide, exendin4, TGFβ-1, 0.5X ITS+ premix (BD Biosciences, Beford, MA United States) and transferred to 100 mm ultra-low attachment non-tissue culture treated plates (Corning).

Immunohistochemistry

Double immunofluorescence (IF) analysis was performed on paraffin sections of single cells that had first been fixed with 1% formalin (Fisher Scientific, Nepean, ON Canada) and embedded in 2% low melting point agarose (Sigma-Aldrich) or cells which had been differentiated on 12 mm poly-l-lysine cover slips (BD Biosciences). Paraffin sections were processed and immunostained as previously described[23,28]. Cover slips were fixed in 1% formalin for 30 min in the dark at 4 ℃, and then washed twice with 5% normal goat serum (NGS) in PBS. For antibodies requiring permeabilization, 0.3% saponin (Sigma) in PBS was applied for one minute, and another two washes of 5% NGS followed. All cover slips were then blocked with 20% NGS for 1 h in the dark. Primary antibodies were diluted in 5% NGS at the following concentrations: 1/200 anti-epithelial cell adhesion molecule (EpCAM, Stem Cell Technologies, Vancouver, BC Canada), 1/100 anti-vimentin (Dako, Mississauga, ON Canada), 1/25 anti-human proliferating cell nuclear antigen (PCNA, Invitrogen), 1/50 anti-CK19 (Dako), 1/5000 anti-glucagon (Sigma-Aldrich), 1/1000 anti-insulin (Dako), 1/1000 anti-pancreatic polypeptide (Dako), 1/1000 anti-somatostatin (Dako), 1/1000 anti-PDX1 (Abcam, Cambridge, MA, United States). All appropriate species-specific secondary antibodies were AlexaFluor 488 or 594 conjugates (Molecular Probes, Eugene, OR, United States) and diluted 1/200 in 5% NGS. Slides and or cover slips were cover-slipped with ProLong Gold anti-fade reagent with 4',6-diamidino-2-phenylindole (Invitrogen) to counter stain nuclei and preserve fluorescence. Negative controls were incubated without primary antibodies and positive controls were sections of normal human and infant pancreas. All slides were visualized with an Axioscope Ⅱ equipped with AxioCam MRC and analyzed with Axiovision 4.6 (Carl Zeiss, Gottingen, Germany).

Flow cytometry

Single cells from islets and IDPT were stained and analyzed by fluorescence activated cell sorting (FACS) using the FACS Calibur (BD Biosciences) and Cell Quest Pro software and compared to matched isotype controls[23,27]. Cells were permeabilized with 0.3% saponin for 60 min and stained with 1/10 vimentin-FITC, 1/5 EpCAM-FITC and 1/15 PCNA-647 (BioLegend, San Diego, CA, United States). Isotype controls were; IgG1-FITC, IgG2a-FITC and IgG2a-647. Values are expressed as mean percent ± SE.

RNA isolation and real-time PCR

Islets and IDPT cells prior to cell culture, during expansion and post differentiation were preserved in Trizol reagent (Invitrogen) and stored at -80 ℃. RNA was extracted in combination with the RNeasy Mini Kit (Qiagen, Mississauga, ON Canada) as per the manufacturer's protocol. cDNA was synthesized as described[21]. Real-time PCR was performed using the "TaqMan gene expression assay" (Applied Biosystems, Invitrogen) and a 7900HT Fast Realtime PCR System (Applied Biosystems). Relative quantification was performed by utilizing the comparative Ct method and all results were compared to the control samples for each time point after normalizing to an endogenous control (beta 2-microglobulin) using the Relative Quantification Manager software (Applied Biosystems). Values are expressed as mean percent ± SE. cDNA negative controls contained water in place of RNA and RT-PCR negative controls contained water in place of cDNA, β2-microglobulin (β2m) ensured cDNA integrity.

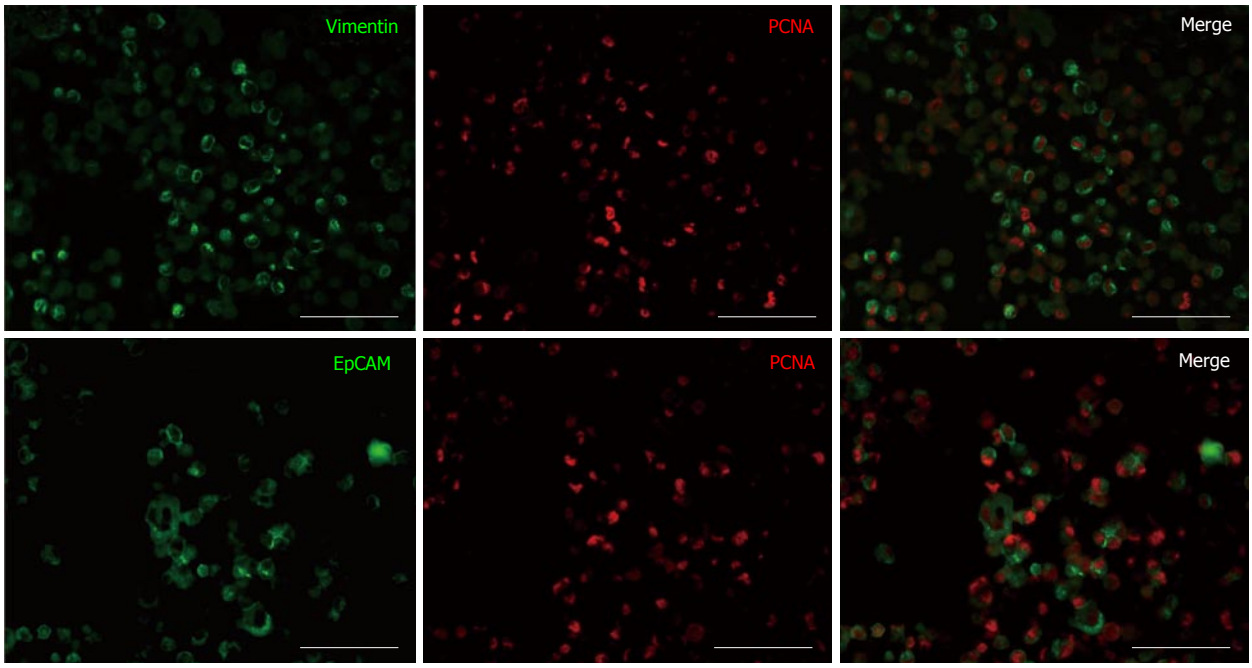

Figure 1 Double immunofluorescence staining of islet depleted pancreatic tissue expanded cells after 14 d in culture. Cells are positive for vimentin (green), EpCAM (green) and PCNA (red). Both vimentin and EpCAM positive cells are positive for PCNA staining (merged) and proliferating. Scale bars are 50 μm. EpCAM: Epithelial cell adhesion molecule; PCNA: Proliferating cell nuclear antigen.

Lentivirus infection

Lentiviral vectors were kindly provided by Dr. James D. Johnson (University of British Columbia, Vancouver, BC, Canada) and described in detail by Szabat *et al*[26]. We received the following vectors: dual reporter mouse PDX1 promoter-mRFP/rat Ins1 promoter-EGFP, single reporter mouse PDX1 promoter-mRFP, single reporter rat Ins1 promoter-EGFP as well as the structural and envelope vectors. Virus was produced by transfection of 293T cells that were a gift from Dr. Patrick MacDonald (University of Alberta, Edmonton, AB, Canada) utilizing FuGENE6 Transfection Reagent (Roche Diagnostics, IN, United States) and the protocol first described by Dr. Garry Nolan Lab (http://www.stanford.edu/group/nolan/index.html). Virus was titred using the rat INS1 cell line (a gift from Dr. Patrick MacDonald) and titres were between 2-4 × 10^6 TU/mL with an infection efficiency of 40%-70%. Single cells from human islets or IDPT were plated at a density of 0.3 × 10^6 cells/well onto a 24 well plate that contained 12 mm poly-l-lysine cover slips and cultured in pancreatic epithelial expansion medium. Cells were allowed to adhere and infected at a multiplicity of infection of < 1. Protein expression (fluorescence) was monitored daily and peak fluorescence of human primary cells was routinely detected between 4-7 d post infection. Differentiation of infected primary cells was started at 4-7 d post-infection. Absolute counts of positive mRFP and EGFP cells were counted using ImageJ software[29].

Statistical analysis

Data is expressed as mean ± SE. Statistical comparisons were performed with STATA11 (StataCorp LP, College Station, TX) using one-way analysis of variance and Bonferroni post-hoc test. Acceptable level of significance was considered $P < 0.05$.

RESULTS

Epithelial cells from IDPT proliferate in pancreatic MSC medium

Previously, we demonstrated that during *in vitro* cell expansion of cells from IDPT, the proportion of epithelial cells decreased while vimentin positive cells (MSCs) significantly increased[21,23]. In this study, to determine if epithelial cells were still capable of proliferation, we assessed cell proliferation after 14 d in culture *via* dual IF staining and flow cytometry. Cells that were formalin fixed and embedded in agarose were stained with antibodies against EpCAM or vimentin (MSC) then co-stained for PCNA. After 14 d in culture we confirmed that vimentin$^+$ cells were the predominant cell population and these cells were PCNA$^+$ and proliferating (Figure 1). A small proportion of epithelial cells (EpCAM$^+$) were still present and were also PCNA$^+$ thus still proliferating (Figure 1). The proportion of vimentin and EpCAM cells that were positive for PCNA were quantified by FACS analysis at Time 0, 14 and 21 d in culture (Table 1). During cell expansion; the percentage of vimentin$^+$ cells proliferating (PCNA$^+$) increased from 22% ± 5.83% to 80.43% ± 3.24% (14 d) and 99.00% ± 0.0% (21 d), and the percentage of proliferating epithelial cells decreased from 74.71% ± 8.34% to 26.57% ± 9.75% (14 d) and 4.00% ± 1.53% (21 d), $P < 0.01$ for all time points. Therefore, MSC expansion culture conditions favor MSC expansion over epithelial cells

Table 1 Cell composition and proportion of proliferating cell nuclear antigen positive cells during pancreatic cell expansion from islet depleted pancreatic tissue

Days in culture	Percent positive				
	Vimentin	EpCAM	PCNA	Vim/ PCNA	EpCAM/ PCNA
0 (n = 7)	22.71 ± 4.93	87.57 ± 3.96	73.57 ± 8.42	22.00 ± 5.83	74.71 ± 8.34

21 (n = 3)	99.00 ± 0.0[b]	3.33 ± 0.88[b]	99.00 ± 0.0	99.00 ± 0.0[b]	4.00 ± 1.53[b]

Data represent means ± SE. Statistical analysis of differences between the groups was performed with STATA11 (StataCorp LP, College Station, TX) using one-way analysis of variance and Bonferroni post-hoc test. [b]$P < 0.01$ compared to Time 0. EpCAM: Epithelial cell adhesion molecule; PCNA: Proliferating cell nuclear antigen.

Table 2 Preservation of epithelial cells during culture in a defined epithelial medium

Condition	Percent positive	
	Vimentin	EpCAM
Epithelial Medium (n = 7)	44.87 ± 4.93[b]	24.10 ± 8.60
MSC Medium (n = 3)	95.67 ± 1.36[b]	17.43 ± 6.88

Data represent means ± SE. Statistical analysis of the differences between the groups was calculated with STATA11 (StataCorp LP, College Station, TX) using one-way analysis of variance and Bonferroni post-hoc test. [b]$P < 0.01$ for vimentin positive cells expanded in epithelial medium *vs* MSC medium. EpCAM: Epithelial cell adhesion molecule; MSC: Mesenchymal stem cell.

Epithelial cell phenotype is preserved when IDPT is cultured in defined pancreatic epithelial expansion medium

Our MSC expansion medium limits pancreatic epithelial cell growth *in vitro*[21,23,27]. We determined that sorted epithelial cells could expand and divide in MSC medium but vimentin$^+$ MSCs were still the predominating cell population (not shown). By reducing the FBS content from 10% to 0.5% and including growth factors known to promote epithelial cell survival under reduced serum conditions such as EGF, 3,5,3'-triiodo-l-thyronine and bovine brain extract[30-32] we were able to minimize MSC overgrowth and preserve the epithelial cell phenotype (Table 2). IDPT cells cultured in pancreatic epithelial expansion medium contained significantly less vimentin$^+$ cells (44.87% ± 4.93%) than cells expanded in MSC expansion medium (95.67% ± 1.36%; $P < 0.01$). Therefore, pancreatic epithelial expansion medium was used to trace cell fate and was supplemented for cell differentiation.

Culture in differentiation medium increases the proportion of PDX1 and insulin positive cells

To determine the progenitor cell content within the pancreatic epithelium, cells from dissociated islets and IDPT were seeded onto poly-l-lysine coated cover slips placed in 24 well plates with pancreatic epithelial expansion medium. Prior to differentiation cells were infected with, the PDX1-mRFP-Ins1-EGFP dual reporter, PDX1-mRFP or Ins1-EGFP single reporter lentivirus then characterized *via* IF staining and real-time PCR. Fluorescence was detected between 4-7 d post infection in both islet and IDPT preparations, at which time differentiation was initiated. Controls were infected but not differentiated. During islet cell differentiation, cell aggregates formed throughout the cell monolayer. Within these adherent aggregates PDX1$^+$ (RFP) and insulin$^+$ (EGFP) expressing cells were observed (Figure 2A). In addition, both single positive (PDX1$^+$ or INS$^+$) and double positive (PDX1$^+$ INS$^+$) cells were observed (Figure 2A). In undifferentiated conditions fewer positive cells and cell aggregates were observed (Figure 2B). When analyzing image fields, in 4/4 cell preparations approximately twice as many PDX1$^+$ and insulin$^+$ cells were observed in differentiated conditions (51.25 ± 17.24 mRFP and 28.13 ± 9.34 EGFP) versus undifferentiated conditions (31.75 ± 10.83 mRFP and 14.50 ± 4.03 EGFP) as determined by absolute cell counts. Relative quantification of gene expression by real-time PCR (Figure 2C) confirmed this observation and demonstrated that differentiated islet cells compared to starting islets had increased expression of PDX1 ($P < 0.05$), insulin ($P < 0.01$) PAX4 ($P < 0.05$) and RFX6 ($P < 0.01$). A similar pattern was observed in differentiated (Figure 3A) and undifferentiated (Figure 3B) wells of cultured IDPT infected with PDX1-mRFP or PDX1-mRFP-Ins1-EGFP, although much less PDX1 and insulin expression (not shown) was observed compared to islet cell cultures.

PDX1 progenitor cells are localized within the pancreatic epithelium

To identify cells within the differentiated cell aggregates that were PDX1$^+$, and to confirm expression after lentiviral infection, cells were characterized by IF staining (Figures 4 and 5) utilizing the following antibodies: EpCAM, vimentin, CK19, PDX1, glucagon, insulin, pancreatic polypeptide and somatostatin. Cells positive for glucagon, pancreatic polypeptide and somatostatin, still remained after 25 d in culture compared to controls although these cells were infrequent and did not express PDX1$^+$ (not shown). PDX1$^+$ cells were shown to be negative for vimentin staining (Figure 4) and CK19 (not shown). PDX1$^+$ cells did however, co-stain with EpCAM (Figure 4) demonstrating that in our experimental conditions PDX1$^+$ cells are localized to the epithelial cell population. PDX1 and insulin expression was verified by, insulin and PDX1 primary antibody staining (Figure 5). Nuclear and cytoplasmic PDX1 staining (Figure 5) was observed while insulin staining was confined to the cytoplasm (Figure 5).

DISCUSSION

Although several recent human studies that involve lineage tracing[13,14,20,26] have been conducted, the debate continues as to the origin of human β-cell progenitors. Sev-

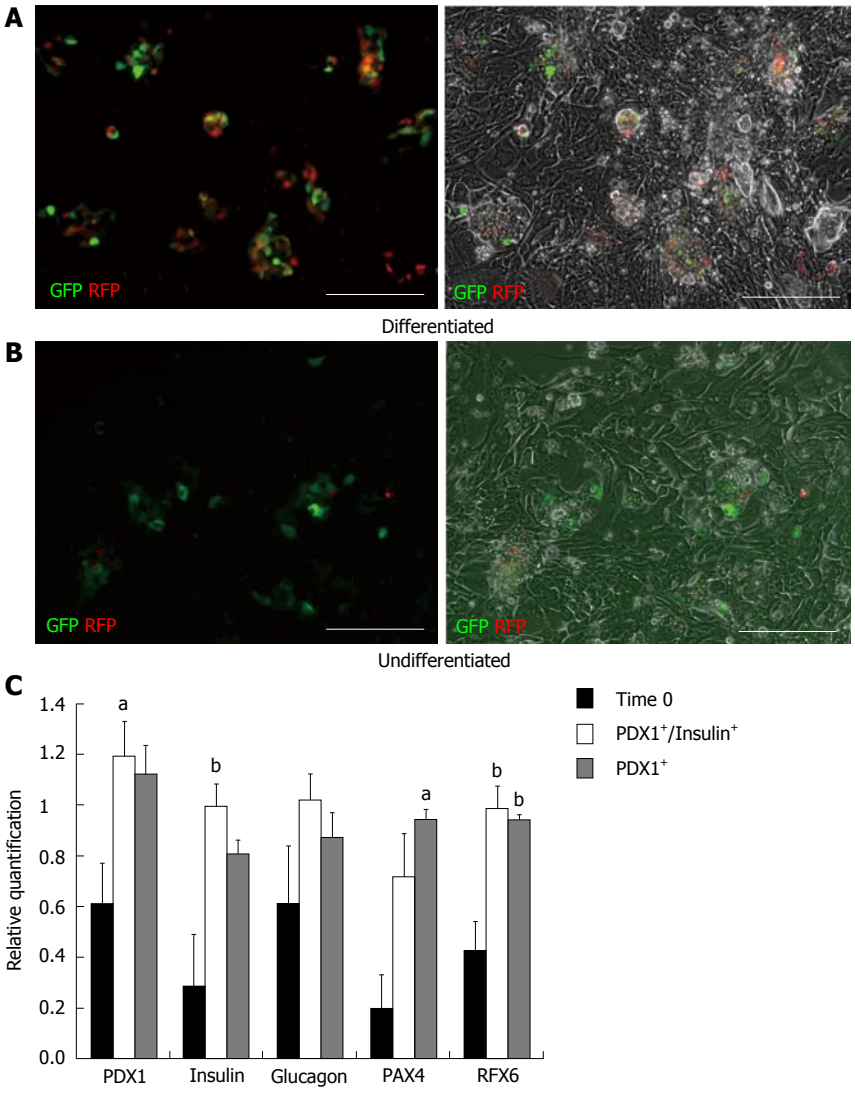

Figure 2 Comparison of differentiated and undifferentiated islet cells infected with PDX1-monomeric red fluorescent protein/insulin 1-enhanced green fluorescent protein. Islet cells cultured in differentiation medium (A) form adherent cell aggregates within the cell monolayer and insulin$^+$ (GFP) and PDX1$^+$ (RFP) expressing cells are localized within these cell aggregates. Islet cells cultured in control medium (B, undifferentiated) have fewer cell aggregates and insulin (GFP) and PDX1$^+$ (RFP) cells. Scale bars are 100 μm. Gene expression (C) of PDX1-monomeric red fluorescent protein (mRFP)/insulin-enhanced green fluorescent protein islet cells (PDX1$^+$ insulin$^+$, white bars; n = 7) and PDX1-mRFP infected islet cells (PDX1$^+$, grey bars; n = 4) post-differentiation compared to starting islet tissue (Time 0, black bars; n = 8) measured by real-time PCR. $^aP < 0.05$ and $^bP < 0.01$ compared to Time 0. RFP: Red fluorescent protein.

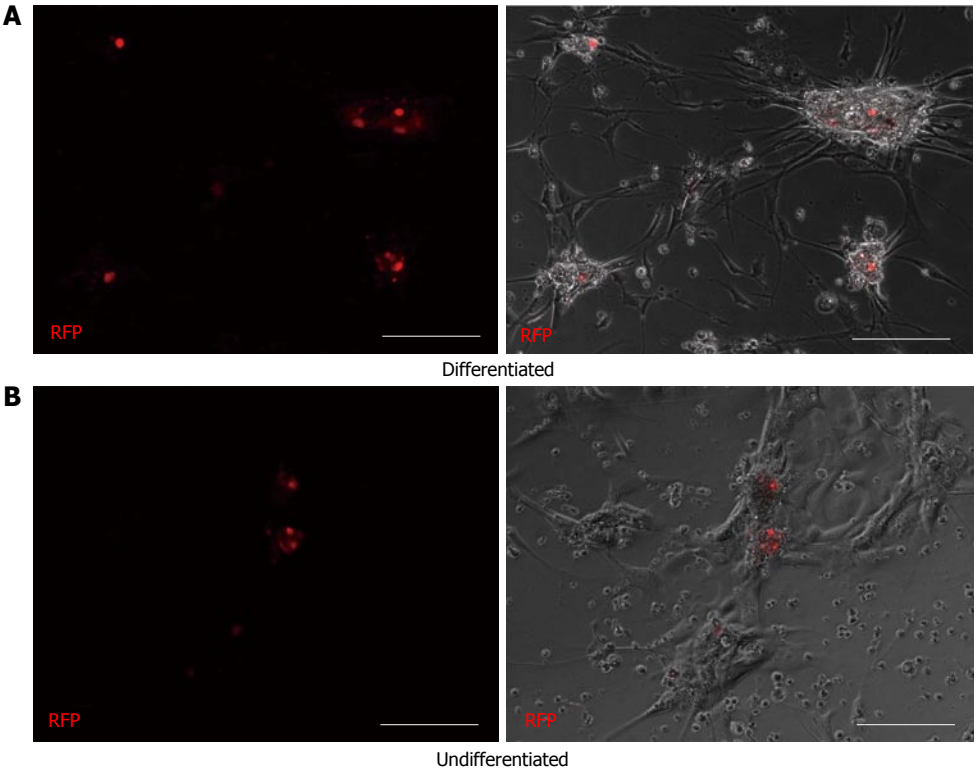

Figure 3 Comparison of differentiated (A) and undifferentiated (B) cells from the islet depleted pancreatic tissue infected with PDX1-monomeric red fluorescent protein. A few PDX1$^+$ cells (RFP) are visible within the adhered aggregates in the differentiated condition (A). Cell aggregates are absent in the undifferentiated cell conditions (B) and PDX1$^+$ cells are within the monolayer. Scale bars are 100 μm. RFP: Red fluorescent protein.

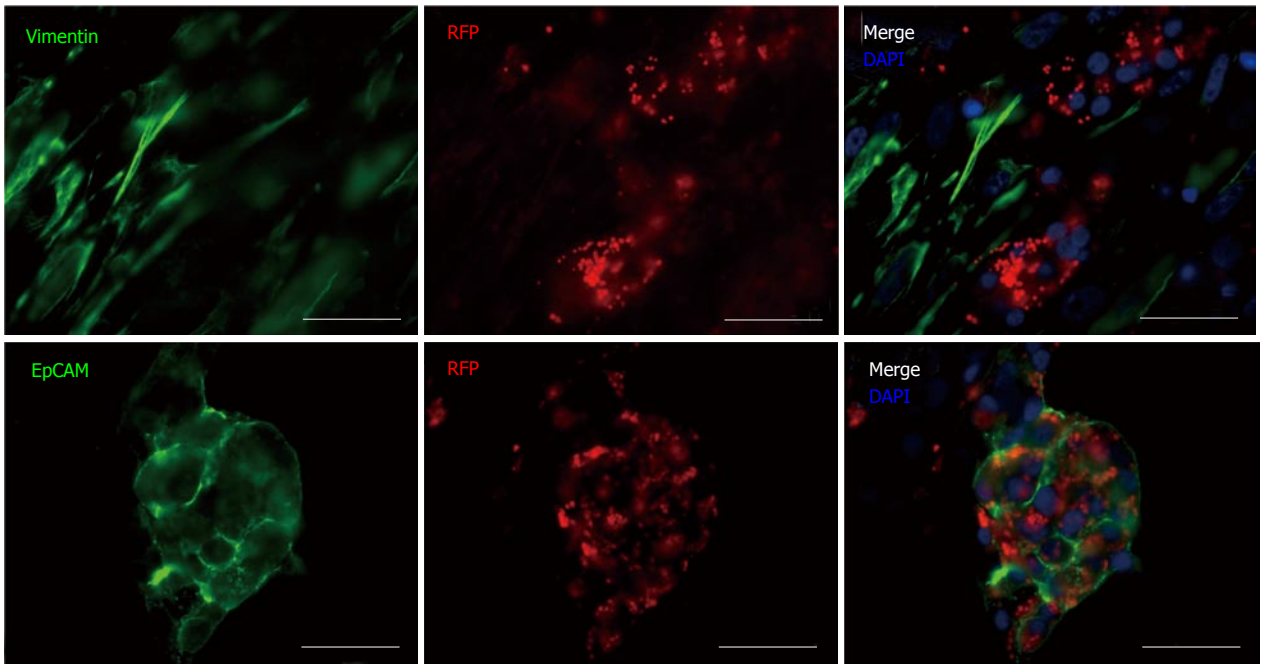

Figure 4 Immunofluorescence staining of differentiated PDX1- monomeric red fluorescent protein infected islet cells with primary antibodies to vimentin and epithelial cell adhesion molecule, with secondary antibodies conjugated to Alexa-488 (green). PDX1$^+$ positive cells (RFP) are not co-localized with vimentin (merged), but are co-localized with epithelial cell adhesion molecule. Nuclei are stained blue with DAPI. Scale bars are 20 μm. RFP: Red fluorescent protein; DAPI: 4',6-diamidino-2-phenylindole.

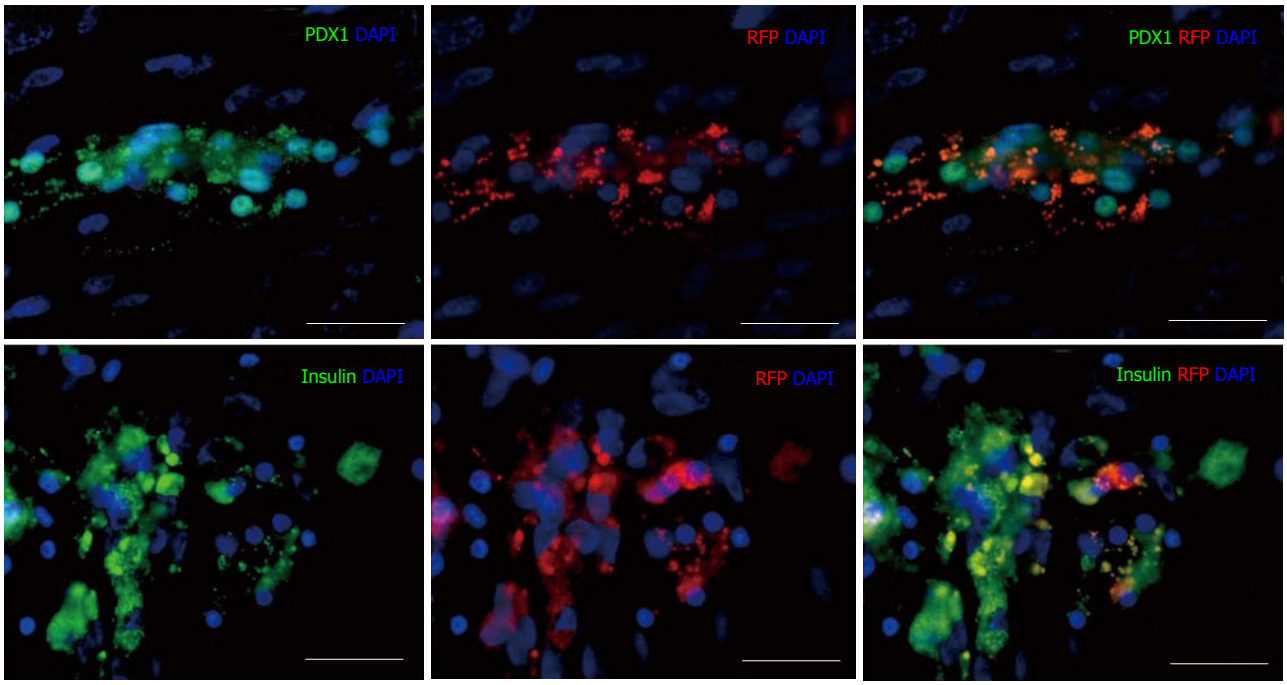

Figure 5 Immunofluorescence staining of differentiated PDX1-monomeric red fluorescent protein infected islets with primary PDX1 and insulin antibodies with secondary antibodies conjugated to Alexa-Fluor488 (green). PDX1$^+$ cells (RFP) nuclei stain positive with PDX1/Alexa-488 antibody confirming lentiviral expression. Insulin/Alexa-Fluor488 (green) stains insulin within PDX1$^+$ infected cells (yellow). Nuclei are stained blue with DAPI. Scale bars are 20 μm. RFP: Red fluorescent protein.

eral studies have proposed that β-cell progenitors can be derived from a mesenchymal cell intermediate *via* EMT. In our previous studies we were also able to expand MSCs from exocrine and endocrine cell explants[21,23]. We determined that when the culture medium contained 10% serum, pancreatic MSCs could be rapidly expanded from pancreatic cells and that these MSCs could be easily differentiated into mesoderm (bone, fat and cartilage)[21,28]. However, in those studies pancreatic MSCs could only be partially differentiated into endocrine cells and we were

unable to restore the epithelial cell phenotype or detect insulin protein by immunostaining[21,23]. We have since hypothesized that in our differentiation conditions it is the low percentage of epithelial cells, which remain after mesenchymal cell expansion, that respond favorably to our differentiation protocol[21,23] and not MSCs or a MSC intermediate. Thus, the dedifferentiation of islet or IDPT cells during long-term culture results in the loss of epithelial cells thus making this population difficult to follow *in vitro*.

In this study we utilized a reduced serum medium supplemented with growth factors known to support epithelial cells (EGF, 3,5,3'-triiodo-l-thyronine, bovine brain extract) and were able to minimize EMT and preserve the epithelial phenotype (Table 2). We determined that by preventing cell dedifferentiation and MSC overgrowth we could maintain the epithelial phenotype for greater than 25 d. If in fact epithelial mesenchymal transition[15,20] is a necessary process where progenitors or β-cells must dedifferentiate to replicate and then be redifferentiated into insulin producing cells then an alternate cell culture model must be employed. However, it is unclear if dedifferentiation, expansion then redifferentiation is a preferential model for increasing β-cells since β-cells generated in this model do not secrete physiologic levels of insulin compared to normal β-cells[15,20].

Lentiviral tracing[26] in combination with our pancreatic epithelial expansion medium, allowed us for the first time to observe morphological changes during *in vitro* differentiation without MSC overgrowth. Compared to lentiviral infected controls (undifferentiated) we have concluded that it is within the adherent differentiated cellular aggregates where PDX1$^+$ and insulin$^+$ cells reside. In addition, it is within these cellular aggregates where epithelial cells (EpCAM) that are PDX1$^+$ are located. More importantly we did not observe vimentin$^+$ or ductal epithelial cells (CK19$^+$) that were PDX1 or insulin positive within the cell aggregates. Although several citations have demonstrated that pancreatic ductal epithelial cells can generate new β-cells[9-12], we did not observe this in our differentiation model. In addition, the infrequent cells we observed that were pancreatic polypeptide, somatostatin, and glucagon positive were also negative for PDX1 and insulin. By relative quantification we observed increased gene expression of developmental transcription factors indicative of a β-cell progenitor[24-26]. Differentiated cells compared to starting islets had at least two fold higher expression of PDX1, insulin, PAX4 and RFX (Figure 2C).

In summary we describe a unique cell culture condition for long-term study of pancreatic epithelial progenitor cells that minimizes overgrowth of MSCs (vimentin$^+$) and dedifferentiation of epithelial cells through EMT. We confirmed that during differentiation *via* lentiviral reporting that PDX1$^+$ cells were confined to epithelial cell aggregates that form during differentiation and not vimentin$^+$ cells suggesting that EMT is not a mechanism for generating pancreatic progenitor cells. Future studies will be to determine overall function of differentiated cells.

ACKNOWLEDGMENTS

We thank the staff of the Edmonton Clinical Islet Transplant Program (Alberta Health Services) for providing islets and IDPT tissue, and Dr. James D. Johnson and Marta Szabat for providing lentiviral constructs. We thank Sheena Lesyk, Mohammed Ahmed, Alana Espheter, Lynnette Elder and Bethany Ostrowerka for technical assistance.

COMMENTS

Background

Islet transplantation is an attractive alternative to daily insulin injections. Identifying and understanding the origin of a potential human β-cell progenitor could alleviate the current shortage of donor islets and contribute to the overall knowledge of β-cell regeneration. However, the study of β-cell progenitors is fraught with controversy, as several conflicting models and mechanisms describing the origin and existence of these progenitor cells have been proposed.

Research frontiers

A popular model describing the origin of human β-cell progenitors that has been proposed is β-cell dedifferentiation and the expansion of a mesenchymal stem cell (MSC) intermediate *via* epithelial-mesenchymal transition (EMT). However, there has been limited success when redifferentiating these mesenchymal cells back into functional β-cells.

Innovations and breakthroughs

The authors previously demonstrated that MSCs, could be expanded 12-fold from human islet depleted pancreatic tissue that remained following islet isolation and demonstrated that these pancreatic MSCs could be partially differentiated into islet-like cells *in vitro*. However, in a follow up study the authors could not restore an epithelial phenotype or generate functional endocrine cells. The authors determined that the few remaining epithelial cells after MSC expansion were the cells that responded to the authors differentiation protocol. In these culture conditions MSC overgrowth prevented pancreatic epithelial progenitor expansion and differentiation. In this study the authors report that by using a novel pancreatic epithelial medium, MSC expansion and epithelial cell dedifferentiation can be minimized and pancreatic epithelial cell progenitors can be successfully expanded and differentiated.

Applications

This study demonstrates that β-cell progenitors reside in the pancreatic epithelium and that EMT should be inhibited *in vitro* to successfully expand and differentiate these progenitors. The authors conclude that EMT is not a mechanism for generating pancreatic progenitor cells.

Terminology

EMT occurs *in vitro* when epithelial cells de-differentiate and lose their phenotype. The resulting cells are MSCs otherwise known as multi-potent stromal cells.

Peer review

The authors describe a new method that could in the future allow for *in vitro* generation of insulin-producing cells. The work is well done and appropriately presented.

Abstract

AIM: To evaluate the safety of four insulin titration algorithms in a homogeneous population of insulin-naïve type 2 diabetic patients.

METHODS: We conducted a 24-wk, open, single-center study with 92 insulin-naïve type 2 diabetes patients who failed treatment with one or two oral drugs. The patients were randomized to one of the four following algorithms: LANMET (n = 26) and LANMET PLUS (n = 22) algorithms, whose patients received a fixed initial insulin dose of 10 U, and DeGold (n = 23) and DeGold PLUS (n = 21) algorithms, whose patients' initial insulin dose was based on their body mass index (BMI). In addition, patients in the PLUS groups had their insulin titrated twice a week from 2 to 8 U. In the other two groups, the titration was also performed also twice a week, but in a fixed increments of 2 U. The target fasting glucose levels for both groups was 100 mg/dL.

RESULTS: There was no significant difference in efficacy parameters. There was no significant difference when comparing moderate hypoglycemia events in algorithms starting with a 10 U fixed dose and algorithms based on BMI. However, there was a significant increase in moderate hypoglycemia events among the PLUS treated patients when the LANMET and DeGold algorithms were compared with the 2 fast-titration PLUS algorithms. We observed 12 hypoglycemia events in the first group, which corresponded to 0.94 events/patient per year, and we observed 42 events in the second group, which corresponded to 2.81 events/patient per year (P < 0.037). No further significant differences were observed when other comparisons between the algorithms were carried out.

CONCLUSION: Starting insulin glargine based on BMI is safe, but fast titration algorithms increase the risk of moderate hypoglycemia.

Key words: Type 2 diabetes; Insulin glargine; Basal insulin; Hypoglycemia; Titration algorithms

Core tip: To start insulin therapy in insulin naïve type 2 diabetes patients, a long-acting basal insulin, such as insulin glargine, is added once a day. The majority of algorithms determine insulin titration according to fasting plasma glucose levels, but the dosage differs at the initial dose, frequency and speed of adjustments. It is difficult to compare the different algorithms employed in trials with populations of different socio-economic strata and variable access to educational materials. Here, we compared the safety of different titration algorithms in a population that was homogeneous in terms of socio-economic strata and with the same degree of education in diabetes.

INTRODUCTION

Type 2 diabetes is characterized by insulin resistance and is associated with the incremental loss of pancreatic beta cell mass and/or function[1]. Patients who are initially capable of maintaining a good metabolic control using oral anti-diabetes drugs (OADs) frequently need to add insulin to their treatment over time[2]. The simplest way to begin insulin therapy is to add a long-acting basal insulin, such as insulin glargine, once per day[3].

Basal insulin therapy is an efficient glycemia-lowering treatment, provided it is delivered in the appropriate doses. Therefore, it must be carefully titrated until patients achieve the established fasting plasma glucose goal (FPG)[4]. Several titration algorithms have been validated in clinical trials, and they can be used to guide basal insulin dose adjustments. Most algorithms determine insulin titration according to FPG levels, but differ in the initial insulin dose, frequency, and speed of dose adjustments[5-7]. A new algorithm (DeGold) has been recently described, and it considers the degree of insulin resistance due to obesity and recommends initial doses ranging from 0.2 to 0.35 U/kg according to the patient's body mass index (BMI)[8].

The initial insulin dose is important for predicting whether a target can be reached and how long titration will take[4] before treatment is started. Treatment compliance may be jeopardized if the treatment period is too long and if patients do not see any significant changes in their FPG levels. The frequency and speed at which insulin doses are adjusted also vary according to the chosen algorithm. For example, in the AT.LANTUS trial with insulin Glargine, titration from 2 to 8 U weekly according to the FPG that was performed by physicians was compared to the increment of 2 U every 3 d until the FPG reached 100 mg/dL that was performed by the patients themselves. The results showed that titration performed by patients could be more effective in achieving A1C targets[6]. In the Canadian INSIGHT Trial, patients titrated their insulin Glargine dose by adding 1 U/d until they reached the target of 100 mg/dL FPG[5].

Provided it is employed correctly according to the "Treat to Target" concept, any algorithm can bring fasting glucose levels to normal and allow patients who are not in need of additional prandial therapy, like rapid acting insulin, to achieve the desired glycated hemoglobin (A1C) values[7].

Hypoglycemia may also be a factor in the achievement of a glycemic target. The occurrence of hypoglycemia events is not solely due to the effects caused by exogenous insulin[9] but is also fundamentally linked to other factors, including the level of education of diabetic patients, especially in regard to compliance to treatment and protective measures against hypoglycemia[10]. It is difficult to compare the efficacy and the safety of all different algorithms used in trials that have populations belonging to different socioeconomic levels and having different access to educative measures[4,7,10]. As such, we decided to compare the safety of different titration algorithms in a population that was homogeneous in terms of socioeconomic level and level of education in diabetes.

The main objective of the study was to evaluate the safety of four insulin glargine titration algorithms applied to a homogeneous sample of insulin-naïve type 2 diabetes patients and to compare the frequency of severe and moderate hypoglycemia (glycaemia < 56 mg/dL) events, the frequency of nocturnal symptomatic hypoglycemia, total number of hypoglycemic events, and serious adverse events. The efficacy parameters analyzed for each algorithm were the changes in A1C from baseline to study end, changes in FPG levels, weight variation during the study, insulin doses, time needed to reach the FPG target, and the proportion of patients who reached an A1C target between 7% and 7.5%, and below 7%.

MATERIALS AND METHODS

Population sample and experimental design

This was a 24-wk, single-centered, randomized, open study. We screened 125 patients diagnosed with type 2 diabetes, > 18 years old and BMI < 40 kg/m^2 who had been on stable treatment with one or two OADs for more than 3 mo, and A1C between 7% and 12%. The main criteria for exclusion were as follows: chronic kidney disease, liver disease with transaminases ⩾ 2.5 times the normal value, and any pathology requiring systemic corticosteroid treatment. A total of 33 patients were excluded because their A1C was above threshold, their hepatic enzymes were above normal, or they had moderate renal failure.

The study was approved by the local institucional review board and was conducted according to the Helsinki Declaration and the GCP-ICH. Informed consent was obtained from all patients. All patients were living in the area outside of São Paulo city, had the same socioeconomic background and were insulin treatment naïve. All patients attended the same education sessions on diabetes, and lessons were always given by the same person.

Comparisons between the algorithms were made using ANOVA/Kruskal-Wallis and Student's *t* tests. The data on patients who completed the protocol were used, and all patients who received at least one dose of insulin to evaluate data on safety parameters were included.

The demographic data of the randomized patients are shown on Table 1. Population homogeneity was tested and showed the groups were similar in terms of age, weight, BMI, time they have had diabetes for, initial A1C level, and previous treatment with OADs. However, the proportion of M/F gender was significantly different in the LANMET PLUS ($P < 0.047$) group.

After 4 wk of a run-in period, 92 patients were ran-

Table 1 Characteristics of the patient population, as grouped according to the four algorithms

	n	Gender	Age (yr)	Weight (kg)	BMI (kg/m^2)	Duration (yr)	Baseline A1C	Baseline FPG (mg/dL)	Previous treatment
Fixed titration 2/2 U									
LANMET	26	8 M	55.0 ± 10	78 ± 16.6	30.7 ± 4.95	8 ± 4.23	9.39% ± 1.67%	193.0 ± 59.4	2 OAD (20) 1 OAD (6)
Variable titration									
LANMET PLUS	22	6 M	52.3 ± 7.7	70.6 ± 13	27.8 ± 4.7	7.8 ± 3.8	9.35% ± 1.34%	179.4 ± 51.4	2 OAD (21) 1 OAD (1)
Fixed titration 2/2 U									
DeGold	23	14 M	54.6 ± 8	78.3 ± 13.5	28.8 ± 4.4	10.2 ± 7.1	9.21% ± 1.30%	196.6 ± 54.8	2 OAD (19) 1 OAD (4)
Variable titration									
DeGold PLUS	21	12 M	53.8 ± 7.6	79.3 ± 15.9	29.5 ± 4.4	9.8 ± 5.4	9.61% ± 1.69%	196.1 ± 53.4	2 OAD (19) 1 OAD (2)

OAD: Oral anti-diabetes drug; FPG: Fasting plasma glucose; BMI: Body mass index.

Table 2 Treatment algorithms used in this study

Initial dose	BMI	Algorithms			
		LANMET fixed	LANMETPlus	DeGold fixed	DeGoldPlus
Fixed initial dose in U	n.a.	10		10	
Variable dose according to BMI (kg/m^2) in U/kg	< 26		0.2		0.2
	26 < 30		0.25		0.25
	30 < 35		0.3		0.3
	> 35		0.35		0.35
Insulin adjustment	FPG				
Fixed Titration twice/week in U		2	2		
Variable titration according to FPG (mg/dL) twice/week in U	< 100			0	0
	101 < 120			-2	-2

	141 < 180			4	4
	> 180			-2	-2

FPG: Fasting plasma glucose; BMI: Body mass index.

domly distributed to the four algorithms and were treated for the next 16 wk. During this period, 10 visits were scheduled and telephone monitoring was performed by the investigators between visits. A follow-up visit was performed 4 wk after the completion of the study. Three patients withdrew their informed consent. No patients dropped out due to hypoglycemia or any other adverse events.

Most patients were being treated with metformin and sulfonylurea, except for one patient in the DeGold PLUS group who received nateglinide and metformin, and another one in the LANMET PLUS group who received rosiglitazone and metformin. Thirteen patients were on monotherapy, of which seven were on sulfonylurea and six were on metformin. All patients were kept solely either on metformin 2 g/d or on the maximum tolerated dose during the treatment period.

Treatment algorithms

LANMET and LANMET PLUS used the same initial Insulin Glargine dose of 10 U, while DeGold and DeGold PLUS used an initial insulin Glargine dose based on BMI, as shown on Table 2. For the LANMET and DeGold algorithms, the insulin doses were increased by 2 U, twice a week, to reach the FPG target of 100 mg/dL. For LANMET Plus and DeGold Plus, titration was performed by increasing insulin doses, from 2 to 8 U total, twice a week, according to the FPG.

Patients administered the insulin at bedtime and adjusted the doses under the supervision of a person over the phone. In all algorithms, the titration of insulin doses was delayed and an immediate reduction of the insulin dose was recommended if hypoglycemia < 70 mg/dL. Insulin titration continued in all algorithms until the targeted FPG, which was between 80 and 100 mg/dL, was reached. The insulin dose was then maintained and considered adequate when at least 50% of the subsequent FPG measurements corresponded to the aimed target.

Rescue therapy with rapid acting insulin was used on one patient who presented with persistent A1C > 8%, even though he had his FPG on target for more than 6 wk.

The patients measured their capillary FPG daily and were instructed to repeat the measurements if they started having symptoms suggestive of hypoglycemia. When necessary, the mean values of 3 d of capillary FPG were used to calculate a new insulin dose.

Classification of hypoglycemia

Severe hypoglycemia: Severe hypoglycemia was defined as an event requiring third party assistance and glucose levels below 30 mg/dL, or if the patient recovered after receiving oral carbohydrates, intravenous glucose, or glucagon.

Symptomatic hypoglycemia: Symptomatic hypoglycemia was defined as an event where the patient presented with symptoms of hypoglycemia, but responded to oral carbohydrate ingestion or had a glycemia < 70 mg/dL (mild) or < 56 mg/dL (moderate).

Asymptomatic hypoglycemia: Asymptomatic hypoglycemia was defined as an event without any hypoglycemia symptoms, but glucose levels below 70 mg/dL.

Asymptomatic nocturnal hypoglycemia: Asymptomatic nocturnal hypoglycemia was determined when glycemia under 70 mg/dL was detected before breakfast.

Table 3 Treatment efficacy data *n* (%)

	LANMET	LANMET PLUS	DeGold	DeGold PLUS
Initial insulin dose (U)	10.0 ± 0	10.0 ± 0	21.0 ± 7.3	18.3 ± 7.0
Initial insulin dose (U/kg)	0.13 ± 0.02	0.13 ± 0.03	0.26 ± 0.05	0.25 ± 0.05
Final insulin dose (U)	41.65 ± 14.00	87.00 ± 26.87	54.68 ± 21.63	48.19 ± 38.50
Final insulin dose (U/kg)	0.54 ± 0.20	0.59% ± 0.27%	0.67% ± 0.24%	0.65% ± 0.52%
Baseline A1C	9.39% ± 1.67%	9.35% ± 1.34%	9.21% ± 1.30%	9.61% ± 1.69%
Final A1C	7.36% ± 1.32%	7.32% ± 0.67%	6.82% ± 0.70%	7.38% ± 0.95%
Reduction in A1C	2.02% ± 1.60%	2.02% ± 1.17%	2.48% ± 1.23%	2.23% ± 1.69%
Proportion of patients reaching FPG target	19/26 (73)	16/20 (80)	22/23 (95)	20/21 (95)

Patients presenting any type of hypoglycemia (*n*)	16 (61)	14 (70)	15 (68)	12 (57)	30 (65)	27 (62)	31 (64)	26 (60)
Number of any type of hypoglycemia events	113	107	48	111	220	159	157	155

Symptomatic nocturnal hypoglycemia: Symptomatic nocturnal hypoglycemia was defined when hypoglycemia occurred during sleep, after the bedtime insulin dose and before wakening. In this case, hypoglycemia was classified as mild (plasma glucose > 56 mg/dL), moderate (36 mg/dL < plasma glucose < 56 mg/dL) or severe (plasma glucose < 36 mg/dL).

The evaluation of insulin titration was based on the patients' diaries and glycemia levels at every visit. Treatment compliance was evaluated based on the aforementioned information.

RESULTS

Table 3 shows insulin glargine doses in U and U/kg, efficacy parameters, namely FPG and A1C at the end of the study, A1C decrease with respect to baseline value, proportion of patients reaching FPG target (A1C < 7.5% or < 7%), and mean titration time to reach the FPG target in the various groups.

There was no significant difference between the groups in the time required to achieve the target. The safety parameters are shown in Table 4. A unique severe hypoglycemia event (glycaemia < 36 mg/dL) occurred after a prolonged fasting period in a patient randomized according to the DeGold PLUS algorithm. No other severe adverse events occurred.

In a pooled analysis, there was no significant difference when comparing moderate hypoglycemia events in algorithms starting with a 10 U fixed dose with algorithms with BMI variation. However, when we compared patients (n = 46) whose titration increment was 2 U twice a week with patients (n = 43) whose titration varied according to FPG, we observed a clear increase in the number of hypoglycemia events in the second group. We observed 12 hypoglycemia events in the first group, which corresponded to 0.94 events/patient per year, and we observed 42 events in the second group, which corresponded to 2.81 events/patient per year (P < 0.037, Figure 1).

There were no other significant differences in the further comparisons between the algorithms.

DISCUSSION

Titration algorithms are important tools for maximizing the benefits of insulin therapy for metabolic control. Many algorithms have been proposed as guides for achieving metabolic control with basal insulin therapy. These algorithms differ in their initial recommended dos-

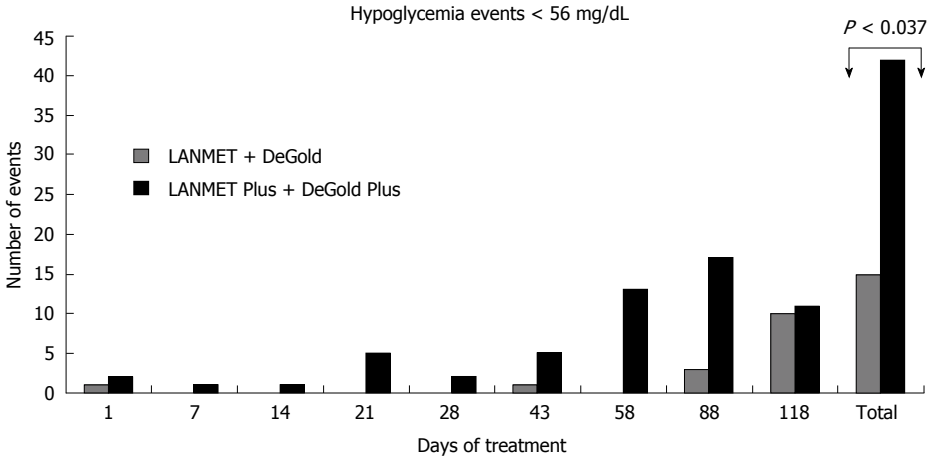

Figure 1 The graphic represents the number of moderate hypoglycemic events occurred throughout the study. The number of hypoglycemia events that occurred in the first 2 wk of treatment was very low. Algorithms that titration increment varied according fasting plasma glucose, had a clear increase in the number of hypoglycemia events.

es, and in the frequency and speed of basal insulin dose adjustments[5,6,11,12]. All were conceived based on the treat-to-target concept, thus becoming comparable in efficiency if correctly used. However, because these algorithms are being used in different populations, it is difficult to compare their safety based on the risk of hypoglycemia because it is unclear whether differences in rates of hypoglycemia are truly due to the algorithm itself or to the patients' varying levels of education. In this study, we evaluated the efficacy and safety of four insulin glargine titration algorithms in a highly homogeneous population to compare the impact of both the initial dose and the titration regimen on hypoglycemia events.

Titration was successfully performed in all groups. The DeGold and DeGold PLUS algorithms used a significantly higher initial insulin doses compared to the other two algorithms, which used a 10 U fixed initial dose. Nevertheless, at the end of the study, the doses were similar in all four groups. The doses were slightly higher (0.67 U/kg) in the DeGold groups, but were comparable to previously reported values (0.69 U/kg) in the LANMET study[11].

As expected, all four algorithms resulted in a decrease in FPG and A1C values, and 85% of all patients actually reached the FPG target and 39% of the patients achieved an A1C < 7% after 18 wk of treatment. This proportion is lower than the 60% reported in the Treat to Target study, where the introduced patient population had lower initial A1C levels (8.6% *vs* 9.5%) and results were reported after 36 wk of treatment. In our case, all groups presented a mean reduction of at least 2% in A1C values.

LANMET is a more conservative algorithm, as it recommends the smallest initial dose and slower titration, as opposed to the DeGold PLUS algorithm, which recommends the initial insulin dose based on BMI and a faster titration protocol. As such, the most important safety outcome to be compared is the frequency of moderate and severe hypoglycemia events, which is a barrier to the acceptance of insulin therapy among clinicians and patients[13,14].

In addition, hypoglycemia is currently acknowledged as risk factor that could lead to cardiovascular events and death[15-22]. Analysis on the incidence of mild, asymptomatic, or total hypoglycemia events showed no significant difference between the groups. However, when comparing the frequency of severe and moderate hypoglycemia events between the two groups on fixed titration and the other two groups using a variable regimen, a significant increase was observed in the latter groups (0.94 events/patient per year *vs* 2.81 events/patient per year, $P < 0.037$).

It has previously been reported that patients typically experience 3 events/patient per year, which is similar to what we observed in the patients who were subject to the titration regimen that varied according to FPG[12]. The frequency of symptomatic hypoglycemia events in the Treat to Target study was higher than in the LANMET trial (4.1 events/patient per year *vs* 13.9 events/patient per year) that used fixed titration, a finding that is in agreement with our observations[12,13].

The performance of the DeGold algorithm was especially notable, and it was recently proposed as an algorithm to guide the introduction of insulin glargine in replacement of OADs for inpatients[8]. We extended its use to outpatients currently being treated with OADs and as a result, after a mean titration period of 22 d, 95% of the individuals reached the FPG target and 69% reached values of A1C < 7%, without increase in any hypoglycemia categories.

Nevertheless, there was no significant difference between the algorithms regarding efficacy parameters, possibly due to a lack of statistical power because of the small sample size.

An increase in the risk of hypoglycemia was associated with the rapid titration algorithms, in comparison to patients receiving higher initial doses. A possible explanation for the observed discrepancy may be the extremely low number of events that occur in the beginning of treatment. Analysis of the distribution of occurrences throughout the study showed that only 14% of all events occurred during the first 4 wk of treatment (data not shown). After this period, the insulin doses in the titration regimens that varied according to FPG were higher, irrespective of the initial dose. Our data suggest that the initial dose is not important for achieving glycemic control, nor was it shown to affect the rates of hypoglycemia

events, as long as titration was performed. However, forced and rapid titration did increase the rates of hypoglycemia events.

In conclusion, there is no increase in the risk of moderate/severe hypoglycemia events when treatment with insulin glargine is initiated on insulin-naïve type 2 diabetes patients using an algorithm where the initial insulin dose is calculated based on BMI, as observed in the DeGold algorithm. However, this risk is increased when a faster titration schedule was used, compared with a fixed 2-U increment twice a week.

ACKNOWLEDGMENTS

Statistical analysis was conducted by Dr. Alves MRC from the School of Public Health, University of São Paulo.

COMMENTS

Background

To start insulin therapy in insulin naïve type 2 diabetes patients, a long-acting basal insulin, such as insulin glargine, is added once a day. The majority of algorithms determine insulin titration according to fasting plasma glucose levels, but the dosage differs at the initial dose, frequency and speed of adjustments.

Research frontiers

It is difficult to compare the different algorithms employed in trials with populations of different socio-economic strata and variable access to educational materials.

Innovations and breakthroughs

Here, authors compared the safety of different titration algorithms in a population that was homogeneous in terms of socio-economic strata and with the same degree of education in diabetes.

Terminology

Insulin algorithm titration: A guideline to modify the insulin dose after starting insulin therapy in a patient.

Peer review

This is an interesting study. The authors tried to compare the safety and efficacy of four insulin glargine algorithms in insulin naive type 2 diabetes patients.

Abstract

AIM: To describe baseline data of the optimal type 2 diabetes management including benchmarking and standard treatment (OPTIMISE) study in Greece.

METHODS: "Benchmarking" is the process of receiving feedback comparing one's performance with that of others. The OPTIMISE (NCT00681850) study is a multinational, multicenter study assessing, at a primary care level, whether using "benchmarking" can help to improve the quality of patient care, compared with a set of guideline-based reference values ("non-benchmarking"). In the Greek region, 797 outpatients (457 men, mean age 63.8 years) with type 2 diabetes were enrolled by 84 office-based physicians. Baseline characteristics of this population are presented.

RESULTS: Hypertension was the most prevalent concomitant disorder (77.3%) and coronary heart disease was the most frequent macrovascular complication of diabetes (23.8%). Most patients were overweight or obese (body mass index 29.6 ± 5 kg/m^2), exhibiting mostly abdominal obesity (waist circumference 102.6 ± 13.6 cm). Biguanides were the most prevalent prescribed drugs for the management of diabetes (70.1% of all prescriptions), whereas statins (93.5% of all prescriptions) and angiotensin receptor blockers (55.8% of all prescriptions) were the most prevalent prescribed drugs for hyperlipidemia and hypertension, respectively. Only 37.4% of patients were on aspirin. Despite treatment, pre-defined targets for fasting plasma glucose (< 110 mg/dL), glycated hemoglobin (< 7%), systolic blood pressure (< 130 mmHg and < 125 mmHg for patients with proteinuria) and low density lipoprotein cholesterol levels (< 100 mg/dL and < 70 mg/dL for patients with coronary heart disease) were reached in a relatively small proportion of patients (29%, 53%, 27% and 31%, respectively). In a Greek population with type 2 diabetes, the control of glycemia or concomitant disorders which increase cardiovascular risk remains poor.

CONCLUSION: Despite relevant treatment, there is a poor control of diabetes, hypertension and hyperlipidemia in Greek outpatients with type 2 diabetes.

Key words: Diabetes; Benchmarking; Treatment target; Glycemic control; Dyslipidemia; Blood pressure

Core tip: This is an epidemiological study assessing the prevalence of comorbidities as well as treatment control in a Greek population of patients with type 2 diabetes. "Benchmarking" is the process of receiving feedback and comparing one's performance to that of others. The optimal type 2 diabetes management including benchmarking and standard treatment (OPTIMISE) study is a multinational, multicenter study comparing the efficacy of two follow-up strategies in the manage-

ment of type 2 diabetic outpatients: "benchmarking" *vs* "non-benchmarking". This paper describes the rationale and the design of the OPTIMISE study as well as the baseline characteristics of patients included in the Greek region.

Rationale, design and baseline patient characteristics of the optimal type 2 diabetes management including benchmarking and standard treatment study in Greece. *World J Diabetes* 2014; 5(1): 76-83 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i1/76.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i1.76

INTRODUCTION

According to the World Health Organization (WHO), > 180 million people worldwide suffer from diabetes[1]. This number is likely to increase by more than double by the year 2030. In 2005 alone, approximately 1.1 million people died from diabetes-related complications[1]. The WHO projects that without urgent action, deaths due to these complications will increase by > 50% in the next 10 years[1]. Type 2 diabetes, which is closely related to an unhealthy lifestyle and obesity, is associated with increased risk of micro- and macrovascular outcomes, including heart attacks, strokes and amputations of the lower limbs[1]. Furthermore, diabetes complications not only decrease life expectancy, but also markedly reduce the quality of life. These outcomes result in increasing health care costs[2].

This burden can be limited with effective treatment practices[2]. However, a marked variability has been documented in preventive and therapeutic approaches, suggesting that the level of diabetes care currently delivered may not produce the predicted health-related benefits[3]. Gaps between medical care as actually practiced and the recommendations derived from evidence-based research are large and widespread[3]. Approaches improving the quality of patient care include the development of guidelines, flowcharting, data collection and graphical data analysis. More recent innovations are benchmarking and computerized decision support[3].

Benchmarking is the process of comparing one's performance with that of others[4]. This process begins with standardized and comparative measurement. It can go further to understand why there are performance differences between seemingly similar processes[4]. Benchmarking is practical and action-oriented in its analysis; it is not a rigorous research methodology. It is, however, a promising technology that breaks through the isolation that many clinicians report as the underlying cause of variation in clinical practice[4].

The optimal type 2 diabetes management including benchmarking and standard treatment (OPTIMISE, NCT00681850) study was a multinational, multicenter study assessing, at a primary care level, whether using benchmarking can help in improving the quality of patient care as compared with a set of guideline-based reference values. In this paper, baseline data of patients included in the OPTIMISE study in the Greek region are analyzed.

The primary objective of this study was the improvement of the quality of diabetic patient care, particularly the control of glycemia, lipids and blood pressure, with benchmarking over a set of guideline-based reference values (non-benchmarking). In this context, the percentage of patients in the benchmarking group achieving pre-set targets for glycated hemoglobin (HbA1c)[1], low density lipoprotein cholesterol (LDL-C)[1,5] and systolic blood pressure (SBP)[1,6] *vs* non-benchmarking group (control group) after 12 mo of follow-up was assessed.

Secondary objectives were to demonstrate that using benchmarking improves the control of diabetes, lipids and blood pressure (1) by means of the proportion of patients achieving pre-set targets for HbA1c[1], glycemia[1], LDL-C levels[1,5] and SBP[1,6] or (2) by determining the improvement in these parameters after 12 mo of follow-up. Other secondary objectives included (3) the preventive screening for several outcomes: retinopathy, neuropathy, dietary counseling, microalbuminuria, smoking habits, body mass index (BMI) and physical activity and (4) the measurement of physical activity by registering the number of steps and the distance walked per day.

MATERIALS AND METHODS

Study design and population

Type 2 diabetic patients, followed by usual physician treatment, were recruited for observation. Selection criteria were male or female subjects (1) with a minimum age of 18 years; (2) with type 2 diabetes, treated or untreated, insulin dependent or not insulin dependent at the time of first visit; and (3) who signed an informed consent to participate in the study. Diabetes was defined by plasma levels of glucose (PG); fasting PG was ⩾ 126 mg/dL or PG levels 2-h post-load was ⩾ 200 mg/dL. Patients who (1) suffered from type 1 diabetes or gestational diabetes, (2) participated in any other clinical study or (3) were hospitalized during the study period (because it is a primary care study) were excluded from the study.

Investigators recruited for this study were physicians from all over the country who were willing to participate. A selection was based on the availability of sufficient diabetic patients in the physician's practice and the motivation to fulfill the administrative procedures linked to the study. All participating investigators performed their usual monitoring, treatment and counseling of their diabetic patients. Investigators were randomized into two groups. The group that performed the usual monitoring of their diabetic patients by knowing the relative level of diabetic control of their patients compared with the patients of other investigators was defined as the benchmarking group. The other group (non-benchmarking) did not receive any information and behaved as a control group. The proportion of investigators receiving that in-

formation (benchmarking) *vs* the control group was 3 to 1.

Follow-up

All investigators received feedback on the risk factors of their patients. Additionally, in the benchmarking group, physicians anonymously received information on the level of control of cardiovascular risk factors for their patients compared with their colleagues. This possibly resulted in an additional motivational stimulus for investigators and patients to follow therapeutic advice and to improve their risk factors.

The time interval between visits in this study corresponded to the four-times yearly control visits for diabetic patients regarding blood pressure, fasting glycemia, HbA1c, body weight, smoking habits and physical activity, as recommended by the "International Diabetes Federation"[7]. Therefore, according to the study protocol, patients were followed-up in four visits. Baseline assessments were recorded at visit 1, and further data were collected after approximately 4 mo (visit 2), 8 mo (visit 3) and 12 mo (visit 4). The serum lipid profile [total cholesterol (TC), LDL-C, high density lipoprotein cholesterol (HDL-C) and triglyceride (TG) levels] was also recorded at baseline and at the same time intervals.

Clinical evaluation

At each visit, blood pressure was measured with the patient in the sitting position following at least 5 min of rest with a manometer with a cuff of the recommended dimensions. The mean blood pressure based on three successive readings was recorded. Somatometrics, including body weight, height (only at the first visit) and waist circumference, were also measured during the follow-up. The patient ideally wore light clothing and no shoes during the weight measurement. Weight was given in kilograms, without decimals (to round up as from 0.5 kg). The patient ideally wore no shoes during the height measurement. Height was given in centimeters without decimals (to round up as from 0.5 cm). For the measurement of waist circumference, a measuring tape was placed in a horizontal plane around the abdomen at the level of the iliac crest. Before reading the tape measure, investigators ensured that the tape was snug without compressing the skin and parallel to the floor. The measurement was made at the end of a normal expiration.

Laboratory evaluation

After an 8-h overnight fast, two blood samples (7 mL) were obtained. The following parameters were analyzed at the central lab BARC (Industriepark Zwijnaarde 7b3, B-9052 Ghent, Belgium): (1) HbA1c, (2) fasting PG and (3) the serum lipid profile, including TC, TG, HDL-C and LDL-C levels. At visits 1 and 4, a urine sample of 4 mL was collected for analysis of microalbuminuria.

Pre-defined targets of treatment

Pre-defined targets of treatment were (1) HbA1c < 7% and fasting PG < 110 mg/dL for glycemic control, (2) SBP < 130 mmHg and < 125 mmHg in the case of renal impairment and proteinuria > 1 g/24 h for blood pressure control and (3) LDL-C levels < 100 mg/dL and < 70 mg/dL for very high-risk patients (*i.e.*, those with diabetes and coronary heart disease) for serum lipids control.

Patient classification

Patients were categorized according to fasting PG levels into (1) "normal" if fasting PG was < 110 mg/dL, (2) "borderline" if fasting PG was 110-125 mg/dL and (3) "diabetics" if fasting PG was ⩾ 125 mg/dL. According to HbA1c levels, patients were classified into "good" if HbA1c ⩽ 7% and "too high" if HbA1c > 7%. SBP levels divided the study population into: "good" if < 130 mmHg and "too high" if ⩾ 130 mmHg. According to LDL-C levels, patients were categorized into "good" if LDL-C < 100 mg/dL and "too high" if LDL-C ⩾ 100 mg/dL.

A four-point verbal rating scale was used to assess the following physical activity: (1) no weekly activity; (2) only limited physical activity during most weeks; (3) intense physical activity (activity that gives rise to shortness of breath, tachycardia and sweating) during at least 20 min, once to twice a week; and (4) intense physical activity (activity that gives rise to shortness of breath, tachycardia and sweating) during at least 20 min, three times or more a week.

Statistical analysis

Descriptive statistics (mean, median, number of observations, standard deviation, standard error, 95%CI, minimum and maximum) of all primary and other variables are presented in tables and, if appropriate and interesting, in graphs. This is applicable for the following variables: HbA1c, glycemia, LDL-C, SBP, TG, TC, HDL-C, diastolic blood pressure, waist circumference, smoking habits, microalbuminuria, BMI, physical activity (rating scale), degree of ophthalmic control and degree of dietary advice.

The null hypothesis for the primary objective is that the proportion of patients who reached targets after 12 mo in both groups is equal. The alternative hypothesis is that this proportion is greater in the benchmarking group compared with the control group. This analysis is performed for the following variables: HbA1c, LDL-C and SBP. For secondary objectives, the null hypothesis is that the proportion of patients who reached the target after 12 mo is the same as the proportion of patients who reached the target at baseline. The alternative hypothesis is that this proportion is even greater after 12 mo than at baseline. This analysis is also performed for HbA1c, LDL-C and SBP. Another null hypothesis is that the mean proportion improvement of these variables after 12 mo is equal to zero. The alternative hypothesis is that the mean percentage improvement is different from zero.

RESULTS

The study design and the global baseline results of the OPTIMISE study have been previously reported[8,9]. Ad-

Table 1 History data of the study population in Greece

Variable	Value
Age (yr)	64 ± 11
Male gender	457 (57.3)
Positive family history of diabetes	483 (64.2)
Family history of premature heart disease	213 (28.4)
Time since diagnosis of diabetes (yr)	9.2 ± 8.3
Age at diagnosis of diabetes (yr)	54 ± 11
Smoking status	
Current smokers	194 (24.3)
Ex-smokers	171 (21.4)
Non-smokers	432 (54.2)

Data are expressed as absolute numbers (percentage) or mean ± SD.

Table 3 Baseline clinical characteristics of the study population in Greece (mean ± SD)

Variable	Value
Height (cm)	167 ± 9
Weight (kg)	83 ± 16
Body mass index (kg/m^2)	29.6 ± 5.0
Waist circumference (cm)	103 ± 14
Systolic blood pressure (mmHg)	138 ± 17
Diastolic blood pressure (mmHg)	80 ± 9

ditionally, the benchmarking process has been schematically described in detail above[8].

History data and clinical evaluation

A total of 797 patients were enrolled in this study (n = 570 in the benchmarking group and 227 in the control group) by 84 participating office-based physicians across Greece. History data of the study population are shown in Table 1. Most patients were middle-aged and had a positive family history of diabetes (Table 1). A small predominance of male gender was noted in our population. Patients were middle-aged at the time of diagnosis of diabetes and presented after approximately a 10-year course of diabetes.

Hypertension was a common concomitant disorder in our population, present in approximately 8/10 patients (Table 2). Among macrovascular complications of diabetes, coronary heart disease was the most prevalent, followed by peripheral artery disease and stroke (Table 2). Only two patients have undergone amputation. Retinopathy was the most commonly observed microvascular complication of diabetes, followed by proteinuria (Table 2).

Table 3 shows the main clinical characteristics of the study population. The vast majority of patients were overweight or obese, as reflected by increased BMI. The predominance of visceral obesity was mirrored by abnormally raised measurements of waist circumference. Most patients (*i.e.*, 77%) reported no or light weekly physical activity and the rest (23%) reported "intense physical activity" for 1-2 times per week.

Both systolic and diastolic blood pressure levels were moderately elevated (Table 3). As expected, SBP was greater in patients with proteinuria than in patients without proteinuria (144 ± 19 mmHg *vs* 138 ± 17 mmHg). Only a small proportion of patients (27%) reached the pre-defined target for blood pressure, whereas most patients (72%) did not reach this target (Figure 1).

Table 2 Macrovascular and microvascular complications of diabetes and concomitant diseases of the study population in Greece n (%)

Clinical condition	Value
Hypertension	615 (77.2)
Coronary heart disease	186 (23.8)
Stroke	50 (6.3)
Peripheral artery disease	85 (11.1)
Amputation	2 (0.3)
Proteinuria	38 (5.6)
End-stage renal disease	1 (0.1)
Retinopathy	54 (7.2)

Table 4 Treatment of the study population in Greece

Treatment	n (%)
Antidiabetic	740 (92.9)
Insulin	145 (19.6)
Biguanide (metformin)	519 (70.1)
Sulfonylurea	343 (46.4)
Glitazone	142 (19.2)
Others	104 (14.1)
Lipid-lowering	553 (69.4)
Statin	517 (93.5)
Ezetimibe	53 (9.6)
Fibrate	17 (3.1)
Others	43 (7.8)
Antihypertensive	591 (96.1[1])
ARBs	330 (55.8)
ACEi	202 (34.2)
CCBs	242 (40.9)
Beta-blockers	179 (30.3)
Alpha-blockers	13 (2.2)
Diuretics	220 (37.2)
Others	19 (3.2)
Anti-obesity	40 (5.0)
Aspirin	298 (37.4)

[1]The percentage value refers to patients with hypertension. ARBs: Angiotensin receptor blockers; ACEi: Angiotensin converting enzyme Inhibitors; CCBs: Calcium channel blockers.

Medical treatment

Prescribed medications are shown in Table 4. Biguanides were the most commonly prescribed antidiabetic drugs, followed by sulfonylureas. Approximately one fifth of the patients in our population were treated with insulin. The mean insulin dosage among insulin-treated patients was 48 ± 28 units/d. From all antidiabetic drug combinations, biguanide + sulfonylurea was the most commonly prescribed (20% of all prescriptions).

Almost all patients on lipid lowering therapy were taking statins (Table 4). Simvastatin was used by 34% of the statin-treated patients at a mean dose, atorvastatin by 36% and rosuvastatin by 24% at a mean dose of about 30, 20 and 12 mg/d, respectively. Statins with a mild lipid-lowering potency, including fluvastatin and pravas-

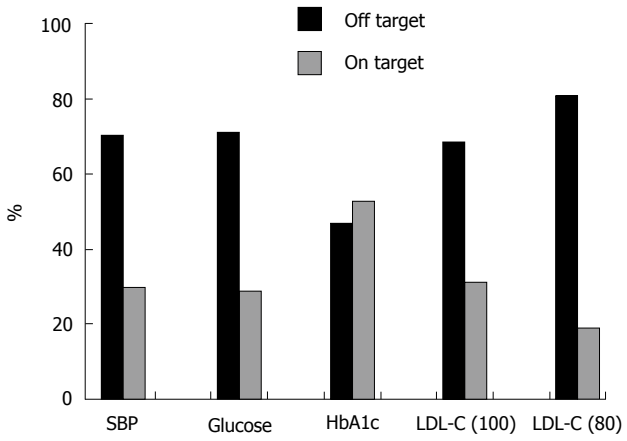

Figure 1 Proportion of patients who did not reach or reached pre-defined targets of treatment. SBP: Systolic blood pressure; HbA1c: Glycosylated hemoglobin; LDL-C: Low density lipoprotein cholesterol.

tatin, were less frequently prescribed. The use of other hypolipidemic drugs was limited in our population. The dose of 100 mg/d was the predominant dose of aspirin, corresponding to 92% of all prescriptions.

Renin-angiotensin-aldosterone system blockade was the most popular antihypertensive strategy, with angiotensin receptor blockers (ARBs) being prescribed in more than half and angiotensin converting enzyme inhibitors (ACEi) in approximately one third of our population (Table 4). ARBs were the most commonly prescribed antihypertensive drug category, followed by calcium channel blockers (CCBs), diuretics, ACEi and beta-blockers (Table 4). From combinations of two antihypertensive drugs, ARBs with diuretics or CCBs were the more prevalent (each representing approximately 5% of all prescriptions), followed by ACEi with the same categories (approximately 3% of all prescriptions for each combination). ARBs, CCBs and diuretics combination were the most frequent among triple combinations (5% of all prescriptions).

Target achievement for laboratory parameters

Table 5 shows the glycemic control and serum lipid profile. Glycemic control was poor, with 71% of all patients being out of the pre-defined target according to fasting PG and 47% according to HbA1c (Figure 1). Interestingly, glycemic control was better when assessed by HbA1c rather than by fasting PG levels.

Only 31% of patients reached the pre-defined target for LDL-C (< 100 and < 70 mg/dL for patients with coronary heart disease). This proportion was greater (*i.e.*, 40%) for the target of LDL-C < 100 mg/dL and lower (19%) for a more aggressive LDL-C target of < 80 mg/dL (Figure 1). Consequently, the LDL-C target was not reached in the vast majority of patients with coronary heart disease (82%).

DISCUSSION

The OPTIMISE study is designed to compare two different strategies in the follow-up of type 2 diabetic

Table 5 Laboratory evaluation of the study population in Greece (mean ± SD)

Variable	Values
Glucose (mg/dL)	138 ± 47
HbA1c (%)	7.2 ± 1.3
LDL-C (mg/dL)	112 ± 35
HDL-C (mg/dL)	50 ± 13
TC (mg/dL)	192 ± 42
TG (mg/dL)	154 ± 85
Albuminuria (mg/g Cr)	66.6 ± 249.2

outpatients regarding the control of diabetes and its concurrent morbidities. Benchmarking is a relatively recent innovation in the quality management sciences, representing a useful tool in the understanding of why there are performance differences between seemingly similar processes[4]. Feedback methods such as benchmarking in which clinicians receive reports of their performance compared with the mean performance of a peer group have been used and studied extensively[3,10]. One underlying theory holds that viewing personal performance within the context of peer performance is a powerful motivator for change[3,11]. In the OPTIMISE study, the hypothesis whether "benchmarking" is superior to a "non-benchmarking" follow-up strategy in the control of diabetes and concurrent morbidities is evaluated.

In the present paper, we discuss baseline characteristics of a relatively large population of type 2 diabetic patients in the Greek region participating in the OPTIMISE study. To the best of our knowledge, this study represents one of the larger diabetes registries in the country.

Type 2 diabetes is becoming an increasingly prevalent morbidity in Greece. In the ATTICA study, the prevalence of diabetes in 3042 subjects who were free of cardiovascular disease was raised from 8% in 2001 to 12.8% in 2006[12]. According to the same study, the age-adjusted five-year incidence of type 2 diabetes was 5.5%[13].

The mean age at diagnosis of diabetes in the OPTIMISE study was 54 years. This finding is in accordance with the "Aegaleo" studies in which the increase in diabetes begins in those > 50 years of age[14]. Interestingly, current data showed clearly that the prevalence is considerably increased after the age of 30 years[15]. Age was found to independently correlate with increased risk for diabetes (OR = 1.07, 95%CI: 1.06-1.08)[15].

In the OPTIMISE study, a mild predominance of the male gender over female was noted. This finding is consistent with epidemiological data from the ATTICA study in which the prevalence of diabetes was higher in men than in women (8% *vs* 6%, respectively)[16]. Likewise, in another analysis, male gender was recognized as an independent predisposing factor for diabetes (OR = 1.43, 95%CI: 1.04-1.95)[15]. The possible explanation for these sex differences may be that men are more susceptible than women to the consequences of indolence and obe-

sity, possibly due to differences in insulin sensitivity and abdominal fat deposition[17].

Most of our diabetic patients had a positive family history of diabetes. It has been shown that Greek subjects with a positive family history of diabetes may have approximately a seven-fold higher risk for diabetes compared with co-responders without a family history of diabetes[15]. Approximately 1/4 of diabetic patients in our population (*i.e.*, 24%) exhibited coronary heart disease, a proportion which is similar to that reported for the prevalence of diabetes among Greek patients who had suffered a myocardial infarction (*i.e.*, 25%)[18]. Coronary heart disease represented the most prevalent disorder among all macrovascular complications of diabetes, with the rates for other forms of cardiovascular disease being relatively low.

The prevalence of hypertension was high among our subjects. Hypertension was considered as an independent contributing factor for diabetes in Greek adult subjects with self-reported diabetes (OR = 2.19, 95%CI: 1.60-2.99)[15]. The prevalence of hypertension in our population was greater compared with that recorded in an urban Greek population of self-reported diabetes (77% *vs* 51%, respectively)[15]. The great prevalence of hypertension among Greek subjects with metabolic syndrome (*i.e.*, 71%)[19], which represents a pre-diabetic condition, may account for high rates of hypertension in type 2 diabetic patients.

According to BMI values, approximately all patients were overweight or obese with increased measurements of waist circumference. Being overweight and obese was associated with a two-fold increase in the risk for diabetes in a Greek population[15]. Abdominal obesity, which is present in 82% of patients with metabolic syndrome in Greece[19], may play a major role in the pathogenesis of type 2 diabetes by promoting insulin resistance[20]. Physical inactivity was another important finding of this study. The proportion of our diabetic patients who reported physical inactivity was greater than that recorded in the ATTICA study (77.41% *vs* approximately 50%, respectively)[19]. This unhealthy lifestyle pattern could be related to the development of obesity and diabetes.

The most important finding of this study lies in the low rates of patients who reached pre-defined targets of treatment for SBP, glycemia and LDL-C levels. Approximately 72% of patients were off target regarding SBP. This rate is in accordance with the Didima study, which shows that only 27% of treated hypertensive subjects reached treatment targets for arterial blood pressure in a rural Greek area[21]. In the EUROASPIRE Ⅱ study, 50% of patients with coronary heart disease in 15 European countries (including Greece) had raised blood pressure levels[22]. Similar were the results of a Greek trial performed in patients with coronary heart disease of whom only 50% had desirable blood pressure levels[18].

Suboptimal control was noted for LDL-C levels. Seven out of 10 patients did not reach the pre-defined target of LDL-C levels < 100 mg/dL and < 70 mg/dL for diabetic patients with coronary heart disease. This rate was even lower for a more promising target of < 80 mg/dL. Interestingly, this was evident despite high rates of patients who were treated with statins (*i.e.*, 65% of the total study population or 94% of those receiving lipid lowering medications), particularly the most potent ones. Nevertheless, few patients were treated with drugs that could offer further LDL-C lowering, including ezetimibe. Lipid-lowering drug combinations, which are currently underused, could contribute to a greater percentage of patients reaching the targets for LDL-C levels. In the EUROASPIRE Ⅱ study, 58% of patients with coronary heart disease had elevated TC levels[22]. In Greece, the OLYMPIC study showed that only 26% of 2660 adults with dyslipidemia, who had been receiving lipid-lowering treatment for at least 3 mo (of whom 36% had diabetes), achieved the NCEP-ATPIII targets for LDL-C levels[23]. A greater proportion (*i.e.*, 49%) of patients achieving the 2004-updated NCEP ATPIII targets was reported in the CEPHEUS (Centralized Pan-European survey on the undertreatment of hypercholesterolemia in patients using lipid lowering drugs). This study was performed in 1321 Greek patients who were on lipid lowering treatment for at least 3 mo were stable for at least 6 wk. Interestingly, 25% of these patients had diabetes[23].

In the OPTIMISE study, 34% of the statin-treated patients were on simvastatin, most of them at low doses (49% of them 20 mg/d and 9% 10 mg/d). If these patients were switched to a more potent statin (either atorvastatin or rosuvastatin), they might have reached the targets for LDL-C. Moreover, > 36% of patients on atorvastatin were using low-to-moderate doses (38% of them 10 mg/d and 44% 20 mg/d). It is possible that these patients would reach their targets if titrated to a higher atorvastatin dose or switched to a more potent statin, such as rosuvastatin. Finally, 24% of patients were treated with rosuvastatin (76% of patients used 5-10 mg/d and only 22% 20 mg/d). A higher rosuvastatin dose could potentially offer a higher proportion of patients achieving LDL-C goals. According to international recommendations, statin treatment should be optimized and if the target is not reached, then a second agent should be added. Nevertheless, it appears that statin treatment was far from optimal in the OPTIMISE population. An optimization of statin dose or switching to a more potent statin could help more patients reach the target. If the target is not reached, then the addition of a second agent could be useful.

Poor glycemic control was also noted in our population; only 30% according to fasting PG levels and 50% according to HbA1c levels. The results of the EUROASPIRE Ⅱ study were similar among diabetic patients with coronary heart disease, with more than 70% being out of target for PG levels[21]. In a Greek population of 819 diabetic patients with coronary heart disease, only half of the patients exerted HbA1c levels < 7.5%[18]. Although insulin is considered as a first-line treatment choice for the management of type 2 diabetic patients, only one fifth of patients in the OPTIMISE study were treated with insulin. This could have attributed to low

rates of glycemic control.

The OPTIMISE study was designed to compare the efficacy of "benchmarking" compared with "non-benchmarking" in the control of type 2 diabetes in an outpatient basis. In Greek participants of this study, poor control of diabetes, hypertension and hyperlipidemia were noted at baseline despite treatment.

COMMENTS

Background

The optimal type 2 diabetes management including benchmarking and standard treatment (OPTIMISE, NCT00681850) study was a multinational, multicenter study assessing, at a primary care level, whether using benchmarking can help more in improving the quality of patient care as compared with a set of guideline-based reference values.

Research frontiers

Benchmarking is practical and action-oriented in its analysis; it is not a rigorous research methodology. It is, however, a promising technology that breaks through the isolation that many clinicians report as the underlying cause of variation in clinical practice.

Innovations and breakthroughs

The OPTIMISE study was designed to compare the efficacy of "benchmarking" compared with "non-benchmarking" in the control of type 2 diabetes on an outpatient basis.

Applications

Despite relevant treatment, there is a poor control of diabetes, hypertension and hyperlipidemia in Greek outpatients with type 2 diabetes.

Peer review

The manuscript is well-written and its aim to confirm the importance of benchmarking to improve diabetes care in clinical setting is of interest.

World J Diabetes 2014 February 15; 5(1): I-V
ISSN 1948-9358 (online)

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

Aims and scope

WJD covers topics concerning α, β, δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

WJD is edited and published by Baishideng Publishing Group (BPG). BPG has a strong professional editorial team composed of science editors, language editors and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJD* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cuttingedge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, *etc.*; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in diabetes; (12) Brief Articles: To briefly report the novel and innovative findings in diabetes; (13) Meta-Analysis: Covers the systematic review, mixedtreatment comparison, meta-regression, and overview of reviews, in order to summarize a given quantitative effect, *e.g.*, the clinical effectiveness and safety of clinical treatments by combining data from two or more randomized controlled trials, thereby providing more precise and externally valid estimates than those which would stem from each individual dataset if analyzed separately from the others; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJD*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of diabetes; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

Indexed and abstracted in
PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJD* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Com-

mittee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1948-9358/g_info_20100107165233.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to bpgofficw@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, *e.g.*, Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-85381892 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJD*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/"), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, *e.g.*, 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$), and CONCLUSION (no more than 26 words).

Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are

applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, *e.g.*, PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1948-9358/g_info_20100107145507.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

Examples for paper writing

All types of articles' writing style and requirement will be found in the link: http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1948-9358/g_info_20100107144846.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1948-9358/g_info_20100107170340.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

STATEMENT ABOUT ANONYMOUS PUBLICATION OF THE PEER REVIEWERS' COMMENTS

In order to increase the quality of peer review, push authors to carefully revise their manuscripts based on the peer reviewers' comments, and promote academic interactions among peer reviewers, authors and readers, we decide to anonymously publish the reviewers' comments and author's responses at the same time the manuscript is published online.

PUBLICATION FEE

WJD is an international, peer-reviewed, OA online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium and format, provided the original work is properly cited. The use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 600 USD per article. All invited articles are published free of charge.

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α, β, δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Ischemic stroke is a leading cause of mortality and long-term disability worldwide. Given the detrimental effects of acute stroke, several neuroprotective agents have been evaluated in these patients. However, the benefits of the evaluated agents appear to be limited and none is currently recommended for clinical use. On the other hand, prior treatment with agents that are used for the primary and secondary prevention of stroke, including statins and antiplatelets, has been associated with better outcome in patients who experience an acute stroke. In contrast, there are limited data as to whether prior treatment with antidiabetic agents is beneficial in diabetic patients who suffer a stroke. In this context, the findings of a recent study that showed reduced stroke size following pretreatment with linagliptin, a dipeptidyl peptidase-4 (DDP-4) inhibitor, compared with glimepiride, in both diabetic and non-diabetic mice, appear promising. Despite these preclinical findings suggesting neuroprotective effects of DPP-4 inhibitors in acute stroke, it is still unclear whether these actions will also be observed in humans. Of note, two recent large randomized, placebo-controlled studies did not show any effect of DPP-4 inhibitors on cardiovascular events, including stroke. Several other ongoing trials are evaluating the effects of DPP-4 inhibitors on cardiovascular morbidity and mortality. These studies also provide a major opportunity to assess whether patients treated with this class of antidiabetic agents will suffer from less severe strokes and whether their outcome after stroke will be more favorable.

Key words: Type 2 diabetes mellitus; Stroke; Dipeptidyl peptidase-4 inhibitors; Sulfonylureas; Neuroprotection

Core tip: A recent study showed reduced stroke size following pretreatment with linagliptin, a dipeptidyl peptidase-4 (DDP-4) inhibitor, compared with glimepiride, in both diabetic and non-diabetic mice. It remains to be shown whether these neuroprotective actions of DPP-4 inhibitors will also be observed in humans.

INVITED COMMENTARY ON HOT ARTICLES

Ischemic stroke is a leading cause of mortality and long-term disability worldwide[1]. This often disabling and frequently fatal event puts a substantial burden on the family members and medical professionals who care for stroke victims[1].

The increasing prevalence of obesity results in an increased incidence of type 2 diabetes mellitus (T2DM) worldwide[2]. T2DM is a major risk factor for cardiovascular events, including stroke[3,4]. In addition, patients with T2DM appear to suffer more severe strokes and have a worse outcome than subjects without T2DM[3,5-7]. The increased incidence of cardiovascular events in patients with T2DM is not only due to hyperglycemia, but insulin resistance, low-grade inflammation and activation of the

Table 1 Major studies that have evaluated the effects of antidiabetic agents on stroke severity and outcome

Ref.	Design	*n*	Agent	Results
Weih *et al*[14]	Retrospective	146	Sulfonylureas	No effect on stroke severity or outcome
Kunte *et al*[15]	Retrospective	61	Sulfonylureas	Better neurological and functional outcome at discharge in patients who were on sulfonylureas prior to stroke
Favilla *et al*[16]	Prospective	1050	Sulfonylureas, metformin, insulin	Less severe stroke on admission in patients who were on sulfonylureas, metformin or insulin prior to stroke than in patients who were not receiving any antidiabetic agent, but no difference in functional outcome and mortality rates at 90 d between the 2 groups Similar stroke severity and outcome between patients treated with different antidiabetic agents prior to stroke (sulfonylureas, metformin and insulin)
Lee *et al*[17]	Case-control	60	Thiazolidinediones	Enhanced functional recovery in patients treated with thiazolidinediones

coagulation cascade are also involved[3,8].

Given the high morbidity and mortality rates associated with acute ischemic stroke, several neuroprotective agents have been evaluated in these patients[9]. However, the benefits of the evaluated agents appear to be limited and none is currently recommended for clinical use[9]. On the other hand, prior treatment with agents that are used for the primary and secondary prevention of stroke, including statins and antiplatelets, has been associated with less severe stroke, better functional outcome and reduced mortality in patients who experience an acute stroke[10-13]. In contrast, there are limited data whether prior treatment with antidiabetic agents is beneficial in diabetic patients who suffer a stroke. In an early study, prior treatment with sulfonylureas had no effect on stroke severity or outcome[14]. In contrast, a more recent study suggested that patients who were on sulfonylureas prior to stroke and continued to receive these agents during hospitalization were more likely to have a better neurological and functional outcome at discharge[15]. In another study, diabetic patients who were on sulfonylureas, metformin or insulin prior to stroke had a less severe stroke on admission than patients who were not receiving any antidiabetic agent. In contrast, functional outcome and mortality rates at 90 d after stroke were similar in patients who were on glucose-lowering treatment and in those who were not[16]. Stroke severity and outcome did not differ between patients who were on sulfonylureas, metformin or insulin prior to stroke[16]. A small retrospective study also suggested that thiazolidinediones enhance functional recovery in patients with stroke[17] (Table 1).

In this context, the findings of a recent study that compared the effects of pretreatment with glimepiride, a sulfonylurea, and linagliptin, a dipeptidyl peptidase-4 (DDP-4) inhibitor, on the outcome of stroke in diabetic and non-diabetic mice, appear promising[18]. It has been previously reported that administration of sulfonylureas after stroke reduces infarct size and mortality, primarily by preventing cerebral edema[19,20]. In this study, 44 male C57BL mice were divided into 2 groups. The first group (n = 21) was exposed to a high-fat diet for 32 wk, which resulted in substantial weight gain and development of insulin resistance and hyperglycemia[18]. At week 25, this group was assigned to oral administration of 10 mg/kg per body weight (bw) linagliptin daily, 2 mg/kg per body weight glimepiride daily or vehicle[18]. The second group (n = 23) was fed a normal diet and was also assigned to linagliptin, glimepiride or vehicle at the same doses with the first group[18]. After 4 wk of treatment, stroke was induced in all mice in both groups by transient occlusion of the middle cerebral artery[18]. Treatment with linagliptin, glimepiride or vehicle was continued for 3 wk following stroke, after which all mice in both groups were sacrificed[18]. The extent of ischemic stroke was assessed with measuring stroke volume and with stereological quantification of surviving neurons in the striatum/cortex[18].

In high-fat diet-fed mice, fed and fasting blood glucose levels decreased in both linagliptin- and glimepiride-treated mice[18]. This reduction was greater in mice treated with glimepiride. In contrast, in normal diet-fed mice, fed and fasting blood glucose levels decreased in glimepiride-treated animals but did not change in linagliptin-treated animals[18]. On the other hand, both high-fat- and normal diet-fed mice that were treated with linagliptin showed an increase in blood glucagon-like peptide-1 (GLP-1) levels due to a significant reduction in DPP-4 activity[18]. In contrast, GLP-1 levels and DPP-4 activity did not change in glimepiride- or vehicle-treated mice regardless of the diet they were fed[18].

Immunohistochemical staining of the cortex/striatum of high-fat diet-fed mice without stroke revealed GLP-1 receptor expression exclusively in the neurons[18]. Cortical pyramidal neurons showed the most pronounced expression of GLP-1 receptors[18].

In high-fat diet-fed mice, treatment with linagliptin resulted in a noticeable, albeit not statistically significant, trend towards reduction of stroke volume[18]. In contrast, glimepiride had no effect on stroke volume[18]. Moreover, stereological counting of surviving neurons revealed significantly more (approximately 30%) surviving neurons in linagliptin-treated mice than in either glimepiride- or vehicle-treated animals[18]. In contrast, in normal diet-fed mice, treatment with both linagliptin and glimepiride resulted in a comparable and non-significant trend for reduced stroke volume and was associated with a comparable and significantly higher number of surviving neurons compared with vehicle treatment[18].

Overall, this study[18] suggests that treatment with linagliptin prior to stroke increases the number of surviving neurons more than glimepiride in diabetic mice. This

neuroprotective effect of linagliptin appears to be glucose-lowering-independent since the reduction in blood glucose levels was smaller during treatment with linagliptin compared with glimepiride. In addition, linagliptin also prevented neuronal death in non-diabetic mice even although it did not affect glucose levels, further supporting a glucose-lowering-independent neuroprotective effect. Similar results have been reported very recently with another DPP-4 inhibitor, alogliptin[21]. Moreover, in humans, even although increased glucose levels at admission are associated with a worse outcome in patients with acute ischemic stroke[22-24], correction of hyperglycemia with administration of insulin does not reduce infarct size or neurological deficit[25-27].

Several alternative mechanisms besides glucose lowering may underpin the beneficial effects of linagliptin in the setting of acute stroke. First, treatment with linagliptin results in increased blood GLP-1 levels and pretreatment with exendin-4, a GLP-1 agonist, was shown to reduce stroke volume and neurological deficit in animal stroke models[28-30]. Antiapoptotic, anti-inflammatory and antioxidant actions, as well as stimulation of the proliferation of neural stem cells and attenuation of microglial activation, appear to contribute to these neuroprotective effects[29-31]. Interestingly, administration of exendin-4 in non-diabetic animals immediately after stroke also reduces stroke volume and improves outcome through similar mechanisms without affecting glucose levels[32]. These effects appear to be GLP-1 receptor-mediated since they are not observed in GLP-1 receptor knockout (-/-) mice[28]. Moreover, GLP-1 readily crosses the blood-brain barrier[33-35] and GLP-1 receptors are expressed in brain neurons in humans[36-39]. In addition, both ischemia and treatment with exendin-4 up-regulate the expression of GLP-1 receptors in pyramidal neurons[29]. Given the putative neuroprotective effects of GLP-1, this increased expression might be a defense mechanism against ischemic damage[29].

A second possible pathway through which linagliptin might exert its neuroprotective effects is the increased bioavailability of other bioactive DPP-4 substrates. Indeed, DPP-4 has many other substrates except GLP-1, some of which appear to exert neurotrophic or neuroprotective effects[40,41]. The latter include glucose-dependent insulinotropic polypeptide[42], pituitary adenylate cyclase-activating polypeptide[43] and stromal cell-derived factor 1a[44], which were reported in preclinical models to promote synaptic plasticity, neurogenesis and neuronal differentiation, to inhibit apoptosis and to reduce stroke size.

Another possible explanation of the different effects of linagliptin and glimepiride on stroke volume is that glimepiride exerts detrimental effects rather than that linagliptin is protective. Indeed, several recent studies suggested that patients treated with sulfonylureas have increased cardiovascular morbidity compared with patients treated with metformin[45-47]. Therefore, it would be of interest to compare the effects of prior treatment of DPP-4 inhibitors with prior treatment with metformin in experimental models of stroke or in patients who suffer a stroke.

Despite these promising preclinical findings suggesting neuroprotective effects of DPP-4 inhibitors in acute stroke, it is still unclear whether these actions will also be observed in humans. Interestingly, a recent randomized double-blind study showed that the addition of linagliptin to metformin reduces the risk of non-fatal stroke more than the addition of glimepiride, despite comparable decreases in HbA_{1c}[48]. Preliminary data also suggest similar reductions in stroke risk with other DPP-4 inhibitors[49]. However, these studies were neither planned nor powered to assess the effects of DPP-4 inhibitors on cardiovascular events[48,49]. On the other hand, two recent large randomized, placebo-controlled studies did not show any benefit of DPP-4 inhibitors on cardiovascular events, including stroke[50,51]. Several other ongoing trials are evaluating the effects of DPP-4 inhibitors on cardiovascular morbidity and mortality. These studies also provide a major opportunity to assess whether patients treated with this class of antidiabetic agents will suffer from less severe strokes and whether their outcome after stroke will be more favorable.

Abstract

Hyperglycemia, a commonly exhibited metabolic disorder in critically ill patients, activates the body's inflammatory defense mechanism, causing the waterfall release of numerous inflammatory mediators and cytokines, and eventually leads to organ damage. As the only glucose-lowering hormone in the body, insulin not only alleviates the detrimental effects of hyperglycemia through its metabolic regulation, but also directly modulates inflammatory mediators and acts upon immune cells to enhance immunocompetence. In this sense, hyperglycemia is pro-inflammatory whereas insulin is anti-inflammatory. Therefore, during the past 50 years, insulin has not only been used in the treatment of diabetes, but has also been put into practical use in dealing with cardiovascular diseases and critical illnesses. This review summarizes the recent advances regarding the anti-inflammatory effects of insulin in both basic research and clinical trials, with the hope of aiding in the design of further experimental research and promoting effective insulin administration in clinical practice.

Key words: Insulin; Inflammation; Hyperglycemia

Core tip: Hyperglycemia is closely correlated with poor outcomes of morbidity and mortality in critically ill patients. As the only glucose-lowering hormone in the body, insulin not only alleviates the detrimental effects of hyperglycemia through its metabolic regulation, but also directly modulates inflammatory mediators and acts upon immune cells to enhance immunocompetence. This review summarizes the recent advances regarding the anti-inflammatory effects of insulin from our laboratory as well as others, in the hope of leading to a better understanding of this old, classic and wonder hormone and its wider and effective applications in clinical practice.

INTRODUCTION

Since its discovery in 1921, the importance of insulin in glucose homeostasis has been established, and it is universally used as a therapeutic agent for diabetes mellitus. Thousands of lives have been saved and many scientists were drawn into the study of this wonder drug. Under continuous intensive research, the mechanisms underlying the effect of insulin in its metabolic modulation, mainly glucose homeostasis, has become clearer, but there remains much interest in the elucidation of further

effects of insulin.

Glucose-insulin-potassium (GIK) has been used as an adjunctive therapy in patients with acute myocardial infarction (AMI) since its introduction in 1962. However, the mechanism underlying GIK's cardioprotection has remained largely speculative and controversial during the past 50 years. It was not until early in this century that we provided convincing *in vivo* evidence that insulin, rather than glucose or potassium, is the predominant protective component of GIK, and demonstrated for the first time that insulin exerted anti-apoptotic and pro-survival effects in the ischemic/reperfused (I/R) myocardium through the PI3K-Akt-eNOS-NO signaling pathway[1]. This prompted us to conceive the notion of the "survival signal", a new mechanism of cell protection which is totally independent of the metabolic effects of insulin, and explained its cardioprotective effects. In 2001, the classical landmark clinical trial by van den Berghe[2] revealed that maintaining blood glucose at or below 110 mg/dL with low-dose insulin infusion, significantly reduced mortality and morbidity resulting from multi-organ failure among critically ill patients in the surgical intensive care unit (ICU). A further study reported that markers of inflammation, such as intercellular cell adhesion molecular-1 (ICAM-1) and E-selectin were suppressed in the liver of these patients as was inducible NO synthase (iNOS) expression, which is mainly in monocyte/macrophage cells[3], suggesting an anti-inflammatory role for insulin. This article will summarize the relationship between insulin, glucose and inflammation, and discuss the implications for the management of patients with AMI and critical illness.

GLUCOSE, OXIDATIVE STRESS AND INFLAMMATION

Hyperglycemia is common in critical illness, and may lead to severe complications. It has been reported that pronounced hyperglycemia is associated with poor outcomes of morbidity and mortality in patients with AMI, stroke and coronary artery bypass grafting[4-6]. Glucose is pro-inflammatory, and hyperglycemia is even detrimental to these patients. A total of 75 g glucose intake causes acute oxidative and inflammatory stress, as reflected in increased superoxide radical O_2^- generation by polymorphonuclear leukocytes, mononuclear cells and the enzyme nicotinamide adenine dinucleotide phosphate[7]. Free radical O_2^- generation, on the one hand, reduces NO bioavailability, as it combines with NO to form peroxynitrite $ONOO^-$; on other hand, it activates a number of redox-sensitive major pro-inflammatory transcription factors such as nuclear factor kappa B (NFκB), activator protein-1 (AP-1), hypoxia induced factor-α (HIF-α) and early growth response-1 (Egr-1), leading to increased transcription of the pro-inflammatory genes and thus inflammation[8-10]. Meanwhile, glucose increases the expression of tumor necrosis factor alpha (TNF-α), interleukin-6 (IL-6) and monocyte chemoattractant protein-1 (MCP-1) in mononuclear cells. Moreover, it has led to increased TNF-α and IL-6 concentrations in plasma in a steady state of hyperglycemia with intravenous insulin secretion with somatostatin[11]. To sum up, glucose, oxidative stress and inflammation are inter-related, with reciprocal causation. As the only glucose-lowering hormone in the body, insulin therapy alleviates the detrimental effects of hyperglycemia through metabolic regulation, therefore hyperglycemia is pro-inflammatory whereas insulin is anti-inflammatory.

INSULIN MODULATES INFLAMMATORY MEDIATORS

The discovery of the anti-inflammatory effect of insulin can be traced back to the observation that insulin exerts a vasodilatory effect through endothelial NO release in arteries, veins and capillaries[12,13]. By inducing vasodilatation, it reduces leukocyte adhesion to the endothelium and subsequent infiltration. Furthermore, it has inhibitory effects on platelet adhesion and aggregation.

Studies have further confirmed that insulin suppressed three important inflammatory mediators: intercellular cell adhesion molecular-1 (ICAM-1), MCP-1 expression and NFκB binding in human aortic endothelial cells *in vitro*[14,15]. These suppressive effects can be blocked by the NOS inhibitor N(G)-nitro-L-arginine, indicating the effects are mediated by NO release. Among all the pro-inflammatory cytokines, TNF-α is the most active one in triggering the production of other cytokines such as IL-6 and other expression molecules[16]. We provided direct evidence in myocardial ischemia/reperfusion (I/R) rats that insulin inhibits TNF-α induction locally and systemically, and demonstrated for the first time that *in vitro* treatment with insulin attenuated I/R-induced TNF-α production in cardiomyocytes *via* the Akt-eNOS-NO signaling pathway[17]. Polymorphonuclear neutrophils (PMN) are the first defense line against infection and invasive microorganisms. Adherence of PMN to endothelial cells is an early requisite event in I/R-induced inflammatory injury. Thus we performed *in vivo* and *in vitro* experiments in a rabbit model to investigate whether insulin inhibits PMN-mediated adherence[18]. It was found that insulin reduced P-selectin and ICAM-1 expression in endothelium which mediates the initial interaction between PMNs and the endothelial cell surface, thus insulin attenuated PMN adherence and I/R-induced inflammatory injury. The Akt-eNOS-NO signaling pathway was involved in these effects. Moreover, insulin has been reported to ameliorate the endotoxin-induced systemic inflammatory response by decreasing IL-6, TNF-α expression and increasing the anti-inflammatory cascade in the context of normoglycemia in rat[19] and porcine models[20]. All these data indicate that insulin alleviates inflammation through suppression of pro-inflammatory cytokines and immune mediators, pointing strongly to its role as an anti-inflammatory agent.

INSULIN SUPPRESSES TOLL-LIKE RECEPTOR EXPRESSION

Toll-like receptors (TLRs) are a variety of conserved pattern recognition receptors that have been implicated in innate immune responses. Accumulating evidence suggests that TRLs play an essential role in tissue inflammation and damage such as cardiac I/R, post-ischemic remodeling and atherosclerosis[21-23]. TLR signaling and its critical roles in inflammatory cardiac conditions has been intensively studied, especially TRL2, TRL4' role with myocardial infarction and reperfusion injury. TRL2 aggravated myocardial tissue injury in I/R-based experimental animal models and its deletion was associated with a smaller MI size compared with control[24]. The TLR-deficient model, TLR2$^{-/-}$ mice, exhibited improved left ventricular dysfunction following I/R[25]. Besides, administration of anti-TLR2 antibody prior to reperfusion reduced MI sites and preserved cardiac function. TLR4 is the specific receptor of endotoxin, thus it mediates inflammatory changes induced by endotoxins. Oyama *et al*[26] first demonstrated that TLR4-deficient mice had more than 50% reduction in MI area, which was associated with attenuated myocardial inflammation, as evidenced by less neutrophil infiltration and fewer lipid peroxides. Inhibited by eritoran, a specific TLR4 antagonist, resulted in a 40% reduction in MI and decrease in TNF-α, IL-1β, IL-6 and MCP-1 expression[27,28]. Moreover, TRL4 has been found to act as a determinant of neutrophil infiltration after global MI through mediating KC and MCP-1 expression[29]. Suppression of TRL signaling is associated with smaller MI size and is beneficial in I/R-based animal models. It has been reported that insulin infusion (2 U/h) with type 2 diabetes (T2D) patients within 2 h has significantly suppressed TLR1, -2, -4, -7 and -9 mRNA expressions in MNCs, and this prompt suppression may be mediated by the suppression of PU.1 binding and subsequent activation of TLRs[30]. Thus, insulin suppresses the expression of several TLRs at the transcriptional level and alleviates TRL-mediated inflammatory injury.

INSULIN ACTS UPON IMMUNE CELLS

Peripheral blood mononuclear cells (PBMCs) is a critical component in the immune system, and mainly comprised of lymphocytes and monocytes. Investigations have been conducted to study the effects of insulin upon mononuclear cells in obese non-diabetic subjects[31]. The results showed that insulin reduced activation of the pro-inflammatory transcription factor NFκB, with downregulation of plasma soluble intercellular adhesion molecular-1, which facilitates the attachment of monocytes to endothelial cells and chemotactic factor MCP-1, which encourages monocyte migration into the subintimal space. This suppressive effect on NFκB in PBMC has also been reported in critically ill patients with intensive insulin therapy[32]. Similarly, Egr-1, another important pro-inflammatory transcription factor, was notably reduced in mononuclear cells with insulin treatment, resulting in decreased plasma concentrations of tissue factor and plasminogen activator inhibitor-1 (PAI-1)[33]. Taken together, insulin suppresses pro-inflammatory transcription factors in mononuclear cells and the subsequent inflammatory mediators regulated by them, thus ameliorating MNC-mediated inflammation.

Monocytes/macrophages (Mo/Mϕ) initiate immune and inflammatory responses. Insulin administration (10^{-7} mmol/L) retarded macrophage apoptosis and enhances BclxL mRNA expression by activating phosphatidylinositol 3'-kinase (PI3K) in a dose-dependent manner, thus improving macrophage survival[34]. Use of wortmannin, a specific inhibitor of PI-3K, has further confirmed its position in the anti-apoptotic effect of insulin in lipopolysaccharide-challenged THP-1 cells[35]. HLA-DR is a cluster of membrane molecules of Mo/Mϕ which are involved in the Mo antigen presentation to T cells. The intensity of HLA-DR expression is associated with immunocompetency of Mo/Mϕ[36]. Insulin treatment with blood glucose maintained between 4.4-6.1 mmol/L increased HLA-DR expressions of peripheral Mo cells. This upregulation means enhanced antigen presentation of Mo cells, indicative of improved immune function. Moreover, the phagocytosis, chemotaxis, and oxidative burst capacity of Mo have also been assessed in a burn-injured rabbit model, suggesting that insulin improved the capacity for phagocytosis and oxidative burst, but had no effect on chemotaxis[37].

T cell differentiation is important in the immune response. A single naïve T cell under cell differentiation is able to generate multiple subsets of memory T cells with different phenotypic and functional properties in response to infections, resulting in acquisition of immune functions required for pathogen clearance. Insulin was first confirmed to induce a shift in Th cell differentiation toward Th2 cells which is involved in secretion of inflammatory mediators (IL-4, IL-10, IL-13, *etc.*) and enhanced antibody-mediated responses[38]. Myocarditis is a severe disease of myocardial inflammation and often results from an autoimmune reaction. Significant T cell reduction was observed in cardiac myocarditis[39]. Thus, we investigated the effect of insulin on myocardial inflammation in experimental myocarditis in mice and its potential role in T cell regulation. The results showed that insulin promoted T cell recovery, particularly $CD3^+$ T cells without changing the naïve-to-memory T-cell ratio and had a direct effect on T cell proliferation, thus alleviating myocarditis[40]. It is possible that insulin may promote T cell recovery in myocarditis, especially in diabetic or hyperglycemic patients.

ANTI-INFLAMMATORY EFFECTS OF INSULIN IN HUMAN STUDIES

Cardiovascular disease (CVD) is the leading cause of death worldwide, and remains a great challenge in healthcare. Various risk factors of CVD, including hy-

pertension, diabetes and smoking, can initiate a chronic inflammatory reaction. Accumulating epidemiological and clinical studies have found strong and consistent relationships between markers of inflammation and the risk of future cardiovascular events[41]. Thus, inflammation is established as a definitive cardiovascular risk factor.

Hyperglycemia is pro-inflammatory and damaging, especially in critically ill patients. Pronounced hyperglycemia at hospital admission is associated with poor outcomes of morbidity and mortality in patients with AMI, thus effective glucose management is a necessary therapeutic intervention. It has been shown in large pilot studies, Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI)[42] and the Estudios Cardiologicos Latinoamerica (ECLA) study[43], that small doses of intravenously delivered insulin markedly improved clinical outcomes in patients with AMI. There was a marked 29% reduction in 1-year mortality in the insulin-glucose infusion group in the 1995 DIGAMI study, and a statistically significant reduction in mortality and a consistent trend toward fewer in-hospital events in the GIK group in the 1998 ECLA pilot trial, possibly as a result of rigorous glycemic control. The anti-inflammatory effect of insulin have been applied clinically. Plasma C-reactive protein (CRP) and serum amyloid A (SAA) concentrations are the two accepted markers of systemic inflammation which were impressively reduced to 40% in patients with AMI when treated with low-dose insulin infusion[44]. As the CRP concentration is correlated with the size of the infarct in AMI, a reduction is indicative of insulin's cardioprotective effects. Moreover, intensive insulin therapy has been given to critically ill patients in surgical and medical ICUs with improved outcomes[2,45]. In 1548 critically ill patients undergoing surgery, insulin infusion which maintained fasting blood glucose concentrations under 110 mg/dL dramatically improved the clinical outcomes with a reduction in total mortality by 48%, the incidence of bacteremia by 46%, acute renal failure requiring dialysis by 41%, ICU poly-neuropathy by 44%, and the need for red cell transfusion by 50% when compared with controls[2]. Mortality and morbidity in the surgical ICUs was dramatically reduced, as was morbidity in medical ICUs. No other agent has been shown to reduce mortality and morbidity by this magnitude in so many diverse ways in the ICU setting. Glucose control seems crucial, but several potential mechanisms may add to the benefits, including reduction of systemic inflammation[46], prevention of immune dysfunction[37], and protection of the endothelium[3,47]. The exact mechanisms underlying this simple and cost-effective intervention need further investigations.

INSULIN RESISTANCE AND INFLAMMATION

Insulin resistance (IR) is a pathological condition wherein insulin-stimulated glucose uptake and clearance in targeted organs are decreased. A few studies suggested that obesity, inflammation and IR are inextricably linked through the actions of specific inflammatory immune cells. The development of IR is thought to occur in response to increased production of pro-inflammatory cytokines by adipose tissue in obesity, that then have an inhibitory effect on insulin signaling pathways in multiple tissues. TNF-α was first found to be increased in adipose tissue of obese mice and able to induce IR[48]. In animal studies, administration of exogenous TNF-α induces IR, whereas neutralization of TNF-α improves insulin sensitivity. IL-1β, another key inflammatory cytokine, interferes with insulin signaling which leads to IR. TNF-α, and more generally, inflammation, activates and increases the expression of several proteins that suppress and impair specific pathways of insulin signaling, making the human body less responsive to insulin and increasing the risk of IR. In turn, IR states are pro-inflammatory. Increased levels of markers and mediators of inflammation such as fibrinogen, CRP, IL-6, PAI-1 and white cell count were shown to correlate with T2D[49-53]. These inflammatory mediators perpetuate and promote the progression of IR. Polycystic ovary syndrome, another IR state, was found to have chronic low-grade inflammation[54]. In other words, inflammation causes IR, and IR is inflammatory. Thus, anti-inflammatory treatment could be proposed as a therapeutic strategy in the treatment of IR.

ANTI-INFLAMMATION THERAPY FOR INSULIN RESISTANCE

Inflammation is hallmark of diabetes and a main cause of its long-term complications. Particularly in obese conditions in humans and animals, it contributes to the pathogenesis of T2D through IR. Therefore, anti-inflammation therapy may be proposed as a strategy for the improvement of IR.

TNF-α is a critical mediator of inflammation, and its increased expression was found to be associated with IR in the adipose tissue of obese mice[48]. *In vitro* studies demonstrated that TNF-α had a direct inhibitory effect on insulin signaling and impaired insulin-stimulated glucose uptake and metabolism in human subjects[55]. Clinically, neutralization of TNF-α with infliximab in patients with rheumatoid arthritis has significantly improved IR as reflected by the significant reduction in the Homeostasis Model Assessment Index[56]. Peroxisome proliferator-activated receptors (PPAR)γ inactivation leads to suppression of IRS-2, which is a signaling molecular in insulin pathways, thus further promotes IR. The anti-diabetic thiazolidinediones (TZDs), which include pioglitazone, rosiglitazone and troglitazone, are clinically used to improve insulin sensitivity in patients with T2D by lowering free fatty acids (FFA) in blood by activating PPARγ. Aspirin, another therapeutic agent, inhibits the activity of multiple kinases induced by TNF-α, and thus enhances insulin sensitivity by protecting proteins from serine phosphorylation[57]. Statins, as a class of anti-inflammatory drugs, have been shown to downregulate

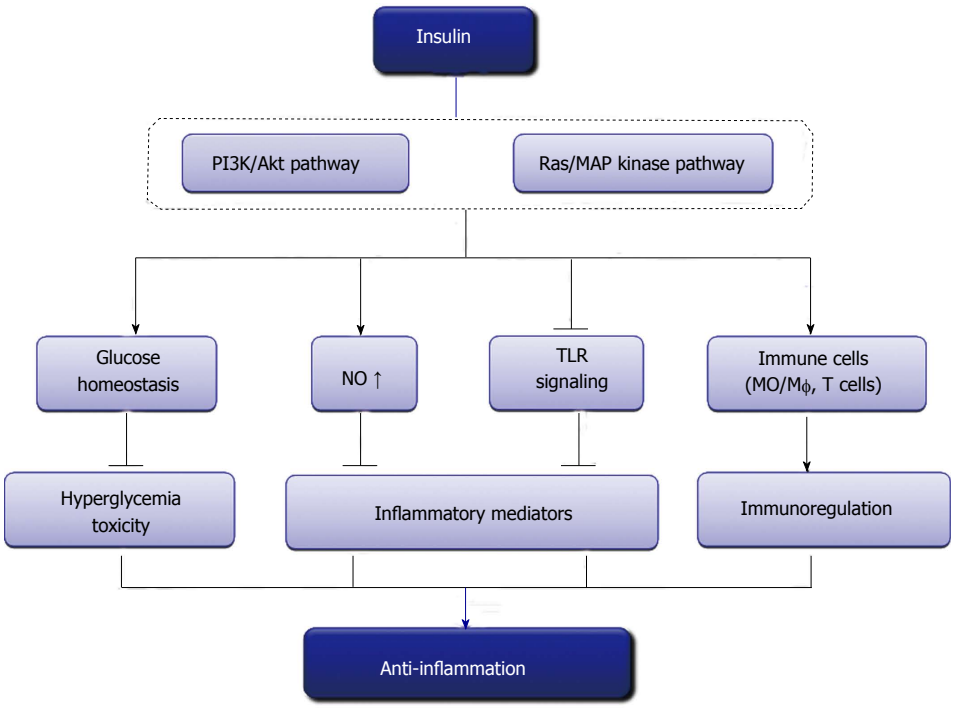

Figure 1 Anti-inflammatory effects of insulin. TLR: Toll-like receptor.

transcriptional activities of NFκB, AP-1 and HIF-1α, with reductions in inflammatory cytokines[58]. Despite these modest anti-inflammatory properties, the statins do not appear to significantly influence either IR or glycemic status. In contrast, high-dose salicylates directly suppress inflammation by targeting NFκB, which improves insulin sensitivity and reduces blood glucose in patients with diabetes[59-61]. The anti-inflammatory properties of TZDs and statins have associated side effects apart from their primary modes of action, thus they may not be safe in the long term. It is necessary to investigate new classes of drugs.

Histone deacetylases (HDACs) are key enzymes that regulate gene expression. Inhibition of histone deacetylase activity has been reported as a new approach to treat diabetes mellitus. Butyrate or trichostatin A, which are histone deacetylase inhibitors, prevented high fat-induced obesity and improved IR in mice[62]. The multiple beneficial effects included: reduced systemic chronic inflammation[63-66], reduced lipid toxicity[67,68], promotion of beta-cell development, proliferation, differentiation and function[69]. Thus HDAC inhibitors may represent a novel drug in the treatment of IR.

CONCLUSION

Hyperglycemia, a commonly exhibited metabolic disorder in critically ill patients, activates the body's inflammatory defense system, causing the cascade release of numerous inflammatory mediators and cytokines, and eventually leads to organ damage. Insulin inhibits hypermetabolism, such as hyperglycemia and lipid degradation, thus could attenuate glucose and FFA-mediated inflammation and improve immunocompetence. More importantly, insulin directly suppresses pro-inflammatory cytokines and induces anti-inflammatory mediators through non-metabolic pathways (Figure 1). Currently, the effects are dependent upon its suppression of innate immune mechanisms and the suppression of transcription factors such as NFκB and Egr-1. With further investigation, the discovery and understanding of the mechanisms underlying the anti-inflammatory effects of insulin opens up the possibility that insulin therapy could be used in multiple clinical practices.

Hyperglycemia, inflammation and IR are inter-related and of reciprocal causation. The relationships between the three entities are far from being elucidated. Hyperglycemia leads to oxidative stress, which further results in inflammation. IR, commonly as a manifestation of hyperglycemia, is pro-inflammatory. Reactive oxygen species is believed to be an important cause of many pathological conditions, including inflammation and IR. It has been established that hyperglycemia is inflammatory whereas insulin is anti-inflammatory. From simple glucose maintenance to the discovery of cardiovascular protection, the knowledge and understanding about insulin is increasing. The pleiotropic effects of insulin including glucose control, and reduction in apoptosis, oxidative/nitrative stress and inflammation, contribute to cardiovascular protection and are beneficial in critical illness. It is not a single effect that mediates the important role of insulin, but it is the whole scenario that promotes its myriad effects. With consistent research, we will gain a better understanding of these working mechanisms, and in doing so, are likely to find more therapeutic targets and wider applications for this wonder drug.

Abstract

Type 2 diabetes (T2D) is a common metabolic disorder which is caused by multiple genetic perturbations affecting different biological pathways. Identifying genetic factors modulating the susceptibility of this complex heterogeneous metabolic phenotype in different ethnic and racial groups remains challenging. Despite recent success, the functional role of the T2D susceptibility variants implicated by genome-wide association studies (GWAS) remains largely unknown. Genetic dissection of transcript abundance or expression quantitative trait (eQTL) analysis unravels the genomic architecture of regulatory variants. Availability of eQTL information from tissues relevant for glucose homeostasis in humans opens a new avenue to prioritize GWAS-implicated variants that may be involved in triggering a causal chain of events leading to T2D. In this article, we review the progress made in the field of eQTL research and knowledge gained from those studies in understanding transcription regulatory mechanisms in human subjects. We highlight several novel approaches that can integrate eQTL analysis with multiple layers of biological information to identify ethnic-specific causal variants and gene-environment interactions relevant to T2D pathogenesis. Finally, we discuss how the eQTL analysis mediated search for "missing heritability" may lead us to novel biological and molecular mechanisms involved in susceptibility to T2D.

Key words: Type 2 diabetes; Single nucleotide polymorphisms; Expression quantitative trait locus; Expression regulatory SNPs; Gene-environment interaction; Genome-wide association study

Core tip: Identification of genetic variants that modulate the susceptibility to disease and elucidating their function at the molecular level is a major focus of type 2 diabetes (T2D) research. This article highlights the utility of expression quantitative trait analysis in discovering regulatory variants that increase susceptibility to T2D by modulating the expression of transcripts in tissues important for glucose homeostasis.

GENETIC DISSECTION OF TYPE 2 DIABETES SUSCEPTIBILITY

Diabetes is one of the most prevalent metabolic disor-

ders, characterized by elevated levels of plasma glucose, and is responsible for significant mortality and morbidity in human populations worldwide[1]. The latest estimate from the International Diabetes Federation indicates a global prevalence rate of 8.4% in adults and 382 million cases of diabetes in 2013[2]. It is one of the common diseases with a well-accepted genetic contribution[3]. Type 2 diabetes (T2D), a late onset subtype of diabetes, results from a derangement in the complex interplay of multiple physiological processes known to be involved in systemic glucose homeostasis. These processes include peripheral glucose uptake in muscle, secretion of hormones and incretins form pancreas and intestine, secretion of cytokines/adipokines from adipose tissue, hepatic glucose production, and neuro-endocrine regulation by central nervous system[4,5]. However, the relative contribution of these processes to T2D pathogenesis is debated. Based on this knowledge on intertwined and complex physiological processes it can be anticipated that T2D is a heterogeneous conglomeration of phenotypes, caused by multiple genetic perturbations and affecting different biological pathways. Predictably, deciphering the genetic etiology of T2D has remained challenging.

Until the last decade, searching for an association between T2D and sequence variants of selected candidate genes was the mainstay of research for finding genetic susceptibility factors. Based on available technology in those studies, researchers selected candidate genes either from loci detected by genome-wide linkage analyses or based on known physiological functions. In our earlier reviews, we discussed the knowledge gained from such studies in detail[6,7]. Success from those endeavors was very limited. However, this approach has identified genetic variants in the *TCF7L2* gene, to date is the best replicated and strongest (relative risk approximately 1.4) genetic susceptibility factor for T2D[8], but its role is still controversial[9-11].

In the middle of the last decade, a transformative change took place in the field of genetics of complex disease research. Advances in high-throughput genotyping technology, availability of the complete human genome sequence, a dense catalogue of common genetic variants, and a population-specific linkage disequilibrium map of these variants lead to the implementation of genome-wide association studies (GWAS), which interrogate the entire genome to identify common genetic variants (minor allele frequency $\geqslant 0.05$) associated with a disease[12]. GWAS have yielded unprecedented success in identifying well-replicated susceptibility loci for T2D, glucose homeostasis traits, obesity, and related metabolic phenotypes[3,13-15]. Nevertheless, these successes come with significant caveats. Based on the most recent analyses, the 63 T2DM-associated loci discovered so far in Caucasian populations together account only for 5.7% of the liability-scale variance in disease susceptibility, and sibling relative risk (λ_s) attributed jointly by these variants is 1.104[13]. Moreover, few of the T2D loci identified primarily in European- or Asian-derived populations are convincingly replicated in African American, Native American, and Hispanic populations, all of whom have a higher prevalence of T2D than Caucasians[14,16]. These GWAS-identified loci do not appear to explain the well-established roles for adipose, muscle, and liver in diabetes pathogenesis[17], and few of these loci have been linked to a molecular mechanism. Several investigators have attempted to implicate function to T2D-associated loci based on their proximity to a gene, assuming that the associated single nucleotide polymorphisms (SNP) alters the function of a nearby gene[18]. Some have drawn enthusiastic conclusions about the role of these variants exclusively in insulin secretion[19]. However, proof of such an assumption is lacking. Given the small effect on T2D susceptibility and the statistical noise inherent in performing 10^6 or more tests, exclusive reliance on larger T2D GWAS alone is unlikely to identify the source of undefined T2D susceptibility (often referred to as "missing heritability"[20]).

EXPRESSION QUANTITATIVE TRAITS: MOLECULAR ENDOPHENOTYPES

One of the major findings from the T2D GWAS is that most of the trait-associated SNPs are located in intronic, intergenic, or other non-coding regions of the genome[3,21]. Further fine mapping analysis also failed to find any coding or other variants that would provide a molecular biological explanation of the elevated disease risk attributed by these loci.

The abundance of a transcript is a quantitative trait. Studies in human populations showed a wide, heritable variation of transcript levels among individuals, and thus lead to the concept of "expression quantitative trait loci" (eQTL)[22,23]. The heritability of eQTLs has been replicated in multiple human tissue or cell types, with approximately 30% of eQTLs having $h^2 > 0.3$, and an estimated 58%-85% being heritable[24-28]. The abundance of a transcript can be directly modified by polymorphisms in non-coding regulatory elements. Many SNPs are associated with quantitative transcript levels and are considered as expression regulatory SNPs (eSNPs). eSNPs close to the transcription start sites (TSS) of the eQTLs are named "*cis*" or "local" eSNPs , whereas eSNPs located $> \pm 500$ kb from the TSS or on a different chromosome are considered "*trans*" or "distal" eSNPs[22,29]. Similar to a published study[30], here we will refer to eQTLs as the transcripts rather than SNP-transcript pair, and eSNPs as the genetic variants (SNPs) associated with the expression profile of a transcript.

Based on this knowledge, many laboratories (including ours) hypothesized that GWAS-associated non-coding variants are eSNPs and can modulate T2D susceptibility by altering transcript levels (or splicing). This concept is based on the "central dogma" of gene expression and presents a causal model of genetic susceptibility (Figure 1). In this model, transcript abundance is considered as an intermediate phenotype between genetic loci (DNA sequence variants) and subclinical (*e.g.*, insulin resistance)

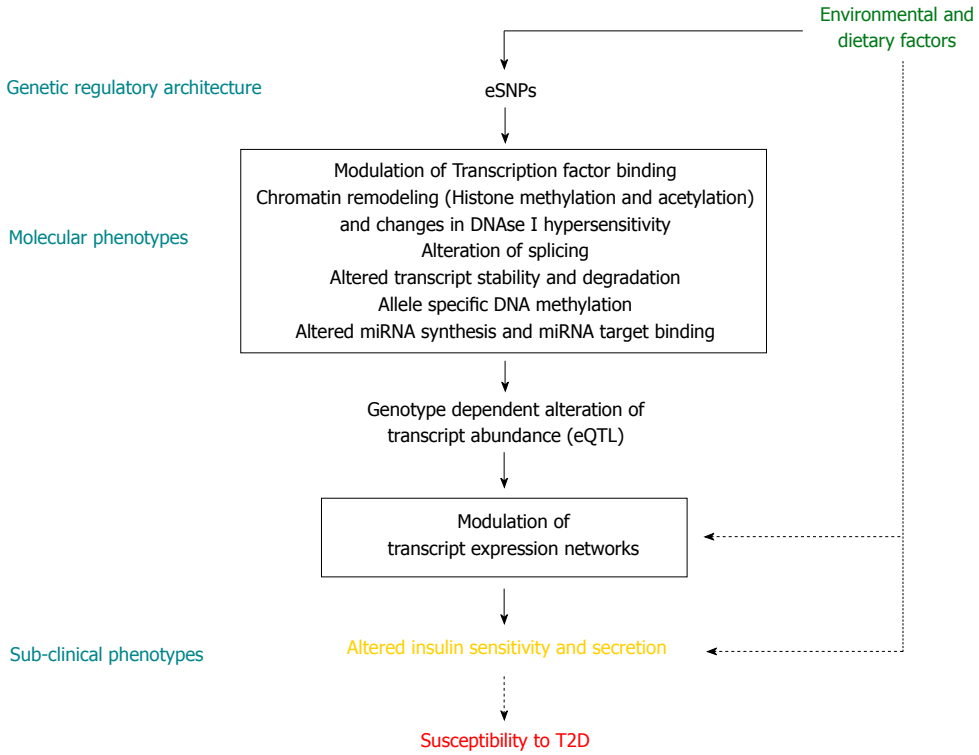

Figure 1 A causal model of genetic susceptibility. Genetic regulatory architecture modulates molecular phenotypes in interaction with environmental factors and alters disease susceptibility. eSNP: Expression regulatory SNP; eQTL: Expression quantitative trait loci; T2D: Type 2 diabetes.

or clinical (*e.g.*, T2D) phenotypes. Since transcript abundance is a proximal molecular endophenotype affected by genetic variants, it is likely to be a less heterogeneous phenotype (compared to complex clinical phenotypes like those of T2D), and thus more amenable to genetic mapping methods due to superior statistical power.

EQTL MAPPING

Study designs and analytical frameworks for eQTL mapping are similar to those for mapping any other quantitative traits [*e.g.*, body mass index (BMI), fastin glucose, glycosylated hemoglobin]. However, genetic analysis of human phenotypes including QTLs carries a unique set of problems[29]. In general, eQTL analyses integrate genome-wide expression (in tissues or cells) and genotype data in multiple individuals (related or unrelated). These analyses use linkage- or association-based statistical genetic methods to map regulatory regions and genetic variants that may explain individual variations in transcript expression. Microarray- or RNA-seq[31-33] based methods are used to generate large numbers of quantitative transcript phenotypes. Therefore, the number of statistical tests involved in eQTL mapping studies is significantly higher than in traditional QTL analysis[34]. A detailed discussion on methods used in eQTL analysis is beyond the scope of this article, and we refer our readers to other reviews on this specific subject[29,34-36].

Published eQTL studies have implemented linkage analysis by using 400-2000 microsatellite makers[24,26] to localize regulatory intervals, whereas other studies have genotyped large numbers of common SNPs (> 100000) to discover the eSNPs[25,28,37] associated with eQTLs. With the advancement of genomic technology, we can now simultaneously genotype more than 4.5 million SNPs or can have a whole genome sequence for each individual included in an eQTL study by highly multiplexed "next generation" sequencing methods[38]. These advances pose additional statistical and computational challenges, and will require appropriate correction and adjustment of significance thresholds for the massive number of independent tests performed (and hypotheses tested) to control false discovery. The power to detect eSNPs depends on their effects (average difference in the transcript abundance between genotypes, scaled by the standard deviation of the transcript abundance within genotype classes) and allele frequency[34]. Consequently, detection of eSNPs with a lower effect allele frequency and a lower effect size will require a larger sample size.

One interesting observation from published eQTL studies is that most of the strong eSNPs are located near the TSS with no discernable trend in the 5' or 3' direction[28,39,40]. As a result, most studies consider SNPs within close proximity of the TSS (± 500 kb window) as *cis*-eSNPs. Since the genomic context of most eQTL transcripts are known, statistical adjustment for the actual number of SNPs tested within 500 kb will be more appropriate for *cis*-eSNP discovery. Any SNP outside the *cis*-region is tested as a *trans*-eSNP for a transcript. The molecular biological basis of trans-regulation is less studied;

current information suggests that the variants that affect transcription factors, miRNAs, or long-range chromatin interaction may act as trans-eSNPs. To identify *trans*-eSNPs, the number of tests needed is far greater, and the tests require more stringent significance threshold criteria and a larger sample size. Thus, use of a false discovery rate based on a permutation analysis to correct for multiple testing[34], and considering the correlation among transcript levels and highly correlated SNP structures, are useful approaches to identify this biologically important class of regulatory SNPs.

Several heterogeneous sources of variability hidden in the data may lead to both spurious eSNPs and missed associations in eQTL analyses if not properly addressed. Statistical models that correct for hidden structures within the sample (such as race, admixture, and family relatedness), artifacts in expression data (including batch effects and probe bias), environmental influences, and other known and unknown factors are required to improve sensitivity and interpretability of eQTL analyses[41]. Methods that showed significant usefulness in tackling these confounding factors include Bayesian approaches developed by Stegle *et al*[42] (implemented in probabilistic estimation of expression residuals or probabilistic estimation of expression residuals software), linear mixed-effects model-based approaches developed by Listgarten *et al*[43] (implemented in LMM-EH-PS or Linear Mixed Model-Expression Heterogeneity-Population Structure software), surrogate variable analysis, and inter-sample correlation emended approaches[44,45].

The heavy computational burden involved in eQTL analyses sometimes forces researchers to restrict their analysis to a small subset of selected transcripts and SNPs. Improvement of computational algorithms, parallelization of programs by efficient scripting, and utilization of efficient processing hardware are among many approaches needed to improve scalability and computational efficiency required for eQTL analyses. Implementation of these approaches will enhance discovery by increasing the capacity to utilize the complete data set[46,47].

EQTLS AND DISEASE GENE MAPPING

Molecular and cell biological experiments in model organisms and cells have significantly advanced our understanding about the role of non-coding DNA sequences in genetic regulation, transcriptional circuitry, the transcriptional apparatus, and chromatin regulation. This work has led to new insights into the complex mechanisms involved in dysregulation of gene expression in various human diseases[48]. Recent genome-wide studies in human cells by different international consortia [including ENCyclopedia Of DNA elements (ENCODE)][49] further have improved our mechanistic understanding of the role of DNA sequence variants in quantitative modulation of gene expression[50-52]. eQTL studies have been extensively used to identify genetic regulators involved in natural variation of gene expression[28,37,39] and to understand tissue-specific architecture of genetic regulatory mechanisms[24,30,53-59].

However, an intriguing application of eQTL mapping is the use of eSNP data to interpret disease or disease-related phenotypic association signals, and thereby elucidate specific biological mechanisms underlying the increased genetic risk attributed by the DNA sequence variants. Identification of genetic variants simultaneously associated with disease and eQTLs (in relevant tissue) significantly facilitates identification of potential causal genes. Discovery of genetic variants in *ORMDL3* as a susceptibility factor for childhood-onset asthma[60] and *VNN1* variants that influence high-density lipoprotein cholesterol concentrations[26] are two early examples of the successful implementation of eQTL mapping in disease gene hunting. The review by Cookson *et al*[36] offer a more detailed discussion on those success stories.

Several recent studies have integrated GWAS and eQTL analyses (data generated in different sets of subjects) and have used the overlap of two signals as a tool to interpret GWAS findings. Although this work is a good starting point, we need to be cautious about using the overlap of two statistical signals (eSNP and the disease phenotype-associated SNP/phSNP). Careful thought is required before making a claim of identifying a disease-causing variant. Montgomery and Dermitzakis (2011) described three situations[41] when a coincidence of eQTL and disease phenotype GWA signal may distract from identification of causal variants: (1) eSNP and phSNP are in the same linkage disequilibrium (LD) block but are two different SNPs. This is not considered as exact overlap, and they may tag different causal variants; (2) eSNPs and phSNPs are the same but SNP density differs between the eQTL and GWAS data. Lack of proper resolution in one or both studies may be misleading and will not elucidate the correct functional SNP; and (3) eSNPs may have a pleiotropic effect and may regulate the expression of "gene Y" in "tissue 1", but the same eSNP may regulate the expression of "gene X" in "tissue 2". Thus, if the eQTL study is done in "tissue 1" (a "surrogate" tissue) but not in "tissue 2" (the "disease-relevant" tissue in which the true causal effect is manifested), then despite the overlap of eSNPs and phSNPs, we will incorrectly link "gene Y" to the disease phenotype.

In general, eSNPs that are universal have a stronger effect, but a significant proportion of eSNPs show tissue-specific effects[30,53,54]. However, it is difficult to select "relevant" tissue, or the relevant tissue may not be accessible from human subjects for analysis for many complex diseases. Ongoing efforts of international consortia, including GTEx, to develop multi-tissue eQTL databases (Table 1) is a significant step forward in addressing this limitation[61-64].

Many investigators have developed statistical approaches to formally test the overlap of GWAS and eQTL signals to distinguish accidental colocalization from true sharing of causal variants. The regulatory trait concordance method designed by Nica *et al*[65] accounts for local LD structure and integrates eQTL and GWAS results to reveal the subset of association signals due to

cis- or *trans*-eQTLs. He *et al*[66] (2013) developed an algorithm named "Sherlock" based on a Bayesian statistical framework to identify potential gene-disease associations by matching genetic signatures of expression (collective information of *cis*- and *trans*-eSNPs) of a gene to that of the disease phenotype by using GWAS data of the disease and the eQTL data of related tissue. These novel approaches are likely to expand our ability to harvest new insights from genetic association studies for disease phenotypes.

T2D-ASSOCIATED VARIANTS ARE ESNPS IN TISSUES IMPORTANT FOR GLUCOSE HOMEOSTASIS

Genome-wide eQTL analyses in transformed lymphocytes (lymphoblastoid cell lines, or LCLs) provided the first evidence that SNPs associated with complex diseases phenotypes are more likely to be eSNPs than minor allele frequency-matched SNPs randomly selected from high-throughput GWAS genotyping platforms. Nicolae *et al*[67] (2010) utilized an Affymetrix GeneChip Human exome 1.0 ST array to generate exon-level expression data of LCLs from 87 Caucasian (CEU) and 89 African (YRI) subjects from the HapMap project. They performed a quantitative-trait transmission disequilibrium test to identify eSNPs from 2 million genotyped SNPs. A study by Nica *et al*[65] (2010) utilized an Illumina Sentrix WG-6-V2 whole-genome expression array to generate total transcript-level expression data of LCLs from 109 unrelated CEU subjects (from the HapMap 3 project) and performed Spearman rank correlation analysis to identify eSNPs from 1186075 genotyped SNPs. Key findings from these studies[65] include: (1) SNPs reproducibly associated with complex human traits are likely to be eSNPs; (2) Enrichment of complex trait GWAS-implicated SNPs are more evident among *cis*-eSNPs but not among *trans*-eSNPs; and (3) eSNPs discovered in LCLs are more strongly enriched for SNPs associated with immunity-related conditions (*e.g.*, Crohn's disease, type 1 diabetes, rheumatoid arthritis), but such enrichment was not observed for metabolic disorders (*e.g.*, T2D and coronary artery disease). These studies indicate that eQTL studies using surrogate tissue samples may be helpful for some diseases. However, understanding the functional role of T2D-associated SNPs will probably require expansion of eQTL studies into tissues more relevant for T2D pathophysiology. These studies also had significantly lower power to identify *trans*-eQTLs due to comparatively small sample sizes, and will require reevaluation of the role of *trans*-eSNPs in larger sample sets.

Zhong *et al*[68] (2010) used genetics of gene expression (GGE) analysis in tissues from two cohorts of human subjects (Cohort 1: liver-specific GGE cohort with post mortem liver samples from 427 subjects; Cohort 2: liver, subcutaneous adipose and omental adipose from 922 subjects who had Roux-en-Y gastric bypass surgery). They identified 18785 unique eSNPs in the combined set of data. They found 2189, 2286, and 1999 eSNPs specific to liver, omental adipose, and subcutaneous adipose, respectively. However, they also noticed that 72% of *cis*-eSNPs identified in liver, 79% of those found in omental adipose and 80.5% from subcutaneous tissue were also found in the other two tissues. Given the metabolic relevance of these tissues, they further interrogated data from three large-scale T2D GWAS datasets to test whether the set of eSNPs were more likely to be associated with T2D compared to randomly selected SNPs. These tissue eSNPs showed a significant enrichment of T2D-associated SNPs. For example, in the DIAGRAM (DIAbetes Genetics Replication and Meta-analysis) GWAS data set, 7.34% of the eSNPs showed a significant association with T2D ($P < 0.05$) compared to an average of 6.12% SNPs in the random sets, representing a modest 1.20-fold enrichment for SNPs in the eSNP (or SNP in LD at $r^2 > 0.89$) set over the random sets (p-enrichment = 1.33×10^{-9})[68]. In that study, omental adipose tissue eSNPs also showed

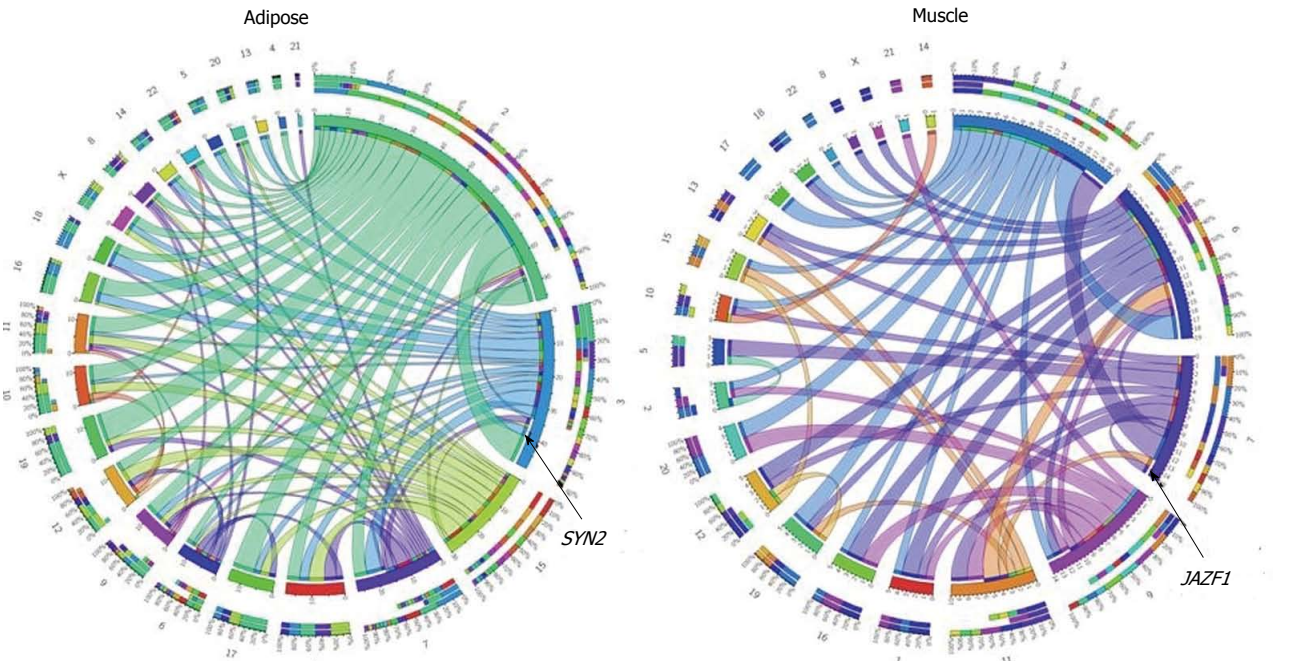

Figure 2 Type 2 diabetes or glucose homeostasis traits associated variants are expression regulatory SNP. We tested *Cis* and *Trans* regulatory role of 68 SNPs that showed reproducible associations with T2D or Glucose homeostasis traits[72]. At a threshold of $P < 0.0001$, 25 and 19 of these SNPs in adipose and muscle, respectively, showed association with expression of a *cis*- or trans-transcript. This figure represents a CIRCOS plot of eQTL and eSNP chromosomal location relationships, indicating the predominance of *trans*-regulation among 183 and 62 significant ($P < 0.0001$) eQTL-eSNPs associations in adipose and muscle respectively. Rare *cis*-regulation (*SYN2* in adipose and *JAZF1* in muscle) is marked. eSNP: Expression regulatory SNP; eQTL: Expression quantitative trait loci; T2D: Type 2 diabetes.

further significant enrichment when restricted to adipose expression network genes differentially expressed with T2D. Thus, these studies support the notion that T2D-associated SNPs may modulate expression of transcripts in tissues relevant for glucose homeostasis.

Fu *et al*[53] (2012) analyzed eQTLs in blood ($n = 1240$) and other tissues (liver, $n = 62$; muscle, $n = 62$; subcutaneous adipose, $n = 83$; and visceral adipose, $n = 77$); out of 1954 SNPs associated with complex disease traits from a GWAS catalogue, 907 were *cis*-eSNPs. However, 28.7% of these trait-associated *cis*-eSNPs showed a tissue-specific (in blood versus other tissue) and discordant effect on gene expression. The discordant effect includes tissue-specific regulation, alternative regulation by different eSNPs, different effect size and, in a few cases, opposite allelic direction. The study also showed that SNPs associated with complex traits are more likely ($P = 2.6 \times 10^{-10}$) to exert a tissue- specific effect on gene expression[53]. No comparisons were made between other tissues due to small sample size. This study indicates that use of tissues in eQTL analysis may have implications for inferring transcriptional effects of SNPs, especially for the complex disease susceptibility variants.

This work also emphasizes the importance of investigating disease-relevant tissue for characterizing functional effects of T2D and other disease-associated variants. However, it is difficult to determine "relevant tissue" even for diseases with known pathophysiology. T2D is clearly of polygenic etiology, and relevant tissue could be distinct for genes involved. Moreover, gene expression is regulated by environmental (*e.g.*, diet), epigenetic, and other unknown factors, and eQTL discovery from tissue samples may be affected by the physiological state of the donors[41]. For example, profound hyperglycemia and dyslipidemia observed in T2D subjects will modulate and even may mask primary causal changes in genetic regulatory networks. Thus, multi-tissue eQTL analysis in physiologically characterized individuals could be a safe option to scrutinize the circularity of cause and effect in genetic regulatory signals, and holds the promise to offer insights into the novel mechanisms driving genetic susceptibility to T2D.

Most initial eQTL studies seeking to identify a regulatory role for T2D-associated SNPs have focused on *cis*-eQTLs. However, studies by Voight *et al*[69] (in adipose, $n = 603$; and blood, $n = 745$ subjects) and our laboratory (in adipose and muscle of 168 non-diabetic subjects who were physiologically evaluated) showed that only a few top T2D GWAS-identified signals can be explained as *cis*-eQTLs, and T2D-associated non-coding SNPs are less likely to regulate expression of the closest gene[70]. Results were similar in an eQTL analysis that used human islet cells from 63 cadaver donors[71]. A genome- wide study by our laboratory[72] in adipose and muscle tissue of 62 subjects (31 insulin- resistant and 31 insulin-sensitive subjects matched for BMI) showed that at a less stringent threshold ($P < 0.0001$), among 68 well-replicated T2D/glucose homeostasis-associated SNPs, 25 and 19 of them were eSNPs in adipose and muscle, respectively (Figure 2). However, after stringent (Bonferroni) correction, only SNP rs13081389 was a *cis*-eSNP for the *SYN2* gene in adipose ($P < 4.7 \times 10^{-8}$, 15507 expressed transcripts were

tested in adipose). Interestingly, these 68 SNPs showed significant enrichment for *trans*-eSNPs in adipose and muscle, but not in LCLs[72]. Many of these *trans*-eSNPs show associations with expression of ⩾ 10 transcripts and may be a "master regulator". Expanding this search for the top 1000 T2D-associated SNPs from a Wellcome Trust Case Control study also confirmed the *trans*/distal regulatory SNPs[72]. We also showed that replicated T2D- and glucose homeostasis-associated SNPs are enriched for *trans*-eQTLs for transcripts differentially expressed between insulin-resistant and insulin-sensitive people[72]. A recent eQTL study using a large cohort of blood samples also supported the *trans*-regulatory role of 233 complex trait-associated SNPs[73]. Thus, the genetic regulatory architecture of T2D is complex, tissue-specific, and likely extends beyond the *cis*-regulatory mechanism.

EQTL ANALYSIS FOR PRIORITIZING T2D-ASSOCIATED VARIANTS TO IDENTIFY NOVEL CANDIDATE GENES

The multiple testing corrections utilized in genome-wide statistical analyses allow detection of only the strongest effects and penalize weaker associations that may be biologically meaningful[74]. Investigators have implemented several approaches to prioritize T2D association signals from large GWAS datasets to identify biological mechanisms responsible for genetic predisposition. One common approach includes selection of genes close to T2D GWAS-implicated SNPs and shows differential expression in T2D subjects compared to normoglycemic subjects (or in animal models of T2D). This approach is based on the idea that T2D-associated variants may modulate the expression of nearby genes in tissues important for glucose homeostasis. Parikh *et al*[75] used publicly available expression microarray data from different tissues (pancreas, adipose, muscle, and liver from T2D patients and rat models of T2D) to prioritize among the 275 genes located near 1170 T2D GWAS-implicated SNPs. A recent study by Taneera *et al*[71] used expression profiling of human pancreatic islet cells for functional prioritization of genes in the vicinity of 47 T2D-associated SNPs. However, available data from several human tissue eQTL analyses indicate that only a few T2D-associated SNP act as *cis*-eSNPs, and no enrichment of differentially expressed genes was observed around T2D GWAS-implicated variants[72]. Thus, a logical alternative for prioritizing T2D-associated variants is to utilize a reverse genetics approach and restrict the genetic search space to the subset of variants that are eSNPs in relevant tissues. These eSNPs are statistically associated with expression of transcript and thus have a strong possibility of being a "key driver" in perturbing gene-expression regulatory networks.

Selecting the genes based on eSNPs among those also associated with T2D in large GWAS datasets will prioritize genes with a significantly high chance of being causally involved with susceptibility to T2D, and thus may be helpful in identifying additional genetic susceptibility loci from GWAS datasets. A genome-wide analysis of adipose tissue transcriptomes from 62 insulin-resistant and -sensitive subjects identified 172 differentially expressed transcripts[76]. We checked adipose eQTL data from the MuTHER study[55] to find eSNPs of these differentially expressed transcripts. We further mined the DIAGRAM GWA meta-analysis results[13] for association of these eSNPs with T2D. This analysis[77] identified that the strongest *cis*-eSNP (rs11037579, $P = 4.21 \times 10^{-6}$) for the *HSD17B12* in adipose tissue was also associated with T2D [$P = 3.80 \times 10^{-4}$, OR = 1.06 (95%CI: 1.03-1.1)]. Individuals carrying the T2D risk allele T for the intronic SNP rs11037579 had lower expression of *HSD17B12* in adipose tissue. This result corroborates the finding that *HSD17B12* expression is downregulated in the adipose tissue of insulin-resistant subjects. The *HSD17B12* gene codes a bifunctional enzyme involved in the biosynthesis of estradiol and the elongation of very long chain fatty acids. Several variants within ± 500 kb of this gene are eSNPs (including a 3'UTR SNP rs1061810) in adipose, LCL, and other tissues, and show an association with T2D (although below the genome-wide threshold) (Figure 3). Further functional studies will be required to identify true causal SNPs. However, this integrative approach demonstrates the validity of such an approach in prioritizing novel T2D susceptibility loci. In fact, two recent integrative genomic studies showed that eSNPs for *PFKM* (SNP rs11168327) gene in muscle and *ARAP1* (SNP rs11603334) gene in pancreatic beta cell are associated with T2D[78,79].

EQTL AND BIOLOGICAL NETWORK ANALYSIS TO IDENTIFY ETHNIC-SPECIFIC GENES FOR T2D:

Age-standardized prevalence of T2D varies among ethnic and racial groups[14,80]. T2D is almost twice as prevalent in adult non-Hispanic African Americans (14.9%) in the United States compared to European Americans (7.6%)[81]. Yet only a few of the associated T2D-loci - identified primarily in European- or Asian-derived populations - are replicated in African American, Hispanics, and Native Americans[14,16,82-84]. Intriguingly, studies have identified distinctive physiologic features of glucose homeostasis in African Americans and Hispanics[85-87]. Compared to non-Hispanic Caucasians matched on age, gender, and BMI, African Americans are more insulin-resistant (lower S_I), but show a greater acute insulin response to intravenous glucose (AIR_G) and a higher disposition index ($DI = S_I \times AIR_G$). A genetic basis for these physiological differences seems likely, but remains unidentified.

Published studies of expression across ethnic groups (mostly restricted to lymphocytes or HapMap LCLs) showed distinct ethnic-specific expression[37,88-90]. Zhang *et al*[90] (2008) reported differential expression of up to 67% of transcripts between LCLs from subjects of

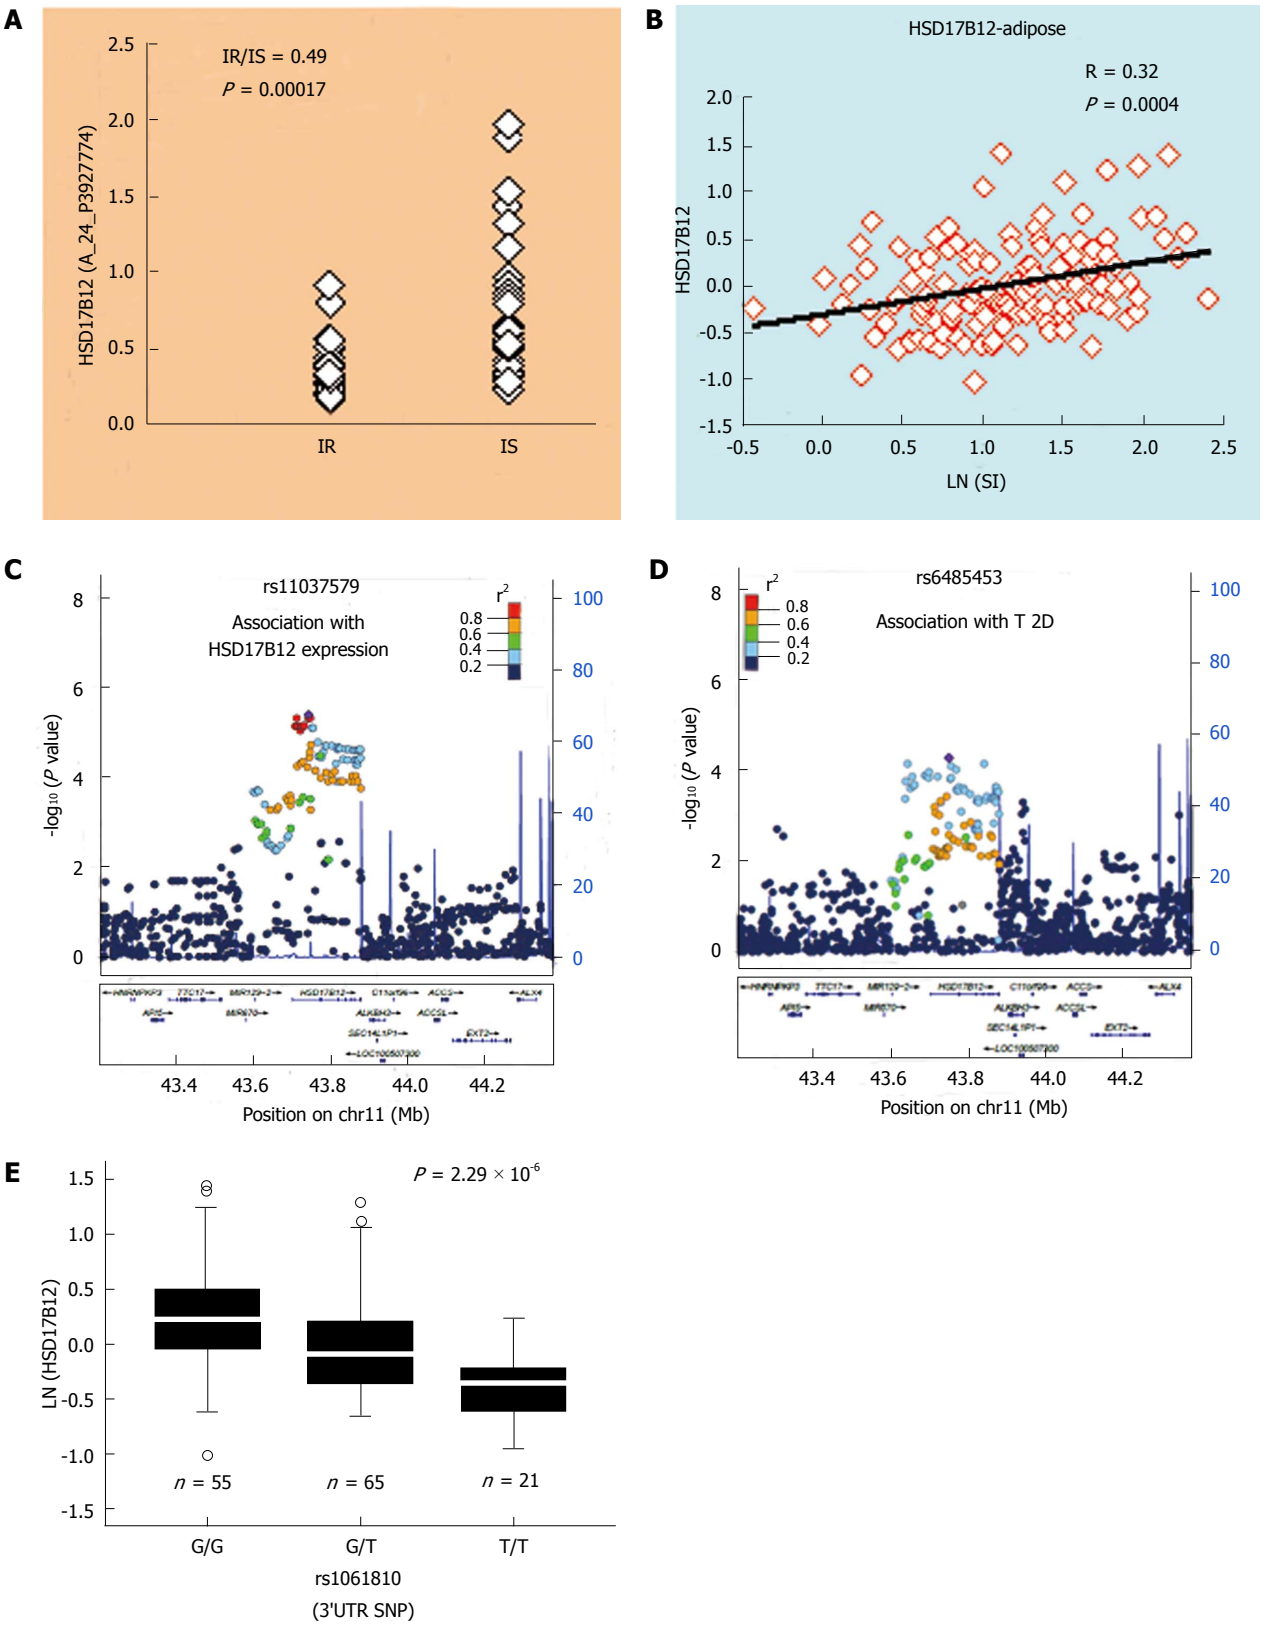

Figure 3 Prioritizing type 2 diabetes-associated variants by expression quantitative trait loci analysis: An example. *HSD17B12* is one of 172 genes differentially expressed in adipose tissue of insulin-resistant (IR, $n = 31$) *vs* insulin-sensitive (IS, $n = 31$) subjects in a genome-wide study (A) by Elbein *et al*[76]. Its expression in subcutaneous adipose of non-diabetic subjects ($n = 141$) also shows a significant correlation (B) with insulin sensitivity (SI). Strongest *cis*-eSNP for adipose tissue (C) expression of HSD17B12 (in adipose eQTL from the MuTHER project)[55] is also associated with T2D (D) in a large GWAS meta-analysis (in DIAGRAM.v3 data from 12171 T2D and 56862 controls)[13]. This locus also includes a 3'UTR SNP rs1061810 that shows association (E) with T2D and expression of HSD17B12 (in qRT-PCR analysis in adipose tissue from 141 non-diabetic subjects). eSNP: Expression regulatory SNP; eQTL: Expression quantitative trait loci; T2D: Type 2 diabetes.

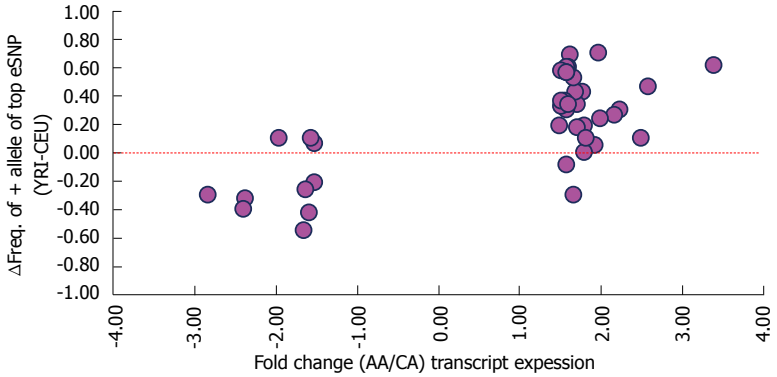

Figure 4 Population differences in expression of transcripts in adipose tissue is accounted for by the effect allele frequency difference of expression regulatory SNPs among racial groups. X axis: Fold change in average expression of 41 transcripts between African-American (AA, *n* = 37) and Caucasian (CA, *n* = 99) subjects. Y axis: Differences in strongest eSNP allele frequency of these transcripts between HapMap subjects of Caucasian (CEU) and African (YRI) ancestry for alleles associated with higher expression. *e*SNP: Expression regulatory SNP.

European (CEU) and African (YRI) descent, with enrichment of ribosome biogenesis, antimicrobial response and cell-cell adhesion. Spielman *et al*[37] (2007) attributed the 1097 genes that differed between CEU and Asian (CHB) LCL samples to eSNP frequency. Our comparison of genome-wide expression profiles (using an Agilent 44K expression array) from adipose and muscle tissue of non-diabetic Caucasians (n = 40) and African Americans (n = 22) identified transcripts associated with insulin sensitivity (S_I), many of which (*e.g.*, *CLIC6*, *HSD11B1*, *SERPINA3*, *THBS1*, *TMEM135* and *TNMD* in Adipose) show distinct ethnic-specific expression[76].

Comparison of adipose tissue expression data between Caucasians and African Americans in a larger cohort (using an Illumina –HT12.V4 array for 99 Caucasians and 37 African Americans) identified 117 differentially expressed (fold change $\geqslant$ 1.5 and false discovery rate $\leqslant$ 5%) transcripts[91]. By mining adipose tissue eQTL data from the MuTHER project[55], we found that about 35% of these differentially expressed transcripts are strongly modulated ($P < 1 \times 10^{-5}$) by *cis*-eSNPs in adipose tissue. In line with the findings by Spielman *et al*[37] (2007) in LCL, we also found that in adipose tissue, the degree of differential expression (fold change African Americans/Caucasians) shows strong concordance with the difference in the effect allele frequency of top *cis*-eSNPs (Figure 4) between HapMap African (YRI) and Caucasian (CEU) subjects.

These studies suggest that the distinct genetic architecture of eSNPs determines the ethnic-specific expression profile in tissues important for glucose homeostasis. Ethnic-specific derangements of gene expression networks in tissues involved in glucose homeostasis may explain distinctive physiologic effects, including differences in insulin action and secretion between ethnic and racial groups. Perturbation of gene expression networks associated with early pathophysiologic events (including insulin resistance) is driven by regulatory variants (eSNPs). The distinct genetic architecture of these variants (including linkage disequilibrium and allele frequency) may determine their ethnic-specific (or predominant) effect on expression and T2D susceptibility. Thus, integration of genome-wide expression analysis and eQTL analyses may be a useful approach to identify the primary genetic factors for ethnic-specific susceptibility to T2D.

Expression of transcripts involved in the same biological function tend to be co-regulated by similar factors (genetic or environmental) and can be identified as distinct network modules, where genes within a module are more highly interconnected (correlated) with each other than genes in other modules. Statistical approaches like weighted gene co-expression network analysis (WGCNA software package developed in "R" programming environment implements this analytical method) are useful for identifying modular structures of the co-expression networks[92,93] in tissues important for glucose homeostasis. Evaluation of the correlation of each module eigengene with the S_I and other T2D-related metabolic phenotypes, and determination of the preservation of these modules between ethnic groups based on observed network density and connectivity, will identify molecular processes or molecular interaction structures associated with phenotypes that undergo ethnic-specific reconfiguration by genetic or non-genetic causal regulators.

Several recently developed statistical metrics[94,95], including modular differential connectivity, offer powerful tools to identify the modules with significant ethnic-specific changes in interaction strength. The eSNPs are causal variants (or in linkage disequilibrium with causal variants) that regulate the expression level of neighboring (or distal) genes. Thus, eSNPs serve as a primary source of natural perturbation to infer causal relationships among and between genes in gene-expression networks[96]. The distinct allelic architecture of these SNPs may determine ethnic-specific modular differential connectivity. Genes with eSNPs can be considered as "parent nodes" in expression networks. This information is used as a "structure prior" in the network reconstruction analysis to orient the edges of the networks. Reconstructing ethnic-specific networks by utilizing different causality modeling methods, including Bayesian network reconstruction approaches, may identify key causal regulators of these networks[97,98]. Thus, a multiscale biological network analysis that utilizes eQTL information to distinguish causal from correlated disease effects is a novel approach to understand how causal regulators propagate their effects in mediating ethnic-specific susceptibility to disease.

A similar approach was used recently to identify genetic factors in animal models of diabetes and other complex human diseases, including Alzheimer's disease[95].

A study by Zhong *et al*[68] (2010) in adipose tissue of C57BL/6-ob/ob × BTBR-ob/ob mice F2 progeny identified a strong causal subnetwork for T2D traits (called the "purple" module, enriched for genes involved in plasma glucose and insulin levels). They found that 37 eSNPs of genes in this module showed significant association with T2D in a GWAS report. Through additional prioritization steps and subsequent function validation studies, they identified mallic enzyme (*ME1*) as a key causal gene in this T2D subnetwork. A strong *cis*-eSNP of *ME1* was associated with T2D. Future applications of such integrative genomic strategies in T2D or related disorders in human populations may prove insightful.

EQTL ANALYSES TO IDENTIFY GENE-ENVIRONMENT INTERACTIONS RELEVANT FOR T2D

As discussed above, GWAS have identified DNA sequence variants in the susceptibility to T2D, but these variants account for only a part of the estimated heritability[13,14]. Interactions between sequence variants and environmental stimuli are a logical step in better understanding the development of T2D. Thus, some of the missing heritability for T2D susceptibility may be explained by studies of the interaction between environmental factors and genetic variants or gene-environment (GXE) interactions[99]. Modeling GXE interactions in clinical or epidemiological settings is challenging and costly, due to few validated tools for assessing exposure (including dietary exposure), the need for large sample sizes, and the heterogeneity of exposures in populations[100-103]. Environmental factors usually influence insulin resistance and T2D risk over long periods of time; thus, accurate assessment of long-term exposure is needed to identify GXE interactions. A recent series of studies by Patel *et al*[104-106] utilized data resources from the National Health and Nutritional Examination Survey and integrated GWAS and environment-wide association studies to identify environmental factors, genetic factors, and GXE interactions involved in T2D susceptibility. However, they noted several significant limitations of such epidemiological approaches in adequately addressing influence of genetic variations on differences in environmental response in human populations.

Environmental factors, including diet and derived metabolites, can influence phenotypes by modulating gene expression in several ways. Variations in responses to environmental factors among individuals, and how these responses predispose to metabolic and other disorders, have been recognized[107]. Genetic variants modulate the environmental factor-mediated transcriptional response, which in turn dictates cellular response and may explain variability in metabolic responses to those factors[99]. Such dependency on external conditions or GXE interactions has been reported for genetic effects on gene expression in different organisms[108-110]. Transcripts responsive to environmental perturbation factors may manifest as eQTLs and are modulated by *cis*- and *trans*-eSNPs. A subset of these eSNPs associated with T2D, obesity, and/or glucose homeostasis traits may thus exhibit distinctive patterns of GXE eSNPs. Thus, identifying environmental factors that modulate insulin sensitivity and other early pathophysiological manifestations of T2D and its integration into eQTL analyses will further improve the power to construct causal gene regulatory networks involved in T2D susceptibility.

A few recent studies implemented a novel "cellular genomics" approach[111] to elucidate genetic controls on GXE interactions, critical to understanding the pathophysiology of complex diseases. In this novel paradigm, researchers analyzed the molecular consequences of genetic variants to assess interactions with environmental factors *via* quantification of processes (like gene expression) in cells from human subjects grown in uniform culture conditions. This concept is illustrated in Figure 5. Utilizing transformed lymphocytes, the studies examined genetic control in response to radiation, chemotherapeutic drugs, and hormones (glucocorticoids)[112-114]. Two similar studies in primary human cells mapped genetic regulators responding to growth factors (BMP-2), hormones (dexamethasone), cytokines (prostaglandin E2 in human osteoblasts), and oxidized low density lipoprotein (in human aortic endothelial cells)[115,116]. Despite the encouraging success of these studies, no studies so far have evaluated GXE interactions with a cellular genomic model relevant to T2D and related metabolic disorders. Although this model may miss some whole organism-level complexity[117] of T2D pathogenesis (which involves multiple tissues), it does represent an innovative approach by going from cellular to organismal phenotype analysis for identification of function of genetic variants involved in T2D susceptibility. Mapping GXE eSNPs for function-based prioritization of T2D and related metabolic disease-associated SNPs is a critical step towards designing efficacious strategies to reduce the public health burden of common metabolic disorders triggered by increased exposure to dietary and other environmental factors.

EQTL AND PHARMACOGENOMIC STUDIES FOR T2D

Several classes of anti-diabetic medications are used for the treatment of T2D[118]. Pharmacogenomic studies reviewing the role of genetic variants on drug responses (including adverse drug reactions) have yielded significant findings, including novel disease mechanisms for several complex diseases[119]. But a similar success for T2D has not been achieved[5,120]. Pharmacological interventions using peroxisomal proliferator activated receptor gamma (PPARγ) agonists like pioglitazone improve insulin sensitivity and can reduce the risk of progression to T2D[121]. However, approximately 25% of patients do not respond adequately to PPARγ agonists[122]. Genome-wide transcriptomic analysis by our laboratory showed significant

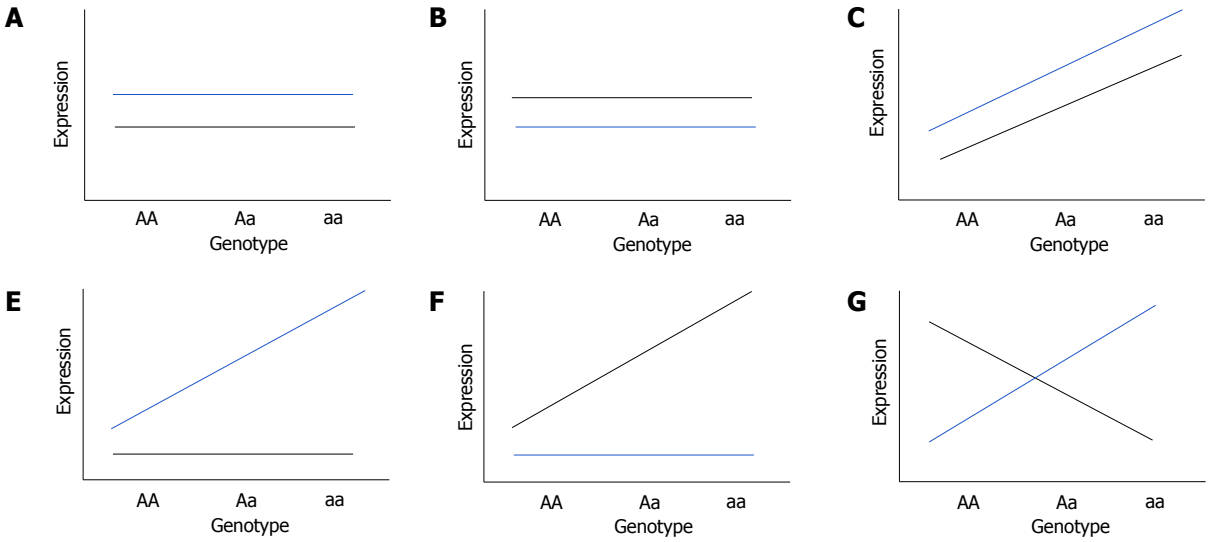

Figure 5 Types of gene-by-environment interactions in cellular genomic models to study gene-by-environment expression quantitative trait locis. Cells from a cohort of subjects are grown in pairs under uniform *in vitro* treated and untreated conditions to study environment-dependent or -independent effects of genotype on expression of transcripts (a quantitative trait). β1 and β2 are genotype effects on transcript expression under treated and control conditions, respectively. Different models of gene-by-environment (GXE) includes Null model: β1 = β2 = 0 (A and B); No-interaction eQTL model: β1 = β2 ≠ 0 (C); Treated-only expression quantitative trait loci model: β1 ≠ 0 and β2 = 0 (D); Control-only eQTL model: β1 = 0 and β2 ≠ 0 (E); and General interaction eQTL model: β1 ≠ 0 and β2 ≠ 0 but β1 ≠ β2 (F). Black line indicates expression in cells under control condition (untreated) while blue line indicates expression in environmental/dietary factor treated cells.

inter-individual variability in gene-expression response after pioglitazone treatment in people with impaired glucose tolerance[123]. However, little is known about the genetic architecture of variation in pioglitazone-mediated transcriptional response in human populations. Identifying the genetic variations that interact with pharmacological treatments like PPARγ agonists is of high clinical interest. eSNPs may modulate the expression of key transcripts in response to anti-diabetic drugs in target tissues and can explain the interindividual variability in treatment outcome[124,125]. Identifying genetic (and epigenetic) variants that modulate the pharmacological treatment-mediated transcriptional response, which in turn dictates the treatment outcome in T2D, is an open area of research. A novel approach that systematically characterizes the set of eSNPs involved in anti-diabetic medicine-mediated transcriptional modulation (gene-drug interaction eSNPs, or GXD eSNPs) in tissues relevant to glucose homeostasis will be useful in stratifying populations in efficacy studies, to improve the quality of clinical decision-making and treatment options for T2D.

FINDING EQTLS: END FOR A NEW BEGINNING

eQTL analyses provide statistical evidence for genotype-dependent variations in transcript abundance and should be considered a starting point for investigating the effects of DNA polymorphisms at the molecular level[34]. Transcript abundance depends on a dynamic relationship between transcript synthesis, stability, and degradation[48]. Thus, DNA polymorphisms may affect transcript abundance by several known and unknown mechanisms. Studies in human subjects have shown that sequence-specific regulation of mRNA expression is mediated by several molecular mechanisms, including allelic variability in transcription factor binding, chromatin remodeling, changes in DNase I hypersensitivity by histone methylation and acetylation, interaction between chromatin segments, alteration of splicing, sequence-dependent allele-specific DNA methylation, alteration of miRNA synthesis, and miRNA target binding[50-52,126-130]. GWAS-implicated variants for complex diseases are enriched in non-coding functional domains of the genome, including sequences involved in chromatin remodeling[131-133]. Many transcripts that show strong co-expression and *cis*-eSNPs for one transcript may appear as trans-eSNPs for a co-regulated transcript located in other chromosomes. Thus, a functional role of prioritized *cis*- and *trans*-eSNPs needs to be validated by appropriate molecular experiments to distinguish causal from correlative effects[134-136]. Studies have used allelic expression imbalance analysis, electrophoretic mobility shift assays, and transient transfection based luciferase reporter assays[56,137-141] to identify the molecular effects of genetic variants (*cis*-eSNPs) on gene expression; however, high-throughput methods are needed to validate in parallel the large number of findings from genomic studies[134,135,142]. Several novel high-throughput methods, including massively parallel reporter assays and massively parallel functional dissection, are now available to show evidence of causality for regulatory variants[143-146]. Functional relevance of the candidate eQTL transcripts in T2D pathophysiology also need to be validated by demonstrating their effects upon experimental up- or down-regulation in *in vitro* or *in vivo* experimental models[147,148].

In summary, many factors (including genetic, epigenetic and environmental factors) affect susceptibility to

T2D. Instead of investigating different sources of variation in isolation, an integrative functional omics paradigm that traces early molecular changes through layers of biological information, including eQTLs, promises to be a useful approach[136]. Such an approach will promote optimal understanding of the etiology of T2D and lead to the identification of ethnic-specific primary causal variants. Ultimately, the knowledge gained from studies using these approaches can be used to build better classifiers of T2D risk than those based on DNA sequence variants alone.

ACKNOWLEDGMENTS

Abstract

Aspirin (ASA) irreversibly inhibits platelet cyclooxygenase-1 (COX-1) leading to decreased thromboxane-mediated platelet activation. The effect of ASA ingestion on thromboxane generation was evaluated in patients with diabetes (DM) and cardiovascular disease. Thromboxane inhibition was assessed by measuring the urinary excretion of 11-dehydro-thromboxane B_2 (11dhTxB_2), a stable metabolite of thromboxane A_2. The mean baseline urinary 11dhTxB_2 of DM was 69.6% higher than healthy controls (P = 0.024): female subjects (DM and controls) had 50.9% higher baseline 11dhTxB_2 than males (P = 0.0004), while age or disease duration had no influence. Daily ASA ingestion inhibited urinary 11dhTxB_2 in both DM (71.7%) and controls (75.1%, P < 0.0001). Using a pre-established cut-off of 1500 pg/mg of urinary 11dhTxB_2, there were twice as many ASA poor responders (ASA "resistant") in DM than in controls (14.8% and 8.4%, respectively). The rate of ASA poor responders in two populations of acute coronary syndrome (ACS) patients was 28.6 and 28.7%, in spite of a significant (81.6%) inhibition of urinary 11dhTxB_2 (P < 0.0001). Both baseline 11dhTxB_2 levels and rate of poor ASA responders were significantly higher in DM and ACS compared to controls. Underlying systemic oxidative inflammation may maintain platelet function in atherosclerotic cardiovascular disease irrespective of COX-1 pathway inhibition and/or increase systemic generation of thromboxane from non-platelet sources.

Key words: Diabetes; Cardiovascular disease; Platelets; Thromboxane; Aspirin

Core tip: The effect of aspirin (ASA) on platelet thromboxane (11dhTxB_2) generation in diabetes (DM) and symptomatic cardiovascular disease (CVD) was reviewed. Consistent with a heightened platelet hyperactive background, baseline 11dhTxB_2 was significantly higher in DM and acute coronary syndrome (ACS) than healthy individuals. ASA ingestion inhibited 11dhTxB_2 in all subjects, but there were more ASA poor-responders (ASA "resistant") in DM (14.8%) and ACS (28.7%) than controls (8.4%). Only post-ASA 11dhTxB_2 levels predicted adverse cardiovascular outcomes. ASA poor-

responders had higher isoprostane (8-isoPGF$_{2\alpha}$) levels suggesting an underlying systemic oxidative inflammatory process not affected by ASA that may maintain platelet hyperactivity in DM and atherothrombotic CVD.

INTRODUCTION

Thromboxane A2 (TxA$_2$) is a clinically important prostaglandin metabolite derived from arachidonic acid through the cyclo-oxygenase (COX) pathway with roles in hemostasis and cardiovascular disease (CVD)[1,2]. Platelet enzyme COX-1 converts arachidonic acid into prostaglandin G$_2$ (PGG$_2$), followed by the action of peroxidases into PGH$_2$ and into the biologically active TxA$_2$ by thromboxane synthases[3]. Mainly produced by stimulated platelets, TxA$_2$ behaves as a vasoactive agent that affects blood flow and pressure[4] as well as a pro-thrombotic agent capable of promoting the activation and subsequent aggregation of nearby platelets. The latter function is accomplished by TxA$_2$ binding to thromboxane platelet receptors (TPR), a typical G protein-coupled receptor system with trans-membrane segments. Once bound to TPR receptors, phospholipase C is activated to stimulate cytoplasmic Ca^{2+}-dependent Rho Kinases that activate phospholipase A$_2$ and the up-regulation and expression of glycoprotein complex GP Ⅱb/Ⅲa on the surface of platelets[5,6].

Because TxA$_2$ is the bioactive and clinically relevant pro-thrombotic thromboxane metabolite, it would be the logical choice for testing in the clinical laboratory. However, its high instability and very short half-life (20-30 s) makes the routine measurement technically difficult and impractical. Indeed TxA$_2$ is quickly hydrolyzed into a biologically inactive but more stable thromboxane B$_2$ (TxB$_2$) metabolite[7]. Serum TxB$_2$ may be measured in the laboratory but its concentration can be overestimated due to *ex vivo* platelet activation during blood collection and processing. Other serum factors may also interfere with TxB$_2$ measurements. TxB$_2$ is further metabolized by the liver primarily into an 11-dehydro-thromboxane B$_2$ (11dhTxB$_2$) form. This and other minor stable metabolites like 11dehydro-2,3-dinorTxB$_2$ and 2,3-dinorTxB$_2$ are excreted in the urine (Figure 1). Urinary 11dhTxB$_2$ directly reflects the platelet production of TxA$_2$[8,9], and represents a good and reliable biomarker for the laboratory assessment of platelet activity.

Aspirin (Acetylsalicylic acid, ASA) irreversibly acetylates platelet COX-1 for the entire life cycle of the platelet. Ingestion of low doses of ASA blocks over 95% of platelet COX-1 activity resulting in the inhibition of TxA$_2$ production. For these reasons, ASA is widely prescribed as an aid in the primary and secondary prevention of CVD. Despite its widespread use, not all individuals respond to ASA in the same way[10,11]. In addition, ASA effectiveness is limited because over 15%-25% of patients with arterial thrombosis may develop recurrent vascular events while on ASA treatment. This incomplete ASA response (or poor-responsiveness) to therapeutic doses has been referred to as "aspirin (ASA) resistance", a phenomenon described in healthy populations as well as in patients with diabetes (DM) and CVD. The exact mechanisms responsible for this clinical unresponsiveness remain unclear[12,13].

Currently, ASA is largely prescribed for the primary prevention of cardiovascular events in DM but the evidence supporting its efficacy is surprisingly scarce and controversial[14-16]. Recent observations demonstrate that healthy subjects and DM patients with poor ASA response not only seem to manifest an incomplete inhibition of COX-1, but also display a pro-inflammatory milieu and enhanced oxidative stress[17-19]. On the other hand, diet-induced weight loss in subjects with central obesity reduced platelet reactivity and restored platelet sensitivity to nitric oxide, prostacyclin, and physiologic anti-aggregating agents. High on-ASA Platelet Reactivity (HAPR) has been proposed as a more appropriate term than "ASA resistance" to describe a high platelet reactivity status despite ASA therapy in an individual patient. Further, HAPR has been associated with atherothrombotic events following major vascular procedures and may identify patients at high risk for re-occlusion following percutaneous intervention (PCI) with stenting[20].

11DHTXB$_2$ DETERMINATION AND ASA RESPONSE

There are two distinct groups of tests commonly used to measure platelet activity and response to ASA. The first group is blood-based and relies on platelet aggregation response to exogenous agonists or inhibitors by various means[21]. Because platelet activation or inhibition can be mediated by different receptors and pathways, it is not surprising to see a lack of correlation between the assays[22-24]. The second group of tests consists of serologic or urine-based immunoassays that measure both platelet (COX-1) and non-platelet (COX-2) production of thromboxanes. This discussion will focus on the measurement of urinary 11dhTxB$_2$ as a direct indicator of TxA$_2$ activity and platelet activation. One advantage of this type of assays is that thromboxane production is the primary target of ASA through an effective and irreversible COX-1 inhibition.

11dhTxB$_2$ is a biologically inactive down-stream metabolite of TxA$_2$ with a long (stable) circulating half-life that is readily excreted in the urine and relatively unaffected by *ex vivo* platelet activation and other pre-analytical variables[25,26], hence 11dhTxB$_2$ usefulness as a reliable biomarker to assess platelet activation. Due to its relative

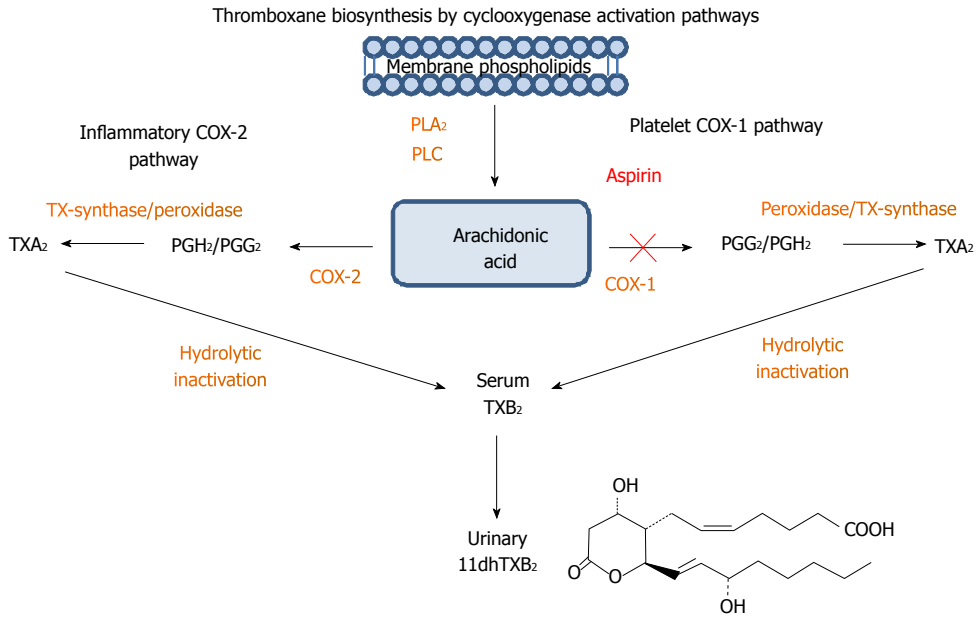

Figure 1 A schematic representation of the arachidonic/thromboxane metabolic pathway: Arachidonic acid generated from membrane phospholipids by phospholipase A2 and phospholipase C undergoes additional enzymatic transformation by cyclooxygenases (COX-1 and COX-2) into prostaglandin and thromboxane metabolites. In platelets, Arachidonic acid (AA) is metabolized by COX-1 into prostaglandins PGG_2, PGH_2 and by thromboxane synthase into the bioactive thromboxane A_2 (TXA_2), which is a potent activator of platelet aggregation with a short half-life. TXA_2 is quickly inactivated into a more stable thromboxane B_2 (TXB_2) and converted in the liver into an 11-dehydro-thromboxane B_2 ($11dhTXB_2$) metabolite excreted in the urine. Aspirin (ASA) irreversibly inhibits platelet COX-1 leading to decreased thromboxane-mediated platelet activation. TXA_2 and $11dhTXB_2$ can be generated by COX-2 present in various inflammatory cells, pathway not affected by ASA.

small size and low concentrations, urinary $11dhTxB_2$ levels are measured by a competitive enzyme-linked immunsorbent assay (ELISA) that uses a spot urine sample without time constraints. Spot urine $11dhTxB_2$ levels are normalized against urine creatinine concentration making the 24 h collection unnecessary. It is important to point out that this ELISA measures the systemic production of thromboxanes (COX-1 and COX-2-derived), and directly reflects COX-1 inhibition by ASA. $11dhTxB_2$ results are first calculated against a reference curve prepared from a reference solution and the final results are reported as pg/mg (pg $11dhTxB_2$ per mg creatinine) to normalize results for urine concentration.

To assess the demographic and clinical variables influencing urinary excretion of $11dhTxB_2$ we first studied apparently healthy adults before and after receiving controlled doses of ASA. Based on the resulting frequency of $11dhTxB_2$ levels, we established a cut-off value to assess an adequate ASA response at 1500 pg/mg of $11dhTxB_2$. This cut-off has been re-confirmed in subsequent studies using both healthy and diseased populations before and after ASA ingestion[27]. Those individuals with urinary $11dhTxB_2$ levels after ASA ingestion below the cut-off of 1500 pg/mg are considered good ASA responders while those with levels above 1500 pg/mg are poor ASA responders ("ASA resistance"). It is important to assess high platelet reactivity in spite of ASA ingestion because a series of actions may be undertaken to manage and reverse the incomplete effect of ASA. The rest of this discussion will focus on a series of clinical studies performed on DM and coronary artery disease (CAD) patients measuring $11dhTxB_2$ and using the quoted 1500 pg/mg cut-off to assess the significance of the ASA response in the development of CVD complications.

ASA poor response or "resistance": definition and clinical implications

ASA "resistance" has been referred to as the lack of a clinical and/or laboratory beneficial effect from ASA ingestion[28-30]. A true or complete ASA "resistance", defined as a lack of response to ASA ingestion due to pharmacologic and/or genetic deficiencies, has not been described to date. The great majority of individuals respond to ASA ingestion as defined by *ex vivo* measurements of platelet aggregation or thromboxane production. However, in most individuals the response seems to be only partial or incomplete. From the clinical point of view, the term ASA "resistance" has neither been fully described nor properly standardized, thus it lacks a nosological clinical definition. Furthermore, consensus guidelines for treatment or management of ASA resistance have not been put forward[31]. Most experts prefer the term ASA "poor or incomplete response" or ASA "insensitivity" to the term ASA "resistance". Throughout this discussion, we will occasionally use the term ASA "resistance" but with the clear understanding that we definitely prefer "poor or incomplete" ASA response as a more appropriate term.

Increased platelet turnover, platelet activation by alternative pathways, alternative/additional sources of TxA_2 production such as macrophage/monocyte COX-2, drug bioavailability, and genetic polymorphisms, have

been implicated in ASA poor responsiveness[13]. Recent reports suggested that CAD patients with high serum concentrations of cholesterol, triglyceride and C-reactive protein had reduced response to ASA measured by platelet aggregation and urinary 11dhTxB$_2$[29]. Compared to asymptomatic patients, those with full blown CAD had significantly higher levels of urinary 11dhTxB$_2$ following ASA ingestion. The HOPE[32] and CHARISMA[33] studies showed that urinary 11dhTxB$_2$ levels in ASA-treated patients predicted the future risk of stroke, myocardial infarction and cardiovascular death. These findings raised the possibility that elevated urinary 11dhTxB$_2$ excretion identifies patients on ASA treatment that are at elevated risk of adverse events and may benefit from additional anti-platelet agents or treatment modification.

Patients who experience a vascular ischemic event while taking ASA have been referred to as having a clinical ASA "resistance". Patients who show a limited inhibition of thromboxane levels, platelet activation, or aggregation after ASA ingestion assessed by biochemical or laboratory tests are referred to as having a laboratory ASA "resistance"[30]. This discussion focuses on the biochemical or laboratory ASA resistance, and more specifically on the clinical impact of the reduced inhibition of COX-1 thromboxane levels. As with any other drug, the dose, drug interference and poor patient compliance should be kept in mind when evaluating ASA responsiveness. The prevalence of laboratory ASA "resistance" ranges from 10% to 25% with occasional peaks up to 60%. However, this wide variability depends on the methods used to measure the ASA response and the patient population under study rather than on the individual response. Nonetheless, other important causes of a poor response to ASA are emerging amongst which is stress-induced inflammation/oxidation[34,35].

An overall poor response to ASA has been associated with up to 13-fold increase risk of atherothrombotic complications in patients with CVD[13,36,37]. A recent meta-analysis of over 20 clinical studies performed on a total of 2930 CVD patients taking ASA (75-325 mg) demonstrated a 4-fold increased risk for any cardiovascular (CV) event including CV death in those patients with poor ASA response[38]. About twenty-eight percent (28%) patients were classified as ASA poor responders ("resistance") suggesting an association with CVD risk. CV-related events were observed in 41%, death in 5.7%, and acute coronary syndrome (ACS) in 39.4% of patients with poor ASA response. It must be pointed out that the clinical studies included in the meta-analysis used different methods to measure platelet ASA inhibition and their own criteria to classify the response to ASA. An interesting observation of the meta-analysis is that ASA poor responders did not benefit from other anti-platelet therapy. The HOPE[32] study screened 5529 patients and measured urinary 11dhTxB$_2$ in 488 ASA-treated CVD patients. Age and sex matched controls also received ASA. CV outcomes including CV death were recorded during a 5-year follow-up. Poor ASA responders with urinary 11dhTxB$_2$ levels in the upper quartile had a 2-fold increasing risk of heart attacks and 3.5-fold risk of CV death. A sub-study of CHARISMA[33] that included 3261 ASA treated CVD patients confirmed the increased CVD risk in patients with 11dhTxB$_2$ in the upper quartile as previously reported by the HOPE study.

11DHTXB$_2$ AND ASA RESPONSE IN DM

CVD has been long recognized as a leading cause of morbidity and mortality in patients with type 1 and type 2 DM mainly by ischemic heart disease[39,40]. The use of ASA is known to reduce future secondary events in DM[41], however, a meta-analysis of randomized controlled trials failed to demonstrate a clear benefit of aspirin in the primary prevention of major cardiovascular events in patients with DM[42]. To further assess thromboxane levels and aspirin response in DM patients, two clinical studies were conducted on consecutive type 2 DM patients attending the endocrinology and diabetes outpatient clinics in Mexico. The diagnosis of DM was made by the attending physician following internationally accepted diagnostic criteria (World Health Organization DM criteria, 1985) that relied on the presence of abnormal fasting glucose (normal range 70-110 mg/dL), abnormal glucose tolerance test, chronic hyperglycemia and metabolic disturbances of lipid, carbohydrate and protein metabolism due to defects in insulin production or activity. Males and females between 18 and 79 years of age who had not taken ASA or other non-steroidal anti-inflammatory drugs for the previous 2 wk were included. Subjects with liver and kidney disease, symptomatic cardiovascular disease requiring ASA therapy (myocardial infarction, angina, stroke, peripheral artery disease), concomitant acute or chronic inflammatory diseases (bacterial or viral infections), autoimmune disorders, pregnancy, allergy or intolerance to ASA, and bleeding disorders were excluded. The use of ASA in Mexican patients with DM for primary prevention of CVD was significantly less common compared to the US, ensuring a good recruitment of DM patients not taking ASA while avoiding possible unethical discontinuation of the medication.

Baseline 11dhTxB$_2$ levels in DM

Baseline (ASA-free) urinary 11dhTxB$_2$ levels were measured in 100 subjects, 53 with DM and 47 healthy volunteers. None of the patients or controls in this group had received ASA for at least 2 wk prior to testing. The main objective of this study was to establish an average baseline urinary 11dhTxB$_2$ level in DM. The hypothesis was that patients with DM had increased baseline urinary 11dhTxB$_2$ levels hence a higher risk of developing cardiovascular atherothrombotic complication and would receive ASA therapy compared to healthy controls. The mean age of the population studied was 53.9 ± 12.6 years (54 females, 46 males) with mean disease duration of 9.1 ± 7.7 years.

The distribution of baseline (ASA-free) 11dhTxB$_2$ levels of DM patients and healthy volunteers is shown in Figure 2A. DM patients presented with a baseline mean

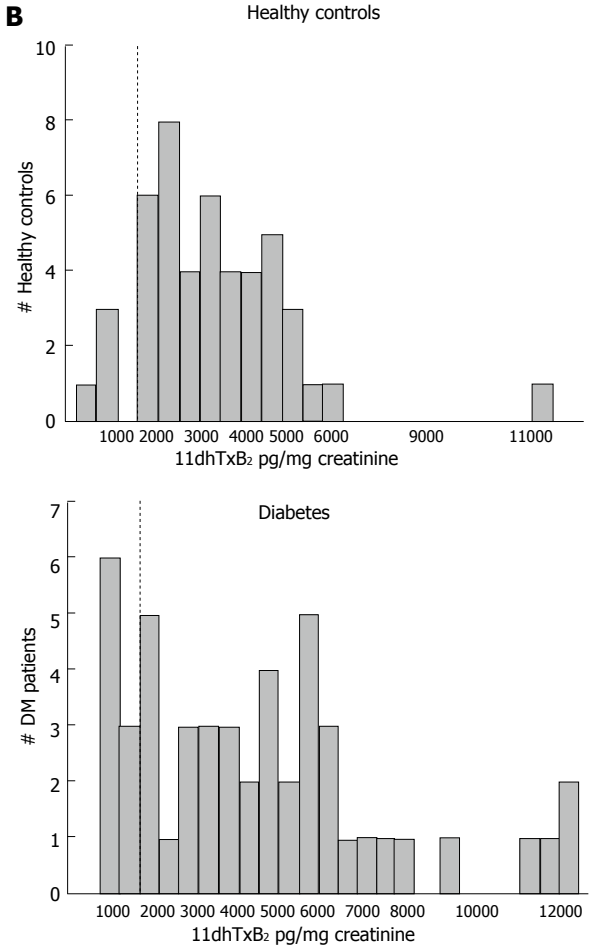

Figure 2 Distribution of baseline (aspirin-free) urinary 11-dehydro-thromboxane B2 levels (pg/mg) measured in healthy individuals and diabetes patients (A, top), and frequency distribution (histogram) of baseline urinary 11-dehydro-thromboxane B2 levels in the two groups studied (B, bottom). A: Comparison of baseline 11-dehydro-thromboxane B2 levels of diabetes and controls; B: Frequency (Histogram) of baseline 11-dehydro-thromboxane B2 levels in diabetes and controls.

urinary 11dhTxB2 excretion of 5656 pg/mg, a value 69.5% higher than the mean baseline 11dhTxB2 excretion of healthy controls at 3337 pg/mg, ($P = 0.024$). The highest 11dhTxB2 value seen in the DM group reached 27661 pg/mg while the highest value in healthy controls was 11323 pg/mg. Figure 2B shows the cumulative baseline frequency of urinary 11dhTxB2 excretion of healthy controls (up) and DM patients (down). The frequency of healthy controls followed a normal (Gaussian-like) distribution while DM patients had a distinctive flat distribution.

Influence of gender, age and disease duration on 11dhTxB2 levels

There were 34 females plus 19 males with DM, and 20 females plus 27 males in the healthy control group. Figure 3 depicts the urinary baseline (ASA-free) 11dhTxB2 levels according to gender. When evaluating all 100 subjects (DM patients and healthy controls), females exhibited a mean baseline urinary 11dhTxB2 excretion 50.9% higher than that of males (5902 *vs* 2998 pg/mg, $P = 0.0004$). When evaluating the influence of gender separately in DM patients and healthy controls, females consistently display significantly higher baseline 11dhTxB2 levels than males (DM $P = 0.01$, controls $P = 0.02$).

The mean age of DM patients was 56 years (range 29-80 years) and that of healthy controls 35 years (range 22-82 years). Figure 4 depicts the association of urinary baseline (ASA-free) 11dhTxB2 levels with the subject's age (in years). In this analysis all 100 subjects (DM patients and healthy controls) were included. The mean disease duration for the DM patients was 9.6 years (range 1-29

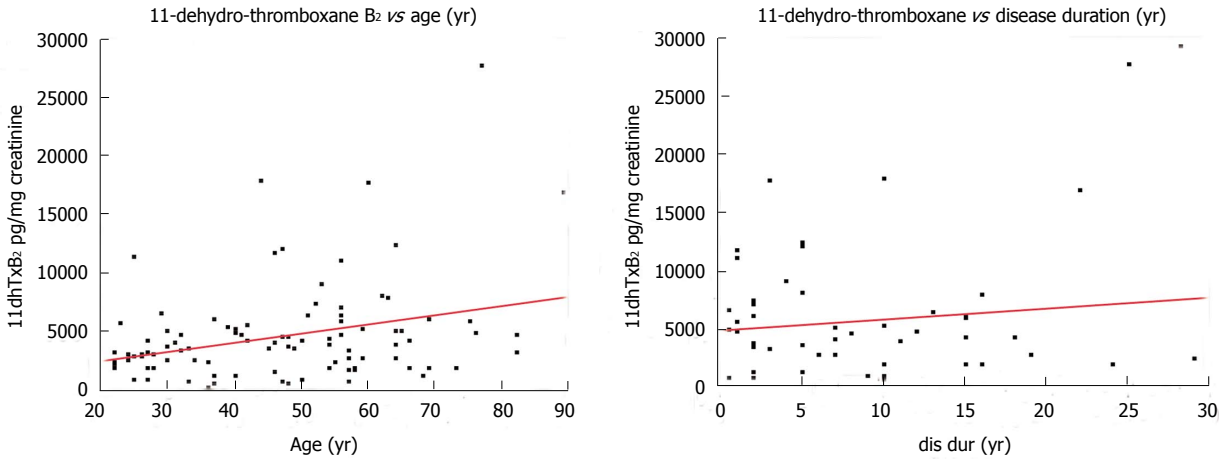

Figure 4 Correlation of baseline (aspirin-free) urinary 11-dehydro-thromboxane B2 levels (pg/mg) measured in healthy individuals and diabetes patients with age (left), and disease duration of diabetes patients (right). Red lines: Linear regression fit.

years). There was weakly positive correlation (r = 0.322, P = 0.001) between age (in years) and baseline urinary 11dhTxB2 levels (left), and a weak (but not statistically significant) positive correlation (r = 0.124, P = 0.3) between disease duration (in years) and baseline urinary 11dhTxB2 levels (right).

These variables were entered into a linear regression model to predict 11dhTxB2 levels (as a dependent variable). Only female gender remained as a significant (P = 0.02) predictor of 11dhTxB2 levels. Sex-related differences in platelet function and aspirin pharmacokinetics in rabbits and man have been previously described[43]. These results support previous findings that ASA reduces the risk of first heart attack in men but not in women suggesting that the ASA effect in women is different[42,44,45]. The results also support the relevance of measuring urinary 11dhTxB2 levels in DM patients to assist health care providers in assessing the risk for CVD and implementing an ASA preventive regimen.

Effect of ASA on 11dhTxB2 levels in DM

The effect of ASA in DM was studied in 137 subjects, 54 patients with DM and 83 healthy volunteers. Each DM patient or control subject contributed two urine samples: one before receiving ASA (baseline) and a second sample after receiving 100 or 325 mg of ASA for 7 d. The main objective of the study was to corroborate that ASA ingestion reduces 11dhTxB2 levels in DM patients. The hypothesis was that ASA would inhibit urinary 11dhTxB2 excretion in DM patients but with more ASA non-responders (11dhTxB2 levels > 1500 pg/mg) compared to healthy controls. The mean age of the final population under study was 54.3 ± 13.1 years with 90 females and 47 males. The mean disease duration was 9.6 ± 7.6 years.

The baseline (ASA-free) and post-ASA ingestion values of DM patients and healthy controls are shown in Figure 5. ASA ingestion suppressed the mean baseline 11dhTxB2 excretion of DM patients by 71.5% (P < 0.0001) as well as the mean baseline of healthy controls (75.1%, P < 0.0001). The baseline 11dhTxB2 excretion of DM patients was greater than that of controls (3664 *vs* 2450 pg/mg, P = 0.001). Similarly, post-ASA 11dhTxB2 excretion of DM patients was greater than that of healthy controls (995 *vs* 624 pg/mg, P < 0.0001). Regarding the effect of the dose of ASA, the mean 11dhTxB2 excretion of subjects taking 100 mg of ASA was 708 pg/mg ± 507, whereas the mean of subjects taking 325 mg was 827 pg/mg ± 811 (P = 0.8). In this study, ASA dose used in DM and healthy controls had no significant influence of post-ASA 11dhTxB2 levels. Furthermore, a regression model to predict 11dhTxB2 levels (as a dependent variable) showed ASA (P = 0.0293) and obesity (P = 0.0467) as statistically significant predictors of 11dhTxB2 levels.

11dhTxB2 excretion shifted below the cut-off (1500 pg/mg) after ASA treatment in the majority of healthy controls, leaving 8.4% (7/83) of subjects classified as non-responders. In DM patients, 11dhTxB2 excretion shifted below the cut-off (1500 pg/mg) after ASA ingestion in the majority of patients, except for 14.8% (8/46) of subjects subsequently classified as ASA non-responders. These results confirm that ASA treatment significantly inhibits baseline urinary 11dhTxB2 levels in both healthy individuals and DM patients, However, there were twice as many ASA poor responders among the DM patients possibly implicating a high platelet reactive phenotype associated with DM [40,46,47].

Having established that DM patients express elevated baseline levels of 11dhTxB2 and twice as many ASA non-responders, we investigated the effect of oxidative stress and anti-oxidant biomarkers on 11dhTxB2 excretion in DM[35]. Urinary 8-iso-prostaglandin-F2α (8-isoPGF2α) and sP-Selectin, nitrite (NO_2^-), nitrate (NO_3^-) and paraoxonase 1 (PON1) activity were measured in baseline (ASA free) and post-ASA samples from these DM patients and controls. Compared to controls, DM expressed increased levels of 8-isoPGF2α (1457 *vs* 1009 pg/mg, P < 0.0001), NO_2^- (11.8 *vs* 4.8 μmol/L, P < 0.0001), NO_3^- (50.4 *vs* 20.9 μmol/L, P < 0.0001) and sP-Selectin (120.8 *vs* 93.0 ng/mL, P = 0.02). ASA demonstrated no effect on 8-isoPGF2α, NO_2^-, NO_3^-, sP-Selectin or PON1 activity in either DM or controls. Again, higher urinary 11dhTxB2 levels in DM suggest a state of heightened platelet acti-

Figure 5 Distribution of baseline (aspirin-free) and post-aspirin urinary 11-dehydro-thromboxane B_2 levels (pg/mg) measured in healthy individuals (right) and diabetes patients (left). 14.8% of diabetes patients were classified as aspirin (ASA) poor responders compared to 8.4% of healthy controls (post-ASA 11-dehydro-thromboxane B_2 over the cutoff 1500 pg/mg).

vation. In addition to platelet hyperactivity, DM patients presented with an inflammatory/oxidative background not affected by ASA. In fact, among the biomarkers measured, only urinary 8-isoPGF$_{2\alpha}$ was significantly higher ($P < 0.009$) in DM patients with poor ASA response. These findings are in agreement with the hypothesis that an oxidative and inflammatory stress may maintain platelet activation irrespective of COX-1 pathway inhibition and/or increase the systemic generation of thromboxane from non-platelet sources *via* COX-2 pathway[34,48-50].

ASA treatment for CVD prevention is a widely accepted practice according to recommended guidelines, but evidence supporting its efficacy is somewhat conflictive and scarce, particularly for patients with DM[51]. The JPAD study (Japanese Primary Prevention of Atherosclerosis with ASA for Diabetes) involved 2539 type 2 DM patients between 40-85 years with no history of atherosclerosis randomized into ASA (81 or 100 mg/d) or non-ASA groups. ASA did not demonstrate a significant reduction in risk for any of the CVD-related endpoints. The POPADAD study (Prevention of Progression of Arterial Disease and Diabetes) included 1276 adults (> 40 years) with type 1 or 2 DM asymptomatic for CVD (ankle-brachial index less than 0.99). ASA (100 mg/d) also failed to demonstrate a significant reduction in risk for any CVD endpoint. Finally, the AAA study (Aspirin for Asymptomatic Atherosclerosis) included 3350 adults (50-75 years) asymptomatic for CVD (ankle-brachial index less than 0.95). ASA (100 mg/d) again did not demonstrate a significant reduction in risk for any endpoint. These studies suggest that DM somehow blunts the beneficial effect of ASA in CVD prevention. Additional mechanisms to explain these clinical findings are forthcoming and likely will help clarify the controversy surrounding the concept of clinical ASA "resistance".

11DHTXB$_2$ AND ASA RESPONSE IN ACS

Two clinical studies of ACS patients will be discussed. One study measured urinary 11dhTxB$_2$ levels after ASA ingestion on 77 consecutive patients attending acute care facilities. ACS patients over 18 years of age undergoing elective PCI at the participating institutions were enrolled. All patients were treated with 325 mg of ASA for at least one week. Each patient provided one urine sample while on ASA. The main objective of the study was to assess urinary 11dhTxB$_2$ excretion in response to 325 mg of ASA in relation to the manufacture's cut-off value of 1500 pg/mg established in apparently healthy individuals. The mean levels of urinary 11dhTxB$_2$ after 325 mg of ASA ingestion was 1550 pg/mg. The majority of ACS patients responded to ASA with 11dhTxB$_2$ levels below the cut-off. However, the percent of ASA non-responders in this ACS population was 28.6%. One common question ponders the dose of daily ASA necessary to inhibit COX-1 and overcome ASA poor response. Urinary 11dhTxB$_2$ levels were measured in 71 consecutive patients with stable CAD and randomized to receive 81 mg, 162 mg and 325 mg per day of ASA for 4 wk. The mean 11dhTxB$_2$ decreased from 931 to 763 pg/mg ($P = 0.046$) with increasing doses of ASA. In this study, the rate of ASA poor responders decreased with increasing ASA dosage. This ASA dose-dependent response is in agreement with previous reports by Gurbel *et al*[22]. Thus,

Figure 6 Distribution of baseline (aspirin-free) and post-aspirin urinary 11-dehydro-thromboxane B2 levels (pg/mg) measured in acute coronary syndrome patients. 28.7% of acute coronary syndrome patients were classified as ASA poor responders (post-ASA 11-dehydro-thromboxane B2 over the cutoff 1500 pg/mg). ACS: Acute coronary syndrome; ASA: Aspirin.

ASA dose should be considered when evaluating ASA poor responses.

A second study included 287 consecutive aspirin-free ACS patients admitted to a hospital in Japan for PCI to evaluate a possible association between urinary 11dhTxB2 levels before and after aspirin ingestion with adverse events (AE)[52]. Inclusion criteria included ST elevation myocardial infarction (STEMI), non-STEMI or early onset (within 24 h) invasive revascularization procedure. Upon enrollment and prior to PCI, a baseline (ASA-free) urine sample was obtained, followed by a daily regimen of 100 mg of ASA. Urine samples from ASA-treated patients were collected at hospital discharge (7-14 d) and upon follow up at 6 and 12 mo. Adverse cardiovascular events (AE) were recorded during a 12 mo patient follow-up. Primary end-points included stent thrombosis, Q wave myocardial infarction (QMI), non-QMI, and death (cardiac and non-cardiac). Secondary end-points included stroke, transient ischemic attack (TIA), target lesion revascularization of PCI or CABG, or other vascular event.

The mean age of these ACS patients was 68.9 years. Age did not influence baseline 11dhTxB2 levels (r = 0.060, P = 0.310), but females had significantly higher mean baseline 11dhTxB2 (7675 pg/mg) compared to males (6949 pg/mg, P = 0.0171). The mean baseline ASA-free 11dhTxB2 was 7322 pg/mg for this cohort of ACS patients and was 2-3 times higher than healthy individuals (range 2450-3337 pg/mg). ASA significantly suppressed (81%, P < 0.0001) of baseline 11dhTxB2 levels to 1349 pg/mg at discharge and subsequent time points. The distribution of baseline (before ASA) 11dhTxB2 levels of the ACS patients is shown in Figure 6. In spite of a significant inhibition of 11dhTxB2 by ASA, 28.7% of ACS patients were classified as poor responders by failing to achieve levels below the 1500 pg/mg cut-off. The overall rate of AEs was 17.1%. The rate of AEs according to baseline (ASA-free) 11dhTxB2 levels decreased slightly from 19.4% in quartile 1 to 15.5% in quartile 4. In contrast, the rate of AEs in ASA treatment quartiles increased from 9.1% in quartile 1 to 24.2% in quartile 3 and 20% in quartile 4. The relative risk for AEs of quartile 3 was 2.7 (P = 0.019). When upper quartiles (3 and 4) were compared to lower quartiles (1 and 2), the relative risk was 2.1 (P = 0.011).

High baseline 11dhTxB2 levels were consistent with an underlying platelet hyperactivity that may contribute to the development of atherothrombosis. However, baseline ASA-free 11dhTxB2 levels did not predict 1-year AEs. High levels (> 1500 pg/mg) of 11dhTxB2 after ASA ingestion likely represent extra-platelet (*i.e.*, monocyte/macrophage-derived) COX-2 production of thromboxane. The increased relative risk (2.7) for AEs associated with high post-ASA 11dhTxB2 levels (upper quartiles) suggest that COX-2 production of thromboxane may be a factor associated with a cardiovascular inflammatory process. It is important to point out that ASA insensitive thromboxane generation has been associated with a pro-inflammatory milieu and enhanced oxidative stress in diabetes. Among several biomarkers tested, only baseline urinary 8-isoPGF2α discriminated between normal and poor thromboxane responders, suggesting that oxidative stress may maintain platelet function irrespective of COX-1 inhibition and/or increased systemic generation of thromboxane from non-platelet sources. Thromboxane alone may not be directly implicated in atherothrombosis. Nonetheless, these results confirm previous reports that post-ASA urinary 11dhTxB2 may be useful in predicting adverse outcomes in ACS patients.

Oxidative inflammation (stress) refers to prevailing levels of reactive oxygen species (ROS) in biological systems that overcome their removal by cellular or plasma repair (anti-oxidant) mechanisms[53]. The excess of superoxide anion ($O_2^{\bullet}$) produced by inflammatory cells may exert a free radical attack on cell membranes and/or lipoproteins in a process called lipid peroxidation. While the arachidonic acid metabolism mediated by enzymatic (COX) pathways has received most attention, a non-enzymatic free radical pathway is demonstrating relevance. The free radical oxidation of arachidonic acid generates biologically active F2-isoprostanes reflecting the oxidative status of the organism; is considered a reliable marker of oxidative stress *in vivo*; and has been shown to be an independent risk factor for CAD[54,55]. Some *in vitro* studies have demonstrated that 8-isoPGF2α is capable of stimulating platelet activation while other studies described pro-atherogenic properties through its interaction with the thromboxane platelet receptor (TPR). If 8-isoPGF2α binds to TPR, it may also be capable of competing with TxA2 and activating the Ca^{2+}/Rho kinase

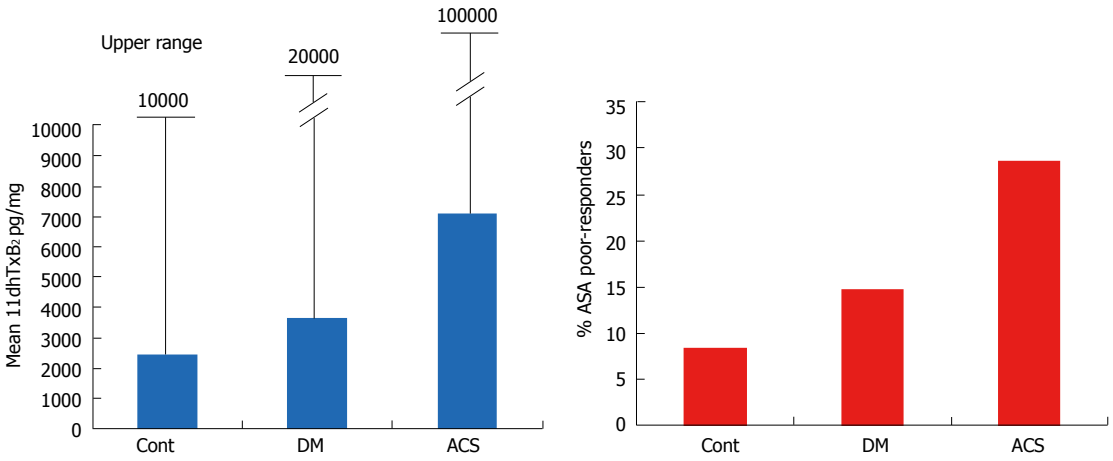

Figure 7 Mean and upper range of baseline (aspirin-free) urinary 11-dehydro-thromboxane B_2 levels (pg/mg) measured in healthy controls, diabetes and acute coronary patients (left), and percent (%) of aspirin poor responders (post-aspirin 11-dehydro-thromboxane B_2 over the cutoff 1500 pg/mg) in the populations studied (right). DM: Diabetes; ACS: Acute coronary syndromes.

pathway[56,57]. This may be particularly important because while TxA_2 enzymatic synthesis is inhibited by ASA, the non-enzymatic 8-isoPGF$_{2\alpha}$ production increases, perhaps as an alternative mechanism to maintain physiologic platelet activity.

Low dose ASA ingestion blocks COX-1 but has no effect on COX-2 or 8-isoPGF$_{2\alpha}$. During an oxidative inflammatory response, increased platelet hyperactivity would come from the combined COX-1, COX 2 and isoprostane (8-isoPGF$_{2\alpha}$) pathways. If ingesting ASA, platelet hyperactivity would be induced by COX-2 and 8-isoPGF$_{2\alpha}$ alone. Limited or no COX-1 TxA_2 production after ASA ingestion would leave unoccupied TPR available to bind 8-isoPGF$_{2\alpha}$ that has a longer half-life (1-10 min *vs* 20-30 s) and higher plasma concentration (351-1831 *vs* 1-66 pg/mL) than TxA_2[6]. Thus, blocking F_2-isoprostane derived from oxidative inflammatory pathways not affected by ASA may be considered in CVD management especially in those individuals with poor ASA response.

CLINICAL SIGNIFICANCE OF 11DHTXB2 MEASUREMENTS

The irreversible inhibition of platelet COX-1 and subsequent reduction of TxA_2 production by ASA has been recognized long ago, making ASA a cost-effective prevention regimen for atherothrombotic CVD. Low doses of ASA have been claimed to prevent over 150000 heart attacks annually. Furthermore, ASA ingestion has accounted for an overall 25% risk reduction of CV events, including a 34% reduction of non-fatal heart attacks, 25% of non-fatal strokes and 18% of all-cause mortality. However, between 25% to 50% of the patients with CAD and ACS did not fully benefit from ASA ingestion[12,13,58]. Thus, TxB_2 measurements to detect those individuals with poor ASA response and higher CVD risk is clinically relevant.

Our studies demonstrated that baseline (ASA-free) urinary 11dhTxB$_2$ excretion showed an upward trend across healthy controls, DM and ACS (Figure 7). The mean 11dhTxB$_2$ of the two control groups studied was 2893.5 pg/mg with an upper range up to 11702 pg/mg. The mean for DM groups was 4660.5 pg/mg with an upper range up to 20619 pg/mg and for ACS patients the mean was 7322 pg/mg with an upper range over 100000 pg/mg. The rate of ASA poor responders had a similar upward trend: controls with 8.4%, DM 14.8% and ACS over 28%.

Baseline 11dhTxB$_2$ levels in both the healthy and diseased populations clearly indicated a wide range of platelet reactivity with a considerable overlap among the groups. This wide range observed likely prevented the establishment of an ASA-free 11dhTxB$_2$ cut-off or even a normal range for clinical use. One relevant observation from the ACS study was that over 40% of ACS patients with high baseline (ASA-free) 11dhTxB$_2$ showed a poor response after ASA ingestion. This observation is in agreement with the concept that higher baseline levels in DM and ACS patients may predict higher rates of ASA poor responders. An explanation for these findings comes from reports that patients with metabolic syndrome (obesity, dyslipidemia, insulin resistance) have increased oxidative stress (oxLDL), higher CVD risk[59], platelet hyperactivity[60] and suboptimal inhibition of platelet COX-1 by aspirin[61], suggesting that higher TxB_2 places these patients at higher risk for thromboembolic events.

Russo *et al*[18] described that diet-induced weight loss in subject with central obesity reduces platelet activation restoring the sensitivity to anti-platelets agents. The Health Aging and Body Composition Study reported that the inflammatory marker interleukin-6 was a robust predictor for new negative health-related events and high urinary 8-isoPGF$_{2\alpha}$ and 11dhTxB$_2$ were associated with higher mortality risk[62]. More recently, Santilli *et al*[63] reported that high intensity physical exercise has broad beneficial effect on platelet activation biomarkers; urinary 11dhTxB$_2$ and 8-isoPGF$_{2\alpha}$ decreased 26% and 21% re-

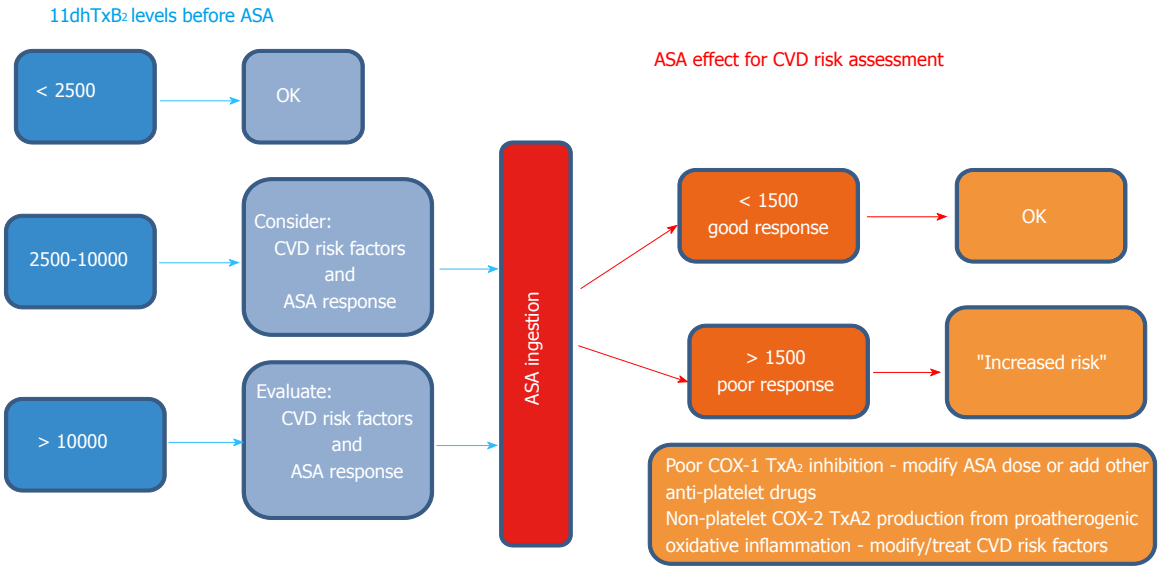

Figure 8 Proposed schematic representation (algorithm) to guide the clinical interpretation and decision making process for assessing CVD risk using baseline (aspirin-free) urinary 11-dehydro-thromboxane B2 (left), and post-aspirin 11-dehydro-thromboxane B2 levels (right). Baseline 11-dehydro-thromboxane B2 levels suggested were taken from the mean and upper range of healthy controls. The cut-off of 1500 pg/mg applies only for subjects on aspirin (ASA) therapy to be classified as good or poor responders.

spectively and esRAGE increased 61% compared to the sedentary control group and multiple regression analysis demonstrated that 8-isoPGF$_{2\alpha}$ and esRAGE were the only significant predictors of 11dhTxB$_2$ levels.

The suggestive algorithm discussed below (Figure 8) was developed taking into account the clinical studies discussed above and is proposed to interpret urinary 11dhTxB$_2$ results for CVD risk management.

If the subject is not taking aspirin and the 11dhTxB$_2$ level is

Below 2500 pg/mg: no action is necessary; Between 2500 and 10000 pg/mg: consider giving ASA to assess ASA response and/or consider other underlying CVD risk factors; Over 10000 pg/mg: give ASA to assess ASA response and/or look for other CVD risk factors.

If the subject is taking ASPIRIN and the 11dhTxB$_2$ level is

Below 1500 pg/mg: no action is necessary (good ASA response), continue monitoring CVD risk; Above 1500 pg/mg: the subject is a poor ASA responder ("resistance"). Consider patient compliance, adjusting ASA dosage, additional anti-platelet therapy, *etc*. And more importantly investigate and modify underlying CVD risk factors such as dyslipidemia and inflammatory/oxidative pro-atherogenic background likely responsible for the incomplete inhibition of thromboxanes.

The major impact of this algorithm is that consistently high baseline 11dhTxB$_2$ levels in subjects not taking ASA may justify further investigations for underlying CVD risks. However, only the presence of post-ASA high 11dhTxB$_2$ levels predicts increased risk of atherothrombotic disease. This highlights the need of a comprehensive (multimodal-approach) management that includes both anti-platelet as well as anti-atherogenic treatments.

CONCLUSION

Poor response to ASA frequently indicates an underlying incomplete COX-1 inhibition and increased CVD risk. Among several assays used to measure ASA effect on platelets, urinary 11dhTxB$_2$ reflects systemic production of thromboxanes and platelet reactivity directly affected by ASA. The incidence of ASA poor responders increases in DM and ACS patients, suggesting an active oxidative/inflammatory background likely responsible for both a continued platelet hyperactivity and a pro-atherogenic phenotype not affected by ASA.

Our studies of urinary 11dhTxB$_2$ levels in response to ASA ingestion in diseased populations indicate the following: (1) patients with DM and CAD have significantly higher mean baseline levels of urinary 11dhTxB$_2$ than healthy controls likely indicating a higher platelet activation and risk for CVD. Female gender seems to have a weak positive influence on 11dhTxB$_2$ and platelet reactivity; (2) ASA ingestion significantly inhibited urinary 11dhTxB$_2$ in DM, ACS and controls. However, the rate of DM ASA poor responders (14.8%) was about 2 times higher than controls (8.4%). This may also be a reflection of an increased platelet activation status in DM patients; (3) the rate of ACS ASA poor responders (28.7%) was about 3 times higher than controls; and (4) The results of the studies provide additional support to the laboratory measurement of urinary 11dhTxB$_2$ levels not only in apparently healthy individuals but also in patients with DM and CAD to assess their response to ASA ingestion.

Abstract

Type 2 diabetes mellitus (T2DM) is a complex disease in which both genetic and environmental factors interact in determining impaired β-cell insulin secretion and peripheral insulin resistance. Insulin resistance in muscle, liver and fat is a prominent feature of most patients with T2DM and obesity, resulting in a reduced response of these tissues to insulin. Considerable evidence has been accumulated to indicate that heredity is a major determinant of insulin resistance and T2DM. It is believed that, among individuals destined to develop T2DM, hyperinsulinemia is the mechanism by which the pancreatic β-cell initially compensates for deteriorating peripheral insulin sensitivity, thus ensuring normal glucose tolerance. Most of these people will develop T2DM when β-cells fail to compensate. Despite the progress achieved in this field in recent years, the genetic causes of insulin resistance and T2DM remain elusive. Candidate gene association, linkage and genome-wide association studies have highlighted the role of genetic factors in the development of T2DM. Using these strategies, a large number of variants have been identified in many of these genes, most of which may influence both hepatic and peripheral insulin resistance, adipogenesis and β-cell mass and function. Recently, a new gene has been identified by our research group, the *HMGA1* gene, whose loss of function can greatly raise the risk of developing T2DM in humans and mice. Functional genetic variants of the *HMGA1* gene have been associated with insulin resistance syndromes among white Europeans, Chinese individuals and Americans of Hispanic ancestry. These findings may represent new ways to improve or even prevent T2DM.

Key words: Genome-wide association study; Candidate gene; Genetic variants; High-mobility group A1; Insulin resistant diabetes

Core tip: Despite the progress in clinical and laboratory investigations, the fundamental cause of type 2 diabetes mellitus (T2DM) remains uncertain. Candidate gene, linkage and genome-wide association studies have highlighted the role of genetics in the development of T2DM. Using these strategies, a large number of variants have been identified in many genes, most of which may influence an individual's risk of developing T2DM. In this review, we compile information on genetic factors that influence the risk of T2DM. In addition, we discuss the results from recent studies on the role of HMGA1 on the issue, which might be important for future breakthroughs in this field.

INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a chronic endocrine

and metabolic disease that is often associated with being overweight or frank obesity. It affects millions of people worldwide, with a rapidly increasing incidence and prevalence[1,2]. The latest estimate from the International Diabetes Federation (http://www.idf.org) is equivalent to a global prevalence rate of 8.4% of the adult population, while worldwide diabetes cases hit a new record at 382 million in 2013. Among the determinants of this steadily increasing trend is the combination of genetic and environmental factors responsible for either a positive energy balance resulting in body fat accumulation and weight gain and/or a reduced energy expenditure from a reduction in physical activity and a sedentary lifestyle. Despite extensive attempts at clinical management of T2DM, many diabetic patients will develop a wide variety of long-term complications, including retinopathy, nephropathy and cardiovascular diseases that are among the most frequent causes of morbidity and mortality in affected people, whose effective prevention and treatment require enormous efforts and funding[3]. Typically, T2DM is presented as a common, heterogeneous, complex disease in which both predisposing genetic factors and precipitating environmental factors interact together and cause hyperglycemia, which constitutes the primary hallmark of T2DM[4,5]. Although still poorly understood, the role of genetics in T2DM is well documented. This is supported by a series of evidence, including the strong familial aggregation of the disease, in which the risk of developing T2DM is 40% for those who have an affected parent (higher if the mother rather than the father) and 70% if both parents are diabetics[6]. The highest risk in first-degree relatives, compared to the general population, persists even after removal from the family of origin, for example, as a result of adoption. Furthermore, in identical monozygotic twins (with identical genetic makeup), the concordance rate for the disease approaches 100%, much higher than that seen in non-identical (dizygotic) twins or among siblings[7]. Genetic predisposition in T2DM is also supported by the observation that differences in disease prevalence rates exist among populations, even after migration of entire ethnic groups to another country, thus independent from the environmental influences[8].

On the other hand, the role of environmental factors in influencing susceptibility to T2DM is equally well known. Among these factors are increased caloric intake and a sedentary lifestyle, two conditions common in populations with a higher standard of living and a more westernized lifestyle, responsible for most of the excess weight and obesity in the modern adult's life[9]. The spread of the western way of life in developing countries also explains the epidemic explosion of the disease[1,2], whereas the existing epidemiological data show that the spatial and temporal distribution of T2DM in the geographical areas examined is comparable to the trend of being overweight and obesity[10]. The excess weight causes insulin resistance, which represents the initial step in the natural history of T2DM. Initially, in individuals destined to become diabetic, pancreatic β-cells compensate for the insulin resistance by secreting increased levels of insulin, thus ensuring post-prandial euglycemia[11]. Hyperglycemia in insulin resistant subjects develops later when the β-cells fail to compensate. Thus, from a pathophysiological standpoint, T2DM is characterized by a combination of peripheral insulin resistance and inadequate insulin secretion by the pancreatic β-cells. As supported by numerous studies in the literature[12,13], both defects are the result of a complex interaction between genetic and environmental factors (Figure 1), including chemical agents (calcium and zinc ions) and polluting organic substances that are suspected to play a role in amyloid fiber formation in pancreatic β-cells, thus contributing to the pathology of T2DM[14-17]. The involvement in the pathogenesis of T2DM of multiple genes that interact with each other in an epistatic manner may explain why, despite the enormous efforts made to date, the identification of genetic determinants responsible for an increased susceptibility to T2DM still remains unsolved[18,19].

The present review aims to give an overview of the recent findings in this context. We also discuss the results from some recent studies which might be important for future breakthroughs in this field.

GENETIC STUDIES

Over the past few years, various international research centers have been involved in the study and identification of genes predisposing to T2DM using various methods of investigation. Linkage analysis was used to identify potential genes associated with the disease, starting from the analysis of families and then studying a small number of individuals genetically related to each other. Genotyping for genetic markers in family members with and without T2DM has allowed the identification of DNA regions containing loci associated with disease risk. Thanks to this method, the association of T2DM with the calpain-10 (*CAPN10*) gene[20] was initially identified and later its association with the transcription factor 7-like 2 (*TCF7L2*) gene[21], whose genetic variants in affected individuals increase the risk of diabetes approximately 1.5 times[19].

Another approach used was to search for genetic variants within functional candidate genes encoding for protein(s) with important implications for glucose homeostasis and positional candidate genes that have a genetic association on the basis of a previous linkage study. This experimental strategy is applied to population studies rather than studies of families. Association studies of functional candidate genes represent one of the most powerful approaches as the pathogenetic mechanism of any genetic abnormality would be easily explained. The limit of this strategy, however, is constituted by the fact that it allows focused attention on a single gene at a time. Although many studies have reported associations of functional and positional candidate genes with T2DM, only some of these showed a significant and reproducible association with the disease (Table 1).

From 2007 onwards, the list of candidate genes has grown considerably, largely due to genome-wide associa-

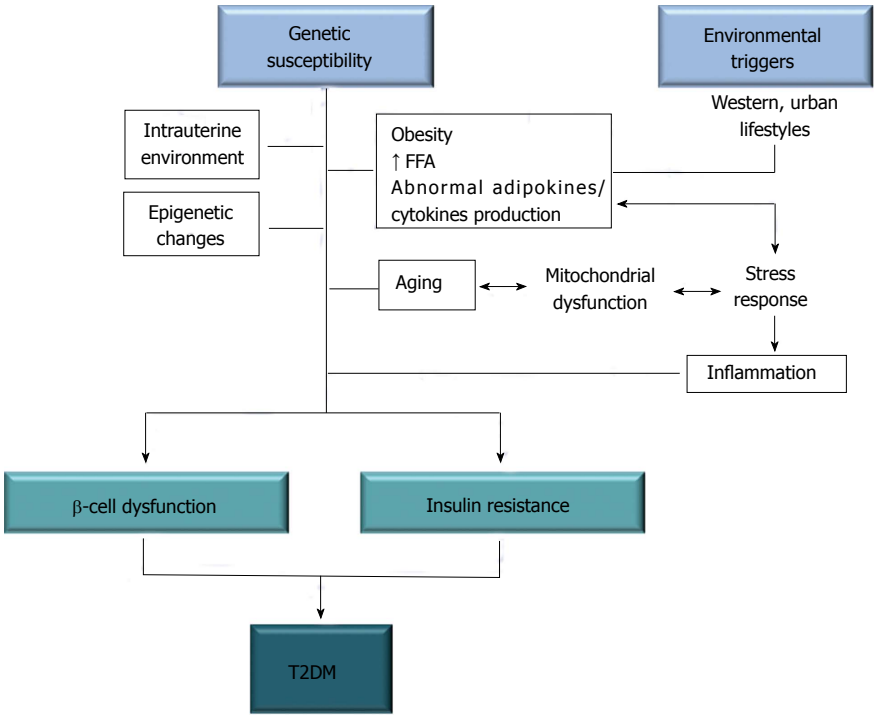

Figure 1 Overview of the pathogenic factors underlying development of type 2 diabetes mellitus. As a complex disease, T2DM is caused by a combination of genetic, environmental and lifestyle factors, all of which interact together to produce insulin resistance and β-cell dysfunction, leading to hyperglycemia, which is the clinical hallmark of diabetes. FFA: Free fatty acids. T2DM: Type 2 diabetes mellitus.

tion studies (GWAS), a technique commonly used to find links between genes and diseases across a substantial population. This strategy uses a database of over a million known genetic variants, which represent the majority of all common variants (minor allele frequency > 5%-10%), thus offering the possibility of simultaneously analyzing thousands of variations in a large number of patients and to perform meta-analysis of data from multiple studies. This methodology has helped to identify dozens of new associations between T2DM and genes with known or unknown functions (Table 1)[22-57], confirming some of the results from previous studies. However, despite the great potential of this approach, it is estimated that genetic variants identified through GWAS explain only 10% heritability for T2DM[58,59]. These relatively modest results can be explained taking into account some important limits of this strategy, such as the involvement of novel genetic variants not yet covered in the GWAS database, or the presence of variants with a frequency lower than the minimum threshold value. This means that the genes identified by GWAS so far are just the tip of the iceberg and that T2DM, far from being a condition limited to a few genetically and phenotypically prevalent forms, actually encompasses a heterogeneous group of genetically distinct disorders[18].

However, in many genetic studies carried out to date, the functional mechanism(s) by which the associated gene may increase susceptibility to T2DM is often poorly understood. In this respect, the intrinsic limitations of both the linkage analysis and GWAS are amplified by the fact that, in most cases, the genetic variants identified are located in non-coding regions of the DNA, whereby it becomes even more difficult to trace the role and influence of the associated gene in the development of the disease. In cases in which it was possible to ascertain the precise pathogenic mechanism, for example, through the study of association with the circulating levels of insulin or through the direct analysis of the gene's protein product, it has been seen that most of the genes identified are involved in pancreatic β-cell mass and/or function, thus with implications in insulin secretion defects (Table 1). This observation suggests that most of the risk associated with T2DM in the general population relates to genetic defects in β-cells, while peripheral insulin resistance predominantly suffers from the environmental component[18,19,60].

GENES INVOLVED IN β-CELL INSULIN SECRETION

Figure 2 depicts some of the genes whose alteration confers an elevated risk of T2DM. Using the analysis of functional or positional candidate genes, several variants have been identified, including polymorphisms of the gene insulin receptor substrate-1 (*IRS-1*)[22,24,43]. The Gly972Arg variant of IRS-1 determines a defect in the

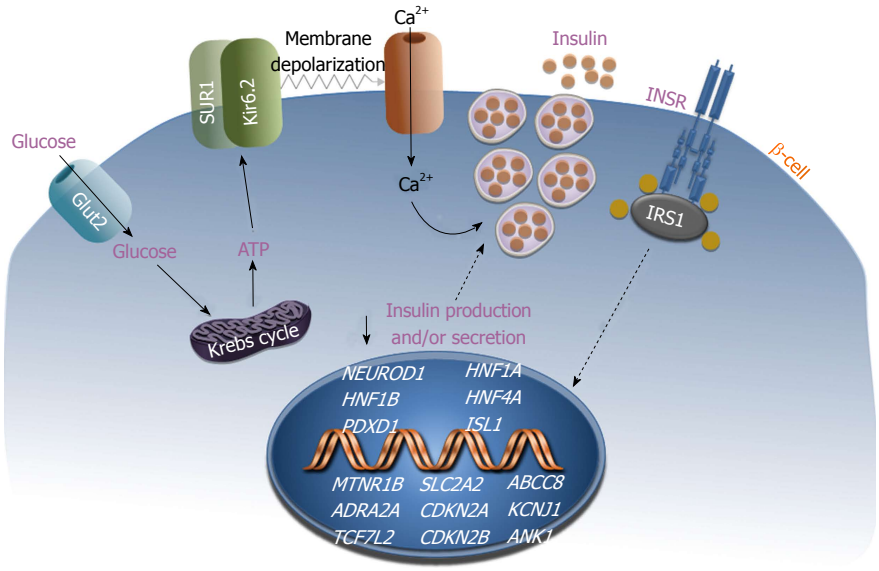

Figure 2 Schematic representation of the pancreatic β-cell. Reduced insulin secretion is shown in β-cells with gene variants linked to T2DM. Genes associated with defects in β-cell mass and/or function are indicated in white italic uppercase. T2DM: Type 2 diabetes mellitus.

binding of the p85 subunit of the phosphatidylinositol 3-kinase (PI3K) which in pancreatic β-cells causes a marked decrease in insulin secretion in response to glucose and sulfonylureas[61]. Other polymorphisms implicated in T2DM have been identified in the *ABCC8* (also known as *SUR1*) and *KCNJ11* genes, whose protein products take place in the formation of the Adenosine triphosphate (ATP)-sensitive potassium channel/sulfonylurea receptor of the pancreatic β-cell. The therapeutic response to sulfonylureas is compromised in patients with mutations in these genes. Other genes whose mutations were initially considered responsible for the less common forms of diabetes mellitus have subsequently been associated with an increased risk of T2DM[19]. Among these are the hepatocyte nuclear factor-1 homeobox A (A*HNF1A*) gene, whose mutations are responsible for the most common monogenic form of MODY (MODY3), a form of maturity onset diabetes of the young (also known as HNF1A-MODY), and the gene hepatocyte nuclear factor-1 homeobox B (*HNF1B*), which determines a less frequent but more severe monogenic form of diabetes, the MODY5. Both of these genes encode nuclear transcription factors involved in the development and function of pancreatic islets.

As already mentioned, the association between *TCF7L2* gene polymorphisms and susceptibility to T2DM was highlighted initially by linkage studies and confirmed thereafter by GWAS. However, only recently has the role played by the transcription factor TCF7L2 in the β-cell insulin secretion become evident[62]. Another gene that has recently been associated with T2DM is the melatonin receptor 1B (*MTNR1B*) gene which encodes for the receptor of the pineal hormone melatonin, MTNR1B, that is involved in the regulation and facilitation of sleep. Genetic variants of the *MTNR1B* gene, associated with gain-of-function of the MTNR1B receptor protein and a reduction in insulin secretion, have been reported in diabetic patients with abnormalities in melatonin secretion and circadian rhythm disorders of the sleep-wake cycle[63]. Another example of genetic abnormality associated with β-cell dysfunction and the risk of T2DM involves the *ADRA2A* gene that encodes for the alpha 2A-adrenergic receptor, which mediates the adrenergic suppression of insulin secretion[60]. Diabetic patients with polymorphisms of the *ADRA2A* gene may have overexpression of the alpha 2A receptor, resulting in insulin secretion deficiency. In pancreatic islets obtained from diabetic patients carrying this variant, pharmacological treatment with alpha (2A)-AR antagonists rescued insulin secretion[64].

Recently, large scale GWAS meta-analyses and imputation-based GWAS studies have demonstrated that the ankyrin 1 gene, a gene encoding for a protein of the ankyrin family, is associated with T2DM in different ethnicities[26-28]. Ankyrin 1 is typically expressed in the erythrocytes and functions as an adaptor molecule between membrane and skeleton proteins. Interestingly, mutations of this gene are known to determine hereditary spherocytosis. How this protein can be implicated in T2DM is not yet understood; however, ankyrin 1 is also expressed in β-cells, where a cognate protein, ankyrin B, plays a role in regulating ATP sensitivity by interacting with the sulphonylurea receptor isoform SUR1.

Another recent study has identified new loci and variants in a large-scale gene-centric meta-analysis that included the *SLC2A2* (solute carrier 2A2) gene[24]. This gene encodes the glucose transporter Glut2, which is expressed in pancreatic β-cells, liver and kidney, and functions as a glucose sensor to maintain glucose homeostasis. These findings support a previously postulated role of Glut2 in T2DM[65]. Also, variants of genes involved in the cell cycle, like the *CDKN2A* and *CDKN2B* (cyclin-dependent kinase inhibitor 2A and 2B) genes, have been associated with T2DM. Although not proved in humans, data from animal models support the idea that these genetic variants may affect β-cell mass later in life[66].

GENES INVOLVED IN INSULIN RESISTANCE

The first step in the mechanism of action of insulin is

the interaction of the hormone with its specific receptor, the insulin receptor (INSR), on the cell surface of insulin responsive cells and tissues (Figure 3). The functional activation of INSR is a key moment in the pathophysiology of insulin action, followed by the selective activation of specific intracellular signaling pathways which are necessary for proper hormonal signal transduction. Although defects in INSR have been reported in a large number of patients with T2DM, mutations in the *INSR* gene have been found only in a small percentage (3%-4%) of these patients in whom genetic defects leading to receptor protein abnormalities were identified as cause of disease. However, certain patients with apparently normal *INSR* genes have reduced expression of both the INSR protein and INSR mRNA levels[13,18,19]. In these patients, it is possible that there are mutations in genes encoding transacting factors which regulate the level of *INSR* gene expression[40].

The mechanisms by which gene variants may impair insulin action in insulin target tissues are schematized in Figure 3. Among the genes involved in insulin resistance are those encoding for the glucokinase regulatory protein, GKRP, and the insulin-like growth factor- I , IGF- I . Genetic variants of these genes that predispose a person to develop insulin resistance have been recently identified by GWAS[25]. In addition, T2DM risk alleles at three loci (at *FTO*, *KLF14* and *PPARG*) have been associated with higher fasting insulin (which is consistent with a primary defect on insulin action) and reduced insulin sensitivity[22]. In particular, variations in the fat mass and obesity-associated (*FTO*) gene appear to influence predisposition to T2DM through a positive effect on body mass index and obesity. Instead, the Krüppel-like factor 14 (*KLF14*) gene is considered a super gene with the ability to control other genes linked to body fat. The risk alleles at *KLF14*, along with those at peroxisome proliferator-activated receptor gamma (*PPARG*), appear to have a primary effect on insulin action which, unlike the alleles at *FTO,* is not driven by obesity[22].

A recently uncovered gene implicated in T2DM is the growth factor receptor-bound 14 (*GRB14*) gene[26,27], which codes for the Grb14 adaptor protein. Grb14 contains a C-terminal SH2 domain implicated in the interaction with a number of tyrosine kinase receptors and signaling proteins, and a domain called BPS (between pleckstrin homology), also required for binding to the INSR. This protein has been shown to specifically attenuate insulin action by inhibiting the catalytic activity of the INSR in insulin target tissues[67]. Many other recently identified diabetes-associated genes play still unknown roles in the pathophysiology of T2DM. Among them, the sterol regulatory element-binding transcription factor 1 (*SREBF1*) gene, which is involved in the transcriptional regulation of lipid homeostasis[24], and the high mobility group 20A (*HMG20A*) gene, which encodes a chromatin-associated protein and has previously been associated with a greater incidence of diabetes in obese subjects[26,27].

THE HIGH MOBILITY GROUP A1 GENE

Among the group of genes recently associated with insulin resistance and T2DM is the *HMGA1* gene, which encodes the architectural transcription factor, High Mobility Group A1 (HMGA1), a nonhistone basic protein that binds to AT-rich sequences of DNA *via* AT hooks, facilitating the assembly and stability of a multicomponent enhancer complex, the "enhanceosome", which drives gene transcription[68]. We previously found that HMGA1 is a key regulator of *INSR* gene expression[69-71] (Figure 4). Consistent with these findings, we identified two patients with insulin-resistant T2DM who had defects in HMGA1 expression and concomitant decreased INSR mRNA and protein in muscle, fat and circulating monocytes[72]. These individuals had normal *INSR* genes but had a novel genetic variant (*c.*369del*) in the 3' noncoding region of the HMGA1 mRNA that contributed to the reduction of mRNA half-life and subsequent decline in HMGA1 expression. Epstein-Barr virus (EBV)-transformed lymphoblasts from these patients demonstrated defects in HMGA1 and INSR expression, indicating that the defects observed *in vivo* were not due to the altered metabolic state of the patients. In addition, the *in vitro* restoration of HMGA1 RNA and protein expression in these cells normalized *INSR* gene expression and restored both cell-surface INSR protein expression and insulin binding capacity[72]. The pathogenetic role of HMGA1 in T2DM was confirmed in genetically modified mice, in which the loss of HMGA1 expression (induced by disrupting the *HMGA1* gene) considerably decreased INSR expression in the major target tissues of insulin action[72], thus supporting the concept that functional *HMGA1* gene variants decrease INSR expression in human and mice.

In the context of these investigations, we later showed that four functional variants of the *HMGA1* gene, leading to reduced INSR expression, were associated with insulin resistance and T2DM[40]. The most frequent functional *HMGA1* variant, c.136-14_136-13insC (also designated rs146052672), was detected in 7%-8% of patients with diabetes in individuals of white European ancestry[40]. Analysis of cultured EBV-transformed lymphoblasts from patients with T2DM and the rs146052672 variant revealed that these cells had lower levels of HMGA1 and INSR protein than cells from either patients with wild-type T2DM or controls. Once again, in transformed lymphoblasts from the patients with the *HMGA1* rs146052672 variant, restoration of HMGA1 protein expression by complementary DNA transfection (in the sense but not antisense direction) restored INSR protein expression and insulin binding to these cells[40]. Although not replicated in a heterogeneous French population[73], the *HMGA1* rs146052672 variant was significantly associated with T2DM among Chinese[41] and Hispanic-American[38] individuals. Further evidence, implicating the HMGA1 locus as one conferring a high cross-race risk for the development of insulin

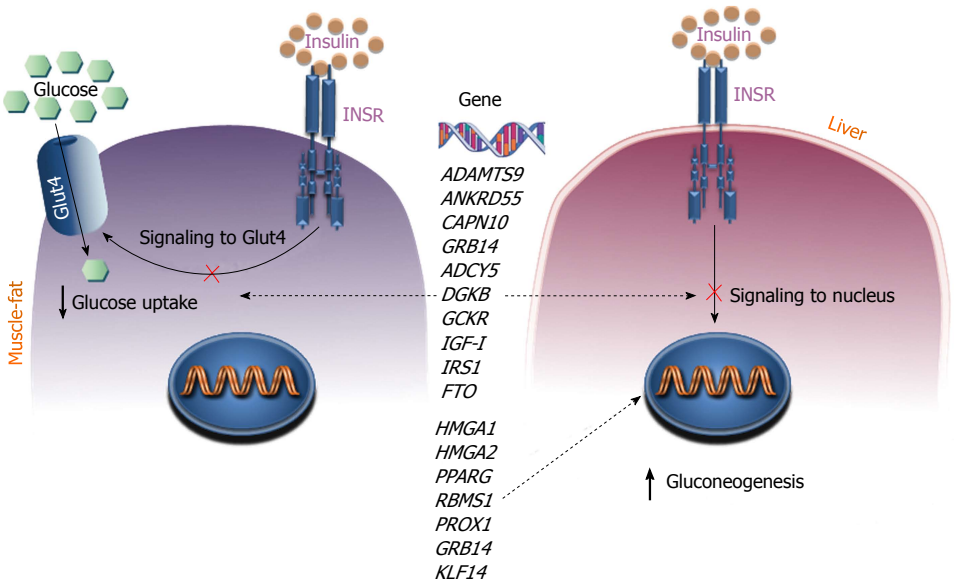

Figure 3 Mechanisms of insulin resistance. The figure shows the mechanisms by which gene variants may impair insulin action in the insulin target tissues muscle, fat and liver. Peripheral insulin resistance in muscle and fat reduces cellular glucose uptake, whereas insulin resistance in liver results in a failure to suppress glucose production and gluconeogenesis. Genes whose variations can influence the risk of developing insulin resistance and T2DM are indicated in black italic uppercase. T2DM: Type 2 diabetes mellitus.

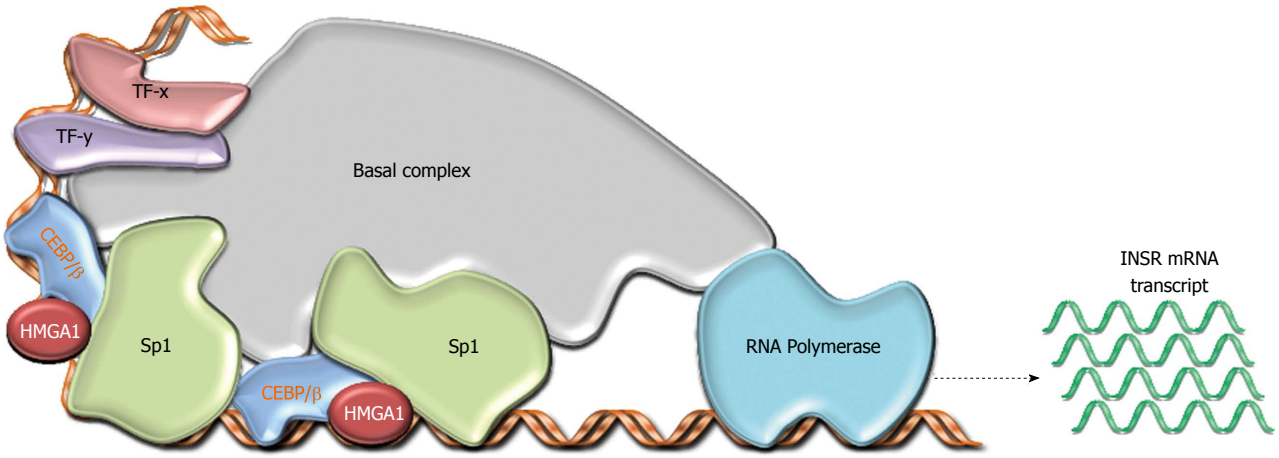

Figure 4 Model for the role of High Mobility Group A1 in type 2 diabetes mellitus. As a transcriptional regulator of the *INSR* gene, *HMGA1* gene variants may lead to decreased *INSR* gene transcription. This loss of insulin receptor (INSR) underlies the resultant insulin resistance and T2D in affected individuals. T2D: Type 2 diabetes.

resistant diseases, has been provided recently by showing that the *HMGA1* rs146052672 variant significantly associates with the metabolic syndrome in Italian and Turkish individuals and predisposes these (and other) populations to the unfavorable anthropometric and metabolic traits of the metabolic syndrome[74,42].

Overall, these data are consistent with the impression that the association of *HMGA1* gene variants with T2DM is accomplished through a pathogenetic mechanism related to peripheral insulin resistance. However, additional studies *in vitro* and *in vivo*, in normal and mutant mice, indicate that HMGA1, in addition to its role on *INSR* gene and protein expression, acts as a novel downstream target of the INSR signaling pathway[75], thus representing a critical nuclear mediator of insulin action and function. In this regard, evidence has been provided indicating that HMGA1 plays an essential role in the transcriptional regulation of a variety of insulin-target genes, such as the *IGFBP-1* gene, as well as the gluconeogenic genes *PEPCK* and *G6Pase*[76], contributing to the transcriptional regulation of glucose homeostasis.

PERSPECTIVES

Significant advances have been made in recent years in relation to the pathogenesis of T2DM. This has significantly improved our knowledge of one of the most serious health threats in the world, allowing identification of genes and pathways involved in the development and progression of the disease. It has recently become possible to acquire molecular and genetic level information from an individual (*i.e.*, DNA genotyping, gene expression, epigenomic profile, *etc.*). However, while such information is becoming increasingly available, how the identified genes and pathways impact on T2DM still remain largely unknown, due to the multifactorial nature of the disease. Understanding the pathogenesis of T2DM is necessary to enable the identification of prognostic and predictive biomarkers, as well as new therapeutic targets, which in turn should lead to improved outcomes in affected patients. Thus, once new therapeutic targets of

interest are identified, it is necessary to develop molecules that can rescue function to disease-associated genes or pathways and conduct studies that provide new strategies for the treatment of T2DM.

CONCLUSION

T2DM is a heterogeneous disease with a strong genetic component and familial inheritance. Considerable effort has been made in the last decades to identify genes that may explain all the diabetic phenotypes. Currently, however, genetic studies on T2DM can explain only a small percentage of its heritability. Until now, the *HMGA1* gene displays the strongest association with T2DM and its most frequent variant, rs146052672, confers the highest risk for human T2DM. Hence, from a strategic point of view, this finding suggests directing future research towards the identification of rare genetic variants with a stronger association, rather than common variants with a relatively small effect on the disease. It is evident that if a genetic variant confers a high susceptibility to T2DM it may become a useful biomarker to search for. For example, the genetic variants identified in the *HMGA1* gene may represent a predictive marker for early detection of T2DM, especially in those individuals with a family history of the disease. Moreover, variants in the human *HMGA1* gene may induce a different clinical course of disease compared to diabetic patients without the variant and may predict response to therapy, allowing identification of a priori patients who could most benefit from a specific pharmacological treatment[77]. Another important point in support of genetic studies in T2DM is the fact that they may integrate and improve our knowledge about the molecular mechanisms underpinning the pathophysiology of this disease.

Abstract

The P2X$_7$ receptor is one of the members of the family of purinoceptors which are ligand-gated membrane ion channels activated by extracellular adenosine 5′-triphosphate. A unique feature of the P2X$_7$ receptor is that its activation can result in the formation of large plasma membrane pores that allow not only the flux of ions but also of hydrophilic molecules of up to 900 Da. Recent studies indicate that P2X$_7$-mediated signaling can trigger apoptotic cell death after ischemia and during the course of certain neurodegenerative disorders. Expression of the P2X$_7$ receptor has been demonstrated in most types of cells in the retina. This purinoceptor mediates the contraction of pericytes and regulates the spatial and temporal dynamics of the vasomotor response through cell-to-cell electrotonic transmission within the microvascular networks. Of potential clinical significance, investigators have found that diabetes markedly boosts the vulnerability of retinal microvessels to the lethal effect of P2X$_7$ receptor activation. This purinergic vasotoxicity may result in reduced retinal blood flow and disrupted vascular function in the diabetic retina. With recent reports indicating an association between P2X$_7$ receptor activation and inflammatory cytokine expression in the retina, this receptor may also exacerbate the development of diabetic retinopathy by a mechanism involving inflammation.

Key words: P2X$_7$ receptor; Diabetic retinopathy; Vasotoxicity; Retinal microvessels; Interleukin-1β; Tumor necrosis factor-α

Core tip: This review summarizes the studies regarding the putative role of the P2X$_7$ receptor in triggering purinergic vasotoxicity in the retina and thereby contributing to the progression of diabetic retinopathy.

Sugiyama T. Role of P2X$_7$ receptors in the development of diabetic retinopathy. *World J Diabetes* 2014; 5(2): 141-145 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i2/141.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i2.141

INTRODUCTION

One of the most important characteristics of diabetic retinopathy (DR) is the death of microvascular pericytes and endothelial cells[1]. The loss of pericytes, contractile cells located on the abluminal wall of capillaries[2], appears to play a critical role in the development of microaneurysms and neovascular tufts[3]. Damage in the endothelial cells can result in a breakdown of the blood–retinal barrier and macular edema[4].

Currently, the mechanisms by which diabetes induces apoptosis in the retinal microvasculature remain uncertain, although oxidative stress, formation of advanced glycation end products, upregulation of protein kinase C, increased polyol pathway flux and focal leukostasis may be taken as important factors[5]. In fact, multiple lethal pathways may be activated during chronic hyperglycemia[6].

Extracellular adenosine 5'-triphosphate (ATP) is an excitatory transmitter both in the peripheral and central nervous systems. P2X receptors are a family of ligand-gated membrane ion channels activated by extracellular

ATP. P2X receptors consist of seven isoforms designated P2X1 to P2X7[7,8]. They are widely distributed in most types of cells in nearly every origin. They are involved in many actions, such as synaptic transmission in the peripheral and central nervous systems, contraction of smooth muscle, platelet aggregation, macrophage activation, cell death and immunomodulation[9,10].

In contrast to other ligand-gated channels in the purinoceptor family, the P2X7 receptor possesses unique features that are likely to be of both physiological and pathophysiological significance. Most importantly, not only does the initial activation of these receptors result in the opening of a non-selective plasma membrane channel, but with sustained activation there is in many types of cells the formation of trans-membrane pores that are permeable to hydrophilic molecules of up to 900 Da[11,12]. Indicative of P2X7 receptors having a role in cell pathology, this receptor has been found to be highly up-regulated in neurons and glial cells located in the ischemic cerebral cortex[13]. P2X7-mediated signaling is also implicated in neurodegenerative diseases, such as Parkinson's disease, Alzheimer's disease and multiple sclerosis[14].

P2X7 RECEPTOR IN THE RETINA

Expression of the P2X7 receptor has been demonstrated in most types of cells in the retina; these include neurons such as the ganglion cells[15,16], as well as glia[17,18] and vascular cells[19]. The P2X7 receptor was found to mediate the contraction of pericytes through an increase in intracellular calcium levels[19]. Interestingly, the spatial and temporal dynamics of this vasomotor response are established by the ability of P2X7 activation to potently inhibit cell-to-cell electrotonic transmission within the retinal microvascular network[19].

In the adult rat retina, immunolabeling for the P2X7 receptor is detected in a number of cells in the inner nuclear layer and ganglion cell layer, suggesting amacrine cells and ganglion cells[15]. This receptor was also found in processes presynaptic to rod bipolar cells, as well as other conventional synapses, suggesting that purines play a role in neurotransmission within the retina and may modulate both photoreceptor and rod bipolar cell responses[20].

In addition to the putative physiological roles of P2X7 receptors, it is reported that stimulation of these receptors can kill retinal ganglion cells *in vitro* and *in vivo* by a mechanism that appears to be dependent on a rise in intracellular Ca^{2+}[21,22]. One of those reports also suggested that the balance between extracellular ATP and its protective metabolite adenosine can influence ganglion cell survival in the living eye[22]. Another study suggested that an early up-regulation of neuronal P2X7 receptors may cause injury of retinal neurons and thereby contribute to the retinal damage[23]. Furthermore, data from our laboratory indicate that the activation of P2X7 receptors is involved in hypoxia-induced death of retinal neurons[24]. Other researchers have indicated mechanical strain triggers ATP release directly from retinal ganglion cells and that this released ATP autostimulates P2X7 receptors.

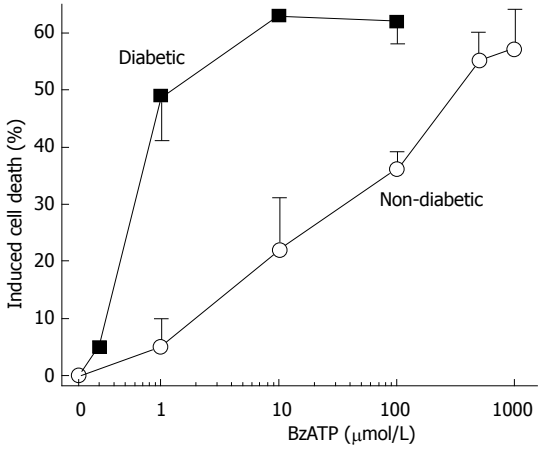

Figure 1 Cell death induced in non-diabetic and diabetic retinal microvessels by the P2X7 agonist, benzoylbenzoyl adenosine triphosphate. From Sugiyama *et al*[30] with permission from Investigative Ophthalmology and Visual Sciences. BzATP: Benzoylbenzoyl adenosine triphosphate.

Since extracellular ATP levels in the retina increase with elevated intraocular pressure and stimulation of P2X7 receptors on retinal ganglion cells can be lethal, this autocrine response may exert a deleterious effect on retinal ganglion cells in glaucomatous eyes[25].

P2X7 RECEPTOR AND DIABETIC RETINOPATHY

A study showed that human primary fibroblasts in a medium with a high glucose concentration underwent substantial ATP-mediated morphological changes and increased apoptosis. P2X7 was identified as the main purinergic receptor involved in these responses[26]. It has also been reported that fibroblasts from type 2 diabetes patients are characterized by a hyperactive purinergic loop based either on a higher level of ATP release or on increased P2X7 reactivity[27]. Another study revealed that changes in Müller cell membrane conductance in proliferative diabetic retinopathy (PDR), *i.e.*, the down-regulation of active Kir channels and the membrane depolarization, likely disturb voltage-dependent Müller cell functions, such as regulation of local ion concentrations and uptake of neurotransmitters[28]. The enhanced entry of calcium ions from the extracellular space and the subsequent stimulation of calcium-activated potassium channels may trigger Müller cell proliferation in PDR. Others reported that prolonged stimulation of the P2X7 receptor elicited permeabilization exclusively in microglial cells but not in neurons of the inner retina[29].

Our experiments, using pericyte-containing retinal microvessels, have shown a diabetes-induced increase in the vulnerability of retinal microvessels to the lethal effect of P2X7 receptor activation[30]. In other words, the agonist concentration needed to open large membrane pores and trigger apoptosis decreased markedly soon after the onset of streptozotocin-induced hyperglycemia in rats (Figure 1). It was also found that extracellular nicotinamide adenosine dinucleotide (NAD^+) caused cell death in the

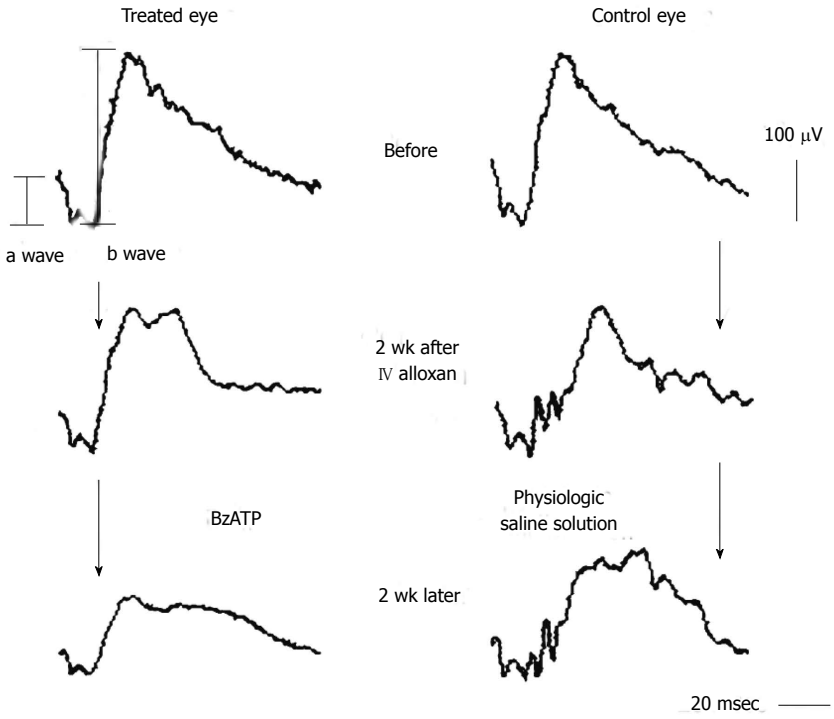

Figure 2 Typical changes of electroretinography after intravitreal injection (Ⅳ) of benzoylbenzoyl adenosine triphosphate (50 nmol) or physiological saline solution in an alloxan-induced diabetic rabbit. The amplitudes of a and b waves and oscillatory potentials were reduced in the BzATP-treated eye. From Sugiyama *et al*[32] with permission from Archives of Ophthalmology. BzATP: Benzoylbenzoyl adenosine triphosphate.

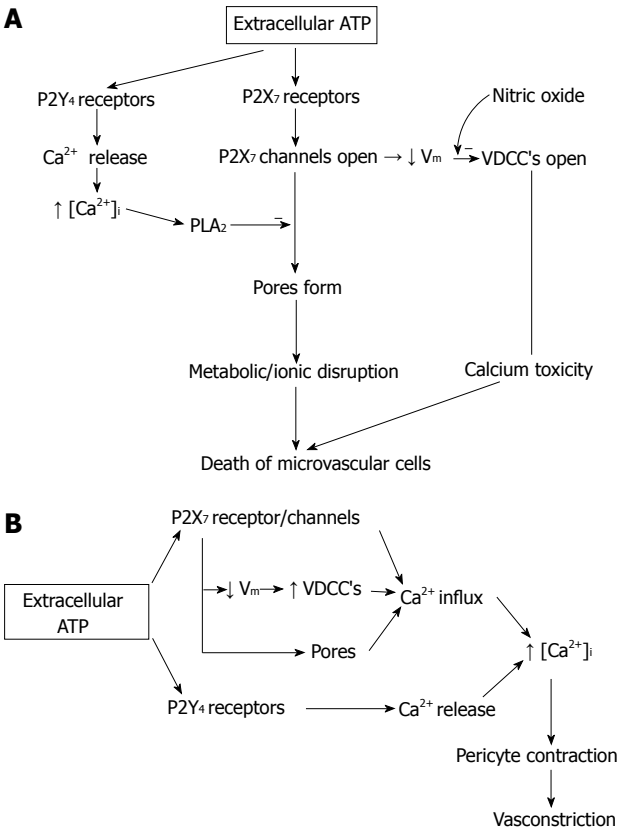

Figure 3 Models of the physiological and pathobiological effects of adenosine 5'-triphosphate in the retinal microvasculature. A: Putative mechanisms regulating purinergic vasotoxicity; B: Putative mechanisms by which extracellular adenosine 5'-triphosphate (ATP) causes pericyte Ca^{2+} levels to rise and thereby the contraction of these mural cells and the constriction of adjacent lumens. From Sugiyama *et al*[33].

retinal microvasculature by a mechanism involving the activation of the P2X7 purinoceptor and the formation of transmembrane pores. Soon after the onset of diabetes, the sensitivity of retinal microvessels to the vasotoxic effect of extracellular NAD^+ increased by approximately 100-fold[31]. In our *in vivo* study using the laser speckle circulation analyzer and electroretinography, soon after the onset of alloxan-induced diabetes, retinal blood velocity and function become more vulnerable to reduction initiated through the P2X7 receptor (Figure 2)[32]. Additional investigations indicate that, under physiological conditions, the formation of P2X7 pores is tightly regulated *via* a nitric oxide- and P2Y4-dependent pathway that limits the rise in pericyte calcium during the activation of these purinoceptors[33]. However, if this regulatory mechanism becomes dysfunctional, as appears to occur in the diabetic retina (Figure 3)[33], then purinergic vasotoxicity may contribute to the microvascular cell death that is a hallmark of DR.

Of additional interest, recent studies of DR in experimental models suggest the P2X7 receptors may have a role in mediating cytokine-induced vascular inflammatory reactions that can degrade the integrity of the blood-retinal barrier and thereby contribute to retinal vascular occlusion and ischemia[34]. More specifically, there are a number of reports linking P2X7 receptor activation in the retina with the expression of inflammatory cytokines[35]. For example, P2X7 agonists enhance the release of interleukin (IL)-1β and tumor necrosis factor (TNF)-α from hypoxia-activated retinal microglia[17]. In addition, our recent data suggest that the up-regulation of TNF-α, IL-1β and IL-6 may be involved in the retinal ganglion cell death that can occur with P2X7 receptors activated after an elevation in the intraocular pressure[36]. Although it is clear that more investigation is needed, these new findings further suggest that this purinoceptor may have a role in the progression of DR.

In conclusion, a variety of recent experimental studies are providing evidence that the P2X7 purinoceptor is a potential therapeutic target of a pharmacological strategy designed to diminish or prevent cell death in the diabetic retina.

ACKNOWLEDGMENTS

I would like to express my appreciation to Professor Donald G. Puro for leading me to this research topic during my stay in 2001 as a research fellow in his laboratory at the University of Michigan as well as for kindly editing this manuscript, and also to Professor Tsunehiko Ikeda for giving me the opportunity to study abroad and then to continue investigating this topic in Department of Ophthalmology at Osaka Medical College.

Abstract

Insulin resistance is a hallmark of type 2 diabetes. In an effort to understand and treat this condition, researchers have used genetic manipulation of mice to uncover insulin signaling pathways and determine the effects of their perturbation. After decades of research, much has been learned, but the pathophysiology of insulin resistance in human diabetes remains controversial, and treating insulin resistance remains a challenge. This review will discuss limitations of mouse models lacking select insulin signaling molecule genes. In the most influential mouse models, glucose metabolism differs from that of humans at the cellular, organ, and whole-organism levels, and these differences limit the relevance and benefit of the mouse models both in terms of mechanistic investigations and therapeutic development. These differences are due partly to immutable differences in mouse and human biology, and partly to the failure of genetic modifications to produce an accurate model of human diabetes. Several factors often limit the mechanistic insights gained from experimental mice to the particular species and strain, including: developmental effects, unexpected metabolic adjustments, genetic background effects, and technical issues. We conclude that the limitations and weaknesses of genetically modified mouse models of insulin resistance underscore the need for redirection of research efforts toward methods that are more directly relevant to human physiology.

Key words: Insulin resistance; Mice; Knockout; Disease models, Animal; Glucose/metabolism; Signal transduction

Core tip: Insulin resistance is central to the pathophysiology of type 2 diabetes. The molecular origins of insulin resistance have been investigated using genetically modified mice. Much has been learned from this work, but new treatments for insulin resistance have not been forthcoming. Knockout mouse models of diabetes are limited by several factors including species differences in glucose metabolism. These are due partly to species differences in physiology, and partly to the failure of genetic modifications to produce an accurate model. Advancement may require a redirection of research efforts toward methods that are more directly relevant to human physiology.

INTRODUCTION

Type 2 diabetes is a growing public health problem affecting approximately 26 million adults in the United States, with pre-diabetes affecting an additional 79 million[1]. The natural history of type 2 diabetes starts with insulin resistance, which develops over time and often

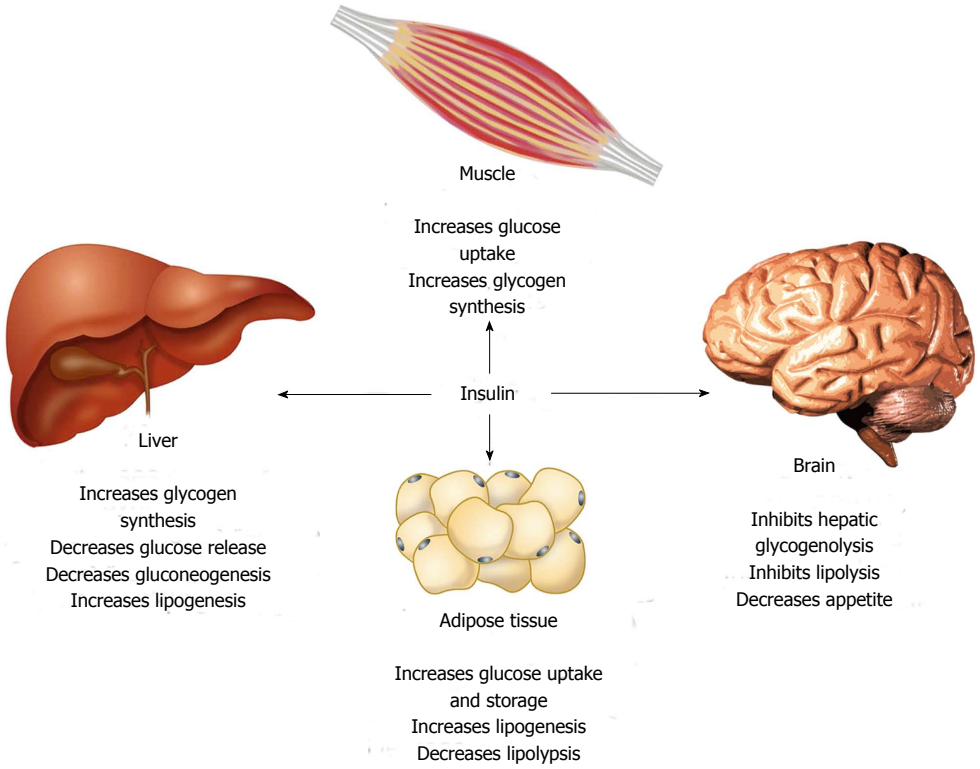

Figure 1 Insulin actions in main insulin-sensitive tissues. Insulin has different actions in each of the main insulin-sensitive tissues. In muscle, insulin promotes glucose uptake and glycogen synthesis. In liver, insulin promotes glycogen synthesis and lipogenesis and reduces gluconeogenesis and the release of stored glucose. In adipose tissue, insulin increases glucose uptake and lipogenesis and decreases lipolysis. In the brain, insulin Inhibits hepatic glycogenolysis and lipolysis and decreases appetite.

precedes a diagnosis by many years. The pancreas compensates for insulin resistance by increasing insulin secretion, often leading to hyperinsulinemia. For many insulin-resistant patients, the pancreas is unable to sustain a high level of insulin secretion. As the pancreas fails to meet the demand for insulin, plasma glucose rises. Patients are then at risk of morbidity and mortality associated with complications such as neuropathy, retinopathy, nephropathy, and increased risk of cardiovascular disease. Overall, type 2 diabetes decreases life expectancy at age 50 or older by about 8 years[2]. Aside from diabetes and the metabolic syndrome, insulin resistance is also associated with polycystic ovarian syndrome and other problems. Understanding the cellular and molecular causes of insulin resistance is an area of active research because of the need to discover new therapies to help patients.

Animal models are often used to investigate mechanisms of insulin resistance and develop therapeutic agents. In the field of type 1 diabetes, serious limitations of animal models have become apparent[3]; we therefore sought to assess the utility of select mouse models used in type 2 diabetes research, specifically insulin signaling and resistance. We begin with a brief summary of insulin signaling, followed by a closer look at general limitations of mouse models and specific limitations of knockouts lacking select insulin signaling molecule genes.

Insulin resistance is defined as the failure of cells to respond normally to insulin, and most importantly, to insulin's glucose-lowering effects. It can be measured by a number of approaches, including the Homeostatic Model Assessment of Insulin Resistance, which is based on fasting glucose and insulin levels, and the gold standard approach, a hyperinsulinemic-euglycemic clamp test[4]. On a cellular level, insulin resistance manifests differently in different tissues (Figure 1). Insulin-resistant muscle cells fail to uptake glucose and other nutrients in response to insulin, whereas in adipose tissue, insulin resistance leads to greater hydrolysis of stored triglycerides in addition to decreased nutrient uptake. In the liver, insulin promotes glycogen synthesis and prevents the release of stored glucose, thereby raising blood glucose levels. In the brain, insulin decreases appetite and hepatic glucose production[5].

The molecular mechanisms of insulin resistance in type 2 diabetes have not been fully characterized, although many important biochemical, metabolic, and genetic features have been identified. Accumulated findings have highlighted several pathways to insulin resistance, including lipid accumulation, oxidative stress, and inflammation[6]. An important common feature of these mechanisms is the activation of stress-sensitive kinases including protein kinase C ζ (PKCζ) that cause a dampening of insulin signaling[6,7].

Insulin is involved in a number of cellular processes apart from nutrient metabolism, including protein synthesis, mitochondrial biogenesis, growth, autophagy, proliferation, differentiation, and migration[8-10]. As illustrated in Figure 2, the binding of insulin to its receptor triggers a cascade of cellular events that leads to nutrient uptake

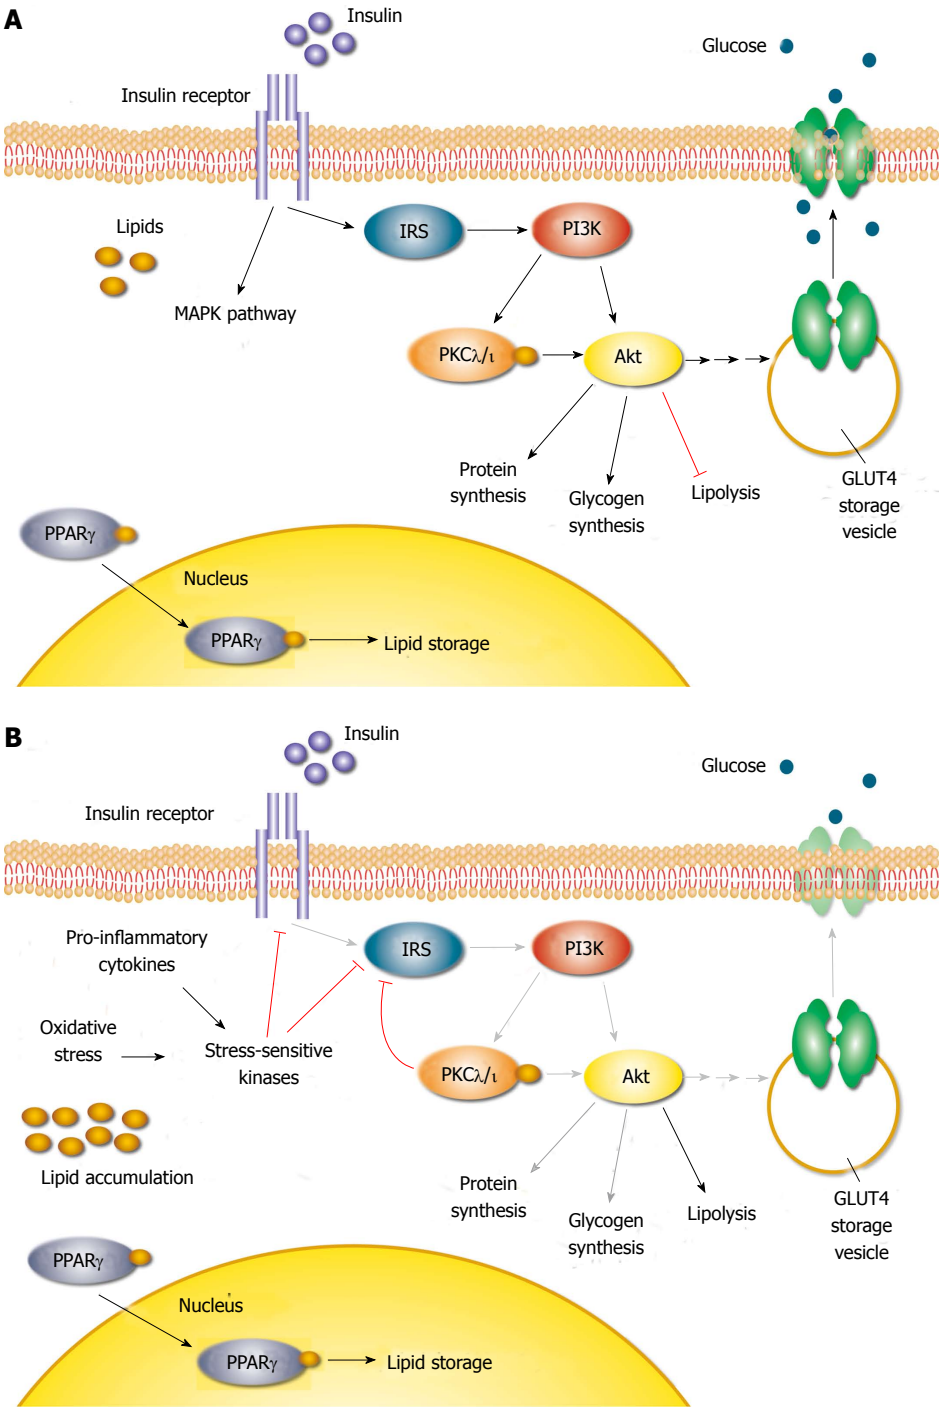

Figure 2 Insulin signaling in health and disease. Insulin signaling in health and disease. A: The binding of insulin to its receptor triggers a cascade of cellular events that lead to nutrient uptake and activation of various cellular programs. Insulin receptor substrate (IRS) activates phosphoinositide 3-kinase (PI3K) which produces a metabolite that activates protein kinase B (AKT) and protein kinase C λ/ι (PKCλ/ι). PKCλ/ι, which also depends on lipids for activation, can inhibit insulin signaling by a feedback mechanism. The nuclear receptor peroxisome proliferator-activated receptor gamma (PPARγ), is important in lipid metabolism, and is the target of insulin sensitizing thiazolidinedione drugs. PPARγ becomes activated upon binding of lipids and promotes expression of genes involved in fat storage; B: Under insulin-resistant conditions, accumulation of lipids, oxidative stress, and pro-inflammatory cytokines cause activation of stress-sensitive kinases such as protein kinase C θ (PKCθ), inhibitor of nuclear factor kappa-B kinase subunit β (IKKβ) and c-Jun N-terminal kinase 1 (JNK1), which inhibit insulin signaling.

and activation of these various cellular programs[8]. Under insulin-sensitive conditions, as shown in Figure 2A, insulin receptor substrate (IRS) activates phosphoinositide 3-kinase (PI3K), which produces a metabolite that activates protein kinase B (AKT) and PKCλ/ι. PKC λ/ι, which also depends on lipids for activation, can inhibit insulin signaling by a feedback mechanism. The nuclear receptor peroxisome proliferator-activated receptor gamma, or peroxisome proliferator-activated receptor γ (PPARγ), is important in lipid metabolism, and is the target of insulin sensitizing thiazolidinedione drugs (TZDs). PPARγ becomes activated upon binding of lipids and promotes expression of genes involved in fat storage. As shown in Figure 2B, under insulin-resistant conditions,

accumulation of lipids, oxidative stress, and pro-inflammatory cytokines cause activation of stress-sensitive kinases such as PKCθ, inhibitor of nuclear factor kappa-B kinase subunit β (IKK-β) and c-Jun N-terminal kinase 1 (JNK1), which inhibit insulin signaling[6,7].

Evidence for insulin signaling pathways and mechanisms of insulin resistance comes from human and animal cell and tissue studies, clinical studies, and whole animal experiments. While data from various models have been useful in formulating and testing hypotheses, some approaches are more promising than others. Rodent models have been used in the study of type 2 diabetes and insulin resistance for decades. Conditions relevant to the study of insulin resistance and diabetes are induced in rodents using several approaches, including genetic, pharmacological, surgical, and dietary inductions. A number of these approaches and models have been reviewed elsewhere[11-14]. Many researchers favor targeted genetic manipulation because it allows specific and complete or near-complete removal of target gene function in a whole organism or specific tissues[15]. In combination with pharmacological, cell-based and molecular studies, these knockout mouse studies have mapped the insulin signaling pathway in mice to a high level of detail. Other authors have described how pathway connections tested in humans have been shown to be conserved (*i.e.*,[16]). Many would argue that knockout mouse studies have been especially important in defining the function of genes for which no pharmacological or other molecular-based functional ablation is available[17]. In this respect, the genetic approach has become a central component of preclinical research in diabetes and other fields.

Despite this progress in our understanding of insulin action, the causative molecular basis for acquired human insulin resistance remains unclear and controversial. Furthermore, improved understanding of rodent cell signaling has not translated into improved human therapeutics. To wit, it has been almost 20 years since the first insulin signaling knockout mouse studies were published[18,19], but no new drugs targeting the insulin signaling phosphorylation cascade have emerged to treat insulin resistance in type 2 diabetes[9]. While much of this research is conducted for the purpose of hypothesis testing rather than drug development *per se*, the identification of drug targets is often a primary or secondary goal[20]. In light of this, we discuss the limitations of research on insulin resistance using knockout mice of select proteins important in the insulin signaling cascade (Figure 2). The following sections will focus mainly on peripheral insulin resistance and extrapancreatic insulin-sensitive tissues, since many therapeutic and research efforts are in this area. We first address physiological, cellular, and molecular differences in glucose metabolism between mice and humans that limit translatability. We then review select knockout mouse models of insulin signaling dysfunction, identifying cases with contradictory or untranslatable results. Finally, we briefly discuss the limitations of genetic manipulations of these targets in mice in regard to the search for safe and effective drugs for type 2 diabetes.

GLUCOSE DISPOSAL IN MICE AND HUMANS

A central aspect of glucose homeostasis is glucose disposal, meaning the facilitated transport of glucose from blood into storage tissues and organs. Insulin resistance in humans with type 2 diabetes involves defects in glucose sensing and disposal in a number of tissues, but the most significant effects on glucose homeostasis result from insulin resistance in the major glucose-disposing tissues: skeletal muscle, liver and adipose tissue.

Glucose disposal and glycogen storage patterns differ in mice and humans. In healthy humans, about one-third of glucose is taken up by the liver[21]. Estimates of skeletal muscle glucose uptake vary widely, in part because they are often based on indirect measurements and assumptions regarding muscle mass and blood flow. One report that measured muscle glucose more directly using nuclear magnetic resonance demonstrated muscle absorbing 64%-91% of infused glucose in a single male volunteer[22]. A follow-up study of 11 subjects reported muscle glucose uptake of 90% in normal subjects and 67% in diabetic subjects[23]. In a separate study of 10 healthy volunteers, muscle accounted for 38.3% of systemic glucose disposal, based on data from blood sampled from a forearm vein[24]. Overall, the data show greater glucose uptake in skeletal muscle than liver in humans. Genetic evidence underscores the importance of skeletal muscle to whole-body glucose tolerance in humans. Polymorphisms in the gene for the primary glucose transporter in muscle, glucose transporter isoform 4 (GLUT4), have been linked to type 2 diabetes and insulin resistance[25]. Overall, defects in skeletal muscle glucose disposal are a major component of insulin resistance in humans[26].

By contrast, the liver is much more important for glucose disposal in mice. Interfering with glucose uptake in mouse liver causes whole-body insulin resistance and glucose intolerance, but similar manipulations in muscle usually do not. The muscle-specific insulin receptor knockout mouse has normal glucose tolerance, insulin sensitivity, and glucose and insulin levels, with only mild dyslipidemia[27]. Muscle-specific deletion of IRS1 and IRS2 also does not produce a diabetic phenotype, nor does a whole-body knockout of the major muscle glucose transporter, GLUT4[28,29]. One exception to this pattern may be a muscle-specific GLUT4 knockout strain that developed a diabetic phenotype in one study[30], a result that has not been replicated by others[31,32]. In contrast to the above strains deficient in muscle insulin signaling, a liver-specific insulin receptor knockout mouse strain was insulin resistant and severely hyperinsulinemic, and developed hyperglycemia and glucose intolerance at an early age (2 mo)[33]. Liver-specific deletion of IRS1 and IRS2 also cause insulin resistance under certain conditions[34]. Mice with a deletion of the primary glucose transporter in the liver, GLUT2, are hyperglycemic and die at 2-3 wk of age[35].

Glycogen storage is a major destination for glucose in mammals. In mice, approximately 8 times more glyco-

gen is stored in the liver than skeletal muscle[36], but the reverse is true in humans, where 3-8 times more glycogen is found in skeletal muscle[37]. These physiological differences in glucose disposal and storage have implications for modeling insulin resistance, since muscle and liver have different roles and different metabolic and signaling pathways.

There are two important differences in glucose transport between liver, the primary glucose disposal organ in mice, and skeletal muscle, the primary glucose disposal organ in humans. First, skeletal muscle cells have multiple pathways for glucose transport. Contraction-stimulated glucose transport in skeletal muscle is insulin-independent, mediated through 5' adenosine monophosphate activated protein kinase-mediated signaling mechanisms[38]. In contrast, liver has no such activity-stimulated transport method. Second, the transporters involved in glucose uptake are different in the two tissues. In liver, the low-affinity GLUT2 is present at high levels on cell membranes independent of insulin or other signaling[39], and glucose transport rates vary with the extracellular concentration of glucose[40]. In contrast, in skeletal muscle cells, the high-affinity glucose transporter GLUT4 is translocated from internal vesicles to the plasma membrane in response to glucose uptake signals[41]. In human skeletal muscle cells, this transport is facilitated by clathrin isoform CHC22, which is not present in the mouse[42]. The rate-limiting step in glucose metabolism in liver is phosphorylation, while in skeletal muscle it is transport through GLUT4[43]. The divergent features of cells in these organs, combined with the divergent physiology of rodents and humans, means that glucose disposal is affected very differently in the different species.

Because mice rely principally on the liver for glucose homeostasis, while humans rely on skeletal muscle where transport mechanisms and biochemical pathways differ, mice may not be expected to be analogous to type 2 diabetes patients in regards to mechanisms of glucose metabolism or its dysfunction.

Mice and humans have a number of other metabolic differences. The small size and fast metabolism of mice enables heart rates in the range of 350-550 beats per minute, while in humans, normal heart rate is about 70 beats per minute[44]. Mice are capable of the physiological state of torpor, a state of reduced metabolic rate, while humans are not[45]. Prolonged fasting in humans impairs insulin-stimulated glucose utilization, but causes enhancement in mice[46]. In regards to eating patterns, mice consume most of their food at night[45], and an overnight fast of 14-18 h, typical for laboratory experiments, induces a state akin to starvation[47]. In addition, circulating lipids have an inverted composition in mice, with high-density lipoprotein (HDL) being typically higher than low-density lipoprotein (LDL), while HDL is lower in humans[48]. The thermoneutrality point, that is, the temperature at which an organism expends minimal energy for temperature regulation, is higher in mice[49]. This last difference could be compensated for if mice were housed above room temperature, but that is not standard practice.

Finally, experiments investigating mouse metabolism present technical challenges. Insulin sensitivity is often measured using a hyperinsulinemic-euglycemic clamp test, which involves either implanted arterial catheters or repeated blood sampling. The results of this test are dependent on a number of experimental factors which are not standardized between laboratories, including fasting time, anesthesia use, and blood sampling site[46]. Fasting glucose, insulin, and lipid levels are often measured after 14-18 h overnight fasts, but this induces a catabolic state in mice, who normally eat mostly at night. Data shows that a 6 h fast is best to assess glucose tolerance in mice[50].

KNOCKOUT MODELS OF INSULIN SIGNALING

Mouse models of diabetes are often used to explore signaling pathways[13]. The following sections highlight cases relevant to insulin signaling dysfunction where similar or identical genetic manipulations produced disparate results. These cases are consistent with other results showing differences in insulin action, secretion, and responses to hypoglycemia in different inbred mouse strains[51]. Previous reviewers have also noted the strong effect of genetic background in knockout mouse experiments[52]. Other factors influencing disparate findings include compensatory metabolic adjustments and technical challenges associated with evaluating mouse metabolism. Later, we will focus on the challenges of translating mouse knockout results to humans.

INSULIN RECEPTOR AND INSULIN RECEPTOR SUBSTRATE

Binding of insulin to the insulin receptor is the first step in the insulin signaling pathway. Mice with complete deletion of the insulin receptor are about 10% underweight and suffer from chronic hyperglycemia[53,54]. They die within several days of birth due to diabetic ketoacidosis. In humans, donohue syndrome is a rare monogenic disease resulting from mutation of the insulin receptor. Individuals with this disease suffer from severe pre-natal and post-natal growth retardation, fasting hypoglycemia, and post-prandial hyperglycemia[55]. They generally die before adulthood. The difference between the glucose homeostasis in mice and humans with this mutation may be attributable to the fact that the human pancreas develops earlier in gestation, hence better enables the compensatory hyperinsulinemia[55].

The pancreatic beta-cell specific insulin receptor knockout mouse strain (called BIRKO) has impaired insulin response to glucose challenge and develops impaired glucose tolerance and high insulin levels[56]. In the initial description of this mutant strain, glucose levels and body weight were normal, however, a follow-up report from the same laboratory described consistent hyperglycemia and sporadic obesity[57]. In the same report, a muscle

Table 1 Knockout mouse reproducibility

Model	Ref.	Genetic background	Observed discrepancy
IRS1 knockout	Tamemoto *et al*[19]	C57BL/6 × CBA	Growth defect twice as severe in Araki 1994
	Araki *et al*[18]	C57BL/6	
IRS2 knockout	Withers *et al*[60]	C57BL6 × 129Sv	Growth defect observed only in Withers *et al*[60]. Much more severe glucose dysregulation in Withers *et al*[60]
	Kubota *et al*[61]	C57BL/6 × CBA mixed	
IR and IRS1 double heterozygous knockout	Kulkarni *et al*[62]	C57BL/6 129/Sv DBA/2	Diabetes not observed in 129/Sv mice, observed in 85% of C57BL/6 mice and 64% of DBA/2 mice. Glucose intolerance only in C57BL/6 strain
AKT2 knockout	Cho *et al*[64]	C57BL/6	More severe hyperglycemia and hyperinsulinemia in Garofalo *et al*[63]. Growth defect only in Garofalo *et al*[63]
	Garofalo *et al*[63]	DBA/1lacJ	
AKT1 knockout	Chen *et al*[65]	C57BL/6 × 129R1	High neonatal mortality only in Cho *et al*[64]. Improved glucose tolerance and insulin sensitivity only in Buzzi *et al*[68]
	Cho *et al*[66]	C57BL/6	
	Buzzi *et al*[68]	129/Ola, C57BL/6 mixed	
Pik3r1 heterozygote	Mauvais-Jarvis *et al*[72]	129Sv, C57BL/6 mixed	Improved glucose tolerance and insulin sensitivity and low glucose and insulin levels on normal diet only in Mauvais-Jarvis *et al*[72]
	McCurdy *et al*[73]	C57BL/6SVJ	
Liver-specific *Pik3ca*	Sopasakis *et al*[74]	129Sv, C57BL/6, FVB mixed	Insulin resistance and glucose intolerance on normal diet in Sopasakis *et al*[74] only
	Chattopadhyay *et al*[75]	129, C57BL/6J mixed	
GLUT4 heterozygous knockout	Stenbit *et al*[76]	CD1, C57BL/6 mixed	Unexpected more severe phenotype in heterozygous knockout than homozygous
PKCλ heterozygous knockout	Farese *et al*[79]	C57BL/6, 129P2/Sv, FVB mixed	Unexpected more severe hepatic steatosis in heterozygous knockout than homozygous
PKCδ knockout	Leitges *et al*[81]	129/SV × Ola	High neonatal mortality observed only in Bezy *et al*[82]
	Bezy *et al*[82]	C57BL6/J	
PPARγ	He *et al*[86]	C57BL/6J	Resistance to diet-induced insulin resistance only in Jones *et al*[85] study
	Jones *et al*[85]	C57BL/6J, FVB mixed	
Muscle-specific PPARγ	Norris *et al*[87]	129/sv, C57BL/6, FVB mixed	Insulin resistance and glucose intolerance on normal diet in Hevener *et al*[88] only. Improvement with rosiglitazone in Norris *et al*[87] only
	Hevener *et al*[88]	C57BL6/J	

Reproducibility problems in knockout mouse studies. Some variant results can be explained by differences in genetic background. IRS: Insulin receptor substrate 1; IR: Insulin receptor; AKT2: Protein kinase B isoform 2; GLUT4: Glucose transporter isoform 4; PKCλ: Protein kinase C λ; PPARγ: Peroxisome proliferator-activated receptor γ.

and beta-cell double insulin receptor knockout (BIRKO-MIRKO) mouse strain had an unexpectedly mild condition. This strain had impaired glucose tolerance, mild hyperglycemia, high triglycerides and free fatty acids, and extra fat pad mass. These findings would seem to indicate that muscle-mediated glucose disposal is dispensable for normal glucose homeostasis in mice, but 2-deoxyglucose uptake studies showed that both muscle-specific insulin receptor knockout (MIRKO) and BIRKO had normal muscle glucose uptake, suggesting most muscle glucose uptake under these conditions is insulin-independent[57]. Studies of liver glycogen synthesis and liver glycogen content confirm that mice with insulin insensitive muscle shifted glucose utilization away from muscle and towards liver[57].

Mouse strains lacking insulin receptor in other tissues have been developed. A knockout of insulin receptor in neuronal tissue (NIRKO) demonstrated elevated body weight, white adipose tissue, serum triglycerides, and circulating leptin, with most of these changes being more pronounced in the females[58]. In addition, both sexes of NIRKO mice had reduced fertility, demonstrating the importance of insulin in reproduction. A knockout of insulin receptor in adipose tissue (FIRKO) had low fat mass, and the normal relationship between leptin levels and fat mass was disrupted[59]. These mice were protected against age-related glucose intolerance.

The IRS proteins transmit signals from the insulin and IGF1 (insulin-like growth factor 1) receptors. Two groups independently showed a significant pre-natal and post-natal growth defect in IRS1 knockout mice[18,19] (Table 1). Despite having similar genetic backgrounds, only one of the strains exhibited glucose intolerance as measured by a glucose tolerance test[18]. In addition, the two strains had significantly different growth defect severities, with a 40%-60% decrease in weight at various life stages observed in one study[18], and a 20%-30% decrease in the other[19]. These differences could have been due to the genetic manipulation approaches or the genetic backgrounds.

Two independent groups described IRS2 knockout mouse models, and the phenotypes were different despite similar genetic backgrounds. Withers *et al*[60] observed a 10% decrease in body weight throughout all life stages for the IRS2 knockout mice in a C57BL6 × 129Sv background, while Kubota *et al*[61] observed the IRS knockouts to be of normal size in a C57BL/6 × CBA mixed background. Fasting hyperglycemia was observed at age 6 wk in Withers *et al*[60], but average glucose levels did not reach hyperglycemic levels in Kubota *et al*[61]. Hyperinsulinemia and glucose tolerance showed a similar pattern: more severe, earlier phenotypes observed in Withers *et al*[60] than in Kubota *et al*[61]. Reduced β-cell mass was observed by both groups.

Kubota *et al*[61] suggested that the difference in glucose and insulin levels between the two reports was likely due to low β-cell mass in their strain, caused either by β-cell death or by the failure of insulin-resistance induced hyperplasia, and acknowledge that genetic differences other than the intended manipulation may influence the results. The authors concluded based on their data and data from a related study that both β-cell dysfunction and reduced β-cell mass can contribute to the murine diabetic state, but only studies of human patients can validate whether one or both mechanisms are more important in the pathogenesis of type 2 diabetes in humans.

Double heterozygous knockout of IR and IRS1 were generated in three different genetic backgrounds: C57BL/6, 129/Sv and DBA/2[62]. While all three strains had mild growth retardation, the results in regards to glucose homeostasis were drastically different. In C57BL/6 mice, the double heterozygous knockout caused severe hyperglycemia and hyperinsulinemia in the vast majority of cases, whereas the glucose levels of 129Sv mice were not significantly different from control littermates. In DBA mice, more than half of the mice were hyperglycemic but maintained normal glucose tolerance. Triglycerides were significantly reduced in the double heterozygous knockouts of the B6 and DBA strains, and the wild type DBA strain had significantly elevated triglycerides as compared to the other wild type strains[62].

AKT/PROTEIN KINASE B

The metabolite phosphatidylinositol 3,4,5-trisphosphate (PIP3) activates AKT/protein kinase B and atypical protein kinase C. AKT has three isoforms in mammals, of which AKT1 and AKT2 are most important for metabolism. Two independently developed AKT2 knockout mouse strains in different backgrounds developed hyperglycemia, glucose intolerance, and insulin resistance[63,64]. Garofalo *et al*[63] observed hypoinsulinemia due to pancreatic β-cell death in a subset of male mice, and hyperinsulinemia with no pancreatic changes in the remainder, while Cho *et al*[64] observed hyperinsulinemia and associated pancreatic hyperplasia. In Garofalo *et al*[63], both hyperglycemia and hyperinsulinemia were more severe than in Cho *et al*[64], with average fed insulin measurements five times higher. Also, Cho *et al*[64] observed normal growth in the AKT2 knockout, but Garofalo *et al*[63] observed a mild growth deficiency evident at all life stages. Only Garofalo *et al*[63] observed lipoatrophy and high levels of serum triglycerides. The control mice in Garofalo *et al*[63] had near-diabetic random fed glucose levels that were almost as high as the knockout mice in Cho *et al*[64] Neither of these knockout strains were obese.

The characteristics of AKT1 knockout mouse strains are also sensitive to genetic background and environmental factors. Two labs independently reported that AKT1 knockout mice with different genetic backgrounds had a growth defect causing 15%-20% reduced body weight[65,66]. One of the studies observed high neonatal mortality among the knockout mice[66], while the other observed high mortality with γ-radiation[65]. Glucose tolerance in Chen *et al*[65] appeared normal, but the glucose tolerance test was performed using a longer fasting time and lower glucose dose than is optimal[50]. One study demonstrated a non-significant improvement in glucose tolerance and insulin sensitivity in males. A similar strain was later shown to be resistant to diet-induced obesity[67]. Later data on a third, independently developed AKT1 knockout strain showed dramatic improvement in glucose tolerance and insulin sensitivity[68].

Studies of spontaneous human genetic variants in AKT1 and AKT2 have confirmed the importance of these proteins in growth and glucose homeostasis, mostly respectively, although the manifestations of the mutations differ between humans and mice[16]. For example, the human patients with a specific AKT2 mutation display asymmetric hypertrophy[69], while the above-described AKT2 knockout mouse models have normal growth[64] or a growth deficiency[63].

PHOSPHOINOSITIDE 3-KINASE

PI3K, an enzyme complex composed of a regulatory subunit and a catalytic subunit that produces the metabolite PIP3. PI3K is activated by IRS proteins in the insulin signaling cascade (Figure 2). In humans, *PI3K* gene polymorphisms are associated with cancer risk[70] but not diabetes, to our knowledge.

Complete loss of the *Pik3r1* gene, which encodes isoforms of the regulatory subunit of PI3K, results in perinatal lethality in mice, perhaps due to impaired B cell development[71]. Mice heterozygous for *Pik3r1* deletion, having attenuated expression of all isoforms of the regulatory subunit, had improved glucose tolerance and insulin sensitivity and low glucose and insulin levels[72]. Lipid metabolism was unchanged except for a modest increase in serum free fatty acids, indicating that the observed insulin sensitivity was not due to indirect effects *via* changes in lipid metabolism. A minor increase in basal muscle glucose uptake was observed, but the authors note that changes in liver were likely most responsible for the increased insulin sensitivity[72]. A later, independent study observed that the heterozygous knockout mice were essentially indistinguishable from control mice on a normal diet[73]. On a high-fat diet, these mice showed lower fasting insulin levels, improved overall insulin sensitivity, and improved glucose uptake in fat and muscle[73]. Macrophage accumulation was reduced in the adipose tissue of these heterozygous knockout mice, but results from bone marrow transplant experiments suggested the improved insulin sensitivity did not occur solely *via* PI3K's role in inflammation.

The catalytic subunits of PI3K have also been studied using knockout mouse strains. Liver-specific deletion of *Pik3ca* caused mild obesity, insulin resistance, glucose intolerance, and high glucose and insulin levels[74]. The same genetic manipulation in a second laboratory produced a strain with normal glucose and insulin levels and body weight[75]. The *Pik3ca* knockout mice in the second

study were resistant to high-fat diet induced hepatic steatosis and somewhat resistant to diet-induced glucose intolerance as well[75]. For this gene, liver-specific deletion produced diabetes-like symptoms in one laboratory, but in another laboratory, glucose homeostasis was identical in control and knockout mice[74,75].

GLUT4

As described above, GLUT4 is the major glucose transporter in muscle, the most important tissue type for glucose disposal in humans. Unexpectedly, in GLUT4 knockout mice, glucose levels are normal except for mild fed hyperglycemia and fasted hypoglycemia observed only in males[29]. Consistent with results regarding insulin signaling and growth[18], these animals display significant growth retardation, shortened life spans, cardiac hypertrophy, and reduced adipose tissue[29]. Somewhat surprisingly, mice heterozygous for the GLUT4 knockout have a more severe phenotype. A diabetes-like condition developed at varying ages, with a majority of males both hyperinsulinemic and hyperglycemic by age 5-7 mo[76].

The authors pointed out that the unexpectedly mild condition of the homozygous GLUT4 knockout and more severe condition in the GLUT4 knockout heterozygote were likely due to compensatory metabolic adjustments that occur during development. These could include the transfer of glucose disposal from tissues that primarily use GLUT4 to tissues that primarily use GLUT2, as observed in the muscle-specific GLUT4 knockout[30], or the upregulation of alternative glucose transporters[52].

PROTEIN KINASE C

Protein kinase C enzymes (PKCs) are involved in regulating a variety of cellular functions in mammals, including insulin signaling[77]. Atypical PKCs include the isoforms PKCλ/ι and ζ (PKCλ refers to the mouse isoform of PKCι)[78]. Activated PKCs can inhibit insulin signaling by a feedback mechanism that prevents signal transduction between insulin receptor and IRS[7,78].

Atypical protein kinase C family member PKCλ was knocked out specifically in mouse muscle, resulting in diabetic symptoms including glucose intolerance, insulin resistance, hyperglycemia, and high insulin levels[79]. Altered fat metabolism was also observed: high triglycerides, and mildly elevated free fatty acids and liver triglycerides. While some symptoms were observed in both the heterozygous and homozygous muscle-specific knockout of PKCλ, the heterozygotes were as insulin resistant and glucose intolerant as the homozygous knockouts, and had more abdominal obesity and hepatic steatosis[79]. This is unexpected, since the heterozygous knockout had reduced, but not ablated, expression of PKCλ.

Differential expression of PKCδ has been identified as one factor in the different vulnerability of common laboratory mouse strains to diabetes[80]. One study of a PKCδ knockout mouse strain in a 129/Sv × Ola genetic background had normal growth and development[81]. Surprisingly, the same deletion in the C57BL6/J strain caused a high mortality rate, with survivors being 14% underweight[82]. The C57BL6/J PKCδ knockout mouse had better glucose tolerance than control mice[82], but glucose tolerance was not tested in the original knockout. The authors noted that improved glucose tolerance may have been due to decreased inflammation in adipose tissue[82]. In humans, PKCδ deficiency can cause B-cell deficiency with severe autoimmunity[83].

PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR γ

The nuclear receptor PPARγ, becomes activated upon binding of lipids and is important for lipid metabolism and storage, adipogenesis, and insulin sensitivity. This nuclear receptor is the target of insulin-sensitizing TZDs[84].

Two independently generated adipose tissue-specific PPARγ knockout strains showed important differences in glucose homeostasis under high-fat diet conditions. On normal chow, both these strains had reduced adipose tissue mass, high blood lipid levels, and hepatic steatosis, but glucose tolerance was normal[85,86]. On high-fat diet with 40% of calories from fat, He *et al*[86] observed hyperinsulinemia and insulin resistance in both the knockout and control mice, although these traits were more severe in the knockout. The knockout strain studied by Jones *et al*[85] was resistant to diet-induced hyperinsulinemia and insulin resistance despite being subjected to a more extreme high-fat diet, with 60% of calories from fat. The knockout strains in both studies were more prone to high-fat diet induced hepatic steatosis.

Two studies on independently developed muscle-specific PPARγ knockout models have provided contradictory findings regarding the mechanism of action of TZDs. The first strain was more susceptible to diet-induced obesity, glucose intolerance, and insulin resistance but was indistinguishable from controls on a normal diet[87]. Rosiglitazone reduced the hyperinsulinemia and impaired glucose homeostasis observed in this strain on high-fat diet, therefore the authors suggested that muscle PPARγ is not required for the positive effects of this TZD[87]. In contrast, the second strain developed insulin resistance and glucose intolerance on a normal diet[88]. Glucose disposal in a hyperinsulinemic-euglycemic clamp experiment was not improved with rosiglitazone treatment, suggesting that the insulin sensitizing effect of TZDs is dependent on muscle PPARγ. In this case, two mouse models have provided conflicting data not just on the role of a gene, but also on a drug mechanism of action.

In conclusion, we above described several cases where genetic modification of insulin signaling genes produced significantly, sometimes dramatically, different results in separate studies or varied genetic backgrounds (Table 1). We also described two cases where heterozygous knockouts had unexpectedly severe phenotypes: GLUT4 and

PKCλ. Although the mechanisms behind the unexpected observations are unknown, it is known that organisms respond unpredictably to the absence of gene products during development. Compensatory metabolic adjustments that may occur during development constitute a general limitation of knockout mouse models. These concerns are mitigated by the use of conditional knockouts, however, those strains require injection or gavage of an inducing drug, which can produce artifacts[89]. These examples illustrate the challenges associated with producing reliable, reproducible, and translatable results in mice.

CLINICAL TRANSLATION

In the following section, we will address factors which limit the applicability of mouse models to human therapeutic treatment development. As described above, insulin signaling gene knockout mice often have phenotypes unrelated to type 2 diabetes including growth defects[18,33,60,63], neonatal mortality[66], and others, including resistance to tumor formation[90]. These phenotypes are a result of the loss of diverse non-metabolic insulin functions, and these studies have yielded information about those biological processes in mice. At this juncture, it is worth examining whether these mouse models of insulin resistance are contributing positively to the development of new, unique, safe, and effective type 2 diabetes treatments. Here we focus on select pharmaceuticals targeting the signaling proteins discussed above.

As might be predicted based on the importance of insulin to growth, several drugs targeting insulin signaling molecules PI3K and AKT are under investigation as therapeutics for cancer[91,92]. Unsurprisingly, some PI3K inhibitors have been shown to induce insulin resistance[93].

The nuclear receptor PPARγ is an important drug target, and is genetically linked to insulin sensitivity and type 2 diabetes risk[94,95]. However, PPARγ-activating TZD drugs are associated with a number of side effects and risks, including congestive heart failure[96]. Although some studies have been inconclusive in regards to certain risks associated with the TZD rosiglitazone[97], one meta-analysis of 42 studies found that the risk of cardiovascular death increased 64%[98]. Rodent studies did not predict these deaths, and in fact have provided conflicting evidence regarding cardioprotective and cardiotoxic effects of TZDs. The TZD pioglitazone was shown to limit myocardial infarct size after coronary occlusion in mice[99]. Similar results have been seen for rosiglitazone after ischemia/reperfusion injury[100]. TZDs have been shown to have both positive and negative effects on cardiac hypertrophy in rodents[101,102].

An inhibitor of PKCβ, LY333531, or ruboxistaurin, has been investigated as a potential treatment for diabetic microvascular complications[103]. Although initially promising results were observed in a trial for diabetic neuropathy, the drug was not shown to be effective in a larger, placebo-controlled study[104]. Promising results were also seen in a small trial for diabetic kidney disease[105], but these have not been replicated at a larger scale. Eli Lilly withdrew the marketing authorization application for ruboxistaurin as a treatment for diabetic retinopathy. Rather than diabetes or its complications, PKC inhibitors are now being investigated as potential treatments for cancer[106] and conditions requiring immunosuppressive therapy[107].

CONCLUSION

The limitations of these mouse models of insulin signaling dysfunction arise from a number of sources. Described above are physiological and molecular-level differences between mice and humans, reproducibility problems in mouse experiments, and complicating factors in drug discovery efforts that interfere with translating mouse results to human patients.

Researchers in a variety of fields have commented on the limitations of mouse models of human disease[108,109]. No single mouse model can accurately represent the spectrum of symptoms and complications associated with type 2 diabetes[11]. The translation of results from mice is further complicated by a plethora of immutable species differences at every level of glucose regulation from the molecular to the population level[110-113]. In addition, mice are not prone to hypertension, high LDL cholesterol, atherosclerosis, sedentary behavior, obesity, insulin resistance, or many other features common to human type 2 diabetes patients. Although all laboratory mice are more insulin resistant and have more fat tissue than their free-living counterparts[114], the risk for mice developing these symptoms varies widely depending on the specific inbred strain[62,80]. Genetic background, housing conditions, and diet can dramatically affect results. Examples highlighted here have shown that different studies even from the same laboratory often obtain different results with identical genetic modifications.

The idea that the limitations of genetically modified mouse models of human disease, and rodent models in general, are severe enough to warrant a shift in research approaches is controversial, and will likely continue to be for the next decade. Nonetheless, science in many medical fields has been progressing away from crude, animal-based experiments and towards more high-tech and human-based research methods, and that trend will continue. For example, one area of active research is additional uncharacterized insulin signaling cofactors, which could be identified using phosphoproteomics[115], protein array techniques, or protein interaction-based techniques[116] including yeast two-hybrid and computational approaches. Similar approaches could be used to identify gene products involved in acquired insulin resistance. In addition, insulin resistance can be investigated in human cells by gene silencing[117], metabolomics[118], and microarray technology. Remaining questions about the role of inflammation and accumulated intracellular lipids can be studied using tissue biopsy samples from various patient populations[119]. Many more *in vitro*[120], in silico[121], non-invasive[122], and minimally invasive[123] approaches are available and in development.

In the last 20 years, the use of genetically modified mice to investigate diabetes has become routine. While some findings have borne out in humans, investigations of insulin resistance using knockout mouse models are inherently limited by physiological, genetic, and metabolic differences between mice and humans. Researchers and patients would benefit from a transition towards human-based research methods.

Abstract

Chromium is considered to have positive effects on insulin sensitivity and is marketed as an adjunctive therapy for inducing glucose tolerance in cases of insulin resistance ("the glucose tolerance factor"). Case reports on patients who received prolonged parenteral nutrition indeed showed that the absence of trivalent chromium caused insulin resistance and diabetes. However, whether patients with type 2 diabetes can develop a clinically relevant chromium deficiency is unclear. This review summarizes the available evidence regarding the potential effectiveness of chromium supplementation on glycemic control (Hemoglobin A1c levels) in patients with type 2 diabetes. No studies investigating the long-term safety of chromium in humans were found. All clinical trials that have been performed had a relative short follow-up period. None of the trials investigated whether the patients had risk factors for chromium deficiency. The evidence from randomized trials in patients with type 2 diabetes demonstrated that chromium supplementation does not effectively improve glycemic control. The meta-analyses showed that chromium supplementation did not improve fasting plasma glucose levels. Moreover, there were no clinically relevant chromium effects on body weight in individuals with or without diabetes. Future studies should focus on reliable methods to estimate chromium status to identify patients at risk for pathological alterations in their metabolism associated with chromium deficiency. Given the present data, there is no evidence that supports advising patients with type 2 diabetes to take chromium supplements.

Key words: Chromium; Type 2 diabetes mellitus; Insulin resistance; Therapy; Supplements

Core tip: In some patients who received prolonged parenteral nutrition, absence of trivalent chromium caused insulin resistance and diabetes and supplementation with trivalent chromium "cleared" this metabolic disease. The question is, whether chromium deficiency is a relevant factor in the cause of type 2 diabetes in general and whether supplementation with trivalent chromium can have beneficial effects in type 2 diabetes. Unfortunately, no reliable methods to estimate chromium status exists and according to current evidence, chromium does not improve glycemic control in patients with type 2 diabetes and patients should be advised not to take chromium supplements.

INTRODUCTION

Insulin resistance is an important target for pharmacological and non-pharmacological interventions in patients with type 2 diabetes. In addition to the well-established interventions, a multitude of suggested alternative solutions outside the field of regular conventional medicine is available. One of these suggested beneficial interventions is oral supplementation with chromium. Chromium is marketed as a substance that improves insulin sensitivity (being as part of the "Glucose Tolerance Factor" molecule), weight loss and improving glycemic control in patients with diabetes[1,2]. Chromium has become the second most popular dietary supplement after calcium in the United States, with sales amounting to approximately 100 million dollars annually[1,2].

Some studies have demonstrated that chromium supplementation in chromium deficient states indeed led to beneficial effects[3-6]. There are strong arguments supporting the hypothesis that chromium supplementation improves glycemic control in chromium deficient patients by improving insulin sensitivity[7]. In addition, patients with diabetes are thought to have a chromium deficient status that is induced by an altered chromium metabolism[4,8,9]. However, other studies have suggested that chromium metabolism is not altered in type 2 diabetes[10]. Unfortunately, cut-off points for chromium levels correlating with relevant changes in glucose metabolism and insulin resistance are lacking. There is no clinically defined chromium deficiency state, nor is there a validated method for estimating the total body chromium status[11-13]. A reliable assessment of the chromium status in biological tissues and fluids is difficult due to extremely low chromium levels[12]. Although some studies have demonstrated successful chromium level determination in hair, sweat, and blood, there is still no exact method for defining chromium deficiency[8]. In this theoretical framework the "diabetic state" is linked to chromium deficiency and chromium supplementation would amend glycemic control by improving insulin sensitivity. This review discusses chromium physiology and summarizes the current evidence that chromium supplementation improves glycemic control in patients with type 2 diabetes.

Several case reports demonstrated beneficial effects of chromium supplementation in patients requiring total parenteral nutrition for prolonged periods[3,5-7,14,15]. One case report, published in 1977, discussed a 40-year-old woman who had undergone a total enterectomy after mesenterial thrombosis and became dependent on total parenteral nutrition[14]. After three years, she started losing weight and developed diabetes mellitus. She was young, had a low body weight, and required 50 IE of insulin daily to reach a near-normoglycemic state. Chromium deficiency was considered as a possible cause. The chromium concentration in her serum and hair was measured and found to be low [154 ng/g (N > 500 ng/g) and 0.55 ng/g (N = 4.9-9.5 ng/g), respectively]. She was treated intravenously with 250 micrograms of chromium chloride daily for two weeks. This treatment decreased the amount of insulin needed, and after four months of chromium supplementation, she remained normoglycemic without insulin. After this and several other case reports[3,9,14], chromium was added to parenteral nutrition as a standard ingredient[6]. Nevertheless, the extent of chromium supplementation necessary during total parenteral nutrition is still debated[16,17].

CHROMIUM PHYSIOLOGY

The two most common forms of chromium are the trivalent (3+) and the hexavalent (6+) forms. Chromium 6+ is not present in nature and is toxic. The chromium found in food and in dietary supplements is the trivalent form. Whole grain products, such as whole grain bread, vegetables, nuts, and some spices contain low concentrations of trivalent chromium. Chromium supplements are available as chromium chloride, chromium nicotinate, chromium picolinate, high-chromium yeast, and chromium citrate. Chromium chloride appears to have a poor bioavailability, although there is limited data on chromium absorption in humans[12,15,18].

The role of trivalent chromium in glucose metabolism has been known since the 1950s[15]. Chromium can alter insulin sensitivity at the cellular level. The oligopeptide Apo-Low-Molecular-Weight-Chromium binding peptide (also known as Apo-chromodulin) plays an important role in potentiating the insulin response in insulin sensitive cells[18,19]. The Apo-chromodulin is loaded intracellularly with a maximum of four chromium ions. Chromium-loaded Apo-chromodulin is called Holo-chromodulin. The Holo-chromodulin molecule binds to the insulin receptor and potentiates the insulin response by activating the receptor. The degree of insulin receptor activation depends on the number of chromium ions bound to this peptide, with a minimum of 0 and a maximum of 4 ions. This chromium binding may lead to an 8-fold difference in insulin receptor activation (when 4 ions are bound compared to 0). Experiments using rat adipocyte cells with equal serum insulin concentrations confirmed that insulin receptor activation is eight times stronger in the presence of chromium than in the absence of chromium[18].

ADVERSE EFFECTS OF CHROMIUM

Several cell culture and animal studies using supraphysiological chromium doses yielded results suggesting that chromium may increase DNA damage[20-23]. Chromium is not unique in this respect; a number of other nutrients such as vitamins A and D, nicotinic acid, and selenium have also been implicated in causing toxicity when taken in excess[24]. Clinical trials of oral chromium supplementation did not demonstrate toxicity in patients on parenteral nutrition[24,25]. We could not find long-term chromium safety studies. The DNA damage identified in cases of supraphysiological trivalent chromium concentrations did not translate into potentially carcinogenic effects when a more physiological dose of oral trivalent chromium was

used in humans[24,26].

CLINICAL EVIDENCE FOR CHROMIUM USE

In 1997, the intervention trial by Anderson *et al*[27] was one of the first chromium-intervention studies in patients with type 2 diabetes. In this randomized controlled trial, chromium picolinate supplements or placebo were administered to 180 Chinese patients with type 2 diabetes. The patients were randomized into three groups: placebo, 200 mg chromium, and 1000 mg of chromium daily. After four months, the hemoglobin A1c (HbA1c) levels in the placebo group were unchanged (8.5%), while they decreased significantly in the 200 mg group, from 8.5% to 7.5%, and decreased in the 1000 mg group, from 8.5% to 6.6%.

In 2007, Balk *et al*[28] performed a systematic review of randomized controlled trials investigating chromium supplementation in patients with type 2 diabetes. At that time, 14 studies with 18 different chromium-based interventions had been performed using HbA1c levels as an endpoint. In 11 out of these 14 trials, there was no significant effect of chromium supplementation. The review by Balk *et al*[28] concluded that, due to the poor quality and heterogeneity of the data, additional studies addressing these limitations were needed before definitive claims could be made about the effect of chromium supplementation[28]. Nevertheless, the meta-analysis by Balk *et al*[28] reported an overall significant effect of chromium supplementation on HbA1c levels (-0.6%; 95%CI: -0.9% to -0.2%). This -0.6% mean benefit was largely due to the inclusion of the data reported by Anderson *et al*[27]. When the Anderson study was excluded, the effect of chromium on HbA1c levels was -0.3% (95%CI: -0.5% to -0.1%; NS)[28]. It should be noted however, that the Anderson study was inadequately blinded with concerns for detection bias and selection bias, and should be considered to be of poor-methodological quality[27,28].

Significant effects in the meta-analysis were only found in studies with poor methodological quality or in studies sponsored by chromium supplement producing companies. In addition, the effects of chromium supplementation were shown to be absent or non-relevant after stratifying the studies according to methodological quality, sponsor involvement, and a western *vs* non-western study location[6,29].

After the review written by Balk *et al*[28], a second Dutch double blind trial was performed in 2008 that studied the effects of chromium on HbA1c levels in patients with type 2 diabetes[29]. After 6 mo, the effect of chromium supplementation compared to placebo on HbA1c levels was 0.24% (95%CI: -0.06% to 0.54%). HbA1c levels were lower in the placebo group compared with the chromium group. All of the trials that have been performed had a relatively short follow-up period. No studies have been performed with sufficient follow-up and the ability to reliably investigate cardiovascular and/or microvascular end-points. All studies used surrogate end-points. None of the trials investigated whether patients had risk factors for chromium deficiency.

Although this review focuses on the most relevant method of estimating glycemic control (HbA1c levels)[30-32], several studies investigated the effect of chromium on other markers of glycemic control[11,13,33-35]. Meta-analyses showed that chromium supplementation did not improve fasting plasma glucose levels[33,36] and had no clinically relevant effect on body weight in individuals with or without diabetes[37-39].

DISCUSSION

Chromium plays a role in insulin physiology, and severe chromium deficiency can lead to insulin resistance. Chromium supplementation may be beneficial in rare cases of prolonged total parental nutrition when standard chromium supplementation is lacking[6]. Despite the lack of sufficient evidence that chromium supplementation improves glycemic control[28,29], chromium is still widely marketed as an effective supplement for improving glycemic control in patients with type 2 diabetes.

Do we need to worry that a low chromium status contributes to hyperglycemia in our patients?

For the average patient with type 2 diabetes, the answer is no. Trivalent chromium is sufficiently available in food, and the occurrence of severe chromium deficiency is highly unlikely. The sparse evidence that chromium supplementation might have effects on glycemic control in a broader population is derived from studies with important methodological flaws[27,28]. Well-performed trials and meta-analyses consistently show that there is no evidence for consistent beneficial effects on glycemic control (as assessed by HbA1c levels) that support prescribing chromium supplements to patients with type 2 diabetes[6,40]. Furthermore, the long-term safety of chromium supplementation has not been established.

Is all hope lost for chromium supplementation in patients with type 2 diabetes?

An important concern when interpreting the data from studies investigating chromium effects is the lack of a validated and precise estimate of chromium status. There is no reliable method for assessing the body's chromium status, and there is no information on the bioavailability of the different forms of chromium[41]. Performing randomized trials in patients with type 2 diabetes will become interesting only when we can properly assess the chromium status in patients at risk for chromium deficiency and when clinically relevant end points are defined.

Recommendations

Future research on chromium should focus on establishing a reliable method for assessing the body's chromium status. The bioavailability of different forms of chromium in Western and non-Western patients should be investigated in order to define a potential effective dose

and to identify patients at risk for chromium deficiency. New randomized trials should only be considered in type 2 diabetes patients with an established chromium deficiency. The long-term safety of chromium supplementation should be investigated in large population studies. Currently, chromium supplementation in patients with type 2 diabetes should not be recommended.

Abstract

Hypertriglyceridaemia (HTG) is a risk factor for cardiovascular disease (CVD) in type 2 diabetes and is caused by the interaction of genes and non-genetic factors, specifically poor glycaemic control and obesity. In spite of statin treatment, residual risk of CVD remains high in type 2 diabetes, and this may relate to HTG and atherogenic dyslipidemia. Treatment of HTG emphasises correcting secondary factors and adverse lifestyles, in particular, diet and exercise. Pharmacotherapy is also required in most type 2 diabetic patients. Statins are the first-line therapy to achieve recommended therapeutic targets of plasma low-density lipoprotein cholesterol and non-high-density lipoprotein cholesterol. Fibrates, ezetimibe and n-3 fatty acids are adjunctive treatment options for residual and persistent HTG. Evidence for the use of niacin has been challenged by non-significant CVD outcomes in two recent large clinical trials. Further investigation is required to clarify the use of incretin-based therapies for HTG in type 2 diabetes. Extreme HTG, with risk of pancreatitis, may require insulin infusion therapy or apheresis. New therapies targeting HTG in diabetes need to be tested in clinical endpoint trials. The purpose of this review is to examine the current evidence and provide practical guidance on the management of HTG in type 2 diabetes.

Key words: Diabetes; Triglyceride; Therapy

Core tip: Diabetic dyslipidemia relates collectively to hyperglycaemia, insulin resistance, hyperinsulinaemia, abdominal visceral adipose disposition, increased liver fat content, and dysregulated fatty acid metabolism. Insulin resistance in diabetes induces hypertriglyceridaemia by increasing the enterocytic production of chylomicrons and an impaired clearance capacity is also involved. Usual care for diabetic dyslipidemia is statin treatment, but a significant proportion of patients have residual dyslipidemia, related to hypertriglyceridaemia and atherogenic dyslipidemia. Current evidence supports the use of fenofibrate in type 2 diabetics with high triglyceride levels.

INTRODUCTION

Hypertriglyceridaemia (HTG) is an important risk factor for cardiovascular disease (CVD)[1] and is defined as a fasting plasma triglyceride concentration > 95th percentile for age and sex in a population. HTG may be as prevalent as 50% in type 2 diabetes and is often unresponsive to statin treatment[2,3]. We review recent evidence on the role of HTG in atherosclerotic CVD and provide practical guidance on the management of HTG in type 2 diabetes.

PATHOPHYSIOLOGY OF HYPERTRIGLYCERIDAEMIA IN TYPE 2 DIABETES

Triglycerides, which originate from the intestine postprandially or endogenously from the liver, are packaged into lipoprotein particles containing apolipoprotein B-48 (apoB-48; chylomicrons) and apolipoprotein B-100 (apoB-100; very-low density lipoprotein, VLDL), respectively. Abnormalities in triglyceride-rich lipoprotein (TRL) metabolism are cardinal features of type 2 diabetes. Metabolic dysregulation resulting in HTG include enhanced hepatic secretion of TRL due to insulin resistance and delayed clearance of TRL involving lipoprotein lipase (LPL)-mediated lipolysis. Several genes causing loss of function of LPL can result in severe HTG, such as *LPL*, *APOC2*, *APOA5*, *GPD1*, *CPIHBP1* and *LMF1*[4,5]. Very few patients will have a monogenic disorder. Individuals with severe HTG are likely to be homozygous or compound heterozygous for mutations which impair the TRL catabolic pathway. However, HTG in type 2 diabetes due to several genes with mild effects that interact with non-genetic factors is probably more likely. These non-genetic factors include hyperglycaemia, alcohol abuse, concomitant medication, sedentary lifestyle, chronic kidney disease and insulin resistance[6].

Insulin resistance activates *de novo* lipogenesis, resulting in oversecretion of hepatic TRLs. This is also evident in the postprandial state, with enterocytic oversecretion of TRLs in the form of chylomicrons. With both secretion pathways on overdrive, competition between the TRLs and their remnants for lipolytic and receptor-mediated clearance further induces HTG. Insulin resistance is also associated with increased rates of apolipoprotein C-Ⅲ (apoC-Ⅲ) secretion, which further impairs receptor-mediated uptake of hepatic chylomicron remnants[7]. Glucose has also found to activate apoC-Ⅲ transcription, which may be the link between hyperglycaemia, HTG and CVD in type 2 diabetics[8].

Both LPL and hepatic lipase (HL) control the clearance of triglycerides. HL plays a particularly important role in the delipidation cascade from VLDL to LDL. Triglyceride-rich VLDL derives small, dense LDL particles which are more susceptible to oxidation[9]. Additionally, increased TRL in postprandial diabetic dyslipidemia leads to the exchange of TRL-triglyceride for HDL-cholesteryl ester and hence, triglyceride enrichment of HDL *via* cholesteryl ester transfer protein (CETP). CETP progressively decreases postprandially and limits the efficient removal of cholesterol[10]. Triglycerides in HDL are good substrates for hepatic lipase which leads to the production of small dense HDL particles and enhanced apolipoprotein A-Ⅰ (apoA-Ⅰ) clearance[11].

Given that HTG is related to a plethora of risk factors, the lack of independent association between triglyceride and CVD is expected[12], although two recent Mendelian randomisation studies have shown a causal association between variations in two related genes (*LPL* and *APOA5*) and myocardial infarction[13]. This supports that TRL causes CVD, and this probably applies to diabetes.

Hence, diabetic dyslipidemia relates collectively to hyperglycaemia, insulin resistance, hyperinsulinaemia, abdominal visceral adipose disposition, increased liver fat content, and dysregulated fatty acid metabolism. Diabetic dyslipidemia may also be exacerbated by chronic kidney disease and by co-prescribed medications, such as thiazide diuretics, non-selective beta-blockers and steroids.

MANAGEMENT OF HYPERTRIGLYCERIDAEMIA IN TYPE 2 DIABETES

Measurement and assessment

Triglyceride concentration is commonly measured with a fasting lipid profile. The fasting triglyceride level facilitates the calculation of the LDL cholesterol by the Friedewald equation[14]. Non-fasting triglyceride concentrations are reflective of the postprandial state and can be useful as a simple and practical screening test for HTG. A second non-fasting measurement is recommended if the initial triglyceride is > 2.0 mmol/L. Two or more measurements of elevated triglyceride in both postabsorptive and postprandial states are clinically indicative of HTG. Categories of HTG are differentially defined in international guidelines (Table 1).

Non-HDL cholesterol is another appealing method of assessment as it does not attract additional costs. Non-HDL cholesterol (total cholesterol minus HDL-cholesterol) does not rely on a fasting triglyceride concentration and provides a simple amalgamated measure all the atherogenic lipoproteins[15]. ApoB, on the other hand, does not adequately reflect chylomicron remnants and involves additional laboratory expenses. Discordance between non-HDL cholesterol and apoB measures, particularly in patients with type 2 diabetes and HTG, questions its value in assessing risk and defining treatment targets[16]. In the context of statin-treated patients, a meta-analysis has shown that non-HDL cholesterol is superior in its association with risk of future major cardiovascular events compared with LDL cholesterol and apoB[17]. Other TRL markers such as remnant-like particle cholesterol, apoC-Ⅲ and apoB-48 are expensive and are yet to be clinically established.

The hypertriglyceridaemic waist (HTWC) phenotype has suggested to be useful in assessing glucometabolic risk[18-21], in particular, among patients with a family history of diabetes[22]. The HTWC phenotype is defined by a waist circumference of ⩾ 90 cm in men and ⩾ 85 cm in women and triglyceride concentration ⩾ 2.0 mmol/L. Men with the HTWC phenotype have been shown to have a four-fold risk of diabetes compared to those with waist circumference and triglyceride in the normal ranges[23]. There is also a two-fold risk for development of coronary artery disease (CAD) in women[24] and an overall deterioration of cardiometabolic risk[25] in relation to progression of type 2 diabetes[26].

Table 1 Clinical categorisation of hypertriglyceridaemia according to guidelines based on fasting triglyceride concentrations

Ref.	Year published	Triglyceride categories	Triglyceride concentration (mmol/L)
National institutes of Health[31]	2001	Normal	1.7
		Borderline high	1.7-2.3
		High	2.3-5.6
		Very high	> 5.6
Rydén *et al*[33]	2011	Desirable	< 1.7
		Elevated	1.7-5.5
		Very high	5.5-25.0
		Extremely high	> 25.0
Berglund *et al*[34]	2012	Normal	< 1.7
		Mild	1.7-2.3
		Moderately high	2.3-11.2
		Severely high	11.2-22.4
		Very severely high	> 22.4
Hegele *et al*[37]	2013	Normal	< 2.0
		Mild-to-moderate	2.0-10.0
		Severe	> 10.0

Table 2 Clinical guide for the assessment and treatment of hypertriglyceridaemia in type 2 diabetes

Steps	
1	Obtain fasting lipid profile
2	Classify LDL-cholesterol concentration (primary target of therapy) < 2.60 mmol/L – optimal 2.60-3.39 mmol/L – above optimal 3.40-4.14 mmol/L – borderline high 4.15-4.90 mmol/L – high > 4.90 mmol/L – very high Establish therapy: LDL-cholesterol > 2.60 mmol/L – initiate dietary and lifestyle modifications LDL-cholesterol > 3.40 mmol/L – consider pharmacotherapy simultaneously with dietary and lifestyle modifications
3	Identify presence of atherosclerotic disease Clinical coronary heart disease Symptomatic carotid artery disease Peripheral artery disease
4	Assess: Glycaemic control Obesity Dietary intake (*e.g.*, Fructose, simple sugars, caloric intake) Physical activity Determine presence of other risk factors: Smoking Hypertension Family history of premature coronary heart disease (*i.e,*. in first-degree relative, male < 55 years, female < 65 years) Low HDL-cholesterol, < 1.0 mmol/L
5	Order of treatment considerations: Improve glycaemia (dietary and lifestyle modifications) Treat secondary risk factors Statins Fibrates n-3 fatty acids/niacin
6	Treat elevated triglyceride if triglyceride concentrations are > 2.30 mmol/L after LDL-cholesterol concentration target of < 2.60 mmol/L is reached Target non-HDL cholesterol (< 3.40 mmol/L) Triglyceride > 2.30 mmol/L – intensify LDL-lowering therapy or add fibrate Triglyceride > 5.60 mmol/L – very low-fat diet (< 15% of calories from fat), weight management, physical activity and add fibrate

Adapted from the NCEP ATP Ⅲ guidelines[31]. LDL: Low density lipoprotein; HDL: High density lipoprotein.

Guidelines and recommendations

Guidelines for managing HTG in diabetes have been published, with lifestyle modifications being first-line therapy followed by statins, fibrates, n-3 fatty acids and/or niacin[27-30]. The national cholesterol education program (NCEP) adult treatment panel (ATP) Ⅲ guidelines recommend LDL cholesterol as the primary treatment target and non-HDL cholesterol as a secondary target, with the exception of a fasting triglyceride > 5.60 mmol/L, only then, triglyceride becomes the primary target owing to the risk of pancreatitis[31]. A simplification of the NCEP ATP Ⅲ guideline is presented in Table 2. Regardless of atherosclerotic disease and presence of other cardiovascular risk factors, type 2 diabetes is considered a coronary heart disease risk equivalent by the NCEP ATP Ⅲ.

The American Diabetes Association (ADA)/American College of Cardiology Foundation consensus statement recommends a non-HDL cholesterol target of 3.40 mmol/L in diabetic patients with no other cardiovascular risk factor and a target of 2.60 mmol/L if there is one or more cardiovascular risk factor such as hypertension, smoking, dyslipidemia and family history of CAD[32]. The LDL cholesterol target is 2.60 and 1.80 mmol/L, respectively[32] or alternatively a 30%-40% reduction from baseline levels[30]. The ADA position statement is the only guideline that provides desirable targets for triglyceride levels for patients with type 2 diabetes: less than 1.70 mmol/L[30]. Both the NCEP ATP and ADA guidelines place emphasis on weight loss and physical activity. A summary of recommended treatment targets is presented in Table 3.

The Scientific Statement from the American Heart Association (AHA) on triglycerides and CVD particularly emphasises the dietary and lifestyle modifications (weight loss, macronutrient distribution and aerobic exercise) for the treatment of elevated triglycerides, presenting a practical algorithm for screening and management[28]. The European Society of Cardiology (ESC) guidelines on diabetes and CVD developed in collaboration with the European Association for the Study of Diabetes (EASD) suggests targeting residual risk in patients with elevated TG (> 2.2 mmol/L), with dietary and lifestyle advice and improved glucose control[33], post first-line treatment. The Endocrine Society task force agrees with the NCEP ATP Ⅲ treatment goals and recommends fibrates as first-line treatment for lowering triglycerides in patients at-risk for pancreatitis[34].

The International Atherosclerosis Society position paper recognises the atherogenicity of VLDL and triglycerides and also favours non-HDL cholesterol as the main target for therapy, optimally at < 3.40 mmol/L[35]. The American College of Cardiology (ACC)/AHA published a new clinical practice guideline for the treatment of elevated blood cholesterol in people at high risk for CVD.

Table 3 Recommended treatment targets for diabetic dyslipidaemia

		NCEP ATP Ⅲ[31]	ADA[30]	NVDPA[128]	European Guidelines[33]
LDL-cholesterol (mmol/L)	Very high risk	< 1.8	< 1.8	< 2.0	< 1.8
	High risk	< 2.6	< 2.6	< 2.0	< 2.5
Triglycerides (mmol/L)			< 1.7	< 2.0	< 1.7
HDL-cholesterol (mmol/L)	Male		> 1.0	⩾ 1.0	> 1.0
	Female		> 1.3	⩾ 1.0	> 1.2
Non-HDL cholesterol (mmol/L)	Very high risk	< 2.6	< 2.6	< 2.5	< 2.6
	High risk	< 3.4	< 3.4	< 2.5	< 3.3
ApoB (g/L)	Very high risk		< 0.8		< 0.8
	High risk		< 0.9		< 1.0

NCEP ATP Ⅲ: Third Report of the National Cholesterol Education Program (NCEP) expert panel on detection, evaluation and treatment of high blood cholesterol in adults (Adult treatment panel Ⅲ); ADA: American diabetes association; NVDPA: National vascular disease prevention alliance of australia; LDL: Low density lipoprotein; HDL: High density lipoprotein.

The guidelines do not provide recommendations for specific LDL-cholesterol or non-HDL targets and instead defines four major groups of primary and secondary prevention patients for whom LDL lowering is proven to be most beneficial[36]. Future guidelines to cover the treatment of HTG are proposed. A recent review by Hegele *et al*[37] recommended the simplification and redefinition of HTG: < 2.0 mmol/L as normal, 2.0-10.0 mmol/L as mild-to-moderate and > 10.0 mmol/L as severe; with desirable targets of < 1.7 mmol/L for triglycerides, < 2.6 mmol/L for non-HDL cholesterol and < 0.8 g/L for apoB in high-risk patients

Treatment of HTG depends on its severity, co-existing lipid abnormalities and overall cardiovascular risk. Severe HTG serves as increased risk of pancreatitis and warrants treatment to acutely reduce triglyceride levels. Current therapeutic strategies include diet and lifestyle modification, pharmacotherapy and in rare cases, continuous insulin infusion and apheresis.

Dietary and lifestyle modifications

Lifestyle interventions are central for controlling hyperglycaemia and HTG in patients with type 2 diabetic patients and impaired fasting glucose. These interventions include weight reduction, altered dietary composition, exercise and regulation of alcohol consumption. In type 2 diabetes, modest (5%-10%) weight loss can lower plasma triglyceride levels by up to 25%[38,39] and normalise postprandial triglyceride concentration[40]. Physical activity can aid the maintenance of weight loss achieved through caloric restrictions[41], although evidence for linking lifestyle modifications and sustained weight is limited[42].

The recently published look AHEAD trial, an intensive lifestyle intervention in type 2 diabetics, employing weight loss through caloric restriction and increased physical activity did not reduce the rate of cardiovascular events[43]. Whether alterations in dietary composition, such as with the Mediterranean diet, improves clinical outcome in diabetes warrants additional investigation[44], though the Mediterranean and low-carbohydrate diet can produce a greater reduction in triglyceride levels compared to the restricted-calorie diet in moderately obese individuals[45,46]. Plant sterols have been suggested for lowering TG in individuals with overt HTG[47]. Alcohol abstinence in patients with excessive alcohol intake can markedly lower plasma triglyceride levels[48,49]. Smoking cessation is also imperative[50].

Pharmacotherapy

Statin monotherapy: Statin therapy is the cornerstone of treatment of dyslipidemia in diabetes. Whilst reaching the LDL cholesterol target in most patients, only modest effects are exerted on triglyceride and HDL cholesterol. Hence, diabetics with HTG often have residual CVD risk[51] in spite of an optimal LDL cholesterol target. Statins may lower plasma triglyceride by increasing lipolysis and the clearance of TRLs, particularly with potent statins such as atorvastatin and rosuvastatin (up to 26% and 28% reduction in plasma triglyceride, respectively)[52-54]. Large statin outcome trials have supported its use in reducing coronary events and mortality[55-58]. All trials to-date have not specifically selected for HTG and in diabetics. However, sub-group analyses have been undertaken showing risk prevention with pravastatin[59], simvastatin[60] and rosuvastatin[61] in a subset of patients with high plasma triglyceride, recently reviewed by Maki *et al*[62], and supporting statins as first line of therapy. Whilst use of higher doses of statin has been linked to incidence of diabetes[63-65], the benefits of statin therapy for reducing CVD risk and events are outweighed for all diabetic patients with high CVD risk[57,63]. Aminotransferase, creatine kinase, creatinine and glucose should be monitored prior to initiating statins and before initiating a second agent, if required.

Fibrates and statin-fibrate combination: Fibrates (gemfibrozil, fenofibrate) act on peroxisome proliferator-activated receptor alpha. Fibrates decreases hepatic VLDL secretion and can confer an up to 30% reduction in plasma triglyceride, TRL remnants and apoB[66]. Five fibrate trials have undertaken secondary analyses in high triglyceride subgroups[67-79], two of these trials were in type 2 diabetic patients[70-72] and one had a subset of diabetics[73,74]. Collectively, these trials advocate the use of fibrates in reducing CVD events among patients with

a high triglyceride and low HDL cholesterol levels[75-78]. Of note, the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study showed that fenofibrate decreased progression of diabetic retinopathy[79], though unrelated to dyslipidemia, and the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study also showed a delay in the onset of eye complications[80]. Meta-analyses suggest that fibrates are useful for treatment of HTG[76] in diabetic patients[71,81,82]. Every 0.10 mmol/L reduction in triglyceride with fibrates confers a 5% reduction in CVD event, although no benefits were found on cardiovascular mortality[77,78].

Niacin and statin-niacin combination: Niacin can decrease plasma triglyceride by 30%[83] *via* the inhibition of hepatic diacylglycerol acyltransferase-2 (DGAT-2), a rate-limiting enzyme of triglyceride synthesis. Despite the earlier studies showing reduced mortality[84] and regression of subclinical atherosclerosis[85-87], the current use of niacin has been challenged by two large recent clinical trials which have failed to show significant benefits on CVD events[88,89] in spite of positive changes in lipid parameters. Both trials have limitations. The Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health (AIM-HIGH) study was underpowered and confounded by the higher statin and/or ezetimibe doses to match LDL cholesterol between groups[88]. The Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) study is the largest extend-release niacin trial to-date combined with laropiprant, a prostaglandin D2 inhibitor[89]. Despite no significant benefit on primary CVD endpoints, a recent sub-analysis in patients with both high triglyceride (> 2.24 mmol/L) and low HDL cholesterol (< 0.85 mmol/L) showed a trend towards benefit with niacin, although not reaching statistical significance (HR = 0.74, $P = 0.073$)[90]. Of note, the lack of potential benefit or harm in the HPS2-THRIVE study may not necessarily be due to niacin, but potentially to laropiprant. The safety of niacin use in type 2 diabetes has previously been questioned owing to impairment in glycaemic control and insulin sensitivity[91-93]. However, two prospective trials have showed that the effect of niacin on glycaemic control is minimal in a majority of patients with stable diabetes[94] and with no changes in low-dose (1 g/d) niacin[95].

Ezetimibe and statin-ezetimibe combination: Ezetimibe inhibits intestinal cholesterol absorption and primarily lowers LDL cholesterol *via* the Niemann-Pick C1-Like 1 protein. Ezetimibe has minimal effects in lowering plasma fasting triglyceride (8%)[96]. A more prominent effect is observed in ameliorating postprandial lipaemia and lowering TRL remnants in spite of background statin[97,98]. In a 6-wk trial of simvastatin-ezetimibe vs. simvastatin monotherapy, fasting and postprandial plasma triglyceride and apoB-48 concentrations were lowered in type 2 diabetic patients[99]. However, intensive lipid lowering with a statin plus ezetimibe may not consistently lower subclinical carotid atherosclerosis in type 2 diabetes, although progression of carotid artery intima-media thickness was inhibited with the combination[100,101]. The Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) study that is currently entering completion will endeavour to provide definitive evidence for the role of ezetimibe in high risk subjects on optimal statin therapy[102,103].

n-3 fatty acid and statin-n-3 fatty acid combination: Supplemental n-3 polyunsaturated fatty acids (PUFAs), mainly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are well known to improve HTG[104]. However, recent clinical outcome trials with have failed to show significant CVD benefits in high risk subjects including diabetics[105,106]. Both trials were undertaken against a background of optimal therapy, including statins. Also, patients were not selected for elevated plasma triglyceride levels. Pure EPA (1800 mg/d), added to statin therapy, showed promise in the Japan Eicosapentaenoic acid Lipid Intervention Study (JELIS) with major coronary events reduced by 19% ($P = 0.011$) in hypercholesterolaemic patients[107]. Two 12-wk EPA (AMR101) intervention trials in patients with very high[108] and persistent[109] baseline triglyceride observed significant reductions in triglyceride levels. The greatest decrease was seen in the highest triglyceride tertile where there was a 31% reduction compared to placebo on 4 g/d of AMR101. The Reduction of Cardiovascular Events with EPA-Intervention Trial (REDUCE-IT) is in progress and will endeavour obtain the CVD outcome data with AMR101 4 g/d in high-risk patients with HTG and at-target LDL cholesterol on statin therapy[110]. There are also recent data suggesting an increased risk of prostate cancer with high dietary intake of n-3 PUFAs[111]. Hence, caution is warranted when recommending long-term intake.

Incretin-based therapy: Incretins, such as glucagon-like peptide-1 (GLP-1), are insulinotropic, gut-derived hormones secreted in response to diet. GLP-1 receptor analogs such as liraglutide and exenatide, delay gastric emptying and this parallels the reduction in postprandial triglyceride response[112]. This mechanism may ameliorate impaired TRL metabolism in type 2 diabetes. By increasing plasma concentrations of GLP-1, Dipeptidyl peptidase-4 (DPP-4) inhibitors, such as sitagliptin, saxagliptin and alogliptin, can improve insulin sensitivity, β-cell function[113] and postprandial glycaemia[114] and lipaemia[115]. These agents could potentially prevent CVD events, independent of changes in glucose and lipid metabolism. A recent saxagliptin outcome trial failed to demonstrate significant changes in ischaemic events, though the rate of heart failure increased significantly[116]. Similarly, a trial in type 2 diabetic patients post-acute coronary syndrome with aloglipitin did not improve cardiovascular event rates compared with placebo[117]. Further investigation is required to clarify

their mechanism and use in type 2 diabetes.

MANAGEMENT OF SEVERE HYPERTRIGLYCERIDAEMIA IN TYPE 2 DIABETES

Insulin infusion, apheresis and gene replacement therapy

In severe cases of diabetic HTG and poorly controlled diabetes, continuous intravenous insulin infusion appears to be beneficial in restoring serum glucose and triglyceride[118]. Most of these patients will have an underlying genetic defect in TRL metabolism. A recent study in a group of 15 diabetics with a median triglyceride concentration of 26.23 mmol/L at admission had their triglyceride levels corrected to a median of 5.75 mmol/L at discharge with an average of 48 h of continuous insulin infusion[119]. For prevention of recurrent severe HTG in susceptible patients, counselling on medication adherence and long-term diet and lifestyle medications should be considered[120].

In extremely severe HTG and drug refractory HTG, plasma apheresis may be required[121,122], particularly with severe chylomicronaemia complicated by acute pancreatitis. A single session of apheresis can dramatically lower excessive triglyceride levels, 65.8% reduction in 2 h[123,124]. This method of triglyceride lowering is only indicated in medical emergencies owing to high costs and limited availability[125]. Further study is required to clarify the role of plasma exchange in the treatment of hyperlipidaemic pancreatitis.

In patients genetically diagnosed with familial LPL deficiency, Glybera® (alipogene tiparvovec; Amsterdam Molecular Therapeutics, Amsterdam, the Netherlands) is the first approved gene-replacement therapy[126,127]. Glybera® has only been studied in 27 patients, in whom the agent was well tolerated and with plasma triglyceride concentration significantly lowered with reduced rates of acute pancreatitis[126]. Long-term follow-up data and cost-effectiveness studies is warranted[126,127].

CONCLUSION

HTG is common in type 2 diabetes. HTG associates with a spectrum of cardiometabolic risk factors and increases CVD risk in type 2 diabetes. Dietary and lifestyle modification involving weight loss and exercise is fundamental to the management of HTG. Improved glycaemic control with use of metformin, DPP-4 inhibitors and insulin can also improve HTG. The expression of HTG in context of diabetes may depend on co-existing monogenic and/or multigenic disorders of lipid metabolism, such as familial combined hyperlipidaemia, familial hypertriglyceridaemia and type Ⅱ hyperlipoproteinaemia. Statins are the first-line of lipid-lowering therapy to target LDL cholesterol and triglycerides. Current evidence supports the use of fenofibrate in type 2 diabetics, with high triglyceride and low HDL, but also to prevent and treat diabetic retinopathy. More evidence is required from CVD outcome trials for the other add-on options, some of which are currently underway. Several new therapies with potential applications for treating HTG are DGAT inhibitors, microsomal triglyceride transfer protein inhibitors, and apoC-Ⅲ antisense oligonucleotides. These will agents will require to be tested for efficacy, safety and cost-effectiveness in future clinical trials.

Abstract

Diabetes mellitus (DM) is a widely spread epidemic disease that results from the absence of insulin, decreased secretion and/or impaired function. Since DM is a multifactorial disease, the available pharmaceuticals, despite their sensible treatment, target mostly one pathway to control hyperglycemia and encounter several side effects. Therefore, new therapeutic paradigms aim to hit several pathways using only one agent. Traditionally, antidiabetic plants and/or their active constituents may fulfill this need. More than 200 species of plants possess antidiabetic properties which were evaluated mostly by screening tests without digging far for the exact mode of action. Searching among the different literature resources and various database and in view of the above aspects, the present article provides a comprehensive review on the available antidiabetic plants that have been approved by pharmacological and clinical evaluations, and which their mechanism(s) of action is assured. These plants are categorized according to their proved mode of action and are classified into those that act by inhibiting glucose absorption from intestine, increasing insulin secretion from the pancreas, inhibiting glucose production from hepatocytes, or enhancing glucose uptake by adipose and muscle tissues. The current review also highlights those that mimic in their action the new peptide analogs, such as exenatide, liraglutide and dipeptidylpeptidase-4 inhibitors that increase glucagon-like peptide-1 serum concentration and slow down the gastric emptying.

Key words: Hypoglycaemic nutraceuticals; Antidiabetic phyto-constituents; Medicinal plants; Phytotherapy; Diabetes mellitus

Core tip: Diabetes is a serious metabolic disorder that is currently treated by different types of synthetic oral hypoglycemic agents, in addition to insulin. However, due to the unwanted side effects, the efficacies of these compounds are debatable and there is a demand for new compounds for the treatment of diabetes. Therefore, attention has been directed towards nutraceuticals originating from plants that are rich in antidiabetic phyto-constituents. Although the evidenced-based therapeutic usage of many plants is scarce, the plants cited in this review are those reputed traditionally for their antidiabetic effect and that were verified either experimentally or clinically.

INTRODUCTION

Diabetes mellitus (DM) is a common disorder of car-

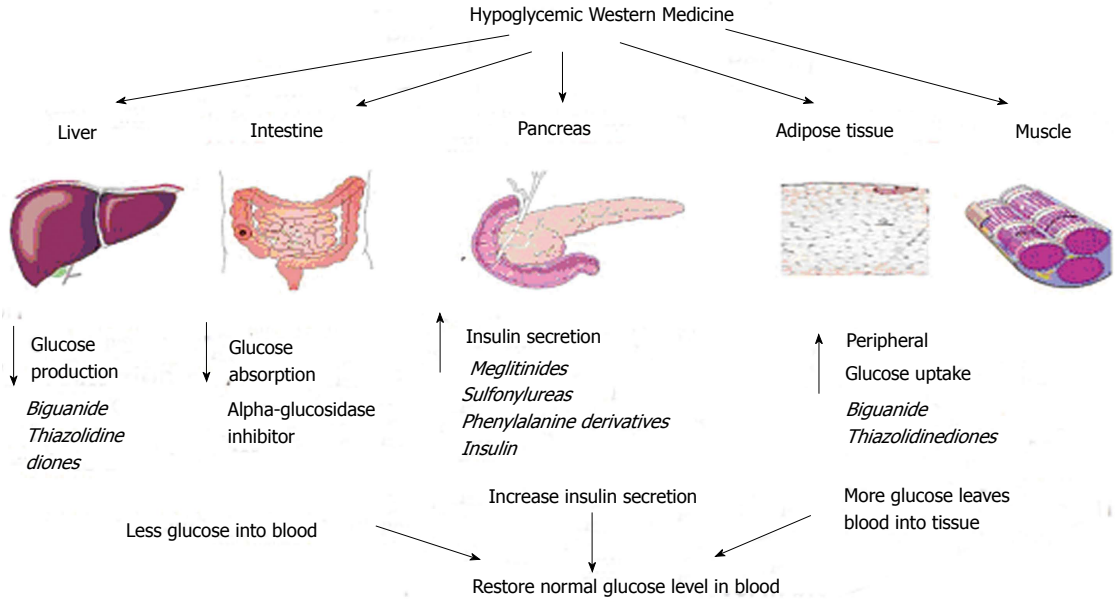

Figure 1 Pathophysiological mechanisms of hyperglycemia matched with the suitable pharmacotherapeutics (Data adapted from Hui *et al*[3]).

bohydrate, fat and protein metabolism reflected by an inappropriate fasting and postprandial high blood glucose levels (hyperglycaemia). This ailment results from the absence or scantiness of insulin secretion with or without concurrent impairment of insulin action. Consequently, the disease was classified into two types known as type I (insulin dependent, IDDM) and II (non-insulin dependent, NIDDM) according to the degree of the pancreatic defect. This classification has been even recognized since the time of Ibn Sinaa who mentioned it in his book "The Canon of Medicine".

DM is not confined to abnormal blood glucose level, but it progresses to affect other body systems. This fact was confirmed by several epidemiological studies and clinical trials that linked hyperglycemia to several complications at the macrovascular (coronary artery disease and cerebrovascular disease), as well as the microvascular levels (renal failure, blindness, limb amputation, neurological complications and pre-mature death)[1].

Based on the pathophysiology and severity of this disease, it can be controlled by dietary restriction, exercise, different types of synthetic oral hypoglycemic agents and/or insulin. Since DM is one of the multi-factorial based diseases, therefore, a balanced modulation of several targets can provide a superior therapeutic effect and a decrease in the side effects profile compared to the action of a single selective agent[2]. Hence, the current strategy used for the treatment of type II DM depends on combining an insulin secretagogue and an insulin sensitizer to provide a sensible therapeutic approach (Figure 1)[3]. Albeit reasonable management provided by these drugs, yet over time, some of the type II diabetic patients lose response towards conventional antidiabetics, leading to an inadequate control of their blood glucose level. Moreover, several side effects could hinder their capability in alleviating the symptoms of diabetes, such as severe hypoglycemia, lactic acidosis, idiosyncratic liver cell injury, permanent neurological deficit, digestive discomfort, headache, dizziness and even death. In addition, treatment of IDDM using insulin has also its complications, since continuous exposure to insulin causes a reduction in the number of receptors on the cell surface by promoting internalization, as well as degradation of hormone-occupied receptors[4].

In spite of the introduction and extensive utilization of hypoglycaemic agents, diabetes and its related complications continue to be a major health problem worldwide. Globally, around 150 millions of people are believed to be diabetic and the incidence rate is expected to double by 2025[5]. These expectations are "good to be true", especially for NIDDM, since the slothful lifestyle along with the high consumption of westernized diet, are considered to be the cornerstone for the development of this type of DM. Hence, it is a requisite to have safer and more effective oral hypoglycemic agents which can hit many targets to fulfill the new paradigm in drug discovery[6]. To achieve this objective, one may either employ a single compound to strike multiple targets; this can be termed as a one compound-multiple-target strategy[2], or use a combination of active compounds in one drug[7]. Therefore, attention has been directed towards nutraceuticals, since they can fulfill these criteria.

Herbal products may contain several active constituents or compounds that can act by several modes of action to influence multiple biological pathways and to alleviate the diabetic symptoms, providing thereby multifaceted benefits[8]. Nevertheless, this vision is not totally new, since prior to and after the discovery of insulin, herbs with hypoglycaemic effect have been used in folk medicine and are still prevalent[9-11]. As a support for this concept, metformin, which is notable for its substantial favorable impact on diabetes prevention, was purified from the French lilac *Galega officinalis* L.[12]. Moreover, the low cost of these compounds and the minimal side effects are

other reasons behind the hunt for effective natural agents to be used as complementary and/or alternative medicine.

Since restoring glucose homeostasis is influenced by several aspects, the current article classifies the hypoglycemic herbs that are available in literature resource from various database, into poroper categorization according to their potential mode of action to reduce blood glucose level. Different search engines were explored including Pubmed, Google, Asci database by using different keywords, as well as some of the traditional tertiary resources. Priority was given to research articles and information given by authentic organizations and federations. Plants cited in this review are those reputed traditionally for their antidiabetic effect and that were verified, either experimentally or clinically. The efficacy of hypoglycemic herbs is achieved by inhibiting glucose absorption from intestine, increasing insulin secretion from the pancreas, inhibiting glucose production from hepatocytes, or enhancing glucose uptake into the peripheral tissue *via* the glucose transporters (GLUT). Additionally, the plants that act by simulating the action of the new incretin peptide analogs were also mentioned in the present review.

INHIBITION OF GLUCOSE ABSORPTION

Postprandial hyperglycemia plays an important role in the incidence of type Ⅱ DM, since recent studies suggest that it could induce the non-enzymatic glycosylation of various proteins, resulting in the development of chronic complications. Therefore, controlling its level, *via* inhibiting the activities of α-glucosidase enzymes, is believed to be an important strategy to manage this disease. Alfa-glucosidase enzyme is a member of the glucosidases located in the brush-border surface membrane of the intestinal cells and is a rate-limiting step in the conversion of oligosaccharides and disaccharides into monosaccharides, necessary for gastrointestinal absorption[13]. In addition, α-amylase, which is present in both salivary and pancreatic secretions[14], is responsible for cleaving large malto-oligosaccharides to maltose which is a substrate for the intestinal α-glucosidase. Hence, the inhibition of α-glucosidase and/or α-amylase enzymes is currently in vogue, especially if these inhibitors stem from natural bases. The following are some examples of plants or their constituents that are proven to possess anti-enzymatic properties.

Methanolic extract of *Adhatoda vasica* Nees (*Acanthaceae*) was shown to have the highest sucrase inhibitory activity among forty species tested in an experimentally screening study by Gao *et al*[15]. This effect was attributed to its active constituents, *viz.,* vasicine and vasicinol, beside other constituents, offering thus, a possibility to develop successful α-glucosidase inhibitors. Previous studies by Gao *et al*[15] also reported the isolation of maltase inhibitory principles from the fruits of *Terminalia chebula*[16] and *Tussilago farfarae*[17].

Belonging to the same *Acanthaceae* family*, in vitro* studies on the ethanolic extract of *Andrographis paniculata* (*Burm. f.*) Nees and its principal active constituent, andrographolide (AG), seem to possess an antihyperglycemic activity[18]. They delay the quick digestion of starch, as well as sucrose, and prolong the absorption time of carbohydrates, pointing to an α-glucosidase inhibitory activity. Moreover, essential oils obtained from the woods of *Cedrus libani* A. Rich (*Pinaceae*), but not its leaves or cones, were able to inhibit the α-amylase activity[19].

Nigella sativa L. (*Ranunculaceae*), a plant commonly used in the Middle Eastern and North African traditional medicine was validated for its multi-factorial anti-diabetic actions. The crude aqueous extract tested in experimental rats was able to restore glucose homeostasis[20] and to improve glucose tolerance as efficiently as metformin. Apart from its effect to enhance insulin sensitivity in liver cells[21], and to possess an insulinotropic and insulin-like activities in cultured pancreatic β-cells, skeletal muscle cells and adipocytes[22], it is now documented[23] that the crude aqueous extract of *Nigella sativa* seeds directly inhibits the electrogenic intestinal absorption of glucose *in vitro*. This effect is mediated by reducing the intestinal sodium-dependent D-glucose cotransporter-1 (SGLT1) which is the major transporter of glucose in the intestine[24,25]. SGLT1 is also considered a key molecule in the sensing of glucose entry that is highly regulated by peptides and hormones[26].

Another plant that is widely used as an anti-diabetic in folk medicine in México is *Tournefortia hartwegiana,* where the decoction of its aerial parts controls the disease, when given orally for 10-14 d to alloxanized rats. The plant is thought to control the glucose level *via* several routes, including the inhibition of the intestinal α-glucosidase and other intestinal enzymes, as maltase and sucrase that are implicated in the digestion of polysaccharides and oligosaccharides[27,28]. The inhibitory effect of this decoction suppresses the absorption of carbohydrates from intestine and thereby reduces the post-prandial increase in the glucose level. On the other hand, Ortiz-Andrade *et al*[27] referred the anti-diabetic effect of the methanolic extract of the same plant to the enhancement of insulin secretion and/or action. Furthermore, other machineries , such as the modulation of the pancreatic and extrapancreatic effects[29-32], besides the enhancement of β-cell glucose metabolism or an activation of enzyme system generating cyclic adenosine mono phosphate (AMP) or phospholipid derived messenger[33], and/or blockage of glucose co-transporters from intestine to circulation[34], cannot be ruled out. These diverse mechanisms are attributed to the different components that were tested for their individual hypoglycemic action, where the "cocktail" of these constituents could trigger a synergic effect.

In 2004, Asano *et al*[34] in their search for an anti-glycosidase, succeeded to isolate new alkaloids from the bulbs of *Scilla peruviana* (*Hyacinthaceae*) that display an inhibitory action of bacterial β-glucosidase and bovine liver β-galactosidase to varying degrees. In addition, the methanolic extract of the rhizome of *Rheum emodi*, known as Himalayan rhubarb, inhibited the activity of both mild yeast and mammalian intestinal α-glucosidase as proven by Suresh Babu *et al*[35]. This action correlates with the

active components isolated from this rhizome such as chrysophanol-8-O-β-D-glucopyranoside, desoxyrhaponticin and torachrysone-8-O-β-D-glucopyranoside which showed a potent to moderate mammalian α-glucosidase inhibitory activity.

In a recent study, Loizzo *et al*[36] examined the influence of nine extracts of plant species collected in Lebanon, *viz*., Calamintha origanifolia, Satureja thymbra, Prangos asperula, Sideritis perfoliata, Asperula glomerata, Hyssopus officinalis, Erythraea centaurium, Marrubium radiatum and Salvia acetabulosa. The authors prepared different extractions with methanol, *n*-hexane and chloroform, yet the methanolic extracts of *Marrubium radiatum* and *Salvia acetabulosa* exerted the strongest activity against α-amylase and α-glucosidase. The leaf extract of the *Marrubium* related species, *viz., Marrubium vulgare*, is used in Brazilian and Mexican traditional medicine for its antidiabetic role, an effect that was documented clinically in patients with type Ⅱ non-controlled diabetes mellitus[37]. Several *Salvia* species have been reported for their hypoglycaemic effect in Iranian folk medicine[38,39] where they act by different mechanisms. For example, *Salvia lavandulaefolia* extract acts by decreasing the intestinal absorption of glucose, increasing the peripheral uptake of glucose, potentiating glucose-induced insulin release, and causing pancreatic islet cells hyperplasia[40].

The hypoglycemic mechanisms of another anti-diabetic plant, *Plantago ovata* husk, has also been studied and it was found that its aqueous extract hinders markedly the intestinal glucose absorption in rats; however, the extract failed to affect insulin secretion nor glucose transport in adipocytes[41].

Salacia species (*Celastraceae*) are widely distributed in East Asian countries and many plants from this genus (*e.g.*, *S. oblonga, S. reticulata* and *S. prinoides*) have been used for thousands of years in traditional medicines, particularly for the treatment of diabetes and obesity. Pharmacological studies have demonstrated that *Salacia* roots modulate multiple targets, including the inhibition of α-glucosidase, aldose reductase and pancreatic lipase, as well as the activation of peroxisome proliferator-activated receptor-alpha (PPAR-α)-mediated lipogenic gene transcription. All these mechanisms reinforce its usage in Ayurvedic medicine for diabetes and obesity. The methanolic extracts of *S. reticulata* and *S. oblonga* stems and roots reduced, dose-dependently, the postprandial hyperglycemia induced in rats by maltose, sucrose or starch, but not by glucose or lactose[42-44], pointing to their inhibitory effect on intestinal enzymes. Moreover, the aqueous extract of *S. reticulata* inhibited strongly the activities of α-glucosidase and α-amylase[42], while that of *S. chinensis* inhibited the α-glucosidase activity only[45]. These favorable effects are attributed to the identified components of the plant, *viz.,* mangiferin, salacinol, kotalanol and kotalagenin 16-acetate. Mangiferin causes concentration-dependent α-glucosidase inhibition *in vitro*[46], while salacinol, kotalanol and kotalagenin 16-acetate inhibited the increased serum glucose levels in maltose and sucrose loaded rats more than acarbose[43,44]. Thus, these findings suggest that the anti-diabetic property of *Salacia* is partially attributed to its intestinal α-glucosidase inhibitory activity.

Mangifera indica Linn. (*Anacardiaceae*) is a plant that possesses several properties, one of which is hypoglycemia that favors it to control type Ⅱ DM in some rural African communities[46]. Mangiferin is one of the active constituents of this plant, besides the polyphenolics, flavonoids, triterpenoids, and other chemical compounds. Therefore, the mangiferin-mediated inhibition of α-glucosidase activity[47], offers one mechanism for the hypoglycemic effect of this plant.

The potential antidiabetic activity of six pentacyclic triterpenes (oleanolic acid, arjunolic acid, asiatic acid, maslinic acid, corosolic acid and 23-hydroxyursolic acid) were isolated from the ethyl acetate extract of the leaves of *Lagerstroemia speciosa* (LSL) and were investigated by α-amylase and α-glucosidase inhibition assay[48]. However, the compounds showed week α-amylase inhibitory effect, while α-glucosidase was moderately inhibited, mainly by corosolic acid. In a search for an α-amylase inhibitory compound from plant origin, Ali *et al*[49] studied extracts of six selected Malaysian plants with a reputation of usefulness in treating diabetes using an *in vitro* model. Their work depicted that the hexane extract of *Phyllanthus amarus* had α-amylase inhibitory properties, an effect that was provoked by only three pure pentacyclic triterpenoids, namely, oleanolic acid, ursolic acid and lupeol.

The antidiabetic capacity of the standardized extract of maritime pine bark, derived from *Pinus pinaster*, Aiton. subs. Atlantica des Villar (Pycnogenol®), was documented clinically by Liu *et al*[50]. In their study a double-blind, placebo-controlled, randomized, multicenter study was performed with 77 type Ⅱ diabetic patients to investigate the potential antidiabetic effects of the French matitime pine bark extract, Pynogenol (100 mg) for 12 wk. Supplementation of Pycnogenol to conventional diabetes treatment loweres glucose levels and improves the endothelial functions, as evidenced by the significant reduction in HbA1c and endothelin-1. To characterize the possible mechanism of action, the authors attributed the effect of Pycnogenol to the suppression of α-glucosidase enzyme[50], rather than enhancing the insulin secretion, an effect that was more potent than green tea or acarbose[51]. The clinical antidiabetic effect was found also to be dose dependent and correlates positively with the procyanidins comprising of catechin and epicatechin subunits with varying chain lengths[52,53].

Another plant that is used extensively in folk medicine is the Fenugreek (*Trigonella foenum-graecum* L.), which is a member of the *Leguminosae* family, and is cultivated predominantly in Asia, the Mediterranean, and North African regions. Mainly the seeds are the part used for centuries for a wide range of diseases, as they were shown experimentally to possess significant hypoglycemic[54], antiathrosclerotic[55], anti-inflammatory[56], antinociceptive[57], antiulcerogenic[58], and antineoplastic effects[59]. Studies carried to elucidate its anti-diabetic mechanism(s) reveal that the plant works by inhibiting the intestinal glycosidase[60], in addition to its positive effect on glycolytic,

gluconeogenic, and lipogenic enzymes to restore glucose homeostasis in various animal models[60,61].

The *in vitro* α-glucosidase inhibitory model has been used by several research teams to verify the potential antidiabetic properties of different plant parts/extracts. In this context the antidiabetic effect of the Corni fructus (*Cornus officinalis Sieb. et* Zucc.) extract is mediated partly by inhibiting the α-glucosidase activity, an effect that reached to over 80% by one of the extract tested fractions[62]. Likewise, the alcohol extract of Alismatis Rhizoma-related hypoglycemic effect is mediated *via* the same mechanism, owing to its protostane-type triterpenes, besides promoting the glucose uptake *in vitro*[63]. Similarly, chemical components isolated from the safflower seed (*Carthamus tinctorius* L.)[64] and from the leaves of Ficus deltoidea, *viz.*, vitexin and isovitexin[65], as well as the methanolic extract of the aerial parts of Swertia corymbosa (used in Ayurveda herbal preparations in India)[66] exhibited *in vitro*/*in vivo* α-glucosidase inhibition.

Moreover, the same *in vitro* technique showed that the grape seed extract inhibits the intestinal α-glucosidases and α-pancreatic amylase that may delay carbohydrate digestion and absorption. Recently, this fact has been further documented, where grape seed extract has lowered the postprandial plasma glucose concentration in an acute, randomized, controlled crossover design study, in which healthy subjects received high carbohydrate meal with or without grape seed extract[67].

A prospective epidemiology links heavy coffee consumption to a substantial reduction in risk for type 2 diabetes, yet there is no evidence that coffee improves insulin sensitivity. Thus, it is reasonable to suspect that coffee influences the risk for beta cell "failure" that precipitates diabetes in subjects who are already insulin resistant. Indeed, coffee was proven to increase the production of the incretin hormone glucagon-like peptide-1 (GLP-1), possibly by its chlorogenic acid constituent (CGA-the chief polyphenol in coffee). The latter was also found to inhibit the intestinal glucose transport, as documented by the consumption of plants containing CGA, to be including coffee[68]. Further studies correlated the presence of CGA, the main polyphenolic compound in coffee, to the decreased diabetic risk where CGA slows carbohydrate absorption by its effect on the intestinal brush border membrane glucose transport, thus mimicking the effect of acarbose at the experimental level[69], as well as acutely modifies gastrointestinal hormone secretion and glucose tolerance in humans[70]. CGA inhibits also the activity of glucose-6-phosphate translocase[71] which is now believed to play a role in glucose absorption[72,73]. In 2008, Andrade-Cetto *et al*[74] have tested the hypoglycemic effect of butanolic extracts of some Mexican plants and have found that *Malmea depressa* Baill R.E. and *Acosmium panamense* Benth. extracts resemble the effect of acarbose and decrease the plasma glucose level significantly by affecting the α-glucosidase enzyme. Nevertheless, the effect of the butanolic extract of *Cecropia obtusifolia* Bertol. was the most potent and it produced the highest reduction in the plasma glucose level that was even lower than the fasting level after 90 min, an effect that suggests an additive mechanism of action. This assumption could be true since this plant contains CGA which hits several targets in the diabetes metabolic pathways, besides its acarbose-like effect[75,76].

ENHANCEMENT OF GLUCOSE UPTAKE AND UPREGULATION OF GLUCOSE TRANSPORTERS

Stimulating the peripheral glucose uptake is one of the multiple mechanisms that control blood glucose level; hence, targeting this point is among the most promising goals for the treatment of type-Ⅱ DM. Basically, several factors assimilate to facilitate the glucose uptake process, including the activation of the GLUT in liver (GLUT-2), adipocytes and skeletal muscles (GLUT-4), the induction of the nuclear receptors, *viz.,* PPARs, especially the gamma subtype, as well as increasing the release of positive adipocytokines, such as adiponectin[77].

As illustrated in Figure 2, the cell membrane lipid bilayer is impermeable to carbohydrates, which necessitates the presence of specific transporters. These carriers are differentiated into two families, the first one is a sodium-linked GLUT that works actively and is limited to the intestine and kidney. The second family consists of eight homologous transmembrane proteins, GLUT-1-8, that are encoded by distinct genes, and they convey glucose by the facilitated diffusion down the glucose-concentration gradients[77]. However, the GLUT proteins have distinct substrate specificities, kinetic properties, and tissue distributions that dictate their functional roles. GLUT-1 is expressed in the brain, erythrocytes and endothelial cells, while GLUT-2 is found in the liver, kidney, small intestine, and pancreatic β-cells. This low-affinity GLUT (GLUT-2) has a role in sensing glucose concentrations in the islets of Langerhans. GLUT-3 is responsible for transporting glucose in neurons and placenta, while GLUT-4 is present in skeletal muscles, cardiac muscles and the adipose tissue. Of all the GLUT, only GLUT-4 is insulin-responsive. GLUT-5 has high affinity to transport fructose rather than glucose and it exists in the small intestine, sperm, kidney, brain, and adipose cells[77]. In 2003, Gorovits *et al*[78] found that GLUT-8, present in liver, plays a role in the regulation of glucose in case of diabetes. GLUT-4 is sequestered intracellularly and is translocated to the plasma membrane upon its stimulation by insulin. Thus, a decrease in the expression of GLUT-4 mRNA and protein reduced the insulin-mediated glucose uptake in diabetes[79]; in other words, imperfect GLUT-4 function could be a causative factor for insulin resistance[80].

From this point of view, herbs or their active constituents that can up-regulate GLUT-4 expression or that increase the translocation of this transporter could aid in the treatment of insulin resistance and hyperglycemia.

Cecropia obtusifolia Bertol (*Cecropiaceae*) is a plant extensively used for the empirical treatment of type Ⅱ diabe-

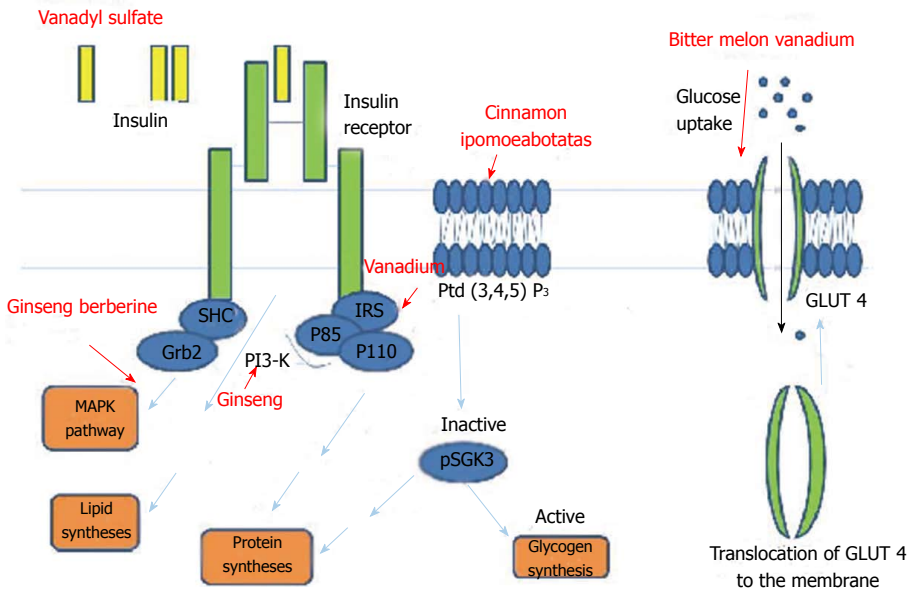

Figure 2 Insulin signaling pathway and insulin insensitive. The inner part of insulin receptor (IR) reveals a tyrosine kinase activity and coupled with multifunctional docking proteins IRS-1 and IRS-2. The in turn signaling leads to an activation of the MAPK cascade involved in mitogenesis and the open status of a hexose transporter protein (GLUTs) which is located in the cell membrane and is the only channel for glucose entery into cells. The decreased serine/threonine phosphorylation of IR, inactivates hexokinase and glycogen synthase, as well as defects in the phosphorylation of glucose transporter protein (GLUT4) and genetic primary defect in mitochondrial fatty acid oxidation, leading to insulin resistance and an increase of triglyceride synthesis contribute to this insulin insensitivity. The action sites of hypoglycemia herbs are indicated with red arrows[3].

tes in México[76]. The active hypoglycemic compounds found in this plant are CGA and isoorientin which are also found in other anti-diabetic plants as mentioned before[76]. In 2008, Alonso-Castro *et al*[76] studied the anti-diabetic mechanisms of *Cecropia obtusifolia* aqueous extract and its active compound CGA, and reported that the two preparations exert their anti-diabetic effects by stimulating glucose uptake in both insulin-sensitive and insulin-resistant adipocytes without appreciable pro-adipogenic effects. Thus, they could act by potentiating the insulin action or by activating a signaling pathway parallel to the insulin pathway.

Other anti-diabetic plants that act *via* increasing the glucose uptake in adipocytes, alone and in combination with insulin, include the ethanolic extract of *Amomum xanthioides* seeds[81], *Lagerstroemia speciosa*[82] and plants used by the Cree Nation in Canada, such as *Abies balsamea*, *Pinus banksiana* and *Rhododendron groenlandicum*[83]. Moreover, an aqueous extract from *Cinnamomum zeylanicum*[84], aqueous and ethanolic extracts of *Momordica charantia*[85], and aqueous extract of *Guazuma ulmifolia*[86], stimulated glucose uptake in 3T3-L1 adipocytes. However, none was evaluated on insulin-resistant adipocytes, except for *Guazuma ulmifolia*, which similar to *Cecropia obtusifolia,* mediated its action by stimulating glucose uptake in normal and diabetic adipocytes without inducing adipogenesis; nevertheless, its hypoglycemiant component(s) are not fully characterized.

Miura *et al*[87] validated the antidiabetic activity of *Lyophyllum decastes* (*Tricholomataceae*) in KK-Ay mice, an animal model of genetically type Ⅱ diabetes with hyperinsulinemia. The results of their work reported that mice receiving the aqueous extract showed an increase in the muscle content of GLUT-4 protein, which is responsible, at least in part, for decreasing insulin resistance. In 2004, Miura *et al*[88] again used the same model to test the hypoglycemic effect of corosolic acid, and found that it increased GLUT-4 translocation in muscle, without affecting the insulin level. This acid is one of the active constituents of *Lagerstroemia speciosa* L., banaba leaf. The plant is used traditionally in Philippines to treat diabetes and was studied by Takagi *et al*[89] who referred the antidiabetic effect to the inhibition of sucrose hydrolysis. However, the effect of corosolic acid on GLUT-4 can not be ruled out, although this requires further verification

In another study[90], the 3T3-L1 adipocytes were used to prove that the methanolic extract of *Liriope platyphylla Wang et Tang* (*LPWT*), *Liliaceae*, increased insulin-induced glucose uptake in adipocytes, by virtue of its homoisoflavone. This uptake was mediated through the translocation of GLUT-4 to the plasma membrane, *via* Insulin receptor Substrate - phosphatidyl inositol 3 kinase-Akt signaling mechanism. Aside from delaying the carbohydrate absorption *via* affecting α-glucosidase enzyme[19], *Andrographis paniculata* adopts another mechanism of action for its hypoglycemic effect through increasing the expression of GLUT-4. This was confirmed by the administration of its main constituent andrographolide in diabetic mice using streptozocin (STZ)[91].

Panax ginseng, also known as Korean red ginseng, appears to be a powerful anti-diabetic plant that has multi modes of action, due to its potent active constituents including ginsenoside Rh2. In a study by Lai *et al*[92], the authors reported that the ginsenoside Rh2 increases the gene expression of GLUT-4, at the mRNA and protein levels, in soleus muscle obtained from STZ-diabetic rats. They also suggest that the GLUT-4 expression is increased as a result of the increased β-endorphin secretion which will be detailed later in this review.

In an attempt to develop new substances for treating insulin resistance, obese Zucker rats were employed to screen the effect of myricetin, an active principle of *Abelmoschus moschatus* (*Malvaceae*), on insulin resistance[93]. The findings showed that myricetin increased insulin sensitivity by increasing the expression of GLUT-4 and by activating the phosphorylation of insulin receptor substrate-1. These results were also obtained from another study[94] using the methanolic extract of *Aegles marmelos*

and *Syzygium cumini* that are anti-diabetic medicinal plants used in Indian traditional medicine. The latter study reported an additive mechanism for lowering glucose level *via* the elevation of PPAR-γ, a nuclear receptor that will be discussed in the following section. *Azadirchata indica* Neem is among the Indian herbs that possess an antidiabetic effect. The hydroalcoholic extract of this herb exerted its antihyperglycemic activity by increasing glucose uptake, as well as glycogen deposition[95]. Furthermore, the anti-diabetic action of Tinospora cordifolia is mediated by increasing the expression of GLUT-4 by about 5 folds, as well as PPARα and γ, as tested in differentiated myocytes, L6 cells[96].

ACTIVATION OF THE NUCLEAR RECEPTOR PPAR-γ

The PPAR family belongs to type Ⅱ nuclear hormone receptors involved in the regulation of fatty acid, carbohydrate and glucose metabolism[97]. There are three isoforms of PPARs with specific tissue distribution and biological activity; they are identified as α, β or δ and γ with two subforms PPAR-γ1 and PPAR-γ2[98]. The receptors are ligand dependent, with the antidiabetic thiazolidinediones (TZDs) being the potent PPAR-γ agonist[97]. After their stimulation by their specific ligands, they regulate the transcriptional process *via* their heterodimerization with RXR, a retinoid X receptor, and then bind to peroxisome prolixferator-response element (PPRE)[97,98]. Clinical data demonstrated that the PPAR-γ agonists TZDs modulate glucose homeostasis by enhancing the peripheral glucose uptake through increasing GLUT-4 expression and translocation in adipocytes[99], as well as decreasing hepatic glucose output[100]. TZDs alleviate insulin sensitization by the redistribution of adipose deposits where these agents minimize visceral adipose content, responsible for the induction of insulin resistance, and redeposit it subcutaneously, in a phenomenon known as the "fatty acid steal" hypothesis[101]. In addition, activating PPAR-γ increased adipocyte fatty acid uptake, and decreased lipotoxic damage to insulin-sensitive tissues[102].

To date, the chief research interest in finding a nutraceutical compound(s) that mimics the PPAR-γ ligands constitute promising approaches for the treatment of diabetes, obesity and metabolic syndrome. Previously, multiple trials have shown conflicting results whether cinnamon lowers glucose or hemoglobin A1c (HbA1c). In 2009, Crawford[103] tested the cinnamon hypoglycemic activity in patients with type 2 diabetes through a randomized, controlled trial to evaluate whether daily cinnamon plus usual care versus usual care alone lowers HbA1c. Cinnamon lowered HbA1c (0.83%) compared with usual care alone lowering HbA1c (0.37%). Because one of the proposed mechanisms of cinnamon is increasing insulin sensitivity, hence, the treatment of patients with metabolic syndrome by adjunct cinnamon may yield weight loss, improved lipid profiles, and better glucose tolerance.

Park *et al*[104] used db/db mice, a typical non-insulin-dependent model, to study the anti-diabetic mechanism of Mulberry leaf water extract, Korean red ginseng and/or banaba leaf water extract. Herbs alone and their combination increased the expressions of liver PPAR-α mRNA and adipose tissue PPAR-γ mRNA in animals fed diets supplemented with the test herbs, in addition to restoring glucose and lipid homeostasis. Furthermore, the *Labiate* herbs rosemary and sage were documented in a recent study[105] as activators of the human PPAR-γ, possibly by their active constituents carnosol and carnosic acid.

What provides a potential validation for using traditional herbs as antidiabetics are the results of the screening study attained by Rau *et al*[106]. Among 52 ethanolic extracts, obtained from traditionally used herbs, the researchers found amazingly that nearly half the extracts activated PPAR-γ and 14 activated PPAR-α, while three of them were pan-PPAR activators, findings which were considered exceptionally high hit rate. The most active extracts were those of *Alisma plantago aquatica* (ze xie/European waterplantain), *Catharanthus roseus* (Madagascar periwinkle), *Acorus calamus* (sweet calamus), *Euphorbia balsamifera* (balsam spurge), *Jatropha curcas* (barbados nut), *Origanum majorana* (marjoram), *Zea mays* (corn silk), *Capsicum frutescens* (chilli) and *Urtica dioica* (stinging nettle).

The effect of the North American ginseng (*Panax quinquefolius*), a close relative to *Panax ginseng,* on glucose control was verified in a study by Banz *et al*[107], using male Zucker diabetic fatty rats. The findings showed that ginseng had marked effects on the expression of genes involved in PPAR actions and triglyceride metabolism. The authors encourage further research to determine the therapeutic value of this medicinal herb in treating human diabetes.

Green tea (*Camellia sinensis* L.) leaf extract on triglyceride and glucose homeostasis was evaluated in a fructose-fed insulin-resistant hamster model[108]. Supplementation of the green tea epigallocatechin gallate-enriched extract improves lipid and glucose homeostasis and increases the expression of PPAR-α and PPAR-γ proteins. These data suggest that intake of the green tea extract increases insulin-sensitivity, at least through boosting up PPAR.

Clematis species (*Ranunculaceae*) have been used continuously as anti-inflammatory agents by indigenous Australians. During examining the ethanol extract of *C. pickeringii*, *C. glycinoides* and *C. microphylla*, on COX-1, COX-2 and 5-lipoxygenase[109], the authors found that *Clematis pickeringii* has activated significantly the protein expression of both PPAR-α and PPAR-γ. These results merit the study of the potential antidiabetic mechanism(s) of these species. In a search for a natural PPAR-γ agonist, Atanasov *et al*[110] reported that the natural product honokiol from the traditional Chinese herbal drug Magnolia bark stimulates the basal glucose uptake in a comparable pattern to pioglitazone, but without inducing adipogenesis.

INCREASING ADIPONECTIN RELEASE

An additive role for PPAR-γ in the manipulation of glu-

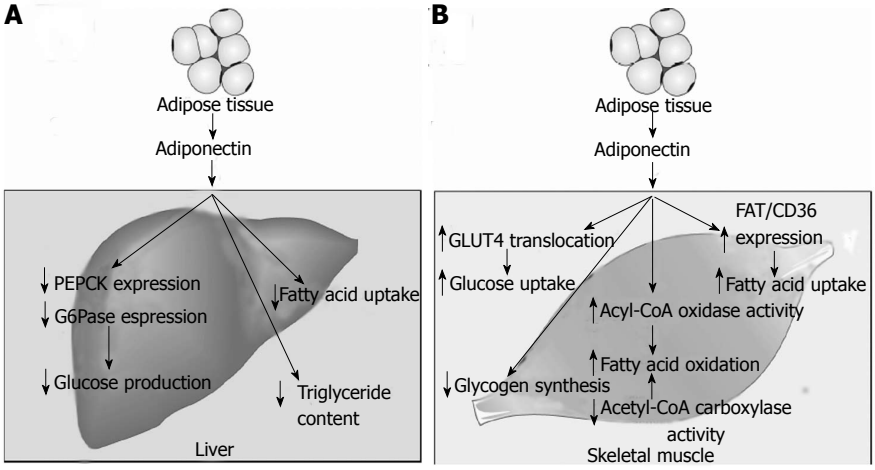

Figure 3 Effects of adiponectin on carbohydrate and lipid metabolism in liver and skeletal muscle (c.f. www.jpp.krakow.pl/.../articles/08_article.html[119]). FAT: Fatty acid translocase.

cose homeostasis is the modulation of adipocytokines. These bioactive substances are produced and secreted from adipose tissues which happened to be an endocrine organ[111]. Adipocytokines play central role in body insulin resistance, where the dysregulation of their production participates in the pathophysiology of the metabolic syndrome.

The plasma level of adiponectin is documented to be lower in patients with diabetes[112] and ischemic heart disease[113] than their age- and body mass index (BMI)-matched nondiabetic mates. This fact was further documented in a screening study on Japanese patients with type 2 diabetes and their age- and BMI-matched nondiabetic control subjects, and is attributed to the genetic mutation of the adiponectin gene associated with metabolic syndrome, including insulin resistant diabetes and atherosclerotic disease[114].

Consequently, adiponectin possesses antidiabetic and antiatherogenic properties[115]. The antidiabetic mechanism(s) involves enhancement of glucose uptake in skeletal muscles, activation of IRS-1-mediated phosphatidylinositol-3 kinase[115,116], acceleration of muscle β-oxidation *via* the activation of AMP-kinase[117], and suppression of hepatic glucose production[118,119]. These events are summarized in Figure 3.

Normal adiponectin plasma level is under the influence of PPAR-γ, where stimulation of this nuclear receptor potentiates its direct binding with the PPRE responsive element in the promoter region of the adiponectin gene, thus, enhancing the production and secretion of this cytokine.

Clinical studies now assure the beneficial effects of some plants in controlling glucose disorders. For instance, the extract of white-skinned sweet potato *Ipomoea batatas* (Caiapo) has been evaluated in type II diabetic patients, and was shown to control plasma glucose level through increasing insulin sensitivity along with the level of adiponectin[120]. Moreover, the mushroom *Agaricus blazei Murill* (ABM) extract was documented to improve insulin resistance and to elevate adiponectin level in subjects with type II diabetes receiving metformin and gliclazide; the latter cytokine provides at least one potential antidiabetic mechanism of this plant[121]. Concerning the antiatherogenic property of adiponectin, the extract of *Aronia melanocarpa* E. was administered to forty-four patients who survived myocardial infraction and have received statin therapy[121]. Compared to placebo, the chokeberry flavonoid extract increased adiponectin level, among other corrected parameters that nominate this extract as an adjunct therapy in patients with ischemic heart disease.

Momordica charantia owes its anti diabetic effect to its insulin-like action[122,123], antioxidant property[124,125], and glucose uptake enhancement[79]. The latter mechanism could be explained by the finding of Ryu *et al*[126], who stated that *Momordica*-induced glucose uptake is accompanied by, and may be the result of, increased adiponectin secretion, which is the communication between adipose tissue and skeletal muscle.

Adiponectin was also induced by the oral ingestion of *Plum ekisu*, tested on insulin- resistant obese Wistar fatty rats[127]. Dried plum is highly consumed in the West as a healthy food and is used in India as medicine to protect against geriatric related diseases, possibly by their phenolic compounds. Rats receiving plum concentrated juice showed better insulin sensitivity, increased PPAR-γ mRNA expression and marked elevation in adiponectin. These mechanisms are tightly correlated, where stimulation of PPAR-γ initiates the cycle, leading to increased production of adiponectin and alleviation of insulin sensitivity.

Apart from the multiple machineries by which *Salacia reticulate* extract mediates its antidiabetic effect[42], increasing the release of adiponectin adds also to these effects, which make it useful in the treatment of diabetes mellitus, insulin resistance and other metabolic diseases[128].

GLYCOGEM METABOLISM

Another cornerstone in controlling blood glucose level is the "hepatic output", which correlates with liver metabolic functions, including lipogenesis and glycogenesis. The latter process is precisely adjusted by adequate levels of insulin[129], which stimulates glycogen synthase and inhibits glycogen phosphorylase, resulting in the proper glycogen deposition in various tissues, especially skeletal

muscle. Since glycogen is the storable form of glucose, thus, insulin inadequacy initiates muscle protein breakdown to provide gluconeogenic precursors that could be the reason behind diabetes-induced weight loss. Consequently, compounds that enhance glycogen formation and/or increase its content in liver and muscles are considered beneficial anti-diabetic agents.

In an attempt to elucidate the anti-diabetic mechanism(s) of some plants used in the management of diabetes, it was found that *Caralluma sinaica* L. (*Asclepiadaceae*)[130] found in south Hejaz, west of Saudi Arabia, and Sinai region of Egypt, showed an anti-diabetic effect. This plant exerts its effect through opposing the STZ-induced glycogen depletion in liver and muscle, and by reversing weight loss in the diabetic rabbits, results that may be promoted by the realease of insulin.

Panax ginseng is suggested to induce glycemic control by sparing insulin and increasing glucose transport. Various preparations of *Panax ginseng* have been shown to upregulate insulin and non-insulin stimulated glucose transport in different animal models and cell lines[131-133]. Furthermore, *Momordica charantia* was able to renovate β-cells in the pancreas or partially destroyed ones[85] and to stimulate pancreatic insulin secretion[134]. These insulin-like properties[122,123] kindle glycogen storage by the liver and improve peripheral glucose uptake[126]. The anti-diabetic property of the aqueous extract of *Tamarindus indica* seed (*T. indica*) was also verified in a type I and II experimental models[135]. This action is mediated by restoring glycogen levels in liver and skeletal muscles, as well as inhibiting the glucose-6-P-ase activity. Increasing insulin level, however, was limited only to the type I model. Recently in 2012 the aqueous extract tested on STZ-induced diabetes showed that complex mechanisms stand behind its antidiabetic effect, such as β-cell neogenesis, calcium handling, as well as increasing GLUT-2 and GLUT-4. These findings show the scope for formulating a new herbal drug for diabetes therapy[136].

INSULINOMIMETIC AND INSULINOTROPIC EFFECT

In 2007, Eidi *et al*[137] studied again the hypoglycemic effect of the fenugreek seeds which was previously found to inhibit α-glucosidase, and they reported that the ethanolic extract significantly decreased serum glucose, triacylglycerol, cholesterol, urea, uric acid, AST, and ALT, whereas it increased serum insulin levels in treated STZ-induced diabetic rats. As a result, the authors concluded that fenugreek seeds extract encompasses antidiabetic activities similar to that observed for glibenclamide used as a standard drug. Eidi *et al*[138] have tested also the possible antidiabetic mechanism of Garlic (*Allium sativum*, *Liliaceae*) which is a common spice flavoring agent believed to lower plasma glucose level in diabetic patients. Therefore, using STZ-induced diabetic rats, they found that the alcoholic extract of garlic potentiates the insulin effect by increasing its pancreatic secretion from existing β-cells or its release from bound insulin. These effects are attributed mainly to the allicin-type compounds[139,140] which are disulphide compounds that can react with endogenous thiol containing molecules, such as cysteine, glutathione, and serum albumins to spare insulin from SH inactivation[141]. In another study, using STZ/high-fat diet Sprague Dawley rats, a comparison between the anti-diabetic effects of dietary freeze-dried ginger and garlic, was conducted. The experimental results revealed that ginger and garlic are insulinotropic rather than hypoglycemic, and that the anti-diabetic effects of ginger are better than those of garlic[142]. Using the same rat model, Islam *et al*[143] investigated the insulinotropic effect of dietary red chilli (*Capsicum frutescens* L.) in low and high concentrations and revealed that 2% dietary red chilli is insulinotropic rather than hypoglycemic at least in this experimental condition.

The effects of the ethanol extract and five partition fractions of the *Asparagus racemosus* root and *Ocimum sanctum* leaf were evaluated on insulin secretion together with exploration of their mechanisms of action. The ethanol extract and each of the hexane, chloroform and ethyl acetate partition fractions stimulated insulin secretion in isolated perfused rat pancreas, isolated rat islet cells and clonal β-cells. These findings reveal that constituents of both extracts have wide-ranging stimulatory effects on physiological insulinotropic pathways[144]. Similarly, the aqueous extract of *Asparagus adscendens* induced a significant increase in glucose-dependent insulinotropic actions in the clonal pancreatic β-cell line, enhanced glucose uptake in 3T3-L1 adipocytes and decreased starch digestion *in vitro*. These outcomes revealed that *Asparagus adscendens* possesses insulinotropic, insulin-enhancing activity and inhibitory effects on starch digestion[145].

The antihyperglycemic action of *Stevia rebaudiana (Asteraceae)* Bertoni leaves extracts were confirmed using type II diabetic Goto-Kakizaki rats[146]. The large quantities of the glycoside stevioside in the *Stevia rebaudiana* leaves are responsible for the anti-hyperglycaemic, insulinotropic, and glucagonostatic actions of the herb; results which support the traditional use of this herb in the treatment of diabetes in Paraguay and Brazil. Similar efficacy pattern was obtained by the crude extract of *Viscum album* (*V. album*) leaf which produced about 35.3% decrease in glucose concentration in STZ-induced diabetic rats and stimulated insulin secretion by about 81.5%. Although, only a subtle suppression in glucagon level was observed, yet it was significant. Thus, the *V. album* leaves extract may possess antihyperglycaemic, insulinotropic, and possibly, mild glucagonostatic agent(s) and may, therefore be a candidate for the anti-diabetic drugs[147].

Butanol extract of *Zizyphus spina-christi* L. (*Rhamnaceae*) leaves and its major saponin glycoside, christinin-A, were tested to evaluate their effect on serum glucose and insulin levels in non-diabetic control, type- I and type- II diabetic rats[148]. Both the extract and the saponin compound improved the oral glucose tolerance , potentiated glucose-induced insulin release, reduced the serum glucose level and increased the serum insulin level of non-diabetic control

and type-Ⅱ diabetic rats, but not those of type-Ⅰ diabetic rats. They also enhanced the glucose lowering and insulinotropic effects of glibenclamide. The data pointed to the insulinotropic capacity of the tested plant.

Furthermore, in traditional Nepalese folk medicine the leaf extract of the annual herb *Biophytum sensitivum* is used for the treatment of hyperglycemic patients. This property was documented by Puri[149] who ascribed the leaf extract hypoglycemic response to its insulinotropic effect, where he found that the tested extract induces the release and/or synthesis of insulin.

Similar insulinotropic effect was presented by pterostilbene, a flavonoid constituent derived from the wood of *Pterocarpus marsupium,* a herb used in the Indian folk medicine; the active compound causes pancreatic β-cell regranulation[150]. Marsupin, pterosupin and liquiritigenin obtained from the plant showed also antihyperlipidemic activity. Moreover, epicatechin, an active principle, has been found to be insulinogenic, enhancing the insulin release and the conversion of proinsulin to insulin *in vitro.* Like insulin, epicatechin stimulates oxygen uptake in fat cells and increases glycogen content of rat diaphragm. Aloe vera (Liliaceae) exerts its hypoglycemic effect in rats by its bitter principle through stimulating the release of insulin from the β-cells of Langerhans as documented after the use of single, as well as repeated doses of the bitter principle of the Aloe vera in diabetic rats[150]. Other insulinptropic Indian herbs include *Acacia Arabica* (Babhul), *Eugenia jambolana* (Indian gooseberry), *Annona squamosa* (sugar apple), *Caesalpinia bonducella* (Fevernut), *Hibiscus rosa-sinesis* (Gudhal), *Scoparia dulcis* (sweet broomweed) and *Tinospora crispa*[96].

Patel *et al*[151] presented a thorough review on 65 species of plants with insulinomimetic or insulin secretagogue. Most of these belong to the family Leguminoseae, Lamiaceae, Liliaceae, Curcubitaceae, Asteraceae, Moraceae, Rosaceae and Araliaceae. The most active plants are Allium sativum, Gymnema sylvestre, Citrullus colocynthis, Trigonella foenum greacum, Momordica charantia and Ficus bengalensis. *Citrullus colocynthis* (Cucurbitaceae) pulp ethanolic extract at 300 mg/kg, *p.o.* was found to increase insulin and decrease plasma glucose levels significantly in alloxan-induced diabetic rats. Moreover, the aqueous extract also showed a dose-dependent increase in the insulin release from isolated islets, as well as other different extracts, such as crude extract, aqueous, alcoholic, purified extract and beta-pyrazol-1-ylalanine, the major free amino acid derivative present in the seeds[151].

Trigonella foenum-graecum has been observed to cause glucose-induced insulin release *in vitro* and *in vivo*. 4-Hydroxyleucine, a novel amino acid from fenugreek seeds, increased glucose-stimulated insulin release from isolated islet cells in rats, mice and humans, and possibly hydroxyisoleucine which represents 80% of the free amino acids in *Trigonella foenum-graecum* seeds. The extracts, powder and gum of *Trigonella foenum-graecum* seeds may help to improve insulin sensitivity presumably due to the presence of fibers, which slow the metabolism of carbohydrates, resulting in reduced insulin levels and lowered blood glucose[151].

Alcoholic extract of *Gymnema sylvestre* (Asclepiadaceae) stimulated insulin secretion from the rat islets of Langerhans and several pancreatic β-cell lines. In another study, the oral administration of the water-soluble leaves extract (400 mg/d) to 27 IDDM patients on insulin therapy lowered their fasting blood glucose and their insulin requirements. In type II diabetic patients on *Gymnema sylvestre* supplementation the pancreatic β-cells is suggested to be regenerated or repaired as supported by the raised insulin levels in their serum. This assumption has been concluded also when the number of the pancreatic islet and β-cells, as well as insulin levels wre increase after oral administration of the aqueous extract to diabetic rats. Gymnemic acid molecules dihydroxy gymnemic triacetate had the ability to release the insulin by the stimulation of a regeneration process and revitalization of the remaining β-cells. The aqueous extract of *Gymnema sylvestre* leaves stimulated insulin secretion from mouse cells and isolated human islets *in vitro*, without compromising cell viability[151].

Among the glucagonostatic Indian herbs are *Caesalpinia bonducell, Coccinia indica, Boerhavia diffusa, Enicostema littorale and Murraya koenigii.* These herbal extracts increase glycogenesis, restore the activities of lipoprotein lipases and decrease the glucose-6-phosphatases, thereby inhibiting the glycogenolysis, and gluconeogenesis processes, as well as increasing the peripheral glucose utilization[150].

In a recent study, the ethanolic extract of ethanolic extract of Schizandra arisanensis and its isolated constituents provided some insulinotropic effects by ameliorating cytokine-mediated β-cell death and dysfunction *via* anti-apoptotic and insulinotropic actions[152].

ELEVATION OF D-CHIRO-INOSITOL

D-chiro-inositol (D-CI) is a rare inositol isomer present in inositol phosphoglycans (IPGs) which are putative insulin second messengers. These mediators are released from cell membranes, cells and human blood by insulin and other growth factors[153] and mediate some, but not all, of insulin actions[154]. D-CI acts as an insulin surrogate where it exhibited an anti-hyperglycaemic effect *in vivo*[155], and enhanced insulin-induced glucose incorporation into glycogen, *in vitro*[155]. Albeit, D-CI modulates favorably insulin's effect on peripheral glucose utilization under physiological conditions, Kennington *et al*[156], reported abnormal low or immeasurable levels of D-chiro-inositol in urine and muscle from type Ⅱ diabetic patients, suggesting that D-CI deficiency might be related to the insulin resistance. Accordingly, D-chiro-inositol when administered to STZ diabetic rats[157] and humans[158] decreased hyperglycemia and enhanced glucose disposal (Table 1).

Cucurbita ficifolia is traditionally used in Asia for the management of diabetes; however, its mechanism of action was not clarified. In 2006, Xia *et al*[159] found that *C. ficifolia* may be a natural source of D-CI which is present in fairly high levels in this plant and may be the cause for its anti-diabetic character. Using STZ diabetic rats,

Table 1 Following is a list of plants that are reported to have insulin mimetic or insulin secreatory action

1 Abies pindrow (Pinaceae)	34 Momordica charantia (Cucurbitaceae)
2 Aegle marmelos (Rutaceae)	35 Mucuna pruriens (Leguminosae)
3 Agrimony eupatoria (Rosaceae)	36 Nigella sativa oil (Ranunculaceae)
4 Aloe barbadensis (Liliacea)	37 Olea europia (Oleacea)
5 Annona squamosa (Annonacea)	38 Panax ginseng (Araliaceae)
6 Averrhoa bilimbi(Oxalidacea)	39 Pandanus odorus (Pandanaceae)
7 Bixa orellana (Bixaceae)	40 Parinari excelsa (Chrysobalanaceae)
8 Boerhaavia diffusa (Nyctaginaceae)	41 Prunella vulgaris (Labiatae)
9 Bougainvillea spectabilis (Nyctaginaceae)	42 Psidium guajava (Myrtaceae)
10 Brassica nigra (Cruciferae)	43 Pterocarpus marsupium (Fabaceae)
11 Camellia sinensis (Theaceae)	44 Radix glycyrrhizae (Fabaceae)
12 Capsicum frutescens (Solanacea)	45 Radix rehmanniae (Scrophulariaceae)
13 Catharanthus roseus (Apocyaceae)	46 Rehmania glutinosa (Scrophulariacea)
14 Cinnamon zeylaniucm (Lauraceae)	47 Ricinus communis (Euphorbiaceae)
15 Coccinia indica (Cucurbitaceae)	48 Salvia lavandifolia (Lamiacea)
16 Cornus officinalis (Cornaceae)	49 Sarcopoterium spinosum (Rosaceae)
17 Elephantopus scaber (Asteraceae)	50 Scoparia dulcis (Scrophulariaceae)
18 Enicostemma littorale (Gentianaceae)	51 Selaginella tamariscina (Selaginellaceae)
19 Ephedra distachya (Ephedraceae)	52 Semen coicis (Ggramineae)
20 Eriobotrya japonica (Rosaceae)	53 Smallanthus sonchifolius (Asteraceae)
21 Euccalyptus globulus (Myrtaceae)	54 Stevia rebaudiana (Asteraceae)
22 Fermented unsalted soybeans	55 Swertia chirayita (Gentianaceae)
23 Ficus bengalensis (Moraceae)	56 Swertia punicea (Gentianaceae)
24 Genistein	57 Syzygium cumini (Rutaceae)
25 Ginkgo biloba (Ginkgoaceae)	58 Tabernanthe iboga (Apocynaceae)
26 Helicteres isora (Sterculiaceae)	59 Teucrium polium (Lamiaceae)
27 Hibiscus rosa (Malvacea)	60 Tinospora crispa (Menispermaceae)
28 Hordeum vulgare (Gramineae)	61 Tribuluks terrestris (Zygophyllaceae)
29 Ipomoea batata (Convolvulaceae)	62 Urtifca dioica (Urticaceae)
30 Juniperus communis (Pinacea)	63 Vinca rosea (Apocyanacea)
31 Lausena anisata (Rutacea)	64 Zingiber officinale (Zingiberaceae)
32 Lepechinia caulescens (Lamiaceae)	65 Zizyphus spina-christi (Rhamnaceae)
33 Medicago sativa (Fabaceae)	

the fruit extract of *C. ficifolia* lowered the blood glucose level and increased the hepatic glycogen content, and the plasma insulin. Furthermore, the same extract improved the blood glucose tolerance when an oral glucose tolerance test was performed in fasted diabetic and normal rats. The results of this experimental animal study lend a pharmacological credence to the suggested folkloric uses of the plant in the management and control of diabetes mellitus, owing to its high content of the insulin-mimetic, D-CI. This compound is also the active constituent of *Fagopyrum tataricum* L. Gaench that possesses an insulin-like bioactivity. Yao *et al*[160] illustrated that the D-CI-enriched extract of *Fagopyrum tataricum* lowered plasma glucose, C-peptide, improved glucose tolerance, and enhanced insulin immunoreactivity in KK-Ay mice.

INCRETIN MIMETICS AND INCRETIN ENHANCERS

A new target for the management of type Ⅱ DM is the gut hormone, GLP-1 (incretin) which is secreted as a riposte to meal. This hormone maintains glucose balance by different routes where it stimulated glucose-dependent insulin secretion, delays gastric emptying, inhibits glucagon secretion, and protects or even exerts a trophic effect on β-cells, as illustrated in Figure 4. However, the hormone is rapidly degraded by dipeptidylpeptidase-4 (DPP-4), an enzyme that inactivates also glucose-dependent insulinotropic peptide (GIP)[161]. Thus, the aim in pharmaceutical research is either to inhibit DPP-4, to prolong GLP-1 duration of action, or to use compounds that can partially resist DPP-4. These compounds are either incretin-mimetic agents that simulate GLP-1 (exenatide) or a long-acting incretin analogue (liraglutide)[162]. Incretin, thus, challenged the pharmaceutical researchers to find a nutraceutical compound that could modulate this hormone.

In this regard, recent data reported that inulin-type fructans extracted from chicory roots regulated glucose and lipid homeostasis by enhancing colon production of GLP-1. Therefore, Urías-Silvas *et al*[163] evaluated the fructans extracted from *Agave tequilana* Gto. and *Dasylirion spp.* on glucose and lipid metabolism. The data showed a decrease in body weight of mice fed fructans-containing diet, besides the restoration of glucose and lipid levels. As a conclusion, the authors reported that fructans from any botanical origin initiates the production of GLP-1 from colon, and it is responsible for the amendment of glucose and lipid metabolism.

The potential antihyperglycemic activity of an ethanolic extract of *Artemisia dracunculus* L., called Tarralin, in diabetic mice was studied by Ribnicky *et al*[164]. This extract posed a positive antidiabetic action, *via* decreasing the mRNA expression of phospho-enolpyruvate carboxykinase (PEPCK), the main catalyzing enzyme in gluconeogenesis, and increasing the binding of incretin (GLP-1) to its receptor.

Impairment of β-cell function results from the improper insulin/IGF-1 signaling cascade through insulin receptor substrate-2 (IRS-2). Thus, induction of IRS-2 in β-cells can potentiate its function and mass, an effect that was attained by the GLP-1 receptor agonist, exendin-4, through elevation of intracellular cyclic Adenosine mono phosphate (cAMP)[165]. GLP-1/exendin-4 is known to enhance glucose-stimulated insulin secretion and to increase β-cell transcription factors, such as pancreas duodenum homeobox-1 (PDX-1), to promote β-cell growth and survival[165]. These promising actions of exendin-4 were associated with the induction of IRS-2, the pathways of

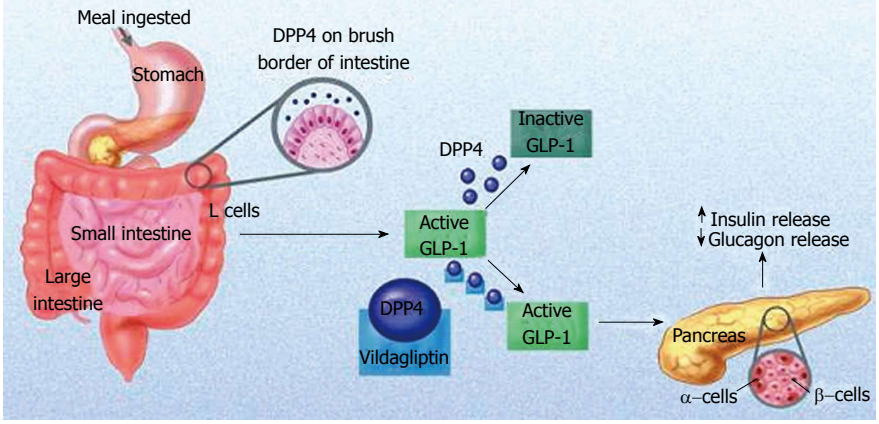

Figure 4 Effects of active glucagon-like peptide-1 and dipeptidylpeptidase-4 on glucose homeostasis [(c.f. www.medscape.com) Am J Health Syst Pharm, 2007]. GLP-1: Glucagon-like peptide-1; DPP-4: Dipeptidylpeptidase-4.

which play an important role in β-cell expansion, and augmentation of insulin secretion.

In a recent study, Park *et al*[165] examined the potential antidiabetic mechanism(s) of six herbs used in Chinese medicine to treat diabetes. These herbs were *Galla rhois*, *Rehmanniae* radix (*Rehmannia glutinosa* Liboschitz var. *purpurea* Making), *Machilus* bark (*Machilus thynbergii* Siebold et Zuccarini), *Polygonatum* radix (*Polygonatum odoratum* Miller Druce), *Ginseng* radix (*Panax ginseng* C.A. Meyer), and *Scutellariae* radix (*Scutellariae baicalensis* Georgi). The authors reported that these herbs induced IRS-2 in rat islets, improved glucose-stimulating insulin secretion and increased β-cell survival. In addition, *Rehmanniae* radix, *Ginseng* radix and *Scutellariae* radix were found to mediate insulin secretion through cAMP/PKA-dependent and/or -independent pathways. These herbs also induced PDX-1 and glucokinase, besides the increased expression of IRS-2. Activation of glucokinase could vindicate the enhancement of glucose stimulated insulin secretion, while induction of PDX-1 was associated with β-cell proliferation[165]. The promising effects of *Ginseng* radix and *Scutellariae* radix could be ascribed to the active constituents, ginsenosides and the flavonoid baicalein, respectively. The finding, hence, point to the presence of natural agents that possess incretin-like action and that mimic exendin-4.

ROLES OF ENDOGENOUS OPIOIDS ON GLUCOSE HOMEOSTASIS

Apart from the well known pharmacological actions of opiates, their binding to opioid receptors located in the pancreatic β-cells and their ability to manipulate diabetic disorders has been documented[166]. The opioid peptide β-endorphin, secreted from the adrenal gland[167] has been shown to induce insulin secretion also *via* activating the pancreatic opioid receptors[168]. Besides, this peptide also was found to regulate glucagon and somatostatin release from isolated islets of Langerhans[169,170]. Therefore, increased glucose utilization and decreased hepatic output may be a consequence to the increased release of β-endorphin and the activation of peripheral opioid μ-receptors (MOR). Activation of these receptors might enhance the expression of muscle GLUT and/or reduce hepatic gluconeogenesis at the gene level[171]. MOR-induced glucose uptake is accomplished by increased gene expression of GLUT-4 *via* a phospholipase C-protein kinase (PLC-PKC) dependent pathway[172]. It has also been observed that stimulation of α_1-adrenoceptors in the adrenal gland provokes the secretion of β-endorphin[173] depending also on the PLC-PKC pathway[174,175].

In STZ-diabetic rats, Hsu *et al*[176] stated that β-endorphin biosynthesis increases in the adrenal gland, along with the opioid μ-receptors gene expression[177]; events that may compensate for the glucose disturbed homeostasis. Therefore, development of pharmaceutical or nutraceutical agents that target β-endorphin secretion and/or stimulate peripheral MOR, *via* an insulin-independent action, donates a new hit that may have merit in glycemic control.

Since application of herbal plants or their products in the management of glucose metabolism is extensively searched, investigations were conducted to study their potential effect on β-endorphin and peripheral opioid μ-receptor. One of the early studies in this regard, is that carried out by Hsu *et al*[178] using caffeic acid, which is a phenolic compound contained in the fruit of *Xanthium strumarium*. After an intravenous injection of caffeic acid into diabetic rats of both STZ-induced and insulin-resistant models, a dose-dependent decrease in the plasma glucose was observed; moreover, it increased the glucose uptake in isolated adipocytes. This trial was followed by another study[179] to verify the mechanism of caffeic acid using STZ-induced diabetic rat. In this experiment, caffeic acid increased the release of β-endorphin from the adrenal gland through the activation of α_{1A} -adrenoceptors. These receptors were adopted as one of the antidiabetic mechanisms of andrographolide present in the leaves of *Andrographis paniculata* (*Burm. f.*) Nees. Using cultured myoblast C2C12 cells, andrographide was documented to activate these adrenoceptors *via* PLC-PKC dependent pathway to fascilitate glucose uptake[180]. Inhibiting α-glucosidase[19] and increasing GLUT-4 mRNA[91] were other mechanisms mediated by this active constituent. A recent study by Yu *et al*[181] validated the andrographolide-induced α_{1A}-adrenoceptors activation in type I diabetes-like animals, which enhance β-endorphin release that in turn stimulates the opioid micro-receptors. The authors reported also an increased expression of the GLUT-4 in

soleus muscle and a reduced expression of PEPCK in liver, effects that may explain the registered reduction in hepatic gluconeogenesis and enhancement of the glucose uptake. A similar pattern was recorded to rationalize the antidiabetic mechanisms of myricetin, the active principle of *Abelmoschus moschatus* (*Malvaceae*) using STZ-diabetic rats[182]. Myricetin, in insulin-deficient animals, activated peripheral MOR, in response to increased β-endorphin secretion. Opioid μ-receptor activation is held responsible for the enhancement of muscle *GLUT-4* gene expression and the attenuation of hepatic *PEPCK* gene expression observed in these myricetin-treated diabetic animals.

Another study was carried out to investigate the antihyperglycemic mechanisms of syringin, an active principle purified from the rhizome and root parts of *Eleutherococcus senticosus* (*Araliaceae*). STZ-diabetic rats showed an increased release of β-endorphin from the adrenal medulla after receiving a bolus intravenous injection of syringing[183]. Niu *et al*[183] concluded that the decreased plasma glucose, in the diabetic rats lacking insulin, is mediated by the effect of β-endorphin on peripheral micro-opioid receptors.

The antidiabetic potency of isoferulic acid, one of the active components in *Cimicifugae rhizoma*, is attained by lowering glucose level, improving glucose uptake in skeletal muscle along with inhibiting hepatic gluconeogenesis in rats with an insulin deficiency[184]. For precise clarification of its mode of action, Liu *et al*[185] tested its impact on the α_{1A}-adrenoceptor/β-endorphin system in a STZ diabetic rats. Formerly, Liu *et al*[186] showed that isoferulic acid can activate α_{1A}-adrenoceptor, leading to increased glucose uptake into cultured mouse myoblast C2C12 cells; however, the role of β-endorphin in the plasma glucose-lowering action of isoferulic acid is still unclear. In this work[187], the authors proved that isoferulic acid increased β-endorphin level *via* affecting α_{1A}-adrenoceptors, leading to stimulation of peripheral opioid receptors, resulting in increased expression of GLUT-4, and reduction of hepatic gluconeogenesis. Moreover, the same laboratory examined the mechanism(s) of plasma glucose lowering action of puerarin in STZ-induced diabetic rats and concluded that this isoflavone can act as a ligand to activate α_{1A}-adrenoceptors on the adrenal gland to initiate the aforementioned cascades[187].

ANTIOXIDANTS

In the course of normal aerobic metabolism, oxygen free radicals are produced during the reduction of oxygen into water. Since these radicals are inherently toxic, cells have built up defense systems to quench them. These defense systems are either enzymatic, including superoxide dismutase (SOD), catalase (CAT), glutathione-S-transferase (GST), glutathione reductase and glucose-6-phosphate dehydrogenase, or non-enzymatic, such as vitamins C and E as well as thiols, especially the reduced glutathione molecule[188]. If these oxygen free radicals, referred as reactive oxygen species (ROS), are excessively produced and are able to overwhelm the endogenous defense systems, then a state of oxidative stress originates. These ROS can bind with most normal cellular components to "pair up" its unpaired electrons; thus, they react with the unsaturated bonds of membrane lipids, denature proteins, and attack nucleic acids, resulting in cellular oxidative damage[189]. It has been suggested that oxidative stress plays an important role in many diseases, including DM, since hyperglycemia alone could not be exclusively responsible for the later complications associated with the disease[190]. ROS are considered an important independent risk factor that is developed in DM *via* what is known as "auto-oxidative glycosylation, a process which is relevant at elevated blood glucose level[191]. Hyperglycemia may also raise aldose reductase which depletes NADPH cell stores, thus perturbing defense system[192]. The elevated blood glucose level causes also non-enzymatic glycation of plasma proteins[193] leading to the production of more powerful oxidizing species[194]. Furthermore, it induces mitochondrial superoxide overproduction, which influences again the previous steps[195], creating what is known as "hyperglycemic memory"[196]. As oxidative stress plays a key role in insulin-resistance and β-cell dysfunction[197], ample of data allows the hypothesis that a viscous circle exists between hyper-insulinemia and free radicals that may be responsible for deterioration of insulin action[198], possibly *via* down-regulating insulin-mediated glucose uptake[199].

Given that antioxidants are favorably used as complementary agents in diabetic patients to reduce diabetic complications[200-203], attempts to discover antioxidants as useful drug candidates to combat diabetic complications are going on persistently.

Of the plants that exert their positive effects in experimental DM through their antioxidant characters are *Ficus carica via* restoring levels of fatty acids and vitamin E[204], as well as some Indian herbs, *viz*., *Allium sativum, Azadirachta indica, Momordica charantia,* and *Ocimum sanctum extracts,* which not only lowered the blood glucose level, but also inhibited the formation of lipid peroxides, reactivated the antioxidant enzymes, and restored levels of GSH and metals[124]. These results may authorize the use of the aforementioned herbs in the prevention of diabetes-associated complications. In addition, *Momordica grosvenori,* a traditional medicinal herb in China used as a substitute sugar for obese and diabetic patients, was tested in alloxan-induced diabetic mice[205]. The plant corrected the altered glucose level and effectively regulated the immune imbalance in diabetic mice. The authors assigned these effects to the plant-induced upregulation of heme oxygenase-1 (HO-1) protein, which has anti-inflammatory activities and antioxidant properties.

The ethanolic extract of *Scutellaria baicalensis*, as well, proves its antioxidant role in a STZ-induced diabetic model, and enhances the antidiabetic effect of metformin[206]. In addition, in a study on the antioxidant and antiglycation properties of some traditional Chinese medicine used to treat DM, *Aralia taibaiensis* outperformed other extracts in most of the assays except for the inhibition of early glycation products formation which was

mostly inhibited by *Acanthopanax senticosus* extract[207]. The antioxidant and antiglycation activities of these extracts were correlated with their saponin content[207]. The aqueous extract of *Albizzia lebbeck* was also verified for its antioxidant property using alloxan-induced diabetic rats[208]. The authors registered that the extract rescued all altered parameters caused by alloxan which confirmed the ability of the herb to resist the oxidative insult.

The hypoglycemic and hypolipidemic effects of *Lycium barbarum* fruit extract, its crude polysaccharides (LBP) extract and purified polysaccharide fractions (LBP-X), were documented in alloxan-induced diabetic rabbits[209]. Although the hypoglycemic effect of LBP-X surpassed the other extracts, yet the latter exhibited stronger antioxidant activity because crude extracts were identified to be rich in antioxidants (*e.g.*, carotenoids, riboflavin, ascorbic acid, thiamine, nicotinic acid). In Li[210] has isolated *Lycium barbarum* polysaccharides (LBP), which are identified as one of the active ingredients of the fruits, and tested its capacity to stand the oxidative insult using a STZ-induced hyperglycemic model. The author found again that the LBP reinstated the STZ-induced abnormal oxidative indices, results that are in line with another study by Wu *et al*[211], who also studied the antidiabetic effects of these polysaccharides, using rats with NIDDM. The authors found that LBP can control blood glucose and modulate the metabolism of glucose, leading to a significant improvement of oxidative stress markers (SOD, MDA), in addition to its ability to decrease DNA damage, possibly *via* leveling off oxidative stress. These findings point to the potential protective effect of LBP against deleterious oxidative stress, hence, preventing the development of diabetic complications.

Additionally, *Strobilanthes crispus* (*Acanthaceae*), which is used traditionally for the treatment of several ailments including DM, has shown antihyperglycemic and antilipidemic properties when tested in STZ-induced diabetic rats. The antioxidant effect of the herbal hot water extract (fermented and unfermented) contributed possibly to its and polyphenol contents[212].

Clinically, the valuable antioxidant effect of the herbal medicine, *Silybum marianum* seed extract (silymarin), was confirmed in a randomized, double-blind, placebo-controlled, clinical study of 51 type Ⅱ diabetic patients[213], where this extract induced a marked improvement in the glycemic profile of these patients.

In an attempt to study the effect of some herbal components against free radicals, Xiong *et al*[214] assessed the protective effect of puerarin, an isoflavone purified from Chinese herb radix of *Pueraria lobata*, on hydrogen peroxide (H_2O_2)-induced rat pancreatic islets damage. The results emphasize that puerarin can preserve islet cells from the ROS-induced damage. Likewise, the extract of *Plantago depressa var. montata*. was able to correct glucose and lipid homeostasis and to restore redox status in alloxan-induced diabetic mice, effects that are probably due to its antioxidant and free radical scavenging properties[215].

Another herbal drug evaluated for its hypoglycemic and anti-oxidant activities is the dried roots of *Morinda officinalis,* which was tested in STZ-treated rats and resulted in a decrease in fasting glucose and lipid peroxide levels, along with the restoration of the assessed redox indices. The study concluded that *Morinda officinalis* has anti-diabetic and antioxidant potentials[216]. Similarly, *Amaranthus esculantus* grain and oil fraction were found effective as both antioxidant and anti-diabetic, suggesting their beneficial effect in correcting hyperglycemia and preventing diabetic complications[217].

In the Turkish folkloric medicine *Gentiana olivieri* Griseb. (*Gentianaceae*) is used as a hypoglycemic plant, an effect that was verified by a recent study[218]. The hypoglycemic effect was attributed to its main active constituent, isoorientin, a compound that was documented for its favorable action on glucose homeostasis[219] partly *via* saving β-cells from oxidative damage by virtue of its potent antioxidant properties. Additionally, this compound may sensitize the insulin receptor to insulin or stimulate the stem cell of islets of Langerhans in pancreas of STZ-induced diabetic rats to restore plasma level of insulin[219]; however, these assumptions need to be tested.

Moreover, the ability of ginseng to scavenge free radicals is thought to add to its antidiabetic mechanisms[220]. Ginseng was found to decrease the rate of monosaccharide auto-oxidation, to elevate the activity of defence enzymes as SOD; and directly eliminate the superfluous free radicals. The same hold true for garlic (*Allium sativum* L., *Liliaceae*) which mediates its antidiabetic action by acts by its antioxidant character and by increasing insulin secretion[221].

The methanolic extract of *Phyllanthus amarus* (*Euphorbiaceae*), used traditionally in Indian herb medicine, was found to have a potent antioxidant activity added to its antihyperglycemic efficacy tested in alloxan-induced diabetic rats[222]. Other plants known for their antioxidant properties include *Capparis deciduas, Camellia sinensis, Emblica officinalis, Ficus bengalensis, Musa sapientum and Punica granatum*[151]. Additionally, the antidiabetic effects of fruit of *Vaccinium arctostaphylos* L. (Ericaceae), which is traditionally used in Iran for improving of health status of diabetic patients, was found to encounter several machinaries among which were the notable rising of the erythrocyte superoxide dismutase (57%), glutathione peroxidase (35%) and catalase (19%) activities of the alloxan-treated rats[223].

Hyperglycemia-induced aldose reductase activation results in the depletion of NADPH which is required for GSH reductase, hence, altering endogenous defense system. Therefore, inhibitors of aldose reductase could offer new approaches for the treatment of diabetes. Feng *et al*[224] reported in his study that some herbal active constituents, *viz*., flavonoid compounds and their derivates, have the ability to inhibit the activity of this enzyme, such as *quercetin, silymarin, puerarin,* and others. In addition, some *Salacia* root species possess this function, for example, the crude methanolic extract and ethyl acetate soluble fractions of *S. oblonga* showed inhibitory activity on rat lens-derived

aldose reductase[43]. In addition, the extract of *S. reticulata* stems, with its active constituent mangiferin, exhibited aldose reductase inhibitory activity[225], as well as the aqueous methanolic extract of *S. chinensis*[45].

CONCLUSION

From the previous data reviewed in the current article, it is obvious that herbs and/or their active constituents could attack several pathways of the hyperglycemic process. The multi-modes of their action allow them to outperform the conventional diabetic agents, besides the cost effectiveness and higher safety profile. These plants could be used as valuable therapeutic agents or as add-on conventional therapies for controlling glucose homeostasis. Although the evidenced-based therapeutic usage of many plants is scarce, the plants cited in this review are those reputed traditionally for their antidiabetic effect and that were verified, either experimentally or clinically.

Abstract

Neonatal diabetes mellitus (NDM) is a type of diabetes mellitus caused by genetic abnormality which develops in insulin dependent state within 6 mo after birth. HbA1c is widely used in clinical practice for diabetes mellitus as the gold standard glycemic control indicator; however, fetal hemoglobin (HbF) is the main hemoglobin in neonates and so HbA1c cannot be used as a glycemic control indicator in NDM. Glycated albumin (GA), another glycemic control indicator, is not affected by HbF. We reported that GA can be used as a glycemic control indicator in NDM. However, it was later found that because of increased metabolism of albumin, GA shows an apparently lower level in relation to plasma glucose in NDM; measures to solve this problem were needed. In this review, we outlined the most recent findings concerning glycemic control indicators in neonates or NDM.

Key words: Glycemic control; HbA1c; Glycated albumin; Fructosamine; 1,5-anhydroglucitol; Neonatal diabetes mellitus

Core tip: Neonatal diabetes mellitus (NDM) is a type of diabetes mellitus caused by genetic abnormality which develops in insulin dependent state within 6 mo after birth. Because fetal hemoglobin (HbF) is the main hemoglobin in neonates, HbA1c cannot be used as a glycemic control indicator in NDM. On the other hand, glycated albumin (GA), another glycemic control indicator, is not affected by HbF. We reported that GA can be used as a glycemic control indicator in NDM. In this review, we outlined the most recent findings concerning glycemic control indicators in neonates or NDM.

INTRODUCTION

To prevent chronic diabetic complications, it is necessary to try to achieve normoglycemia as much as possible. Previously, glycemic control used to be evaluated by plasma glucose or urinary glucose. However, these indicators fluctuate continuously due to factors such as dietary intake, and it was difficult to evaluate glycemic control correctly by taking measurements at a particular time. Therefore, hemoglobin A1c (HbA1c), which reflects mean plasma glucose during the past 1 to 2 mo, was introduced as a glycemic control indicator[1], and is now widely used in clinical practice for diabetes mellitus. HbA1c can be used to evaluate glycemic control status; if poor glycemic control is observed, it is possible to make additions, changes, *etc.* to the treatment of diabetes mellitus[2].

Large-scale researches such as the Diabetes Control and Complications Trial revealed that HbA1c is related to the development and progression of diabetic microan-

giopathy[3]. That is, the development and progression of diabetic microangiopathy can be prevented by maintaining excellent glycemic control using HbA1c as an indicator. Recently, it also became possible to use HbA1c for the diagnosis of diabetes mellitus[4].

However, the following problems of HbA1c were pointed out: (1) abnormal HbA1c values may be observed because of variantl hemoglobin, hemolytic anemia, *etc.*; (2) HbA1c does not correctly reflect short-term glycemic control status; and (3) HbA1c does not correctly reflect postprandial plasma glucose/fluctuation of plasma glucose. Accordingly, new glycemic control indicators such as fructosamine, 1,5-anhydroglucitol (1,5-AG), and glycated albumin (GA) were introduced. Although these indicators compensate the disadvantages of HbA1c, they have their own disadvantages. For example, 1,5-AG is affected by the threshold of urinary glucose excretion in the kidney, and fructosamine and GA are affected by albumin metabolism[5].

Because fetal hemoglobin (HbF) is the main hemoglobin in neonates, HbA1c cannot be used as a glycemic control indicator in neonates. Therefore, glycemic control in neonatal diabetes mellitus (NDM) was traditionally performed using blood glucose measured by self-monitoring of blood glucose as an indicator, without using a glycemic control indicator. We demonstrated that GA, which is not affected by HbF, reflects glycemic control in NDM and can be used as a glycemic control indicator in NDM[6]. We also obtained various other findings about GA and HbA1c in neonates/infants or NDM. In this review, we outlined the most recent findings concerning glycemic control indicators in neonates or NDM.

NEONATAL DIABETES MELLITUS

NDM is a type of diabetes mellitus caused by single-gene abnormality which develops acutely in insulin dependent state; NDM accounts for the majority of cases of diabetes mellitus which develops within 6 mo after birth[7]. The frequency of NDM according to this definition is 1 in 89000 births, showing that NDM is a rare disease[8]. So far, more than 20 causative genes of NDM have been discovered; genetic mutations of some kind have been identified in not less than 70% of patients[8,9]. NDM is similar to type 1 diabetes mellitus in terms of the form of development (diabetes mellitus develops acutely); however, type 1 diabetes mellitus very rarely develops within 6 mo after birth, judging from studies on the frequency of human leukocyte antigen risk alleles and the presence of pancreatic autoantibodies[10,11]. Based on the clinical course, NDM is classified into two major categories: transient NDM (TNDM) and permanent NDM (PNDM)[12]. TNDM is a condition in which insulin secretion is restored spontaneously and normoglycemia is achieved without treatment; PNDM is a condition in which remission is not achieved and life-long treatment is required. The frequency of TNDM is about 60%, and that of PNDM is about 40%.

Although patients with TNDM require insulin therapy at the time of onset because of marked hyperglycemia, they can be weaned from insulin therapy at an average of 3 mo after the start of treatment[13-16]. This is called the remission period. However, in about half of patients, diabetes mellitus relapses from childhood to adolescence[14,17]. In 70% of patients with TNDM, the cause is overexpression of an imprinted gene *PLAGL1* which is located in the chromosome 6q24 region and is expressed from paternal allele (6q24-TNDM)[14,15,18,19]. In 25% of patients with TNDM, mutations of *KCNJ11* and *ABCC8* genes which encode the ATP-sensitive potassium channel (K_{ATP} channel) essential for glucose-stimulated insulin secretion have been identified (K_{ATP}-TNDM)[14,20,21]. 6q24-TNDM has the following characteristics: (1) it often develops within 1 wk after birth; (2) it is often diagnosed asymptomatically on routine blood collection; and (3) it is rarely accompanied by ketoacidosis[15,19]. On the other hand, the time of diagnosis of K_{ATP}-TNDM is 1 to 4 mo after birth, which is later than that of 6q24-TNDM[14].

The main causes of PNDM are K_{ATP} channel abnormality [*KCNJ11* gene (31%); *ABCC8* gene (10%)] and insulin gene mutations (12%); the median age at the time of diagnosis is 8 wk after birth and 10 wk after birth, respectively[9]. In contrast to TNDM, PNDM shows symptoms such as dehydration, poor sucking, and poor weight gain at the time of onset and is often accompanied by ketoacidosis[15,19]. A large proportion of other causative genes are expressed by autosomal recessive inheritance and account for about 10% of PNDM. In about 35% of patients with NDM, causative genes have not been identified[7].

Insulin therapy is required at the time of onset of NDM regardless of disease type in order to improve metabolic abnormality and weight increase[22]. It has been reported that because neonates have a small body and then receive a small dose of insulin, excellent glycemic control is achieved by an insulin pump which is capable of fine regulation[23-25]. As a treatment after withdrawal from the acute phase, a switch to high-dose administration of sulfonylurea (SU) drugs is an effective causal therapy for K_{ATP} channel abnormality; in not less than 90% of patients, a dramatic improvement of glycemic control is observed immediately without hypoglycemia and is maintained for a long period[26-28]. Therefore, when NDM is diagnosed, it is important to determine by gene analysis whether or not K_{ATP} channel abnormality is present. Early diagnosis makes it possible to switch to SU drugs during infancy, resulting in an extremely high quality-of-life[29-32].

1,5-ANHYDROGLUCITOL IN NEONATES

1,5-AG is a polyol with a structure in which hydroxyl at the 1st position of glucose is reduced; 1,5-AG is contained in a wide variety of food, but is hardly metabolized in the body[33]. Therefore, after being absorbed from the intestine, 1,5-AG contained in food is widely distributed in various organs to form an internal pool. The amount of 1,5-AG supplied from daily food intake is smaller than the internal pool, and so there is no change in serum

1,5-AG concentration before and after meal. Excessive intake of 1,5-AG is excreted in urine.

Usually, about 180 g of glucose is excreted daily from glomeruli; about 100% of the excreted glucose is reabsorbed by sodium glucose cotransporter 2 (SGLT2), which is located in proximal renal tubules and are specific to glucose[34], and SGTL1, which is located downstream of SGLT2. After the onset of diabetes mellitus, excretion of glucose will increase; when the increased excretion of glucose exceeds the reabsorption capacity of SGLT2 and SGLT1, reabsorption of glucose *via* 1,5-AG/mannose/fructose cotransporter (SGLT4), which is located downstream of SGLT2 and SGLT1, will start. Because glucose is usually not present, 99.9% of 1,5-AG is reabsorbed by SGLT4; however, this reabsorption mechanism is common to glucose; therefore, if inflow of glucose into tubules increases, reabsorption of 1,5-AG will be inhibited[35-37]. Therefore, in a hyperglycemic condition, excretion of 1,5-AG into urine will increase and serum 1,5-AG will decrease. Thus, serum 1,5-AG is a glycemic control indicator which reflects the degree of urinary glucose excretion.

Because serum 1,5-AG increases and decreases by excretion of urinary glucose, serum 1,5-AG reflects short-term changes in glycemic control more subtly than HbA1c. When glycemic control has worsened rapidly, serum 1,5-AG will decrease rapidly because the increased excretion of a large amount of glucose will inhibit reabsorption of 1,5-AG *via* SGLT4. In patients with marked hyperglycemia and a high excretion of urinary glucose, serum 1,5-AG will not increase in a short period even if glycemic control has improved rapidly because the internal pool of 1,5-AG has decreased.

Serum 1,5-AG is also affected by the threshold for urinary glucose excretion, and therefore shows a low level in renal glycosuria in which the threshold decreases. In addition, serum 1,5-AG shows an abnormally low level in conditions such as chronic renal failure in which reabsorption of 1,5-AG decreases[38-40], pregnancy[41], oxyhyperglycemia in which urinary glucose is observed transiently[42], patients receiving long-term hyperalimentation[43], and liver cirrhosis[44,45]. One of the causes of an abnormally high level of 1,5-AG is oral administration of a kind of Chinese medicines such as Ninjin-yoei-to and Kami-kihi-to which contain large amounts of 1,5-AG[46].

It is known that serum 1,5-AG during the neonatal period shows an apparently low level[47]. This is considered to be due to a small intake of 1,5-AG during the neonatal period. We reported that serum 1,5-AG is significantly lower in subjects with a habit of consuming dairy products than in subjects without such a habit[48]. The fact that breast milk or formula which contains galactose is the main source of nutrition during the neonatal period may be related to a low level of serum 1,5-AG in neonates.

FRUCTOSAMINE IN NEONATES

Protein undergoes glycation reaction in accordance with plasma glucose concentration, and ketoamine, an early Maillard reaction product, is produced *via* aldimine. Because the side chain binding of ketoamine takes a fructose structure, ketoamine is generically named fructosamine. Fructosamine is measured using the property that fructose-lysine (fructosamine), in which glucose is bound to the lysine residues of protein, has reducing ability under alkaline conditions. A large proportion of measurements are made by the chemical method; measurements are made by colorimetric determination by producing reduction color reaction using nitroblue tetrazolium (NBT) as a chromogen. Because 60% to 70% of serum protein is albumin, the main component of fructosamine is glycated albumin, but fructosamine contains glycated lipoprotein and glycated globulin as well. Fructosamine is not affected by anemia or variant hemoglobin. In addition, because the turnover of albumin, which accounts for the most part of serum protein, is faster than that of hemoglobin, it is possible to evaluate short-term glycemic control by measuring fructosamine[49]. A low fructosamine level is observed in hyperthyroidism[50,51] and nephrotic syndrome[52] in which protein (albumin) metabolism is accelerated; a high fructosamine level is observed in hypothyroidism[50,51] in which protein (albumin) metabolism is prolonged.

HbA1c and GA are glycation products of hemoglobin and albumin (single proteins), respectively, whereas fructosamine is the generic name of all glycated proteins and lacks specificity. Because albumin accounts for 60% to 70% of serum protein, fructosamine has similar properties to GA; however, there is a problem that because other glycated proteins are measured as well, a high fructosamine level is observed in myeloma[53]. Because HbA1c and GA are expressed as the ratio of hemoglobin and the ratio of albumin, respectively, they are not affected by dilution of serum; on the other hand, because fructosamine is expressed as reducing ability per 1 mL of serum, it is affected by serum protein concentration, and an apparently low level of fructosamine is observed in dilutional anemia. The level of fructosamine in young children is lower than that in adults[54], which is also partly due to low serum protein concentration. Because fructosamine is measured by colorimetric determination based on reduction color reaction, fructosamine is affected by bilirubin with reducing ability, *etc*. It is considered that the effects of ascorbic acid and vitamin E are mild; however, if a large amount of ascorbic acid or vitamin E is consumed, measurement of fructosamine may be affected.

GLYCEMIC CONTROL INDICATORS OF CORD BLOOD

The composition of hemoglobin in healthy adults is as follows: adult hemoglobin (HbA): 97%; HbA2: 2.5%; HbF: 0.5%[55]. On the other hand, HbF accounts for 80% to 90%, and HbA accounts for only 10% to 20% immediately after birth. After then, HbF decreases logarithmically and is replaced by HbA; by 6 mo after birth, the largest proportion of Hb is HbA; however, it is not until

1 year after birth when the proportion of HbF decreases to less than 1% (level of HbF in adults)[56,57]. Therefore, it is difficult to use the cation exchange high-performance liquid chromatography (HPLC) method, the immunological (latex immunoturbidimetry; LA) method, and the enzyme method which specifically measure HbA1c as glycemic control indicators in NDM.

We measured glycohemoglobin (GHb) in cord blood by various methods[58]. GHb measured by the HPLC method was less than the detection limit when Arkray's HA-8180 was used and was as low as 1.8% ± 0.2% when Tosoh's G8 was used. GHb measured by the LA method was less than the detection limit; HbA1c measured by the enzyme method was 1.1% ± 0.3%. Because these methods for measuring GHb measure HbA1c specifically and do not measure glycated HbF, the result is less than sensitivity or a very low level, and it was confirmed that these methods cannot be used as glycemic control indicators in NDM.

It is considered that measurement of GHb by the affinity method using boronic acid may be used as a glycemic control indicator during the neonatal period as well because it measures all glycated hemoglobins[59,60]. It has been reported that GHb in cord blood is higher in patients whose mother has diabetes mellitus than in patients whose mother does not have diabetes mellitus[61-63]. Our investigation revealed that GHb was 3.9% ± 0.2%, which was slightly lower than the reference value for adults (4.6% to 6.2%)[58]. Plasma glucose in cord blood was normal (94 ± 27 mg/dL); therefore, it is considered that the low GHb levels were due to shortened life span of red blood cells[64].

GA in cord blood was 9.4% ± 1.1%, which was slightly lower than the reference value for adults (11.6% to 16.2%)[58]. We demonstrated that low GA levels are observed in neonates because albumin metabolism in neonates is accelerated[65,66]. Low GA levels in cord blood are considered to be due to accelerated metabolism of albumin.

The level of 1,5-AG in cord blood measured in pregnant women including those with diabetes mellitus was similar to that in maternal blood at the time of delivery[67]. This finding was considered to be due to the fact that 1,5-AG in maternal blood was distributed in the fetus *via* the placenta.

The above results show that both GHb measured by the affinity method and GA were slightly lower than the reference value for adults, but could be used as glycemic control indicators in NDM. On the other hand, HbA1c measured by the HPLC method, the LA method, or the enzyme method and 1,5-AG cannot be used as glycemic control indicators.

GLYCEMIC CONTROL INDICATORS IN NDM: HBA1C AND GA

The etiologic diagnosis and treatment of NDM have been making rapid progress; however, there have been few studies on glycemic control indicators useful for evaluating the diagnosis of NDM and effects of therapy. Therefore, we hypothesized that GA is a useful glycemic control indicator in NDM[58] and conducted an investigation[6]. We found that GA, as a glycemic control indicator in NDM, has various advantages: (1) GA is not affected by HbF; (2) unlike fructosamine, GA is not affected by serum protein (albumin) because it is expressed as a ratio to albumin; (3) unlike fructosamine, GA is not affected by other proteins and has a high specificity because it reflects glycation products of a single protein (albumin); (4) GA reflects plasma glucose during a shorter period than HbA1c; and (5) HbA1c reflects mean plasma glucose, whereas GA reflects fluctuation of plasma glucose (postprandial hyperglycemia) in addition to mean plasma glucose[68-70]. HbA1c (%) is expressed as HbA1c/total Hb; therefore, if HbF is high, a relatively low HbA1c level will be observed. At the time of onset of NDM (mostly 1 to 2 mo after birth), a large amount of HbF remains in blood; therefore, a lower HbA1c level is observed in relation to plasma glucose level. In addition, it is estimated that during infancy, during which HbA increases, if plasma glucose level is constant, HbA1c will increase. In fact, in an investigation of five patients with NDM (age at the time of diagnosis: 38 ± 20 d), plasma glucose was markedly high [29.7 ± 13.1 mmol/L (535 ± 236 mg/dL)], whereas HbA1c measured by the HPLC method was within the normal range (5.4% ± 2.6%)[6]. As the course of treatment progressed, plasma glucose tended to decrease (Figure 1A), whereas HbA1c tended to increase (Figure 1B). A significant negative correlation was observed between HbA1c and HbF (Figure 2A), whereas no significant correlation was observed between HbA1c and plasma glucose level (Figure 2B). On the other hand, GA at the time of diagnosis was abnormally high (33.3% ± 6.9%)[6]. In contrast to HbA1c, GA decreased as treatment progressed (Figure 1C) and showed a strong positive correlation with plasma glucose level (Figure 2C). Thus, it was found that GA, but not HbA1c, is an appropriate glycemic control indicator in NDM.

From what age can HbA1c be used as a glycemic control indicator? Alternatively, if the effect of HbF is excluded or if a different principle of measurement is employed, might HbA1c be an appropriate indicator? And when using GA as a glycemic control indicator in NDM, what should be taken into account? In the following chapters, we will discuss these issues in relation to the current status and challenges in infants and NDM.

HBA1C IN NEONATES AND NDM

As mentioned above, when HbA1c is expressed as HbA1c/total Hb, it cannot be used as a glycemic control indicator in NDM. There are two ways to eliminate the effect of HbF. One way is to determine the HbA1c level corrected by HbF (HbF corrected HbA1c) by the formula: HbA1c/(total Hb-HbF), resulting in the correction of an apparently low HbA level. The other way is to determine GHb relative to all hemoglobins including HbF and to use this as a glycemic control indicator. For the latter, it

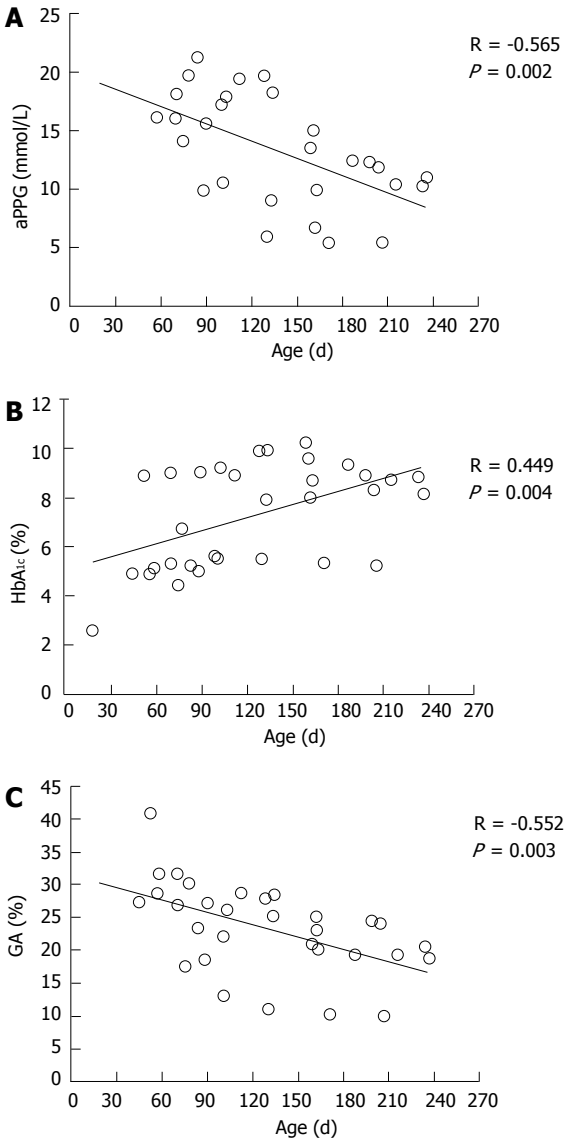

Figure 1 Time course of average preprandial plasma glucose for 1 mo (A), HbA1c (B), and glycated albumin (C) according to treatment in 5 patients with neonatal diabetes mellitus (modified from Ref[6], with permission from Copyright Clearance Center Inc.).

is possible to measure all GHb by the affinity method[71].

We measured HbA1c by the HPLC method and the LA method in 26 healthy infants (0 to 8 mo old), calculated HbA1c values corrected by HbF [Adj-HbA1c (HPLC) and Adj-HbA1c (LA), respectively], measured GHb by the affinity method [GHb (Affinity)], and evaluated correlations between these values and plasma glucose and between these values and GA[72]. As a result, only GHb (Affinity) had a significant correlation with both plasma glucose and GA (Figure 3A). Adj-HbA1c (LA) was correlated only with GA (Figure 3B); Adj-HbA1c (HPLC) was not correlated with either plasma glucose or GA (Figure 3C). These results suggest that GHb (Affinity) may be used as a glycemic control indicator in NDM. In this research, however, GHb (Affinity) within one month was lower than the reference range of HbA1c during 8 to 12 mo (4.8% to 6.0%)[73], and a large proportion of GHb values from 1 to 5 mo were lower than the reference range. The following three factors are thought to contribute together to this finding. The first factor is the effect of a low plasma glucose level during infancy, especially within one month after birth[65,74]. The second factor is the short half-life of red blood cells (about 90 d) during infancy[64]. The third factor is the glycation rate of HbF which is considered to be lower than that of HbA. In this regard, Little *et al*[75] reported that GHb measured by the affinity method is low when a sample which contains not less than 15% of HbF is used. In the LA method, HbA1c is measured using antibodies which specifically recognize peptides including glycated valine of hemoglobin β-chain N-terminal[76]. Theoretically, when interpreting Adj-HbA1c (LA) levels, it is necessary to consider a low plasma glucose level and shortened half-life of red blood cells of the infant; however, it is considered that Adj-HbA1c (LA) may be used as a glycemic control indicator; in fact, a correlation between Adj-HbA1c (LA) and GA was observed. However, the LA method is too complicated to be used in clinical settings because it is necessary to measure HbF using the HPLC method. In addition, our investigation revealed that Adj-HbA1c (HPLC) is not an appropriate indicator for the evaluation of HbA1c in infants. In the HPLC analysis, HbF and HbA1c migrate to adjacent locations. When a high HbF level is observed, separation of HbF and HbA1c becomes insufficient and so HbA1c cannot be measured correctly, which is considered to be one of the causes of the above-mentioned phenomenon. On the other hand, Little *et al*[75] and Rohlfing *et al*[77] reported on HbF-corrected HbA1c as follows: if HbF is not more than 30%, HbA1c measured by the HPLC method using Tosoh's G7 and G8 can be used as a glycemic control indicator. However, they did not use samples which contained 30% or more of HbF, and they did not state whether or not Hb in the samples used was derived from infants; therefore, these facts may be the reason for the difference from our data obtained from samples of infants.

So far, there have been no studies on the age at which HbA1c can be used for patients with NDM, and so research is needed to clarify the relationship between mean plasma glucose and HbA1c and between CGM and HbA1c. Regarding the reference value of HbA1c in healthy infants, there is only a report by Jansen *et al*[73] who investigated 100 healthy infants of 8 to 12 mo old. In that report, the reference value of HbA1c for infants was 4.8% to 6.0%, which was similar to the reference value of HbA1c for adults (4.6% to 6.2%). From our results, HbA1c levels in most infants of 6 mo of age or older were also within the reference range shown by Jansen *et al*[73] HbF decreases to less than 5% by 6 mo after birth[56,57]; therefore, it is considered possible to use HbA1c as a glycemic control indicator in patients with NDM of 6 mo of age or older.

GA IN NEONATES AND NDM

GA is a useful glycemic control indicator under conditions in which hemoglobin metabolism is affected. On

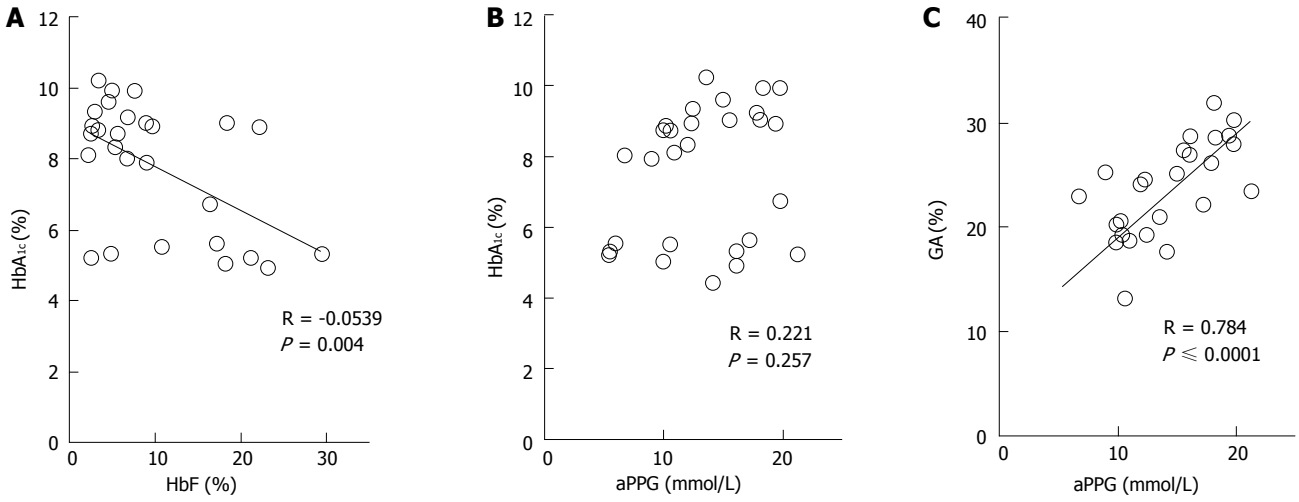

Figure 2 Correlations between HbA1c and HbF (A) and between HbA1c and average preprandial plasma glucose for 1 mo (B) and correlation between glycated albumin and average preprandial plasma glucose in 5 patients with neonatal diabetes mellitus (C) (modified from Ref[6], with permission from Copyright Clearance Center Inc.).

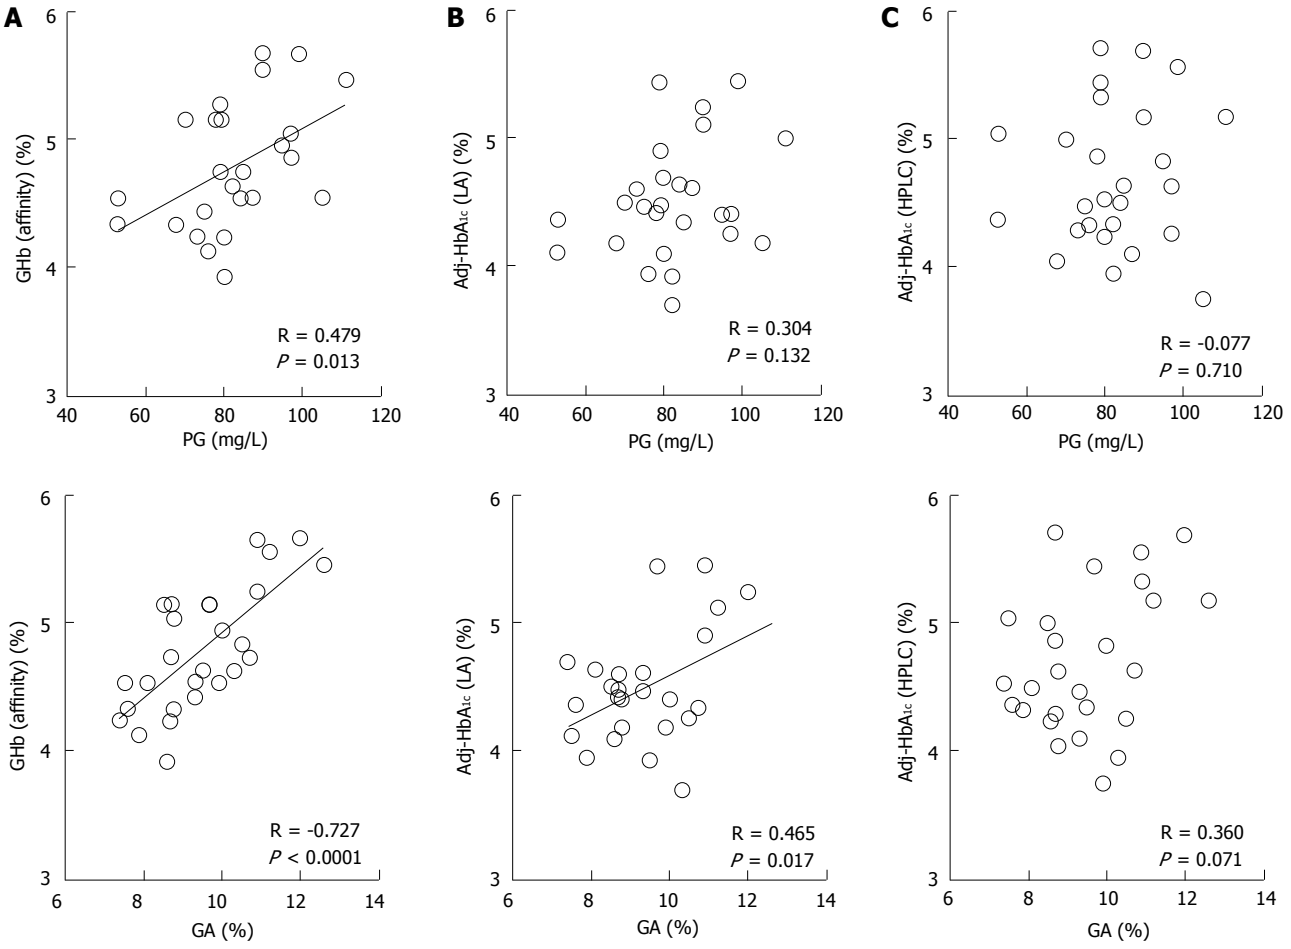

Figure 3 Correlations between glycated hemoglobin measure by various methods and plasma glucose or glycated albumin. Correlations between GHb measured by the affinity method [GHb (affinity)] (A), HbF-adjusted HbA1c measured by the immunological method [Adj-HbA1c (LA)] (B), and HbF-adjusted HbA1c measured by the HPLC method [Adj-HbA1c (HPLC)] (C), and PG or GA in 26 healthy infants were shown (modified from Ref[72], with permission from Copyright Clearance Center Inc.). GA: Glycated albumin; PG: Plasma glucose; GHb: Glycated hemoglobin; HbF: Fetal hemoglobin.

the other hand, abnormal albumin metabolism affects GA. It has been reported under various conditions that GA shows a low level when albumin metabolism is accelerated and shows a high level when albumin metabolism is suppressed[78].

While GA is a useful glycemic control indicator in

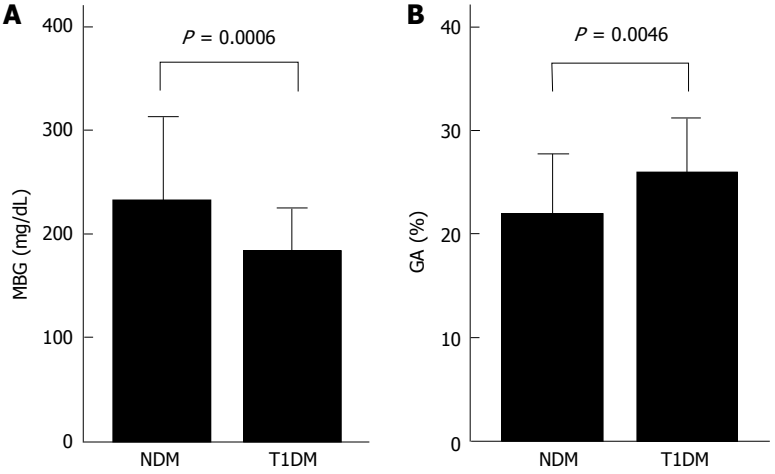

Figure 4 Comparisons of mean blood glucose for 1 mo (A) and GA (B) in 6 patients with neonatal diabetes mellitus and in 18 patients with type 1 diabetes mellitus (modified from Reference[65], with permission from Copyright Clearance Center Inc.).

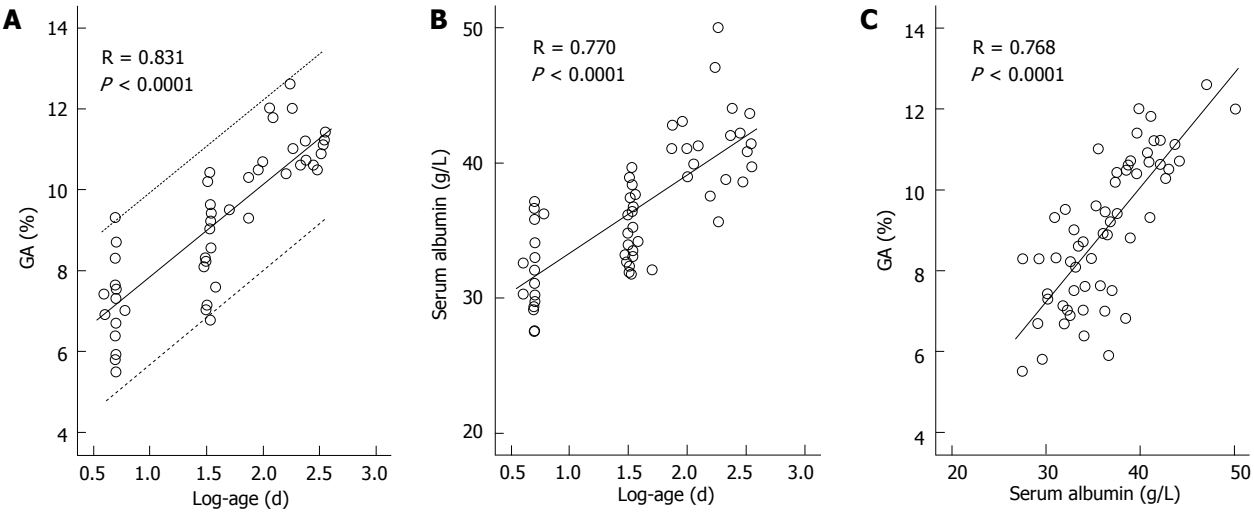

Figure 5 Correlations between glycated albumin and age and between serum albumin and age and correlation between glycated albumin and serum albumin in healthy infants. A: Correlation between glycated albumin (GA) and log-age. The dotted line shows the 95%CI; B: Correlation between serum albumin and log-age; C: Correlation between GA and serum albumin (modified from Ref[66], with permission from Copyright Clearance Center Inc.).

patients with NDM, it is necessary to keep in mind the following characteristics of GA during infancy: (1) it shows a lower level in relation to plasma glucose; and (2) it shows a positive correlation with logarithmically transformed age[65,66]. For GA in healthy infants, before the currently widely used enzyme method was developed[79], it had already been reported that GA measured by the HPLC method was lower than the reference value for adults[54]. It is known that protein metabolism is accelerated during infancy[80,81]. In addition, it has been reported that albumin synthesis is accelerated as well[82]. Therefore, acceleration of albumin metabolism may contribute to a low GA level during infancy. We compared the relationship between GA and plasma glucose level in patients with NDM and in patients with juvenile type 1 diabetes mellitus (T1DM), and found that patients with NDM had higher plasma glucose levels but lower GA levels than patients with T1DM (Figure 4); thus, we obtained a result which supports the phenomenon of accelerated metabolism of albumin during infancy[65]. In addition, we investigated in healthy infants the relationship between change in GA according to age and plasma glucose and between change in GA according to age and serum albumin. As a result, a strong positive correlation was observed between GA and logarithmically transformed age in days (Figure 5A), and multivariate analysis revealed that age and serum albumin affect GA levels more significantly than plasma glucose[66]. Because GA is expressed as a percentage relative to serum albumin, it is not affected by serum albumin, which is an advantage of GA over fructosamine[54]. However, an increase in serum albumin associated with aging is observed during infancy (Figure 5B) and there is a positive correlation between GA and serum albumin during this period (Figure 5C)[66]. Accordingly, we determined the reference value of GA in infants according to age in mo from the regression equation of GA and age, and proposed that a comparison between GA level and the reference value[65].

On the other hand, we found that regardless of age, GA can be evaluated based on the reference value for adults without using the reference value for infants by determining age adjusted GA (Aa-GA)[83]. We investigated

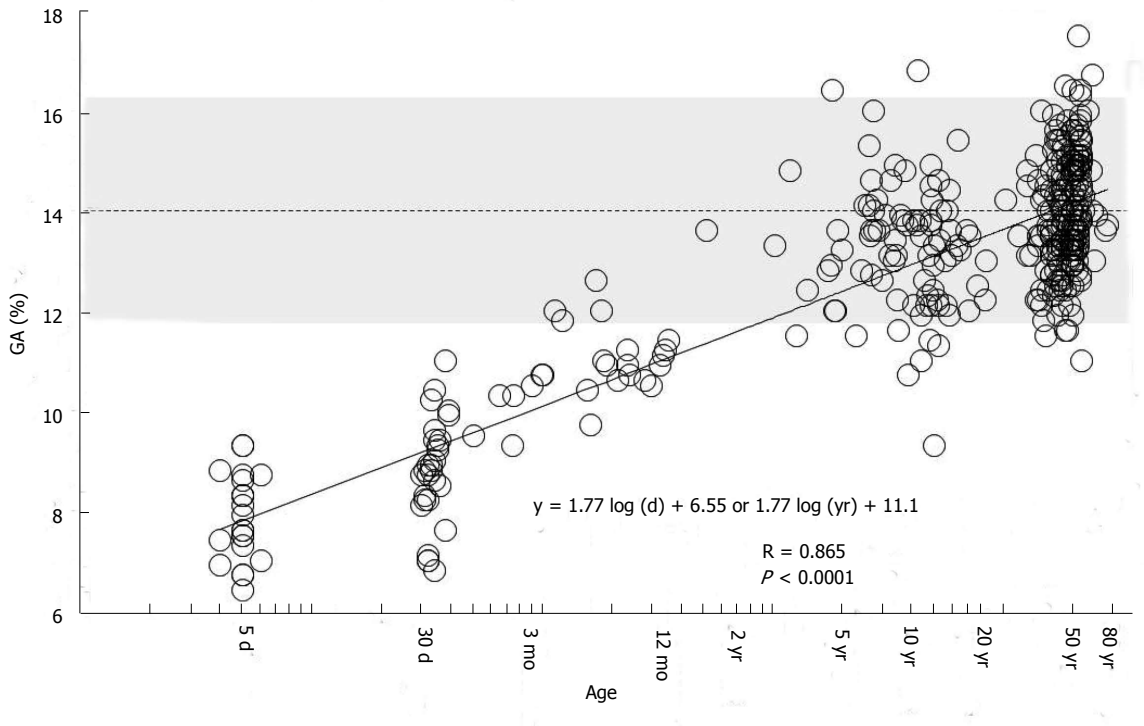

Figure 6 Correlation between glycated albumin and age in days (logarithmic transformation) in 376 healthy subjects (age: 4 d to 78 years). The dotted line indicates the mean reference value for adults (14%), and the shading indicates the range of reference values for adults (11.7% to 16.2%) (modified from Ref[83], with permission from Royal Society of Medicine).

GA in 376 subjects without diabetes mellitus of a wide range of age (neonates, children, and adults), and found that GA can be expressed as a primary regression equation of logarithmically transformed age (Figure 6). Based on this equation, the following formula for calculating Aa-GA was derived: Aa-GA = GA × 14.0 /[1.77 × log-age (d) + 6.55] or Aa-GA = GA × 14.0 /[1.77 × log-age (yr) + 11.1]. As mentioned above, GA in NDM shows an apparently low level; therefore, if GA in NDM is compared with the reference value for adults, the glycemic control status may be underestimated. By calculating Aa-GA and comparing it with the reference value for adults, it is possible to accurately evaluate the glycemic control status in NDM. The advantages of evaluating Aa-GA by the reference value for adults instead of evaluating GA by the reference value for infants according to age in month are as follows: (1) it is not necessary to consider the reference value according to age in month; and (2) regardless of age, it is possible to make comparisons of longitudinal changes in glycemic control status.

It is known that because the half-life of GA is shorter than that of HbA1c, GA reflects short-term plasma glucose correctly[84,85]. This characteristic also indicates the usefulness of GA as a glycemic control indicator in NDM. Because a large proportion of NDM develops within one month, the duration of the hyperglycemic status is short. This form of development is similar to that of fulminant type 1 diabetes mellitus[86]. In fulminant type 1 diabetes mellitus, pancreatic beta cells are destroyed in a very short period, and ketoacidosis develops shortly after the onset of diabetic symptoms. Therefore, at the time of onset, HbA1c is normal or only slightly high, but GA is already obviously high[87]. We reported that GA at the time of onset of NDM was abnormally high (33.6 ± 6.9%) in all patients[6], and an abnormally high GA level in NDM may be useful for differential diagnosis from transient hyperglycemia. In addition, when evaluating remission of patients with TNDM and when evaluating the effect of SU drugs administered to patients with PNDM, it will be possible to promptly evaluate an improvement of such glycemic control by using GA[5].

CONCLUSION

The usefulness of GA as a glycemic control indicator in NDM was demonstrated. However, it was found that GA is affected by albumin metabolism and shows an apparently low level. Therefore, it is necessary to compare GA with the reference value according to age or to calculate age-adjusted GA (Aa-GA). On the other hand, HbA1c measured by the HPLC method, the LA method, or the enzyme method does not correctly reflect the glycemic control status because it is affected by a high HbF level. GHb measured by the affinity method reflects the glycemic control status in NDM; however, this method is currently hardly used and cannot easily measure GHb routinely. In addition, it is unknown whether the kinetics of glycation reaction of HbF are similar to those of HbA. Taking into account such circumstances, it is desirable to select GA as a glycemic control indicator for patients with NDM and to evaluate the glycemic control status using Aa-GA.

Abstract

AIM: To investigate the presence and potency of natural enzyme inhibitors with hypoglycemic potentials amongst *Eucalyptus* Spp. by *in vitro* assays.

METHODS: The leaf extracts of the three different *Eucalyptus* species [*E. globulus* (EG), *E. citriodora* (EC), *E. camaldulensis* (ECA)] were subjected to *in vitro* assay procedures to explore the prevalence of natural enzyme inhibitors (NEIs) after preliminary qualitative and quantitative phytochemical evaluations, to study their inhibitory actions against the enzymes like α-amylase, α-glucosidase, aldose reductase, angiotensin converting enzyme and dipeptidyl peptidase 4 playing pathogenic roles in type 2 diabetes. The antioxidant potential and total antioxidant capacity of the species were also evaluated.

RESULTS: Major bioactive compounds like polyphenols (341.75 ± 3.63 to 496.85 ± 3.98) and flavonoids (4.89 ± 0.01 to 7.15 ± 0.02) were found in appreciable quantity in three species. Based on the IC_{50} values of the extracts under investigation, in all assays the effectivity was in the order of EG > ECA > EC. The results of the ferric reducing antioxidant power assay showed that the reducing ability of the species was also in the order of EG > ECA > EC. A strong correlation (R^2 = 0.81-0.99) was found between the phenolic contents and the inhibitory potentials of the extracts against the targeted enzymes.

CONCLUSION: These results show immense hypoglycemic potentiality of the *Eucalyptus* Spp. and a remarkable source of NEIs for a future phytotherapeutic approach in Type 2 diabetes.

Key words: Natural enzyme inhibitors; Hypoglycemic; *Eucalyptus*; *In vitro* assays; Pathogenic; Polyphenols; Flavonoids

Core tip: Enzymes play an essential role in mediating important biochemical processes of life but hyper or hypo activity of such enzymes leads to malfunctions of the processes. Etiopathogenesis of diseases at molecular level has shown that enzyme inhibitors can serve as effective therapeutic bullets for several diseases. The plant kingdom is a giant hub of phytomolecules with variant pharmacology, largely unexplored. Volatile and non-volatile fractions of *Eucalyptus* include bioactive compounds like terpenes, triterpenoids, flavonoids, polyphenols, *etc.* The exploration of enzyme inhibitors amongst *Eucalyptus* species by *in vitro* assays will help in bioactivity guided isolations of such inhibitors to be targeted as natural hypoglycemics.

tus Spp. by *in vitro* assays. *World J Diabetes* 2014; 5(2): 209-218 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i2/209.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i2.209

INTRODUCTION

Diabetes mellitus (DM) is fast becoming the epidemic of the 21st century, becoming one of the major killers of the health of mankind after Acquired Immuno Deficiency Syndrome, cancer and cerebrovascular diseases[1]. The statistics of the global diabetic population is expected to show a steady growth to 366 million by 2030. The international diabetes federation has estimated the number of diabetics in India to be 40.9 million, which is expected to grow to 60.9 million by 2025[1,2]. Diabetes is a common metabolic disorder with abnormal elevations in the blood glucose lipid profile, leading to major complications like diabetic neuropathy, nephropathy leading to end stage renal disease, retinopathy leading to blindness and diabetic foot ulcers necessitating limb amputations[1,2]. But despite tremendous strides in modern medicines, the availability of insulin therapy and synthetic hypoglycemics, their failure to restore normoglycemia without adverse effects calls for phytotherapy and alternative medicine[3,4]. Enzymes play a vital role in mediating essential biochemical life processes like metabolism, cell cycling, signal transduction, *etc*. However, hyper or hypo activity of such enzymes leads to malfunctions of the respective biochemical processes which in many cases are the underlying causes of diseases like diabetes, Alzheimer's disease, myasthenia gravis and Parkinson's disease, as depicted by their etiopathogenesis at the molecular level. It is anticipated that enzyme inhibitors serve as important therapeutic targets for these diseases[5]. It has been found that enzymes like α-amylase, α-glucosidase, dipeptidyl peptidase 4 (DPP4), aldose reductase (AR), angiotensin converting enzyme (ACE) and peroxisome proliferator activated receptor-γ (PPAR-γ) contribute significantly to the pathogenesis of type 2DM. Reactive oxygen species (ROS) also play a pathogenic role in type 2DM.

Phytomolecules, as natural enzyme inhibitors (NEIs), can serve as successful therapeutic bullets in the control of this chronic disease[2,5-8]. The World Health Organization has recommended phytotherapy for diabetes due to safety, effectivity, availability and affordability. The NAPRALERT database (NAtural PRoducts ALERT) and the ethnobotanical literature have reported more than 800 anti-diabetic plant species[4,7-9].

Eucalyptus, also known as "gum tree", is taxonomically from the family Myrtaceae, indigenous to Tasmania, Australia and cultivated mostly in subtropical and warm temperate regions of the world. The bark and leaves of *Eucalyptus* Spp. have been used in folk medicine for the treatment of ailments such as colds, fever, toothache, diarrhea and snake bites. Uses of *Eucalyptus* leaf hot decoctions as "herbal tea" have been recorded in Aboriginal, European and British Pharmacopeias for the traditional remedy of type DM[10-21]. A rich literature exists, reporting over 500 *Eucalyptus* species with different pharmacological actions[11-22]. Hypoglycemic potentials of *Eucalyptuses* are documented, but the mechanistic actions need to be explored further[11-21].

Table 1 List of phytochemicals of *Eucalyptus* Spp. inhibiting the enzymes

Phytochemicals	Enzymes inhibited ↓
Flavonoids, like quercetin, kaempferol, myricetin; Phenolics-tannins, ellagic acid, and gallic acid; terpinoids-ursolic acid, oleanolic acid, p-cymene, and 1,8-cineole, 1-(S)-α-pinene	α-amylase
Polyphenols, proanthocyanidins, anthocyanins	α-glucosidase
Flavonoids, flavonols, terpenoids, mono-terpenes	Aldose reductase
Flavonoids, flavonols, terpenoids, mono-terpenes	Angiotensin converting enzyme
Terpenoids	Peroxisome proliferator activated receptor
Triterpenoids, phenolic compounds	Di-peptidyl peptidase 4

Inhibiting the actions of carbohydrate hydrolyzing enzymes like α-amylase and α-glucosidase helps to reduce post-prandial (PP) hyperglycemia. Inhibition of other enzymes like AR, DPP-4, ACE and PPAR-γ also presents an effective strategy to combat type 2 DM naturally[5,6,8,11]. Extensive literature surveys and our previous works have reported that *Eucalyptus* shows the presence of terpenoids, triterpenoids, flavonoids, polyphenols and tannins in its various volatile and non-volatile fractions[8,21,22]. Major phytomolecules isolated from the Eucalyptus *Spp* and their inhibitory activity against the enzymes are depicted in Table 1.

AR, a member of the aldo-keto reductase super family, is the first and rate-limiting enzyme in the polyol pathway and reduces glucose to sorbitol, utilizing reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor. In type 2DM, due to increased availability of glucose in sensitive tissues like lens, nerves and retina, there is an increased formation of sorbitol through the polyol pathway. Intracellular accumulation of sorbitol leads to cataract, retinopathy and neuropathy. AR-inhibitors prevent the conversion of glucose to sorbitol and are capable of controlling diabetic complications[8,23-32]. Limited literature data and molecular docking analysis have shown that natural biomolecules with potent aldose reductase inhibitory actions include flavonoids like quercetin, quercitrin, myricitrin, coumarins, monoterpenes, stilbenes, *etc*. Flavonoids with binding energy (BE) ranging between -9.33 to -7.23 kcal/mol exhibited AR inhibitory properties, as evidenced by *in-silico* docking studies[8,32,33]. Five bioactive compounds, namely macrocarpals A-E detected in the ethanol extracts of the leaves of *E. globulus,* showed antibacterial actions, HIV-RTase (HIV-reverse transcriptase) inhibitory activity and also inhibited AR[8,32,33].

Attenuation in ROS level may be due to increased

production or diminished depletion of enzymes, like catalase, glutathione peroxidase and superoxide dismutase. Natural antioxidants which scavenge free radicals can provide a synergistic action to the overall antidiabetic potential of a plant[12,13]. Osawa and Namiki (1981, 1985) reported the presence of a powerful antioxidant, 4-hydroxytritriacontane-16,18 dione, in the leaf wax of different *Eucalyptus* species[24,25].

The enzyme ACE is associated with hypertension, a long term complication of diabetes. ACE activates histidyl leucine dipeptide called angiotensin-I into a potent vasoconstrictor called angiotensin-Ⅱ. Angiotensin-II influences aldosterone release which increases blood pressure by promoting sodium retention in distal tubules. Biomolecules like flavonoids, flavonols, anthocyanins and triterpenes are potent ACE inhibitors[8,34,35]. Molecular docking studies also recommend the use of herbal ACE inhibitors in the management of type 2 DM[8,34,35].

PPAR-γ is a key receptor in lipid and glucose homeostasis because of its ability to reduce the plasma free fatty acids and phytomolecules can exert their insulin sensitizing actions with their high affinity for the receptor PPAR-γ. Terpenoids act as PPAR modulators regulating carbohydrate and lipid metabolism. Several terpenoids have been isolated from the *Eucalyptus* species and PPAR antagonism is amongst the suggested modes of hypoglycemic action of *Eucalyptus*[8,36].

Glucagon-like peptide-1 (GLP-1) is a remarkable antidiabetic gut hormone with combinatorial actions of stimulating insulin secretion, inhibiting glucagon secretion, increasing beta cell mass, reducing the rate of gastric emptying and inducing satiety. DPP4 rapidly deactivates GLP-1. Phytomolecules, mostly triterpenoids, steroids and phenolic constituents with DPP4 inhibitory activity, help to increase the levels of endogenous active GLP-1 and act as an important therapeutic compound against type 2 DM, the fact being further supported by molecular docking studies[8,37].

The present report documents our studies aiming to explore the major phytochemicals amongst three *Eucalyptus* species, *E. globulus* (EG, blue gum or Tasmanian blue gum), *E. citriodora* (EC, lemon scented gum) and *E. camaldulensis* (ECA, river red gum or Murray red gum), along with the existence of NEIs of enzymes like α-amylase, α-glucosidase, AR, DPP4, ACE and antioxidant enzymes by *in vitro* assays, with the perspective to evaluate the potentiality of these three species to combat type 2 DM and its complications. Furthermore, such research will help in bioactivity guided isolation of potent NEIs.

MATERIALS AND METHODS

Plant materials

Fresh leaves of EG, EC and ECA were collected from natural and man-made forest areas of IIT Kharaghpur and adjoining areas, like Balarampur, Gopali and Arabari forest areas, and authenticated by Dr Shanta AK, Biotechnologist, Nirmala College of Pharmacy, Guntur, India.

Reagents and chemicals

Yeast α-glucosidase, bovine serum albumin, sodium azide, para-nitrophenyl α-D-glucopyranoside solution (pNPG), ACE (from rabbit lung, 3.5 units/mg of protein), starch azure, porcine pancreatic amylase, Tris-HCl buffer, hippuryl-L-histidyl-L-leucine (HHL) and 1,1-diphenyl-2-picrylhydrazyl (DPPH) were obtained from Sigma Chemicals, United States. Other chemicals like diagnostic reagents, surfactants, polyphosphate, dextran sulphate, *etc.*, were purchased from Merck Co, India. Acarbose was a kind gift sample from Zota Pharmaceuticals Pvt. Ltd, Chennai, India.

Preparation of eucalyptus leaf extracts

A uniform methodology was followed for preparing the leaf extracts of the three different species of *Eucalyptus*. Typically, the leaves were washed first with tap water and then with distilled water to remove all dust, subjected to shade drying at 25 ± 3 ℃ temperature, and then finely powdered in an electrical grinder (Bajaj GX 11, India). The leaf powder was stored at room temperature in an airtight container until use and labeled separately as EG, EC and ECA. Extraction was carried out as described by Sugimoto *et al*[20,21] with few modifications. Briefly, 500 g of leaf powder of each species was extracted separately with ethanol-water (1:2 v/v) under reflux for 2 h, filtered through a Whatman filter paper no. 1, concentrated using a rotary evaporator (Buchi, Flawil, Switzerland) and dried in a vacuum oven. The percentage yield of extracts was calculated with regard to the initial weight of dry powders and final weight of the extracts. These extracts were then subjected to preliminary and quantitative phytochemical evaluations and *in vitro* assay procedures.

Phytochemical investigations of the eucalyptus leaf extract

Phytochemical analysis of the major bioactive compounds of interest of the three different extracts (EG, EC and ECA) was performed using the methods of Harbone (1984), Trease and Evans (1989) and other literature methods[22,38]. The three extracts were analyzed for glycosides (Keller Killiani and Borntrager's tests), alkaloids (Mayer's, Dragendorff's reagents), saponins (Foam test), triterpenes (Salkowski and Libermann Burchard tests) and 1,8-cineole (Marquis reagent, Gallic acid reagent, conc. H_2SO_4 and phloroglucinol).

The total polyphenol content of the extracts was determined by ultra violet (UV) spectrophotometry (Perkin Elmer Lambda 25 UV-vis) at 760 nm using Folin-Ciocalteu reagent by the method of Othman *et al*[39] and Modnicki *et al*[40] (2009)[41,42]. The concentrations of the total polyphenols were determined in Gallic equivalents (GAE) per gram of the extract. The polyphenol content was calculated by the formula: $X = (5.6450 \times A)/m$. Where X is total phenolic compounds (%), A is absorbance of investigated extract and m is mass (g) of the investigated sample.

The total flavonoid content of the extracts was determined by the method of Djeridane *et al*[43], 2006, which

is based on the formation of a complex of flavonoid-aluminium, and the concentration of the flavonoids was expressed in terms of QE per gram extract.

The flavonol content of the extracts was determined according to Abdel-Hameed, 2009, which is based on the formation of a complex between the extract with $AlCl_3$ and sodium acetate and the total flavonol content was expressed in terms of quercetin equivalent (QE) per gram extract[42].

Tannins were measured according to the protocol of Hagerman and Butler, 1978, which is based on the obtention of a colored complex Fe^{2+}-phenol whose absorbance was measured spectrophotometrically at 510 nm. The tannin content was obtained in mg of tannic acid equivalent (TAE) per gram extract[44].

The three extracts were subjected to color reactions with Marquis Reagent, gallic acid reagent, concentrated H_2SO_4 and phloroglucinol reagent. Standard 1,8-cineole gives orange color with Marquis reagent, yellow color with gallic acid, dark yellow color with concentrated H_2SO_4, and no coloration with phloroglucinol reagent[22,38].

Gas chromatographic analysis of 1,8-cineole

Fresh leaves of the three *Eucalyptus* spp. (EG, EC and ECA) were air dried and 100 g leaves of each variety were subjected to hydrodistillation for 3-4 h to extract the essential oil, employing a Clevenger type apparatus[45]. Extracted oils were decanted from the water layer and dried over anhydrous sodium sulfate. The extracted oils of the three species were subjected to gas chromatographic (GC) analysis (perkin elmer clarus 500, with Flame Ionization Detector) as described by Quereshi *et al*[45]. The operating conditions were: nitrogen as carrier gas, injector and detector temperature of -250 ℃; column of 30 m (length) × 0.25 mm (inner diameter) and film thickness of 0.25 μm. The temperature was gradually increased at a rate of 15 ℃/min to 240 ℃ for 4 min.

In vitro assay procedures

After phytochemical investigations of the leaf extracts of EG, EC and ECA, *in vitro*-inhibitory assays of α-amylase, α-glucosidase, aldose reductase, ACE, DPP4, antioxidant assays like DPPH free radical scavenging activity, scavenging of hydrogen peroxide and total antioxidant activity in the ferric reducing antioxidant power (FRAP) assay were carried out following standard methods[46-57].

The enzymes mentioned above contribute to the pathogenesis of type 2 DM in one way or another. Inhibition of such enzymes helps to combat type 2 DM naturally. There are ample research works highlighting the hypoglycemic potentials of *Eucalyptus*. We explored such NEIs by the above mentioned *in vitro* assays and once again evaluated the hypoglycemic potentiality of *Eucalyptus*.

α-Amylase inhibitory assay: The study was carried out following standard literature methodologies with slight modifications[12,46,47]. Briefly, 2 mg of starch azure was suspended in a tube containing 0.2 mL of 0.5 mol tris-phosphate buffer (pH = 6.9) containing 0.01 mol calcium chloride as the substrate. After boiling the tube for 5 min, it was preincubated for 5 min at 37 ℃. Different concentrations (10, 20, 40, 60, 80 and 100 μg/mL) of the extracts of EC, EG and ECA were prepared by dissolving in 1 mL of 0.1% dimethyl sulfoxide. Then 0.2 mL of the extract of particular concentrations was put in the tube containing the substrate solution. Next, 0.1 mL of porcine pancreatic amylase in tris-HCL buffer (2 units/mL) was added to the tube containing extracts and substrate, at 37 ℃. After 10 min, the reaction was stopped by adding 0.5 mL of 50% acetic acid in each tube and the reaction mixture was centrifuged (Eppendorf-5804R) at 3000 *g* for 5 min at 4 ℃. The absorbance of the resulting supernatant was measured at 595 nm. Acarbose (A_{car}) in the concentration range of 1.25, 2.5, 5 and 10 μg/mL in distilled water was used to create the calibration curve. The assay was performed in triplicate. The concentration of the *Eucalyptus* extracts of three species (EG, EC and ECA) required to inhibit 50% of α amylase activity under the assay conditions is referred to as IC_{50} values. Absorbance was calculated using the formula: a amylase activity = [(Ac+) - (Ac-) - (As-Ab)]/[(Ac+) - (Ac-)] × 100.

α-glucosidase inhibitory assay: The assay procedure was developed as described by Basak *et al*[12] and Subramanian *et al*[47], with slight modifications. An aqueous ethanol extract of the three species (EG, EC and ECA) was used for the study. The yeast α-glucosidase enzyme solution was prepared by dissolving at a concentration of 0.1 U/mL in 100 mmol phosphate buffer, pH = 7.0, containing bovine serum albumin and sodium azide which was used as enzyme source. This enzyme solution was added to the aqueous-ethanolic extracts of EG, EC and ECA in increasing concentrations (1, 1.5, 2, 2.5, 3, 3.5 μL/mL). The reaction was initiated by adding 0.20 mL of para-nitrophenyl α-D-glucopyranoside solution (pNPG); 2 mmol pNPG in 50 mmol sodium phosphate buffer pH = 6.9) which acted as the substrate. The reaction was terminated by adding 1 mL 0.1 mol/L Na_2HPO_4. The test tubes were cooled under tap water and α-glucosidase inhibitory activity was determined at 405 nm by measuring the quantity of *P*-nitrophenol released from pNPG. The assay was performed in triplicate for each extract and the data presented as mean ± SD. The concentration of the *Eucalyptus* extracts (EG, EC and ECA) required inhibiting 50% of α-glucosidase activity under experimental conditions is defined as the IC_{50} value. Acarbose (A_{car}) was dissolved in distilled water to prepare a series of dilutions (1.25, 2.5, 5, 10 mg/mL) and was used as the positive control. The percentage inhibition was calculated according to the formula: %inhibition = (Abs400 control - Abs400 extarct)/Abs400 control.

IC_{50} values were determined from the plots of percentage inhibition *vs* log inhibitor concentration and were calculated by nonlinear regression analysis from the mean inhibitory values.

Aldose reductase inhibitory assay: The assay was carried out following reported literature methods and the experimental protocol approved by the Institutional Ethical Committee[48-50]. Two to three mo old healthy adult Wistar albino rats weighing about 150-200 g were acclimatized to laboratory conditions (12 h light and 12 h dark cycle, 25 ± 5 ℃, 30%-60% relative humidity) with free access to pelleted food and water *ad libitum*. Immediately after sacrifice, lenses were removed from the eyes, washed with saline and the fresh weights of a lens were measured. Next, a 10% homogenate was prepared from the rat lens in 0.1 mol/L phosphate-buffered saline (PBS) at pH 7.4, centrifuged at 5000 *g* for 10 min in the cold and the supernatant collected. The protein content of the supernatant was determined by literature methods[48-50].

For the determination of the aldose reductase (AR) inhibitory activity, 0.7 mL of phosphate buffer (0.067 mol), 0.1 mL of NADPH (25×10^{-5} mol), 0.1 mL of DL-glyceraldehyde (substrate, 5×10^{-4} mol) and 0.1 mL of lens supernatant were mixed in the sample cuvette. Absorbance was taken against a reference cuvette containing all other components except the substrate, DL-glyceraldehyde. The final pH of the reaction mixture was adjusted to pH = 6.2. On adding substrate to the solution mixture, the enzymatic reaction starts and absorbance (OD) was recorded at 340 nm for 3 min at 30 s intervals. AR activity was calculated and expressed as OD/min per milligram protein.

For the determination of the AR inhibitory activity of the *Eucalyptus* extracts, a stock solution was prepared by dissolving the *Eucalyptus* extracts (EG, EC and ECA) in PBS and different concentrations prepared from stock solutions were added to both the reference and standard cuvettes. The reaction was initiated by the addition of 0.1 mL DL-glyceraldehyde and the reaction rate measured as mentioned above. Percentage inhibitions of AR activity of the extracts were calculated with reference to normal rat lens to have 100% activity. The concentrations of the extracts required to inhibit 50% of AR activity under assay conditions is defined as the IC_{50} values which were calculated for each sample by plotting a graph between log dose concentrations *vs* percentage inhibition. Quercetin, a known AR inhibitor, was used as the positive control.

ACE inhibitory assay: The assay method was based on the liberation of hippuric acid from hippuryl-L-histidyl-L-leucine (HHL) catalyzed by the ACE. The assay procedure was carried as described [51,52] and other methods with slight modifications. Briefly, 50 μL of sample solutions (extracts of EC, EG and ECA) in the concentration range of 0.1-2.5 mg/mL were preincubated with 50 μL of ACE (25 mU/mL) at 37 ℃ for 10 min. Next, 150 μL of substrate solution (8.3 mmol HHL in 50mmol sodium borate buffer containing 0.5 mol NaCl at pH 8.3) was added and incubated for 30 min at 37 ℃. The reaction was terminated by addition of 250 μL 1.0 mol HCl. To the resulting solution, 0.5 mL of ethyl acetate was added and centrifuged (Eppendorf-5804R) for 15 min. Then, 0.2 mL of the upper layer was transferred to a test tube, evaporated under room temperature in vacuum and the liberated hippuric acid was dissolved in 1 mL distilled water and the absorbance was measured at 228 nm. Experiments were performed in triplicates. Captopril was used as standard (3.5 μg/mL) in the assay. The percentage of inhibition (ACEI) was calculated using the formula: %inhibition = (A-B)/(A - C) × 100. Where A is the OD at 228 nm with ACE but without inhibitor, B is the OD in presence of both ACE and inhibitor, C is the OD without ACE and inhibitor.

DPP4 inhibitory assay: The assay was carried out following reported literature methods using GPN-Tos (Gly-Pro p-nitroanilide toluenesulfonate salt) as the substrate[53-55]. Briefly, 0.5 mL of the assay mixture contained 40 mmol K-Na-phosphate buffer, pH 7.5, an enzyme sample. The reaction was initiated by adding a substrate to a concentration of 0.24 mmol and stopped by adding 0.2 mol acetic buffer at pH 5.5. The differential absorption at 390 nm was recorded against an identical mixture without the enzyme and the amount of p-nitroaniline depleted was evaluated from its extinction coefficient at the wavelength of 9.9 mmol/L/cm^{-1}.

Evaluation of antioxidant activity

Dpph free radical scavenging activity: The antioxidant activity of the *Eucalyptus* extracts (EC, EG and ECA) was determined on the basis of the scavenging effect on the stable DPPH free radical activity[12,39,51,56]. A stock solution of DPPH in methanol (33 mg in 1 L) was freshly prepared and kept in the dark at 4 ℃; after checking its initial absorbance, 5 mL of this stock solution was added to 1 mL of the solution of the extracts prepared in concentrations of 50-500 μg/mL. Next, 2.8 mL of 95% methanol was added and the mixture was shaken vigorously and after 30 min the absorption was measured at 517 nm. Ascorbic acid was used as the standard. The radical scavenging capacities of the test samples were expressed as percentage inhibition and calculated according to the equation: % inhibition of DPPH activity = (Absorbance control - Absorbance)/(Absorbance control) × 100.

Plotting was done of percentage inhibition *vs* concentration, and the concentration of sample required for 50% inhibition is regarded as IC_{50} value for each of the test samples.

Total antioxidant activity (FRAP assay): Total antioxidant activity was determined by the FRAP assay as described by Pracheta *et al*[56] and Shahwar *et al*[57]. It is a direct test of antioxidant capacity. The assay of reducing activity is based on the reduction of ferric to ferrous form in the presence of antioxidants in the tested samples (extracts of *Eucalyptus* species). The stock solutions included 10 mmol/L 2,4,6-tripyridyl-s-triazine (TPTZ) in 40 mmol HCl and 20 mmol $FeCl_3$, and 300 mmol acetate buffer (pH 3.6). The working solutions were freshly prepared by mixing 25 mL acetate buffer, 2.5 mL TPTZ and 2.5 mL of $FeCl_3$. The temperature of the solution

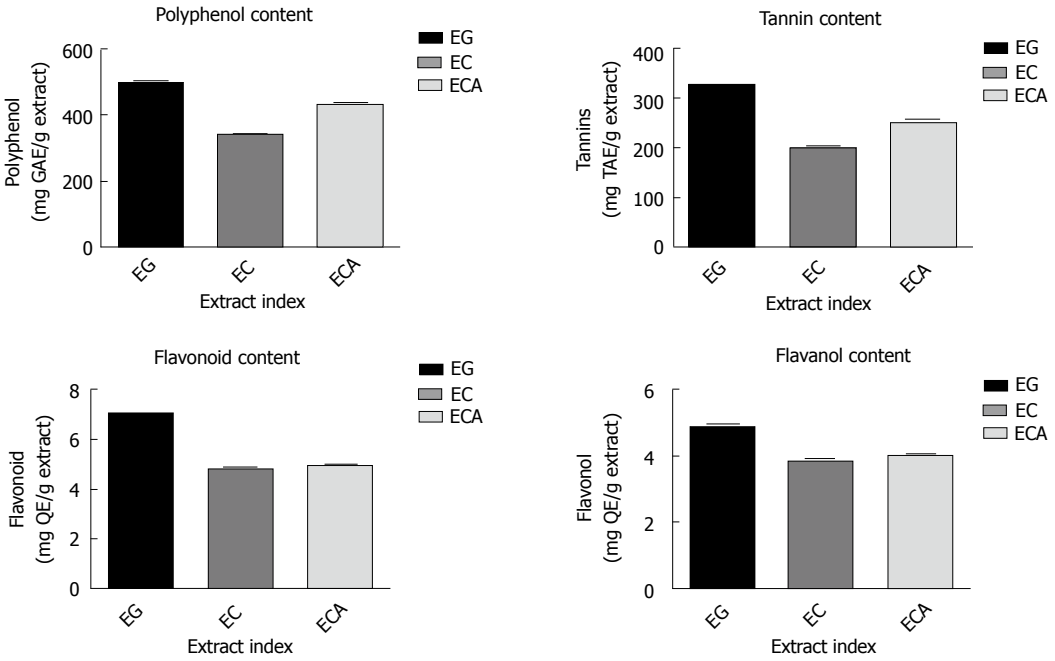

Figure 1 Graphical presentations of the presence of phytochemicals in Eucalyptus extracts. Data are presented as the mean ± SD of each triplicate test. EG: *E. globulus*; EC: *E. citriodora*; ECA: *E. camaldulensis*.

Table 2 Total polyphenol, flavonoid, flavonol and tannin contents of *E. globulus*, *E. citriodora* and *E. camaldulensis*

Extract[1]	Polyphenol (mg/g extract[2])	Tannins (mg/g extract[2])	Flavonoid (mg/g extract[2])	Flavonol (mg/g extract[2])
EG	496.85 ± 3.98	329.06 ± 6.25	7.15 ± 0.02	4.98 ± 0.01
EC	341.75 ± 3.63	199.75 ± 5.49	4.89 ± 0.01	3.87 ± 0.05
ECA	429.91 ± 4.03	253.15 ± 4.96	5.01 ± 0.02	4.09 ± 0.01

[1]Content expressed per gram of relevant extracts (EG, EC and ECA); [2]Values are expressed as mean ± SD from triplicate determination. EG: *E. globulus*; EC: *E. citriodora*; ECA: *E. camaldulensis*.

Table 3 Color test results for the presence of 1,8-cineole in *E. globulus*, *E. citriodora* and *E. camaldulensis* extracts

Extracts	Marquis test	Gallic acid test	Concentrated H_2SO_4	Phloroglucinol
EG	Orange	Yellow	Dark yellow	No color
EC	Orange	Dark Yellow	Dark yellow	No color
ECA	Orange	Yellow	Bright orange-yellow	Pink

EG: *E. globulus*; EC: *E. citriodora*; ECA: *E camaldulensis*.

was raised to 37 ℃ prior to use. *Eucalyptus* extracts (200 μL) were allowed to react with FRAP solution (2900-3000 μL) for 30 min in the dark. Absorbance of the colored product formed (ferrous tripyridyl triazine complex) was recorded at 595 nm. Results were expressed in μM equivalent to $FeSO_4$ by extrapolation from the calibration curve.

Statistical analysis

The experimental results were expressed as mean ± SD of three replicates. The data were subjected to one way analysis of variance (ANOVA) using commercially available software (Prism version 5.0; Graph Pad Software, San Diego, CA, United States). Results were analyzed by Student's *t* test (paired or unpaired, as appropriate) or Tukey's multiple comparison test. Statistical analysis was performed by using GraphPad Prism where $P < 0.05$ was considered statistically significant.

RESULTS

The yield of the *Eucalyptus* leaf extracts (extractions carried out in triplicates) were 49% ± 3.3% for EG, 46.5% ± 4.2% for EC, and 45.8 ± 3.9% for ECA. The details of phytochemicals amongst *Eucalyptus* Spp. and the enzymes inhibited by them are presented in Tables 1 and 2 and Figure 1. The color test results for the presence of 1,8-cineole in the extracts of EG, EC and ECA are presented in Table 3. GC analysis of the oils extracted from three species (EG, EC and ECA) showed the highest 1,8-cineole content in EG (about 50%). ECA also showed the presence of 1,8-cineole in addition to several other peaks indicating the presence of other compounds. In EC citronellal was found to be the major component.

All three extracts (EG, EC and ECA) showed promising inhibitory potentials for enzymes, including α-amylase, α-glucosidase, AR, ACE and DPP4. The antioxidative potential of the extracts were determined by DPPH radical scavenging and the total antioxidative capacity by the FRAP assay. The results of all such inhibitory assays are presented in Figure 2 and the summary of the IC_{50} values of tested samples in Table 4.

The correlation coefficient (R^2) between polyphenol and flavonoid content and IC_{50} inhibitory values of the enzymes ranged between 0.81-0.99 and 0.57-0.99 respec-

tively.

The polyphenol content of three *Eucalyptus* Spp. (EG, EC and ECA) was compared with the IC_{50} values of different inhibitory assays using Tukey's multiple comparison test (one-way ANOVA), considering $P < 0.05$ as significant. All P values were found to be < 0.05. The results suggested that the inhibitory potentials of the extracts are largely dependent upon the polyphenol content in *Eucalyptus* Spp.

DISCUSSION

Qualitative and quantitative phytochemical investigations of the *Eucalyptus* leaf extracts EG, ECA and EC showed appreciable levels of bioactive components like polyphenols and flavonoids. From the IC_{50} values of *Eucalyptus*

Table 4 IC_{50} inhibitory values of Eucalyptus extracts *E. globulus*, *E. citriodora* and *E. camaldulensis* in different assays

Assays	EG	EC	ECA
α-amylase	3.01 ± 0.01	4.13 ± 0.09	3.65 ± 1.04
α-glucosidase	2.08 ± 0.01	2.68 ± 0.11	2.11 ± 0.19
Aldose reductase	2.06 ± 0.03	6.72 ± 0.65	2.56 ± 0.84
Angiotensin converting enzyme	4.31 ± 0.09	30.83 ± 0.45	6.85 ± 0.98
Dipeptidyl peptidase	3.098 ± 0.09	6.138 ± 0.68	3.99 ± 0.91
1,1-diphenyl-2-picrylhydrazyl (DPPH)	12.32 ± 0.91	68.42 ± 0.05	14.44 ± 1.91

EG: *E. globulus*; EC: *E. citriodora*; ECA: *E. camaldulensis*.

extracts in different assays (Table 4), it appears that all three extracts showed significant inhibitory potentials against the six enzymes assayed, in the order EG > ECA > EC. Based on the results of FRAP assay, the reducing ability of EG was highest and that of EC lowest (Figure 2). 1,8-cineole is the major constituent of the volatile fractions in EG and ECA, whereas in EC the major constituent is citronellal with citronellol and spathulenol. According to the literature, compounds with highest reducing ability have delocalized chemical bonds[56-60]. Prior research suggested a strong positive correlation (R^2 = 0.99) between phenolic content and antioxidative potential[12,18,58,59]. Polyphenols received wide attention because of their antioxidant properties which refers to their ability to prevent damage from ROS through radical scavenging or prevent the generation of these species by iron chelation[61]. Polyphenols also bind and inhibit the enzymes α-amylase and α-glucosidase[61]. Polyphenols have also been shown to facilitate insulin response and attenuate secretion of glucose dependent insulinotropic polypeptide and glucagon like GLP-1. Other suggested mechanisms for the hypoglycemic actions of polyphenols were down regulation of the expression of liver glucokinase, upregulation of phosphoenolpyruvate carboxykinase (PEPCK), induction of the AMP-activated protein kinase (AMPK) pathway, enhancing peripheral glucose utilization by stimulating glucose transporter subtype 4 (GLUT-4), *etc.*[62]. In this context, it is to be mentioned that green tea extract (GTE) contains polyphenols like catechin, epicatechin, *etc.* Epigallocatechin gallate (EGCG), an abundant form of catechin, is the major attributable factor for the beneficial effects of green tea. EGCG inhibits adipocyte proliferation, increases fat oxidation and enhances the expression of GLUT-4, as shown in animal studies[63,64].

Literature surveys have shown that flavonoids and its subfamilies significantly inhibit the ACE enzyme by generating chelate complexes within the active center of ACE[65]. Flavonoids were found to attenuate hepatic gluconeogenesis by decreasing the activity of glucose-6-phosphate and PEPCK, subsequently improving glycemic control[65]. Our research data are in accordance with this phenomenon. A strong correlation was found between polyphenol (R^2 = 0.81-0.99) and flavonoid contents (R^2 = 0.57-0.99) with the antioxidative and enzyme inhibitory potentials of the extracts.

NEIs can serve as an important therapeutic tool against type 2 DM. The current research aims to provide the state-of-the-art search of NEIs amongst *Eucalyptus* Spp. by *in vitro* assays which can be further utilized for bioactivity-guided isolations of such enzyme inhibitors. Our research results show the hypoglycemic potential of the *Eucalyptus* Spp. (extracts) for future exploitations in phytotherapy of type 2 DM. However, further extensive pharmacology and toxicological studies in animal and human models are warranted.

ACKNOWLEDGMENTS

The authors deeply acknowledge the research facilities provided by Central Research Facilities, IIT Kharaghpur and the laboratory facilities of Nirmala College of Pharmacy, Guntur. Our special thanks go to Dr. Shanta AK for identification of the plant specimens.

COMMENTS

Background

The current research aims to explore the presence of biomolecules by *in vitro* assays amongst three eucalyptus species acting as natural enzyme inhibitors for enzymes with significant pathogenic roles in type 2 diabetes.

Research frontiers

Enzymes like α-amylase, α-glucosidase, aldose reductase, angiotensin converting enzyme and dipeptidyl peptidase 4 play important pathogenic roles in type 2 diabetes. Phytomolecules acting as inhibitors of such enzymes can act as effective therapeutic targets in type 2 diabetes. Volatile and non-volatile fractions of *Eucalyptus* Spp. include biomolecules like terpenes, triterpenoids, flavonoids, polyphenols, *etc.* The exploration of enzyme inhibitors amongst *Eucalyptus* Spp. by *in vitro* assays will help in bioactivity guided isolation of such inhibitors to be targeted as natural hypoglycemics.

Innovations and breakthroughs

Enzymes play a vital role in mediating essential biochemical life processes. However, hyper or hypo activity of such enzymes leads to malfunctions of the respective biochemical processes, which in many cases are the underlying causes of diseases like diabetes. The current research aims to provide the state-of-the-art search of natural enzyme inhibitors amongst *Eucalyptus* Spp. by *in vitro* assays which can be further utilized for bioactivity-guided isolations of such enzyme inhibitors. Those research findings have shown that the *Eucalyptus* Spp. under study have immense hypoglycemic potentials with high IC_{50} values against the targeted enzymes. Moreover, the inhibitory potentials of the species are also well correlated with the polyphenol-flavonoid contents of the species.

Applications

The *Eucalyptus* Spp. (extracts) under study showed significant hypoglycemic potentialities for future exploitations in phytotherapy of type 2 DM.

Terminology

Natural Enzyme Inhibitors: Malfunctions of certain enzymes are the root causes of many diseases. Effective enzyme inhibitors have great clinical significance and a substantial role in the drug delivery process. Such enzyme inhibitors of natural origin are more acceptable due to safety and lower incidences of side effects on short and long term treatment modalities.

Peer review

Dey *et al* investigated the potential hypoglycemic actions of Eucalyptus extracts *in vitro*. The extracts were found to significantly inhibit a number of enzymes related to T2DM, such as amylase, glucosidase, dipeptidyl peptidase 4, *etc.* The rationale of this study and methodology were adequately described. The selection of enzymes and antioxidant activity is based on the hypothesis that these activities are involved in the pathogenesis of type 2 diabetes. The three extracts show broad enzyme inhibitory activity and antioxidant activity, which differs in

magnitude between the three extracts. The authors conclude that the extracts might serve as starting material for new therapeutic modalities for type 2 diabetes and that their data fit with the idea that leaves from trees could provide a base material for drug discovery and development programs.

Abstract

AIM: To examine the contribution of toll-like receptors (TLRs) expression and activation to the prolonged inflammation often seen in human diabetic wounds.

METHODS: Debridement wound tissue was collected from diabetic patients with informed consent. Total RNA and protein were isolated and subjected to real-time polymerase chain reaction and Western blot analyses.

RESULTS: TLR1, 2, 4, and 6 mRNA expressions were increased significantly in wounds of diabetic patients compared with non-diabetic wounds ($P < 0.05$). MyD88 protein expression was significantly increased in diabetic wounds compared to non-diabetic wounds. Interleukin-1beta, tumor necrosis factor-alpha concentration nuclear factor-kappa B activation, and thiobarbituric acid reactive substances were increased in diabetic wounds compared to non-diabetic wounds ($P < 0.01$).

CONCLUSION: Collectively, our novel findings show that increased TLR expression, signaling, and activation may contribute to the hyper inflammation in the human diabetic wounds.

Key words: Interleukin-1β; Inflammation; Toll-like receptors 2; Toll-like receptors 4; Tumor necrosis factor-α; Type 2-diabetes mellitus; Wound healing

Core tip: Increased TLR2/4-MyD88-nuclear factor-kappa B expression and signaling with attendant oxidative stress may contribute to the hyperinflammation frequently seen in human diabetic wounds.

INTRODUCTION

Diabetes mellitus (DM) is a constellation of metabolic aberrations that collectively manifest as debilitating pathological complications affecting the quality of life in DM patients. Around 348 million people worldwide and 36 million people in United States have DM and 40%-60% of these patients develop foot wounds accounting to more than 20% of all hospitalizations equating to one amputation every 30 s[1-3]. Emerging experimental data and human studies suggest that systemic inflammation orchestrated by innate immune receptors plays a role in the pathogenesis of DM complications[4]. Toll-like receptors (TLRs) are pivotal innate immune receptors that induce inflammatory responses[5] and their expression and activation is increased in a plethora of inflammatory disorders including DM and its complications[6-9]. Recent data from our group and others have provided evidence that TLR expression, activation, and signaling are significantly increased in monocytes of DM patients, non-obese diabetic (NOD) mice, and db/db mice (see review, 4). In addition, we showed that genetic ablation of TLR2/4 in diabetic mice attenuates inflammation as indicated by decreased circulating cytokine/chemokine

levels and improved wound healing[8-10]. However, it is not known if TLR expression and activation contributes to the uncontrolled inflammation seen in wounds of DM patients. Thus, in the present study, we examined TLR expression, signaling, and inflammation in human DM wounds.

MATERIALS AND METHODS

Patients

The study population consisted of type 2 DM patients presenting for care of a diabetic ulcer located anywhere on the foot and non-DM patients (controls) with a leg ulcer, aged between 45-65 years. We collected wound tissues from diabetic (n = 8) and non-diabetic subjects (n = 4) during initial debridement as part of standard of care, with informed patient consent at the Sacramento VA clinics. Patient evaluations consisted of a medical history, physical examination, and wound site measurements (including location, size, presence of periulcerative tissue, and clinical infection) were recorded. Serum glucose and HbA1c levels were extracted from patient charts that were done within the last 60 d. All the human study protocols were approved by the Institutional Review Board at University of California at Davis and VA of Northern California, MatherField CA.

Collection of debridement wound tissue

Study inclusion criteria were as follows: age 18 or older; ulcer size > 2 cm^2 and < 25 cm^2; ulcer duration of ⩾ 4 wk; no clinical signs of infection; glycosylated haemoglobin (HbA1c) < 12%; and adequate circulation to the affected extremity Patients were excluded if any of the following preexisting conditions: presence of charcot foot, index ulcer probing to bone; currently receiving radiation or chemotherapy; known or suspected malignancy of current ulcer; diagnosis of autoimmune connective tissue disease; received a biomedical or topical growth factor for their wound within the previous 30 d; taking medications considered to be immune system modulators, antibiotics, with C-reactive protein levels (> 10 mg/dL), and CBC (white blood cells < 4 to > 11 K/mm^3) indicative of infection. Debridement tissue was collected using sharp debridement technique[11] and immediately snap frozen in liquid nitrogen for mRNA and protein analyses.

Real time-polymerase chain reaction

Total RNA was isolated from all the snap frozen wound tissues and mRNA expression was determined by REal time-polymerase chain reaction (RT-PCR) using commercial sequence-specific primers and probes purchased from SA Biosciences, Gaithersburg, MD, United States). The first strand of cDNA was synthesized using total RNA (1 μg per reaction). cDNA (50 ng) was amplified using primer probe sets for TLR1, TLR2, TLR4, TLR6, Myeloid differentiation factor-88 (MyD88), Interleukin receptor activated kinase-1 (IRAK-1), myeloid differentiation protein-2 (MD2), nuclear factor-kappa B (NF-κB), tumor necrosis factor-alpha (TNF-α) and 18s (SA Biosciences) following the manufacturer's cycling parameters. Data were calculated using the $2^{-\Delta\Delta Ct}$ method and are presented as ratio of transcripts for *TLR* gene normalized to 18s as described previously[8,9].

Western blot and ELISA

For Western blot assays, wound tissues were homogenized in tissue lysis buffer and total protein was determined using bicinchoninic acid protein quantitation method[8-10]. Equal amounts of protein (25 μg) were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis, transferred to polyvinylidene fluoride membranes, and were probed with MyD88 (Imgenix, United States) and β-actin (Santa Cruz, United States) antibodies as reported earlier[8,9]. Densitometric ratios of the bands were calculated as reported earlier[8,9] and expressed as MyD88/β-actin ratio. Interleukin-1beta (IL-1β) and TNF-α levels were measured in the wound tissue lysates using ELISA (R and D systems) assay as reported earlier[8-10]. Intra- and interassay coefficient of variation (CV) of ELISA assays were determined to be < 10%[8-10]. Nuclear extracts were used to perform NF-κB transcription factors activation assays (Active Motif, Carlsbad, CA, United States) to verify activation of NF-κB in the diabetic wounds, indicative of increased inflammation. Assays were performed in accordance to the manufacturer's protocols. Intra- and inter-assay CV for transcription factor assays was < 8%[8-10].

Thiobarbituric acid reactive substances

We measured oxidative stress through lipid peroxidations [Thiobarbituric acid reactive substances (TBARs)] in wound tissues to reflect the pathogenic mechanisms in impaired wound healing in DM wounds compared with control wounds. TBARs are a surrogate marker of oxidative stress and malondialdehyde equivalents were determined by reading the absorbance at 532 nm using 1,1,3,3-tetramethoxypropane as an external standard[8,12]. Results were expressed as malondialdehyde equivalents (nmol/mg protein) as reported previously[8,12].

Statistical analyses

Data are presented as mean ± SD. We used two-tailed t tests with appropriate *post hoc* analyses. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using GraphPad Prism software[8-10].

RESULTS

All the patients had DM for > 5 years (mean glucose of 132 ± 10 mg/dL and HbA1c of 7.5% ± 0.8%) and are on routine standard care for a chronic diabetic foot ulcer of at least 4-wk duration and showed no signs of clinical infection. We first examined mRNA levels of TLRs and associated inflammatory signaling mediators in DM and control wound tissue to test the hypothesis that increased TLR expression and activation accentuate inflammation in diabetic wounds, using RT-PCR. TLR1, TLR2, TLR4, TLR6, MyD88, IRAK-1, NF-κB, IL-1β, and TNF-α mRNA expression were significantly increased compared

Table 1 Toll-like receptor pathway genes expressed in debridement wound tissue

Gene	Non-diabetic wounds mRNA/18s ratio	Diabetic wounds mRNA/18s ratio[a]
TLR1	0.6 ± 0.1	1.9 ± 0.4
TLR2	1.2 ± 0.3	3.6 ± 0.5
TLR4	1.3 ± 0.2	3.8 ± 0.2
TLR6	0.2 ± 0.1	2 ± 0.5
MyD88	1.4 ± 0.2	3.1 ± 0.4
IRAK-1	1.1 ± 0.1	2.8 ± 0.6
MD2	0.2 ± 0.04	1.6 ± 0.3
NF-κB	0.8 ± 0.05	2.3 ± 0.2
TNF-α	1 ± 0.4	2.6 ± 0.6

Human diabetic wounds (n = 8) show significantly higher mRNA/18s ratio compared to non-diabetic wounds (n = 4) ([a]P < 0.05 *vs* non-diabetic wounds). TLR: Toll-like receptor.

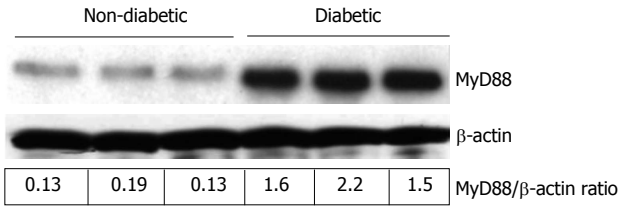

Figure 1 Representative Western blot showing the MyD88 protein expression in non-diabetic and diabetic wound tissues. Wound tissues were collected, lysed and 25 μg protein was blotted for MyD88 and β-actin. Densitometric ratios (MyD88/β-actin) are indicated below. Each lane presents protein from an individual patient wound debridement tissue (n = 3/group).

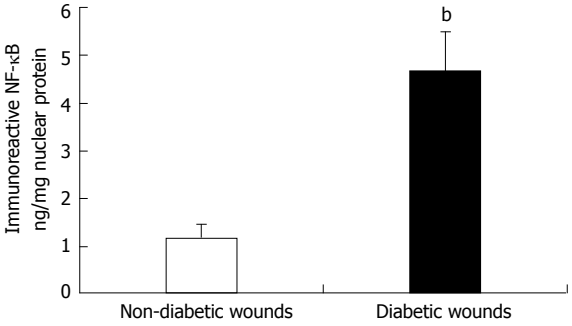

Figure 2 The DNA-binding activity of nuclear nuclear factor-kappa B p65 in wound tissues was determined using ELISA technique. Values are normalized to mg nuclear protein and expressed as mean ± SD. [b]P < 0.001 *vs* non-diabetic.

to non-diabetic wounds (P < 0.05) (Table 1) implicating a role for TLR-MyD88-NF-κB signaling on hyperinflammatory phenotype often seen in DM wounds[7-9]. The mRNA data was validated using Western blot and enzyme-linked immunosorbent assay (ELISA) assays[7-9]. MyD88 is an immediate and common downstream adaptor molecule recruited by activated TLRs through their TIR domain. MyD88, in turn, recruits IRAK-1, leading to the activation of NF-κB transcription factor, and attendant inflammatory cytokine gene expression[5]. Thus, we chose MyD88 for further validation. As shown in Figure 1, MyD88 protein expression was significantly higher in DM wounds compared to the non-diabetic wounds (P < 0.05 *vs* non-diabetic wounds). Figure 2 depicts significantly increased NF-κB activation in the nuclear extracts of diabetic wounds compared to non-diabetic wounds (P < 0.001). Next, local IL-1β and TNF-α levels known to be expressed as a result of TLR-MyD88-NF-κB activation, were determined using ELISA assay. Figure 3 shows significantly increased IL-1β and TNF-α levels in DM wounds compared to non-diabetic wounds (P < 0.05) supporting our hypothesis that TLR signaling and activation contribute to the prolonged inflammation seen in DM wounds[7-9]. Because oxidative stress and inflammation are linked by TLRs[13] as a surrogate index of oxidative stress, we measured TBARS formation during an acid-heating reaction in wound tissues as described earlier[8,12]. Figure 4 depicts significantly higher TBAR levels in diabetic wounds compared to non-diabetic wounds (P < 0.01). Thus our data for the first time attests to the concept that persistent activation of TLR-MyD88-NF-κB signaling pathway and increased oxidative stress contribute to the hyperinflammation frequently seen in human DM wounds.

DISCUSSION

The interactions among increased glucose levels elevated free fatty acids and resultant proinflammatory cytokines in DM have clear implications for the immune system[14,15]. A diabetic foot ulcer is primarily comprised of keratinocytes, dermal cells, and leukocytes with a coexisting paucity for angiogenesis[16]. All the evidence point towards uncontrolled inflammation and frequent bacterial colonization at the site of injury as the main causes for foot ulcers not healing in a timely manner or not heal at all[7,16]. In addition, chronic diabetic ulcers may also persist due to disrupted formation of granulation tissues and deep tissue necrosis[7,16,17]. Along with cell specific abnormalities, inflammatory cytokine expression such as IL-1β and TNF-α are elevated and sustained by hyperglycemia implying the role of innate immunity[14,18]. TLRs in the wound bed environment play an important role in mediating innate immune functions and inflammation whereby potential healing may be impaired[6,8,9].

Studies in animal models as well as humans have suggested that inflammation is a major contributing factor to DM pathology primarily orchestrated by the innate immune receptors[8-10]. Mohammad *et al*[19] reported increased TLR2 and TLR4 expression in bone marrow derived macrophages of non-obese diabetic (NOD) mice, correlating with increased NF-κB activation and increased pro-inflammatory cytokines. Kim *et al*[20] using TLR2$^{-/-}$, TLR4$^{-/-}$ knockouts, and NOD mice have demonstrated that TLR2 senses beta cell death and contributes to the instigation of autoimmune diabetes. Recently, we showed increased TLR2 and TLR4 expression, intracellular signaling, and TLR2/4 mediated inflammation in monocytes with significant correlation to HbA1c levels in DM patients[21,22]. Creely *et al*[23] showed increased TLR2 expression in the adipose tissue of type 2 diabetes (T2DM) patients with strong correlates to plasma endotoxin levels. Also, Song *et al*[24] reported increased TLR4 mRNA expression in differentiating adipose tissue of

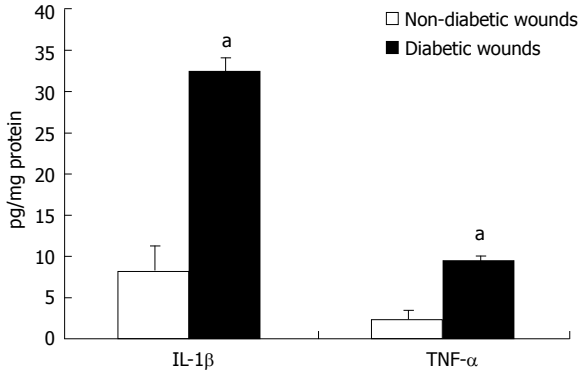

Figure 3 Interleukin-1β and tumor necrosis factor-α concentration in wound tissues were determined by ELISA assay. Values are normalized to mg protein and expressed as mean ± SD. $^{a}P < 0.05$ *vs* non-diabetic. IL-1β: Interleukin-1beta; TNF-α: Tumor necrosis factor-alpha.

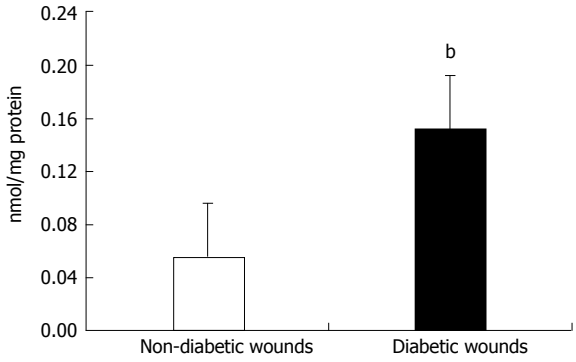

Figure 4 Lipid peroxidation in wound tissue lysates were determined using thiobarbituric acid reactive substances assay as described in Materials and methods. Values are normalized to mg protein and expressed as mean ± SD. $^{b}P < 0.01$ *vs* non-diabetic.

db/db mice. Furthermore, Davis *et al*[25] have shown that the TLR4-deficient 10ScN mouse strain fed with diet rich in saturated fat is protected from systemic inflammation. Taken together, these observations suggest a potential role for TLR2 and TLR4 in the pathology of DM. Furthermore, recent findings have shown increased TLR2/4 expression, signaling, ligands, and functional activation in DM subjects with and without complications[20,26]. All the above studies suggest that TLR activation and signaling contribute to the prolonged inflammatory condition seen in DM and may lead to complications in line with our current data.

Functional activation of TLRs includes dimerization and this results in cytokine production. TLR2 requires heterodimerization with TLR1 or TLR6 for activity[27]. We have previously shown that hyperglycemia induces TLR2/TLR6 heterodimerization resulting in cytokine secretion in human monocytes[14] consistent with the increased mRNA expression as seen in this study. However, it is to be noted that characterization of dimerization events *in vivo* is technically challenging. Besides, we also observed changes in TLR1 mRNA expression and it is not known if either TLR1 or TLR6 by themselves are inflammatory and if TLR2/1 heterodimerization play a role in the peristent inflammation. TLR2 primarily activates MyD88-dependent signaling pathway[28]. The activation of MyD88-dependent signaling pathway leads to the induction of inflammatory cytokines[28]. There are studies showing delayed dermal wound healing in nondiabetic MyD88-deficient mice[29], suggesting that alternate TLR pathways may be active in diabetic milieu (for example, TLR4/MD2). Here, we provide the first evidence, that in human DM wounds, there is increased TLR2 and TLR4 expression, with corresponding increased NF-κB activity, increased expression of downstream adapter proteins such as MyD88 and IRAK-1, resulting in increased local pro-inflammatory cytokines. Similar findings were found when cells were treated *in vitro* under hyperglycemic, dyslipidemia, and increased oxidative stress conditions[4,6,27]. Thus, we suggest that abrogating inflammation in human DM wounds using TLR2/4 as a target appears to be a reasonable approach to alleviate inflammation accelerating DM wound-healing process.

Collectively, these findings are best valued when recognizing that TLR activation, signaling, and inflammation may be undesirable for proper healing of wounds in DM patients. The limitations of the current study include the lack of correlative evidence between hyperglycemia, duration of diabetes, wound size, and TLR expression due to small sample size. Future and ongoing studies are focussed on collecting sequential wound debridement specimens, infected wound tissues to record the relationship between TLR activation and wound healing as this will aid in establishing the timing of the receptor expression and activation and the relationship between innate immunity and infection in manifesting the impaired wound healing phenotype. At the same time, TLR expression and activation may be used as a cue for healing. Prolonged and exacerbated cytokine production leads to sustained inflammatory responses and impaired healing, causing extensive tissue damage (amputations in case of diabetic wounds). Therefore, it is important to understand local inflammatory mechanisms that might be useful in developing therapeutic strategies for the management of difficult wounds burdened by excessive inflammation. Our findings suggest a role for TLRs in the human DM wound pathology and emphasize the importance of understanding the various pathogenic mechanisms involved in a complicated wound-healing process.

COMMENTS

Background

Toll-like receptors (TLRs) are sentinel pathogen recognition receptors with a pivotal role in inflammation, tissue injury, diabetes and its complications.

Innovations and breakthroughs

Increased TLR expression, signaling, and activation may contribute to the hyper inflammation in the human diabetic wounds.

Peer review

This manuscript is well written and shows results of potential interest.

Abstract

We experienced a case of liver abscess due to *Clostridium perfringens* (*CP*) complicated with massive hemolysis and rapid death in an adequately controlled type 2 diabetic patient. The patient died 6 h after his first visit to the hospital. *CP* was later detected in a blood culture. We searched for case reports of *CP* septicemia and found 124 cases. Fifty patients survived, and 74 died. Of the 30 patients with liver abscess, only 3 cases survived following treatment with emergency surgical drainage. For the early detection of *CP* infection, detection of Gram-positive rods in the blood or drainage fluid is important. Spherocytes and ghost cells indicate intravascular hemolysis. The prognosis is very poor once massive hemolysis occurs. The major causative organisms of gas-forming liver abscess in diabetic patients are *Klebsiella pneumoniae* (*K. pneumoniae*) and *Escherichia coli* (*E. coli*). Although *CP* is relatively rare, the survival rate is very poor compared with those of *K. pneumoniae* and *E. coli*. Therefore, for every case that presents with a gas-forming liver abscess, the possibility of *CP* should be considered, and immediate aspiration of the abscess and Gram staining are important.

Key words: Liver abscess; Gas-forming; *Clostridium perfringens*; Hemolysis; Diabetes

Core tip: Gas-forming liver abscess caused by *Clostridium perfringens* can result in massive hemolysis and death within several hours. For survival, urgent surgical intervention and antibiotic administration are necessary.

INTRODUCTION

Gas-forming infections are an example of a severe type of infection in diabetic patients. Although life threatening, there still remains time for treatment[1,2]. However, in rare cases of *Clostridium perfringens* (*CP*) infection, the time remaining for the patient is very limited[3-7]. *CP* is an anaerobic Gram-positive rod that is found in the soil and the human gastrointestinal and urogenital tracts. *CP* causes septicemia in cases of food intoxication, wound-associated soft tissue infections, liver abscess, and lung abscess. *CP* may cause septicemia without any apparent wound through bacterial translocation[5-8]. Patients typically have an underlying condition such as diabetes, malignancy, liver cirrhosis, or an immunosuppressive state[4-23].

In some reports, *CP* septicemia occurred after an invasive procedure in the hepatobiliary tract[24-26] or gastrointestinal tract or following gynecological treatment[27,28] or line insertion[29]. Early diagnosis is difficult because only nonspecific inflammation and gas formation in the focus are present. However, once α-toxin triggers hemolysis, it progresses very rapidly and is followed by acidosis and renal failure[30,31]. According to the literature, the mortality rate ranges from 70% to 100%[3]. For survival, surgical removal of the focus, appropriate antibiotics, control of hemolysis, and supportive care including hemodialysis are necessary. These treatments should be started before the blood culture result is returned. For early diagnosis, the detection of spherocytes and Gram-positive rods in the blood is important[5,32,33]. We experienced a case of liver abscess in an adequately controlled diabetic patient without any triggering event. The patient died within hours following massive hemolysis and cardiac arrest. Although the majority of gas-forming infections in diabetics are caused by *Escherichia coli* (*E. coli*) and *Klebsiella pneumoniae* (*K. pneumoniae*)[34], the possibility of *CP* infection should be considered.

CASE REPORT

The patient was a 65-year-old Brazilian of Japanese origin. He had a 3-day history of fever, appetite loss, nausea, and upper abdominal pain. The patient had type 2 diabetes treated with an oral hypoglycemic agent. He also had hypertension and dyslipidemia. He had a history of coronary stenting but no history of liver cirrhosis or malignancy. On physical examination, consciousness was clear, his blood pressure was 157/90 mmHg, and hyperventilation and coldness of the limbs were noted. Slight scleral jaundice and slight tenderness of the abdomen were noted. Laboratory examinations indicated mild liver dysfunction and elevation of serum bilirubin, C-reactive protein, and the white blood cell count (Table 1). At this time, the serum did not show any sign of intravascular hemolysis (Figure 1A). CT of the abdomen revealed a liver abscess 4 cm in diameter with gas formation in the right lobe (Figure 1C). A blood culture sample was taken, and ceftriaxone injection was started immediately. The patient briefly returned to his dormitory to prepare for admission and was found unconscious by a fellow worker. He was transferred to the hospital, and CPR was performed in vain. The serum color at this time point revealed strong hemolysis (Figure 1B). He died 6 h after his first visit to the hospital. The remarkably high levels of serum potassium (11.8 mEq/L) and lactate dehydrogenase (LDH) (6203 IU/L) during CPR suggested massive intravascular hemolysis. *CP* was later detected in the blood culture. Autopsy was refused, and we were unable to determine whether he had an occult malignancy.

Recently, van Bunderen *et al*[3] reported 40 cases of *CP* septicemia and hemolysis between 1990 and 2010. In total, 80% of the patients had died; among the 11 cases with liver abscess, 10 (90.9%) had died. These 10 cases included two cases of microabscess. In one case, the focus of infection was removed, and the patient survived. On the other hand, Fujita *et al*[35] studied patients with systemic inflammatory response syndrome (SIRS) with *CP*-positive blood cultures and reported that 5 of 18 cases had died (27.8%). Yang *et al*[36] reported the prognosis of *CP* septicemia in a tertiary care hospital. They found 93 cases over 10 years, and the 30-d mortality rate was 26.9%. Therefore, the mortality rate of *CP* septicemia differs considerably. We hypothesized that the complication of liver abscess decreases the survival rate. We searched PubMed for papers published since 2010 and the database of the Japan Medical Abstract Society since 1994 with the keywords "Clostridium perfringens" and "septicemia". We found 20 cases from PubMed and 104 cases from Japan, including our case[4-33,35,37-39]. Fifty patients survived, and 74 (59.7%) died.

Several possible triggers of septicemia were found, including transarterial embolization of the hepatoma[24,25], laparoscopic cholecystectomy[26], amniocentesis[27], abortion[28], and intravenous line insertion[29]. Among the 30 cases with liver abscess, 27 (90%) died. Six cases underwent drainage or laparotomy, and three cases survived[8,30,38]. Among the cases with liver abscess, 23 were male and 7 were female; the average patient age was 67.2 years old, and 11 patients had diabetes. The median time from the first visit to death was only 6 h. Of the 74 deceased patients, 45 were male, 21 were female, and 8 were not described; the average age was 64.4 years old. Malignancy was the frequent underlying disease. Twenty-one cases had a history of cancer in the liver, stomach, colon, rectum, gall bladder, biliary duct, lung, pancreas, breast, prostate gland, or uterus. Ten cases had a history of leukemia, lymphoma, or multiple myeloma. One patient had

Table 1 Serial laboratory results for a patient with liver abscess and massive hemolysis caused by *Clostridium perfringens*

Parameter	Admission	On CPR	Reference range
White blood count (× 10^9/L)	24.8	26.0	3.5 to 9.7

APTT: Activated partial thromboplastin time.

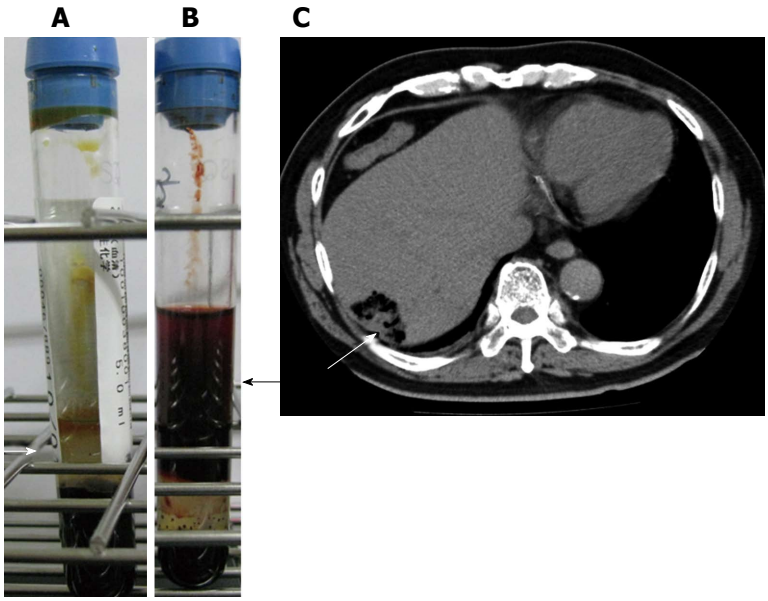

Figure 1 The serum color before and after massive hemolysis and computed tomography imaging results. A: Patient serum color on admission showed no sign of hemolysis (white arrow); B: The dark red color of serum taken during CPR indicated massive hemolysis (black arrow); C: Computed tomography of the abdomen revealed a 4 cm × 2 cm abscess with gas formation in the right lobe (white arrow).

a brain tumor. In total, 30 cases (45.5%) had a history of at least one malignancy. Eighteen cases had diabetes. Four cases had liver cirrhosis. The median time from the first visit to death was 6 h. Only 12 cases (16%) had undergone emergency surgery or drainage. Two patients received hemoperfusion using a polymyxin B-immobilized fiber column (PMX-F), which is used for endotoxin removal in Japan and Italy[40-43]. Of the 50 surviving patients, 16 were male, 19 were female, and 15 were not described. Females were significantly more prevalent among the survivors, according to a chi-squared test ($P < 0.05$). Three cases involved children younger than 2 years old. The average age, excluding these small children, was 58.1 years. The age difference between the deceased and surviving cases was not significant ($P = 0.06$), according to a two-sided t test. Six cases had leukemia, and 4 cases had cancer or sarcoma in the breast, uterus, or colon. Six cases had diabetes. Twenty (40%) cases underwent surgical removal or drainage of the focus. A significantly greater number of patients who underwent surgical debridement or drainage were among the surviving cases compared with the deceased cases, according to a chi-squared test ($P < 0.01$). PMX-F was used to treat 5 patients who survived. Among the surviving cases, steroid pulse therapy was performed in three cases and hyperbaric oxygen therapy was used in two.

DISCUSSION

Although our case did not show anemia at first presentation and the size of liver abscess was only 4 cm, he developed massive fatal hemolysis within hours, despite prompt treatment with the appropriate antibiotics. Therefore, *CP* septicemia should be considered in diabetic patients with fever and gas-forming lesions before any signs of hemolysis develop. van Bunderen *et al*[3] reported 40 cases of septicemia caused by *CP* during 1990-2010. Over half of the patients presented elevated bilirubin and LDH as well as anemia, suggesting hemolysis at the initial presentation. Thirty-two of the patients died, and the median time from admission to death was only 8 h. We searched new cases of *CP* septicemia. We found 124 cases, and the death rate was 59.7%. However, in cases with liver abscess, the death rate reached 90%, and the median time from visit to death was only 6 h. Rapid hemolysis caused by α-toxin is an important complication that makes rescue difficult. The α-toxin of *CP* has two domains plus one loop in between. The N-terminal domain has phospholipase activity, and the C-terminal domain is hydrophobic and inserts into the cell membrane[44]. The loop between the N- and C-terminal domains contains a GM1 ganglioside-binding motif and specifically binds GM1a. In addition to disrupting membrane phospholipids through phospholipase activity, α-toxin binding to GM1a triggers specific signaling events. The activation of a tyrosine kinase A (TrkA)[45] and the subsequent signaling cascade results in the release of tumor necrosis factor-α (TNF-α). The catastrophic events induced by α-toxin may in part be mediated by TNF-α signaling. The hemolysis of erythrocytes by α-toxin is reported to depend on Ca^{2+} uptake[46].

The key for patient rescue is how fast the appropriate treatments are started. At the moment of suspicion of *CP* septicemia, aggressive early management is warranted, including timely debridement or drainage of the focus, initiation of appropriate antibiotics without delay, and support of circulation with a multi-disciplinary team approach. For the early diagnosis of *CP* infection, Gram staining of the blood or drainage sample is important because *CP* is a Gram-positive rod, whereas *K. pneumoniae* and *E. coli* are Gram negative. The early signs of hemolysis are elevated LDH, total or indirect bilirubin, and potassium. Spherocytes or ghost cells may be found in the blood film. A red color of the serum or hemoglobinuria may be observed after substantial hemolysis.

Shah *et al*[47] reported 25 cases of *CP* septicemia in a tertiary-care hospital from 1995 to 2003 and classified antibiotics into two categories. The antibiotics classified as "appropriate" for *Clostridium* were penicillin G, clinda-

mycin, cefoxitin, metronidazole, ampicillin/sulbactam, piperacillin/tazobactam, and imipenem/cilastatin; other antibiotics were classified as "insufficient". Patients treated with "insufficient" antibiotics had a significantly higher 2-d mortality rate (75%) compared with patients treated with "appropriate" antibiotics (12.5%). Clindamycin, metronidazole, and rifampicin have been shown to be effective methods to reduce the release of α-toxin[48]. However, penicillin and cephalosporin do not have such activity. Oda *et al*[49] have reported that erythromycin pretreatment reduces the release of TNF-α from activated neutrophils and suppresses hemolysis.

Because α-toxin has enzymatic activity, methods to neutralize or eliminate this toxin are needed. Unfortunately, we were unable to find any established method of doing so. PMX-F is used in septic shock treatment. PMX-F binds endotoxin, monocytes, activated neutrophils, and anandamide, decreasing inflammatory cytokines and other mediators. A review by Cruz *et al*[40] analyzed 987 patients treated with PMX-F and 447 patients treated with conventional medical therapies. PMX-F increased the mean arterial pressure by 19 mmHg while reducing the dopamine/dobutamine dose by 1.8 μg/kg per min. PMX-F therapy was associated with a significantly lower mortality risk (RR = 0.53; 95%CI: 0.43-0.65). However, the number of reported cases is currently too small to discuss the effectiveness of PMX-F in the treatment of *CP* septicemia. Ochi *et al*[46] reported that flunarizine, a T-type Ca^{2+} channel blocker and tetrandrine, an L- and T-type Ca^{2+} channel blocker, inhibited hemolysis by α-toxin. Nagahama *et al*[50] reported that the C-terminal recombinant peptide of α-toxin was effective as a vaccine to protect against hemolysis in an animal experiment.

Empirical antibiotic therapy should be started before the culture results are returned. The major causative organisms of gas-forming liver abscesses are *K. pneumoniae* and *E. coli*[1,2,34]. These organisms can also cause fatal infections, and endophthalmitis or meningitis may occur[51], but the mortality rate is not as high as that of *CP*. A review of 46 cases reported death in *K. pneumoniae* liver abscess for 11 of 43 (25.6%) patients[51]. According to a report from China, 95% of the patients with liver abscess were eventually cured if treated radically[34]. Fortunately, *CP* septicemia is rare. Kasai *et al*[52] reported that among cases of severe infection in diabetic patients in Japan, 119 cases presented with a gas-forming abscess, and only 8 cases were positive for *Clostridium*. Kurai *et al*[53] reported that among 5011 blood samples that were positive for any bacteria, only 41 were positive for *Clostridium*. Of the 41 samples, 16 were confirmed as septicemia, and 9 of the 16 were positive for *CP*. According to a report from Canada, the incidence of *CP* septicemia in the community is 0.7 in 100000 per year[54]. Additionally, in hospital-based studies, *CP* septicemia is very rare. Zahar reported 45 cases of anaerobic bacteremia among 7989 positive blood cultures in a cancer center during 1993-1998[55]; seven of them were *CP* septicemia. Woo *et al*[53] reported 38 cases of *Clostridium* septicemia in a large hospital from 1998 to 2001; 79% of them were caused by *CP*, and the overall mortality was 29%. Younger age and gastrointestinal/hepatobiliary tract disease were associated with mortality. However, considering the very high mortality rate associated with liver abscess, excluding *CP* infection is important.

In summary, *CP* septicemia is a rare but well-known cause of massive intravascular hemolysis. Diabetic patients with fever and gas-forming lesions should always be suspected of having *CP* septicemia.

COMMENTS

Case characteristics

A 65-year-old male with treated diabetes presented with fever and upper abdominal pain.

Clinical diagnosis

Hypertension, hyperventilation, coldness of limbs, scleral jaundice, and tenderness of the abdomen were noted.

Differential diagnosis

Obstructive jaundice complicated with biliary infection and liver abscess.

Laboratory findings

White blood cell 24.8 × 10^9/L, hemoglobin 135 g/L, total bilirubin 6.4 mg/dL, aspartate aminotransferase 140 IU/L, alanine aminotransferase 178 IU/L, creatinine 1.33 mg/dL, C-reactive protein 23.2 mg/dL, and glucose 226 mg/dL.

Imaging diagnosis

Computed tomography imaging showed a gas-forming mass (4 cm × 2 cm) in the right lobe of the liver.

Pathological diagnosis

Autopsy was not allowed, and blood culture revealed infection by *Clostridium perfringens*.

Treatment

Injection of ceftriaxone was started immediately.

Related reports

The reported mortality rate of *Clostridium perfringens* septicemia varies widely from 26.9% to 80%; however, 90% of patients with liver abscess have been reported to die.

Term explanation

Polymyxin B-immobilized fiber column (PMX-F) is hemoperfusion with a polymyxin B-immobilized fiber column used to remove endotoxin in cases of septic shock.

Experiences and lessons

Although rare, fatal liver abscess patients should be under close observation, and the possibility of *Clostridium perfringens* infection should be considered upon the slightest sign of hemolysis.

Peer review

This is a well written manuscript in which the author gave detailed description of death report associated with *CP* infection.

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α, β, δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

Abstract

Blood glucose control in intensive care unit (ICU) patients, addressed to actively maintain blood glucose concentration within defined thresholds, is based on two major therapeutic interventions: to supply an adequate calories load and, when necessary, to continuously infuse insulin titrated to patients needs: intensive insulin therapy (IIT). Short acting insulin analogues (SAIA) have been synthesized to improve the chronic treatment of patients with diabetes but, because of the pharmacokinetic characteristics that include shorter onset and off-set, they can be effectively used also in ICU patients and have the potential to be associated with a more limited risk of inducing episodes of iatrogenic hypoglycemia. Medical therapies carry an intrinsic risk for collateral effects; this can be more harmful in patients with unstable clinical conditions like ICU patients. To minimize these risks, the use of short acting drugs in ICU patients have gained a progressively larger room in ICU and now pharmaceutical companies and researchers design drugs dedicated to this subset of medical practice. In this article we report the rationale of using short acting drugs in ICU patients (*i.e.*, sedation and treatment of arterial hypertension) and we also describe SAIA and their therapeutic use in ICU with the potential to minimize iatrogenic hypoglycemia related to IIT. The pharmacodynamic and pharmachokinetic characteristics of SAIA will be also discussed.

Key words: Insulin analogues; Short acting drugs; Intensive insulin therapy; Glycemia management; Intensive care

Core tip: In this article we report the rationale of using short acting drugs in intensive care unit (ICU) patients (*i.e.*, sedation and treatment of arterial hypertension) and we also describe short acting insulin analogues (SAIA) and their pharmacokinetic (PK) and pharmacodynamic profile. SAIA have been synthesized to improve the chronic treatment of patients with diabetes but, because of the PK characteristics that include shorter onset and offset, they can be effectively used also in ICU patients and have the potential to be associated with a more limited risk of inducing episodes of iatrogenic hypoglycemia.

INTRODUCTION

Blood glucose control in intensive care unit (ICU) patients, addressed to actively maintain blood glucose concentration (BGC) within defined thresholds, is based on two major therapeutic interventions: to supply an adequate calories load and, when necessary, to continuously infuse insulin titrated to patients needs: intensive insulin therapy (IIT)[1,2]. Among the most relevant risks related to active management of BGC is the induction of iatrogenic hypoglycemia[1-4]. Endogenous insulin is a 51 amino acids protein formed by 2 chains (A and B chains) linked

by disulphide bridges: "A" chain comprises 21 amino acids and has an N-terminal helix linked to an anti-parallel C-terminal helix with a critical role in the tertiary structure; "B" chain comprises 30 amino acids and has a central helical segment where it joins the N- and C-terminal helices of the A chain[5]. Physiologically, insulin is released by the pancreas with a characteristic biphasic profile as response to BGC increase: a rapid phase, due to exocytosis of "ready pool" granules and associated with the release of 5%-10% of the insulin contained in the beta cells, is activated within few minutes after an increase in BGC and terminates rapidly; a slow phase, due to the release of "reserve pool" granules, and lasts longer. Beside BGC driven insulin release, there is also a continuous insulin secretion throughout the day, not associated with meals that accounts for about 50% of the whole daily endogenous insulin secretion[5].

As underlined by several authors and by the pathophysiology of chetoacidosis in diabetic patients and in ICU patients, to supply an adequate calories load is a preliminary step for optimal management of BGC and should be established before insulin infusion is instituted, even in patients with high BGC values[1,2,6].

Currently the standard of care for the treatment of hyperglycemia in ICU patients is to establish intensive insulin therapy by infusing rapid (R) insulin but-and this is among the most important drawback of this therapeutic approach-it induces some additional risk of iatrogenic hypoglycemia[1]. Various strategies have been used to minimize the risk of inducing hypoglycemia when IIT is instituted, these include: to adopt a tighter BGC monitoring protocol, to target a narrower BGC range, to increase the supplied calories load[1,7-10].

In 2001, a large randomized controlled trial in critically ill surgical patients demonstrated that tight glucose control (defined as the restoration and maintenance of BCG at or below 6.1 ± 2.1 mmol/L) by IIT was associated with a decreased mortality and rate of complications[6]. Currently, other authors demonstrated that the incidence of moderate hypoglycemia was significantly increased when target was BGC < 6.7 mmol/L and BGC < 8.3 mmol/L may be a reasonable target for clinical practice[8]. Widening the target-range BGC might reduce the risk of hypoglycemia and hyperglycemia developing, thus limiting neuronal damage[2]. In the subgroup of neurocritical care patients both hypoglycemia and hyperglycemia may cause extended neuronal damage and potentially long-lasting brain injury[1,2]. These patients must therefore undergo strict glycemia monitoring and abnormal blood glucose values should be immediately corrected[1].

In this article we report the rationale of using short acting drugs in ICU patients (*i.e.,* sedation and treatment of arterial hypertension) and we also describe short acting insulin analogues (SAIA) and their therapeutic use in ICU with the potential to minimize iatrogenic hypoglycemia related to IIT. The pharmacodynamic and pharmachokinetic characteristics of SAIA will be discussed.

RATIONALE FOR USING SHORT ACTING DRUGS IN CRITICAL CARE PATIENTS

In pharmaceutical research there is a trend to provide short acting drugs-also called "soft" drugs-to treat critically ill patients and the unstable phase of acute illness and for anesthesia/sedation and perioperative management[11]. The use of short acting vasodilators (*i.e.,* nitroglycerin) in the acute phase of acute myocardial infarction, acute episodes of arterial hypertension in the treatment of the acute phase of heart failure and pulmonary edema is the paradigm of the need for short acting drugs in the treatment of acute illness[12-14]. Recent antihypertensive drugs (as esmolol) and short acting opioids (as remifentanil) are prototypical "soft" drugs designed to fulfill the need for limiting drug-related residual effects when infusion is discontinued[11]. These molecules frequently rely on plasmatic metabolism by non specific bloodstream esterases. A common molecular paradigm to reduce pharmacokinetic (PK) characteristics (including onset and half life) is to modify the parent compound into a "soft" drug by adding an ester linkage, thus, increasing its susceptibility to bloodstream metabolism[11]. In anesthesia new drugs have been developed (midazolam, propofol, desflurane) modifying existing compounds in order to shorten anesthesia induction and awakening times[11,15].

Antihypertensive

Sympathetic stimulation contributes to cerebral hyperemia during emergence from craniotomy. B-blocking drugs may be considered to limit hemodynamic changes of neurosurgical recovery. Esmolol blunted the increase in cerebral blood flow during recovery from neurosurgical anesthesia[16]. Hypertensive emergencies generally require intravenous treatment to achieve a rapid decrease in blood pressure and patients admitted to these care settings may be sicker than patients treated with oral agents. The first choice antihypertensive drug varied by treatment location. In ICU nitroglycerine was by far the most widely used (60%); in the emergency department furosemide was used in 34% of patients and nitroglycerine was used in 27%; perioperatively urapidil was used in 34% of patients and clonidine was used in 28%[12]. While nitroglycerine should be used as an adjunctive therapy, the high rates of use in the European registry for Studying the Treatment of Acute hypertension population likely reflect familiarity with its use, together with its ease of administration, titration and rapid reversibility[12].

Analgesia-sedation

Analgesics and sedatives are commonly prescribed in ICU environment for patient comfort; however, recent studies have shown that these medications can themselves lead to adverse patient outcomes[17]. The use of short acting medications is associated with improved outcomes such as decreased time of mechanical ventilation and ICU length of stay[17]. Using a short-acting opioid

with short context-sensitive half-life in an analgesia based sedation protocol may significantly decrease the duration of mechanical ventilation and the ICU length of stay even though not significantly in long term sedation, while improving the achievement of sedation goals despite a lower requirement for adjunctive hypnotic agents, with no additional costs. The context-sensitive half-life of remifentanil is significantly shorter than those of other opiates. In the remifentanil group, the decreases in need for mechanical ventilation and ICU length of stay were associated with a significant decrease in the use of add-on hypnotics, suggesting that remifentanil was faster adjustable to the required sedation level[18].

Regarding sedation, Clinical Practice Guidelines[19] recommend the use of propofol-rapid onset of sedation (highly lipid soluble and quickly crosses the blood-brain barrier), and rapid offset (quickly redistribution with high hepatic and extrahepatic clearance)-and dexmedetomidine (selective α2-receptor agonist rapidly redistributed into peripheral tissues) over benzodiazepines fot ICU sedation.

Inhaled anesthetics (short acting drugs) may be ideal sedatives for the ICU[20] because of their pulmonary elimination, limited amount of metabolism, bronchodilation and cardioprotective effects[21]. However, inhaled anesthetics are not widely used for sedation in the ICU, since most modern ICU ventilators do not readily accommodate an anesthetic vaporizer. The new anesthetic conserving device, AnaConDa (Sedana Medical™, Sweden) uses a syringe pump to deliver inhaled anesthetic in liquid form into the breathing circuit of a standard ICU ventilator. Belda *et al*[22] adapted a classical PK model to obtain an infusion scheme for the clinical use of the AnaConDa with sevoflurane. Another short acting drug in ICU.

SHORT ACTING INSULIN ANALOGUES

SAIA were developed to improve postprandial glycemic control and to minimize BGC excursions in diabetic patients[23-25]. Due to a PK profile closer to that of endogenous insulin, when physiologically released by the trigger of meals, SAIA have a faster rise in plasma concentration, higher peak concentration and shorter subcutaneous residence time than unmodified human insulin[26]. The clinical use of SAIA is associated with lower postprandial peak BGC as compared with rapid insulin and doesn't increase the incidence of hypoglycemia[23-25].

Currently, 3 SAIA are available for clinical use: lyspro insulin (Humalog®; Eli Lilly, Indianapolis, IN, United States), aspart insulin (Novolog®/NovoRapid®; Novo Nordisk, Bagsvaerd, Denmark) and glulisine insulin (Apidra®; Sanofi, Paris, France).

Lyspro insulin, first SAIA that became available for clinical use in 1996, is characterized by a change in the amino acid sequence of insulin B chain-proline in position 28 and lysine in position 29 are inverted [Lys(B28), Pro(B29)]-that results in a reduced self association[27-29]. These changes result in an insulin molecule with a reduced capacity for self-association[27,28]. Proline at position B28 near the COOH-terminal of the B-chain of human insulin is important for the proper configuration of a p-sheet involving residues B24 through B26. Two insulin molecules align along this surface in an antiparallel orientation to form a nonpolar dimer. At this point, the nonpolar dimer interacts with zinc to form a hexamer, the basis of Regular insulin formulations. The sequence of lysine at B28 and proline at B29 can be found in insulin-like growth factor I (IGF- I) and is thought to be responsible for its lower degree of self-association in comparison to insulin. Accordingly, IGF- I is the model upon which the structure of lyspro is based[27-29]. As a result of these modifications, lyspro exhibits monomeric behavior in solution, binds zinc less avidly, and displays faster pharmacodynamic action than human Regular insulin (Humulin R®). These findings are consistent with the rapid absorption expected from monomeric insulin injected subcutaneously[27,29].

Aspart insulin, second SAIA to achieve regulatory approval in 2000, is characterized by a change in the amino acid sequence of insulin B chain-proline in position 28 is substituted with the charged aspartic acid-this reduces self-association of the molecule, allowing only weak dimeric and hexameric formation and thereby rapid dissociation after subcutaneous injection[27,29,30]. Receptor interaction kinetic studies have shown that aspart insulin behaves essentially like human insulin with regard to both the insulin and IGF- I receptor with a similar potency to that of human insulin[29,30]. Aspart insulin is absorbed twice as fast as regular insulin and reaches a maximum concentration in plasma of approximately twice that of human insulin. Its activity profile is very similar to that of human insulin[29,30].

Glulysin insulin, third SAIA to receive regulatory approval, is characterized by a change in the amino acid sequence of insulin B chain-lysine and glutamic acid are substituted for asparagine and glycine in positions 3 and 29 respectively-it is thought that this latter substitution is predominantly responsible for its PK properties[27,29,31]. Studies indicate that glulisine has a very comparable PK and pharmacodynamic profile to insulin lispro[27,29,31]. Overall, the bioequivalence of glulisine is similar to that of human insulin[27,29,31].

DISCUSSION

In this review article we originally report the use of SAIA in critical care patients. The pharmacodynamic and pharmacokinetic characteristics of SAIA available for clinical use are described and the rationale for using shorter acting insulin is presented.

Altered pharmacology in the intensive care unit

Critically ill patients, not infrequently present alterations of physiological parameters that determine the success/failure of therapeutic interventions as well as the final outcome[32]. Most common and complex syndromes occurring in ICU affect drug absorption, disposition, metabolism and elimination[33]. Pharmacological man-

agement of ICU patients requires consideration of the unique PKs associated with these clinical conditions and the likely occurrence of drug interaction[34]. Rational adjustment in drug choice and dosing contributes to the appropriateness of treatment of those patients[35].

Adverse drug events in intensive care unit

Intensive care medicine provides great benefits to patients with life-threatening acute illness or trauma. These benefits are a consequence of advancements in diagnostic testing, technological interventions and pharmacotherapy. Simultaneously, the complexity and intensity of care required by ICU patients is also associated with greater risks resulting from care[36]. Adverse drug events (ADEs), including adverse reactions and medication errors, are harmful and occur with alarming frequency in critically ill patients[37].

Patients in ICUs may be at especially high risk of an ADE for the following reasons[38,39]: (1) The complexity of diseases; (2) Pathophysiological status characterized by a wide range of changes in organ dysfunction (altering PKs); (3) The high number of medications administered; (4) Administration of complex drug regimens; and (5) Increased length of hospital stay. Hypoglycemia and hyperglycemia are in the 10 top ADE in the ICU[40].

Drug-drug interactions in ICU

Drug-drug interactions (DDIs) in the ICU are associated with longer ICU stays, ADE and end-organ damage[41]. Critically ill patients are at an increased risk of ADE related to DDIs because of the large number of medications that they receive and PK characteristics of the administered medications[42].

The 10 most frequently ocurring DDI in the ICU include insuline/metoprolol (moderate severity rating, β-blockers may enhance the hypoglycemic effects of insulin) and insulin/prednisone (moderate severity rating, corticosteroids may diminish the hypoglycaemic effect of antidiabetic agents)[43].

In this context, medical therapies carry an intrinsic risk for collateral effects; this can be more harmful in patients with unstable clinical conditions like ICU patients[44]. To minimize these risks, the use of short acting drugs in ICU patients have gained a progressively larger room in ICU and now pharmaceutical companies and researchers design drugs dedicated to this subset of medical practice[11]. SAIA have been synthesized to improve the chronic treatment of patients with diabetes but, because of the PK characteristics that include shorter onset and offset, they can be effectively used also in ICU patients and have the potential to be associated with a more limited risk of inducing episodes of iatrogenic hypoglycemia. Clinical studies addressed to assess the dosing profile and the safety of SAIA when used-as intravenous continuous therapy- to accomplish IIT in ICU patients.

Abstract

Diabetes mellitus (diabetes) is a devastating disease that affects millions of people globally and causes a myriad of complications that lead to both patient morbidity and mortality. Currently available therapies, including insulin injection and beta cell replacement through either pancreas or pancreatic islet transplantation, are limited by the availability of organs. Stem cells provide an alternative treatment option for beta cell replacement through selective differentiation of stem cells into cells that recognize glucose and produce and secrete insulin. Embryonic stem cells, albeit pluripotent, face a number of challenges, including ethical and political concerns and potential teratoma formation. Adipose tissue represents an alternative source of multipotent mesenchymal stem cells, which can be obtained using a relatively simple, non-invasive, and inexpensive method. Similarly to other adult mesenchymal stem cells, adipose-derived stem cells (ADSCs) are capable of differentiating into insulin-producing cells. They are also capable of vasculogenesis and angiogenesis, which facilitate engraftment of donor pancreatic islets when co-transplanted. Additionally, anti-inflammatory and immunomodulatory effects of ADSCs can protect donor islets during the early phase of transplantation and subsequently improve engraftment of donor islets into the recipient organ. Although ADSC-therapy is still in its infancy, the potential benefits of ADSCs are far reaching.

Key words: Diabetes mellitus; Diabetes; Insulin; Stem cells; Adipose; Pancreas; Beta-cells; Differentiation

Core tip: Adipose-derived stem cells (ADSCs) can provide a promising cell therapy for treatment of diabetes and associated complications. ADSCs' multipotency allows differentiation into insulin-producing β-cells. Anti-inflammatory and immunomodulatory capabilities of ADSCs can facilitate enhanced engraftment of transplanted donor islets. Although many challenges lie ahead for ADSC-based cell therapies are used clinically to treat diabetic hyperglycemia, ADSCs represent a novel treatment option to many diabetic patients worldwide.

INTRODUCTION

Diabetes mellitus (diabetes) is a chronic disease, affecting over 347 million people globally[1-8]. Due to diets with high fat and high sugar accompanied by sedentary lifestyles, the global epidemic of diabetes is expected to rise. Furthermore, the economic burden imposed by diabetes and its complications easily exceeds $100 billion annually[9].

The most common treatment for type 1 and some type 2 diabetes is insulin therapy. Intensive insulin treat-

ment can maintain normoglycemia, and control acute hypoglycemia as well as long-term complications[10,11], however, fails to achieve normal hemoglobin A1c levels. Advancements in commercial glucose monitors, insulin formulation, and insulin pumps are also providing improved control of diabetic symptoms[10,12]. However, even with widely available insulin therapy, the life expectancy of diabetic patients is approximately 12 years shorter on average than that of non-diabetic individuals[9,13]. Additionally, those with child-onset type 1 diabetes have a significantly increased risk of retinopathy, nephropathy, neuropathy, and various cardio-, cerebro- and peripheral vascular diseases[5,6,9,10,14-21].

More definitive treatment options for type 1 diabetes, which is characterized by autoimmune destruction of insulin-producing β-cells in pancreatic islets of Langerhans, are pancreas or pancreatic islet transplantation[22-26]. Over a century ago, pancreas extracts were the first transplants tested in diabetic patients[27]. Modern-day pancreas and pancreatic islet transplantations are relatively effective in normalizing fasting and postprandial blood glucose levels, hemoglobin A1c levels as well as restoring insulin and C-peptide production[9]. However, the severe shortage of available donors limit the widespread adoption of this form of therapy[10,28], and thus, appear to only benefit less than 0.5% of type 1 diabetics[28]. Additionally, life-long requirement of immunosuppression and adverse effects caused by immunosuppressants, such as nephrotoxicity, hypertension, and hypersensitivity to infection, often leads to patient non-compliance[10,28,29]. Lastly, reoccurring autoimmunity against pancreatic β-cells continues to be a major challenge associated with transplantation therapies[9].

Recent advancements in stem cell isolation and differentiation methodologies have resulted in production of cell lines with the capability to synthesize, package, and subsequently secrete insulin in response to glucose. Albeit pluripotent, embryonic stem (ES) cell differentiation often leads to the development of multiple cell lineages, resulting in a mixed population of cells along with target cells[9]. Definitive endodermal markers are also absent in ES cells, and undifferentiated teratogenic ES cells may pose serious risks as well[9,28]. Due to ethical and legal concerns and risks of teratoma formation, embryonic stem cells face austere challenges in becoming a clinically viable solution although cellular isolation device may provide a method to implant embryonic stem cells with insulin producing capabilities[30].

Multipotent progenitor cells are now known to be localized in many different organs[31]. Although multipotent, adult stem cells provide a relatively reliable source of mesenchymal stem cells for cell-based therapies. Recently, adult stem cells from bone marrow, umbilical cord blood, pancreatic duct, periosteum, and adipose tissue have shown a capacity to differentiate into insulin-producing cells[32-43].

Among the many tissue sources for adult stem cells, adipose tissue is particularly attractive based on its stem cell abundance and ease of tissue procurement through a minimally invasive and relatively inexpensive procedure[44-48]. Mesenchymal stem cells from bone marrow and adipose tissue share similar cell populations, along with cell characteristics[49-51]. Adipose tissue has also been reported to contain a significantly greater number of mesenchymal stem cells than bone marrow per unit weight[6,52-54]. In this review, adipose-derived stem cells will be specifically examined for their utility in developing treatments for diabetes and diabetic complications.

Direct differentiation into pancreatic hormone producing cells

Kodama *et al*[55] proposed four mechanisms of pancreatic regeneration: (1) replication of mature β-cells; (2) differentiation of stem cells; (3) cell fusion; and (4) transdifferentiation of one stem cell type to another. Most studies on cell-based therapies focus on direct differentiation of stem cells into insulin-producing β-cells.

Mesenchymal stem cells derived from adipose tissue exhibit unique characteristics well suited for transdifferentiation into a pancreatic endocrine lineage, which is of the endodermal origin. Freshly isolated adipose-derived stem cells (ADSCs) also expressed stem cell factor (SCF) and its receptor (c-kit)[44,56], but not ABCG2, nestin, Thy-1, and Isl-1. Lin *et al*[6] reported that ADSCs constitutively expressed glucagon and NeuroD as well as insulin. The proliferative ADSCs, on the other hand, expressed the transcription factor Isl-1 and Pax-6, which are critical transcription factors required for β cell development[44,56], as a previous study showed that formation of insulin- and glucagon-positive cells were found inhibited during development of Isl-1 knock-out mice[57]. Therefore, the intrinsic expression of Isl-1 in ADSCs provides a considerable advantage for generating insulin-producing cells. Proliferative ADSCs also express stem cell markers nestin, ABCG2, SCF, and Thy-1. Nestin was originally thought to be a neural stem/progenitor cell marker but was recently reported to be a multipotent pancreatic stem cell marker as well, detected within pancreatic islets[16,58]. ABCG2 has also shown to be associated with pancreatic islet-derived precursor cells and neural stem cells[10,59]. Kojima *et al*[60] demonstrated that extrapancreatic insulin-producing cells, which were positive for proinsulin and insulin, were present in the adipose tissue of streptozotocin-induced diabetic rodents. Based on these intrinsic characteristics, ADSCs can serve as a promising source of pancreatic hormone-producing cells following differentiation.

Derivation of insulin producing cells from stem cells is made possible through the understanding of key steps during embryonic development and the coordinated activation of intracellular transcription factors. Similar to embryonic stem cells[61-65], derivation of insulin-producing cells from ADSC is executed through a progressive multistage differentiation protocol: starting from definitive endoderm into pancreatic endoderm and finally into pancreatic hormone-expressing cell[2,44,56,66-68]. Outlines the culture conditions used by various groups to stimulate ADSCs into an insulin-producing cell lineage.

All of the differentiated cell populations reported

were stained positively for dithizone, indicating the presence of endogenous insulin. Furthermore, these stem cell-derived insulin producing cells exhibited abundant expression of Pdx-1, C-peptide, insulin, glucagon, somatostain, pancreatic polypeptide, and Glut-2[2,44,56]. Enhanced expression of Isl-1, Pax-4, Ngn-3, Ipf-1, Pax-6, Nkx-2.2, Nkx-6.1, FoxA2, GLP-1 receptor, and glucokinase was also confirmed in differentiated cells, implicating pancreatic lineage[2,16,44,56,69]. Interestingly, transcription of leptin and adiponectin was also well maintained in differentiated cells, still demonstrating adipose tissue characteristics. Additionally, expression of visfatin, which activates insulin receptors and has a blood glucose lowering effect similar to insulin, was significantly upregulated following differentiation into an insulin producing phenotype[44].

Following transplantation of human ADSC-derived insulin producing cells into streptozotocin-induced diabetic mice, a significant level of human C-peptide was detected in subjects, demonstrating successful insulin production *in vivo*. Although these differentiated cells demonstrated a capacity to lower blood glucose levels, the insulin secretion level compared to mature pancreatic islets was significantly lower, and they failed to restore normoglycemia in STZ-induced diabetic mice[6,44,67].

The ability of ADSCs to differentiate into insulin-producing cells akin to mature native pancreatic cells also remains under question. Dor *et al*[70] used a genetic lineage tracing method to determine whether pancreatic stem cells contribute to pancreatic β-cell replenishment during adult life. In this study, they demonstrated that terminally differentiated mature β-cells maintain their proliferative capacity and serve as a major source of new β-cells in mice, contrary to previously reported studies[71-74]. Although this study directly rejected pluripotent adult stem cells' role in replacing β-cells *in vivo* following partial pancreatectomy, it does not directly refute the utility of insulin-producing cells, differentiated from adult stem cells *in vitro*, as a potential new treatment option for diabetics as demonstrated by a number of studies previously reported[71-74].

Engraftment of transplanted islets

Success of pancreatic islet transplantation depends on successful engraftment into the recipient liver where donor islets are transfused through the hepatic portal vein. However, apoptosis, inflammation and ischemia frequently interfere with successful engraftment[75], and therefore two or more pancreata are frequently required to procure sufficient numbers of islets for each transplant. This is a major limitation to the widespread use of this therapy, considering the acute shortage of donor organs. Due to unavoidable destruction of native islet structures, including intraislet vasculature, during isolation, islet engraftment could take up to several weeks[76,77]. Further deterioration of islets and β-cell death can occur due to ischemia and inflammation, ultimately leading to graft failure[78,79]. A mean to improve engraftment of transplanted islets will lead to a reduction of the required number of pancreata and more positive clinical outcomes.

Adipose-derived stem cells have been reported to possess inherent regenerative angiogenic potential and anti-apoptoic capability through their secretion of trophic factors[80-82]. ADSCs also have anti-inflammatory and immunomodulatory properties, including suppression of T-cell proliferation[82-88]. Therefore, ADSCs can potentially allow improved engraftment of transplanted islets with enhanced vascularization and suppression of inflammation.

Ohmura *et al*[79] tested hybrid islet transplantation by co-transplanting allogeneic mouse pancreatic islets along with autologous ADSC under the kidney capsule of recipient mice and demonstrated that autologous murine ADSCs were able to significantly prolong allogeneic islet survival and achieve normoglycemia for up to 14 d. Allogeneic islets alone could not survive under the kidney capsule for longer than 2 d, and normoglycemia was never achieved. The islets following hybrid transplantation showed well-preserved islet architecture and were surrounded by endothelial cells compared to islet grafts transplanted without ADSCs, suggesting vascularization had been improved. Infiltration by $CD4^+$/$CD8^+$ T cells and $CD68^+$ macrophages were also markedly reduced, suggesting successful anti-inflammation and immunomodulation by ADSCs and prolonged graft islet retention when ADSCs were co-transplanted with donor islets[79]. Although it is still uncertain whether this hybrid transplantation method will work in a clinical model, which utilizes the hepatic portal vein route for islet transplantation rather than the kidney capsule, the potentially enormous benefits of ADSCs in islet engraftment is clearly promising.

Veriter *et al*[89] also showed the utility of ADSCs by co-encapsulating xenogeneic porcine islets with autologous primate ADSCs in semipermeable capsules and transplanting them in primates. Compared to islets encapsulated alone, improved oxygenation, graft survival and function, and glycated hemoglobin correction, as well as greater vasculogenesis were observed in co-encapsulated implants, consequently reducing the cellular stress immediately following transplantation[89].

It is widely accepted that a significantly large number of pancreatic islets are lost during the first 10-14 d following infusion into human liver through the portal vein[90], even in the presence of immunosuppression. Furthermore, 60% of transplanted islets were reported to die during this period even in syngeneic animal models[91]. An ability to prevent such early death immediately following transplantation, as demonstrated by Ohmura *et al*[79], Veriter *et al*[89] and Cavallari *et al*[92], using ADSCs, may prove to be enormously beneficial to the successful engraftment of transplanted islets.

Challenges and opportunities for ADSCs in diabetes

Several uncertain factors in stem cell-based cell therapy for diabetes still remain: (1) the absence of gold-standard,

reproducible differentiation protocol for generating insulin-producing cells from adult stem cells; (2) an exact dosage of stem cell-derived β-cells to reverse diabetic conditions and feasibility of producing such dosage *in vitro*; (3) proliferative capacity and maintenance of differentiated insulin-producing cells; (4) sensitivity to counter-regulatory hormones; (5) potential adverse effects of undifferentiated adult stem cells; and (6) potential *in vivo* migration of differentiated cells following implantation[8,15]. Consensus of investigators on the criteria for transdifferentiation and plasticity to avoid confusion with cell fusion, contaminating stem cell populations, and to prevent over interpretation of the data, is necessary[8,93-95].

A major challenge also lies in imitating the physiological mechanism of insulin secretion. Insulin secretion occurs through complex regulatory systems, involving multiple hormonal feedback mechanisms and neurological stimulation, within the islet of Langerhans. For instance, insulin secretion by β-cells can inhibit glucagon secretion by α-cells[96]. Somatostatin secreted by δ-cells also regulates insulin secretion by β-cell[97]. In order to mimic normal or near normal metabolic control, differentiated cells must be able to interact with existing pancreatic endocrine cells. Another mechanism of controlling insulin release is through the secretion of incretin hormones, including glucose-dependent insulinotropic peptide and glucagon-like peptide 1[10,98-101]. These intestinal tract signaling hormones have shown to be responsible for up to 70% of glucose-induced postprandial insulin secretion[99,100]. An ability to respond to these signals is also a critical characteristic that stem cell-derived β-cells need to possess in order to closely mimic physiological processes. Lastly, insulin secretion is a pulsatile rather than a constant release, and such pulsatility may be significant in its action[102]. Stem cells differentiated into a pancreatic lineage that simply produces insulin, even in a glucose-responsive manner, without capability to accommodate these complex interactions, will unavoidably fail to reverse diabetic conditions.

The general architecture of natural pancreatic islets also poses another challenge for the efficacy of differentiated insulin-producing cells. Individual islets are highly vascularized and innervated. The endothelial cells comprising the microvasculatures of pancreatic islets of Langerhans may even be glucose responsive[10,103]. Stem cell-derived islet-like structures thus far have not shown to contain any intrinsic vascularity within them when derived *in vitro*, and therefore rely on the circulation external to the cell aggregates. The distance between β-cells and capillaries can potentially affect the kinetics of insulin release, and non-physiological integration of islet-like structures to circulation may in turn affect the engraftment, survival, and efficacy of implants[104]. Insulin release by β-cells is affected not only by increased blood glucose level but also by nervous control (cephalic phase) mostly through cholinergic neurons during meal ingestion[10,105]. Even with whole organ or pancreatic islet transplantation, complete restoration of the cephalic phase of insulin secretion will fail due to a lack of innervation[106,107]. These structural challenges are critical to overcome for stem cell-derived β-cells or islets to be clinically viable in the future.

Nearly all of the insulin-producing cells derived from adult stem cells co-express glucagon, somatostatin, pancreatic polypeptide along with insulin, all of which are characteristic of immature pancreatic islets of Langerhans. This suggests an incomplete differentiation of stem cells, and could be one of the main reasons why these cells were unable to achieve normoglycemia in diabetic animals. Further differentiation and maturation are required to achieve a more mature substitute capable of functioning similarly to a normal pancreas. However, others also argue that terminally differentiated mature β-cells might not be required for treatment of diabetes. Konno *et al*[108] and Kajiyama *et al*[109] reported that transplantation of adipose-derived stem cells overexpressing Pdx-1 ameliorated hyperglycemia and improved survival rate. Furthermore, ecto-pancreatic transplantation enabled normalization of hemoglobin A1c levels and subsequently attenuated or partially reversed nerve and kidney damages caused by diabetes[10,110,111]. Achieving normal hemoglobin A1c levels may also prove to be critical for future stem cell-based therapies.

Diabetic conditions present a uniquely detrimental environment to various cell types. The proliferative capability of mesenchymal stem cells isolated from adipose tissue of streptozotocin-induced type 1 and 2 diabetic rats was reported to be compromised[112]. When ADSCs were exposed to high glucose concentration *in vitro* prior to implantation into a hindlimb ischemia model, their proliferative capacity and ability to reverse hindlimb ischemia were significantly and irreversibly reduced, compared to ADSCs cultured at a normal glucose concentration[112]. In type 1 diabetic patients, however, autoimmunity did not seem to fundamentally influence the regenerative capability of islets and their progenitor cells[34,113]. Hess *et al*[114] demonstrated that bone marrow derived stem cells initiated pancreatic regeneration and reversed hyperglycemia by stimulating proliferation of the recipient's innate pancreatic progenitor cells and β-cells. It is highly possible the same mechanism can be utilized for ADSCs, and therefore, warrants further investigation as well. Improving the relative regenerative capacity of pancreatic islets using ADSCs would potentially benefit diabetic patients.

Transplantation of islet-like cells or pancreas-like tissues generated from stem cells *in vitro* may be accompanied by graft rejection, graft hypertrophy with subsequent chronic hypoglycemia, and potentially malignant transformation. The intrinsic immunomodulatory capabilities of ADSCs have shown to enhance engraftment of multiple types of tissues when co-transplanted[115-117]. Vanikar *et al*[115] reported that transfusion of ADSCs may reduce the need of immunosuppression during renal transplantations. The ability to reduce the required dosage of immunosuppressants would subsequently minimize complications caused by these agents and improve the clinical

outcome of islet transplantation.

Approximately 90% of people with diabetes are suffering from type 2 diabetes. However, only a few cases of stem cell-based research were performed recently[118-122] to develop a therapeutic option for type 2 diabetes, as type 1 diabetes has stood as the forefront. Deriving insulin-secreting β-cells from stem cells for treatment of type 1 diabetes seems relatively straightforward compared to developing an alternative treatment option for type 2 diabetes. Further research on the complex disease mechanisms of type 2 diabetes in association with the potential utility of stem cells may improve the quality of life for hundreds of millions patients.

CONCLUSION

It is now undeniable that the utility of ADSCs in the treatment of diabetes is extremely promising. The abundance of available source tissue, high frequency and multipotency of adipose-derived mesenchymal stem cells, its trophic and regenerative capabilities, all serve as valuable solutions to the ever-increasing diabetic population and associated health crises observed around the world. Understanding of ADSCs and the development of ADSC-based treatments for diabetes are still considered to be in their infancy, and numerous challenges and opportunities still lie ahead. The exact mechanism of generating insulin-producing cells from ADSCs as well as further maturation of those cells into functional pancreatic islets still needs to be further explored. Sustainability of differentiated insulin-producing cells is still under investigation. Autoimmune attack on β-cells, which is a fundamental disease mechanism of type 1 diabetes, has not been completely resolved and can make any future cell-based therapy unfeasible.

Current therapies for diabetes ranging from insulin injection to pancreatic islet transplantation are not truly the best options for patients. Stem cells that are theoretically limitless in numbers and multipotent will provide hopes and viable therapies for millions of diabetic patients in the future. However, if all stem cell-based therapies only eliminate the need for glucose monitoring and insulin injection for convenience and modestly improve diabetic symptoms, it would not justify the adoption of these therapies in the future. Therefore, stem cell-based therapies must be able to provide fundamentally improved multifaceted metabolic controls and concomitantly improve long-term prognosis in diabetic patients to be widely accepted as a clinically viable therapy.

Abstract

In healthy people, balance between glucose production and its utilization is precisely controlled. When circulating glucose reaches a critical threshold level, pancreatic β cells secrete insulin that has two major actions: to lower circulating glucose levels by facilitating its uptake mainly into skeletal muscle while inhibiting its production by the liver. Interestingly, dietary triglycerides are the main source of fatty acids to fulfill energy needs of oxidative tissues. Normally, the unconsumed fraction of excess of fatty acids is stored in lipid droplets that are localized in adipocytes to provide energy during fasting periods. Thus, adipose tissue acts as a trap for fatty acid excess liberated from plasma triglycerides. When the buffering action of adipose tissue to store fatty acids is impaired, fatty acids that build up in other tissues are metabolized as sphingolipid derivatives such as ceramides. Several studies suggest that ceramides are among the most active lipid second messengers to inhibit the insulin signaling pathway and this review describes the major role played by ceramide accumulation in the development of insulin resistance of peripherals tissues through the targeting of specific proteins of the insulin signaling pathway.

Key words: Diabetes; Insulin resistance; Lipids; Insulin signaling; Triglycerides; Palmitate; Sphingolipid; Akt; Ceramide synthase; Protein phosphatase 2A; Protein kinase C ζ/λ

Core tip: Muscle and liver represent major sites for insulin-mediated glucose metabolism. The ability of insulin to promote its peripheral action is reduced significantly by excess of saturated fat that stimulates intracellular production of second-messenger lipids such as ceramide. Studies suggest that ceramide could be important contributors to lipotoxicity, as the inhibition of early steps its biosynthesis pathway has large beneficial effects in rodent models of obesity and diabetes. In this review, we describe mechanisms by which ceramide acts on insulin-sensitive tissues and we propose that targeting this lipid family could be an interesting approach to fight diabetes.

DIABETES EPIDEMIC

Diabetes has become a serious public health problem in

both developed and developing countries. Indeed, there is a dramatic increasing incidence of diabetes in most of these countries. In 2005, 217 million people worldwide had diabetes, and the World Health Organisation predicts that it will increase to 366 million in 2030[1]. In 2050, 33% of the population of the United States will suffer from diabetes[2]. One consequence is that over the years, diabetes has become life-threatening, with increased risk of cardiovascular diseases, retinopathy, kidney failure, and nerve and artery damages[3]. Diabetes is one of the first causes of haemodialysis, of blindness and of non-traumatic amputation of the legs. Another consequence is the increasing of health spending due to diabetes. For example, in the United States, diabetes costing is actually evaluated to more than $174 billion per year and it's expected to increase in subsequent years[2].

PATHOPHYSIOLOGY OF TYPE 2 DIABETES

There are different types of diabetes: (1) type 1 diabetes or maturity onset diabetes of the young associated to impairment of insulin production; and (2) type 2 diabetes, corresponding to 85%-90% of all diabetes, with both insulin secretion defects and peripheral insulin resistance. Type 2 diabetes is associated with obesity and although genetic factors play a role in the pathophysiology of this disease, other environmental factors such as diet and physical activity both play large roles. Several mechanisms have been proposed to explain both insulin resistance and insulin secretion defects observed in type 2 diabetes. Lipotoxicity, glucotoxicity, low grad systemic inflammation, oxidative stress and endoplasmic reticulum stress[4-6] correspond to different mechanisms that converge on a common pathway to induce insulin resistance. In this review we will focus on cellular lipid toxicity, *i.e.*, lipotoxicity.

LIPOTOXICITY

Systemic lipid imbalances are common in metabolic syndrome, in pre-diabetes and in type 2 diabetes and it is now clear that lipotoxicity can induce glucose dysregulation and participate to the pathophysiology of type 2 diabetes[7-9]. For example, prospective epidemiological studies performed in population with low or high risk to develop type 2 diabetes have shown that high free fatty acid (FFA) concentrations in plasma are associated with the risk of incident type 2 diabetes[10-12].

A major characteristic of type 2 diabetes is the loss of the ability of pancreatic β cells to increase insulin secretion to maintain normoglycemia in the face of insulin resistance[13]. Because of genetic predisposition, β cells could be unable to compensate the insulin resistance induced by FFA, but chronic exposition of β cells to high levels of FFA could equally explain defects in β cell function and decreased mass observed in type 2 diabetes. Indeed, *in vitro* studies have shown that FFA are associated with a decrease of insulin expression, synthesis and processing[14-16]. Another mechanism that can explain insulin secretion dysfunction in type 2 diabetes is that high FFA levels in islets induce β cell death[17]. In this review, we will not deal with this topic but we will rather focus our message on lipid-induced peripheral insulin resistance. To more information on lipotoxicity in pancreatic beta cells, confer to the excellent review of Boslem *et al*[18].

Since skeletal muscle constitutes 40% of human body mass and is quantitatively the most important tissue in regard to insulin-stimulated glucose disposal, it is considered the main cellular target in the development of insulin resistance. Thus, most of the studies investigating mechanisms of lipotoxicity induced insulin resistance were mostly performed in muscle tissue.

In 1963, Randle *et al*[19] have postulated that a competition between glucose and fatty acids for their oxidation and uptake is responsible for the onset of insulin resistance in muscle and adipose tissue. *In vivo* studies performed in both rodents and humans confirmed such insulin resistance obtained after lipid infusion but they also demonstrated that, in opposite to Randle's hypothesis, insulin resistance induced by lipids was not secondary to decreased glycolysis[20]. Indeed, lipids act directly on insulin signaling, resulting in an inhibition of the translocation of the insulin sensitive glucose transporter GLUT4 to the plasma membrane in response to the hormone, with subsequent reduced glucose uptake[21-25]. In human, data clearly show a strong correlation between lipid intramuscular content and insulin resistance[26-28] and a cross-sectional analysis performed in young, normal weight and non-diabetic adults reveals that a better correlation exists between muscle insulin sensitivity, assessed by the hyperinsulinaemic-euglycaemic clamp technique, and intramyocellular lipid content rather than with circulating lipid levels, body mass index, fasting blood glucose and age[29].

Liver is another important organ implicated in insulin resistance and, like in muscle indirect data also suggest an inverse relationship between lipid liver content and insulin sensibility. Indeed, ectopic lipid accumulation in the liver, termed nonalcoholic fatty liver disease (NAFLD), is associated with insulin resistance. Interestingly, in an animal model of lipodystrophy with steatosis, but without increased visceral fat, lipid liver content is associated with insulin resistance. Insulin resistance is reversed after reduction of steatosis with liver transplantation or recombinant leptin treatment[30]. Such association between steatosis and insulin resistance has also been observed in patients with severe lipodystrophy with equally a good response to recombinant leptin therapy[31]. Similarly, hepatic specific overexpression of lipoprotein lipase leads specifically to hepatic steatosis and hepatic insulin resistance[32,33]. During type 2 diabetes, reduction of steatosis by caloric restriction, or gastric bypass, is associated with increased insulin sensibility independently of visceral fat mass reduction[34,35].

Strong evidence exists between ectopic lipid accumulation and insulin resistance. However, in some cases, like in the "athlete's paradox", there is a lack of correlation

between ectopic lipid accumulation and peripheral insulin resistance. Indeed, athletes display high insulin sensitivity but also present increased levels of intramuscular fatty acids[36]. Thus, it seems that ectopic accumulation of fatty acids in non-adipose tissues can only be used as markers for the onset of insulin resistance but cannot be considered as a direct cause. Even if they do not seem to be directly involved, fatty acids contribute to insulin resistance as they lead to the synthesis of many lipid derivative intermediates such as diacylglycerol (DAG) and ceramide.

Over the years, studies have provided conclusive proof that ceramide plays a key role in the progression of insulin resistance in insulin sensitive tissues, targeting and inhibiting specific actors of the insulin signaling pathway.

INSULIN SIGNALING PATHWAY AND METABOLIC FUNCTIONS

Insulin is a polypeptide hormone whose major physiological role is to control glucose homeostasis by stimulating glucose uptake into insulin sensitive tissues (skeletal muscle and adipose tissue) and by inhibiting glucose output from the liver[37]. Insulin consists of two polypeptide chains, a α chain of 21 amino acid residues linked by two disulfide bonds to a β chain of 30 amino acid residues. Insulin is produced in the β cells of the Islets of Langerhans found in the pancreas. It is initially synthesized as an immature single polypeptide chain of 110 amino acids called pre-proinsulin. Pre-proinsulin contains an N-terminal domain of 24 amino acids that acts to direct the polypeptide to the endoplasmic reticulum during translation. This domain is later cleaved to yield proinsulin. Proinsulin is transported to the secretory vesicles of the pancreatic β cells, where a proteolytic enzyme removes the central 35 residues of the peptide (termed the C-peptide) that connect α and β chains to produce insulin. Insulin is then released into the blood stream by exocytosis. Secretion of the hormone is regulated by the glucose abundance in the plasma.

In skeletal muscle, insulin promotes the uptake of glucose and its conversion into glycogen. This tissue is an important target of the hormone, representing the major site of glucose disposal *in vivo*[37] and is reported to mediate 70%-80% of whole body insulin-stimulated glucose transport[38]. In the liver, insulin stimulates the synthesis of glycogen while inhibiting gluconeogenesis and glycogenolysis, halting hepatic glucose output. In adipocytes, insulin promotes the uptake of glucose and its conversion into a glycerophosphate of which can be esterified by 3 fatty acids, allowing to form triglycerides for long term storage, whereas simultaneously inhibiting the lipolytic pathway[39]. In addition to glucose metabolism, insulin also regulates many other cellular processes including amino acid transport, lipogenesis, protein synthesis and mitogenesis.

The first step in the activation of the insulin signaling pathway is the binding of insulin with its membrane receptor, the insulin receptor (IR). IR is a heterotetrameric complex of two subunits: α-subunit, and β-subunit that possess a transmembrane domain and an intracellular part. Binding of insulin to α subunits of IR induces a rapid conformational change in the receptor. This in turn stimulates the intrinsic tyrosine kinase activity of the β subunit resulting in trans-autophosphorylation of tyrosine residues in the intracellular region of the β subunits[40]. As a result of this autophosphorylation, the IR becomes catalytically active and promotes the tyrosine phosphorylation of a number of cellular proteins including the IR Substrate (IRS) proteins.

IRS proteins are major physiological targets of the activated insulin receptor kinase. Six different IRS isoforms have been identified so far[41]. In skeletal muscle and adipose tissue, IRS1 is the isoform that mediate insulin signaling. In the liver, however, IRS2 is the one that drives insulin metabolic functions. In the pancreas, IRS2 is an important regulator of cell growth and regeneration[41]. Studies have also shown that both IRS3 and IRS4 can be activated in response to insulin and insulin-like growth factor 1 (IGF1)[42] and that IRS3 can mediate insulin signaling in adipocytes[42]. Mice lacking either IRS3 or IRS4, however, display no major phenotype, suggesting that neither isoform plays a direct role in controlling glucose metabolism[43,44] but may rather act as negative regulators of the IGF1 signaling pathway by suppressing the function of other IRS isoforms[45].

One key molecule that is activated by the IRSs in response to insulin is phosphoinositide-3-kinase (PI3K). PI3K is a lipid kinase, which phosphorylates the D3 position of the inositol ring within inositol lipids resulting in the generation of 3-phosphoinositides (*e.g.*, PI-3P, PI-3,4P_2, and PI-3,4,5P_3). Eight mammalian isoforms of PI3K exist and they are grouped into three classes on the basis of their substrate specificity and structure: class Ⅰ, class Ⅱ, and class Ⅲ. Only class I can phosphorylate phosphatidylinositol, 4, 5-bisphosphate (PIP_2)[46]. Following PI3K activation, PIP_3 is generated from the substrate PIP_2. PIP_3 binds a protein displaying a PH domain and called the 3-phosphoinositide-dependent protein Kinase 1 (PDK1). Activated-PDK1 triggers downstream targets such as protein kinase B (PKB/Akt)[47].

PKB/Akt also called Akt is the third central node activated by insulin. It plays a crucial role in mediating signaling effects on metabolism, cell growth and cell cycle[48,49]. PKB/Akt has three isoforms: PKBα/Akt1, ubiquitously expressed, PKBβ/Akt2 mostly present in insulin responsive tissues (liver, adipose tissue and muscle), and PKBγ/Akt3 predominant in the brain. PKBβ/Akt2 is the isoform implicated in the regulation of glucose metabolism since neither PKBα Akt1 nor PKBγ/Akt3 ablation affects glucose metabolism[50].

PKB/Akt is activated through PI3K-produced PIP_3 which binds its PH domain. Then, PKB/Akt is recruited to the plasma membrane where it is activated by phosphorylation on two critical sites: threonine 308 (T308) in the activation loop and serine 473 (S473) in the hydrophobic motif[51]. PDK1 phosphorylates PKB/Akt on T308.

The kinase that phosphorylates the S473 site is the complex mammalian target of rapamycin complex 2, a regulator of cell growth and proliferation[52].

PKB/Akt is highly activated within minutes following cell exposure to insulin to mediate the metabolic effects of the hormone[49,53].

Indeed, principle roles of PKB/Akt in insulin sensitive tissues are to: (1) Stimulate glucose uptake in muscle and adipose tissue; (2) Trigger glucose storage as glycogen in muscle and in the liver; (3) Stimulate the conversion of glucose excess into lipids in the liver; (4) Induce protein synthesis in muscle; (5) Inhibit glycogen breakdown in both muscle and liver; (6) Suppress liberation of free fatty acids from adipose tissue; (7) Inhibit *de novo* production of glucose in the liver; and (8) Impede protein breakdown in muscle (Figure 1).

Considering the crucial role PKB/Akt plays in mediating insulin metabolic actions in cells, impairing PKB/Akt activity represents the best way to compromise the whole system.

LIPID SECOND MESSENGER AND LOSS OF INSULIN SENSITIVITY

In pathological situations such as obesity and type 2 diabetes that are characterized by insulin resistance, ectopic fatty acid accumulation is increased due to reduced mitochondrial fatty acid oxidation and to enhanced fatty acid uptake[54-57]. This increased fat content inversely correlates with insulin sensitivity in skeletal muscle, liver and adipocytes[58-61].

Interestingly and depending on the degree of saturation, free fatty acid may exert different effects on insulin signaling. Studies have demonstrated that saturated fatty acids such as palmitate (16:0) and stearate (18:0) impair insulin sensitivity in muscle[62,63], whereas mono-unsaturated fatty acids or poly-unsaturated fatty acids have no effect or even enhance insulin action[64-66]. Although the exact reasons behind these differences are unclear, studies have suggested that unsaturated fatty acids may be preferentially targeted for triglyceride synthesis and storage, whilst saturated fatty acids may be used for synthesis of critical lipid intermediates such as DAG and ceramide. These two lipid second messengers have been demonstrated to mediate deleterious actions of saturated fatty acids on insulin signaling.

DAG AND INSULIN RESISTANCE

DAG is a glyceride consisting of two fatty acid chains covalently bonded to a glycerol molecule. DAG, intermediate of both triglyceride and phospholipid metabolism, is an important second messenger involved in intracellular signaling[67].

DAG has been shown to accumulate in insulin resistant liver[68,69] and studies have shown that intra-hepatic DAG is an important mediator of hepatic insulin resistance in obese people with nonalcoholic fatty liver disease[70,71]. Elevated DAG content and activation of protein kinase C (PKC)ε has been associated with hepatic insulin resistance and the involvement of this "lipid-activated pathway" has been validated through the use of antisense oligonucleotide against PKCε in rats. Knocking down PKCε expression in liver protected rats from lipid-induced hepatic insulin resistance, despite increase in hepatic lipid content[72].

Several studies have decrypted the mechanism by which DAG-activated PKCs inhibit insulin signaling in liver. They show that IRS proteins are likely to be PKC's preferential targets. DAG-activated PKCs inhibit IRSs activity through their phosphorylation on several serine residues, preventing consequently insulin activation of IRSs through their phosphorylation on tyrosine residues[73-75].

In muscle, however, data are contradictory. Itani *et al*[76] were the first to point out the positive association between DAG content and muscle insulin resistance by comparing a group of subject receiving a lipid infusion to a control group. Lipid infusion resulted in a 3-fold increase in total DAG content in muscle, and reduced insulin sensitivity. Straczkowski *et al*[77] observed that total muscle DAG concentrations were higher in obese compared to lean controls and lean offspring type 2 diabetics, and this increased DAG content was inversely related to insulin sensitivity. Other studies have also confirmed this correlation[78,79].

However, the association between DAG and muscle insulin resistance is still questioned. Indeed, Vistisen *et al*[80] performed muscle biopsies during glucose clamps and they observed a reduction in insulin sensitivity after lipid infusion, without any changes in muscle DAG content. These results were confirmed by Anastasiou *et al*[81] that compared obese type 2 diabetic patients to non-diabetics subjects and found no difference in muscle DAG content between the groups. Similarly, Perreault *et al*[82] compared insulin resistant obese patients to glucose tolerant obese patients and again found no difference in DAG content between the groups. Even more intriguing, Amati *el al*[83] observed a two-fold increase in DAG content in insulin sensitive human muscle biopsies compared to insulin resistant human muscle biopsies. More recently, the same group showed no difference in muscle DAG content between lean subjects compared to obese insulin resistance patients[84].

Altogether, and in opposite to liver, it seems that DAG does not appear to be a crucial player in the onset of insulin resistance in muscle, and maybe more investigations are needed to really be able to conclude.

CERAMIDE AND INSULIN RESISTANCE

Ceramide biosynthesis

One of the main sphingolipid that has been demonstrated to play a crucial role in insulin resistance is ceramide. During obesity, ceramide is mainly generated from long chain fatty acyl-CoAs[85,86], and has been shown to be toxic lipid when it accumulates in tissues during obesity[87-89].

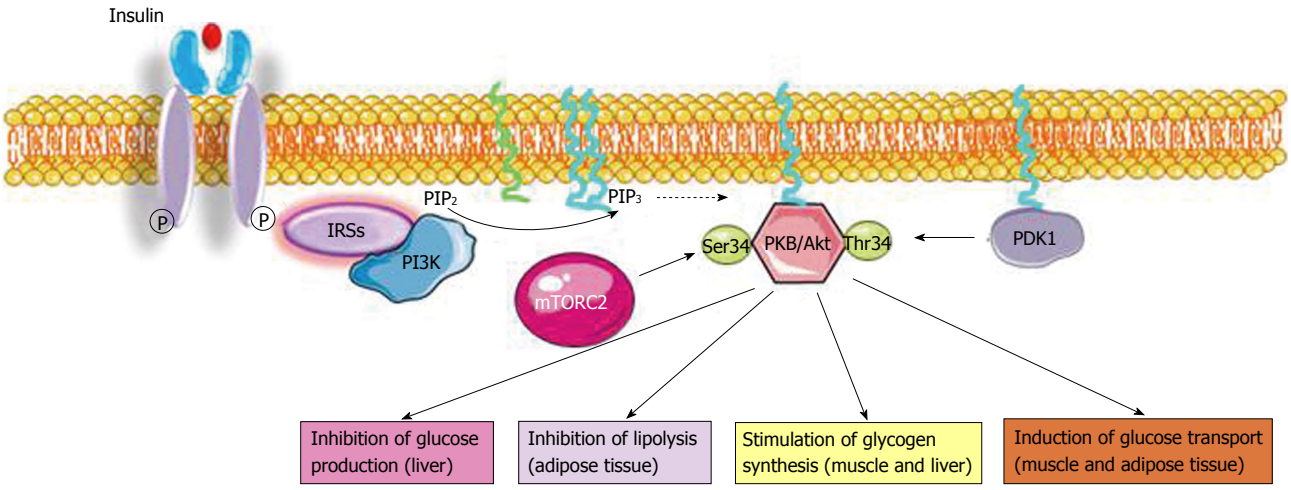

Figure 1 Insulin signaling pathway. Insulin binds with insulin receptor (IR) that activates the IR substrates (IRSs), the phosphoinositide-3-kinase (PI3K), and protein kinase B/Akt (PKBAkt). Activated PKB/Akt mediates insulin metabolic effects and regulates nutrients homeostasis. PIP_2: Phosphorylate phosphatidylinositol, 4, 5-bisphosphate; PDK1: 3-phosphoinositide-dependent protein kinase 1; mTORC2: Mammalian target of rapamycin complex 2.

Ceramide is a bioactive sphingolipid that has been implicated in mediating or regulating many cellular processes, including cell cycle arrest, proliferation, apoptosis, senescence, and stress responses. Ceramide plays also an important role in cell membrane structure[90].

Formation of ceramide can be induced by different stimuli such as tumor necrosis factor-α, heat stress, oxidative stress, ionizing radiation, and chemotherapeutics[91].

Multiple metabolic pathways converge to ceramide (Figure 2): (1) The *de novo* synthesis pathway from saturated fatty acids that takes place in the endoplasmic reticulum; (2) The sphingomyelinase pathway that uses sphingomyelinase to break down sphingomyelin in the cell membrane to release ceramide; and (3) The salvage pathway in lysosomes that occurs through breakdown of complex sphingolipids to give sphingosine, which is then rescued by reacylation to form ceramide.

In time of fatty acid plethora, the *de novo* ceramide biosynthesis pathway is the pathway that is likely to be most harnessed to synthesize ceramide. It occurs in the leaflet membrane of the endoplasmic reticulum where ceramide is synthesized through a series of reactions[92,93]. *De novo* synthesis of ceramide begins with the condensation of palmitate and serine to form 3-keto-dihydrosphingosine (Figure 2). This reaction is catalyzed by serine palmitoyl transferase (SPT) and is the rate-limiting step of the pathway. In turn, 3-keto-dihydrosphingosine is reduced to dihydrosphingosine, which is then followed by acylation by ceramide synthases (CerS) to produce dihydroceramide. In mammals, six CerS isoforms are expressed and are called CerS 1 to 6. They carry out the same chemical reaction, but display distinct specificities for the acyl-CoA chain length they use for N-acylation[94]. Thus, CerS isoforms are responsible for the fatty acid composition of ceramide. Interestingly, several studies have shown distinct cellular functions for ceramides with different N-acyl chain length[95,96]. The final reaction to produce ceramide is catalysed by dihydroceramide desaturase.

Inverse relationship between ceramide content and insulin sensitivity

Studies in animal and models: One of the early studies that analyzed ceramide content in obese Zucker fa/fa rats (rats homozygous for truncated, non-functional leptin receptor) was Turinsky *et al*[97] in 1990. The authors found that these rats present an increase in ceramide content in both muscle and liver. Increased ceramide content was also detected in insulin resistant models of rodents, as in ob/ob mice, mice fed on high fat diet, and in intra-lipid infused mice[85,98,99]. Altogether these reports illustrate the inverse relationship between ceramide and insulin sensitivity in rodent muscle. This association was also confirmed *in vitro* in cultured C2C12 and L6 myotubes, as well as in adipocytes[99-101]. Exposing cultured muscle cells to saturated fatty acids (like palmitate) attenuates insulin activation of glycogen synthesis and glucose transport concomitantly with increasing intracellular ceramide amounts[63,99]. Additionally, incubation of muscle cells and adipocytes with analogues of ceramide mimics the inhibitory effects of FFAs on insulin signaling and suppresses insulin-stimulated glycogen synthesis and glucose transport[100,101].

Studies in human subjects: In accordance with data obtained in rodents, studies in human subjects also support the inverse relationship between ceramide accumulation and insulin sensitivity. It has been shown that under basal conditions, total amount of ceramide in skeletal muscle is increased in obese subjects compared to lean ones[83,84,87]. Another study performed in human skeletal muscle of lean normoglycemic subjects revealed again an inverse relationship between muscle ceramide accumulation and insulin sensitivity[102]. The same authors show in another study a ceramide accumulation in muscle of type 2 diabetic patient offsprings compared to muscle of control subjects[77]. Furthermore, the group of Goodpaster demonstrated that physical exercise reduces ceramide

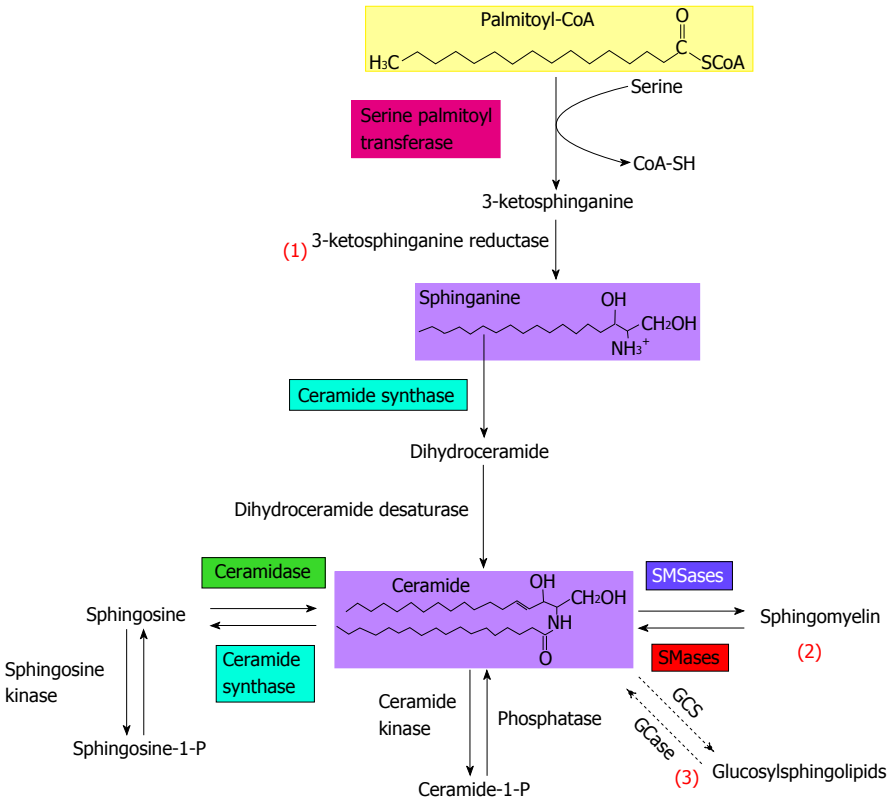

Figure 2 Sphingolipid metabolism. Ceramide can either be newly synthesized in *de novo* ceramide synthesis pathway (1), or it can be the product of complex sphingolipids degradation, including sphingomyelin hydrolysis (2). The degradation of glycosylsphingolipids constitutes the salvage pathway (3). GCase: Glucosyl ceramidase; GCS: Glucosylceramide synthase; SMases: Sphingomyelinases; SMSases: Sphingomyelin synthases.

content in obese and insulin resistant subjects, and this was correlated with improved insulin sensitivity[83,103]. Like in muscle, accumulation of ceramide content in human adipocytes has also been demonstrated to be related to insulin resistance[104,105].

Altogether, these studies prove a solid association between insulin resistance and an increase in ceramide content in both muscle and adipocytes.

Unlike in muscle and adipose cells, a role of ceramide in the onset of hepatic insulin resistance is more debated. Indeed, some studies see no ceramide accumulation in fatty liver[68,70,71], making improbable these lipids as mediators hepatic insulin resistance. This is in contradiction with another study showing increases in hamster hepatic ceramide levels in response to lipopolysaccharide administration[106]. In addition, Longato *et al*[107] saw a dysregulated ceramide metabolism in high fat diet-induced hepatic steatosis.

Interestingly, and in opposite to muscle and adipose tissue, ceramide cannot accumulate in the liver. Indeed, very recently, Watt *et al*[108] have shown that lipid infusion in healthy subjects resulted in a rapid hepatic secretion of ceramide in the circulation, primarily within very low-density lipoprotein[109,110], thereby protecting the liver from the deleterious effects of their intracellular accumulation. It would be interesting, however, to assess whether lipid-induced ceramide secretion is affected in fatty liver (steatosis).

Altogether, if ceramide does not seem to accumulate in liver during lipotoxic conditions, its secretion into the circulation could be deleterious for other peripheral tissues such as pancreatic β cells and muscle cells.

Implication of ceramide in the progression of insulin resistance

Two methods were used to validate the implication of ceramide in impaired insulin sensibility: the first one was to inhibit ceramide production, and the second was to enhance ceramide metabolism towards less harmful sphingolipid species.

Inhibition of ceramide production improves insulin sensitivity: One method used to demonstrate the role of ceramide in the onset of insulin resistance was to inhibit ceramide biosynthesis. The most commonly studied molecular target involved in suppressing ceramide production is the enzyme SPT, enzyme that catalyzes the initial rate-limiting step in *de novo* ceramide synthesis (Figure 3)[90]. Several potent inhibitors of SPT have been documented, although the most widely used is myriocin, a naturally occurring fungal metabolite isolated from Myriococcum albomyces[111]. In studies carried out *in vivo*, administration of myriocin was found to attenuate PKB/Akt inhibition in response to lipid infusion or high-fat feeding, as well as improving glucose tolerance and peripheral insulin sensitivity in obese ob/ob mice and Zucker Diabetic Fatty rats[112-114]. As expected, these beneficial effects of myriocin were associated with reduced

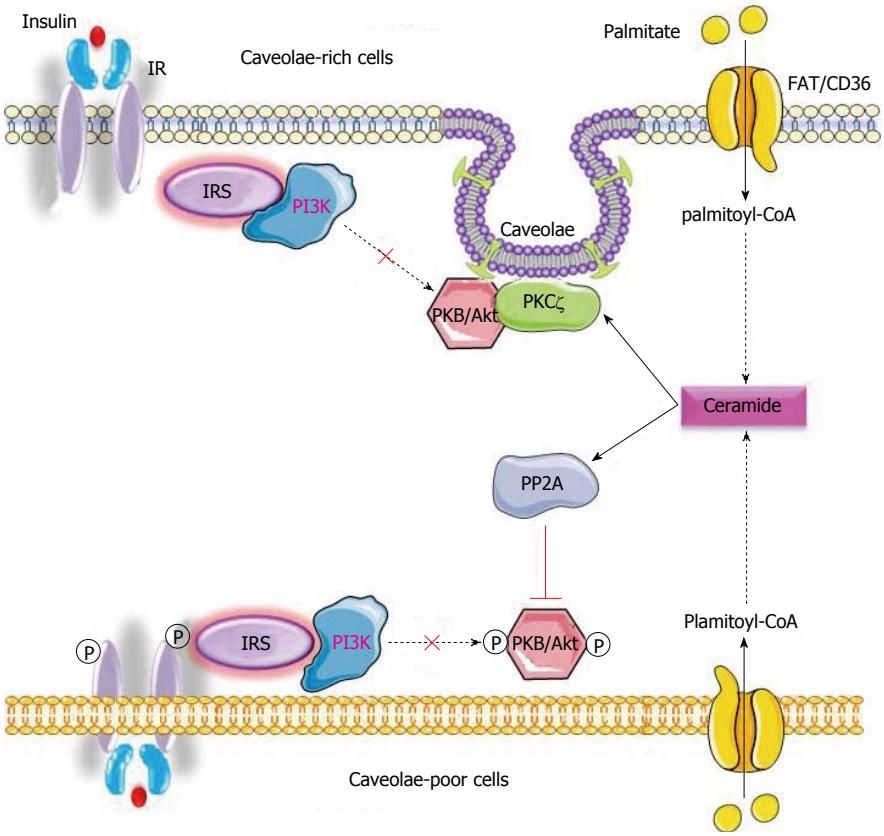

Figure 3 Ceramide inhibits insulin-induced activation of protein kinase B *via* two distinct mechanisms. Ceramide inhibits insulin-activation of protein kinase B (PKB/Akt) either by activating atypical PKC (PKCζ) or by stimulating the phosphatase PP2A. Activation of either mechanism depends on plasma membrane enrichment with caveolae: (1) Ceramide-activated PKCζ phosphorylates the PH domain of PKB/Akt on Thr/Ser34, changing the recognition site of PKB/Akt, and disabling its activation by PIP3; (2) PP2A dephosphorylates PKB/Akt, inhibiting its kinase activity. IR: Insulin receptor; IRS: IR substrates; PI3K: Phosphoinositide-3-kinase; PP2A: Protein phosphatase 2A.

levels of ceramide and were reproduced when alternative inhibitors of *de novo* ceramide synthesis such as L-cycloserine (which also inhibits SPT) and Fenretinide (dihydroceramide synthase inhibitor) were used[63,115].

Studies performed *in vitro* in myotubes confirmed what was observed *in vivo*. They demonstrated that acute inhibition of SPT using myriocin ameliorates the loss in insulin-stimulated PKB/Akt activation in cultured L6 or C2C12 myotubes caused by palmitate-driven ceramide synthesis[62,63].

Interestingly, a very recent study shows that inhibition of the *de novo* synthesis of ceramide using myriocin reduces hepatic lipid accumulation in liver of rats with NAFLD[116]. This inhibition of ceramide biosynthesis is accompanied with decreased in both DAG and triglyceride contents, resulting in amelioration of hepatic insulin resistance and improvement of glucose homeostasis[116].

Stimulation of ceramide conversion into less harmful sphingolipids improves insulin sensibility: The degradation of ceramide is initiated by the action of ceramidase that produces sphingosine, which is then phosphorylated to sphingosine-1-phosphate (S1P) by sphingosine kinase[117]. S1P is the final metabolic product of sphingolipid degradation and can function as an intracellular second messenger or in an autocrine and/or paracrine manner to activate and signal through S1P receptors[118]. Interestingly, S1P itself opposes the effects of ceramide on intracellular signaling. S1P has been shown to ameliorate insulin-stimulated glucose uptake, possibly through the activation of PKB/Akt[118-121]. Therefore, studies have aimed at finding ways to enhance ceramide metabolism into S1P in muscle in order to restore their insulin sensitivity. Bruce *et al*[122] used transgenic mice overexpressing sphingosine kinase. They show that high fat fed transgenic mice display improved insulin sensitivity compared to control mice. In addition, they used a drug called FTY720 which inhibits ceramide synthase activity and decrease ceramide accumulation in skeletal muscle[123]. As expected, they saw an improvement of insulin sensitivity. FTY720 prevented muscle ceramide accumulation in high fat fed mice and subsequently improved glucose homeostasis[124]. Other studies show that overexpression of ceramidase (converting ceramide to sphingosine) protects from lipid-induced muscle insulin resistance in C2C12 myotubes[125].

Altogether, these results demonstrate that preventing the aberrant accumulation of ceramide by promoting its metabolism into sphingosine and sphingosine-derivatives might restore normal insulin sensitivity and glucose me-

tabolism in models of insulin resistance.

Ceramide inhibitory effect on the insulin signaling pathway

Several studies have reported that ceramide may attenuate insulin-stimulated glucose transport and glycogen synthesis by antagonizing early events in insulin signaling such as activation of IRS-1[126] and possibly PI3K[127]. However, these results are controversial, as several groups reported no defects in the activation of these molecules upon challenging cells with ceramide[100,101]. In contrast, a number of groups suggested that PKB/Akt is the target of ceramide, and that inhibition of this kinase may account for reduced glucose transport and apoptosis observed in ceramide treated cells[99-101,128]. Consistent with this, defects in PKB/Akt activation have been noted in a variety of ceramide-treated cell types, including 3T3-L1 adipocytes[101], foetal brown adipocytes[129], L6 rat and C2C12 mouse skeletal muscle[99,100], A75R5 smooth muscle cells[130], and MCF7 breast cancer cells[131].

Furthermore, the inhibition of PKB/Akt by ceramide is not limited to experiments using exogenously supplied lipids. The hormonal activation of PKB/Akt is also blunted in muscle cells treated with free fatty acids in a manner which is dependent on the intracellular conversion of palmitate to ceramide[62,63,99]. Taken together these results suggest that ability of ceramide to impair PKB/Akt activity may be an important determinant of insulin sensitivity.

A key issue is the mechanism by which ceramide inhibits PKB/Akt activity. Depending on the cell enrichment in caveolin-enriched domain[132], ceramide inhibits the insulin-stimulated PKB/Akt either through the protein phosphatase 2A (PP2A), or *via* the atypical PKC (aPKC) pathway (Figure 3).

PP2A depended inhibition of insulin-induced activation of PKB/Akt: PP2A is a cytoplasmic serine/threonine phosphatase ubiquitously expressed that plays an important role in the regulation of diverse cellular processes, including metabolic enzymes, hormone receptors, kinase cascades, and cell growth[133]. It has been shown that insulin inhibits PP2A in physiologic conditions[134]. In contrast, several groups demonstrated that ceramide activates PP2A to promote the de-phosphorylation of PKB/Akt[62,135,136]. Two different inhibitors of PP2A activity, okadaic acid or SV40 small T antigen that binds with PP2A[137] were used to demonstrate the role of ceramide-induced PP2A inactivation of PKB/Akt. The presence of either inhibitor in cells treated with palmitate or short chain ceramide analogue (C2-ceramide), alleviated inhibition on PKB/Akt and re-established a normal, insulin signaling[62,128]. Therefore, one way for ceramide to inhibit PKB/Akt activity is by promoting its dephosphorylation at Thr308 and Ser473 through activation of PP2A.

Atypical PKCs another ceramide-stimulated protein altering PKB/Akt activation: The second mechanism of inactivation of PKB/Akt by ceramide requires the activation of aPKCs (PKCζ/λ). There is mounting evidence in the literature suggesting that aPKC may regulate PKB/Akt signaling and that the relationship between the two kinases may be subject to modulation by ceramide. It is 20 years since investigators first demonstrated that PKCζ/λ could associate with PKB/Akt in COS-7 fibroblasts[138]. It has also been demonstrated that PKCζ interacts directly with PKB/Akt in other cells types such as Chinese hamster ovary cells and COS-1 cells[139], as well as the BT-549 human breast cancer cell line[140].

In pathological conditions, ceramide-activated aPKCs impair insulin signaling. aPKCs phosphorylate PKB/Akt on its Thr34/Ser34 residue (Thr34 in PKBα and PKBβ, Ser34 in PKBγ), thus preventing PIP_3 to bind the kinase on its PH domain, and to translocate to the plasma membrane and its subsequent activation in response to insulin[132,141,142]. Based on these observations, it was proposed that an increase in intracellular ceramide leading to the activation of aPKCs promotes the stabilization of the aPKC-PKB/Akt complex and attenuates the recruitment of PKB/Akt to the plasma membrane as a result of disrupted PIP_3 binding (Figure 3).

CERAMIDE, A THERAPEUTIC TARGET?

Mechanisms by which saturated fatty acids act on insulin signaling are now getting clearer. They involve several lipid and protein intermediates that play an essential role to mediate the deleterious effects of accumulated saturated lipids in insulin sensitive tissues. Thus, two main options exist to counteract the action of these fatty acids on insulin signaling: (1) acting on ceramide downstream signaling targets (aPKCs or PP2A); or (2) modulating directly ceramide content[143]. Considering the large involvement of both aPKCs and PP2A in numerous paths[144,145], it would be more logical to try to directly inhibit the accumulation of ceramides in tissues. Several problems would arise with a complete inhibition of ceramide biosynthesis since these bioactive sphingolipids are in the center of sphingolipid metabolism. Indeed, ceramide signaling has been directly or indirectly involved in the diverse functions such as regulation of cell growth, differentiation, senescence, necrosis, proliferation, and apoptosis[90]. Therefore, inhibiting completely ceramide biosynthesis would be likely to be very harmful to the cells. Targeting specific ceramides species would be more appropriate since it has been shown that specific ceramide species could be associated with different functions, depending upon the cell type[94].

Concretely, it will be important to determine which ceramide species accumulate under lipotoxic conditions and then to evaluate whether these identified ceramide species enhance or reduce the deleterious effects of lipotoxicity in insulin sensitive tissues.

Interestingly, data existing already suggest that ceramide with distinct acyl chain-length are associated with different cell dysfunction in lipotoxic conditions. The

enzyme responsible of generating different ceramide acyl chain-length is the CerS. Six mammalian CerS have been described, with each utilizing fatty acyl CoAs of relatively defined chain lengths for ceramide synthesis[94]. In pancreatic β-cells, C18:0, C22:0 and C24:1 ceramides induce apoptosis, and inhibition of the CerS (CerS4) responsible for their synthesis blocks this phenomenon[146]. In the liver, CerS1 and CerS6, producing mainly C16:0 and C18:0 ceramides are associated with insulin resistance[147], whereas C22:0 and C24:0 ceramides produced through CerS2 are rather protective[148].

In muscle cells, however, no definitive and conclusive investigation has been carried out to date. The expression of C16:0, C18:0 and C24:0 ceramide species are increased in myotubes of type 2 diabetic patients compared to lean donors[149]. However, one recent paper shows that overexpression of each CerS isoform in L6 muscle cells does not point out any ceramide species in the generation of insulin resistance[150]. Since the implication of ceramide in the onset of insulin resistance in muscle has been convincingly demonstrated both *in vivo* and *in vitro* (see previous chapters), more investigations are needed before to make any conclusion in this tissue.

In summary, deciphering the mechanisms by which ceramides act negatively on insulin signaling has already been a step forward. However, the identification of the putative ceramide species that mediates lipotoxicity in cells or pushing ceramides to be converted into less toxic lipids remains the priority in order to find a way to counteract ceramide negative actions.

Abstract

Murry *et al* in 1986 discovered the intrinsic mechanism of profound protection called ischemic preconditioning. The complex cellular signaling cascades underlying this phenomenon remain controversial and are only partially understood. However, evidence suggests that adenosine, released during the initial ischemic insult, activates a variety of G protein-coupled agonists, such as opioids, bradykinin, and catecholamines, resulting in the activation of protein kinases, especially protein kinase C (PKC). This leads to the translocation of PKC from the cytoplasm to the sarcolemma, where it stimulates the opening of the ATP-sensitive K^+ channel, which confers resistance to ischemia. It is known that a range of different hypoglycemic agents that activate the same signaling cascades at various cellular levels can interfere with protection from ischemic preconditioning. This review examines the effects of several hypoglycemic agents on myocardial ischemic preconditioning in animal studies and clinical trials.

Key words: Ischemic preconditioning; Myocardial ischemia; Coronary artery disease; Hypoglycemic agents; Diabetes mellitus

INTRODUCTION

In the last 3 decades, the prevalence of diabetes mellitus in adults 18 years and older has increased 2-fold[1]. Approximately 50%-60% of patients with diabetes die from cardiovascular disease (CVD)[2]. Among various CVDs, acute myocardial infarction (AMI) has a high rate of mortality, and infarct size is a primary determinant of prognosis in these patients[3-5]. Furthermore, patients with diabetes are more likely than patients without diabetes to develop heart failure after AMI[6]. Thus, the development of new cardioprotective strategies capable of protecting the myocardium are imperative in order to improve clinical outcomes in diabetic patients with coronary heart disease. Moreover, hyperglycemia is an important risk factor for coronary artery disease and death; however, the use of some medications to achieve glycemic control is controversial, as their use has not consistently been shown to reduce mortality. The University Group Diabetes Program (UGDP) in 1970 showed that the administration of tolbutamide, a first-generation sulfonylurea, may increase the risk of cardiovascular death[7].

As a cardioprotective strategy, ischemic preconditioning (IPC) has received much attention for its powerful infarct size-limiting effect. This intrinsic mechanism of profound protection was suggested by Murry *et al*[8] in 1986 who found in a canine model that 4 consecutive periods of coronary occlusion of 5 min were able to reduce

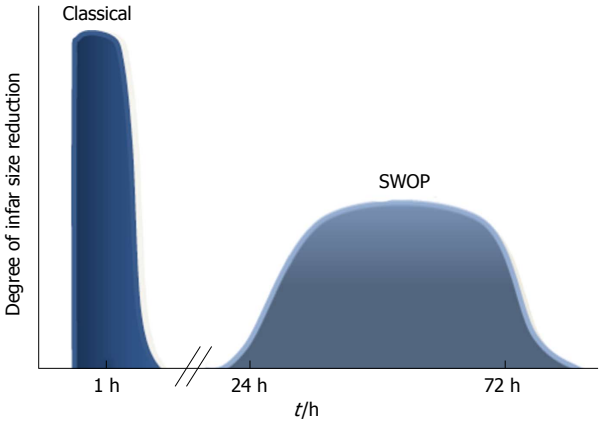

Figure 1 Diagrammatic representation of the temporal nature of the 2 windows of preconditioning (adapted from Baxter *et al*[9]). SWOP: Second window of protection.

the infarct size by as much as 75%, after induction by a subsequent period of occlusion for 40 min. For the first time, it was demonstrated that limitation of infarct size was theoretically possible.

IPC causes 2 phases of protection: "early" or "first window" and "second window of protection" (SWOP). The first window protects the heart for about 2 h and then wanes; the SWOP appears 24 h after the initiation of the IPC protocol and can last for 3 d (Figure 1)[9].

Although IPC was initially referred to as the ability of short periods of ischemia to limit infarct size, some investigators extended this definition to include a beneficial effect on reperfusion-induced arrhythmias[10] and on myocardial stunning[11].

Experimental findings on IPC cannot be directly extrapolated to humans, because of obvious ethical restrictions and because its mechanisms are different from those of other animal species. IPC in human hearts has been demonstrated by results of *in vitro* experiments using human ventricular myocytes[12] and atrial trabeculae[13]. In addition, surrogate clinical endpoints have also been used, including contractile function, electrocardiographic ischemic changes, or biochemical evidence of cell damage.

CELLULAR MECHANISMS OF CLASSICAL PRECONDITIONING

The cellular mechanisms that confer resistance to ischemia have been extensively studied. However, these pathways remain controversial and are only partially understood[14,15]. It has been proposed that endogenous adenosine released during the brief ischemia of the IPC protocol enhances the release of G-protein coupled receptor (GPCR) agonists, such as opioids, adenosine, bradykinin, or catecholamines[16-18]. These GPCR agonists appear to work simultaneously and in parallel to provide redundancy to the preconditioning stimulus. Although these 3 receptors trigger signaling through divergent pathways, this signaling activates prosurvival kinase or reperfusion injury salvage kinase paths, including phosphatidylinositol 3-kinase, protein kinase B, and protein kinase C[14,15]. In turn, it leads to the translocation of protein kinases from the cytoplasm to sarcolemmal receptors[19] and mitochondrial membranes[20], where it phosphorylates a substrate protein, the ATP-sensitive K^+ (KATP) channel[21]. Marinovic *et al*[22] demonstrated in mouse cardiac myocyte cells that the opening of the sarcolemmal KATP channels plays an important role in the prevention of cardiomyocyte apoptosis during metabolic stress, and may interact with mitochondrial channels. Thus, opening of KATP channels are strongly involved in the protection provided by preconditioning[23-26].

Due to the growing knowledge about the cellular pathways of this important protective mechanism, we must consider whether IPC can be applied as a cardioprotective therapy in ischemic heart disease patients.

PHARMACOLOGICAL INTERACTIONS

Pharmacological agents have the capacity to either interfere with signaling or trigger protection. The use of agents capable of mimicking the protective effects of preconditioning, besides brief ischemia, may offer a more benign approach for eliciting cardioprotection. Agents commonly used in coronary disease may interfere with the protection of IPC pathways. Penson *et al*[27] demonstrated in rat-isolated atria and ventricles that activation of beta-adrenoceptors mimics preconditioning. However, β-adrenoceptor blockers impair cardioprotection in animals[28]. Other agents such as Ca^{2+} channel blockers[29] and nonsteroidal anti-inflammatories may interfere with protection by IPC pathways[30,31]. Liu *et al*[16] reported that an adenosine receptor antagonist could block IPC protection and that adenosine or the A1-selective agonist adenosine, instead of brief ischemia, could duplicate IPC protection. Other potential candidates currently in clinical use include nicorandil or diazoxide[32,33]. These drugs have been shown to open KATP channels in ischemic cardiomyocytes, and might act as pharmacological imitators of the preconditioning phenomenon.

HYPOGLYCEMIC DRUGS AND IPC

Hyperglycemia is an important risk factor for coronary artery disease and death. However, the use of some hypoglycemic medications is controversial, because they have not been shown to reduce mortality. Indeed, physicians face challenges regarding the use of new agents in patients with diabetes who are at high cardiovascular risk. Several factors contribute to this concern, and among these is IPC. As described above, the UGDP raised concerns that the administration of tolbutamide may increase the risk of cardiovascular death, but this result remained unexplained until data were reported suggesting deleterious effects of some sulfonylureas (glyburide), specifically in the mechanisms of IPC[23,24].

Insulin secretagogues stimulate insulin secretion by the shutdown of the KATP channel in pancreatic β

cells[34]. KATP channels are composed of 2 types of subunits, inwardly rectifying K^+ channels (Kir6.x) and sulfonylurea receptors (SURx), arranged as tetradimeric complexes (Kir6.x/SURx)[35]. Closure of the KATP channel results in membrane depolarization and influx of calcium (Ca^{2+}) into the β cell. The increase in intracellular Ca^{2+} causes release of insulin from β cell secretory granules. KATP channels are also abundant in both cardiomyocytes[36,37] and arterial smooth muscle cells[38].

The β cell and cardiac muscle KATP channels have been shown to possess a common pore-forming subunit (Kir6.2) but different sulfonylurea receptor subunits (SUR1 and SUR2A, respectively). Although the roles of KATP channel in extrapancreatic tissues are less well characterized, it is likely that they open in response to metabolic stress, such as during cardiac ischemia[39]. Thus, the ideal sulfonylurea for treatment of type 2 diabetes would be one that interacts only with the β cell KATP channel.

EFFECT OF SULFONYLUREAS ON IPC

There is concern about the effect of sulfonylureas on preconditioning protection. Unfortunately, little is known about the ability of the clinically used insulin secretagogues to interfere with IPC. To evaluate studies on the effects of sulfonylureas on IPC, it is important to assess their selectivity for SUR receptor subtypes. These drugs have a range of affinities for KATP channels with different SUR isoform composition, resulting in different abilities to stimulate the KATP channel activity. Tolbutamide has a high affinity for SUR 1 receptors in β cells, but a very low affinity for SUR 2A receptors in the myocardium[40,41]. Glibenclamide (glyburide) inhibits cardiac as well as pancreatic receptors with high affinity[42,43]. Glimepiride has affinity for pancreatic and cardiac SUR comparable to glibenclamide, thereby, does not differentiate between B cells, cardiac muscle, or smooth muscle KATP channels[43,44]. In contrast, preliminary studies reported that glimepiride had less cardiovascular activity than glibenclamide had[45-48]. Several reasons seem to correlate with this finding and, among them, highlight the difference in selectivity for SUR between *in vitro* and *in vivo* studies, and different effects of doses utilized in most studies and in treatment of patients with type 2 diabetes mellitus. In addition, gliclazide, a second generation sulfonylurea, is distinguished by having a higher selectivity for pancreatic SUR receptors[43,49].

Numerous studies using animal models support the hypothesis that IPC is impaired by glibenclamide[23,47,50,51]. Studies using human hearts analyzed IPC in isolated human atrial muscle trabeculae, obtained from type 2 diabetic patients treated with sulfonylureas before coronary artery surgery, and noted that IPC was abolished in patients receiving sulfonylureas[52]. Tomai *et al*[53] evaluated IPC in 20 patients pretreated with either glibenclamide or placebo. They recorded ST-segment changes on ECGs during 2 subsequent episodes of intracoronary balloon inflation. They concluded that human IPC during brief repeated coronary occlusions was completely abolished by pretreatment with glibenclamide. Similar results were shown when the effects of glibenclamide and glimepiride were compared during balloon inflation in percutaneous transluminal coronary angioplasty[45,54].

Tomai *et al*[55] investigated the effects of glibenclamide on the "warm up phenomenon", which is a clinical model of IPC. It refers to an increased tolerance to myocardial ischemia during the second of 2 consecutive exercise tests. In this study, glibenclamide abolished the improvement in ischemic threshold during the second exercise test, compared with placebo[55]. Ovünç[56], in a similar study reported concordant results and suggested that glibenclamide should be used with caution in patients with coronary heart disease and diabetes mellitus, because this agent leads to a decrease in ischemic threshold and exercise capacity. Ferreira *et al*[57], in a study in which IPC was evaluated by 2 consecutive exercise tests, also investigated the effects of chronic treatment with glibenclamide. Forty patients with angina pectoris were allocated into 3 groups: 20 nondiabetic patients, 10 diabetic patients receiving treatment with glibenclamide for at least 6 mo, and 10 diabetic patients receiving other treatments. All patients underwent 2 consecutive exercise tests. The results suggested that IPC protection was blocked in diabetic patients exposed to long-term treatment with glibenclamide. In a recent study, Bilinska *et al*[58] evaluated 64 men, 17 nondiabetic and 47 diabetic, aged 54 ± 5 years. Diabetic patients were allocated into 3 groups: one treated with glibenclamide, one with gliclazide, and the other with diet. All patients performed 2 consecutive exercise tests, with 30 min between them. The authors compared the improvement in ischemic parameters among these groups of patients and concluded that the warm-up effect was preserved in diabetic patients treated with diet, partially preserved in patients treated with gliclazide, and abolished in patients treated with glibenclamide. In contrast, other studies reported no effect of treatment with glibenclamide on the electrocardiographic shifts of the ST-segment during consecutive exercise tests[59,60].

In summary, most studies with glibenclamide (glyburide) reported deleterious effects on IPC, suggesting caution with the use of this agent in patients at high risk for myocardial ischemia.

In animal studies, glimepiride treatment facilitated the cardioprotective effect elicited by IPC[47,48,61-63]. Indeed, data from clinical studies is of great interest. Experimental findings on IPC cannot be directly extrapolated to humans, because in humans its mechanisms are different from those in other animal species. Thus, Klepzig *et al*[45] compared the effects of glibenclamide, glimepiride, and placebo administration on ST-segment shifts during balloon inflation in percutaneous transluminal coronary angioplasty. They concluded that IPC was maintained after glimepiride administration and prevented after glibenclamide. Lee *et al*[46], studied the impact of glibenclamide or glimepiride administration on cardioprotective effects in patients with and without diabetes undergoing coronary angioplasty. The results demonstrated that the

changes in the ST-segment and metabolic parameters were more severe after pretreatment with glibenclamide than with glimepiride, in patients with and without type 2 diabetes.

Only a few studies[45,46] have used IPC protocols in humans to evaluate the effect of glimepiride. To date, these trials have revealed beneficial effects on cardioprotective mechanisms.

In isolated Langendorff perfused rat hearts, the infarct sizes were smaller in the group treated with gliclazide compared with the group treated with glibenclamide. However, the glimepiride group had a smaller infarct size than the gliclazide group[48]. In an *in-vivo* rat study, Maddock *et al*[51] compared the effects of glibenclamide and gliclazide on IPC and nicorandil-induced protection. The IPC protocol consisted of 2 cycles of 5 min of regional ischemia/reperfusion preceding prolonged ischemia. Gliclazide had no adverse effects on IPC or on nicorandil-induced protection. Loubani *et al*[64] assessed the dose-response effect of gliclazide and glibenclamide on IPC. Different doses of glibenclamide and gliclazide were added for 10 min prior to implementation of the IPC protocol. The cardioprotection was abolished by gliclazide only at supratherapeutic concentrations, while glibenclamide prevented IPC at all concentrations.

Bilinska *et al*[58] evaluated the effects of diet, glibenclamide, or gliclazide on the warm-up phenomenon in type 2 diabetic patients with stable angina. They concluded that the warm-up effect was partially preserved in the gliclazide-treated and abolished in the glibenclamide-treated group.

The analysis of the reported data described above suggests that gliclazide does not induce potentially harmful IPC effects.

EFFECT OF GLINIDES ON IPC

The drugs from the glinide class are characterized as insulinotropic agents with a rapid onset and short duration of action. Although glinides do not have a sulfonylurea structure, their role as an insulin secretagogue occurs by binding to the Kir6.2/SUR1 complex, which leads to the closure of KATP channels.

Glinides non-selectively inhibit the pancreatic, myocardial, and non-vascular smooth muscle KATP channels[65]. For these reasons, the selectivity of glinides for the pancreatic compared with the cardiovascular KATP channels has relevance for IPC. Unfortunately, little is known about the ability of the clinically used glinides to interfere with IPC. An original study conducted in our service[66], evaluated the effect of repaglinide on the warm-up phenomenon. Forty-two patients with type 2 diabetes mellitus and coronary artery disease underwent 2 consecutive treadmill exercise tests. After 7 d of receiving repaglinide, 83% of patients no longer had myocardial IPC.

Due to the great difference of *in vitro* selectivity ratios of repaglinide and other drugs in the glinide class (mitiglinide and nateglinide)[43,65], clinical studies assessing the effect of glinides on type 2 diabetic patients with coronary artery disease would be of great interest for both therapeutic and scientific reasons.

EFFECT OF INCRETINS ON IPC

Incretins are gut-derived peptides secreted in response to meals, specifically in the presence and absorption of nutrients in the intestinal lumen. The major incretins are glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide. Incretin is mainly represented by GLP-1. The half-life of GLP-1(7-36) in circulation is very brief (1 to 2 min), as it is rapidly degraded by the enzyme dipeptidyl peptidase-Ⅳ (DPP-Ⅳ) to the metabolite GLP-1(9-36), which does not act on the GLP-1 receptor. GLP-1 receptors are expressed in pancreatic islet cells and in the kidney, lung, brain, gastrointestinal tract, and heart[67]. The incretin modulator class includes the GLP-1 analogues or mimetics, which are functional agonists of the GLP-1 receptor. In addition, oral inhibitors of DPP-Ⅳ, in essence, increase the plasma concentrations of the biologically active form of endogenously secreted incretins[68]. Bose *et al*[69] observed in an isolated rat heart model that GLP-1(7-36) is protective against myocardial ischemia-reperfusion injury when given either as a preconditioning mimetic or at reperfusion. Although several investigators have reported the cardioprotective effect of GLP-1, there is a lack of studies about its effects on IPC. Our research group compared the actions of the DPP-Ⅳ inhibitor (vildagliptin) and repaglinide using an IPC protocol. The results showed that vildagliptin preserved IPC in 72% of 54 patients, while repaglinide maintained the cardioprotective response in only 17% of 42 patients[70]. Our group demonstrated 2 effects of hypoglycemic drugs on IPC. These findings support the importance of identifying underlying mechanisms of endogenous myocardial protection to improve the protective effect of pharmacological therapy (Table 1).

EFFECTS OF GLITAZONES ON IPC

The glitazones or thiazolidinediones offer the first therapeutic option specifically directed at reversing the basic problem of type 2 diabetes, which is resistance to insulin. These drugs act on tissues such as liver and skeletal muscle, sensitizing them to insulin action, and thereby increasing glucose uptake and decreasing its hepatic output. The oldest and best-studied glitazone is troglitazone, which was withdrawn from the market by the United States Food and Drug Administration (FDA) because of concerns about its safety. Muriglitazar, which stimulates both PPARγ and alpha receptors, increased adverse cardiovascular events and was also withdrawn by its manufacturer after rejection by the FDA. Roziglitazone and pioglitazone are also drugs in the PPARγ agonist family. Nissen *et al*[71] reported in a meta-analysis a significant increase in the risk of myocardial infarction with rosiglitazone and a trend towards increased risk of death from cardiovascular causes. This information has been includ-

ed in the prescribing information for all rosiglitazone-containing products. However, the glitazones have been shown to improve many of the traditional as well as the emerging risk factors associated with CVD[72]. The effect of the glitazones, rosiglitazone, and pioglitazone on IPC is still a matter of debate in the literature, as experimental studies demonstrate contradictory results. Methodological differences are one of the reasons for that. In studies using rat models, pioglitazone was associated with beneficial effects on cardiomyocyte injury, limiting infarct size, and ventricular arrhythmias[73-75]. These beneficial effects may be related to the opening of mitochondrial (ATP)-sensitive potassium channels[76] and by other kinases like phosphatidylinositol 3 kinase and P42/44 MAPK by pioglitazone[77]. On the other hand, in a porcine model, pioglitazone and rosiglitazone had the opposite results[78]. Finally, in the clinical setting, the possible actions of the glitazones on IPC are still uncertain.

EFFECTS OF METFORMIN ON IPC

The cardiovascular benefits observed in diabetic patients with chronic coronary artery disease with the use of metformin[79] have also been observed in experimental studies, which have shown positive results of metformin in the cardiovascular system, and that includes its effect in IPC. It is still not completely understood how metformin protects IPC in the heart, but it is postulated that it activates some kinases involved in IPC, such as (AMP)-activated protein kinase[80], which increases adenosine, activating cardioprotective mechanisms. Recent studies have also demonstrated that metformin increases hexokinase Ⅱ, another important kinase found in mitochondria, which seems to be one of the end-effectors of IPC, and that ultimately protects many cell types, including cardiomyocytes, against apoptosis and ischemic cell death[81]. Ischemia inhibits the loss of hexokinase Ⅱ from mitochondria, consequently preventing the opening of the mitochondrial permeability transition pore. This pore is responsible for the stabilization of the mitochondrial membrane potential, the prevention of cytochrome C release and also the reduction in reactive oxygen species production, which all finally lead to mitochondrial protection against ischemic injury[82,83]. These actions

associated with metabolic alterations, such as the prevention of acidosis through enhanced coupling of glycolysis and glucose oxidation and inhibition of fatty acid oxidation[81], are the responsible pathways by which metformin protects the myocardium from ischemia, in addition to its well-known effects in glucose control.

CLINICAL IMPLICATIONS

Ischemic preconditioning is a complex, dynamic phenomenon that can be the target of drug activities affecting the heart's ability to adapt to ischemic stress. In the clinical setting, however, the literature contains conflicting results regarding whether the use of conventional oral hypoglycemic agents affect cardiovascular mortality[84-90]. The findings from studies about the effects of hypoglycemic drugs on IPC have implications for diabetic patients, especially for those with a high risk of myocardial ischemic events, because the results infer that the myocardium may or may not benefit from a cardioprotective response when under the influence of such drugs. The most important consideration in this matter is that therapeutic options for diabetes treatment go beyond glucose-lowering efficacy in populations with increased risk of coronary ischemic events, and further large clinical trials will be necessary to determine whether the interference with myocardial preconditioning translates into clinical evidence.

Abstract

Type 2 diabetes is a complicated metabolic disorder with both short- and long-term undesirable complications. In recent years, there has been growing evidence that functional foods and their bioactive compounds, due to their biological properties, may be used as complementary treatment for type 2 diabetes mellitus. In this review, we have highlighted various functional foods as missing part of medical nutrition therapy in diabetic patients. Several *in vitro*, animal models and some human studies, have demonstrated that functional foods and nutraceuticals may improve postprandial hyperglycemia and adipose tissue metabolism modulate carbohydrate and lipid metabolism. Functional foods may also improve dyslipidemia and insulin resistance, and attenuate oxidative stress and inflammatory processes and subsequently could prevent the development of long-term diabetes complications including cardiovascular disease, neuropathy, nephropathy and retinopathy. In conclusion available data indicate that a functional foods-based diet may be a novel and comprehensive dietary approach for management of type 2 diabetes.

Key words: Type 2 diabetes; Insulin resistance; Functional foods; Whole grain; Legumes; Nuts; Fruits; Herbs or spices; Vegetables; Prebiotics; Probiotics

Core tip: Medical nutrition therapy (MNT) is a main part of type 2 diabetes management. Apparently the therapeutic and medicinal properties of foods maybe a missing step during MNT process, and could enhance the effectiveness of dietary management of type 2 diabetes.

Functional foods-based diet as a novel dietary approach for management of type 2 diabetes and its complications: A review. *World J Diabetes* 2014; 5(3): 267-281 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/267.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.267

INTRODUCTION

Type 2 diabetes is a metabolic disorder characterized by hyperglycemia, developing insulin resistance, β-cell dysfunction and impaired insulin secretion[1,2]. Multiple metabolic disorders including impaired lipid and lipoprotein metabolism, oxidative stress (over production of free

radicals and defect in endogenous antioxidant defense system), sub-clinical inflammation, vascular endothelial dysfunction and hypertension are commonly accompanied by type 2 diabetes[3-5]; these metabolic disorders lead to long-term pathogenic conditions such as micro- and macro-vascular complications including neuropathy, retinopathy, nephropathy, and a decreased quality of life and an increased mortality rate[6,7].

Despite availability of many pharmacological interventions including oral hypoglycemic agents and insulin therapy for diabetes management, current evidence shows an alarming rising trend in the occurrence of undesirable complications among these patients[1].

Medical nutrition therapy (MNT) is also a main part of type 2 diabetes management; estimation of energy and nutrients requirements, carbohydrate counting as well as glycemic index and glycemic load, recommendation for dietary fats and cholesterol and protein intakes, explanation the foods exchange list for patients and common important recommendations for a healthy diet are the main components of diet planning in type 2 diabetic patients[8,9]; however it is not clear whether this approach *per se* is sufficiently adequate for prevention of long-term complications of diabetes. Administration of various supplements, including antioxidant vitamins, fibers, ω_3 fatty acids, numerous nutraceuticals, and herbs has also been proposed for glycemic control but data available supporting these recommendations for diabetic patients are insufficient[10-14]. Apparently the therapeutic and medicinal properties of foods maybe a missing step during MNT process, and could enhance the effectiveness of dietary management of type 2 diabetes.

During the past two decades, the concept of functional food is fast expanding; functional foods beyond the basic nutritional functions have potential benefits to promote health and reduce the risk of chronic diseases and have hence been given much attention[15,16]. In recent years, researchers have focused on properties of the bioactive compounds of functional foods in the control of various aspects of diabetes mellitus; some protective effects of these compounds and food sources have been investigated *in vitro* and *in vivo*, and several clinical trials have even confirmed these advantages in diabetic patients[17-19].

Here, based on the multiple biological properties of functional foods and their bioactive compounds, a functional foods-based diet has been hypothesized as a novel and comprehensive dietary approach for management of type 2 diabetes and prevention of long-term complications.

RESEARCH

The evidence cited in this review was obtained through searches in PubMed, Scopus, and Google scholar using the following key words: "Type 2 diabetes or hyperglycemia", "insulin resistance", "cardiovascular disease", "obesity", "metabolic syndrome", "oxidative stress", "inflammation", long-term diabetic complications" in combination with "functional foods", "nutraceuticals", "bioactive food compounds", "fiber", "polyphenols", "whole grain", "legumes", "nuts", "fruits", "herbs or spices" "vegetables", "prebiotics", "probiotics", and "bioactive peptides". Relevant articles of acceptable quality were used. Briefly, in this article we tried to highlight some of the following important functional foods including whole grains, phytochemical-rich fruits and vegetables, legumes, nuts, dairy products, green tea and some spices, as required components of a health-promoting diet for diabetic patients.

Whole grains

Grains and cereal-based products are the basic sources providing energy and carbohydrate in human diets. Since the dietary carbohydrate sources in type 2 diabetic patients play a determining role in glycemic and insulin secretary response, the use of functional grains including whole grain cereals, and bakery products prepared using whole wheat, rye, oat, and barley is the first step in planning of a functional foods-based diet.

Some previous studies report that dietary carbohydrate modification in patients with metabolic syndrome resulted in favorable metabolic consequences especially increased insulin sensitivity, decreased adipocyte cell size, and modulated expression of adipose tissue genes involved in insulin signaling pathways (insulin-like-growth-factor binding protein-5, insulin receptors, hormone-sensitive lipase[20,21].

Compared to refined grains, whole grains (WGs) have more non-digestible complex polysaccharides including soluble and insoluble fibers, inulin, β-glucan, and resistant starches, as well as non-carbohydrate functional components including carotenoids, phytates and phytoesterogens, phenolic acids (ferulic acid, vanilic acid, caffeic acid, syringic acid, *P*-cumaric acid), and tocopherols. The most well-known protective effects of whole grain-based products against obesity, type 2 diabetes, cardiovascular diseases, hypertension, metabolic syndrome and various types of cancer, have been attributed to these bioactive compounds[22-25]. Among the several mechanisms available in current data regarding the beneficial effects of WGs and cereal-based products in diabetic patients, some of the more important are that bioactive compounds of WGs could effectively regulate glycemic response, increase insulin sensitivity, improve pancreatic β-cell functions and increase insulin secretion[26,27]. High contents of inulin and β-glucan, main soluble and fermentable fibers in WGs, in addition to their hypolipidemic and hypoglycemic effects, act as prebiotics in the gut and modulate gut microbiota *via* stimulation of growth and activity of bifidobacteria and lactic acid bacteria[28,29], effects leading to more metabolic responses (Figure 1).

Long-term follow-ups of diabetic patients indicate that higher consumption of whole grain, cereal fiber, bran, and germ were associated with decreased all-cause and cardiovascular disease-cause mortality[30]. Epidemiological studies also confirmed that regular consumption of WGs products could modify the main risk factors of atherosclerotic diseases including triglyceride and LDL-C

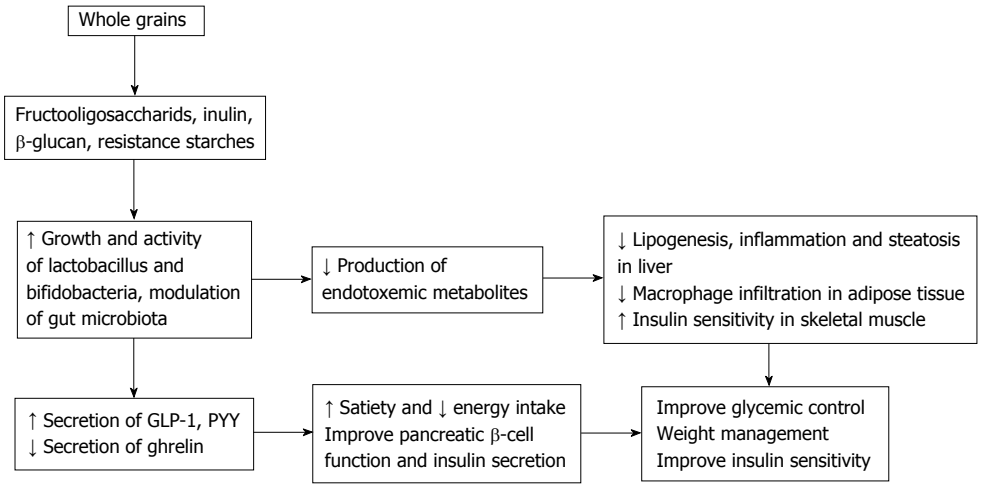

Figure 1 Role of prebiotic compounds of whole grains and cereal-based products in modulation of gut microbiota and con sequent metabolic effects could lead to better glycemic control.

levels, blood pressure and serum homocysteine levels, as well as vascular functions, and oxidative and inflammatory status[31].

Rye, a widely used grain especially in Northern and Eastern Europe, is considered a functional grain. The high fiber content of rye products decreases digestion and absorption of dietary carbohydrates, and increase metabolites derived from colonic fermentation of the soluble fiber of rye products, including propionic and butyric acids which effectively stimulate secretion of insulin from β-cells; studies have indicated that the bioactive compounds of rye (phenolic acids, tannins, benzoic acid, phenylalanine) derivates have a similar efficacy with antidiabetic drugs in insulin secretion[26,32]. In one study, the consumption of rye products in the breakfast meal increased colonic fermentation, decreased ghrelin levels and satiety rating in the late postprandial phase after breakfast as well as energy intake at a subsequent lunch meal, and improved acute glucose and insulin responses[32].

Oat meal products have also been investigated as healthy carbohydrate sources for diabetic patients; they are rich sources of soluble fiber especially β-glucan, antioxidants and bioactive compounds including carotenoids, phytic acid, phenolic acids (hydroxycinammic acids, caffeic acid, ferulic acid), flavonoids and phytosterols[33]. Studies show that consumption of oat products improves glycemic, insulinemic, and lipidemic responses in diabetic patients, and act as active ingredient reducing postprandial glycemia[34,35]. In diabetic animal models, oat products attenuated hyperglycemia-induced retinal oxidative stress, increased glycogen content of liver, decreased plasma free fatty acids and succinate dehydrogenase activity and inhibited pancreatic β-cell apoptosis as well[36].

The beneficial effects of barley and its by products for diabetic patients are mainly attributed to its high content of β-glucan; Administration of barley β-glucan extract in pre-diabetic subjects improved glucose tolerance and insulin resistance index[27]. In addition, barley may use as base of a meal; the use of barley combined with refined grains such as white rice maybe a practical way to attenuate their undesirable effects on glycemic control; in a randomized crossover study, combination of cooked barley with white rice dose-dependently reduced the area under the curves of plasma glucose and insulin concentrations, suppressed postprandial decrease of plasma desacyl ghrelin levels and consequently increased satiety[37]. The hypolipidemic properties, antioxidant and anti inflammatory activities of barley products have also been investigated[38,39]. In animal diabetic models, barley improved some features of fatty liver, decreased lipid content of the liver, increased fatty acid oxidation and adiponectin levels[40].

Several positive effects of whole wheat and its byproducts on carbohydrate and insulin metabolism have also been reported; wheat bran and whole wheat products are rich sources of dietary fiber, magnesium (main cofactor of enzymes involved in glucose metabolism and insulin secretion), potassium, phenolic acids, α-tocopherols, carotenoids and antioxidants[41]. It is believed that the majority of beneficial effects of whole wheat grain are related to bran and germ fractions; wheat bran is a main source of fiber, lignans, phenolic acid and alkylresorcinol, and beyond the health promotion of gastrointestinal tract and weight management, could improve postprandial glycemic response, glycosylated hemoglobin, lipid disorders and other cardiovascular risk factors in diabetic patients[42]. Studies showed that alkylresorcinol of wheat bran inhibited platelet activity and aggregation, decreased triglyceride de novo synthesis, and decreased cardiovascular disease risk factors[43]. Wheat germ is rich in non-digestible oligosaccharides, phytosterols, benzoquinone and flavonoids that play a potent role in induction of antioxidant and anti-inflammatory properties and modulation of immunity responses[44]. Avemar, fermented wheat germ extract, had interesting properties in the treatment of cardiovascular disease, and improved metabolic abnormalities including hyperglycemia, lipid peroxidation and abdominal fat gain[45].

Brown rice and its byproducts is another grain investigated as a functional food. Compared to white rice, brown rice has lower glycemic load and glycemic index, and higher content of fiber, vitamins and minerals, phytic acids, polyphenols, tocopherols, tocotrienols, and other bioactive compounds[46]; consumption of brown rice has benefits on glycemic control, dyslipidemia, endothelial function, abdominal obesity and liver functions in type 2 diabetic patients[47]. Studies show that γ-orizanol found in brown rice modulates high-fat diet induces oxidative stress, improves β-cell function, enhances glucose-stimulated insulin secretion and prevents the development of type 2 diabetes[48]. Germinated and pre-germinated brown rice, as more interesting functional foods, have unique components including γ-amino butyric acid, and bioactive acylated steryl glucosides with potent antidiabetic properties; these bioactive components attenuate oxidative-induced peripheral nervous system, prevent diabetic neuropathy, inhibit oxidative-induced pancreatic β-cell apoptosis and enhance insulin secretion[49-51]. Bran rice, a byproduct of brown rice, contains within 31% fiber (mainly insoluble fiber), β-glucan, pectin, tocopherols, orizanol, ferulic acid, lutein, xanthine, vitamin K, thiamin, niacin, pantothenic acid, α-lipoic acid, coenzyme Q_{10} and other nutraceuticals; administration of bran rice in diabetic patients reduced glycosylated hemoglobin, LDL-C and total cholesterol as well as increased HDL-C[52].

In conclusion, replacement of whole grain and cereal-based products with refined grains in diet planning may be an effective and practical strategy for MNT in type 2 diabetic patients; this approach beyond the improvement of glycemic control, leads to more benefits for management of other aspects of diabetes, attenuation of diabetes-induced metabolic disorders, and prevents long-term complications especially atherosclerosis and cardiovascular disease.

PHYTOCHEMICAL-RICH FRUITS AND VEGETABLES

Fruits and vegetables are rich sources of dietary fiber (soluble and insoluble fiber), vitamins, and various phytochemicals and play a vital role in health promotion and prevention of chronic disease[53]. Dietary modification based on fruits and vegetables certainly is a definitely important strategy for management of type 2 diabetes and prevention of its complications; several studies indicate that regular consumption of various fruits and vegetables in diabetic patients can lead to an improved glycemic control, reduced HbA1c and triglyceride levels, enhanced antioxidant defense system, attenuated oxidative stress and inflammatory markers, decreased risk of diabetic retinopathy, and a lower burden of carotid atherosclerosis[54-57]. Since various fruits and vegetables provide many different micronutrients and bioactive compounds, consumption of varied fruits and vegetables is mainly recommended; it should be noted that the color of fruits and vegetables reflects predominant pigmented phytochemicals, and considering the colors in selection of these food groups provide a wide range of nutraceuticals. In Table 1, some phytochemical-rich fruits and vegetables, their bioactive compounds and favorable effects on diabetic related conditions are reviewed. Studies showed that tomato and its by products, as main sources of lycopene, β-carotene, flavonoids and other bioactive components, could attenuate blood pressure and dyslipidemia, decrease cardiovascular risk factors and enhance antioxidant defense system; other sources of lycopene and carotenoids such as grapefruit and watermelon have also beneficial properties to regulate lipid and lipoprotein metabolism, blood pressure and vascular function. Anthocyanins-rich fruits including red apple, berries family, grapes, cherries, red cabbage, and pomegranate have mainly hypoglycemic effects (↓ digestion and absorption of dietary carbohydrates, ↓ postprandial glycemic response and ↓ glycosylated hemoglobin) as well as protective properties against oxidative damages (Table 1).

LEGUMES

Legumes (peas, beans, lentils, peanuts) are valuable sources of dietary protein, non-digestible carbohydrates including dietary fiber, resistance starches, oligosaccharides, and bioactive compounds such as functional fatty acids (linoleic acid, α-linolenic acid), isoflavones (daidzein, genistein, glycitein), phenolic acids, saponins, and phytic acid; some polyphenols including pelargonidin, cyanidin, delphinidin, and malvidin are also found in legumes[134,135]. Legumes are considered a component of a healthy diet and there is much evidence showing that regular consumption of legumes has protective effects against obesity, type 2 diabetes, and cardiovascular disease[136]. Legumes may be considered as an important component of a functional-foods based diet for management of type 2 diabetes. α-amylase inhibitory peptides are one of the bioactive compounds in legumes and beans that reduce digestion and absorption of dietary carbohydrates, and modulate postprandial glycemic response; other bioactive peptides of grain legumes including the 7S globulin α chain and conglutin γ have unique properties to regulate lipid metabolism and normalize lipid and lipoprotein levels[137]. Low glycemic index, high fiber and phytochemical content of legumes have made them functional food for diabetic patients.

Lentils (Lens culinaris), the most consumed legume grains, are rich sources of dietary fiber, slowly digestible starch and resistant starch, tannins, β-glucan, functional antioxidant ingredients, a wide range of phenolic acids including gallic acid, proanthcyanidins, prodelphinidin, procyanidins, catechins, epicatechin, kampferol, quercetin, cinapic acid and apigenin[138]. Studies show that bioactive proteins of lentil reduce plasma levels of LDL-C, triglyceride content of the liver, and adipose tissue lipoprotein lipase activity; moreover, polyphenols of lentil could prevent angiotensin Ⅱ-induced hypertension, and pathological changes including vascular remodeling and

Table 1 Bioactive compounds and functional properties of some of favorable fruits and vegetables

Ref.	Possible functional properties in diabetes	Main bioactive components and phytochemicals	Fruits and vegetables
[58-62]	↓ Systolic and diastolic blood pressure ↑ apolipoprotein a1 and HDL-C ↓ LDL oxidation, improve diabetes-induced lipid disorders ↓ cardiovascular risk factors ↓ aldose reductase activity and cataract ↑ antioxidative enzymes activity	Lycopene, β-carotene, flavonoids, anthocyanins, phytoan, phyto flava, quercetin, kampferol	Tomato and its by products
[63-65]	↓ Triglyceride levels, enhance endogenous antioxidant defense system, regulation of appetite	Lycopene, pectin, naringin, hesperidin	Grapefruit
[66-69]	↑ Nitric oxide biosynthesis, improve endothelial function ↓ blood pressure ↑ plasma arginine levels and consequently ↓ insulin resistance and adipocyte size	Lycopene, carotenoids, cytrolin	Watermelon
[70-73]	↓ Absorption of dietary carbohydrate ↓ postprandial glycemia, improve pancreatic β-cell function ↓ free radical generation ↓ lipid peroxidation ↑ plasma total antioxidant capacity, prevent vascular damage, improve dyslipidemia	Soluble fiber, quercetin, catechins, epicatechin, *P*-cumaric acid, chlorogenic acid, gallic acid, phlordizin, procyanidins	Red apple, apple peel, apple and its by products
[74-81]	Glycemic control, inhibit α-glucosidase and α-amylase activity ↓ digestion and absorption of dietary carbohydrates ↓ insulin resistance, improve dyslipidemia ↓ postprandial oxidative stress ↓ lipid peroxidation ↑ plasma total antioxidant capacity ↓ systolic blood pressure ↑ antioxidative enzymes activity ↑ adipocytes lipolysis ↓ inflammatory processes, modulation of peroxisome proliferator-activated receptors	Anthocyanins, tannins, ellagitanins, α-carotene, β-carotene, lutein, delphinidins, pelargonidins, ciyanidins, catechins, hydroxy-cinnamic acid	Berries; cranberry, blackberry, black raspberry, blueberry, red raspberry, strawberries
[82-86]	Protective effects on vascular system ↓ platelet hyperactivity and aggregation ↓ cardiovascular diseases ↓ oxidative damage ↓ rennin-angiotensin activity ↑ production of nitric oxide ↓ blood pressure ↑ bone-marrow-derived endothelial progenitor cells	Anthocyanins, resveratrol	Grapes, grape by products
[87-91]	↓ Hyperglycemia ↓ HbA1c, improve lipid disorders, anti-inflammatory properties (inhibit cyclooxygenase) ↓ abdominal fat ↓ microalbuminuria, improve metabolic syndrome and fatty liver features ↓ oxidative stress ↓ production of cytokines, induction of PPARγ ↓ diabetic neuropathy	Anthocyanins, quercetin, hydroxy-cinnamic acid, carotenoids, melatonin, phenolic acids, gallic acid, lutein, xanthine, β-carotene	Cherries
[92-95]	↓ Hyperglycemia, attenuate hyperglycemia-induced metabolic disorders ↓ lipid peroxidation, induction of gluthathione reductase, glutathione peroxidase, superoxide dismutase, delay progression of nephropathy ↓ inflammatory processes, improve dyslipidemia	Isothiocyanates, anthocyanins (red cabbage), carotenoids, lutein, β-carotene	Cabbage, Cauliflower
[96-100]	↓ Hyperglycemia ↑ endothelial nitric oxide synthase activity, inhibit angiotensin converting enzyme ↓ blood pressure, improve vascular function ↓ cholesterol and atherogenic lipids ↓ lipid peroxidation ↓ progression of atherosclerosis ↑ plasma total antioxidant capacity, modulate activation of PPARγ and nuclear factor κB ↑ activity of paraxonase 1 and HDL-C levels ↓ serum resistin levels and ameliorate obesity-induced insulin resistance	Anthocyanins, tannins, catechins, gallocatechins, punicalagin acid, ellagic acid, gallic acid, oleanolic acid, ursolic acid, uallic acid	Pomegranate and its by products, pomegranate peel and seeds

[101-105]	↓ Hyperglycemia, induce insulin secretion from β-cell ↓ blood pressure, inhibit enzyme involved in cholesterol biosynthesis, improve dyslipidemia, prevent atherosclerosis ↓ lipid peroxidation ↓ platelet hyperactivity and aggregation, regulate glycolysis, gluconeogenesis and carbohydrate metabolism pathways ↑ insulin sensitivity	Allyl sulfors, flavonoids, quercetin, dihydroflavonols, anthocyanins (red onion)	Garlic, onions
[106-111]	↓ Endothelial macrophage activation ↓ hyperactivity and aggregation of platelet, improve vascular function ↓ oxidative stress and inhibit stress-sensitive signaling pathways ↓ digestion of dietary lipids, improve dyslipidemia ↓ pro-inflammatory cytokines ↓ lipid peroxidation	Lutein, xanthine, α-cryptoxanthin, β-cryptoxanthin, naringenin, hesperidin, β-carotene, phytosterols	Citrus fruits
[112-113]	↓ Free radical generation and lipid peroxidation, binding to bile acids ↑ cholesterol excretion, improve lipid profile ↑ plasma total antioxidant capacity	Lutein, betaine, violaxanthine, opioid peptides (rubisculins), *P*-cumaric acid, ferulic acid	Spinach
[114-115]	Improve glycemic and insulinemic response ↓ systemic inflammation ↓ cardiovascular disease risk factors	Carotenoids, pectin, oleic and linolenic acids	Pumpkin
[116]	Improve hyperglycemia and dyslipidemia ↑ adiponectin, antioxidant and anti-inflammatory effect	Fiber, polyphenols, chlorogenic acid, flavonoids, anthocyanins	Plums
[117-119]	Improve dyslipidemia, anti-inflammatory properties ↓ lipid peroxidation ↑ plasma total antioxidant capacity	Soluble fiber (pectin), α-carotene, β-carotene lutein, phenolic acids, stilbenes	Carrots
[120-122]	Inhibit α-amylase ↓ postprandial glycemia ↑ glycogen synthesis, improve dyslipidemia ↓ lipid peroxidation, protective effect against diabetic nephropathy	Carotenoids, quercetin, kampferol, gallic acid, caffeic acid, catechins, tannins, mangiferin	Mango
[123-127]	Regulate carbohydrate metabolism (↑ glucokinase and glucose-6-phosphate dehydrogenase activity ↓ glucose-6-phosphatase activity) ↓ lipid peroxidation ↓ protein carbonylation ↑ antioxidant enzyme activity, improve metabolic syndrome features ↑ insulin sensitivity ↓carbohydrate absorption ↓ plasma free fatty acid	Anthocyanins, alkaloid compounds (berberine, oxycontin)	Barberry
[128-131]	Protective effects against diabetic neuropathy ↓ lipid peroxidation, induce antioxidant enzymes, protect liver and kidney against oxidative damage	Dietary fiber, polyphenols, acid cinnamic, melatonin	Date fruit
[132-133]	Improve lipid and lipoprotein metabolism ↑ insulin sensitivity ↓ blood pressure	Dietary fiber, pectin, flavonoids, gallic acid, chlorogenic acid, catechins, anthocyanins	Figs

PPARγ: Peroxisome proliferator-activated receptor γ.

vascular fibrosis[139,140].

Beans are also other important legume grains in the human diet with high content of fiber, phytate, ω_3 fatty acids, antioxidants, phenolic compounds. The hypoglycemic effect of beans (*via* inhibition of α-amylase and β-glucosidase activity) has been reported as being similar to those of anti-diabetic drugs[141-143]. Including beans (pinto, dark red kidney, black beans) in diet planning for type 2 diabetic patients effectively helps weight management, attenuates postprandial glycemic response, and improves dyslipidemia[144-146].

Soybean, a rich source of unique phytoesterogens (genistein, daidzein, glycitein), is another important functional food which has been considered in diabetes; the isoflavones and bioactive peptides of soybean have favorable effects on glycemic control and insulin sensitivity, dyslipidemia, and kidney function[147-149]. It seems that the anti-diabetic effects of soybean mainly occur through interaction with estrogen receptors (ERs); studies show that soy isoflavones selectively bind to both α and β estrogen receptors; ERα is considered as key modulator of glucose and lipid metabolism, and regulate insulin biosynthesis and secretion as well as pancreatic β-cell survival[150]. Soy protein could induce insulin sensitivity and improve lipid homeostasis *via* activation of peroxisome proliferator-activated receptor and liver X receptors, and inhibition of the sterol regulatory element binding protein-1c[151]. Regular consumption of soy products could help diabetic patients in the management of dyslipidemia[152]. Soy protein and isoflavones decrease

production of atherogenic apolipoproteins such as apo B, increase biosynthesis of HDL-C, induce LDL-C receptors, increase biosynthesis and excretion of bile acids, decrease gastrointestinal absorption of steroids, induce favorable changes in hormonal status, including the insulin to glucagon ratio, and thyroid hormones which lead to improvement of dyslipidemia[153,154]. Recently two bioactive peptides, identified in glycinin (a main soy protein), have unique hypolipidemic properties. These peptides inhibit 3-hydroxy-3methyl glutaryl CoA reductase, key enzyme involved in cholesterol biosynthesis. β-conglycinin, another main soy bioactive protein with anti-atherogenic properties *via* regulation of lipogenesis, decease liver lipogenic enzyme activity, inhibits fatty acid biosynthesis in liver, and facilitates fatty acid β-oxidation; other biological activities of soy peptides include antioxidant, anti-inflammatory, and hypotensive effect[155].

Another feature of soybean and soy products as well as other legumes which may highlight them as main part of a functional foods-based diet, is their established effectiveness in weigh management; since the overweight and obesity are the common problems in diabetic patients and main contributors in development of insulin resistance, benefit from anti-obesity properties of legumes is considered another key approach in these patients. Thermogenic effects, induction of satiety through some important appetite regulatory gut peptides, mediation in gene expression and secretion of key adipocytokines such as leptin and adiponectin, as well as inhibitory effects on proliferation and differentiation of adipocytes are some of the mechanisms that could explain the role of legumes on weight management[140,156-159]. In conclusion, considering the potential benefits of legumes and its by products, regular consumption of these functional foods may be an effective strategy for management of various aspects of type 2 diabetes.

NUTS

Based on current evidence, nuts may play a protective effect against cardiovascular disease risk factors. Almonds, pistachios, walnuts and hazelnuts are commonly used nuts; these functional foods are considered as rich sources of high-biological value proteins, bioactive peptides, functional fatty acids (mono and poly unsaturated fatty acids), fiber, phytosterols, polyphenols, tocopherols and other antioxidant vitamins; the antioxidative effect of nuts mainly is related to a high content of α and γ tocopherol, phenolic acids, melatonin, oleic acid and selenium, while the anti-inflammatory effect is related to ellagic acid, α-linolenic acid and magnesium[160,161].

Most current evidence reveals that consumption of nuts in type 2 diabetic patients other than improving the overall diet quality also has beneficial effects on postprandial glycemic response following high-carbohydrate meals, attenuates postprandial oxidative stress and inflammatory processes, normalizes lipid and lipoprotein levels and decreases lipid atherogenicity, and improves insulin resistance[162,163]. Moreover, habitual intake of nuts could help to effectively manage weight especially in diabetic patients; the anti-obesity effects of nuts investigated in some studies may be attributed to thermogenic effects, induction of satiety, decreased dietary fat absorption, and increased fat excretion; bioactive components of nuts also modulate regulatory appetite neurotransmitters and adipose tissue metabolism, as well as decrease proliferation and differentiation of adipocytes, inhibit lipogenesis and induce fatty acid β-oxidation[164,165]. Studies show that consumption of nuts effectively decreases serum levels of high-sensitivity C-reactive protein; a well measure of systemic low-grade inflammation, interleukin 6 (a potent pro-inflammatory cytokine) and fibrinogen while increase plasma concentration of adiponectin, a potent anti-inflammatory cytokine released from adipose tissue; dietary patterns, high in nuts, were also related to lower levels of soluble inflammatory and cardiovascular risk markers including intercellular adhesion molecule 1 and vascular cell adhesion molecule 1[166,167]. Another beneficial effect of nuts which is important especially in diabetic patients is favorably influence on endothelial function; high content of L-arginine, a main precursor of nitric oxide, as well as antioxidants and polyphenols could contribute to this effect[161].

In conclusion, it seems that a diet enriched with nuts may be an effective strategy to improve glycemic control and prevent cardiovascular disease in type 2 diabetic patients.

OTHER BENEFICIAL FUNCTIONAL FOODS AND BIOACTIVE COMPONENTS FOR DIABETIC PATIENTS

Although there are a large number of natural foods, nutraceuticals or bioactive components that could be considered as functional ingredients and have beneficial effects for diabetes management, addressing all these issues is beyond the scope of this article. Table 2 shows some of these potential functional foods including dairy products and probiotics, fish meat, green tea, spices are presented.

CONCLUSION

Type 2 diabetes is a complicated metabolic disorder with both short- and long-term undesirable complications as well as various pathogenic conditions including dyslipidemia, vascular dysfunction, oxidative stress, sub-clinical inflammation, and altered signaling pathways. Ineffectiveness of the current medical treatments in management of long-term diabetes complications confirms that other complementary approaches are required; the use of functional foods and bioactive compounds is one of these new approaches. Functional foods and their bioactive compounds could attenuate carbohydrate metabolism and hyperglycemia, improve pancreatic β-cell function and insulin secretion as well as insulin resistance, regulate lipid and lipoprotein metabolism and adipose tissue metabolism, modulate oxidative/antioxidative balance and

Table 2 Bioactive compounds and functional properties of some of favorable functional foods

Ref.	Possible functional properties in diabetes	Main bioactive components and nutraceuticals	Functional foods
[168-179]	Improve the features of metabolic syndrome, modulate gut microbiota, regulate satiety and food intake ↑ adiponectin, modulate adipocytokines, induce thermogenesis, lipolysis and β-oxidation ↑ dietary fat excretion ↓ adiposity and body weight ↓ oxidative stress and inflammatory markers, hypo-lipidemic and anti-thrombotic effects ↑ insulin sensitivity, modulate immune responses in diabetic patients ↑ total antioxidant capacity ↓ lipid peroxidation ↓ HbA1c	Calcium, vitamin B, bioactive proteins such as casein and whey, immunoglobulines, bioactive peptides (α- and β-lactorphines, lactoferrin, lactoferricin, α-lactalbumin, β-lactoglobulin, growth factors), conjugated linoleic acids, lactic acid bacteria and bifidobacteria	Dairy products and probiotics
[180-185]	Improve hypertriglyceridemia and hypertension ↓ cardiovascular disease ↓ insulin resistance and inflammation, improve glycemic management ↓ proteinuria ↓ oxidative stress, inhibit lipogenesis and induce lipolysis, induce PPARα and PPARβ ↓ adiposity and weight management ↑ thermogenesis and energy expenditure, inhibit angiotensin converting enzyme and modulate blood pressure	Bioactive peptides, antioxidant compounds, ω_3 fatty acids (docosahexaenoic acid, eicosapentaenoic acid), selenium, taurine	Fish and seafood
[186-189]	Regulate cholesterol metabolism ↓ LDL oxidation, protect vascular endothelium against atherogenesis, inhibit platelet aggregation ↓ atherosclerosis development ↓ pro-inflammatory cytokines, activate PPARγ, improve sub-clinical inflammation	Oleic acid, ω_3 fatty acids, Flavonoids, cinnamic acid, benzoic acid, lignans, cumaric acid, ferulic acid, tocopherols, carotenoids, oleuropein, oleocanthal	Olive oil
[190-193]	Promote endogenous antioxidant defense system, induce superoxide dismutase and catalase ↓ lipid peroxidation, improve glycemic control ↑ insulin sensitivity ↓ gluconeogenesis ↑ glycogen content ↓ glycation of collagen and fibrosis, protect cardiac muscle, regulate lipid metabolism as well as adipose tissue metabolism, inhibit lipogenic enzymes ↓ satiety ↑ thermogenesis ↓ proliferation and differentiation of adipocytes ↓ pro-inflammatory cytokines ↓ monocyte chemotactic protein-1	Polyphenols, phenolic acids, catechins, epigallocatechin-3-gallat, chlorophyll, carotenoids, pectin, plant sterols	Green tea
[194-196]	↑ Iinsulin sensitivity, improve peripheral uptake of glucose, increase glycolysis and gluconeogenesis, hypoglycemic and hypolipidemic effects, antioxidant and anti-inflammatory properties	Cinnamaldehyde, cinnamic acid, coumarin, catechins, epicatechin, procyanidins B-2	Cinnamon
[197-199]	Inhibit enzymes involved in inflammation including cyclooxygenase-2, lipoxygenase, and nuclear factor κB, inhibit α-glucosidase and α-amylase activity ↓ postprandial glycemic response ↓ proteinuria, activate PPARγ and regulate carbohydrate and lipid metabolism, prevent diabetic cataract	Curcuminoids, stigmasterol, β-sitosterol, 2-hydroxy methyl anthraquinone, bioactive peptide turmerin	Turmeric
[200-203]	Attenuate oxidative stress, protective effects against oxidative damage ↓ serum creatinine and urea, improve dyslipidemia ↓ atherogenic lipoprotein levels ↓ lipid peroxidation in renal tissue, inhibit α-glucosidase activity ↓ carbohydrate digestion and absorption, protect liver against diabetes-induced oxidative damage	Tannins, flavonoids, anthocyanins, phenolic acid, gallic acid	Sumac

PPAR: Peroxisome proliferator-activated receptor.

inflammatory processes, improve weight management and prevent micro and macro vascular complications.

Considering the beneficial properties of functional foods, it seems that diet planning based on these healthy foods may be considered an effective strategy for management of various aspects of diabetes and promotion of health in diabetic patients.

Abstract

While the lifespan of people with type 1 diabetes has increased progressively since the advent of insulin therapy, these patients still experience premature mortality, primarily from cardiovascular disease (CVD). However, a subgroup of those with type 1 diabetes survives well into old age without significant morbidity. It is the purpose of this review to explore the factors which may help in identifying these patients. It might be expected that hyperglycaemia plays a major role in explaining the increased incidence of CVD and mortality of these individuals. However, while a number of publications have associated poor long term glycaemic control with an increase in both all-cause mortality and CVD in those with type 1 diabetes, it is apparent that good glycaemic control alone cannot explain why some patients with type 1 diabetes avoid fatal CVD events. Lipid disorders may occur in those with type 1 diabetes, but the occurrence of elevated high-density lipoprotein-cholesterol is positively associated with longevity in this population. Non-renal hypertension, by itself is a significant risk factor for CVD but if adequately treated does not appear to mitigate against longevity. However, the presence of nephropathy is a major risk factor and its absence after 15-20 years of diabetes appears to be a marker of long-term survival. One of the major factors linked with long-term survival is the absence of features of the metabolic syndrome and more specifically the presence of insulin sensitivity. Genetic factors also play a role, with a family history of longevity and an absence of type 2 diabetes and hypertension in the family being important considerations. There is thus a complex interaction between multiple risk factors in determining which patients with type 1 diabetes are likely to live into older age. However, these patients can often be identified clinically based on a combination of factors as outlined above.

Key words: Type 1 diabetes; Prognosis; Survival; Coronary artery disease; Cardiovascular disease; Lipids; Metabolic syndrome

Core tip: People with type 1 diabetes are generally assumed to have a shortened lifespan. This contention is supported by a number of epidemiological studies confirming a trend towards premature death, primarily due to cardiovascular disease. However, a subset of type 1 individuals survives for many years, living for over 50 years or more with type 1 diabetes. This review explores the clinical features that are linked to long-term survival in people with type 1 diabetes, allowing identification of these individuals. Recognising these individuals will aid in assessing prognosis, and treating the identified risk factors could improve survival.

INTRODUCTION

Prior to the discovery of insulin, patients with type 1 diabetes had an expected lifespan of less than 3 years[1].

With the advent of modern therapy, survival has increased progressively. However, those with type 1 diabetes remain with an increased incidence of coronary artery disease (CAD) and mortality compared to the general population. By 1991, reported standard mortality rates for those with type 1 diabetes under the age of 60 years were 9.1 for males and 13.5 for females[2]. Subsequently, a cohort of 23751 patients from the United Kingdom and diagnosed with diabetes under the age of 30 years between 1972 and 1993 were analysed for cardiovascular mortality up to 2000[3]. These results confirmed higher mortality rates at younger ages for those with type 1 diabetes (Figure 1). Of interest, not only are the mortality rates for women with diabetes considerably higher than for women without diabetes, but also higher than for men without diabetes. Soedamah-Muthu *et al*[4], utilizing the United Kingdom General Practice research database, have also confirmed that the risk of cardiovascular disease (CVD) remains high in patients with type 1 diabetes. Typically, patients with type 1 diabetes reach a 10-year risk of fatal CVD of 5% about 10 to 15 years before the general population. Furthermore, incidence rates of CAD in type 1 patients range between 1.2% and 2% per year, *vs* 0.1% and 0.5% in the general population[5]. The incidence of stroke is also increased in type 1 diabetes, with overall standardised incidence ratios being 17.94 for men and 26.11 for women[6].

It is therefore clear, that despite a better understanding and treatment of appropriate risk factors and better general care, those with type 1 diabetes still have a tendency towards a shortened life span, primarily due to premature CVD. Yet a subgroup of individuals with type 1 diabetes survives well into old age in relatively good health. This review explores the factors that may help to identify these patients. This can be done either by identifying a group of long-surviving type 1 patients and analysing any unique clinical or biological features that may be specific to this cohort, or by assessing surrogate endpoints of vascular disease, such as carotid artery Intima-Media Thickness (IMT) measurement or arterial calcification and identifying those who appear to be "protected" from vascular disease.

THE ROLE OF GLYCAEMIC CONTROL

Type 1 diabetes is a condition of "pure" hyperglycaemia. The only abnormality is one of β-cell failure and insulin deficiency in an otherwise "normal" or "healthy" individual. It could therefore be expected that hyperglycaemia might play a major role in explaining the increased incidence of CVD and mortality seen in these individuals. A number of publications have associated poor long-term glycaemic control with an increase in both all-cause mortality and CVD in those with type 1 diabetes. Grauslund *et al*[7] demonstrated a direct relationship between HbA1c and survival. When patients were categorized into quartiles of HbA1c measurements, patients in the highest quartile had a significantly higher risk of all-cause mortality, cardiovascular mortality and ischaemic heart disease

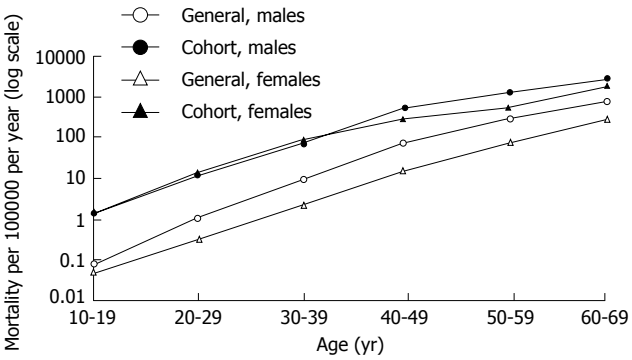

Figure 1 Ischaemic heart disease mortality rates in people with type 1 diabetes *vs* general population (from: Laing *et al*[3]).

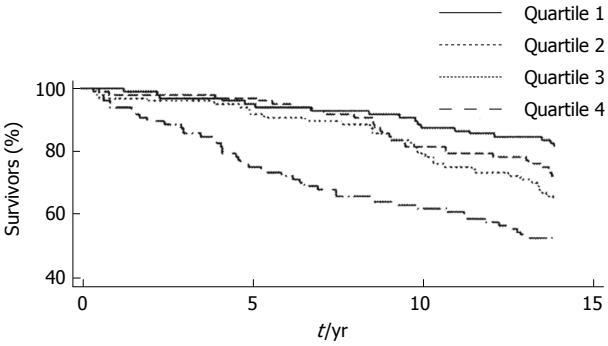

Figure 2 All-cause mortality and the association of glycaemic control (from: Grauslund *et al*[7]).

when compared to patients in the lowest quartile (Figure 2). While at the conclusion of the Diabetes Control and Complications Trial (DCCT) there was no significant difference between the conventional and intensive treatment groups regarding cardiovascular outcomes or death from CVD, the 10-year Epidemiology of Diabetes Interventions and Complications (EDIC) follow-up demonstrated a significant difference between the two groups with regard to both CV outcomes and death. An overall 42% risk reduction was seen in the previously intensively treated group[8]. This sustained effect of improved control in the DCCT years was ascribed to "metabolic memory". Patients followed in the DCCT/EDIC cohort were also submitted to IMT measurements, and it was demonstrated that intensive therapy during the DCCT resulted in decreased progression of IMT six year after the end of the trial[9]. These findings imply that early glycaemic control is an important factor in preventing CVD in type 1 diabetes.

However, good blood glucose levels alone cannot explain why some patients with type 1 diabetes avoid fatal CVD events. In the "Golden Years Cohort" of 400 type 1 patients who survived for over 50 years with diabetes[10], the mean HbA1c was 7.6% (± 1.4), with some of these patients having HbA1c levels as high as 8.5%-9%. None had an HbA1c below 7%. In addition, a number of other publications have shown only a weak correlation between long-term glycaemic control, CVD and mortality. Larsen *et al*[11], performed coronary angiography on 29 asymptomatic patients with a mean duration

of type 1 diabetes of 30.6 years. Of these, 34% had significant coronary artery stenosis. While a significant relationship existed between stenosis and glycaemic control (a 6.1% increase in vessel stenosis for every 1% increase in HbA1c over 18 years), glycaemic control was less significant as a risk factor than the age of the subjects and the effect of elevated serum cholesterol. In another cohort of 125 patients with a mean duration of diabetes of 22 years[12], IMT was compared to an index of lifetime glycaemic exposure. This demonstrated significantly increased IMT only on those at the highest tertile of glycaemic exposure. IMT measurements performed in 148 long-surviving patients with type 1 diabetes (duration > 15 years)[13] showed no significant correlation between HbA1c and IMT, although ordinal logistic regression showed that for every 1% increase in HbA1c, there was a 27% less chance of the IMT falling into the low-risk group (defined as an IMT below 0.6 mm and no plaque). A prospective observational study of a meta-analysis of the relationship between CVD and glycaemic control[14], revealed an only moderate increase in cardiovascular risk with increasing levels of glycated haemoglobin in persons with diabetes mellitus. However, this meta-analysis included patients with both type 1 and type 2 diabetes. The data suggested that there is an increased risk of CVD of 15% for every 1% increase in HbA1c (RR = 1.15; 95%CI: 0.92-1.43).

The evidence therefore suggests that while early good glycaemic control is important in the prevention of CVD and survival, the importance of glycaemic control may diminish as patients survive longer. While glycaemic control is clearly a risk factor for CAD and mortality in type 1 diabetes, this is not the major determinant of survival. Good glycaemic control alone cannot explain why some type 1 patients survive into old age.

LIPIDS IN TYPE 1 DIABETES

Patients with type 1 diabetes may show quantitative lipid disorders. There is a clear relationship between the level of glycaemic control and lipid abnormalities, with an independent correlation between HbA1c and low-density lipoprotein (LDL)-cholesterol, non-high-density lipoprotein (HDL) cholesterol and triglycerides[15]. Abnormal lipid levels are associated with worse cardiovascular outcomes[5]. The lipid profiles of patients with well-controlled type 1 diabetes are very different from those with poor glycaemic control[16], related possibly to the presence of adequate peripheral insulin levels in the better controlled subjects. There are direct metabolic consequences of administering insulin subcutaneously. Peripheral hyperinsulinemia is associated with increased lipoprotein lipase activity[17], which may account for reduced triglyceride levels. In addition, LDL-cholesterol may also be slightly reduced due to decreased very LDL production[18]. The more sensitive the individual is to insulin, the greater is this effect.

As might be expected, Serum LDL-cholesterol and non-HDL-cholesterol levels are positively associated with not only an increase in IMT[9], increased Arterial Stiffness[19] and coronary artery stenosis[11], but also CAD and mortality[5,7,20]. A major factor that appears to be associated with prolonged survival in patients with type 1 diabetes is elevated HDL-cholesterol. HDL levels are often elevated in those with type 1 diabetes. This is more marked with better glycaemic control and may be due to an elevated lipoprotein lipase/hepatic lipase ratio (Increased peripheral lipoprotein lipase activity due to peripheral hyperinsulinemia from subcutaneous insulin administration and normal hepatic lipase activity). Bain *et al*[10] reported a high mean HDL-level in those surviving over 50 years with diabetes (1.84 ± 0.057 mmol/L), and this was associated with lower triglyceride levels (1.49 ± 0.79 mmol/L). In long-surviving type 1 patients, IMT measurements showed a significant inverse association to HDL levels and computed tomography/HDL ratios for all measure of risk (IM thickness and/or plaque)[13]. A number of other studies have supported the protective effects of HDL-cholesterol with regard to CVD[5,7,9,11,20]. In addition to this direct association between HDL-cholesterol and CVD, higher HDL-cholesterol levels may provide protection against the development of albuminuria[21].

Therefore, it can be concluded that in addition to the expected effect of dyslipidaemia (high LDL and non-HDL-cholesterol), HDL-cholesterol itself exerts a significant protective effect on the development of CVD in patients with type 1 diabetes and elevated HDL-cholesterol levels appears to play a major role in longevity in these patients.

BLOOD PRESSURE AS A RISK FACTOR

Hypertension in those with type 1 diabetes is often a manifestation of underlying nephropathy. However, hypertension can also occur as a stand-alone risk factor (non-renal hypertension). A significant positive association between high blood pressure and arterial stiffness in youth with type 1 diabetes was demonstrated in the SEARCH CVD Study[19].

In type 1 diabetes, hypertension without nephropathy has been shown to be a major risk factor for the development of carotid artery plaque [OR = 5.26 ($P < 0.004$)], but the effect of hypertension on IMT was moderate and not significant[13]. In the DCCT/EDIC at 6 years, the presence of hypertension and particularly systolic hypertension was significant, but had less of an effect on IMT than did smoking, lipids or glycaemic control[9]. In the Golden years cohort[10], 29% of the patients were receiving antihypertensive treatment but had nevertheless survived for over 50 years with diabetes.

It therefore appears as though hypertension itself, while a significant risk factor for CVD, if treated does not mitigate against longevity in this population.

MICROVASCULAR DISEASE AS A MARKER OF SURVIVAL

The presence of diabetic nephropathy, microalbuminuria

Table 1 Cox proportional hazard models for risk of cardiovascular disease from nephropathy (from: Grausland *et al*[7])

	All cause mortality	Cardiovascular mortality	IHD
Creatinine > 120 μmol/L	5.1	6.29	4.25
Microalbuminuria	1.32	1.44	1.40
Macroalbuminuria	2.4	2.57	1.77

IHD: Ischaemic heart disease.

or macroalbuminuria is a significant risk factor for CAD, cardiovascular mortality and all cause mortality, and there is a strong independent relationship between albuminuria and CAD (Table 1)[7]. The occurrence of stroke in subjects with type 1 diabetes is also increased by the presence of nephropathy [microalbuminuria: HR = 3.2 (1.9-5.6), macroalbuminuria: HR = 4.9 (2.9-8.2), End Stage Renal Disease: HR = 7.5 (4.2-13.3)][22]. The DCCT/EDIC Study showed a sustained effect of good glycaemic control[23] on the reduction in albumin excretion 7 years after the conclusion of the DCCT study, with an 83% risk reduction in those patients initially treated with intensive therapy, confirming the concept of "metabolic memory". The long-term risk of a reduction in estimated glomerular filtration rate (eGFR) was also shown to be 50% lower among those who were treated early in the course of type 1 diabetes with intensive diabetes therapy than among those treated with conventional diabetes therapy[24]. The development of hypertension was also delayed in the intensively treated group. These effects appeared to be largely mediated by the levels of glycaemia achieved during the DCCT. However, as pointed out by the authors, a long time elapsed between treatment intensification during the DCCT early in the course of the diabetes and the effect on eGFR, and the advantages of improved glycaemic control in persons already with advanced complications may not apply. This further supports the contention that good glycaemic control in the early years of the diabetes may be more important achieved in those who have had the condition for some years.

In type 1 diabetes, the peak incidence of nephropathy occurs between 15 and 20 years after the development of the diabetes[25,26]. Progression from microalbuminuria to overt neuropathy has been shown to reduce from 45% in those with diabetes of less than 15 years, to 26% in those with diabetes of over 15 years duration. By the time someone has had diabetes for over 40 years, it drops to just 4% per year[25]. In this regard, none of the long surviving patient in the "Golden Years cohort"[10] had evidence of overt nephropathy.

It is therefore apparent, that those individuals with type 1 diabetes who are likely to survive, would remain free of any evidence of nephropathy.

No prospective studies in type 1 patients have found a strong independent relationship between retinopathy and CVD or mortality. However, the presence of retinopathy increases the risk of stroke[22]. Severe diabetic retinopathy was common in the "Golden Years Cohort"[10]. Forty-three percent of subjects had had laser therapy and 2% were blind. In relatively long-surviving people with type 1 diabetes, the presence of retinopathy had a significant association with the presence of plaque (OR = 3.65; $P < 0.033$), independent of glycaemic control[13]. However, there was no association between the presence of retinopathy and IMT measurements. It therefore appears as though retinopathy is not a major risk factor for CVD or mortality in those with type 1 diabetes, as opposed to those with type 2 diabetes where the presence of retinopathy may indicate CAD and mortality risk[27].

With regard to peripheral neuropathy, no prospective trials link the presence of neuropathy to either CAD or mortality other than the EURODIAB study, which did detect peripheral and autonomic neuropathy as risk markers for future mortality[20].

TYPE 1 DIABETES AND THE METABOLIC SYNDROME

There is no reason to expect patients with type 1 diabetes to have a lower prevalence of obesity and the metabolic syndrome (MetS) than the general population and a MetS frequency in type 1 patients of over 30% has been reported[28]. A significant relationship exists between mortality and central obesity in those with type 1 diabetes[20] and type 1 subjects with the MetS have been shown to have an increased prevalence of macrovascular disease[29]. The presence of MetS features in patients with type 1 diabetes is associated with risk factors similar to many patients with type 2 diabetes, and the superimposition of the insulin resistance due to obesity or the MetS in a patient who already has type 1 diabetes has been termed "Double diabetes"[30].

Identifying patients with the MetS in the presence of type 1 diabetes is difficult. Of the diagnostic criteria, the presence of dysglycaemia is a foregone conclusion and cannot be used. Hypertension should only be included if it is non-renal as nephropathy-induced hypertension has other implications as outlined above. Quantifying insulin resistance is also difficult and requires a euglycaemic clamp study to document it properly. A derived estimate of glucose disposal rate has been suggested to measure of insulin resistance[31] but this includes the presence of hypertension and waist-hip ratio in the formula and therefore cannot be used in assessing insulin resistance in the context of the MetS, since both of these variables are separate components of the MetS in their own right. Insulin dosage provides a surrogate measurement of insulin resistance in these patients, and in their series of long-surviving type 1 patients, Distiller *et al*[32] arbitrarily chose insulin doses in the top quartile of their series of patients (0.75 U/kg body weight), to be a measure of insulin resistance. In this series, a multiple linear regression analysis showed a significant relationship between waist circumference and insulin dose and carotid artery IMT when corrected for age of onset, current age and duration of diabetes. Interestingly, neither body mass index (BMI) nor HbA1c were significantly associated with carotid artery IMT. Overall, there was a significant

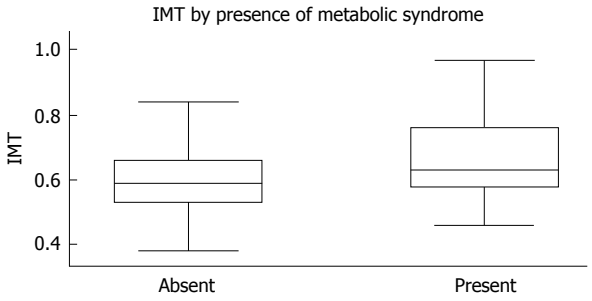

Figure 3 A significant increase in Intima-Media Thickness is seen in patients s with the metabolic syndrome (*P* = 0.003) (adapted from: Distiller *et al*[32]).

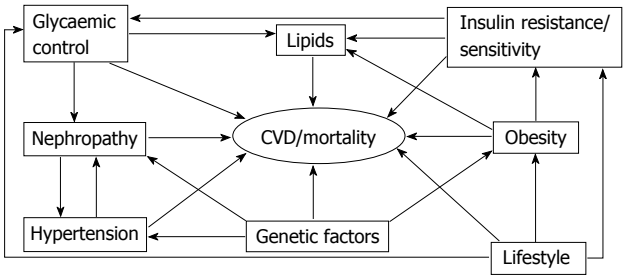

Figure 4 Complex interactions exist between multiple risk factors in determining the outcome for patients with type 1 diabetes. CVD: Cardiovascular disease.

increase in IMT in type 1 subjects with the MetS (Figure 3). A significant association was demonstrated between IMT risk and the number of features of the MetS (P = 0.01). Fifty percent of patients with 0-1 features had low risk IMT, whereas 60% of patients with 3-4 features had high risk IMT measures. This finding was confirmed by the SEARCH CVD Study[16], a longitudinal study of 298 youth with diabetes, where those with the MetS had consistently increased arterial wall stiffness when compared to type 1 patients without the Syndrome and with the same duration of diabetes. This was born out by the "Golden Years Cohort"[10], where the patients were generally on low doses of insulin. The mean daily insulin dose was 37.5 U (± 16.2) (0.52 U/kg body weight), the mean BMI of these long surviving patients was 25 kg/m^2, and HDL-cholesterol was high and triglycerides were low. These features could be considered the antithesis of the MetS.

GENETIC FACTORS

The best predictor of old age is the age one's parents achieved. This adage was supported by the "Golden Years Cohort"[10], where on average, both parents of those surviving 50 years with diabetes lived to over 70 years. Furthermore, a family history of either type 2 diabetes or hypertension has been shown to result in significantly increased IMT in type 1 diabetes subjects[12].

Clearly, a complex interaction exists between multiple risk factors in determining which patients with type 1 diabetes are likely to live into older age (Figure 4). However, these patients can often be identified clinically based on a combination of factors (Table 2).

Table 2 Identifying features of long-surviving patients with type 1 diabetes

Reasonable (not necessarily ideal) glycaemic control
High HDL-cholesterol levels
Low daily insulin requirements ("insulin sensitive")
Normal body weight
Non-smokers
Lower blood pressures
Microalbumin negative after 15-20 yr of diabetes
Family history of longevity

HDL: High density lipoprotein.

CONCLUSION

While the longevity of those with type 1 diabetes has improved considerably over the past century, these patients remain with a reduced life expectancy compared to the non-diabetic population. Nevertheless, a subgroup of these individuals may survive into older age despite their diabetes. Certain clinical and biochemical features can identify these people. This understanding may provide clinicians with further evidence that correction of modifiable risk factors like glycaemic control, blood pressure control, avoidance of excessive weight gain and lipid control is vital in ensuring the ongoing longevity of patients with type 1 diabetes.

Evidence for altered thiamine metabolism in diabetes: Is there a potential to oppose gluco- and lipotoxicity by rational supplementation?

Abstract

Growing prevalence of diabetes (type 2 as well as type 1) and its related morbidity due to vascular complications creates a large burden on medical care worldwide. Understanding the molecular pathogenesis of chronic micro-, macro- and avascular complications mediated by hyperglycemia is of crucial importance since novel therapeutic targets can be identified and tested. Thiamine (vitamin B1) is an essential cofactor of several enzymes involved in carbohydrate metabolism and published data suggest that thiamine metabolism in diabetes is deficient. This review aims to point out the physiological role of thiamine in metabolism of glucose and amino acids, to present overview of thiamine metabolism and to describe the consequences of thiamine deficiency (either clinically manifest or latent). Furthermore, we want to explain why thiamine demands are increased in diabetes and to summarise data indicating thiamine mishandling in diabetics (by review of the studies mapping the prevalence and the degree of thiamine deficiency in diabetics). Finally, we would like to summarise the evidence for the beneficial effect of thiamine supplementation in progression of hyperglycemia-related pathology and, therefore, to justify its importance in determining the harmful impact of hyperglycemia in diabetes. Based on the data presented it could be concluded that although experimental studies mostly resulted in beneficial effects, clinical studies of appropriate size and duration focusing on the effect of thiamine supplementation/therapy on hard endpoints are missing at present. Moreover, it is not currently clear which mechanisms contribute to the deficient action of thiamine in diabetes most. Experimental studies on the molecular mechanisms of thiamine deficiency in diabetes are critically needed before clear answer to diabetes community could be given.

Key words: Diabetes; Thiamine; Vitamin B1; Transketolase; Benfotiamine; Hyperglycemia; Nephropathy; Metabolic syndrome; Cardiovascular disease; Chronic kidney disease

Core tip: Published data suggest deficient action of thiamine in diabetes, however, it is not currently clear by which mechanisms. Plasma levels might be decreased in diabetics (although renal function has a prevailing effect), nevertheless, intracellular concentration of thiamine diphosphate is the crucial parameter and there is not a direct relationship with the plasma thiamine since the rate of transmembrane transport (*via* thiamine transporters) and intracellular activation by thiamine pyrophosphokinase might affected by hyperglycemia at first place. Experimental studies on the molecular mechanisms of thiamine deficiency in diabetes are critically needed before clear answer to diabetes community could be given.

Evidence for altered thiamine metabolism in diabetes: Is there a potential to oppose gluco- and lipotoxicity by rational supplementation? *World J Diabetes* 2014; 5(3): 288-295 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/288.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.288

INTRODUCTION

Diabetes mellitus, the most common metabolic disease resulting from insufficient insulin action (either absolute or relative), is characterized by various degree of chronic hyperglycemia and is often accompanied by specific microvascular complications including nephropathy, retinopathy and neuropathy. Diabetes also substantially increases the risk of macrovascular complications (coronary heart disease, stroke and peripheral vascular disease). Both micro- and macrovascular complications affecting diabetic patients are associated with reduced quality of life and contribute substantially to considerable morbidity and mortality.

Hyperglycemia (the cumulative exposure to excess of glucose as well as individual pattern of glucose fluctuation) together with increased availability of free fatty acids (a consequence of deregulated lipolysis in adipose tissue as well as their "spill over" in case of adipocyte saturation in obese subjects) are the two dominant metabolic alterations characterising gluco- and lipotoxicity in diabetes and are causally responsible for the development of vascular complications.

Although selected aspects of thiamine metabolism abnormalities in relation to diabetes has been reviewed earlier[1,2], comprehensive view and findings from recent studies were not included. In this review we therefore aim (A) to point out the physiological role of thiamine in metabolism of glucose and amino acids, to present overview of thiamine metabolism and to describe the consequences of thiamine deficiency (either clinically manifest or latent). Furthermore, (B) we want to explain why thiamine demands are increased in diabetes and to summarise data indicating thiamine mishandling in diabetics (review of the studies mapping the prevalence and the degree of thiamine deficiency in diabetics). Finally, (C) we would like to summarise the evidence for the beneficial effect of thiamine supplementation in progression of hyperglycemia-related pathology and, therefore, to justify its importance in determining the harmful impact of hyperglycemia in diabetes.

PHYSIOLOGICAL ROLE OF THIAMINE IN GLUCOSE METABOLISM, THIAMINE METABOLISM AND CONSEQUENCES OF ITS DEFICIENCY

Role of thiamine in energy metabolism

Thiamine (vitamin B1) is a water soluble vitamin that belongs to the large group of B vitamins. Several forms of thiamine exist: (1) free thiamine; (2) thiamine monophosphate (TMP); (3) thiamine diphosphate (TDP); (4) thiamine triphosphate; and (5) adenosine thiamine triphosphate. The active form of thiamine-TDP-together with magnesium is an essential cofactor of several enzymes important for carbohydrate [transketolase (TKT), pyruvate dehydrogenase and α-ketoglutarate dehydrogenase] and amino acid (branched-chain α-keto acid dehydrogenase) metabolism[3].

Overview of thiamine metabolism

As thiamine is an essential micronutrient for humans its needs are supplied from diet rich in thiamine, such as yeast, pork, legume and cereal grains. Enzyme called thiaminase I (EC2.5.1.2), present in raw fish, shellfish, tea and coffee, decreases thiamine absorption. Thiamine is absorbed in the small intestine, predominantly in the duodenum. Thiamine esters are hydrolysed by pancreatic nucleotide pyrophosphatase (EC3.6.1.9) or alkaline phosphatase (EC3.1.3.1) to form unphosphorylated thiamine that is taken-up by enterocytes *via* thiamine transporters at low concentrations or *via* passive diffusion at higher concentrations[4]. Within enterocyte thiamine is phosphorylated by thiamine pyrophosphokinase (TPK1, EC2.7.6.2) to TDP preventing its return back to the intestinal lumen. Most of the TDP must be hydrolysed to cross the basolateral membrane using specific ATP-dependent transporter or reduced folate carrier 1 (RFC-1)[5]. Thiamine and TMP are the most abundant forms in plasma. Uptake of thiamine and TMP by cells is mediated by specific thiamine transporters 1 (THTR1 encoded by *SLC19A2* gene) and 2 (THTR2 encoded by *SLC19A3*) and RFC-1. Majority of thiamine in the cytoplasm (approximately 90%) is phosphorylated by TPK1 to TDP and used as a cofactor of cytosolic enzymes while the rest remains unphosphorylated[3]. Most of the TDP (approximately 90%) is transported into mitochondria *via* thiamine transporter from the solute carrier family of proteins encoded by the *SLC25A19* gene[6]. Two mutations in the SLC25A19 cause Amish lethal microcephaly, an autosomal recessive disorder characterized by severe microcephaly, delayed brain development, α-ketoglutaric aciduria and premature death[7]. Overview of intracellular thiamine metabolism is presented in Figure 1. Thiamine also crosses blood-brain barrier[8] and placenta[9].

Thiamine is excreted by kidneys and its rate depends on glomerular filtration, tubular reabsorption and also on plasma thiamine concentration[10]. Normally, thiamine filtered in glomerulus is effectively reabsorbed in the proximal tubule through thiamine/H^+ antiport[11]. Long-term diuretic therapy is known to produce thiamine deficiency[10]. As thiamine deficiency develops, thiamine urinary excretion falls rapidly[12].

Thiamine deficiency

Thiamine reserves are low, limited amount (up to 30 mg) is stored in skeletal muscle, brain, heart and kidneys. Thiamine stores may become depleted within weeks of

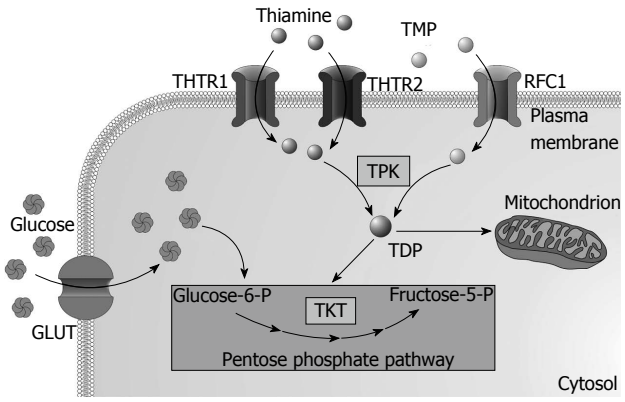

Figure 1 The overview of intracellular thiamine metabolism. GLUT: Glucose transporter; THTR1: Thiamine transporter 1; THTR2: Thiamine transporter 2; TKT: Transketolase; TPK: Thiamine pyrophosphokinase; RFC1: Reduced folate carrier 1; TDP: Thiamine diphosphate.

a deficient diet since the biological half-life of thiamine is 9 to 18 d[13]. Thiamine deficiency can result from decreased intake (most often due to its low content in diet or compromised absorption), increased demands (*e.g.,* in pregnancy) or increased renal loss. In developed countries overt thiamine deficiency due to a malnutrition is rare, however, occurs in various health conditions with alcohol abuse and chronic diseases (*e.g.,* cancer) being the most common causes. Secondary thiamine deficiency can also accompany heart failure, severe infections or long-term diuretic use.

Although all cell types utilize thiamine, the nervous system is particularly sensitive to thiamine deficiency due to its role in the synthesis of acetylcholine and γ-aminobutyric acid in the brain. Also the heart is strongly sensitive to thiamine limitation due to the high level of oxidative metabolism. Early symptoms of thiamine deficiency are in general nonspecific including fatigue, anorexia, nausea, weight loss and depression. Serious thiamine deficiency can clinically manifest as beriberi, Wernicke's encephalopathy or Korsakoff's psychosis[14]. Beriberi, classically categorized as dry or wet, is present in populations relying on diet constituting predominantly of polished rice (very low thiamine content). Wet beriberi (also known as thiamine deficiency with cardiopathy) affects primarily heart and can lead to a congestive heart failure with peripheral oedemas, tachycardia, dyspnoea and weakness[15]. Patients with dry form usually suffer from peripheral neuropathy leading to paralysis, weakness, leg paraesthesia, wasting of muscle and various other symptoms.

Thiamine deficiency is common in alcoholics as alcohol negatively affects thiamine uptake and intracellular phosphorylation, thus contributing to a marked thiamine deficiency. Central nervous system manifestations of thiamine deficiency in alcoholics are known as Wernicke-Korsakoff syndrome. The symptoms include changes of mental status (*e.g.,* confusion), ocular signs (nystagmus) and ataxia. Thiamine deficiency in alcoholics can also be accompanied by severe loss of memory denoted as Korsakoff psychosis. Both symptoms commonly occurs together constituting so called Wernicke-Korsakoff syndrome[16].

Intracellular thiamine deficit due to mutations in the gene *SLC19A2* encoding for THTR1 causes thiamine-responsive megaloblastic anaemia syndrome (TRMA)[17]. TRMA is an autosomal recessive disorder that typically manifests as megaloblastic anaemia, hearing loss and diabetes[18].

Supplementation in case of proven thiamine deficiency can be achieved by free thiamine that was shown to increase plasma thiamine levels as well as intracellular TDP although the rate of thiamine transport through the plasma membrane is quite slow[19]. Several lipophilic thiamine derivatives have been synthesized (*e.g.,* fursultiamine and sulbutiamine) which are able to diffuse through plasma membrane independent of transporters thus being more effective than free thiamine. Within the cell they are converted to thiamine. Benfotiamine (S-benzoylthiamine O-monophosphate) is another derivative with better availability than thiamine (reflected by higher plasma thiamine levels). However benfotiamine must be dephosphorylated to S-benzoylthiamine by ecto-alkaline phosphatase to become lipophilic prior crossing plasma membrane. No adverse effects of either high-dose thiamine or benfotiamine supplementation have been reported so far probably due to an efficient renal excretion or rapid uptake by hepatocytes with subsequent transformation to thiamine and release into the blood, respectively[19].

Laboratory test used for estimation of thiamine status

The two main tests routinely used for the assessment of thiamine status are the measurement of erythrocyte TKT activity and the so called thiamine effect. The former is measured by a kinetic reaction without adding thiamine. Thiamine effect expresses the increase of TKT activity after addition of saturating amount of thiamine to the reaction. The increase up to 15% is considered as normal thiamine status, higher increase is an indicator of mild (up to 25%) or severe (more than 25%) thiamine deficiency[15]. Plasma thiamine levels can also be measured although they predominantly reflect thiamine intake rather than cellular levels. Combination of erythrocyte TKT activity and thiamine effect measurement is considered as the most reliable indicator of thiamine status in clinical settings.

DIABETES AS A STATE OF INCREASED DEMAND FOR THIAMINE AND THE EVIDENCE FOR THE ALTERED THIAMINE METABOLISM IN DIABETES

Consequences of hyperglycemia for thiamine availability

Diabetes of all types is *ex definitione* characterised by hyperglycemia. Contribution of fasting and postprandial glucose elevation is variable though in various degrees of abnormal glucose tolerance and most likely also interindividually. Increased glucose supply stimulates its intracellular metabolism (glycolysis) with subsequent increase in

the production of reactive oxygen species (ROS) in mitochondria[20,21]. Overproduction of ROS in mitochondria links- *via* inhibition of the key glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase-hyperglycemia with activation of several biochemical pathways involved in the development of microvascular complications of diabetes incl. hexosamine and polyol pathways, production of advanced glycation end products (AGEs) and activation of protein kinase C[22]. However, cells in general are capable of either decreasing overproduction of ROS by enzymatic and non-enzymatic antioxidant mechanisms and/or eliminating of damaging metabolites and their substrates (generated by overloaded glycolysis) that accumulate within cells. Pentose phosphate pathway (PPP) is an example of the latter mechanism. PPP represents an alternative pathway for glucose oxidation fulfilling three important functions: (1) production of reducing equivalent NADPH necessary for reduction of oxidized glutathione thus supporting intracellular antioxidant defence; (2) production of ribose-5-phosphate required for the synthesis of nucleotides; and (3) metabolic use of pentoses obtained from the diet. PPP consists of two branches: (1) irreversible oxidative branch necessary for NADPH and pentose phosphates production; and (2) reversible non-oxidative branch in which interconversion of three to seven carbons containing sugars occurs. TKT (EC 2.2.1.1), one of the key enzymes of non-oxidative branch of PPP, can limit the activation of damaging pathways through lowering availability of their precursors. TKT transports two-carbon units and catalyses formation of ribose-5-phosphate from glycolytic intermediates. As a cofactor of TKT, thiamine may have a profound effect on glucose metabolism through the regulation of PPP and indeed, TKT activation by benfotiamine (see below) in endothelial cells blocked several pathways responsible for hyperglycemic damage and prevented development and progression of diabetic complications in animal models[23]. The mechanism responsible for the observed effect upon activation of non-oxidative reversible branch of PPP by thiamine or its derivative benfotiamine was the diminished accumulation of triosephosphates and fructose-6-phosphate induced by hyperglycemia[2].

Thiamine mishandling in diabetes

Little is known about the precise mechanisms how diabetes affects thiamine metabolism. Patients with type 1 and 2 diabetes mellitus (T1DM and T2DM) do not have a marked thiamine deficiency [conventionally defined as an increase of TKT activity in red blood cells (RBC) higher than 15% after addition of saturating amount of TDP]. However, plasma thiamine levels in diabetics are decreased by 75% compared to healthy subjects[24]. RFC-1 and THTR1 protein expression in RBCs obtained from diabetic patients (both T1DM and T2DM) is higher than in healthy subjects[24].

Experimental evidence suggests abnormal thiamine handling in the kidneys in diabetes that might be one of the reasons for decreased plasma thiamine levels in diabetics. Incubation of human primary proximal tubule cells in high glucose conditions (26 mmol/L) decreases both mRNA and protein expression of THTR1 and THTR2 compared to 5 mmol/L glucose[25]. Renal clearance of thiamine is increased by 8-fold in experimental model of diabetes. Interestingly, increased clearance was prevented by high-dose thiamine supplementation[26]. Thiamine renal clearance is also increased in subjects with T1DM (by 24-fold) and T2DM (by 16-fold)[24].

Further changes of thiamine metabolism probably occur with the development of chronic diabetic microvascular complications namely diabetic nephropathy together with chronic kidney disease (CKD). While in diabetics with preserved renal function plasma thiamine levels tend to be lower most likely on account of increased renal clearance, in subjects with CKD stages corresponding with renal insufficiency and failure the situation dramatically changes. We have previously comprehensively studied plasma and intracellular parameters of thiamine metabolism in diabetics with the aim to dissect the complex relationships between the effect of diabetes and renal function[27]. We reported that plasma levels of thiamine and its esters and TKT activity in RBCs increased with severity of diabetic nephropathy (and CKD respectively) being highest in subjects with end-stage renal disease, however, levels of TDP in RBCs did not show proportional trend. Since the effectiveness of intracellular TDP production depends on substrate availability (*i.e.,* the rate of transmembrane transport *via* thiamine transporters) and TPK activity we therefore hypothesized that these could be the processes diminished by hyperglycemia and the causal reasons for the failure of protective action of PPP under hyperglycemia. While T1DM and T2DM patients with normal renal function have been shown to have a higher expression of THTR1 and THTR2 in mononuclear cells compared to healthy subjects by one study[28], data on TPK activity and THTR2 expression in diabetes are missing at all. Obviously, there is still a large gap in our understanding of the precise molecular mechanisms of thiamine deficiency and the problem definitely warrants further study.

OVERVIEW OF *IN VITRO*, ANIMAL AND HUMAN STUDIES WITH THIAMINE OR BENFOTIAMINE SUPPLEMENTATION IN DIABETIC CONDITIONS

In vitro studies

Several studies explored the effect of thiamine and/or benfotiamine on pathways implicated in the pathogenesis of hyperglycemia-induced damage *in vitro*. Cultivation of RBC in hyperglycemia with addition of thiamine increased activity of TKT, decreased production of triose phosphates and methylglyoxal and increased concentrations of sedoheptulose-7-phosphate and ribose-5-phosphate[29]. Benfotiamine as well as thiamine have been shown to correct defective replication of human umbilical vein endothelial cells (HUVEC) and to decrease their

production of AGEs induced by hyperglycemia[30]. Thiamine also suppressed markers of endothelial cell damage (inhibited cell migration and increased von Willebrand factor secretion) induced by hyperglycemia in bovine aortic endothelial cells[31]. Both thiamine and benfotiamine decreased activation of polyol pathway (aldose reductase mRNA expression, enzyme activity and intracellular levels of sorbitol) while increasing expression and activity of TKT in HUVEC and bovine retinal pericytes cultured in hyperglycemia[32]. Notably, benfotiamine restored impairment of endothelial progenitor cells differentiation caused by hyperglycemia[33]. Possible benfotiamine antioxidant properties and protective effect on DNA have also been investigated. Benfotiamine prevented oxidative stress (probably through direct antioxidant effect) and also DNA damage[34]. The same study also confirmed that benfotiamine increased TKT expression and activity. Intermittent exposure of human retinal pericytes to fluctuating glucose levels induced their apoptosis, the effect was however prevented by thiamine and benfotiamine[35]. It has also been studied whether thiamine and/or benfotiamine affect glucose and lipid metabolism in human skeletal muscle cells. Benfotiamine but not thiamine increased glucose oxidation while lipid oxidation and metabolism was influenced by neither of the two. Benfotiamine also down-regulated NADPH oxidase 4 expression[36].

Animal models

The first published study exploring the effect of thiamine and benfotiamine supplementation on peripheral nerve function and production of AGEs in diabetic rats found that benfotiamine but not thiamine had protective effect with respect to both processes[37]. Already mentioned key study provided evidence for the role of PPP in diabetes showing that benfotiamine (activating TKT) inhibited three harmful pathways and NF-κ signalling activated by hyperglycemia and prevented development of diabetic retinopathy in experimental rats[23]. The group of Thornalley published a series of papers investigating the effect of thiamine and/or benfotiamine supplementation on the development of diabetic microvascular complications, predominantly diabetic nephropathy. They found that thiamine and benfotiamine were able to suppress the accumulation of AGEs in the kidney, eye, nerves and plasma of diabetic rats[38]. Furthermore, they reported that high-dose thiamine and benfotiamine therapy prevented diabetic nephropathy through increased TKT expression, decreased level of triosephosphates a decreased protein kinase C activation. Importantly, since no changes in fasting plasma glucose and HbA1c were observed this effect is independent of diabetes compensation[26]. Furthermore, high-dose thiamine therapy had positive effect on diabetes-induced dyslipidaemia (preventing the increase of plasma cholesterol and triglycerides but not high-density lipoprotein decrease). Benfotiamine and low-dose thiamine failed to achieve the same effect[39]. They also quantified AGEs in plasma of diabetic rats. Both thiamine and benfotiamine supplementation have been shown to normalize AGEs derived from methylglyoxal and glyoxal. On the contrary, carboxy methyl lysine and N-epsilon(1-carboxyethyl)lysine residues have been normalized by thiamine only[40]. Finally, they quantified protein damage caused by glycation, oxidation and nitration in diabetic rats and found increased AGEs content in the diabetic kidney, eye, nerve and plasma that was reversed by thiamine and benfotiamine therapy. Thiamine itself also reversed increase of plasma glycation free adducts. Both therapies reversed increased urinary excretion of glycation, oxidation and nitration free adducts[41]. Several studies evaluated the effect of thiamine/benfotiamine treatment with respect to heart function in diabetes animal model. Benfotiamine alleviated abnormalities in parameters related to the contractile dysfunction in diabetic mouse. It also reduced oxidative stress induced by diabetes however production of AGEs was unchanged[42]. High-dose thiamine therapy prevented diabetes-induced cardiac fibrosis through increased expression of genes with pro-fibrotic effect and decreased matrix metalloproteinase activity in hearts of diabetic rats[43]. Another study revealed that benfotiamine therapy protected diabetic mice from heart failure with several pathogenic mechanism suggested including improved cardiac perfusion, reduced fibrosis and cardiomyocyte apoptosis[44]. Same authors found that benfotiamine improved prognosis of diabetic mice after myocardial infarction in terms of survival, functional recovery, reduced cardiomyocyte apoptosis and neurohormonal activation[45]. The same was true for control non-diabetic mice probably due to increased activity of pyruvate dehydrogenase in hearts of diabetic rats by thiamine treatment. Subsequent *in vitro* experiment revealed that responsible molecular mechanism may be suppression of O-glycosylated protein[46]. Both *in vitro* and *in vivo* benfotiamine supplementation had positive effect on cardiac progenitor cells in terms of their proliferation, abundance, functionality and TKT activity (all listed parameters being compromised by hyperglycemia)[47]. In mouse diabetes model of limb ischemia benfotiamine increased TKT activity, prevented toe necrosis, improved perfusion and restored vasodilation. Moreover, benfotiamine prevented accumulation of AGEs in vessels and inhibited pro-apoptotic caspase-3 in muscles[48]. Another work assessed cerebral oxidative stress in diabetic mice. Benfotiamine was found to lower oxidative stress (estimated as reduced/oxidized glutathione) however levels of AGEs, protein carbonyl and tumor necrosis factor-α were unchanged[49]. Administration of benfotiamine and fenofibrate alone or in combination attenuated endothelial dysfunction and nephropathy in diabetic rats. Lipid profile however was normalized only by fenofibrate not by benfotiamine[50].

Human studies

Only few studies in diabetic patients have been published so far that explored the effect of thiamine or benfotiamine treatment on hard endpoints, *i.e.,* development or progression of clinically manifest diabetic complications, namely kidney disease and neuropathy. In the pilot study,

Table 1 The effect of thiamine or benfotiamine supplementation on surrogate markers related to hyperglycemia in human studies

T1DM: Type 1 diabetes mellitus; AGEs: Advanced glycation end products; T2DM: Type 2 diabetes mellitus.

high-dose thiamine therapy for 3 mo significantly decreased urinary albumin excretion (UAE) without affecting glycaemic control, lipids and blood pressure in T2DM patients[51]. In another study however, 3 mo of benfotiamine therapy improved thiamine status (assessed as a TKT activity and the whole blood thiamine concentration) but did not change UAE and/or kidney marker of tubular damage in T2DM patients[52]. The same authors also determined AGEs production and markers of endothelial dysfunction and low-grade inflammation in the same cohort. Benfotiamine did not affect any of the ascertained markers[53]. In patients with diabetic neuropathy, short-term benfotiamine therapy was found to improve neuropathy score and to decrease the pain perception[54]. In the recent study, long-term (1 year) benfotiamine therapy did not affect peripheral nerve function and soluble inflammatory markers (*e.g.*, interleukin-6 or E-selectin) despite significantly increasing the whole blood levels of thiamine and TDP in T1DM patients[55]. This study was however criticized for inappropriate study design and definition of end-points[55]. Several other studies in human diabetics explored various surrogate markers related to pathologic processes occurring in hyperglycemia, the results are summarized in Table 1.

CONCLUSION

Since glucose metabolism depends on thiamine as an enzyme cofactor, it is biologically feasible to suppose that adequate thiamine supplementation in diabetics might have a profound effect on metabolic compensation and thus development of vascular complications. It could also possibly influence earlier stages of abnormal glucose tolerance such as components of metabolic syndrome. Data on surrogate markers of endothelial dysfunction and cardiovascular disease indicate that thiamine could be of interest also for the broader spectrum of diseases apart from diabetes. While experimental studies mostly resulted in beneficial effects clinical studies of appropriate size and duration focusing on the effect of thiamine supplementation/therapy on hard endpoints are missing at present. Moreover, it is not currently clear which mechanisms contribute to the deficient action of thiamine most. Based on the data presented boosting solely plasma levels might not be the right way to go since intracellular TDP levels are not a mere reflection of the plasma levels of their precursor. Apparently experimental studies on the molecular mechanisms of thiamine deficiency in diabetes are critically needed before giving clear answer to diabetes community.

Abstract

Diabetes is the sixth leading cause of death in the United States. To date, most research and resulting clinical strategies have focused on the individual with short-term health improvements that have not been maintained over time. Researchers more recently have recognized the need to consider the social determinants of diabetes and health along with individual factors. The purpose of this literature review is to examine current understanding of the social determinants affecting diabetes and health. A search of medical and nursing literature was conducted using PubMed, PsychInfo, CINAHL and MEDLINE databases, selecting articles published between 2000 and 2013. Search terms included: type 2 diabetes, social determinants, and health determinants. Inclusion criteria were: English language, human studies, social determinants of diabetes and health, and research in the United States. Additional search methods included reference chaining of the literature. Twenty research articles met the inclusion criteria for the review and analysis and included quantitative and qualitative methods. All studies selected for this review were descriptive in nature (n = 20). Fifteen studies were quantitative studies and five were qualitative studies. No intervention studies met inclusion criteria. Each study is summarized and critiqued. Study findings indicate that external or upstream factors consistently affect individuals diagnosed with diabetes, influencing self-management. Significant methodological limitations result directly from small sample sizes, convenience or nonprobability sampling, and low statistical power.

Key words: Type 2 diabetes; Social determinants; Health determinants; Research; United States

Core tip: Social determinants of health and diabetes need to be considered when focusing on improving diabetes outcomes. Future research studies should focus on testing health outcomes of people with diabetes within the social determinants of health framework. Such research is particularly significant due to high rates of diabetes and subsequent disease sequelae.

INTRODUCTION

Diabetes Mellitus affects approximately 25.6 million individuals or 11.3% of those over age 20. It is the sixth leading cause of death in the United States[1]. Diabetes places the individual at risk for serious long term complications including blindness, cardiovascular disease, end stage renal disease, hypertension, stroke, neuropathy, lower limb amputations, and premature death[1]. Estimated annual healthcare cost in 2012 for diabetes and its resulting complications was $245 billion[2]. Given the considerable differences internationally in methods of allocating health care resources, systems of funding and/or paying for care, and cultural attitudes to health and health care, the purpose of this review of the literature is to examine

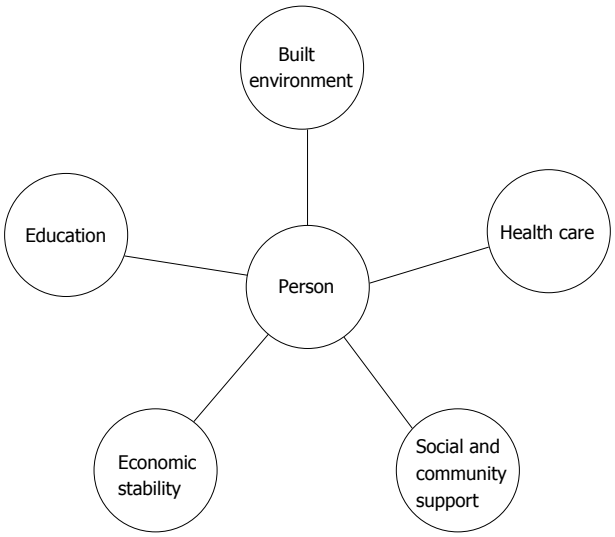

Figure 1 Social determinants influencing the individual's self-management of type 2 diabetes.

current understanding of the social determinants affecting diabetes and health in the United States, and to make recommendations for future research.

Historically, research and resulting clinical approaches focusing on the individual have led to improvement in self-management outcomes and reduction of cardiovascular risk factors; however, these short-term improvements have not been maintained over time. Researchers more recently have recognized the need to consider factors external to the individual, namely the social determinants of diabetes and health in order to achieve the goal of sustainable improvement in health outcomes[3,4]. For example, the United States government document Healthy People 2020 emphasizes the social and environmental factors that affect the individual and his/her health. A Healthy People 2020 goal for the diabetes health indicator is to "reduce the disease and economic burden of diabetes mellitus, and improve the quality of life for all persons who have, or at risk for diabetes"[5].

Social determinants of health are social-ecological factors affecting health[6]. The person, his/her social network, and cultural and environmental conditions form the overall framework. Constructs include external/environmental socio-ecological influences on the individual (Figure 1); for example, culture, environment, education, working conditions, access to medical care, and community infrastructure[5]. Therefore, external or upstream determinants such as social support and elements of the community affect the health of the individual. Specific socio-ecological factors identified from this literature review are examined below.

Built environment/community infrastructure

Components of the physical environment include factors such as transportation, neighborhood safety, and healthy food. When barriers to these factors are present to individuals with diabetes, inadequate access to resources among such disadvantaged populations means fewer resources are available to overcome barriers, thus effects are magnified[7-9]. For example, limited transportation in rural areas may require travel outside the local community to gain access to healthcare providers or access to healthy foods[6]. Urban residents may face transportation barriers such as lack of sidewalks[9], discouraging individuals from walking as a form of physical activity. Lack of public transportation in rural or urban areas can hinder travel for access to healthcare. Lack of neighborhood safety contributes to health disparities. An example of compounding factors is as follows: urban centers may have high crime rates with consequently fewer businesses and employment; reduced access to services including food and medical care; and diminished opportunity for outdoor activity including exercise[10]. Research has shown a relationship between improved health outcomes and access to healthy foods[11,12]. Emerging research in the area of nutraceuticals indicates that certain foods may provide health benefits to reduce disease process progression in diabetes and hyperlipidemia[12]. However, this relationship is a complicated one, as demonstrated by Jones-Smith *et al*[13] who found that, even with access to healthy food, socioeconomic status remains a strong predictor for obesity among African Americans diagnosed with diabetes.

Economic stability

Research has demonstrated a direct relationship between socio-economic status and health outcomes; however, other factors may explain a degree of variance in this relationship[14]. Zheng *et al*[14] found that education level, employment, and family income affect socioeconomic status and therefore health.

Education

Greater educational attainment has been linked with improved health outcomes[15] possibly because of a greater likelihood of socio-economic stability compared to those with lower levels of education. Other related factors may be the stability derived from marriage and/or a wider range of opportunities for better employment[15]. Moreover, research has shown that individuals with higher levels of education are more likely to participate in preventive healthcare including eating healthier (foods), being more physically active, and avoiding obesity[16].

Health care/access to medical care

Individuals may be subject to disparity in the availability of healthcare resources, including access to medical care, based on factors such as socioeconomic status, place of residence, race/ethnicity, and culture. Socioeconomic factors include educational level which in turn influences health insurance status[16]. Low income inner cities and remote rural regions often lack both primary and specialty healthcare providers, decreasing access to healthcare for inhabitants with chronic illnesses such as diabetes, hypertension, and cardiovascular disease. Absent or inadequate care may result in worsening or compounding of long-term effects of chronic diseases[17,18]. For example, recent research focusing on infants born preterm or with low

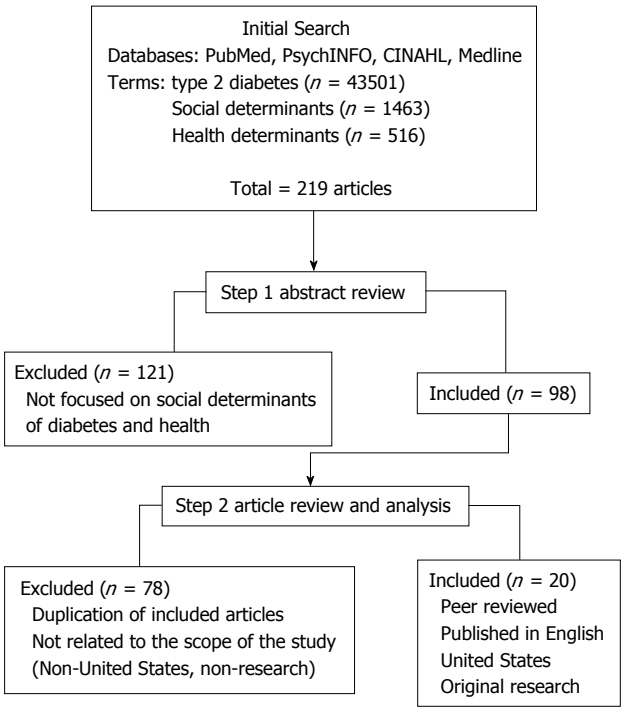

Figure 2 Manuscript selection for systematic review of the social determinants of diabetes and health.

birth weight demonstrates an increase in the development of insulin resistance and impaired glucose tolerance as adults[19,20]. Lower socioeconomic status may be associated with an individual's perception that lack of a collaborative patient-provider relationship is associated with improved diabetes outcomes[21].

Culture/social and community support

Social support includes individuals' "formal and informal relationships that give rise to a belief that one is cared for or supported emotionally in a defined situation such as working toward improving health outcomes"[22]. Degree of social support may vary between individuals and among ethnic groups; for example, research revealed that Hispanic individuals diagnosed with diabetes prefer group medical visits for self-management support whereas individuals from other ethnic groups have no preference[23]. Just as greater social support correlates with improved self-management outcomes, the perception of negative or low levels of social support has been shown to increase the risk of fewer self-management behaviors[24].

RESEARCH

A search of medical and nursing literature was conducted using PubMed, PsychInfo, CINAHL and MEDLINE databases. Additional search methods included reference chaining of the literature. Search terms included type 2 diabetes, social determinants and health determinants. Inclusion criteria were English language, human studies, social determinants of diabetes and health, and research in the United States. Exclusion criteria were type 1 diabetes, reviews, and studies not focusing primarily on social determinants of diabetes and health; for example, biomarkers. The initial search of the literature retrieved 59036 articles on type 2 diabetes; 12871 articles on social determinants; 14866 articles on health determinants. Sixty one duplicate articles, one book review brief, one editorial commentary, and two conference proceeding abstracts were also excluded (Figure 2). Twenty articles met criteria for the review (Table 1).

Twenty articles met the inclusion criteria for the review and analysis. All studies selected for this review were descriptive in nature (n = 20). Fifteen studies were quantitative studies and five were qualitative studies[25-29,32-44]. Although sample size ranged from 15 to 81917 participants, many samples were fewer than one hundred subjects. All studies focused on individuals diagnosed with diabetes. There were no interventional or randomized control trial studies. The majority were cross-sectional, collecting data only once. For quantitative studies, two were mixed methods, including a survey and interview; five were secondary data analysis, and eight were surveys. Qualitative studies used either focus groups or individual semi-structured interviews (n = 5). Fourteen studies focused on social determinants from the patient or client perspective; three studies focused both on staff/healthcare provider and patient/client, while three studies viewed social determinants of health from the perspective of the healthcare provider alone. All studies focused on one or more of the constructs of social determinants of health: built environment, economic stability, health care, or culture/social support.

Built environment/community infrastructure

Authors of four articles discussed the built environment and community infrastructure. Research studies used purposive sampling, limiting the generalizability of findings to other populations. Three studies focused on populations known to have a disproportionate burden of type 2 diabetes, including African Americans and Hispanic/Latino. The built environment was a stronger predictor of health outcomes than race. Three studies[25-27] reported on upstream social determinants and the influence on food environments for at risk immigrant Hispanic population. Findings included high rates of poverty with 60% of living below United States definition of poverty and 40% living at 170% below federal poverty level. Educational attainment was less than the United States average with 80% of individuals not entering college. Thirty-three percent had not completed elementary school. In comparison the national United States rate of high school completion is 89.9% in 2010[25]. One study focused on Asian Americans. No studies included American Indians or Pacific Islanders. Two studies were community-based, focusing on food environment and access to healthy food. Transportation was discussed in three articles as a barrier to access both healthcare and healthy food. Research participants reported lack of access to quality, quantity, and

Table 1 Summary of reviewed studies

Ref.	Purpose	Design/method	Sample	Findings	Strengths/limitations/implications
Chaufan *et al*[25] (2011)	To examine "upstream" social determinants of health in a Latino immigrant population focusing on T2DM risk and food environment	Mixed methods focus groups, Food store survey instrument California	Staff members (n = 6); clients (n = 15)	Poverty prevented Latino immigrants from access to adequate housing, high quality education, and culturally appropriate food choices	Community-based interviews elicited lived experience of Latino immigrant population Limitations: small sample size, nonrandomized, descriptive study Implications: Policy change to enable access to affordable culturally acceptable healthy foods
Carbone *et al*[26] (2007)	To describe factors influencing Latino (Puerto Rican) diabetes self-management	Qualitative-focus groups Health center in Massachusetts, United States	Healthcare providers (n = 15) Patients (n = 37)	Cultural influence of family through traditional gender roles; financial restraints Social network (family and friends) source of strength; spirituality and faith important; discrepancy between healthcare provider and patient focus in self-management	Community-based limitations: Small sample size, qualitative study, not generalizable to all Latino populations Implications: account for inclusion of family and social networks in diabetes self-management education, need for increased cultural awareness by Healthcare provider of influencing factors on patient self-management
Chaufan *et al*[27] (2011)	To gain understanding how food environments influence a low income immigrant population	Qualitative-focus groups	Staff (n = 6) Clients (n = 15)	Barriers to food access: transportation, language barriers, poverty, employment	Strengths: community based Limitations: small sample size, not generalizable Implications: Need for policy to increase food access for immigrant populations in lower socio-economic levels
Tjia *et al*[28] (2008)	To gain understanding of barriers to medication adherence among older adults with T2DM	Qualitative-semi structured interviews	Adults over age 65 (n = 22) Female n = 16	Older adults with T2DM had concerns about medication cost or medication burden but did not discuss with physician	Strengths: perspective of older adults Limitations: small sample size, not generalizable Implications: need for increased patient-physician communication; policy level for messages to encourage open patient-physician dialogue for medical treatment
Denham *et al*[29] (2010)	To explore perceived patient barriers to diabetes education among healthcare providers	Cross-sectional survey	Healthcare providers from three practice settings: federally qualified healthcare centers; health departments; clinics (n = 182)	Perceived barriers: transportation; fewer diabetes educators and physicians; lack of insurance; education materials not screened for literacy levels nor cultural appropriateness	Strengths: look at perceived barriers to diabetes education among healthcare providers Limitations: small sample size, multiple sites, sample bias Implications: policy need to increase diabetes education reimbursement to providers for all individuals nationally; need to screen materials for literacy levels
Heuer *et al*[30] (2006)	To describe Hispanic migrant farmworkers perceptions of diabetes	Qualitative phenomenological study	Migrant farmworkers (n = 12) Female n = 6	Cultural/folk beliefs that diabetes was caused by stress or emotions	Strengths: focused on hispanic explanatory model of diabetes Limitations: small sample size, not generalizable Implications: need to tailor diabetes education to address culture and health beliefs
Shigaki *et al*[31] (2010)	To examine how patients diagnosed with type 2 diabetes view role of nurses in disease management	Qualitative Semi-structured individual interviews	n = 13 Female n = 7 White n = 9 African American n = 3 Other n = 1	Nurse viewed as a positive partner in disease management, patients prefer team-based medical care, open communication between healthcare providers and patient	Strengths: Patient perspective on nurse as partner in healthcare Limitation: small sample size; sample bias Implications: Nurse partner may provide link between patient and improving health outcomes in individuals with multiple co-morbidities including diabetes
Fitzgerald *et al*[32] (2008)	To determine diabetes care perceptions in patient and provider	Quantitative cross sectional survey	Providers n = 71 Patients: n = 273 female 61% White 63% African American 33%	Patient and provider differences included patients with more positive attitudes family support, paying for diabetes care	Strengths: quantitative study using reliable and valid instrument Limitations: may not be representative for patients with no co-morbidities Implications: Importance of communication between patient and provider and not making assumptions about patients

Zulkowski *et al*[33] (2005)	To examine differences between patient self-report and provider documentation in rural health center	Quantitative cross sectional survey; medical record review	*n* = 149 Female *n* = 86	Statistical difference between patient and provider on medical management or diabetes knowledge; most patients had not been seen by diabetes educator or dietician	Strengths: good response rate (61%); limitations: race not documented Implications: Need for increased access to diabetes education in rural areas; need for open communication between patient and provider
Ford *et al*[34] (2002)	To determine relationship between socio-economic status and race on diabetes management	Quantitative-random sampling by socio-economic status and race	*n* = 50 African American *n* = 21 Caucasian *n* = 29 Female *n* = 22	Differences in perception of sense of loss by race but not socio-economic status	Strengths: Limitations: small sample size: not generalizable; underpowered ($\alpha = 0.34$) Implications: Need for education to stress management to prevent disease related complications
Mani *et al*[35] (2011)	To determine the influence of social networks on diabetes self-management	Cross-sectional survey	*n* = 154 Female *n* = 88 White *n* = 78 African American *n* = 61	Diabetes concern increased when larger social network diagnosed with diabetes	Strengths: patient perspective of importance of social networks Limitations: not generalizable-sample from two inner city clinics, only English speaking, data skewed Implications: Important to consider the influence of social networks on diabetes self-management
Song *et al*[36] (2012)	To examine social networks among Korean Americans diagnosed with type 2 diabetes	Cross-sectional survey from a larger study	*n* = 83 Female *n* = 35 Married *n* = 73	Gender differences in source of support, men sought spouse, women had higher unmet needs for social support than men, self-efficacy negatively associated with unmet social support, education level strong predictor of self-care activities, unmet needs for social support negatively associated with diabetes self-care	Strengths: patient perception of social support Limitations: small homogenous sample; not generalizable Implications: need to recognize the role of gender in determining social support among Korean Americans
Kollannoor-Samuel *et al*[37] (2011)	To identify influence of social determinants of health on FPG and HbA1c among low income Latinos	Cross-sectional	*n* = 211 Female *n* = 155 Puerto Rican *n* = 171 Unemployed *n* = 178 Spanish speaking only *n* = 138	Lower socio-economic status had higher FPG and HbA1c levels; better long term glycemic control when insured; increased physical activity associated with lower FPG and HbA1c levels	Strengths: sample size; part of larger RCT Limitations: large number of female participants-not generalizable or transferable to other Latino populations; unknown length of time since diagnosis Implications: Importance of physical activity for improved glycemic control; need for health insurance, increase in education to improve glycemic outcomes over the long term
Chiu *et al*[38] (2011)	To determine how gender influences functional limitations with type 2 diabetes	Secondary data analysis	*n* = 1619 Female *n* = 861	Psychosocial factors mediator between biological and exercise factors	Strengths: consistent with previous research Limitations: participant self report; no causal pathway Implications: Need to incorporate gender and psychosocial factors in diabetes treatment plan
Iida *et al*[39] (2010)	Examine role of spousal support for individual diagnosed with type 2 diabetes	Mixed methods-longitudinal Computer diary survey; individual interviews	*n* = 129 married couples Caucasian 75%; African American 23.6%	Physical symptoms increased spousal support; women gave higher level of support when spouse worried about diabetes; less spousal support when negative emotional effect from previous day	Strengths: sample size Longitudinal study, diary Limitations: unable to determine causal effect Implications: Need to measure and include spousal support in diabetes self-management plan

Mayberry *et al*[40] (2005)	To assess determinants of glycemic monitoring by primary care provider among medicaid beneficiaries	Retrospective cohort study	*n* = 3321 African American (2025) 61%; White (1296) 39%; Female 74.6%; Urban 49.6%; rural 50.4%	African Americans diagnosed at younger age; frequency of physician visits and medication prescription strong predictor of meeting ADA recommendation guideline for HbA1c monitoring; low monitoring of HbA1c and FPG among medicaid beneficiaries with type 2 diabetes, no significance between Black and White Medicaid beneficiaries for diabetes monitoring	Strengths: provides insight into determinants of glucose monitoring in Medicaid beneficiaries Limitations: Secondary data analysis; inability to determine patient-physician relationship Implications: Need to establish ADA evidence guidance protocol in office practice settings
Ford *et al*[41] (2005)	To determine estimates of obesity and diabetes weight information from healthcare providers in 100 United States metropolitan service areas	Cross sectional survey: 2000 Behavioral Risk Factor Surveillance System	*n* =81917 individuals with BMI data Sample size varied due to missing data	Highest prevalence of obesity Appalachian region; OR of being diagnosed with diabetes 3.5 higher in Charleston WV than Santa Fe NM; weight loss or maintenance discussed with physician 11.7%-34.6%	Strength: study at community level Limitation: secondary data analysis, missing data; self report Implications: Policy level- need to examine determinants of obesity and diabetes at local metropolitan service areas. Healthcare providers need to include discussion of weight management for individuals diagnosed with obesity or diabetes
Adams *et al*[42] (2008)	To examine medication adherence as a factor of glycemic control based on race	Secondary data analysis newly diagnosed patients prescribed oral medications	*n* = 1806 Black *n* = 467 White *n* = 1339	Black patients higher A1c at diagnosis; insufficient evidence to determine medication adherence by race	Strengths: limitations: unable to determine causal effect; potential overestimation of medication adherence based on data; implications: Need at policy level to provide screening for earlier diagnosis of Black and female patients
Aikens *et al*[43] (2005)	To examine the relationship of patient-provider communication on diabetes self-management and outcomes	Cross-sectional Telephone survey	*n* = 736 White 51% Black 20% Hispanic 11.9% Female 31.6%	Primary care provider main manager of diabetes (70.9%) General patient-provider communication related to improved quality of life; diabetes specific patient-provider communication related to glycemic control	Strengths: sample across three health systems; limitations: cross-sectional study; self-report; implications: need for open patient-provider communication to enhance problem solving, need to tailor management plan to individual patient
Paris *et al*[44] (2001)	To determine if determinants of type 2 diabetes were present in personnel entering the military	Cross-sectional secondary data analysis	Diagnosed with diabetes *n* = 419 Not diagnosed with diabetes *n* = 627	Enlisted military rank as socioeconomic measure for diabetes diagnosis higher in lower rank, minorities higher level of diabetes; educational not significant variable	Strengths: adequate power Limitations: no causal effect; potential for misclassification of diabetes diagnosis in database; implications: need for focus on policy level for increased physical activity and body mass index monitoring

FPG: Fasting plasma glucose; HbA1c: Glycosylated hemoglobin A1c; BMI: Body mass index; T2DM: Type 2 diabetes mellitus; RCT: Randomized control trial; ADA: American diabetes Association.

culturally-acceptable food choices[25-27]. Study limitations include small sample size and descriptive statistics.

Economic stability

Five articles focused on economic stability. Three studies were cross-sectional survey, one involved focus group interviews, and one was a secondary analysis. Sample size in these studies ranged from 50 to 419. Discussion focused on health insurance, financial barriers, poverty, and affordability of medication from the patient or client perspective. One study focused on indirect economic factors, such as military rank, as a predictor of diabetes diagnosis[44]. Two studies compared patient/client perspectives to healthcare provider perceptions of economic barriers to diabetes self-management[25,32]. Three of the five studies compared race as a factor in economic stability within Latino and African

American populations[26,34,37]. Findings included individual acknowledgement that economic distress in diabetes self-management was important however, factors were also identified as sources of additional strength for individuals diagnosed with diabetes. Sources of support included culture and/or social support[26,34]. The influences of economic factors by race/ethnicity on diabetes outcomes were non-conclusive. Therefore, economic stability may be a strong determinant of diabetes and health regardless of race/ethnicity. Studies focused on target populations, limiting to selected urban regions for study.

Health care/access to medical care

There were nine studies found in which researchers examined the role of health care and/or access to medical care within the social determinants of diabetes and health framework. One study compared patients' and healthcare providers' perspectives on diabetes management[32]. Another research report examined healthcare providers' perception of patient barriers to diabetes management[29]. The remaining seven articles focused on the patient's perceptions of healthcare related to diabetes management and barriers to care. Sample size for the patient-only studies ranged from 13 to 81917. Eight studies were cross-sectional descriptive in design, and one was a secondary data analysis from the Behavioral Risk Factor Surveillance System. Most researchers reported that patients viewed their health in a more positive light than did providers based on medical record reviews. The concerns of healthcare provider included the costs associated with diabetes management[29,32]. Patient-provider communication varied among patients. Three articles focused on positive health outcomes with open patient-provider communication[31,40,43]. One article described physicians as often initiating communication about medication adherence, whereas patients were hesitant to initiate communication with physicians relating to medication burden and costs[28]. This may, in part, explain perceived lack of patient medication adherence which increases the potential for poorer health outcomes. One qualitative study described patients' preference for diabetes care teams in which the team's link between patient and physician was a nurse[31]. Two studies demonstrated increased quality of life and better glycemic control with positive patient-provider communication[40,43]. However, when looking at diabetes prevention and knowledge, two studies reported the need for provision of diabetes education focusing on basic management and the need for discussion of weight management or weight loss for diabetes prevention[33,41].

Culture/social and community support

Seven articles met the inclusion criteria focusing on the constructs of culture and community support. Four of the seven researchers reported on cross-sectional surveys, one study involved focus groups in a community setting, one study used a phenomenological method of analysis, and one used mixed methods incorporating a computer diary and individual interviews. Two of the seven articles included healthcare provider perceptions. Of these two articles, one had a sample of both patient and healthcare provider. Sample size for the seven articles ranged from 12 to 273. Two articles focused on cultural determinants of diabetes and health in Latino/Hispanic populations. Cultural beliefs in Hispanic populations included the belief that diabetes was caused by increased stress[30]. The authors noted that the discovery of this belief provides an opportunity for healthcare providers or trusted community sources to provide education to increase diabetes knowledge. Three articles focused on the traditional roles of gender and culture, whereby married women provided increased support to their spouse when he voiced concerns about diabetes and health[26,36,39]. One article focusing on Korean Americans found that women had an increase in unmet needs when providing support for their spouses, which negatively affected their diabetes self-care[36]. Two articles discussed social support or social networks as positive influences for diabetes self-management and health[26,32]. However, one article described African American patients' concern about their diabetes management and health when multiple members of their social network were diagnosed with diabetes or experienced complications of diabetes[35]. One article discussed healthcare providers' perceived barriers in rural healthcare settings[29], pointing out an apparent lack of culturally appropriate educational materials within healthcare clinic settings.

CONCLUSION

This critique of the literature about social determinants of diabetes and health focused on research of United States populations published between 2000 and 2013. A total of 20 research studies met established criteria. All 20 studies identified for this review were descriptive. The majority of studies were published in journals with a focus on public health or nursing. Results of this review are useful for health professionals who develop programs and/or interventions for people diagnosed with diabetes because evidence indicates that social determinants affect patient adherence, effectiveness of treatments, and overall health outcomes.

Study findings indicate that external or upstream factors prominently affect individuals diagnosed with diabetes, in part by influencing self-management and in turn exerting lasting effects on long-term diabetes and health outcomes. The most significant methodological limitations of the studies examined result directly from small sample size, convenience or nonprobability sampling, and low statistical power. Methodological limitations of studies included in this review also include a lack of intervention studies. Future research needs to include community-based intervention studies focusing on the reduction of diabetes disparities and improvement of health outcomes within the social determinants of health framework. Such research is particularly needed given the high rates of diabetes and subsequent disease sequelae. Cultural tailoring

of diabetes prevention educational materials and cultural tailoring of education in group settings may afford the means to increase patients' knowledge of the disease for earlier diagnosis and earlier intervention to prevent diabetes complications. Encouragement of spousal support within the construct of acknowledging cultural norms may provide a means for improving diabetes outcomes and health. The influence of social determinants of health on diabetes outcomes needs to be tested in intervention studies to provide a foundation for effective interventions to impact the current epidemic of diabetes in the United States and around the globe. Prospective interventional studies evaluating the influence of social determinants will be key to lay a foundation for effective interventions and improvement of diabetes and health outcomes.

Abstract

Type 2 diabetes mellitus is a metabolic disorder of deranged fat, protein and carbohydrate metabolism resulting in hyperglycemia as a result of insulin resistance and inadequate insulin secretion. Although a wide variety of diabetes therapies is available, yet limited efficacy, adverse effects, cost, contraindications, renal dosage adjustments, inflexible dosing schedules and weight gain significantly limit their use. In addition, many patients in the United States fail to meet the therapeutic HbA1c goal of < 7% set by the American Diabetes Association. As such new and emerging diabetes therapies with different mechanisms of action hope to address some of these drawbacks to improve the patient with type 2 diabetes. This article reviews new and emerging classes, including the sodium-glucose cotransporter-2 inhibitors, 11β-Hydroxysteroid dehydrogenase type 1 inhibitors, glycogen phosphorylase inhibitors; protein tyrosine phosphatase 1B inhibitors, G Protein-Coupled receptor agonists and glucokinase activators. These emerging diabetes agents hold the promise of providing benefit of glucose lowering, weight reduction, low hypoglycemia risk, improve insulin sensitivity, pancreatic β cell preservation, and oral formulation availability. However, further studies are needed to evaluate their safety profile, cardiovascular effects, and efficacy durability in order to determine their role in type 2 diabetes management.

Key words: Type 2 diabetes mellitus; Sodium dependent glucose co-transporter 2 inhibitors; 11β-Hydroxysteroid dehydrogenase type 1 inhibitors; Glycogen phosphorylase inhibitors; Protein tyrosine phosphatase 1B inhibitors; G protein-coupled receptor agonists; Glucokinase activators

Core tip: Type 2 diabetes mellitus is a metabolic disorder of deranged fat, protein and carbohydrate metabolism resulting in hyperglycemia. Limited efficacy, adverse effects, cost, contraindications, renal dosage adjustments, inflexible dosing schedules and weight gain significantly limit the use of currently available anti-hyperglycemic agents. In the past, drug researchers targeted defects of pancreatic β-cell failure and insulin resistance, but more recent attention has shifted to other contributing factors. This article reviews new and emerging diabetes classes, including the sodium-glucose cotransporter-2 inhibitors, 11β-Hydroxysteroid dehydrogenase type 1 inhibitors, glycogen phosphorylase inhibitors, protein tyrosine phosphatase 1B inhibitors, G protein-coupled receptor agonists, and glucokinase activators.

litus drug therapies for the type 2 diabetes patient. *World J Diabetes* 2014; 5(3): 305-315 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/305.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.305

INTRODUCTION

Type 2 diabetes mellitus is a metabolic disorder of deranged fat, protein and carbohydrate metabolism resulting in hyperglycemia from insulin resistance and inadequate insulin secretion, which can cause complications of nephropathy, retinopathy, neuropathy, and cardiovascular disorders[1,2].

Diabetes mellitus is an epidemic in the United States and the world. According to the International Diabetes Federation's 2013 statistics, 382 million people worldwide have diabetes, which is estimated to increase to 592 million by 2035[3]. The Centers for Disease Control and Prevention estimates 79 million Americans have pre-diabetes and approximately 26 million have diabetes mellitus of which seven million of these are still undiagnosed[4].

Despite a wide variety of available food and drug association (FDA) approved oral and injectable diabetes therapies, limited efficacy, adverse effects, cost, contraindications, renal dosage adjustments, inflexible dosing schedules and weight gain significantly limit their use[5,6].

In addition, less than 50% of patients with type 2 diabetes in the United States achieve the HbA1c goal of < 7% set by the American Diabetes Association[7].

Currently available oral agent classes include sulfonylureas, meglitinides, biguanide, α-glucosidase inhibitors, dipeptidyl peptidase-4 (DPP-4) inhibitors, dopamine agonist, bile acid sequestrant, thiazolidinediones and their combinations. Injectable agents include insulin, amylin analogue and incretin mimetics.

In the past, drug researchers and manufacturers targeted the primary pathophysiologic defects in type 2 diabetes of pancreatic β-cell failure and insulin resistance, but more recent attention has shifted to other contributing factors including increased glucose reabsorption by the kidneys, and the contributing effects to hyperglycemia by glucagon, glucocorticoid, glycogen, 11β-Hydroxysteroid dehydrogenase-2 and others. As such new and emerging diabetes therapies with new mechanisms of action hope to address these contributing pathophysiologic defects and offer new approaches in order for the patient to achieve therapeutic goals[1,6]. Table 1 lists the new and emerging drug therapy and approaches[8].

An ideal antihyperglycemic agent will be a safe, tolerable, efficacious, cost effective oral agent with a flexible dosage schedule providing clinically significant weight loss with cardiovascular and mortality benefits. This article reviews several new classes of antihyperglycemic agents, including the sodium-glucose cotransporter-2 inhibitors (which are furthest along in development); 11β-Hydroxysteroid dehydrogenase type 1 (11β-HSD-1) inhibitors, glycogen phosphorylase inhibitors, protein tyrosine phosphatase 1B inhibitors, G Protein-Coupled receptor agonists and glucokinase (GK) activators.

SODIUM DEPENDENT GLUCOSE CO-TRANSPORTER 2 INHIBITORS

Kidney and sodium dependent glucose co-transporter 2 transporters

Glucose homeostasis involves the liver, pancreas and the kidney[9]. Glucose transporter proteins (GLUT) and sodium-dependent glucose co-transporters (SGLT) are responsible for glucose transportation across the plasma membrane into cells[10].

Over the course of 24 h, the kidney filters 180 g of glucose while only 500 mg is excreted in the urine, and the rest is reabsorbed as it flows from the glomerulus to the proximal convoluted tubules then to the bloodstream[10]. GLUTs and SGLTs are involved in this glucose reabsorption and active transportation of glucose across cell membranes against concentration gradients[10,11].

SGLT-1 is responsible for 10% of glucose uptake and is expressed in the heart, skeletal muscle, gastrointestinal tract, liver, lung and the S3 segment of the proximal tubule of the kidney, while SGLT-2 is responsible for 90% of glucose uptake and is expressed in the S1 segment of the proximal tubule of the kidneys[11,12].

In addition to the reabsorption of approximately 99% of glucose, recent studies show the kidney takes up lactate, glutamine, glycerol, and alanine and converts them to glucose by the process of gluconephrogenesis, which can account for about 20% of all glucose released into the circulation and nearly 90% of the glucose released by the kidney[13].

The SGLT-2 inhibitors inhibit SGLT-2, which increases renal excretion of glucose thus reducing glucose in the plasma. Due to the minimal glucose uptake by SGLT-1 and the important roles of SGLT-2 in glucose reabsorption, several researchers and manufacturers have turned their attention to SGLT-2 inhibitors for treating hyperglycemia[14-16]. There are several SGLT-2 inhibitors in varying phases of studies including dapagliflozin, empagliflozin, ipragliflozin, ertugliflozin, luseogliflozin, tofogliflozin and LX4211[6,17].

The FDA approved canagliflozin (Invokana®) to treat type 2 diabetes based on the agreement that post marketing studies will be completed for evaluating cardiovascular outcomes, malignancies, severe pancreatitis, hypersensitivity and photosensitivity reactions; liver abnormalities, adverse events during pregnancy, bone safety, and two pediatric studies under the Pediatric Research Equity Act CR[18].

Dapagliflozin was approved in Europe, Australia, Brazil, Mexico and New Zealand as Forxiga®, but the FDA initially delayed its approval as there were concerns of increased breast and bladder cancer in patients taking the drug compared to placebo[19].

In January 2014, the FDA approved dapagliflozin as Farxiga® with six postmarketing studies including a

cardiovascular outcomes trial (CVOT) to evaluate the cardiovascular risk in patients with high cardiovascular disease risk and the evaluation of bladder cancer risk in patients enrolled in the CVOT[20].

Although there are several SGLT-2 inhibitors in varying phases of development, canagliflozin and dapagliflozin will be presented here due to availability of human safety and efficacy data.

Canagliflozin (invokana®) clinical trials

Wilding *et al*[14] designed a randomized, double-blind, placebo-controlled, phase 3, multicenter, 52-wk study to evaluate the safety and efficacy of canagliflozin added to metformin plus sulphonylurea in patients with type 2 diabetes.

The trial, called CANagliflozin Treatment And Trial Analysis-Metformin plus SUIphonylurea, included patients if they were 18-80 years with type 2 diabetes, who were stable on maximum or near maximum dosages of metformin and sulfonylureas with an A1c $\geqslant$ 7% and $\leqslant$ 10.5%[14].

The primary efficacy endpoint was A1c change from baseline to 26 wk. The secondary end points included change in baseline A1c at 52-wk, change in baseline in fasting plasma glucose (FPG), systolic blood pressure (BP), percent change in body weight, triglycerides, and high density lipoprotein (HDL) cholesterol, and percent patients reaching A1c 7%[14]. The investigators evaluated safety by observing adverse event reports, vital signs and laboratory tests[14]. Patients were randomized to receive either 100 mg or 300 mg canagliflozin or placebo in addition to their metformin and sulphonylurea therapies[14].

Results of the study show that 381 (81%) of 469 patients, who were randomized to the study, completed the 52-wk study. By week 26, the A1c was significantly reduced in the canagliflozin 100 mg and 300 mg study arm to -0.85% and 1.06% which was statistically significant compared to baseline and the A1c was sustained over the entire 52 wk study period[14]. Results are presented in Table 2[14]. FPG was significantly improved at 26 wk and 52 wk with both canagliflozin 100 mg and 300 mg compared to placebo. Canagliflozin significantly reduced weight but there were no significant changes with systolic blood pressure, pulse or cholesterol parameters[14].

Safety profile and adverse events: Although investigators reported that adverse effects were higher with canagliflozin than placebo, they were comparable across the treatment groups. Patients on canagliflozin had higher rates of genital mycotic infections compared to placebo, which were described as mild to moderate in severity[14]. Patients who developed a mycotic infection, especially women, had a prior history of genital mycotic infections compared to those women who received canagliflozin and did not have adverse effects[14]. Genital mycotic infections were treated without interrupting canagliflozin therapy[14].

Canagliflozin compared to sitagliptin

Canagliflozin has been shown to be non-inferior to sitagliptin and in another analysis superior to sitagliptin with regard to lowering of A1c[16].

In a randomized, double-blind, active-control, multicenter, phase three, 52-wk study, Schernthaner evaluated the efficacy and safety of canagliflozin 300 mg compared with sitagliptin 100 mg as add-on therapy in patients with type 2 diabetes mellitus inadequately controlled with metformin and a sulfonylurea[16].

The inclusion criteria were similar to the previously described study, and patients were randomized to receive either 300 mg canagliflozin or 100 mg sitagliptin[16]. The primary efficacy endpoint was A1c change from baseline to 52 wk while the secondary endpoints were similar to the previously described study[16].

Results of the study show that 464 (61%) of 755 patients, who were randomized to receive either canagliflozin 300 mg or sitagliptin 100 mg daily, completed the study. Most of the withdrawals were observed in the sitagliptin therapy arm of the trial due to the lack of glycemic rescue therapy[16]. Canagliflozin demonstrated both noninferiority and in another analysis, showed superiority to sitagliptin 100 mg in reducing A1c (-1.03% and -0.66%, respectively). There were greater reductions with canagliflozin *vs* sitagliptin in FPG, body weight, and systolic BP. More patients on canagliflozin compared with sitagliptin achieved A1c < 7.0%, and A1c < 6.5% at week 52, though the authors did not confirm statistical significance[16]. Results are presented in Table 3[16].

Table 2 Results of phase 3, CANagliflozin treatment and trial analysis-metformin plus SUIphonylurea, *n* = 469[14]

Parameters	Canagliflozin 100 mg	Canagliflozin 300 mg	Placebo	Comments

Change in diastolic blood pressure (mmHg)	-3.0	-0.3	Not significant

A1c: Hemoglobin A1c; FPG: Fasting plasma glucose.

Safety profile and adverse events: There were no differences in adverse effects, hypoglycemia or discontinuation of therapy between treatment groups. Nevertheless, canagliflozin had higher rates of genital mycotic infections (vulvovaginitis in females and balanitis in males) compared to sitagliptin[16]. In other studies, canagliflozin is implicated in urinary tract infections, hypoglycemia and gastrointestinal upset when used alone or in combination with other antihyperglycemic therapy[21].

Canagliflozin was associated with a dose dependent increase in serum creatinine, decrease in estimated glomerular filtration rate, renal impairment, and acute failure in patients especially those with moderate renal impairment and hypovolemia[22].

Canagliflozin 100-300 mg is recommended for patients with creatinine clearance > 60 mL/min per 1.73 m^2 and canagliflozin 100-mg is recommended for patients with creatinine clearance of 45-60 mL/min per 1.73m^2[22]. Canagliflozin is not recommended in patients with creatinine clearance of 30-44 mL/min per 1.73 m^2, and it is contraindicated in patients with creatinine clearance of < 30 mL/min per 1.73m^2[22]. Clinicians should assess patients' renal functions when initiating therapy and for long term drug monitoring. This agent will be a safe and efficacious addition to a dual therapy regimen such as metformin and sulfonylurea based on this study[16].

DAPAGLIFLOZIN AS MONOTHERAPY

List *et al*[23] designed a prospective, dose ranging 12-wk, randomized parallel-group, double-blind, placebo-controlled study to evaluate the safety and efficacy of dapagliflozin. The primary objective was to compare the mean change from baseline A1c in type 2, treatment-naïve adult patients (age 18-79) with A1c ≥ 7% and ≤ 10%[23].

Patients were randomly assigned to one of five once-daily dapagliflozin doses (2.5, 5, 10, 20 or 50 mg), metformin XR (750 mg force titration to 1500 mg) or placebo. Investigators also evaluated changes in FPG, weight, and adverse effects[23].

Results of the study show that 348 (89%) of 389, who were randomized to the study completed the study at week 12[23]. At the end of the study, dapagliflozin had statistically significant mean dose-dependent reduction of A1c from -0.55% to -0.90% when compared with placebo -0.18% but not with metformin of -0.73%[23]. Dapagliflozin also had significant reduction in FPG of -16 to -31 mg/dL compared to 6 mg/dL with placebo and -18 mg/dL with metformin[23]. Dapagliflozin caused a weight loss change of -1.3 to 2 kg[23]. In this trial, dapagliflozin did not demonstrate any renal function changes[23]. The percentage of patients achieving A1c < 7% was 40%-59% for the dapagliflozin group *vs* 32% for placebo and 54% for metformin[23]. Hypoglycemia was reported in 6%-10% of patients treated with dapagliflozin but this was not dose related, compared to 4% of placebo patients and 9% of metformin-treated patients[23].

Dapagliflozin in combination with metformin

Henry *et al*[24] conducted two randomized, double-blind,

three-arm 24-wk trials to compare the combination of dapagliflozin plus metformin *vs* dapagliflozin monotherapy and metformin monotherapy to determine if the combination would be an advantage for treatment naïve type 2 diabetes patients with high baseline A1c.

Study 1 compared dapagliflozin 5 mg in combination with metformin XR, dapagliflozin 5 mg in combination with placebo, and metformin XR plus placebo. Study 2 compared dapagliflozin 10 mg in combination with metformin XR, dapagliflozin 10 mg in combination with placebo, and metformin XR plus placebo[24].

Eligible patients had a baseline A1c 7.5%-12%, and the primary endpoint was a change in A1c from baseline while the investigators also evaluated the change in FPG and weight as secondary endpoints[24].

Results show that in both trials, the combination of dapagliflozin and metformin resulted in significantly lower reductions in A1c compared with either metformin or dapagliflozin monotherapy[24]. Results of the study are presented in Table 4[24]. The combination therapy was statistically superior to monotherapy in reduction of FPG and was more effective than metformin for weight reduction. Dapagliflozin 10 mg was non-inferior to metformin in reducing A1c in study 2[24].

Safety profile and adverse events: Adverse effects of mild to moderate cases of genital infection of vulvovaginitis and balanitis and urinary tract infections were reported and treated without discontinuing the study[24]. There were no major hypoglycemic events reported. Diarrhea was more common in patients on combination therapy with metformin than with dapagliflozin therapy alone[24].

Summary of SGLT-2 inhibitors: Canagliflozin and dapagliflozin have been shown to lower renal threshold for glucose in a dose dependent fashion by increasing urinary glucose excretion through SGLT-2 inhibition, which leads to clinical significant reduction in A1c, FPG, and body weight[14,24]. The reduction in renal threshold is above the threshold for hypoglycemia demonstrating this agent has a low risk of hypoglycemia[17]. The SGLT-2 inhibitors can be used with any other agent whether in a treatment naïve patient or a patient with a long history of type 2 diabetes[22,23,25]. Both therapies are safe and tolerable, but clinicians need to observe for genital infections, which can be easily treated without discontinuation of therapy.

METABOLIC APPROACHES TO THERAPY

11β-HSD-1 inhibitors

High levels of glucocorticoids have been associated with hyperglycemia, insulin resistance, dyslipidemia and visceral obesity[4]. 11β-HSD is an enzyme, presenting as two distinct isoenzymes: 11β-HSD-1 and 11β-HSD-2. 11β-HSD-1 is found in the liver and adipose tissue and converts inactive cortisone to active cortisol while 11β-HSD-2 is found primarily in the kidneys and colon and it inactivates glucocorticoids by converting active cortisol to inactive cortisone[4,26].

It has been suggested that the increased glucocorticoid activity in the white adipose tissue by 11β-HSD-1 is a key player in the development of visceral obesity, insu-

lin resistance, diabetes, type 2 diabetes, dyslipidemia and hypertension in mice[27]. Increased levels of 11β-HSD-1 in adipose tissue produce a metabolic syndrome in mice while 11β-HSD-1 deficiency or inhibition has beneficial metabolic effects on liver metabolism[27].

In humans, researchers discover that though patients with glucocorticoid excess develop central obesity, yet the circulating glucocorticoid levels are normal. The metabolic syndrome resembles Cushing's syndrome, but without the elevated circulating glucocorticoid levels. Researchers suggest that it is the increased activity of 11β-HSD-1 in humans, which is metabolizing cortisol from cortisone within adipose tissue that may play a major role in the pathophysiology of obesity[28]. Inhibition of this enzyme may potentially decrease weight and blood glucose.

Non selective 11β-HSD-1 inhibitors

Older non-selective 11β-HSD-1 inhibitors such as liquorice and its active metabolite glycyrrhizic and glycyrrhetinic acids inhibit both 11β-HSD-1 and 11β-HSD-2 enzymes[29].

Ingesting liquorice and glycyrrhizic or glycyrrhetinic acids have been shown to produce a type of "mineralocorticoid excess" syndrome, hypertension encephalopathy, and hypokalemic paralysis[29]. It can also cause weight loss, sodium retention, potassium loss, and hypertension through the inhibition of 11β-HSD-2[29].

Carbenoxolone, a non-selective 11β-HSD-1 inhibitor and product of liquorice reduces glucose concentrations and increases weight loss; inhibits hepatic triglyceride production, inhibits lipolysis, and increase HDL-C levels, but also causes sodium retention, potassium loss, and hypertension by inhibiting 11β-HSD-2[29].

Vitamin A enriched diets also decrease fat and improve insulin sensitivity in animals and humans as it may inhibit 11β-HSD-1 and mRNA[29]. These non-selective agents were evaluated in small trials with short durations[29].

Several 11β-HSD-1 inhibitors have been developed and are being tested for patients with obesity and diabetes, including INCB013739, MK0916, PF915275, AMG221 produced by a variety of manufacturers. Results from INCB013739 clinical studies show that 11β-HSD-1 inhibitors when administered to patients with type 2 diabetes for 2 wk prevented the conversion of oral cortisone to cortisol, decreased hepatic gluconeogenesis, decreased fasting plasma glucose and low density lipoprotein cholesterol[30].

Clinical trial of INCB13739 (a 11β-HSD-1 inhibitor)

Rosenstock *et al*[30] evaluated the efficacy and safety of the agent INCB13739 (an 11β-HSD-1 inhibitor) for patients with type 2 diabetes, who were inadequately controlled on a mean dosage of 1.5 g daily of metformin therapy.

The study was a double-blind, placebo-controlled parallel study conducted with 302 type 2 diabetes mellitus patients on metformin therapy with an A1c of 7% to 11%[30]. Patients received one of five dosages (5, 15, 50, 100 or 200 mg) of INCB13739 or placebo once daily for 12 wk in addition to metformin. The primary end point was a change in A1c at the end of 12 wk. Investigators also reviewed FPG, lipids, weight loss, and adverse events[16,30]. Patients had a mean duration of type 2 diabetes of 6.2 years with baseline body mass index of 32.4 kg/m^2, A1c 8.3% and FPG 173 mg/dL[30].

Results of the study show that 228 of 302 (75%) patients completed the study[30]. At the end of the study, INCB13739 resulted in a dose dependent reduction in A1c of -0.38% and -0.47% in the 100 mg and 200 mg groups respectively[30]. However, it was noted that there were more significant A1c changes in obese patients on the higher dosages[30]. In addition, those with A1c > 8% had more significant decrease in A1c which was dosage dependent[30]. Results of the study are presented in Table 5[30]. The investigators reported that at the end of 12 wk, 25% of patients who were randomized to the 100 mg and 200 mg therapy groups achieved an A1c < 7% compared to 9.5% of placebo patients[30]. FPG decreased in a dose and time dependent fashion in the 100-200 mg treatment groups while there was significant weight loss in the 15, 100 and 200 mg groups[30]. The investigators reported that this study group had generally controlled blood pressure and plasma lipids at baseline but there was a modest dose dependent decrease in total cholesterol -7 mg/dL ($P_{trend} = 0.026$) from baseline in the 200 mg group[30]. There was no significant difference with HDL cholesterol[30].

Safety profile and adverse events: The therapy was well

tolerated and adverse events were similar across all treatment groups[30]. There were no serious events reported except for cardiac arrest unrelated to study therapy and there were no hypoglycemia reported. The most common adverse event in four patients was nausea in the 200 mg group but this resolved during continuation of therapy[30].

It was noted that there was also a dose dependent statistically significant reduction in Homeostasis Model Assessment of Insulin Resistance (HOMA-IR) suggesting an insulin sensitizing mechanism of action in the 200 mg group[30]. The authors concluded that in patients with type 2 diabetes inadequately controlled with metformin, INCB13739 added to metformin significantly improved A1C, FPG and HOMA-IR[30]. INCB13739 also decreased weight though it did not affect the waist to hip ratio[30].

Summary: 11β-HSD-1 is increased in the adipose tissues of obese patients and those with the metabolic syndrome. 11β-HSD-1 inhibitors may be a viable option for these patients since it converts inactive cortisol to active cortisol in target tissues, which inhibits pancreatic beta cell insulin production, and prevents peripheral glucose uptake promoting weight loss, and decrease in blood glucose[30]. Researchers and clinicians have questions with regard to effects on the immune system, duration and timing of therapy, the long term effects of weight and lipids, glycemic control, insulin action, atherosclerotic plaque formation and cardiovascular risk[30]. The reduction in A1c was moderate but further studies will answer many of these questions to determine the safety and efficacy of 11β-HSD-1 inhibitors.

Glycogen phosphorylase inhibitors

The liver contributes to glucose production by both gluconeogenesis (glucose synthesis) and glycogenolysis (glycogen breakdown)[31]. Type 2 diabetes is characterized by excessive glucose production and inadequate suppression of hepatic gluconeogenesis postprandially[31].

Except for metformin, the production of gluconeogenesis inhibitors has yielded disappointing results with an increase in compensatory hepatic glycogenolysis, which maintains excessive hepatic glucose production[31,32]. Researchers hypothesized that glycogenolysis inhibition can improve blood glucose control by observing patients with hepatic glycogen storage disease experience intermittent hypoglycemia[31]. Glycogen phosphorylase is an enzyme that catalyzes the breakdown of glycogen to glucose-1-phosphate in the liver and tissues that demand high energy[33].

Hepatic glycogenolysis has a major role in the regulation of plasma glucose levels in diabetic mice, and suggests that glycogen phosphorylase inhibitors may be useful in the treatment of type 2 diabetes[31]. Further studies will elucidate if this is so.

Two types of glycogen phosphorylase inhibitors exist[31]. One is a glucose analog, which binds near the active site of the enzyme, and the other is caffeine and other heteroaromatic analogs which bind at the purine inhibitory site (I-site). The I-site is a target for therapy as compounds which bind at this inhibitory site are more potent in the presence of high glucose concentrations[31]. Researchers hypothesized that the inhibitory activity can be regulated by blood glucose concentrations and the inhibitory activity can decrease as normal blood glucose is achieved, which would decrease the risk of hypoglycemia[31].

CP-91149-a glycogen phosphorylase inhibitor in animal studies: CP-91149 was identified as a potent inhibitor of hepatic glucose production in *in vivo* studies in diabetic ob/ob mice[31]. CP-91149 exhibited rapid dose dependent decreases in plasma glucose concentrations (36-120 mg/dL) at 10, 25, and 50 mg/kg doses ($P < 0.001$) without producing hypoglycemia. Hypoglycemia was defined as glucose < 60 mg/dL for CP91149 in this study[31]. Administration of CP-91149 to normoglycemia non diabetic mice at 25-100 mg/dL did not affect glucose lowering. The glucose lowering of CP91149 was accompanied by an inhibition of hepatic glycogen breakdown in the diabetic ob/ob mice[31].

CP-316819-a glycogen phosphorylase inhibitor: CP-316819 is an analogue of CP-91149, which binds to the inhibitor site of glycogen phosphorylase to prevent its transformation to a more active form of the enzyme[33].

One of the concerns was that this analogue does not demonstrate hepatic specificity, so potentially affecting skeletal tissues and having possible deleterious effects to patients who exercise[33]. In a study by Baker, CP-316819 reduced glycogen phosphorylation activation in rat skeletal muscle at rest and maximal contraction, which produced a modest reduction in muscle lactate production[33]. According to the researcher, the study demonstrated that the concern related to potential negative effects of glycogen phosphorylase inhibition on quality of life due to impaired muscle function are unfounded[33].

Summary of glycogen phosphorylase inhibitors

These findings support the possible use of the glycogen phosphorylase inhibitors as a possible addition to the treatment of patients with type 2 diabetes. Further studies are needed to evaluate the effects of glycogen phosphorylase inhibition after chronic oral dosages and under a variety of exercise activities[33].

PROTEIN TYROSINE PHOSPHATASE 1B INHIBITORS

Type 2 diabetes and obesity are both characterized by insulin and leptin resistance[34,35].

Insulin resistance is found in tissues important for glucose homeostasis such as the liver, fat, central nervous system and muscle[34]. Leptin suppresses food intake and increases energy expenditure, but its levels are elevated in obesity demonstrating leptin resistance. Protein tyrosine phosphatases play a major role in leptin resistance by suppressing leptin signaling[36].

Protein tyrosine phosphatase 1B (PTP-1B) is an enzyme that removes phosphate from tyrosine residues in protein such as insulin receptors, so it is described as a negative regulator for insulin and leptin, by dephosphorylating phosphorylated tyrosine residues from the insulin receptor[34]. PTP-1B activity is increased in insulin resistance and obese patients[34].

Summary

Diabetes mice treat with specific PTP-1B inhibitors exhibited normalized BG control, improved insulin sensitivity, and modulated fat storage, and lipogenesis in adipose tissue[34]. Therefore these inhibitors have emerged as a potential oral agent that can provide a strategy for the treatment of type 2 diabetes and obesity and may work best in patients with beta cell function that releases insulin[35].

Further studies will elucidate if these agents can also be a potential addition to the armamentarium of oral diabetes agents affecting both obesity and the metabolic syndrome.

G-PROTEIN-COUPLED RECEPTOR 119 AGONISTS

A dysfunction in pancreatic β cell leading to decreased insulin secretion is a major abnormality in type 2 diabetes mellitus[37]. The pharmacotherapy approach of stimulating insulin release in a glucose-dependent manner using G-protein-coupled receptor has been investigated[38]. Specifically, G-protein-coupled receptor 119 (GPR119) is largely distributed in pancreatic islet cells, somewhat in the gastrointestinal tract, and found to be involved in glucose metabolism[39-41].

GPR119 may be stimulated by endogenous ligands or synthetic compounds resulting in an elevated cyclic adenosine monophosphate[42]. Studies have shown that stimulation of GPR119 yields glucose-dependent insulin release from the pancreatic β cells, glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide secretions from intestinal cells[42]. Thus, pharmacological agents that target GPR119 results in glucose reduction with low hypoglycemia risk, body weight loss, and potential for pancreatic β cell preservation[42]. These characteristics are very similar to the commercially available GLP-1 agonists, however the studied GPR119 agents may be orally administered. Several GPR119 molecules (GSK1292263, MBX-2982, PSN-821, AR231453, AR-7947) have been studied in preclinical and/or early clinical trials with poor outcomes due to loss of pharmacological effect or minimal glycemic lowering effect[42]. Furthermore, GPR119 agonists have also been considered in combination with DPP-4 inhibitors in an attempt to enhance the GLP-1 effects[42].

Summary

GPR119 agonists have strong potential to meet the needs of patients with type 2 diabetes because of their relative safety profile, lack of weight gain, oral formulation, and possible β cell preservation effect. However, there have been challenges to their development due to potential tachyphylaxis and low anti-hyperglycemia efficacy.

GK ACTIVATORS

GK is a key enzyme in the hexokinase family that facilitates glucose homeostasis *via* glucose phosphorylation and metabolism mainly in the pancreatic β cells and hepatocytes[43-45]. GK functions as a glucose sensor in pancreatic β cells, thereby stimulating glucose-stimulated insulin secretion and regulating glucose metabolism within the liver, including gluconeogenesis, glycolysis, glycogen synthesis, glucose oxidation, lipogenesis, urea, and uric acid production[43,45-48].

Since the initial development of small molecules known as GK activators (GKAs) that bind to an allosteric site of the enzyme in 2003, more than 150 patents have been established[49-51]. Preclinical and clinical phase trials of GKAs have demonstrated glucose lowering effect in both animal and humans[52]. This novel class of anti-diabetic agents holds promise particularly because both mechanistic actions of GK are impaired in type 2 diabetes[53]. However, there are concerns about potential side effects including hyperlipidemia, hypoglycemia, and fatty liver that may limit the development of GKAs[54]. For example, a small Phase I clinical trial involving the GKA piragliatin was discontinued in type 2 diabetes patients with unrevealed rationale[55].

Another GKA molecule, MK0941 was evaluated in a 54-wk Phase Ⅱ trial in type 2 diabetes patients, but was discontinued because of observed hyperlipidemia, vascular hypertension and early therapy failure[56].

Summary of GKA

GKAs offer a unique pharmacotherapeutics approach to type 2 diabetes management and have demonstrated useful potential in glycemic management. However, further development is needed to address the potential side effects observed in clinical trials. Additional advancements may include modifications of the GKAs structures and activities to minimize hypoglycemia, hyperlipidemia, fatty liver, and vascular hypertension[44].

CONCLUSION

The management of type 2 diabetes present many treatment challenges, but new and emerging drug therapies are a welcome addition to complement the current agents. The SGLT-2 inhibitors have shown significant benefits as monotherapy and in combination with available agents like metformin, sulphonylurea and insulin therapy. The selective 11β-HSD-1 inhibitor is another class of possibly safe and efficacious agent that lowers fasting blood glucose, A1c and weight, although the A1c lowering was modest. The glycogen phosphorylase inhibitors appear to show rapid and safe blood glucose decreases in mice without the risk of hypoglycemia. Hope-

fully similar results translate into human studies. PTP-1B is still in clinical trials and may show significant decrease in weight and glucose levels in insulin and leptin resistant patients. Mice studies show positive results of normalized blood glucose control, improved insulin sensitivity and improvements in lipogenesis. The GPR119 agonists have strong potential for meeting the needs of type 2 diabetes patients because of their safety profile, lack of weight gain and possible beta cell preservation effect. However, the GK inhibitors may have some potential problems as agents so far have been discontinued due to dyslipidemia, vascular hypertension and early therapy failure. Prescribers and pharmacists may have to recognize that these new agents may not be first line agents due to costs, monitoring parameters, modest reductions of A1c, and lack of cardiovascular disease data. Further studies will help to more clearly define these new and emerging anti-hyperglycemia agents' roles in therapy.

Abstract

Genetic linkage analyses, genome-wide association studies of single nucleotide polymorphisms, copy number variation surveys, and mutation screenings found the human chromosomal 12q24 locus, with the genes *SH2B3* and *ATXN2* in its core, to be associated with an exceptionally wide spectrum of disease susceptibilities. Hematopoietic traits of red and white blood cells (like erythrocytosis and myeloproliferative disease), autoimmune disorders (like type 1 diabetes, coeliac disease, juvenile idiopathic arthritis, rheumatoid arthritis, thrombotic antiphospholipid syndrome, lupus erythematosus, multiple sclerosis, hypothyroidism and vitiligo), also vascular pathology (like kidney glomerular filtration rate deficits, serum urate levels, plasma beta-2-microglobulin levels, retinal microcirculation problems, diastolic and systolic blood pressure and hypertension, cardiovascular infarction), furthermore obesity, neurodegenerative conditions (like the polyglutamine-expansion disorder spinocerebellar ataxia type 2, Parkinson's disease, the motor-neuron disease amyotrophic lateral sclerosis, and progressive supranuclear palsy), and finally longevity were reported. Now it is important to clarify, in which ways the loss or gain of function of the locally encoded proteins SH2B3/LNK and ataxin-2, respectively, contribute to these polygenic health problems. SH2B3/LNK is known to repress the JAK2/ABL1 dependent proliferation of white blood cells. Its null mutations in human and mouse are triggers of autoimmune traits and leukemia (acute lymphoblastic leukemia or chronic myeloid leukemia-like), while missense mutations were found in erythrocytosis-1 patients. Ataxin-2 is known to act on RNA-processing and trophic receptor internalization. While its polyglutamine-expansion mediated gain-of-function causes neuronal atrophy in human and mouse, its deletion leads to obesity and insulin resistance in mice. Thus, it is conceivable that the polygenic pathogenesis of type 1 diabetes is enhanced by an SH2B3-dysregulation-mediated predisposition to autoimmune diseases that conspires with an ATXN2-deficiency-mediated predisposition to lipid and glucose metabolism pathology.

Key words: Diabetes mellitus type 1; 12q24; *ATXN2*; Obesity; *SH2B3*; Autoimmune

Core tip: Within the multifactorial pathogenesis of type 1 diabetes mellitus (T1D), a genetic risk mediated by the chromosome 12q24 locus was consistently observed. Mutations in the *ATXN2* gene there trigger the pathogenesis of obesity, while mutations in the SH2B3 gene there trigger the pathogenesis of autoimmune processes. Given that both genes show co-regulated expression, their combined effects may drive these two core aspects of T1D. Tissue and phenotype studies of mouse mutants will identify molecular targets for causal therapies.

ATXN2? *World J Diabetes* 2014; 5(3): 316-327 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/316.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.316

INTRODUCTION

The pathogenesis of many common multifactorial diseases was successfully elucidated over the past years, principally through genome-wide association studies (GWAS) in many thousands of sporadic patients *vs* control individuals. For diabetes mellitus type 1 (T1D), more than 40 chromosomal loci were uncovered to modulate disease risk[1,2]. However, now the challenge consists in establishing causality between one of the multiple genes contained in any locus and one of the disease features. One promising approach is the careful consideration of phenotypes and pathology caused by disruption or overexpression of any candidate gene, *e.g.*, in mouse, and the subsequent comparison with relevant traits that occur within the first years of the disease course. Thus, clinical information may help to guide the characterization of mutant animals, while conversely the tissue analysis of mutant animals may help to elucidate presymptomatic stages of disease. A particularly complex example is the subject of this review-the association of T1D and many other medical conditions with mostly two single nucleotide polymorphisms (SNPs) on chromosome 12q24-rs3184504 and rs653178.

THE EXCEPTIONALLY PLEIOTROPIC DISEASE SUSCEPTIBILITY LOCUS ON CHROMOSOME 12Q24 EXTENDS FROM THE *SH2B3* GENE ACROSS THE *ATXN2* GENE, BUT MAY STRETCH BEYOND THESE BORDERS

Chromosome 12q contains one of the largest blocks of linkage disequilibrium (LD) in the human genome[3]. It was observed early on in European/Asian/African populations and found to span > 1 Megabase pairs (Mbp) across several genes including the growth repressor *SH2B3*, the RNA processing factor *ATXN2*, the nuclear localization inhibitor *BRAP*, the mitochondrial fatty acid beta-oxidation enzyme *ACAD10*, the alcohol metabolism enzyme *ALDH2*, and the stress kinase *MAPKAPK5*[4]. The core LD block was localized to exon 1 of the *ATXN2* gene in a population of European ancestry, and was explained by positive selection of the (CAG)-repeat size in this exon[4]. Indeed, the most frequently observed disease associations at this 12q24 locus are within a 200000 basepairs (bp) fragment, which comprises the *ATXN2* gene and the immediately adjacent *SH2B3* gene (Figure 1). According to the United States National Center for Biotechnology Information reference sequences, human *SH2B3* is transcribed in orientation from the centromere, covering about 46000 bp, and spans 9 predicted exons to constitute an mRNA of 5425 nucleotides, which encodes a protein of 575 amino acids. *ATXN2* is transcribed in orientation from the telomere, covering about 147000 bp, and spans 24 predicted exons with several splice-isoforms, of which the longest constitutes an mRNA of 4712 nucleotides and encodes a protein of 1313 amino acids. The missense SNP rs3184504 in *SH2B3* open reading frame (resulting in the substitution W262R) was observed in perfect cosegregation ($r^2 = 1$) with the SNP rs653178 deep within intron 2 of the *ATXN2* gene[5], in spite of a physical distance of 123148 bp. Since rs653178 is far away from *ATXN2* splice sites and since the W262 codon in SH2B3 is not conserved between human and mouse[6], both of these polymorphisms are probably innocent bystanders and are noticed only through their frequency, depending on their random distribution within population stratifications. They are presumably coinherited with other rare sequence variants, *e.g.*, within the promoters or within the mRNA 3'-untranslated regions, which alter the transcript expression levels slightly upwards or downwards. Indeed, both of these cosegregating *SH2B3* and *ATXN2* variants correlated with significant changes in the expression of both *ATXN2* and *SH2B3* mRNAs[7]. This coinheritance together with correlated expression changes makes it inherently difficult to establish causality between any of the individual traits within a complex disease and any of the neighbouring genes. This is exemplified by the allocation of six hematologic and three blood pressure traits to the region from *SH2B3* to *ATXN2* by genome-wide studies, reflecting the exceptional pleiotropy of this locus[8]. The 12q24 linkage disequilibrium block in some studies of restricted populations included further genes, namely *CUTL2*, *FAM109A*, *SH2B3*, *ATXN2*, *BRAP*, *ACAD10*, *ALDH2*, *MAPKAPK5*, *TMEM116*, *ERP29*[9], *NAA25/C12orf30*, *TRAFD1*, *HECTD4/C12orf51*, *RPL6*, *PTPN11*[10-12], thus extending across 1.5 Mbp. For these reasons it is crucial to consider monogenic mutants for each gene and their phenotypic effects, so as to decide which of them might contribute to each of the diseases. However, for most of these genes the relevant mouse mutants are not yet characterized.

NULL MUTATIONS IN MOUSE AND HUMAN DEMONSTRATE *SH2B3* TO REPRESS THE PROLIFERATION OF WHITE BLOOD CELLS, IN PARTICULAR B-LYMPHOCYTES

The generation of mice with deletion of SH2B3 (also called Lnk) demonstrated primary splenomegaly and extramedullary hematopoiesis with progenitor hypersensitivity to various cytokines[13]. It caused the accumulation of pre-B and immature B-lymphocytes in enlarged spleens as well as an increase in B-lineage cells in the bone marrow, in parallel to unimpaired T-cell de-

SH2B3-ATXN2 genomic locus

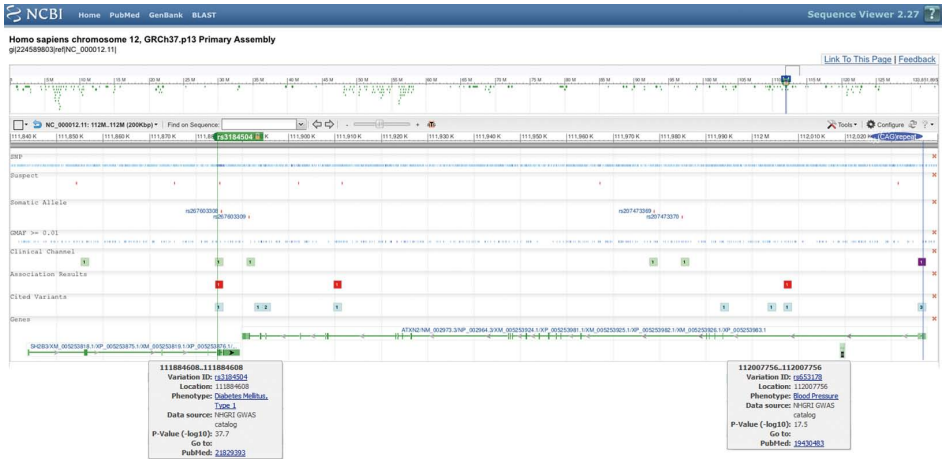

Figure 1 The core 200000 bp region of the chromosome 12q24 locus covering the immediately adjacent *SH2B3* and *ATXN2* genes, with an illustration of the single nucleotide polymorphism rs3184504 encoding the W272R missense variant of the SH2B3/LNK protein (as shown in the United States National Center for Biotechnology Information database) as well as the (CAG)-repeat structure encoding the unstable polyglutamine domain of the ataxin-2 protein.

velopment in thymus[14]. It accelerated and exacerbated oncogenic JAK2-induced myeloproliferative diseases through an expansion of myeloid progenitors, accelerated myelofibrosis and finally features of chronic myeloid leukemia (CML). These murine data supported notions that SH2B3 directly inhibits oncogenic JAK2 and cooperates with the *BCR/ABL* oncogene in the development of CML[15]. Deletion of SH2B3 was also observed in a genomic and transcriptomic study of patients with BCR-ABL1-positive acute lymphoblastic leukemia with poor outcome (Ph-like ALL), together with promising therapeutic benefits from tyrosine kinase inhibitors[16]. Human germline homozygous *SH2B3* mutations including a frameshift with translation stop resulted in growth retardation, high white cell counts in parallel to anemia and thrombocytopenia, splenomegaly and liver cirrhosis, autoimmune Hashimoto thyroiditis, speech delay and ALL. In addition, this study identified homozygous somatic *SH2B3* frameshift mutations in ALL cases[17]. A 5 bp deletion of SH2B3, which was predicted to affect both the PH domain and the SH2 domain, manifested clinically as primary myelofibrosis. In contrast, a somatic *E208Q* missense mutation in the PH domain was observed in a patient with essential thrombocythemia[18]. SH2B3 was also shown to interact with platelet-derived growth factor receptor and repress its downstream signaling[19]. Interestingly, a selective increase in red blood cells (isolated erythrocytosis) was observed in two individuals with the *SH2B3* missense mutations E208X and A215V[20]. However, SH2B3 sequencing in 23 erythrocytosis patients uncovered only one non-synonymous polymorphism of unclear relevance[6]. Systematic SH2B3 sequencing analysis in 42 patients with chronic phase myeloproliferative neoplasms detected a missense mutation in 7% of cases, either in the SH2 domain or in the C-terminal domain, which were always accompanied by a *JAK2* mutation[21]. Myeloproliferative *SH2B3* mutations within the PH domain were also shown to reduce SH2B3 function without altering its binding properties to JAK2, CBL and 14-3-3[22]. An analysis of peripheral mononuclear blood cells stimulated with anti-CD28 and anti-CD3 antibodies detected an increased proliferation of T-lymphocytes in carriers of the W262R missense SH2B3 variant, independent of the presence of juvenile type 1 diabetes[23]. *In vitro* studies had previously shown SH2B3 to attenuate the ability of SH2B1 to promote JAK2 activation and subsequent tyrosine phosphorylation of insulin receptor substrate-1 by JAK2[24]. SH2B3-deficient hematopoietic stem cells displayed an increased postnatal expansion and enhanced thrombopoietin responsiveness[25]. In subsequent studies they showed increased resistance to apoptosis due to enhanced expression of Bcl-xL upon thrombopoietin stimulation[26]. A limitation of growth by SH2B3 was also observed in the rat neuronal PC12 cell line and in primary cortical neurons, where neurotrophin-induced neurite outgrowth was downregulated by the binding of SH2B3 to the phosphorylated neurotrophin receptor TrkA and the repression of downstream signaling[27].

AUTOIMMUNE DISEASES (EOSINOPHIL NUMBERS, COELIAC DISEASE, JUVENILE IDIOPATHIC ARTHRITIS, RHEUMATOID ARTHRITIS, THROMBOTIC ANTIPHOSPHOLIPID SYNDROME, LUPUS ERYTHEMATOSUS, MULTIPLE SCLEROSIS, HYPOTHYROIDISM, VITILIGO) MAY BE MODULATED BY SH2B3

Possibly as an effect of SH2B3 on B-lymphocyte proliferation, the 12q24 locus modulates the risk for various autoimmune diseases. A GWAS in the Icelandic popula-

tion studying eosinophil counts observed association with the *SH2B3* SNP rs3184504[28]. A GWAS into coeliac disease found the *SH2B3* SNP rs3184504 and the *ATXN2* intronic SNP rs653178 to be associated[29]. Follow up studies of coeliac disease focusing on 9 and 11 candidate SNPs confirmed the association with *SH2B3*[30,31], and reported upregulation of *SH2B3* mRNA expression levels in intestinal mucosa to be triggered by coeliac disease and by the risk allele T of the *SH2B3* SNP rs3184504[31]. Further haplotype studies were confirmatory, and functional experiments indicated that carriers of the rs3184504 risk allele show stronger activation of the NOD2 recognition pathway in response to lipopolysaccharides and muramyl dipeptide[32]. A candidate study of sixteen SNPs known from coeliac disease and from T1D found an association of the *ATXN2* SNP rs653178 with juvenile idiopathic arthritis[33]. GWAS studies into rheumatoid arthritis indicated association with *SH2B3* particularly among rheumatoid-factor-positive patients[34]. A GWAS meta-analysis confirmed that the *ATXN2* intronic SNP rs653178 is associated not only with coeliac disease, but also with rheumatoid arthritis[35]. A study of thrombophilia in antiphospholipid antibody positive individuals by array-comparative genomic hybridization analysis of copy number variations with subsequent fine mapping identified a risk haplotype comprising one *SH2B3* SNP and two *ATXN2* SNPs[36]. A GWAS of systemic lupus erythematosus observed association with the SNP rs17696736 within the *ERP29* gene downstream from *SH2B3*[9]. A candidate study of 12 SNPs in almost 3000 Spanish multiple sclerosis patients detected association with the *SH2B3* SNP rs3184504[37]. A GWAS into hypothyroidism reported the *SH2B3* SNP rs3184504 to be associated, with autoimmune Hashimoto thyroiditis as a likely explanation for this observation[38]. A GWAS into the autoimmune skin disease vitiligo reported an association with the 12q24 locus extending from the *SH2B3* across the *ATXN2* gene[39].

T1D MELLITUS

The first GWAS into T1D encountered a maximal association with the 12q24 SNP rs17696736 in an intron of the *C12ORF30/NAA25* gene, while the effect was consistently observed also in its neighbourhood across a 1.5 Mbp LD block[10]. An extended GWAS confirmed this observation and pointed out that the association with the W272R missense variant encoded in exon 3 of SH2B3 was sufficient to model the regional effect[40]. GWAS of additional cases corroborated the association with *SH2B3*[41], a further GWAS with meta-analysis and combined comparisons supported the association with rs3184504[42], and also a GWAS of affected sib-pair families showed association with the region from the *SH2B3* SNP rs739496 across the *ERP29* SNP rs17696736 until the SNP rs10850061 beyond PTPN11[11,43]. GWAS of autoantibody positive T1D patients again detected the association with SH2B3[44,45]. GWAS of soluble intercellular adhesion molecule-1 levels as an endothelium-derived inflammatory biomarker in diabetes and infarction also showed the association with the *SH2B3* SNP rs3184504[46]. Candidate studies of 2 and 21 SNPs in T1D cases from Russia and United States, respectively, replicated the SH2B3 association[47,48]. Since the effect is so consistent, *SH2B3* SNP genotyping was integrated into a signature of 8 polymorphisms that provide optimal prediction of T1D risk[49]. However, it is likely that the *SH2B3* sequence variant rs3184504 is not biologically responsible by itself, since sequencing studies failed to find similar SH2B3 variants in NOD mice that model many T1D features[50].

EVIDENCE FROM MOUSE MUTANTS IMPLICATES *ATXN2* IN METABOLIC SYNDROME

While the autoimmune component of T1D might be explained by the SH2B3 effect on lymphocyte proliferation, some metabolic features of T1D might be exacerbated by the ataxin-2 effect on glucose and lipid metabolism. Mice with targeted deletion of Atxn2 exon 1 and frameshift in homozygous state displayed marked obesity and infertility in two independently generated mutant lines[51,52]. Hepatic lipid and glycogen accumulation was evident already at age 6 mo. As in other insulin resistance syndromes, pancreatic and blood serum insulin levels were increased, in parallel to a reduction of insulin receptor (IR) protein levels in the liver, in spite of increased IR mRNA levels. Serum cholesterol was significantly increased[52]. Although ataxin-2 is mostly localized at the rough endoplasmic reticulum and has strong effects on mRNA processing[53-59], its effect on the IR is possibly explained through interactions with the endocytic internalization machinery of receptor tyrosine kinases[60,61]. TDP-43 is an interactor protein of ataxin-2 *via* joint RNA-binding[57], was also demonstrated to regulate glucose homeostasis and fat deposition, with its levels showing direct correlation with the expression levels of the obesity gene *Tbc1d1*, while its deletion affects the splicing of apolipoprotein A-Ⅱ[62-64].

EVIDENCE FROM HUMAN MUTATIONS IMPLICATES *ATXN2* IN OBESITY

The investigation of obesity in 92 children by systematic sequencing of the *ATXN2* coding regions demonstrated a greatly increased frequency of the SNP rs695872 allele C and an overrepresentation of (CAG)-repeat sizes > 22[65]. Indeed, obesity and polyphagia were marked features of infants in middle stages of the neurodegenerative process caused by (CAG)-repeat expansions in ATXN2[66]. Thus, monogenic evidence links obesity to ATXN2 both in mice and in human. This is possibly reflected by a genome-wide SNP genotyping analysis, where SH2B3 variants were associated with low-density lipoprotein (LDL) cholesterol[67]. Interestingly, an association with obesity was also observed for the ataxin-2

binding protein 1 (A2BP1 or RBFOX1) both in a GWAS among Pima Indians and in a candidate approach among French Caucasian adults[68].

ATXN2 IS IMPORTANT FOR NEURODEGENERATIVE DISEASES

The polyglutamine (polyQ) domain at the N-terminal end of ataxin-2 normally has a size of Q22-23, usually encoded by a $(CAG)_8CAA(CAG)_4CAA(CAG)_8$ sequence in exon 1 of the *ATXN2* gene on chromosome 12q24. Its unstable expansion to large sizes beyond $(CAG)_{31}$ is the monogenic cause of an autosomal dominant multisystem atrophy of the nervous system, which was named spinocerebellar ataxia type 2[69-86]. CAG-repeat expansions with cytosine adenosine adenosine (CAA) interruptions may also manifest as Parkinson's disease[87,88]. Intermediate CAG-repeat sizes of 26-31 units, sometimes with CAA interruptions, act as polygenic risk factor for the motor-neuron disease amyotrophic lateral sclerosis[57,89]. Intermediate CAG-repeat expansions enhance also the risk for progressive supranuclear palsy[90]. Published evidence suggests that the polyglutamine expansions increase the half-life of ataxin-2 and that a gain-of-toxic-function through accumulation of ataxin-2 aggregates with sequestration of interactor proteins such as the poly(A)-binding-protein PABPC1 underlies the neurodegenerative process[57,91]. In spite of the vast evidence that excess ataxin-2 is the biological cause for neuronal death, SNP genotyping and association studies curiously found an *SH2B3* allele haplotype to be more informative and to better predict amyotrophic lateral sclerosis risk than the ATXN2 alleles[92]. This observation underscores old experiences that maximal linkage logarithm of odds scores and maximal haplotype association scores within any chromosomal region depend on random population stratification effects and on the frequency/informativity of alleles. Thus, they are not suitable for the fine mapping of disease genes.

LONGEVITY

Interestingly, the discovery set of a GWAS of exceptional longevity in centenarians detected a significant association with the *ATXN2* SNP rs653178, in parallel to several other disease associated SNPs, while the strongest effect correlated with the SNP rs2075650 at the *TOMM40*/apolipoprotein E (*APOEO* locus. TOMM40 encodes the channel forming subunit of the translocase across the mitochondrial outer membrane, while APOE encodes the apolipoprotein E, which mediates the binding and clearance of lipoprotein particles such as chylomicrons and very LDLs. Apolipoprotein E polymorphisms are the main known genetic factors associated with the risk of Alzheimer's disease[93,94]. While it remained unclear in this longevity GWAS, whether an LD effect was consistently observed also for SNPs that surround ATXN2, and whether blood cell traits, autoimmune disorders, obesity, neurodegenerative processes or vascular pathology were underlying this observation, the authors reported their observation of a reduced frequency of the *ATXN2* SNP rs653178 allele T among centenarians [with a log10(BayesFactor) of 1.2] in the light of previous ATXN2 GWAS association data with hypertension[93,94].

KIDNEY DISEASE, MICROCIRCULATION, HYPERTENSION AND CARDIOVASCULAR INFARCTION

Indeed, several independent GWAS found renal function (estimated glomerular filtration rate on the basis of cystatin c) and chronic kidney disease to be modulated by the rs653178 variant within an intron of the *ATXN2* gene in populations of European and African ancestry[5,95-97]. Also a GWAS into plasma levels of beta-2-microglobulin as a biomarker of kidney function, cardiovascular diseases and mortality reported an association with the *ATXN2* SNP rs653178[98]. Furthermore, a recent GWAS into serum urate concentrations uncovered an association with the *ATXN2* SNP rs653178[99]. The analysis of 83 candidate SNPs showed kidney disease variants to be associated with vascular phenotypes only in the case of rs653178 within the *ATXN2* gene and two SNPs at the *SH2B3* locus[100]. A GWAS studying microcirculation as measured by retinal venular caliber reported 4 loci, with only the rs10774625 SNP within an *ATXN2* intron showing also significant association with hypertension and coronary heart disease[12]. The *ATXN2* SNP rs653178 and the *SH2B3* SNP rs3184504 association with diastolic as well as systolic blood pressure, mean arterial pressure and pulse pressure was reported in three independent GWAS of populations with European and African ancestry[7,101-103]. Similarly, an association of the *SH2B3* SNP rs3184504 with diastolic and systolic blood pressure and hypertension was detected in a GWAS of 200000 individuals of European descent[104]. A GWAS association of the *ATXN2* SNP rs653178 with myocardial infarction was shown in Icelandic individuals[28]. A recent candidate SNP study replicated the association between the *SH2B3* SNP rs3184504 and coronary heart disease also in South Asian patients[105]. Thus, it appears that the 12q24 locus has a marked effect on vascular pathology.

RED BLOOD CELL TRAITS

It is unclear whether the above vascular disorders are consequences of vessel wall pathology or of blood cell pathology. It may therefore be relevant that a GWAS into the genetic basis of six traits of erythrocytes (including hemoglobin concentration, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration and red blood cell count) also showed associations with the 12q24 locus from *SH2B3* across the *ATXN2* gene[106].

CONCLUSION

For further mechanistic insights it will be important to

generate and characterize rodent mutants for each of the genes in the pleiotropic 12q24 disease susceptibility locus.

With the limited knowledge available so far, it is credible that SH2B3 modulates B-lymphocyte proliferation and autoimmune traits. Ataxin-2 gain-of-function is a well-established modulator of several neurodegenerative diseases, while its deficiency appears to predispose to insulin resistance, blood cholesterol elevation, hepatic glycogen and lipid accumulation with overall obesity. Thus, downstream effects of both genes might cooperate to enhance the risk for type 1 diabetes.

Since T1D is an age-associated disease, it will be important to age Atxn2-null mice beyond 6 mo to the end of their natural lifespan around 2 years. This will allow us to assess whether their obesity leads to hypertension and vascular pathology, *e.g.*, in kidneys, whether red blood cell traits are altered, and whether their longevity is abnormal. In particular, the insulin resistance/obesity/dyslipidemia/hepatosteatosis induced by *Atxn2*-null mutations should be studied regarding their long-term consequences. Mechanistically, it will be intriguing to elucidate how the RNA processing effects of ataxin-2 lead to this pathology.

In view of the polyQ expansion effects extending the protein half-life and causing a gain-of-function of ataxin-2, it is conceivable that the polyQ shrinkage sizes (Q13-21) could mediate a decreased half-life of the protein and a partial loss-of-function. Thus, these rare variants might be associated with phenotypes that were observed in the Atxn2-null mouse, such as obesity, insulin-resistance and diabetes mellitus.

ACKNOWLEDGMENTS

We are grateful to Ulrich Müller and Jan Rozman for critical reading of the manuscript.

Abstract

Ghrelin is a 28 amino acid peptide mainly derived from the oxyntic gland of the stomach. Both acylated (AG) and unacylated (UAG) forms of ghrelin are found in the circulation. Initially, AG was considered as the only bioactive form of ghrelin. However, recent advances indicate that both AG and UAG exert distinct and common effects in organisms. Soon after its discovery, ghrelin was shown to promote appetite and adiposity in animal and human models. In response to these anabolic effects, an impressive number of elements have suggested the influence of ghrelin on the regulation of metabolic functions and the development of obesity-related disorders. However, due to the complexity of its biochemical nature and the physiological processes it governs, some of the effects of ghrelin are still debated in the literature. Evidence suggests that ghrelin influences glucose homeostasis through the modulation of insulin secretion and insulin receptor signaling. On the other hand, insulin was also shown to influence circulating levels of ghrelin. Here, we review the relationship between ghrelin and insulin and we describe the impact of this interaction on the modulation of glucose homeostasis.

Key words: Acylated ghrelin; Unacylated ghrelin; Insulin secretion; β-cell functions; Insulin receptor signalling; Glucose homeostasis

Core tip: The present invited review intends to summarize the current knowledge on the relationships between ghrelin, insulin and glucose homeostasis in cellular, animal and human models.

INTRODUCTION

Obesity and ensuing metabolic complications are major concerns for public health and these disturbances are anticipated to cause the first reduction of life expectancy in modern history[1]. Unfortunately, efforts to curb and especially prevent this alarming trend have so far been met with disappointment. Although it was initially hypothesized that metabolic dysfunctions develop in response to overeating and sedentarity, recent advances show that the

pathophysiological process is much more complex than anticipated. That is, obesogenic environmental and genetic factors disturb homeostatic crosstalk between tissues, promote excessive fat deposition and ultimately alter cellular functions[2-7]. Recently, a close relationship between the development of obesity-related disturbances and gut-derived hormonal dysregulations has been clearly established[8-11]. For instance, studies of gut-derived peptides such as peptide tyrosine-tyrosine 3-36, glucagon-like peptide 1, glucose-dependent insulinotropic peptide and oxyntomodulin have provided key information regarding factors promoting satiety, insulin secretion and glucose disposal. More recently, studies on ghrelin have significantly improved our understanding of mechanisms underlying the stimulation of food intake, lipid accumulation in adipose tissues and the development of metabolic dysfunctions such as insulin resistance and type 2 diabetes[12].

Ghrelin is a 28 amino acid peptide predominantly produced by the stomach[13-15] but also expressed at lower levels in other tissues such as the liver, pancreas, heart, central nervous system (CNS), esophagus and testis[16-18]. Although it was isolated from rat stomach extracts[13] ghrelin was initially shown to induce potent somatotrophic activity in the anterior pituitary[19-21]. Subsequent studies have also revealed the relevance of ghrelin in the regulation of appetite, storage and metabolism of energy substrates, inflammation, stress and other key biological functions[22,23]. Strong evidence indicates the effects of ghrelin in the regulation of metabolic functions and its potential role in the etiology of obesity-related dysfunctions such as insulin resistance and type 2 diabetes[24]. For the purpose of the present work, we will emphasize on reviewing the inter-relationships between ghrelin, insulin and glucose homeostasis.

GHRELIN RECEPTOR

In the circulation, ghrelin is present under acylated (AG) and unacylated (UAG) forms[13]. The enzyme ghrelin o-acyltransferase (GOAT) was shown to be mandatory for the posttranslational addition of the acyl chain on serine-3 of ghrelin[25]. In blood, the half-life of AG is approximately 10 min while UAG displays more stability with a half-life of more than 35 min[26]. Although UAG accounts for approximately 50%-90% of total ghrelin concentrations in the circulation, this form was initially considered as an artifact devoid of biological activity[26,27]. However, recent advances indicate that UAG independently mediates specific biological functions while sharing others with AG.

The effects of AG are mediated through the activation of the native growth hormone (GH) secretagogue receptor 1a (GHS-R1a)[13,28]. Following the discovery of ghrelin, the AG form was reported to stimulate the release of GH and to promote appetite through its action on the brain[13,29-31]. In contrast to its acylated counterpart, UAG was not shown to interact with the GHS-R1a. It has recently been suggested that AG and UAG may exert their effects through the interaction with other receptors than the already identified GHS-R1a. The human ghrelin analog BIM-28163, which fully inhibits GHS-R1a receptor activation induced by native ghrelin, was shown to blunt AG-induced GH secretion[32]. However, since both AG and BIM-28163 induce neuronal activation in the dorsomedial hypothalamus, an important nucleus involved in regulating food intake, it is suggested that an unknown ghrelin receptor could mediate AG's action in promoting weight gain[33,34]. Accordingly, it is proposed that the GHS-R1a acutely mediates AG action on appetite, whereas an unknown ghrelin receptor modulates its chronic peripheral weight-increasing effects[35,36]. It has also been suggested that GHS-R1a could heterodimerize with G protein-coupled receptor 83 (Gpr83)[37]. This study shows that the Gpr83/GHS-R1a dimerization affects ghrelin's ability to activate its only known endogenous receptor, indicating that Gpr83 is an important regulator of ghrelin receptor activity. AG was also shown to interact with several other G protein-coupled receptors such as the dopamine receptor subtypes 1 and 2 (DRD1/2) and melanocortin receptor 3 (MC3R) in the central nervous system[37-41]. Because the existence of another ghrelin receptor remains speculative, the following sections will emphasize on the interactions between GHS-R1a and insulin synthesis/release and signalling.

In a landmark article, Tschöp *et al*[30] had observed that AG increases both food intake and adiposity in rats and mice, suggesting that the hormone promotes positive energy balance. GHS-R1a is predominantly expressed in the central areas known to be influenced by insulin, including hypothalamic neuropeptide Y (NPY)/agouti-related protein (AgRP) neurons[42,43]. Furthermore, we and others have reported that the orexigenic effects of AG are mediated through the activation of NPY and AgRP as well as the inhibition of proopiomelanocortin (POMC)/cocaine- and amphetamine-regulated transcript (CART) neurons in the arcuate nucleus (ARC) of the hypothalamus[29,44-49]. It has recently been hypothesized that the adipogenic effects of both AG and UAG could be mediated in the CNS by the activation of GHS-R1a[50]. Mice lacking GHS-R1a are protected against early-onset obesity, indicating the importance of ghrelin signaling in regulating body weight[51]. The effect of AG on food intake is believed to be mainly attributable to its interaction with the melanocortin system[44,52]. In fact, in the hypothalamus, ghrelin promotes the expression of the enzyme prolylcarboxypeptidase and therefore the degradation of melanocortin receptor agonist α-melanocyte-stimulating hormone[53]. Central melanocortin signaling has been shown to directly regulate insulin levels and to be independently involved in the control of glucose homeostasis[54]. Moreover, the melanocortin system is an important downstream target for the effects of insulin to regulate food intake and body weight[55]. The melanocortin system is active in areas where both insulin and ghrelin signalling components are expressed; therefore, potential crosstalks between these systems could be envisaged.

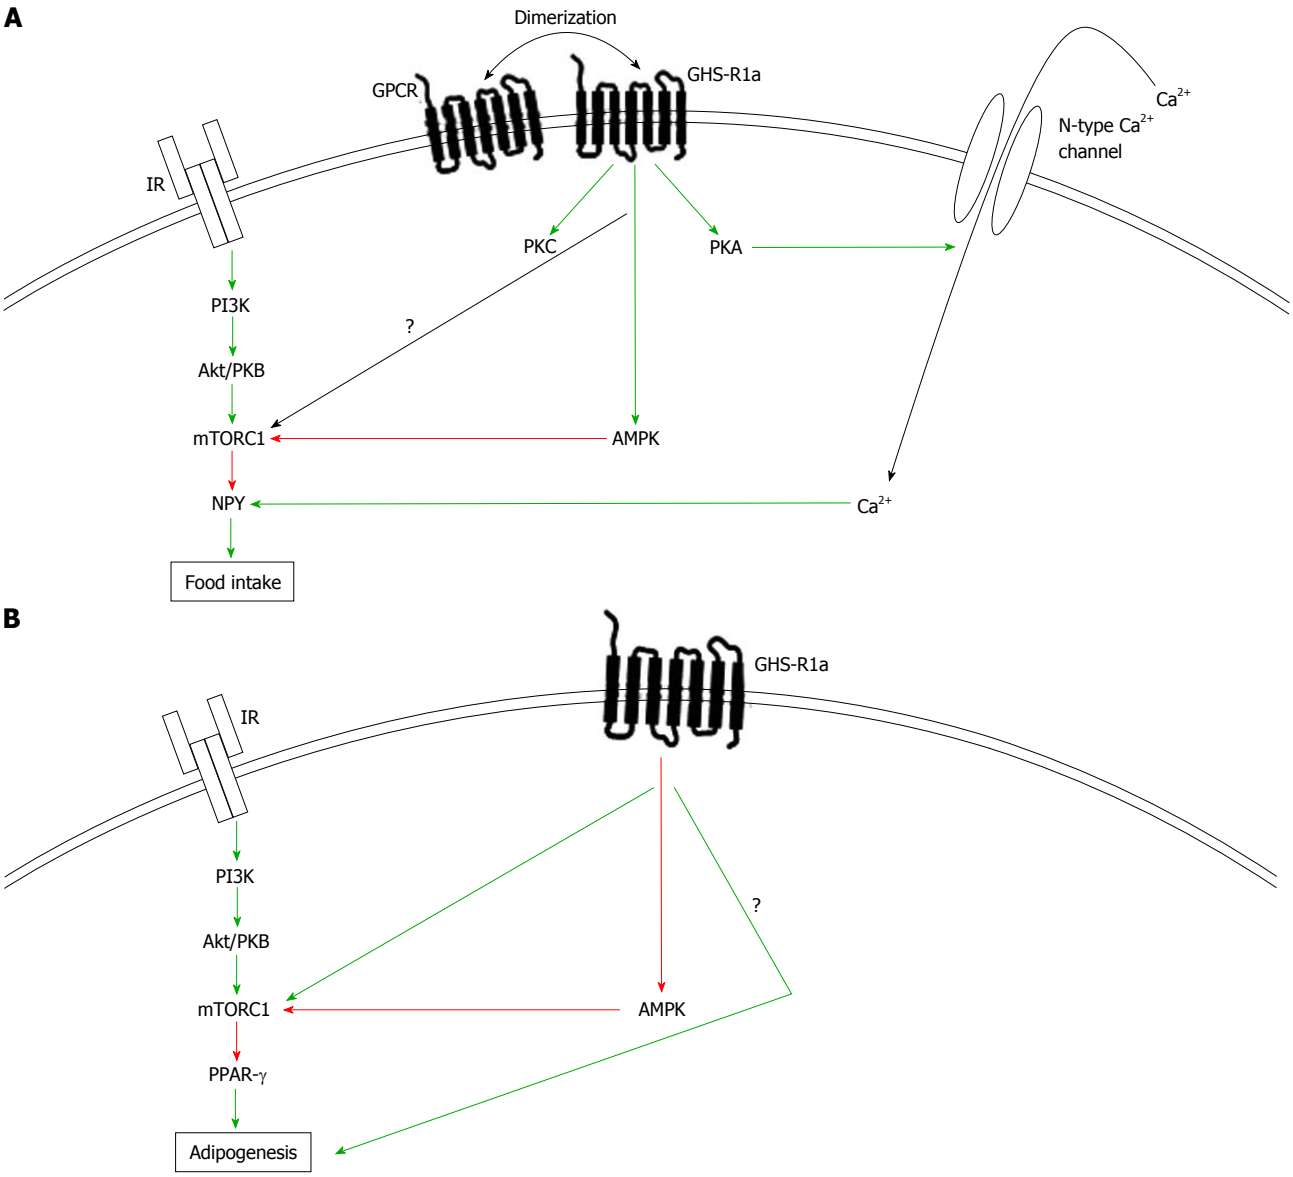

Figure 1 Crosstalks between ghrelin and insulin signaling. A: In the CNS, the interaction between GHS-R1a and ghrelin leads to the activation of PKC and PKA and ultimately to the opening of calcium channels. In the ARC, AG's orexigenic effects are solely mediated through PKA activation and the intracellular entry of Ca^{2+}; which in turn, generate a depolarization/activation of NPY neurons. GHS-R1a activation also triggers AMPK phosphorylation. Also, the activation insulin signaling pathway leads to a phosphorylation cascade that involves PI3K, Akt/PKB and mTORC1. mTORC1 has been shown to reduce food intake by inhibiting NPY expression in ARC neurons. This suggests the existence of a crosstalk between these two signaling pathways, considering that AMPK inhibits mTORC1 activation while ghrelin also reduces the anorexigenic effects of insulin-mTORC1. GHS-R1a could also mediate mTORC1 activation through an AMPK-independent mechanism. Moreover, GHS-R1a has been shown to dimerize with some GPCRs such as Gpr83, DRD1/2 and MC3R; B: In the periphery, the adipogenic effects of ghrelin have been shown to synergize with insulin signaling. In contrast to its central effects, the interaction between GHS-R1a and AG leads to decreases in AMPK activity in the periphery. GHS-R1a also activates Akt, PKB, mTORC1 and ultimately PPAR-γ to stimulate insulin-induced adipogenesis. CNS: Central nervous system; PKC: Protein kinase C; PKA: Protein kinase A; ARC: Arcuate nucleus; GHS-R1a: Growth hormone secretagogue receptor 1a; NPY: Neuropeptide Y; AG: Acylated ghrelin; AMPK: AMP-activated protein kinase; mTORC1: Mechanistic target of rapamycin complex 1; MC3R: Melanocortin receptor 3; DRD1/2: Dopamine receptor subtypes 1 and 2; Gpr83: G protein-coupled receptor 83; GPCR: G protein-coupled receptors; PPAR-γ: Peroxisome proliferator-activated receptor γ; IR: Insulin receptor.

COMMON PATHWAY FOR GHRELIN AND INSULIN RECEPTOR SIGNALING

In the central nervous system

As mentioned above, it is believed that the effects of ghrelin on feeding are mainly exerted through the ARC[29,56,57]. Since the central administration of ghrelin increases the mRNA expression of NPY and AgRP while inhibiting the transcription of POMC and CART, it has been suggested that the orexigenic actions of ghrelin are mediated through the activation of these neurons[29,44-49,58]. As presented in Figure 1A, GHS-R1a activation regulates intracellular calcium through the adenylate cyclase-protein kinase A (PKA) and phospholipase C-protein kinase C (PKC) pathways[43,59]. The PKA pathway has been shown to be related to the orexigenic effects of ghrelin since inhibitors of PKC do not influence the calcium response to ghrelin in NPY neurons of the ARC[43]. Consequently, GHS-R1a activation in the ARC elicits calcium signaling through N-type calcium channel-dependent mechanisms.

AMP-activated protein kinase (AMPK) plays an important role in the regulation of energy metabolism. This kinase is activated following an increase in the AMP/ATP ratio within the cell, a condition linked to cellular energy depletion[60]. Once activated, AMPK phosphorylates acetyl-CoA carboxylase and switches on catabolic processes to promote ATP production[60]. Current evidence indicates that ghrelin could be considered as a signal of energy deficiency since it activates AMPK in the CNS. Moreover, ghrelin-induced calcium entry is substantially suppressed by an AMPK inhibitor[61]. Consistent with these observations, GHS-R1a positively modulates hypothalamic AMPK[61,62]. In turn, the pharmacological activation of AMPK was also shown to stimulate food intake in the hypothalamus[62]. This reinforces the view that AMPK is critical in the control of feeding. However, little is known regarding the potential mechanisms through which AMPK-activation would mediate ghrelin's orexigenic effects. Recent data suggest that in response to fasting, increased ghrelin levels promote feeding through AMPK-mediated activation of hypothalamic fatty acid metabolism in the ventromedial hypothalamus (VMH)[63]. Further studies are needed to identify the mechanisms underlying ghrelin's activation of AMPK and to characterize the neuronal centers involved in the stimulation of appetite.

AMPK influences the insulin signaling pathway, suggesting that ghrelin-induced activation of AMPK could affect this pathway. In fact, the activation of AMPK inhibits the mechanistic target of rapamycin (mTOR) complex 1 (mTORC1) activity, a key protein complex activated downstream of the insulin receptor (IR). mTORC1 is a central regulator of cell metabolism, growth, proliferation and survival and acts as a nutrient/hormone sensor[64,65]. In the CNS, mTORC1 activation reduces food intake at least by reducing the hypothalamic expression of NPY and AgRP[66,67]. Recent data indicate that ghrelin requires an intact hypothalamic mTORC1 to stimulate food intake[68]. In this study, the authors suggest that orexigenic effect of ghrelin is mediated by AMPK in the VMH, but through the mTORC1 in the ARC. These results are rather counterintuitive since the effects of AMPK and mTORC1 usually antagonize each other. AMPK activation promotes food intake whereas mTORC1 does the opposite. Indeed, injection of insulin in rodents inhibits AMPK activity in the hypothalamus, promotes mTORC1 activation, and reduces food consumption[69]. Recently, is has been suggested that ghrelin plays a dual time-dependent role in modulating hypothalamus, since it only transiently affects AMPK, which might explain the conflicting results[70]. More studies are needed to better understand the signaling events mediating the effects of ghrelin on the regulation of food intake.

In the periphery

As indicated in Figure 1B, in contrast to its central effects, ghrelin decreases AMPK activity in the periphery, indicating that the hormone bilaterally controls AMPK in the brain and peripherally. Because of this divergence in AMPK activation between the brain and the periphery, it is expected that ghrelin and insulin signaling crosstalks will be different in the CNS versus the periphery. In the periphery, it was observed that ghrelin stimulates adipogenesis[10,22]. The adipogenic effects of ghrelin are mediated, at least in part, through the activation of peroxisome proliferator-activated receptor γ (PPAR-γ), a nuclear receptor whose activity is positively influenced by key components of the insulin pathway, namely Akt/PKB and mTORC1[71-73]. In fact in the periphery, AG promotes adipogenesis through PPAR-γ. Interestingly, a fully operational form of the mTORC1 complex is required for PPAR-γ activation; suggesting that AG's adipogenic effects could be mediated through mTORC1. Consistently, ghrelin promotes activation of the Akt/PKB pathway in macrophages, and this activation results in an enhanced activation of PPAR-γ[74]. Unlike in the CNS, GHS-R1a adipogenic actions seem to synergize with the insulin signaling pathway, establishing the need to further understand the discrepancies between mTOR, AMPK, insulin and ghrelin action in the brain versus peripheral tissues. It is noteworthy that both endogenous and pharmacological activation of AMPK prevent adipogenesis while downregulating the expression of key adipogenic genes including PPAR-γ in the periphery[75,76]. Overall, these elements suggest that ghrelin needs to inhibit peripheral AMPK to exert its effects on fat accumulation.

It is also suggested that the insulin signaling pathway and insulin *per se* can affect ghrelin production and signaling. It has been shown that components of the mTOR signaling pathway are expressed in the endocrine cells of gastric mucosa, where nearly all ghrelin-positive cells are positively stained for these signaling molecules[77]. Moreover, rapamycin, a mTORC1 inhibitor increases gastric ghrelin mRNA, gastric preproghrelin levels and circulating ghrelin, demonstrating that the mTORC1 signaling pathway is crucial in ghrelin expression and secretion[78]. Therefore, insulin could also directly affect ghrelin secretion. Altogether, these findings strongly suggest the existence of a link between ghrelin and insulin signaling pathways. The following sections will focus on the physiological impact of such a relationship on glucose homeostasis, insulin secretion and ghrelin levels in cellular, animal and human models.

GHRELIN AND GLUCOSE HOMEOSTASIS

The influence of ghrelin on the regulation of glucose homeostasis was first hypothesized following the observation of a negative correlation between circulating ghrelin and insulin levels in humans[79]. Later, an association between ghrelin and the homeostasis model of assessment, an index of insulin resistance, in women with polycystic ovary syndrome (PCOS) further supported the involvement of ghrelin in the development of insulin resistance and type 2 diabetes[80]. Subsequently, the association of ghrelin with insulin, glucose and insulin resistance indexes was investigated in different populations with definite metabolic profiles. For instance, in obese and non-obese

children and obese adults with or without insulin resistance or type 2 diabetes, pre-meal total ghrelin levels were inversely associated to insulin levels and the severity of insulin resistance[81-83]. The recent development of new and more sensitive immunoassays has allowed the characterization of distinct biological activity of AG and UAG in healthy and pathological conditions. This led to the observation that AG, rather than UAG, reduces insulin secretion while promoting insulin resistance in individuals with or without metabolic dysfunctions[27,84].

Soon after its discovery, ghrelin was shown to be secreted in a pulsatile manner in response to the nutritional status[31]. In clinical studies, ghrelin levels were initially measured from a unique sample in participants submitted to an overnight fast. However more elaborate study designs have been developed to allow the determination of ghrelin levels at different time points in pre-meal and postprandial conditions. The first evidence suggesting the involvement of ghrelin in the regulation of insulin secretion was provided by the observation of a positive association between suppression of total ghrelin levels and insulin concentrations in the postprandial condition in participants with uncomplicated obesity[85]. In addition, total ghrelin levels were negatively correlated to insulin resistance in obese children and adolescents[83].

As previously reviewed[86,87], several research teams have reported a link between ghrelin and the regulation of glucose homeostasis but this was often achieved using one single fasting sample of total ghrelin. Although they provided key information, data generated from these studies were often not in line with results obtained using AG or UAG treatments in cell, animal and human models. Accordingly, the inverse correlations of ghrelin with insulin levels and insulin resistance commonly described in the literature seem rather counter-intuitive at first glance for an adipogenic hormone promoting food intake and decreased energy expenditure. Indeed, we would expect that ghrelin, which drives food intake and adiposity would be positively associated with impaired metabolic functions. It is therefore likely that under physiological conditions, ghrelin acts as a regulator of energy balance to stimulate appetite and the storage of energy substrates while reducing energy expenditure in periods of limited food availability. However, when nutrients are abundant, ghrelin levels decrease to prevent the excessive accumulation of energy substrates. Some also suggest the existence of a state of ghrelin resistance since high-fat consumption blunts the effects of intracerebroventricular-administrated ghrelin on GH secretion, ARC neurons activation and NPY/AgRP expression[88]. From an evolutionary perspective, ghrelin could favor survival for individuals having limited access to nutrients. However, impairments in the regulation of ghrelin secretion, caused by the ingestion of specific nutrients or other genetic/environmental factors, could promote the excessive accumulation of lipids and ultimately the development of metabolic dysfunctions such as insulin resistance and type 2 diabetes.

EFFECTS OF GHRELIN ON INSULIN SECRETION

It was initially reported that a population of ghrelin- and insulin-producing cells would have common embryonic progenitors within the developing endocrine pancreas[89]. In the pancreas, ghrelin-positive ε-cells are found as single cells in islet periphery. Ghrelin is also co-expressed with glucagon-secreting cells in humans and rats[17,90-94]. The expression of GHS-R1a was also detected in islets as well as in several pancreatic cell lines, suggesting that ghrelin and its receptor could influence pancreatic functions in a paracrine manner[95].

As presented in Table 1, the first direct evidence suggesting the influence of ghrelin on the regulation of insulin secretion was provided by Broglio *et al*[21] in healthy volunteers. In fasting condition, AG administered at 1 μg/kg intravenously (*iv*) significantly reduced circulating insulin levels while increasing glycemia. Using the same conditions, AG was shown to reduce insulin secretion in young and elderly participants[106]. Since AG has a relatively short half-life in circulation, continuous administrations of the peptide were performed to confirm the results obtained using bolus injections. The continuous infusion of AG (1 μg/kg per hour) decreased the first phase of insulin secretion postprandially, while causing a significant rise in glycemia[96,107]. This increase in blood glucose was also associated to an enhanced second-phase insulin response. Similarly, Vestergaard *et al*[101-105] observed that AG infusions (0.3 μg/kg per hour to 1.0 μg/kg per hour) promote insulin resistance; however they did not detect any fluctuation in insulin secretion[100,101]. At lower concentrations (0.3 to 1.5 ng/kg per hour), AG infusions reduced insulin secretion and glucose levels[108]. The same authors have also observed a decrease in insulin secretion in response to the administration of physiological concentrations of AG (0.2 and 0.6 ng/kg per hour)[26,109]. Consequently, it is suggested that physiological levels of ghrelin directly impair β-cell functions but the mechanisms underlying these effects remain to be clarified[109]. One appealing hypothesis is that these inhibitory effects of AG on insulin release could be mediated through the stimulation of somatostatin production[97]. In contrast, a single bolus of AG (1 μg/kg) did not induce any alteration of glucose or insulin levels in obese women[110]. In a clinical study, UAG was administered for 16 h at 1.0 μg/kg per hour and the postprandial insulin response was potentiated in healthy volunteers[111]. Following a meal, the inhibitory effect of AG on insulin release was abrogated by the co-administration with UAG[96]. Furthermore, Kiewiet *et al*[112] reported that the combined treatment with AG and UAG increased insulin sensitivity in morbidly obese patients. Altogether, these studies show that ghrelin has complex effects when administered to humans and that the impact of this hormone on glucose homeostasis likely depends on the dose, the nutritional status and the metabolic profile of the population studied. Furthermore, the biphasic insulin response observed

Table 1 Effects of ghrelin treatment in human participants

Model	Treatment	Dose	Condition	Endogenous insulin	Insulin sensitivity
Healthy or hypopituitary humans	AG *vs* Ctrl (*iv*) AG + Arg *vs* Arg (*iv*)	AG: 1 to 2.2 μg/kg Arg: 0.5 g/kg	Fasting (overnight)	Decreased	Decreased[21,96-99]
Healthy or hypopituitary humans	AG + FFA *vs* FFA AG + UAG	AG: 1 μg/kg FFA: 25 g UAG: 1 μg/kg	Fasting (overnight)	Decreased	No change[96,98]
Healthy humans	AG + OGTT (*iv*) *vs* OGTT UAG *vs* Ctrl (*iv*) AG + UAG *vs* Ctrl (*iv*)	AG: 1 μg/kg OGTT: 100g UAG: 1 μg/kg	Fasting (overnight)	No change	No change[96,98]
Healthy humans	AG *vs* Ctrl (*iv*)	AG: 1 μg/kg	Fasting (overnight)	Increased	Decreased[96]
Healthy humans	AG *vs* Ctrl infusion 3h (*iv*)	AG: 5 pmol/kg per minute	Fasting (overnight)	-	Decreased[100]
Healthy, gastrectomized or hypopituitary humans	EHC: AG *vs* Ctrl 5 h (*iv*) pancreatic clamp + EHC:AG *vs* Ctrl 5 h (*iv*)	AG: 5 pmol/kg per minute	Fasting (overnight)	-	Decreased[101-104]
Healthy humans	EHC: AG 5 h (intramuscular)	AG: non-specified supraphysiological dose	Fasting (overnight)	-	Increased[105]

AG: Acylated ghrelin; *iv*: Intravenous; Arg: Arginine; Ctrl: Control; UAG: Unacylated ghrelin; OGTT: Oral glucose tolerance test; EHC: Euglycemic/hyperinsulinemic clamp.

after the administration of AG indicates that the peptide could exert distinct effects on β-cells: an initial inhibition of insulin release combined to a subsequent stimulation of insulin synthesis[96,107]. Further studies are needed to clarify the causes of the variability in insulin secretion and glucose homeostasis observed in response to ghrelin. To do so, it is critical to establish the concentrations at which ghrelin will be administered, and to design clinical protocols with well-established nutritional status and sufficient blood samples to allow detecting positive/negative effects on insulin release under specific metabolic conditions.

Similarly to the available data in humans, data derived from most rodent studies indicate that AG inhibits insulin secretion. In wild type mice, *iv* administrations of AG (5 nmol to 150 nmol) were shown to inhibit fasting and glucose-induced insulin secretion[113]. In contrast, insulinotropic effects have been reported in response to an *iv* injection of AG (25 nmol/L) in rats[114]. In mice, the administration of AG (1 to 10 nmol/kg, *iv*) was also shown to induce biphasic responses[115]. In fact AG was shown to inhibit insulin release by blocking the effects of a cholinergic antagonist on the activation of phospholipase C (PLC) after 2 min but this effect was reversed 6 min after treatment[115]. During the early phase (2 min), ghrelin also promoted the stimulation of insulin secretion by potentiating the response of the phosphodiesterase inhibitor IBMX, but this effect could no longer be observed at 6 min. The same group also reported that the stimulatory effect of ghrelin on insulin release was accompanied by increases in nitric oxide and that this outcome was mediated by the activation of the neuronal constitutive nitric oxide synthase[116]. In mice, AG promptly inhibits insulin release but this effect is reversed over time. This suggests that AG could block the first-phase of insulin secretion and subsequently allow β-cells to release the hormone. Although these effects were modulated through PLC and phosphodiesterase, the mechanisms underlying these observations remain to be elucidated. Consequently, following the description of this biphasic response, it is even possible to speculate that AG's effects could be mediated through the activation of more than one distinct receptor. For instance, these effects could potentially be regulated by the formation of homo- and heterodimers between GHS-R1a and other receptors such as Gpr83 and DRD1/2[37,41]. Interestingly, the expression of both GHS-R1 and DRD2 was previously reported in β-cells[41,95]. Furthermore, DRD2 was shown to inhibit insulin secretion through the activation of the β_2-adrenergic receptor[117]. This indicates that under distinct conditions, AG (and potentially UAG) could mediate the dimerization of GHS-R1 and consequently exert different effects on β-cell functions.

Genetic manipulations have also provided key data regarding ghrelin actions. Overexpression of the ghrelin (*Ghrl*) gene was shown to decrease insulin levels in mice, while its inactivation was shown to enhance insulin secretion and to prevent glucose intolerance[118-120]. In leptin-deficient mice, the deletion of the *Ghrl* gene potentiates insulin secretion and improves glucose homeostasis[121,122]. The pharmacological inhibition of GHS-R1 was also shown to increase insulin secretion and improve glucose homeostasis[123]. In contrast, the ablation of the *Ghs-r1* gene decreased glucose control and reduced insulin secretion in leptin-deficient mice[124]. This impaired insulin response was associated with the upregulation of Uncoupling protein-2 (Ucp-2), Sterol regulatory-element binding protein-1c (Srebp-1c), Carbohydrate-responsive element-binding protein (Chrebp) and Macrophage migration inhibitory factor-1 (Mif-1) and with the downregulation of Hypoxia-inducible factor-1α (Hif-1α), fibroblast growth factor-21 (Fgf-21) and Pancreatic and duodenal homeobox-1 (Pdx-1) in whole pancreases[124]. These genes are known to decrease (*Ucp-2, Srebp-1c*, *Chrebp* and *Mif-1*) or improve (*Hif-1α*, *Fgf-21* and *Pdx-1*) β-cell functions. Another group has also suggested that the effect of AG could be mediated through an increased production of the β-cell autoantigen for type 1 diabetes (IA-2β)[125]. In perfused rat pancreases, the influence of AG on insulin release was also investigated. AG (10 nmol/L) was shown

to promptly decrease insulin *in situ* secretion[126].

The effects of ghrelin on the regulation of insulin secretion were also investigated *in vitro*. In pancreatic tissue fragments of normal and diabetic rats, treatments with AG (1 pmol/L to 1 μmol/L) induced insulinotropic effects[127]. This effect was also observed in response to high doses of AG (0.1 to 1 μmol/L) in cultured isolated mice islets[115]. In contrast, AG was shown to inhibit insulin secretion in immortalized pancreatic β-cells (AG at 0.1 μmol/L) and in cultured mouse islets (AG 1 to 100 pmol/L)[115,128]. It is noteworthy that glucose levels and time of incubation were critical elements mediating AG's effects on insulin release. Accordingly, AG's insulinotropic effects were only detected at glucose concentrations above 8.3 mmol/L[94,115,127,128]. Data obtained in rodents indicate that ghrelin promptly mediates its effects on β-cell function[115]. In the circulation, AG must exert its activity quickly before being degraded. However, *in vitro* AG treatments were carried out for at least 30 min. It is therefore necessary to design experiments allowing the characterization of ghrelin's effects on insulin release in a time-resolved manner. This would allow determining whether ghrelin directly mediates insulin release and/or its synthesis within β-cells.

The effects of AG and UAG on β-cells have been explored to clarify the effects of both ghrelin forms on survival, proliferation and insulin release. It has been demonstrated that both AG and UAG stimulate insulin release in different β-cell lines[129,130]. Furthermore, in response to an intravenous glucose tolerance test, the administration of UAG at 30 nmol/kg was shown to potentiate insulin release in anesthetized rats[131]. Although these effects could not be detected in rat and mouse isolated islets, the inhibitory effect of AG on insulin release was reversed by the combined treatment with UAG[132]. Granata *et al*[130,133] also reported that both ghrelin forms promote cell survival and prevent apoptosis in different β-cell lines. This group also reported that UAG treatment (two subcutaneous administrations of 100 μg/kg for 7 d) could prevent diabetes in newborn rats treated with streptozocin. Although UAG has been shown to influence the release of insulin, important questions remain regarding the mechanisms underlying these effects in the pancreas. For instance, it will be critical to determine whether ghrelin influences the acute release of insulin or its synthesis within β-cells.

The information contained in the above paragraphs suggests that AG inhibits while UAG restores insulin secretion. Although there are many discrepancies in the literature, evidence suggests that the influence of ghrelin on β-cell function depends on the dose of ghrelin used for the treatment as well as the glycemic state under which experiments are carried out. The available data also indicates the relevance of establishing a time-frame during which responses occur. In fact, different groups have described that ghrelin mediates a biphasic response with rapid inhibition and subsequent stimulation of insulin release. Also, homo- and heterodimerization of the GHS-R1a receptor could explain the conflictual observations currently reported in the literature. It is therefore critical to fully determine the (1) optimal doses of AG and UAG; (2) conditions; and (3) the time continuum under which ghrelin influences β-cell functions. Due to its adipogenic nature, it is also of potential interest to investigate whether chronic hyperprolinemia could promote lipotoxicity within β-cells.

EFFECTS OF INSULIN ON CIRCULATING GHRELIN LEVELS

Early after the discovery of ghrelin, an inverse relationship was observed between the ghrelin and insulin levels in animal and human models. In the previous section, the effects of AG and UAG on insulin were reviewed. However, the influence of insulin on both ghrelin forms has also been investigated. It was initially observed that ghrelin levels decrease significantly in healthy participants in response to food intake[134,135]. Moreover, under fasting conditions, ghrelin levels were shown to be inversely correlated with insulin values[79]. Taken together, these elements suggest that insulin could reduce circulating ghrelin levels.

Ghrelin levels have been measured following the intake of different types of meals. However, to isolate the effect of insulin and eliminate potential confounding factors, specific models mimicking postprandial conditions such as the oral glucose tolerance test (OGTT) or the euglycemic hyperinsulinemic clamp (EHC) have been used. It was first reported that total ghrelin levels are significantly reduced in response to OGTT or mixed meals in healthy participants after approximately 35 min[136,137]. In these studies, circulating ghrelin levels were decreased in response to insulin but not following the combined parenteral administration of insulin and glucose[136,137]. These results suggest that decreases in ghrelin levels are not directly mediated by insulin but rather through other mechanisms that require nutrients transiting in the gastrointestinal tract.

Clinical protocols were also designed to study the variations in total ghrelin levels under defined hyperinsulinemic conditions. For instance, in healthy and obese volunteers submitted to EHC or hypoglycemia, total ghrelin levels were significantly reduced[85,138]. Interestingly, in slightly overweight individuals submitted to EHC, total ghrelin concentrations were reduced by 25% and these effects were still detectable 15 min after the insulin infusion ended[139]. Also, under the euglycemic/hyperinsulinemic condition, total ghrelin levels were further reduced by the co-administration with GH and an inhibitor of hormone-sensitive lipase activity in GH-deficient patients[140]. Similar results were observed in response to three-steps hypo-, eu- and hyperglycemic/hyperinsulinemic clamps[141]. Although total ghrelin concentrations were stable before the administration of insulin, the levels of the hormone promptly decreased in response to hyperinsulinemia and remained stable during the hypo- and euglycemic states. However, the most important

reductions in ghrelin levels were noted during the hyperglycemic/hyperinsulinemic conditions. In another study, healthy participants were submitted to three different types of clamps[142]. During the first clamp, hyperglycemia and the resulting elevation of endogenous insulin did not alter ghrelin levels[142,143].

The impact of EHC on ghrelin levels was also studied in different pathological conditions including Pradder-Willi syndrome (PWS), PCOS, and hyper- and hypothyroidism. For instance, elevated total ghrelin levels were reported in children with PWS. The influence of EHC on total ghrelin levels was therefore investigated in both patients with PWS and normal children[144]. Under these conditions, total ghrelin levels were decreased to a greater extent but still remained higher throughout the EHC in patients with PWS compared to controls. Total ghrelin levels were higher in PWS children and their response to EHC was proportional to the one of control individuals. Glucose disposal was similar between normal children and PWS patients, suggesting that under hyperinsulinemic conditions ghrelin levels are reduced in function of the degree of insulin resistance rather than being solely influenced by insulin and glucose levels. To confirm this, patients with type 2 diabetes and healthy individuals were also submitted to EHC. In these patients, fasting total ghrelin levels were lower than in healthy individuals. As expected, total ghrelin levels reduction was significantly less pronounced in patients with type 2 diabetes compared to healthy individuals[145]. This suggests that impairments in IR signaling could disturb the physiological regulation of ghrelin levels. It is recognized that ghrelin levels and insulin sensitivity are lower in women with PCOS. To further study the effect of insulin sensitivity on the regulation of ghrelin levels, women with PCOS were submitted to EHC. Unexpectedly ghrelin levels were not differently modulated in PCOS than in normal women, indicating that the androgen levels could also influence the modulation of ghrelin in this population[146].

Patients with hyperthyroidism also exhibit a negative association between total ghrelin levels and energy expenditure[147]. In these patients, ghrelin levels are also decreased. To investigate the effect of hyperthyroidism normalization, ghrelin levels were measured during EHC before and after medical treatment with antithyroid hormones. Similarly, increased ghrelin levels are observed before and after normalization in patients with hypothyroidism[148]. Despite this difference, ghrelin profiles observed during EHC were not altered by antithyroid treatment or by L-thyroxine (T4) replacement[148,149]. These results indicate that the reduction in ghrelin observed during EHC is independent of thyroid status. The effect of ghrelin on the hypothalamo-pituitary-thyroid axis was also investigated in healthy participants. In contrast to the results obtained in patients who underwent hyper- or hypothyroid normalization, the administration of AG (50 μg) directly increased free T4 while reducing thyroid stimulating hormone concentrations in the circulation[150]. This suggests that the thyroid status does not influence the inhibitory effect of insulin on ghrelin secretion; however ghrelin treatment could directly regulate thyroid functions.

Total ghrelin levels are decreased to a greater extent during EHC in individuals with high insulin sensitivity. However the impact of insulin on the circulating levels of AG and UAG remained uncharacterized for many years. To further characterize the effects of hyperinsulinemia on the different forms of circulating ghrelin, we decided to measure AG and total ghrelin (and estimate UAG levels by subtracting total ghrelin-AG values) during EHC in insulin-sensitive (ISO) and insulin-resistant (IRO) obese postmenopausal women[27]. Total ghrelin and UAG levels were significantly decreased by EHC in ISO and IRO women. However, during EHC, AG levels were significantly reduced only in ISO individuals and the maximal amplitude of reduction was more important than in ISO participants. Similarly, the AG/UAG ratio was significantly lower in ISO women in the fasting condition and throughout EHC. Interestingly, in the total population (ISO + IRO), the maximal amplitude of reduction for total ghrelin and AG were both positively correlated with insulin sensitivity. It was later shown that fasting AG and UAG levels are decreased between the second and the third term of pregnancy in women with diabetes[151]. This was also associated with less important decreases in UAG but not in AG during EHC.

The molecular mechanisms by which insulin regulates ghrelin levels were investigated only in a limited number of studies. Similarly to the results obtained in humans, insulin was shown to reduce total ghrelin levels in rats[152]. Data presented in the signaling section also provided evidence that the gastric insulin signaling activation influences ghrelin mRNA, gastric preproghrelin and circulating ghrelin. Results from two different studies in rodents also indicate that a hyperinsulinemic state could enhance ghrelin mRNA expression but there is no information available on protein levels[31,114]. Although the effects of insulin on total ghrelin levels have been abundantly studied in the literature, it remains that AG and UAG profiles need to be further characterized. Therefore it is critical to decipher the mechanisms mediating the effects of insulin and potential receptor signaling impairments on AG and UAG secretion both in animal and human models under normal and pathological conditions.

CONCLUSION

Although it was discovered more than ten years ago and was the object of an impressive number of publications, important questions still remain regarding the physiological control of AG and UAG secretion and the distinct role of both ghrelin forms in the regulation of metabolic functions. The present work intends to highlight the interrelationships between ghrelin, insulin and glucose homeostasis. Available data indicate that ghrelin influences insulin secretion and vice versa. New evidence suggests the existence of crosstalks between the signaling pathways induced by the activation of the native ghrelin receptor, GHS-R1a and the insulin receptor. However, these interactions seem to oppose themselves

as they are taking place in the central nervous system or in the periphery. This suggests that in different tissues and organs, the heterodimerization of GHS-R1a with Gpr83, DRD1/2, MC3R and potentially other receptors could trigger the activation of distinct signaling pathways. Other important issues were denoted in the literature regarding the insulinotropic effects of ghrelin in cellular, animal and human models. This suggests the critical need to better determine doses under which AG and UAG optimally activate distinct metabolic functions. Taking into consideration the complexity of ghrelin's physiology it is also important to characterize the conditions under which altered responses to AG and UAG are observed. Overall, these clarifications should provide a better understanding of the mechanisms underlying AG and UAG secretion as well as to allow the deciphering of their role in the regulation of distinct metabolic functions.

Abstract

Diabetic kidney disease (DKD) is the most common cause of chronic kidney disease, leading to end-stage renal disease and cardiovascular disease. The overall number of patients with DKD will continue to increase in parallel with the increasing global pandemic of type 2 diabetes. Based on landmark clinical trials, DKD has become preventable by controlling conventional factors, including hyperglycemia and hypertension, with multifactorial therapy; however, the remaining risk of DKD progression is still high. In this review, we show the importance of targeting remission/regression of microalbuminuria in type 2 diabetic patients, which may protect against the progression of DKD and cardiovascular events. To achieve remission/regression of microalbuminuria, several steps are important, including the early detection of microalbuminuria with continuous screening, targeting HbA1c < 7.0% for glucose control, the use of renin angiotensin system inhibitors to control blood pressure, the use of statins or fibrates to control dyslipidemia, and multifactorial treatment. Reducing microalbuminuria is therefore an important therapeutic goal, and the absence of microalbuminuria could be a pivotal biomarker of therapeutic success in diabetic patients. Other therapies, including vitamin D receptor activation, uric acid-lowering drugs, and incretin-related drugs, may also be promising for the prevention of DKD progression.

Key words: Diabetic kidney disease; Glycemic control; Renin-angiotensin system inhibitor; Multifactorial therapy; Remission and regression of albuminuria

Core tip: We show the significance of targeting the remission/regression of microalbuminuria in type 2 diabetic patients, leading to protection against the progression of diabetic kidney disease (DKD) and cardiovascular events. To achieve the remission/regression of microalbuminuria, the multifactorial intervention and the early detection of microalbuminuria with continuous screening is important, as management of DKD. Multifactorial intervention includes glucose, blood pressure and lipid control. Additionally, other therapies, including vitamin D receptor activation, uric acid-lowering medicine and incretin-related medicines may be promising for preventing the progression of DKD. We review the current standard treatment for DKD and other prospective therapies for DKD.

INTRODUCTION

The prevalence of diabetes mellitus is increasing. According to the International Diabetes Federation Atlas of 2012, the estimated diabetes prevalence in 2012 was 371 million, representing 8.3% of the world's adult population; it was predicted that by 2030, the number of people with diabetes in the world will have risen to 552 million[1]. Long-term diabetes results in vascular changes and dysfunction, and diabetic complications are the major causes of morbidity and mortality in diabetic patients. Among diabetic vascular complications, diabetic kidney disease (DKD) is a common cause of chronic kidney disease (CKD) and is a leading cause of end-stage renal disease (ESRD)[2]. In addition, microalbuminuria/proteinuria and a decline in the glomerular filtration rate (GFR) are observed in CKD and are recognized as independent risk factors for the development of ESRD and the onset of cardiovascular diseases, respectively. Therefore, it is important to establish therapeutic strategies for DKD.

The pathogenesis of DKD is complex and has not yet been completely elucidated. Hyperglycemia is one major factor that is responsible for the pathogenesis of DKD[3]. Moreover, elevated systemic blood pressure and intra-glomerular pressure, which are associated with the renin-angiotensin system (RAS), several cytokines and growth factors induced by metabolic and hemodynamic factors, and abnormal lipid metabolism are involved in the pathogenesis of DKD[4,5]. Current therapeutic strategies targeting these mechanisms, particularly the control of blood glucose and blood pressure, have been established in many hallmark clinical trials. In addition, a reduction in microalbuminuria is more frequent than progression to overt proteinuria, and a multifactorial control approach is important for this reduction in microalbuminuria, leading to reductions in renal and cardiovascular risk. In this review, we discuss the current standard treatment and other prospective therapies in DKD (especially early stage) that target a reduction of albuminuria.

MECHANISMS OF ALBUMINURIA IN DKD

Albuminuria is a signature feature of DKD. Albuminuria in DKD is predominantly due to impairment in the glomerular filtration barrier, consisting of the glomerular endothelial cells, the glomerular basement membrane (GBM), and the podocytes[6]. Podocytes are the predominant component of this barrier, and the reduced number of podocytes due to increased apoptosis and detachment from the GBM is observed in the diabetic kidney, resulting in leakage of albumin through areas of denuded podocytes[7-12]. In addition to a decrease in podocyte number and density, the widening of the foot processes, shortening of the slit diaphragm/loss of slit diaphragm proteins, changes in the actin cytoskeleton, and decreases in negative charge may cause albuminuria in DKD[13-15]. Furthermore, endothelial cell injuries in diabetic conditions leading to reduced nitric oxide production[16,17], altered vascular endothelial growth factor (VEGF) signaling[18,19] and diminished glycocalyx[20] also play pivotal roles in albuminuria. Glomerular endothelial cells and podocytes crosstalk through several mediators, including VEGF-A[19], angiopoietin-1[21,22] and -2[23] and activated protein C[24]; therefore, the missing link between endothelial cells and podocytes in diabetic conditions contributes to dysfunction of both cell types, resulting in increased albuminuria[25]. Glomerular hemodynamic changes, including hyperfiltration and hyperperfusion, are observed in diabetic conditions and hypertension. Elevated intraglomerular pressure creates a shear stress on the glomeruli and leads to an increase in albuminuria due to endothelial and podocyte dysfunction[26]. Vascular endothelial dysfunction is closely related to the pathogenesis of the initiation of cardiovascular disease (CVD); albuminuria also reflects glomerular endothelial dysfunction. Therefore, albuminuria is a marker of both glomerular and early systemic endothelial dysfunction[27,28].

Tubular cell injury may also contribute to albuminuria by impairing proximal tubular albumin and protein reabsorption. In diabetes, proximal tubular reuptake of albumin and protein may be impaired by high glucose[29], transforming growth factor (TGF)-β[30], or angiotensin Ⅱ [31]. Tubulointerstitial injury is enhanced and the ability to reabsorb albumin and protein is further reduced, along with the development of glomerular disease, and there is a direct correlation between the degree of tubulointerstitial scarring and the extent of albuminuria[32].

SCREENING METHODS AND DIAGNOSIS OF DIABETIC KIDNEY DISEASE

The early clinical sign of DKD is elevated urinary albumin excretion, referred to as microalbuminuria, which progresses to overt proteinuria and leads to nephritic-range proteinuria in some cases. Increasing albuminuria (proteinuria) leads to a decline in renal function, which is defined in terms of the GFR[33] and generally progresses inexorably to ESRD 6-8 years after the detection of overt proteinuria[34]. Microalbuminuria is defined as a urinary albumin-creatinine ratio (ACR) of 30-299 mg/g creatinine (Cr), and macroalbuminuria is defined as an ACR > 300 mg/g Cr[35]. Elevated ACR should be confirmed in the absence of urinary tract infection in two additional first-void specimens collected during the following 3 to 6 mo[35].

Microalbuminuria in diabetic patients has been recognized as a useful biomarker for diagnosing DKD and as a predictive factor for progression to ESRD. In most patients with diabetes, CKD should be attributed to diabetes if any of the following is true: macroalbuminuria is present, microalbuminuria is present in the presence of diabetic retinopathy, or type 1 diabetes has occurred with a duration of at least 10 years[35]. However, other causes of CKD should be considered in the presence of any of the following circumstances: diabetic retinopathy is absent, GFR is low or rapidly decreasing, proteinuria is increasing or there is evidence of nephritic syndrome,

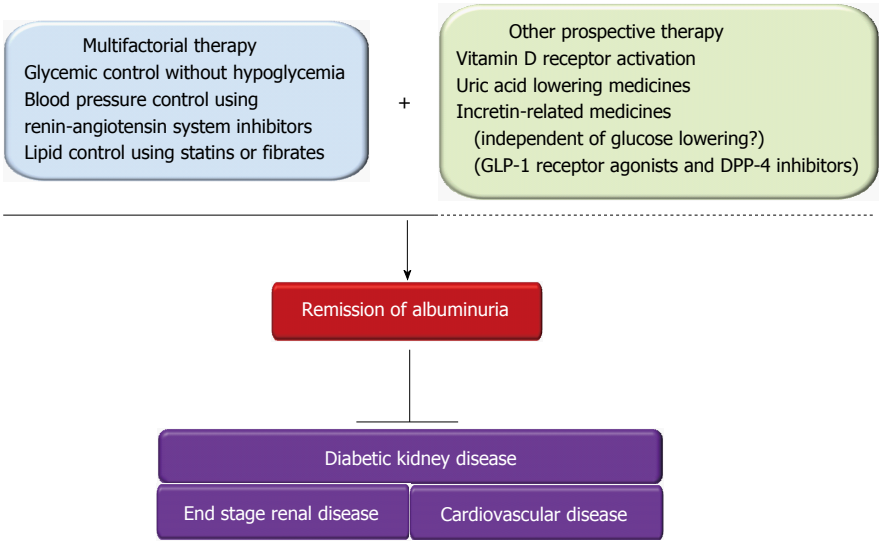

Figure 1 Therapeutic strategy for diabetic kidney disease. Multifactorial therapy, consisting of glycemic, blood pressure, and lipid control, is recommended to prevent the progression of diabetic kidney disease (DKD). The remission and regression of albuminuria by multifactorial therapy may be closely associated with reduced risk of progression of both DKD and cardiovascular disease. In addition to these therapies, vitamin D receptor activation, uric acid-lowering drugs, and incretin-related drugs should be considered in the prospective treatment of DKD.

refractory hypertension is noted, active urinary sediments are present, signs or symptoms of other systemic diseases are present, or a > 30% reduction in GFR has occurred within 2-3 mo after initiation of treatment with an angiotensin converting enzyme (ACE) inhibitor or angiotensin Ⅱ receptor blocker (ARB)[35].

Additionally, microalbuminuria has been shown to be closely associated with an increased risk of cardiovascular morbidity and mortality[36-38]. In a sub-analysis of the United Kingdom Prospective Diabetes Study (UKPDS), the cardiovascular mortality of type 2 diabetic patients with microalbuminuria was reported to be two times higher than that of patients with normoalbuminuria[39]. Therefore, microalbuminuria is not only a biomarker for the diagnosis of DKD but is also an important therapeutic target for improving the prognosis of renal and cardiovascular risk in diabetic patients.

THERAPEUTIC STRATEGY FOR DIABETIC KIDNEY DISEASE

The current therapeutic strategy for DKD is shown in Figure 1. A multifactorial therapeutic approach, including glycemic control, blood pressure management, and lipid control, is recommended to prevent the progression of DKD. The remission and regression of albuminuria as a result of multifactorial therapy may be closely associated with reduced risk of both the progression of DKD and cardiovascular disease. In addition to these therapies, vitamin D receptor activation, uric acid-lowering drugs, and incretin-related drugs are potential treatments for DKD.
