Chronic hyperglycemia is the main causal factor underlying diabetic vascular complications, including DKD. Multiple potential molecular mechanisms have been proposed to explain hyperglycemia-induced diabetic complications. Some of the most-studied mechanisms include disruption of the polyol pathway, activation of the diacylglycerol-protein kinase C pathway, increased oxidative stress, increased formation and activity of advanced glycation end products, and activation of the hexosamine pathway[3]. Additionally, alterations in signal transduction pathways induced by hyperglycemia or toxic metabolites have been reported to cause multiple vascular dysfunctions, such as abnormal blood flow, and increased apoptosis, inflammation, and accumulation of extracellular matrix in the kidney by alteration of gene expression or protein function[3]. Therefore, glycemic control is fundamentally necessary to prevent the onset and progression of DKD by influencing both hyperglycemia itself and hyperglycemia-induced metabolic abnormalities; this premise has been supported by several randomized controlled clinical trials in both type 1 and type 2 diabetes, as described below.

Type 1 diabetes: In the Diabetes Control and Complications Trial (DCCT), the average HbA1c levels were 7% and 9% for the intensive and conventional therapy groups, respectively. Intensive glycemic control was associated with a risk reduction of 34% for the onset of microalbuminuria and a risk reduction of 56% for progression to overt albuminuria[40]. Additionally, in the Epidemiology of Diabetes Interventions and Complications study (the follow-up study to the DCCT), intensive glycemic control prevented the onset of microalbuminuria (yielding a decrease in the odds ratio of 84% for the intensive therapy group) and the progression to overt albuminuria (yielding a decrease in the odds ratio of 59% for the intensive therapy group) at 7-8 years after the end of the DCCT, although the differences in HbA1c

Table 1 Effects of intensive glucose control on the onset and progression of diabetic kidney disease

Study	HbA1c		Outcome of albuminuria or renal events
	Intensive treatment	Conventional treatment	
ACCORD[45]	6.4% *vs* 7.6%		21% ↓ in onset of microalbuminuria 32% ↓ in progression to macroalbuminuria
ADVANCE[46]	6.5% *vs* 7.3%		9% ↓ in onset of microalbuminuria 30% ↓ in progression to macroalbuminuria 21% ↓ in renal events New onset macroalbuminuria Doubling of serum Cr Kidney replacement therapy Death due to kidney disease
VADT[47]	6.9% *vs* 8.4%		32% ↓ in progression from normal to microalbuminuria or macroalbuminuria 37% ↓ in progression from normal to microalbuminuria to macroalbuminuria 34% ↓ in any increase in albuminuria

ACCORD: Action to Control Cardiovascular Risk in Diabetes; ADVANCE: Action in Diabetes and Vascular disease: Preterax and Diamicron MR Controlled Evaluation; VADT: Veterans Affairs Diabetes Trial.

between the intensive and conventional therapy groups had decreased over that time. Moreover, 24 cases exhibited elevated serum Cr levels (≥ 2.0 mg/dL); of these 24 cases, 19 were in the conventional therapy group, and five were in the intensive therapy group[41]. In the follow-up study conducted 22 years after initiation of the DCCT[42], a decrease in the GFR (< 60 mL/min per 1.73 m^2) was observed in the intensive therapy group, with a risk reduction of 50% compared with the conventional therapy group. The decrease in GFR per year was significantly suppressed in the intensive therapy group compared with the conventional therapy group (intensive therapy: conventional therapy, 1.27 mL/min per 1.73 m^2/year: 1.56 mL/min per 1.73 m^2/year).

Type 2 diabetes: In the UKPDS33, the median HbA1c levels were 7.0% and 7.9% for the intensive and conventional therapy groups, respectively. The development of diabetic microvascular complications, including nephropathy, in the intensive therapy group was reduced by 25% relative to the conventional therapy group[43]. In the follow-up study conducted 10 years after the end of the UKPDS, the development of microvascular complications, including nephropathy, in the intensive therapy group was still reduced by 24% compared with the conventional therapy group, although the differences in the HbA1c levels between the intensive and conventional therapy groups had diminished.

In the Kumamoto Study, the average HbA1c levels were 7.5% and 9.8% for the intensive and conventional therapy groups, respectively. The cumulative rates for the development and progression of nephropathy after 6 years were 7.7% for the intensive therapy group and 28.0% for the conventional therapy group in the primary prevention cohort; these rates were 11.5% and 32.0%, respectively, in the secondary intervention cohort. In this study, an HbA1c < 6.9% was identified as the target for preventing the onset and progression of diabetic nephropathy[44]. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, the HbA1c levels at the end of the study were 6.4% and 7.5% for the intensive and conventional therapy groups, respectively. Intensive glycemic control reduced the onset of microalbuminuria by 21% and the progression to macroalbuminuria by 32%[45] (Table 1). In the Action in Diabetes and Vascular disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) study, the HbA1c levels at the end of the study were 6.5% and 7.3% for the intensive and conventional therapy groups, respectively. Intensive glycemic control resulted in a 21% reduction in new onset or worsening nephropathy defined by new onset macroalbuminuria, doubling of serum Cr, need for kidney replacement therapy, or death due to kidney disease. Additionally, intensive glycemic control decreased the development of new onset microalbuminuria by 9%, and development of macroalbuminuria by 30%[46] (Table 1). In the Veterans Affairs Diabetes Trial (VADT) study, the HbA1c levels at the end of the study were 6.9% and 8.4% for the intensive and conventional therapy groups, respectively. Intensive glycemic control resulted in a 32% reduction in the progression from normal albuminuria to microalbuminuria or macroalbuminuria, and a 37% reduction in the progression from normal albuminuria to microalbuminuria to macroalbuminuria, and a 34% reduction in any increase in albuminuria[47] (Table 1). The ACCORD, ADVANCE, and VADT studies showed the beneficial effects of intensive glycemic control on the prevention of microalbuminuria and reduced progression to macroalbuminuria; however, these studies showed no significant benefit of more intensive glycemic control on Cr-based estimates of GFR (eGFR).

Based on the results from these clinical trials, the Standards of Medical Care in Diabetes 2014 of the American Diabetes Association (ADA)[33], the Kidney Disease Improving Global Outcomes (KDIGO) 2012 Clinical Practice Guidelines for the Evaluation and Management of Chronic Kidney Disease and the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines for the management of diabetes with CKD[35] recommend a target HbA1c < 7.0%

Table 2 Target of blood pressure in diabetic kidney disease (different of clinical guidelines)

Clinical guideline	Target population	Target of blood pressure
Standard of Medical Care in Diabetes-2014 (ADA)	Diabetic patients	< 140/80 mmHg (< 130 mmHg, younger patients if it can be achieved without undue treatment burden)
KDIGO 2012 CKD guideline	Diabetes + CKD	
	UAE < 30 mg/24 h or ACR < 30 mg/gCr	≤ 140/90 mmHg
	UAE ≥ 30 mg/24 h or ACR ≥ 30 mg/gCr	≤ 130/80 mmHg
JNC8	Diabetic patients	< 140/90 mmHg
	CKD patients	

CKD: Chronic kidney disease; UAE: Urinary albumin excretion; ACR: Albumin creatinine ratio; ADA: American Diabetes Association; KDIGO: The kidney Disease Improving Global Outcomes; JNC8: The Eighth Joint National Committee.

to prevent or delay the progression of DKD. However, clinical evidence that intensive glycemic control reduces DKD is limited to the prevention of microalbuminuria and reduced progression to macroalbuminuria. Evidence of intensive glucose control effecting renal outcomes, including reduced eGFR or the doubling of plasma Cr levels, or on cardiovascular disease, is still ambiguous. Additionally, no reports have prospectively examined the effect of intensive blood glucose control on overt nephropathy with macroalbuminuria, and ESRD or CKD stage 4.

Risk of hypoglycemia

Recent clinical trials, including ADVANCE[46], ACCORD[48], and VADT[47], which reported HbA1c levels of 6.5%, 6.4%, and 6.9%, respectively, showed 1.5-3-fold increases in hypoglycemia in patients with type 2 diabetes who received intensive therapy to reach target glucose levels (with targeted HbA1c levels of < 6.5%, < 6.0%, and < 6.0%, respectively). However, intensive therapy did not decrease the risk of cardiovascular events. Moreover, in the ACCORD study[48], the mortality rates for patients treated with intensive therapy were significantly higher compared to conventional therapy patients. Although the source of the relationship between hypoglycemia and increased mortality in this study was unclear[49], hypoglycemia should be avoided. Therefore, glycemic control without hypoglycemia is important, and the use of glycemic control to target HbA1c levels should be considered in light of the risk factors pertinent to the individual patient, such as the presence of diabetic vascular complications, history of diabetes, and age. At the advanced stage of overt nephropathy with a reduction in renal functioning, the risk of hypoglycemia may be increased because of decreased gluconeogenesis in the kidney, changes in pharmacokinetics resulting from reduced renal function, and reduced insulin metabolism in the kidney. Therefore, it is necessary to select anti-diabetic medicines while considering the individual patient's renal functioning.

BLOOD PRESSURE CONTROL

Targeting blood pressure

Systolic blood pressure control is universally recommended in patients with diabetes to reduce the incidence of stroke, heart failure, diabetes-related death, and retinal photocoagulation, as well as to reduce the risk of the onset of microalbuminuria or progression to overt proteinuria. The early findings from the UKPDS suggest that a 10 mmHg decrease in systolic blood pressure is associated with a reduction of diabetic microvascular complications, including nephropathy, by 13%[50]. Additionally, in the ADVANCE study, a reduction of blood pressure from 140/73 mmHg (control group) to 136/73 mmHg (indapamide-perindopril group) was shown to reduce the risk of a major macro- or microvascular (mostly new microalbuminuria) event and mortality from any cause, including cardiovascular disease[51]. Therefore, the goal of blood pressure < 130/80 mmHg appears to be appropriate in type 2 diabetes to fight against the development and progression of DKD[52]. However, there are recent clinical guidelines for the management of high blood pressure in patients with diabetes and CKD. The KDIGO 2012 Clinical Practice Guidelines for the Evaluation and Management of Chronic Kidney Disease recommends targets for blood pressure in diabetes and CKD as follows. Blood pressure in diabetic adults with CKD and urine albumin excretion < 30 mg/24 h (or ACR < 30 mg/g Cr) should be treated to ≤ 140/90 mmHg, and blood pressure in diabetic adults with CKD and urine albumin excretion ≥ 30 mg/24 h (or ACR ≥ 30 mg/g Cr) should be treated to ≤ 130/80 mmHg. Moreover, the Standards of Medical Care in Diabetes 2014 of the ADA[33] recommends that people with diabetes and hypertension should be treated to < 140/80 mmHg, and lower systolic targets, such as < 130 mmHg, may be appropriate for certain individuals, such as younger patients. However, the 2014 Evidence-Based Guidelines for the Management of High Blood Pressure in Adults from the Panel Members Appointed to the Eighth Joint National Committee (JNC8)[53] recommend a blood pressure goal of < 140/90 mmHg in the population aged ≥ 18 years with CKD or/and diabetes. Thus, recommendations for blood pressure targets differ between the guidelines (Table 2); however, blood control targets should be considered with the risk of the individual patient, such as the presence or absence of other diabetic vascular complications, history of CVD and age,

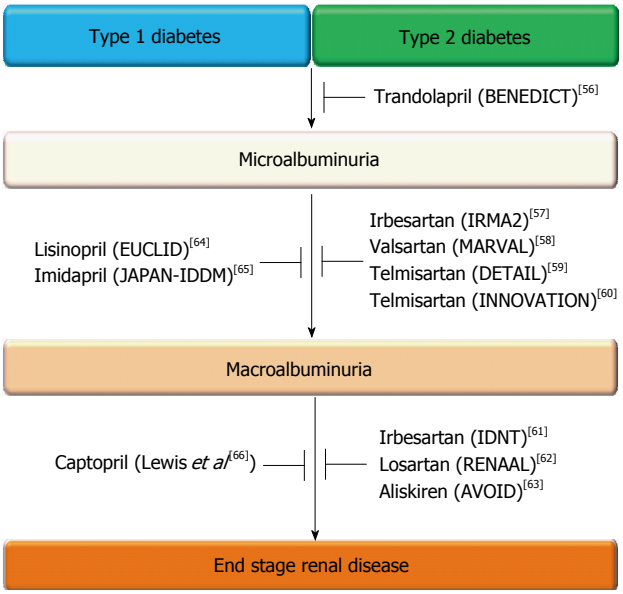

Figure 2 Beneficial effects of renin-angiotensin system inhibitors. Numerous landmark studies have shown the effectiveness of renin-angiotensin system inhibitors on diabetic kidney disease.

as well as glucose control targets.

ACE Inhibitors and ARBs

RAS activation is implicated in the pathogenesis of DKD. In diabetic patients with microalbuminuria or overt proteinuria, RAS inhibitors play a pivotal role in the prevention and treatment of DKD[54,55]. Landmark studies including type 1 and type 2 diabetic patients at various stages of DKD have provided abundant clinical evidence that treatment with RAS inhibitors, including ACE inhibitors and ARBs, slow the progressive decline of GFR, reduce micro- and macroalbuminuria, and reduce cardiovascular mortality and morbidity[54], as shown in Figure 2. Therefore, the use of RAS inhibitors for hypertension and albuminuria in diabetic patients is recommended as a first-line treatment[56-66].

Dual RAS blockade with an ACE inhibitor and ARB may be more effective in reducing proteinuria than monotherapy in patients with DKD. Based on the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial, combination therapy with ramipril and telmisartan reduces proteinuria better than monotherapy; however, it worsens major renal outcomes, including dialysis, the doubling of serum Cr levels, and death[67,68]. Additionally, the Veterans Affairs Nephropathy in Diabetes Clinical Trials showed that combination therapy with an ARB (losartan) and an ACE inhibitor (lisinopril) in type 2 diabetic patients with macroalbuminuria significantly increased the risk of hyperkalemia and acute kidney injury[69]. Thus, combined RAS blockade should not be used in diabetic patients, especially elderly type 2 diabetic patients with normo- or microalbuminuria. First, an ACE inhibitor or ARB should be used, and its dosage should be increased to obtain an optimal anti-albuminuric or proteinuric response. Combination treatment with both an ACE inhibitor and an ARB should be prescribed by a nephrologist and given to patients with overt proteinuria or severe proteinuria, notwithstanding the use of the maximum dosage of the ACE inhibitor or ARBs. In such diabetic patients, monitoring of renal function is necessary, and treatment should be halted in the event of acute kidney injury, low blood pressure, or high potassium levels.

Mineralocorticoid receptor antagonists

Some clinical trials have demonstrated that treatment with spironolactone and eplerenone in addition to an ACE inhibitor or an ARB reduces proteinuria in patients with diabetes[70-75]. However, the long-term effect of mineralocorticoid receptor antagonists on GFR is not clear, and serum potassium levels should be monitored carefully.

Aliskiren

Aliskiren, a direct renin inhibitor, has been promoted for the suppression of DKD and cardiovascular disease. In the Evaluation of Proteinuria in Diabetes study[62], patients with DKD with overt proteinuria were treated with 100 mg of losartan, followed by the addition of a placebo or aliskiren (300 mg). Treatment with 300 mg of aliskiren reduced the mean urinary ACR compared with placebo treatment. However, the Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints study[76], which was performed to confirm the effectiveness of combination treatment with either an ACE inhibitor or an ARB plus aliskiren on both renal and cardiovascular events, was terminated because of adverse outcomes, including hyperkalemia and hypotension, and predicted futility in meeting the cardiovascular and renal endpoints.

Calcium channel blockers and diuretics

Because many hypertensive patients with DKD will require a combination therapy to adequately control blood pressure, commonly used combination therapies include an ACE inhibitor or an ARB plus a diuretic or a calcium channel blocker (CCB).

The Gauging Albuminuria Reduction With Lotrel in Diabetic Patients With Hypertension study tested the effect on albuminuria of initial combination therapy of either a dihydropyridine calcium channel blocker or a thiazide diuretic combined with the same ACE inhibitor in patients with type 2 diabetes and hypertension. In the study, both amlodipine and hydrochlorothiazide (HCTZ) combined with an initial treatment using benazepril decreased the median percent change in ACR from baseline to the end of the study; however, the benazepril plus HCTZ group had a greater reduction in albuminuria compared to the benazepril plus amlodipine group (median percent change in ACR: -72.1 *vs* 40.5, $P < 0.0001$)[77]. In contrast, the mean decrease in the eGFR during the observational period was less in the benazepril plus amlodipine group than in the benazepril plus HCTZ group (-2.03 ± 14.2 mL/min *vs* -13.64 ± 16.1 mL/min, $P < 0.0001$)[77].

The Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial was a randomized and double-blind trial in which 11506 patients with hypertension (60% of whom were diabetics) who were at high risk for cardiovascular events were assigned to receive treatment with either benazepril plus amlodipine or benazepril plus HCTZ. The benazepril-amlodipine combination had a relative risk reduction of 19.6% in cardiovascular events[78]. According to the sub-analysis of the ACCOMPLISH trial on renal outcomes, the events of CKD progression defined as a doubling of serum Cr concentration or ESRD (eGFR < 15 mL/min per 1.73 m^2 or need for dialysis) occurred at a frequency of 2.0% in the benazepril plus amlodipine group compared to 3.7% in the benazepril plus HCTZ group (HR = 0.52, 0.41-0.65, $P < 0.0001$). However, in the patients with CKD (more than half of patients have DKD), both the progression of CKD and cardiovascular mortality did not differ between groups[79].

It is still unclear which additional anti-hypertensive drug (CCB or diuretic) is better for providing both reno- and cardioprotection in DKD. Therefore, the risk of the individual patient, such as the history of CVD and age, should be taken into consideration.

LIPID CONTROL

Dyslipidemia, statins, and fibrates

Dyslipidemia is a major risk factor for atherosclerotic cardiovascular disease, which is a cause of mortality and morbidity in patients with diabetes and CKD[80,81]. In particular, low-density lipoprotein cholesterol (LDL-C) plays an important role in the development of coronary artery disease. Several clinical trials using statin-based lipid-lowering therapies in patients with CKD and diabetes have shown reductions in the risk of major atherosclerotic events. In addition to reducing the risk of cardiovascular diseases in CKD patients, evidence suggests that statin therapy in patients with predialysis CKD may slow the progressive loss of kidney function, measured as changes in urinary albumin/protein excretion or eGFR[82-89]. In the Collaborative Atorvastatin in Diabetes Study, atorvastatin (10 mg/d) treatment was associated with increased GFR in comparison with a placebo, and a modest beneficial effect was observed, particularly in patients with albuminuria. Moreover, atorvastatin was effective at decreasing cardiovascular disease (by 42%) in patients with a moderately decreased eGFR (30-60 mL/min per 1.73 m^2), and this treatment effect was similar to the 37% reduction in cardiovascular disease observed in patients without decreased eGFR[90]. Furthermore, a meta-analysis showed that statin therapy was associated with decreased albuminuria compared to a placebo[87].

The Fenofibrate Intervention and Event Lowering in Diabetes study demonstrated that fenofibrate (200 mg/d) reduced cardiovascular events, reduced albuminuria, and slowed eGFR loss over 5 years, although it initially and reversibly increased plasma Cr levels. In a meta-analysis, fibrates reduced the risk of albuminuria progression in patients with diabetes and reduced the risk of major cardiovascular events and cardiovascular death in patients with an eGFR of 30-59.9 mL/min per 1.73 m^2[91,92].

Statins and fibrates can exert renoprotective effects pleiotropically, such as anti-oxidant, anti-inflammation, and anti-fibrotic effects, independent of their lipid-lowering effects, in experimental animal models[93,94].

KDOQI guidelines and the ADA recommend that the LDL-C target in patients with diabetes or/and CKD should be < 100 mg/dL, and a lower LDL-C goal of < 70 mg/dL is a therapeutic option in individuals with overt CVD, by treatment with statins. Triglyceride levels < 150 mg/dL and high-density lipoprotein cholesterol (HDL-C) > 40 mg/dL in males and > 50 mg/dL in females are desirable[33,35].

MULTIFACTORIAL INTENSIVE THERAPY

Effects on the progression of diabetic kidney disease

The Steno-2 study showed the effect of multifactorial intensive therapy on the progression of nephropathy in patients with type 2 diabetes[95]. In this study, 160 patients with type 2 diabetes and microalbuminuria (average age, 55 years) were randomly divided, with 80 patients assigned to a standard therapy group and 80 patients assigned to an intensive therapy group. The progression of nephropathy was evaluated as a secondary end point. During the 1993-1999 period, the targets for glycemic control, systolic blood pressure, diastolic blood pressure, total cholesterol levels, and triglyceride levels were < 6.5%, < 140 mmHg, < 85 mmHg, < 190 mg/dL, and < 150 mg/dL, respectively, in the intensive therapy group. Patients were administered ARB or ACE inhibitors (regardless of their blood pressure); patients with ischemic heart disease or peripheral vascular disease were given aspirin, and supplementation with vitamin C and E was also provided. Additionally, diet therapy (lipid restriction, < 30% of energy intake per day and < 10% from saturated fatty acid intake) and exercise therapy (3-5 times/wk, moderately intense activity) were prescribed. In the 2000-2001 period, the targets for fasting total cholesterol levels, systolic blood pressure, and diastolic blood pressure were changed to < 175 mg/dL, < 130 mmHg, and < 80 mmHg, respectively, because the treatment guidelines in Denmark changed. In the average observation period of 7.8 years, HbA1c; systolic and diastolic blood pressure; total cholesterol, LDL-C, and triglyceride levels; and fat intake were significantly reduced in the intensive therapy group compared with the standard therapy group. Moreover, the use of aspirin was significantly higher in the intensive therapy group, and urinary albumin excretion was significantly decreased in the intensive therapy group (46 mg/d) compared with the standard therapy group (126 mg/d). Moreover, the risk of onset and progression of nephropathy was reduced to a hazard ratio of 0.39 (CI: 0.17-0.87).

Furthermore, after the Steno-2 study, 63 patients in the standard therapy group underwent intensive therapy with 67 patients of the intensive therapy group in the average follow-up period of 5.5 years[96]. In the follow-up study, the onset and progression of nephropathy were assessed as secondary endpoints. At the end of the follow-up period, glucose, blood pressure, and lipid control in the standard therapy group were improved to almost the same levels as in the intensive therapy group. However, for the total observation period of 13.3 years combined with an average follow-up period of 7.8 years, the onset and progression of nephropathy were decreased in the intensive therapy group [HR = 0.44 (CI: 0.25-0.77)]. Six cases and one case progressed to ESRD in the standard and intensive therapy groups, respectively ($P = 0.04$).

Additionally, a cohort study with a 4-year follow-up of 1290 type 2 diabetic patients with normal albuminuria was performed using multifactorial intensive therapy[97]. In this cohort study, the targets of blood glucose, blood pressure, LDL and triglyceride levels were as follows: HbA1c < 7.0%, < 130/80 mmHg, < 100 mg/dL, < 150 mg/dL, and HDL ⩾ 40 mg/dL (male) per 50 mg/mg per deciliter (female). New microalbuminuria appeared in 211 patients (16.4%) and HbA1c levels < 7% (HR = 0.729, 95%CI: 0.553-0.906, $P = 0.03$), blood pressure < 130 mmHg [HR = 0.645 (CI: 0.491-0.848), HDL ⩾ 40 mg/dL (male) per 50 mg/dL (female), HR = 0.715 (CI: 0.537-0.951)] were associated with the onset of albuminuria.

Accordingly, multifactorial intensive therapy is recommended for suppressing the onset and progression of early diabetic nephropathy; however, it should be noted that this recommendation is based on a small RCT. Moreover, the suppressive effect of multifactorial intensive therapy on nephropathy is not clear in the advanced stage of overt nephropathy.

Effects on the onset of cardiovascular events

In the Steno-2 study described above, the incidence of cardiovascular diseases, including cardiovascular death, non-fatal myocardial infarction, non-fatal stroke, revascularization, and amputation, were evaluated as the primary endpoints over 7.8 years[95]. Thirty-three cardiovascular events (24%) in 19 cases were observed for the intensive therapy group; conversely, 35 cardiovascular events (40%) were observed in the standard therapy group. These results indicate that the risk of cardiovascular disease in type 2 diabetic patients with microalbuminuria was significantly reduced after multifactorial intensive therapy compared with standard therapy [HR = 0.47 (CI: 0.24-0.73)].

In the Steno-2 follow-up study, performed for an average of 5.5 years in addition to the original 7.8 years, the incidence of lower limb amputation, nonfatal stroke, nonfatal myocardial infarction, coronary artery bypass grafting, and percutaneous transluminal coronary angioplasty were assessed as the primary endpoints[96]. At the end of the follow-up period, glycemia, blood pressure, and lipid control for the standard therapy group had improved to levels similar to those found in the intensive therapy group. However, for the total observation period of 13.3 years, the onset of cardiovascular disease was decreased in the intensive therapy group. In addition, there were 48 cases and 158 cardiovascular events in the standard therapy group, in contrast to 28 cases and 51 cardiovascular events in the intensive therapy group.

Remission and regression of albuminuria

Reduction of microalbuminuria in diabetic patients occurred more frequently than we expected. Araki *et al*[98] reported that microalbuminuria in type 2 diabetic patients could improve to normoalbuminuria (remission) or could decrease by more than 50% from the baseline (regression) based on the results of a prospective observational follow-up study over a 6-year period. The 6-year cumulative incidence of progression from microalbuminuria to overt proteinuria was 28% (95%CI: 19%-37%), whereas the remission and regression rates were 51% (95%CI: 42%-60%) and 54% (95%CI: 45%-63%), respectively (Figure 2). In a pooled logistic regression analysis, each modifiable factor was trisected according to the number of patients and was applied as three categories in the analysis. The results showed that microalbuminuria of short duration, the use of RAS blockade, HbA1c < 7.35%, and lower systolic blood pressure (< 130 mmHg) were identified as independent factors associated with remission/regression of microalbuminuria.

ARBs have also been shown to induce remission and regression of microalbuminuria in type 2 diabetic patients. In the Incipient to Overt: Angiotensin Ⅱ Blocker, Telmisartan, Investigation on Type 2 Diabetic Nephropathy study, remission of microalbuminuria at the final observation point occurred in 21.2% of patients treated with 80 mg of telmisartan, 12.8% of patients treated with 40 mg of telmisartan, and 1.2% of patients given a placebo (both telmisartan doses *vs* placebo, $P < 0.001$)[58]. Additionally, patients receiving 80 or 40 mg of telmisartan achieved superior renoprotection, as indicated by lower transition rates to overt nephropathy compared to the placebo patients. Taken together, these results strongly indicate that RAS blockade using an ARB not only prevents the progression of microalbuminuria to overt proteinuria but also induces remission and regression of microalbuminuria in type 2 diabetic patients.

The Steno-2 study also demonstrated that a high proportion of patients with microalbuminuria returned to normoalbuminuria through the multifactorial intervention. After a mean of 7.8 years of follow-up, 46 (31%) patients returned to normoalbuminuria, 58 (38%) patients still had microalbuminuria, and 47 (31%) patients progressed to overt proteinuria[99]. Lower HbA1c levels, initiation of antihypertensive therapy, and initiation of RAS inhibitors during the follow-up period were independently associated with remission of microalbuminuria. A recent analysis focusing particularly on the effect of lowering blood pressure clearly showed that more than half of all type 2 diabetic patients with microalbuminuria and macroalbuminuria returned to normoalbuminuria with receiving any blood pressure-lowering drugs in the

ADVANCE study[100]. However, more patients achieved remission to normoalbuminuria in the perindopril-indapamide treatment group than in the placebo treatment group.

Clinical impact of the remission and regression of albuminuria on cardiovascular events and kidney function

The clinical impact of the remission and regression of microalbuminuria was demonstrated by the observed reduction in the risk of renal and cardiovascular events during an expanded 2-year follow-up (beyond the initial 6 years of the study reported by Araki *et al*[101], described above). The primary outcome measure consisted of "combined incidence," defined as cardiovascular death by and first hospitalization for renal and cardiovascular events. A secondary outcome was kidney function, as determined by the annual decline of eGFR. During the total 8-year follow-up period, 47 patients experienced primary renal and cardiovascular events. Eleven first occurrences of outcomes occurred in subgroups that achieved remission of microalbuminuria; in contrast, 36 such events were observed for the non-remission group. The pooled logistic analysis, adjusted for sex, age, initial ACR levels, history of cardiovascular disease, current smoking, HbA1c level, total cholesterol level, blood pressure, use of RAS inhibitors, use of lipid-lowering drugs, and body mass index, showed that the relative risk for outcomes in patients who achieved remission was 0.25 (95%CI: 0.07-0.87) compared with those whose microalbuminuric status did not change during the follow-up period, whereas the relative risk for patients who progressed to overt proteinuria was 2.55 (95%CI: 1.04-6.30) (Figure 2). First occurrences of these outcomes were classified into subgroups defined by achieving a reduction greater than 50% in urinary albumin excretion in the course of 12 events for the regression group and in 35 events in the non-regression group; these patients were labeled as having failed to achieve remission.

Kaplan-Meier estimations showed that the cumulative incidence of evaluated events was significantly lower in the regression group than in the non-regression group. The 8-year cumulative incidence of these outcomes in the regression group showed a 59% decrease compared to the non-regression group. The adjusted risk for outcomes in patients who achieved regression was 0.41 (95%CI: 0.15-0.96) compared with those whose microalbuminuric status did not show regression during the follow-up. As anticipated, the annual decline of eGFR for the progression group (median: 4.2 mL/min per year) was significantly faster than that for the non-change group (2.4 mL/min per year), whereas the annual decline of eGFR for the remission group was significantly slower (1.1 mL/min per year) and was almost identical to the decline experienced through normal aging reported in healthy people[102].

The effect of reducing microalbuminuria on kidney functioning was also shown in a secondary analysis of the Steno-2 study[101]. The patients who reverted to normoalbuminuria had an average eGFR decrease of 2.3 mL/min per year; however, those who still had microalbuminuria experienced an average eGFR decrease of 3.7 mL/min per year, and those who progressed to overt proteinuria showed the highest eGFR decline of 5.4 mL/min per year. These results show that remission of microalbuminuria is closely related to the improved renal functioning over the long term.

OTHER PROSPECTIVE THERAPEUTIC STRATEGIES

Vitamin D receptor activation

Stimulation of vitamin D receptors exerts protective activity through multiple mechanisms, including inhibition of the RAS, regulation of proliferation and differentiation, reduction of proteinuria, anti-inflammation, and anti-fibrosis[103]. Growing evidence indicates that vitamin D exerts anti-proteinuric and renoprotective effects in DKD patients. The VITAL study demonstrated that treatment with paricalcitol, a selective vitamin D receptor activator, reduced urinary albumin excretion in type 2 diabetic patients treated with RAS inhibitors[104]. Additionally, Kim *et al*[105] showed beneficial effects of vitamin D (cholecalciferol) repletion on urinary albumin and transforming growth factor-β_1 excretion in type 2 diabetic patients with CKD undergoing established RAS inhibition therapy; similar effects were also observed in the VITAL study. Treatment with cholecalciferol led to significantly higher levels of circulating 25(OH)D and $1,25(OH)_2D_3$ relative to baseline, and increased levels of active forms of vitamin D were correlated with a decrease in urinary ACR and TGF-β_1 at the end of a 4-mo intervention period. These data indicate that vitamin D compounds may be useful tools for delaying the progression of DKD beyond the effects expected from established RAS inhibition protocols.

Uric acid-lowering drugs

Multiple longitudinal cohort studies have shown that elevated serum uric acid levels are associated with a higher risk of the onset and progression of microalbuminuria in addition to sustained decline of GFR among type 1 diabetic patients[106-108]. In a cohort study of 263 newly diagnosed type 1 diabetic patients performed by the Steno Diabetes Center group[106], serum uric acid levels measured shortly after the onset of type 1 diabetes were a significant independent predictor of macroalbuminuria 18 years later (HR = 2.37, 95%CI: 1.04-5.37, P = 0.04). Additionally, the Coronary Artery Calcification in Type 1 Diabetes study showed that serum uric acid levels predicted the transition from microalbuminuria to macroalbuminuria[107]. In 324 type 1 diabetic patients, every 1 mg/dL increase in uric acid levels at baseline was associated with an 80% increase in the predicted odds ratio of developing microalbuminuria or macroalbuminuria after 6 years of follow-up (OR = 1.8, 95%CI: 1.2-2.8, P = 0.005). A 6-year follow-up of a prospective cohort study

of type 1 diabetic patients without proteinuria conducted by the Joslin Diabetes Center demonstrated a significant association ($P < 0.0002$) between serum uric acid and an early decrease in GFR, defined as a GFR cystatin decrease exceeding 3.3% per year[108]. When baseline uric acid concentrations were treated categorically (in mg/dL: < 3.0, 3.0-3.9, 4.0-4.9, 5.0-5.9, and ≥ 6), the risk of early decrease in GFR increased linearly (9%, 13%, 20%, 29%, and 36%, respectively). This linear increase corresponds to an OR of 1.4 (95%CI: 1.1-1.8) per 1 mg/dL increase in uric acid levels.

Furthermore, a post-hoc analysis of the Reduction of Endpoints in non-Insulin Dependent Diabetes Mellitus with the Angiotensin Ⅱ Antagonist Losartan trial showed that the decrease in serum uric acid levels induced by losartan accounted for 20% of the renoprotective benefit provided by this medication[109]. However, it is not clear whether reducing uric acid levels could prevent or delay GFR decline in diabetic patients who are at high risk for the progression of DKD; therefore, clinical trials are necessary to elucidate the beneficial effects of uric acid-lowering medicine on preventing DKD.

GLP-1 receptor agonists and DPP-4 inhibitors

Incretin-related therapies, including dipeptidyl peptidase (DPP)-4 inhibitors and glucagon-like peptide (GLP)-1 receptor agonists, have been developed as one of the most promising treatments for type 2 diabetes because of their effectiveness at reducing glucose levels with a low risk of hypoglycemia and no weight gain[110-112]. DPP-4 inhibitors increase the concentration of endogenous incretins, such as GLP-1 and glucose-dependent insulinotropic polypeptides, and GLP-1 analogues that are not degraded by DPP-4 may stimulate GLP-1 receptors in turn. Stimulation of GLP-1 receptors increases glucose-dependent insulin secretion from pancreatic β-cells and suppresses glucagon release from α-cells, leading to improved glucose control[110]. In addition to its action on the pancreas, GLP-1 may have direct effects on other cells and tissues, including the kidney, heart, and blood vessels, *via* stimulation of the GLP-1 receptor[113,114], independent of its glucose-lowering effects.

The GLP-1 receptors in the kidney are expressed in the glomerular endothelial cells, mesangial cells, and proximal tubular cells[115-120], and previous reports have shown that the expression of GLP-1 receptors decreases in the diabetic kidneys of animal models[115]. The renoprotective effect of GLP-1 may be accomplished through anti-inflammation[116], anti-oxidants mediated through cyclic AMP-mediated protein kinase A activation[117,120], or blood pressure regulation *via* sodium handling in proximal tubular cells[121]. DPP-4 is expressed in renal tubular cells, especially in the brush-border and microvillus fractions, podocytes, and endothelial cells[122,123]; however, the physiological role of DPP-4 in the kidney has not been elucidated. Previous reports have shown that DPP-4 expression is increased in the diabetic kidneys of animal models[124]. DPP-4 is a serine exopeptidase that cleaves X-proline dipeptides from the N-terminus of polypeptides. Therefore, DPP-4 cleaves not only incretins but also many substrates, such as cytokines, chemokines, hormones, and neuropeptides[125]. Among these substrates, high-mobility group protein-B1, meprin β, and neuropeptide Y have been identified as candidate targets for GLP-1-independent effects of DPP-4 inhibitors in the kidneys[114].

Several clinical studies have shown beneficial effects of DPP-4 inhibitors[126,127] and GLP-1 analogues[128] on albuminuria in type 2 diabetic patients. Recent reports have demonstrated that linagliptin administration in addition to stable RAS inhibition leads to a significant reduction in type 2 diabetes with albuminuria and renal dysfunction, independent of changes in glucose levels or systolic blood pressure[129]. Further studies, including randomized controlled clinical trials in large populations, are necessary to confirm the long-term effects of incretin-related medicines in DKD.

CONCLUSION

Reduced microalbuminuria may be frequent in diabetic patients. Physicians have to care for these diabetic patients with an aggressive multifactorial management plan as early as possible after the development of microalbuminuria. This multifactorial management regimen includes glycemic control without triggering hypoglycemia, blood pressure control using RAS inhibitors, and lipid control using statins or fibrates. In addition to these therapies, vitamin D receptor activators, uric acid-lowering drugs, and incretin-related drugs for glycemic control are promising therapies for stopping the progression of DKD. However, in the future, the development of novel therapies that not only function to prevent renal decline but also simultaneously attenuate CVD are necessary because the current multifactorial treatment is not still enough.

The remission or regression of microalbuminuria results in reduced risk of both renal and cardiovascular events; therefore, albuminuria is a useful biomarker for the diagnosis of DKD and the assessment of therapeutic effects for DKD. However, some patients with diabetes have advanced renal pathological changes and progressive kidney function decline even though urinary albumin levels are in the normal range, indicating that albuminuria is not the perfect biomarker for early detection of DKD[130]. Recent studies have provided some possible new markers for DKD in type 1[131,132] and type 2 diabetic patients[133]. Serum concentrations of the soluble receptors 1 and 2 for Tissue Necrosis Factor (sTNFR1 and sTNFR2) had a stronger correlation with decline in GFR than urinary ACR[131,132]. sTNFR1 was associated with the development of ESRD in type 2 patients during a 12 year follow-up[133]. However, additional clinical data about such new biomarkers for the early diagnosis and prediction of DKD should be accumulated, and at the same time, it is necessary to determine whether the new biomarker is a

predictive marker for CVD.

Abstract

The traditional perception of adipose tissue as a storage organ of fatty acids has been replaced by the notion that adipose tissue is an active endocrine organ, releasing various adipokines that are involved in the pathogenesis of obesity-related metabolic disturbances. Obesity is a well-known risk factor for atherosclerosis, and accelerates atherosclerosis by many mechanisms such as increase in blood pressure and glucose level, abnormal lipid profiles, and systemic inflammation. Furthermore, growing evidence suggests that some adipokines directly mediate the process of atherosclerosis by influencing the function of endothelial cells, arterial smooth muscle cells, and macrophages in vessel walls. In obese patients, the secretion and coordination of such adipokines is abnormal, and the secretion of specific adipokines increases or decreases. Accordingly, the discovery of new adipokines and elucidation of their functions might lead to a new treatment strategy for metabolic disorders related to obesity, including cardiovascular diseases.

Key words: Adipose tissue; Adipokine; Obesity; Atherosclerosis; Inflammation

Core tip: This review summarizes recent laboratory and clinical studies on the influence of various adipokines, including adiponectin, resistin, adipocyte fatty acid binding protein, omentin-1, and chemerin, on the development of atherosclerosis.

INTRODUCTION

Obesity is an important risk factor for atherosclerosis, but the underlying mechanism for this association is poorly understood. Adipose tissue was considered to be a store of surplus energy, but is now recognized as an independent and active endocrine organ. Various adipokines, such as leptin (a protein secreted by fat cells), tumor necrosis factor-α (TNF-α), resistin, and adiponectin significantly affect obesity-related metabolic diseases by controlling fat metabolism, energy homeostasis, and insulin sensitivity[1]. Independent of their effects on glucose and fat metabolism, some adipokines have been regarded recently as direct links between obesity and atherosclerosis because of their influence on the function of endothelial cells, arterial smooth muscle cells, and macrophages in vessel walls[2] (Figure 1). The identification of a novel adipokine that regulates the atherosclerotic process might provide new opportunities for developing more effective approaches for preventing cardiovascular disease. This review will focus on adipokines that mediate obesity and atherosclerosis, including adiponectin, resistin, adipocyte fatty acid binding protein (A-FABP), omentin-1, and chemerin.

ADIPONECTIN

Adiponectin was the first 30-kDa protein cloned from fat

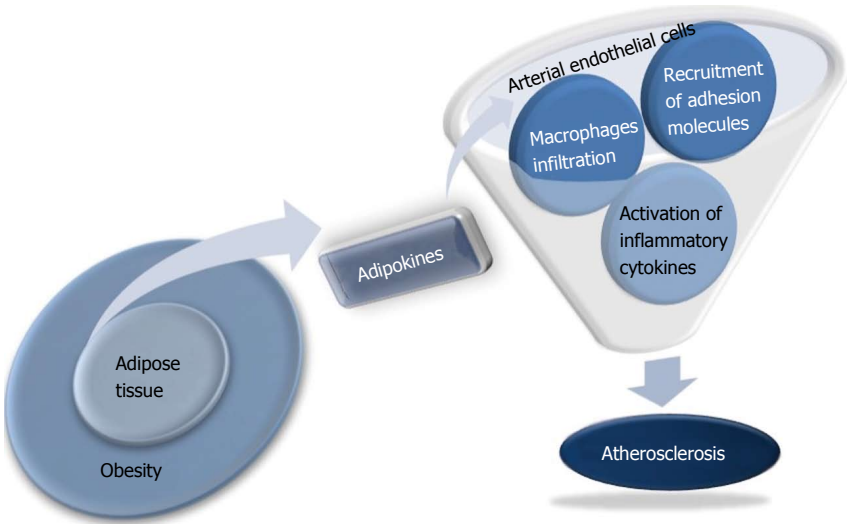

Figure 1 Novel function of adipokines as a direct link between obesity and atherosclerosis.

tissues[3]. Adiponectin is a metabolically active adipokine that is inversely associated with obesity, insulin resistance, and atherosclerosis[4,5]. Adiponectin promotes fatty acid oxidation through the phosphorylation of 5-AMP-activated protein kinase (AMPK), thereby stimulating acetyl-CoA carboxylase. The adiponectin receptors AdipoR1 and AdipoR2 are responsible for adiponectin signaling and biological function. Yamauchi *et al*[6] reported that insulin resistance occurred in AdipoR1/R2 knockout mice, but when AdipoR1 or AdipoR2 were overexpressed in the liver by using adenovirus, glucose metabolism improved in terms of increase in AMPK vitality and peroxisome proliferator-activated receptors α expression. Adiponectin is a metabolically active adipokine which has anti-inflammatory, antiatherogenic, and antidiabetic properties[7] and is therefore inversely associated with obesity, insulin resistance, and atherosclerosis. Hypoadiponectinemia has been established as an independent risk factor for type 2 diabetes and cardiovascular disease (CVD)[8]. We previously showed that, after adjusting for age, sex, obesity, history of impaired fasting glucose or impaired glucose tolerance, hypertension, and dyslipidemia, lower baseline serum adiponectin concentrations are associated significantly with the development of type 2 diabetes and metabolic syndrome[9]. On the other side, the Health Professionals Follow-Up Study showed that high plasma adiponectin levels were associated with a lower risk of myocardial infarction in men during 6 years of follow-up studies[10].

Experimental studies have shown that adiponectin plays a protective role against the development of inflammation and atherosclerosis. Ouchi *et al*[11] demonstrated that adiponectin specifically suppressed TNF-α-induced nuclear factor κ light chain enhancer of activated B cells (NF-κB) activation in human aortic endothelial cells (HAECs) through a cAMP-dependent pathway. Furthermore, adiponectin suppressed TNF-α-mediated induction of adhesion molecule expression in HAECs. Recently, we reported that serum adiponectin levels had a significant negative correlation with vascular inflammation as indicated by the mean target to background ratio (TBR), suggesting a cardio-protective effect of adiponectin[12].

RESISTIN

Resistin was originally discovered as an adipokine with a possible link between obesity and insulin resistance in rodents[13]. In contrast to rodents, human resistin is expressed primarily in inflammatory cells and has been shown to be involved in obesity-related subclinical inflammation, atherosclerosis, and CVD[14]. Reilly *et al*[15] showed that circulating resistin levels are correlated with inflammation markers and are predictive of coronary atherosclerosis, as measured by coronary artery calcification scores, independent of C-reactive protein. Kawanami *et al*[16] found that resistin induces the expression of adhesion molecules, such as vascular cellular adhesion molecule-1 and intercellular adhesion molecule-1 and that adiponectin inhibit the effect of resistin in vascular endothelial cells. Lee *et al*[17] observed that resistin promotes foam cell formation *via* the dysregulation of scavenger receptors macrophages. In men with acute myocardial infarction, a multivariate model revealed that obesity and C-reactive protein were independent variables associated with higher resistin levels[18]. In a cross-sectional study of 3193 Chinese subjects, resistin was more significantly associated with fibrinolytic and inflammatory markers than with obesity or insulin resistance[19]. Moreover, Weikert *et al*[20] reported that individuals in the highest quartile of resistin levels had a significantly increased risk of myocardial infarction compared with those in the lowest quartile of resistin levels after adjustment for cardiovascular risk factors, including C-reactive protein (RR = 2.09; 95%CI: 1.01-4.31) in 26490 middle-aged subjects. Among 397 South Korean patients with acute myocardial infarction, high resistin level was an significant predictor for all-cause mortality, independent of other confounding risk factors[21]. We also showed that serum resistin levels were positively correlated with vascular inflammation mea-

sured using ^{18}F-fluoro-deoxyglucose positron emission tomography[12]. These studies suggest that resistin may represent a novel linkage of metabolic signals, inflammation, and atherosclerosis.

ADIPOCYTE FATTY ACID BINDING PROTEIN

A-FABP is a cytoplasmic protein that combines with saturated and unsaturated fatty acids to control the distribution of fatty acids in various inflammatory response and metabolic pathways[22]. Since Xu *et al*[23] established that the serum concentration of A-FABP, which is synthesized in cytoplasm and secreted into serum, is significantly correlated with components of metabolic syndrome, the role of A-FABP in metabolic syndrome has been studied with renewed interest. Uysal *et al*[24] proved through an oral glucose tolerance test that insulin sensitivity was increased in A-FABP knock out ob/ob mice compared with control mice. In prospective studies, circulating A-FABP has been shown to predict the development of metabolic syndrome and type 2 diabetes independent of adiposity and insulin resistance[25,26].

A-FABP has been shown to be a major mediator of vulnerable plaque formation in various animal and *in vitro* studies. The survival rates of apoE$^{-/-}$ mice null for both A-FABP and mal1 were significantly higher than apoE$^{-/-}$ control mice, primarily because of increased stability of atherosclerotic plaques[27]. In macrophage cell lines, adenovirus-mediated over-expression of A-FABP directly induced foam cell formation by increasing intracellular lipid accumulation, which is an essential step in the formation of atherosclerotic plaques[28]. In contrast, A-FABP$^{-/-}$ macrophages displayed significantly decreased intracellular cholesterol ester accumulation *in vitro*[29] and suppressed production of inflammatory cytokines, such as TNF-α, monocyte chemoattractant protein-1, and interleukin (IL)-6, compared with wild-type controls[30]. Furthermore, Furuhashi *et al*[31] reported that an orally active small molecule inhibitor of A-FABP was an effective therapeutic agent against severe atherosclerosis in mouse models. Recently, a few clinical studies have shown that circulating A-FABP levels are closely related to the development of atherosclerosis in humans. In Korean subjects in whom coronary angiograms were performed for evaluation of chest pain, serum A-FABP levels increased as the number of stenotic coronary arteries increased[32]. Serum A-FABP was shown to be independently associated with carotid intima-media thickness (IMT) in Chinese women after adjusting for other risk factors, including age, obesity, and blood pressure[33]. In patients with coronary artery disease recruited to undergo elective percutaneous coronary intervention, Miyoshi *et al*[34] showed that increased serum A-FABP levels were significantly associated with a greater coronary plaque burden as quantified by intravascular ultrasound. After adjusting for other cardiovascular risk factor in South Korean men without cardiovascular disease or diabetes, we reported that circulating A-FABP levels were independently associated with vascular inflammation as measured by maximum TBR values[35], suggesting A-FABP as a promising key link between different metabolic pathways of adiposity and inflammation.

OMENTIN-1

Omentin is a visceral fat-specific adipokine discovered through expressed sequence tag analysis[36] that has paracrine and autocrine roles in improving insulin sensitivity. Yang *et al*[37] demonstrated that the addition of recombinant omentin stimulated glucose uptake in human adipocytes *via* the activation of Akt phosphorylation. Recent studies showed that omentin increased insulin signal transduction and that it was significantly negatively correlated with metabolic risk factors, including obesity and hyperglycemia, thereby suggesting a beneficial role in energy homeostasis[38-40]. In human clinical studies, it has been suggested that serum omentin-1 levels were significantly decreased in metabolically unhealthy states, such as metabolic syndrome, types 2 diabetes mellitus, and polycystic ovarian syndrome[38-40].

Expression of the omentin gene in interstitial and endothelial cells suggests multi-functionality[41,42]. Fain *et al*[43] were the first to demonstrate the predominant expression of omentin mRNA in human epicardial fat, suggesting that omentin might influence coronary atherogenesis like other periadventitial epicardial adipokines. Some researchers reported that omentin might modulate vascular function through direct action on endothelial cells[44,45]. The vasodilating effect of omentin on isolated rat aorta, mediated by endothelium-derived nitric oxide, was first examined by Yamawaki *et al*[45]. Treatment of human endothelial cells with omentin prevented TNF-α-induced cyclooxygenase-2 expression by inhibiting c-Jun N-terminal kinase signaling, suggesting an anti-inflammatory function of omentin on endothelial cells[44]. Recently, several *in vivo* studies that might explain the mechanism underlying the connection between circulating omentin-1 and the atherosclerotic process have been published. In human endothelial cells, omentin significantly decreased C-reactive protein and TNF-α-induced NF-κB[46]. Xie *et al*[47] reported that adenovirus-mediated overexpression of omentin-1 attenuated arterial calcification in OPG$^{-/-}$ mice, suggesting that increasing concentrations of omentin-1 might be beneficial by protecting arteries. In an *in vitro* study, treatment of calcifying vascular smooth muscle cells (CVSMs) with omentin inhibited osteoblastic differentiation of CVSMCs *via* the phosphatidylinositol 3-kinase/Akt signaling pathway[48]. Very recently, Maruyama *et al*[49] reported that systemic delivery of an adenoviral vector expressing omentin enhanced blood flow recovery and capillary density in ischemic limbs of wild type mice. Taken together, these *in vitro* data suggest the possibility that lower omentin levels contribute to the development of cardiovascular disease from initiating early endothelial dysfunction to arterial calcification.

There have been many clinical studies examining the

significance of correlations of circulating omentin-1 levels with brachial artery vascular reactivity, carotid intima media thickness, and coronary heart disease[50-53]. Moreno-Navarrete *et al*[50] demonstrated that the concentration of circulating omentin-1 contributes independently to endothelial dysfunction, even after controlling for adiposity, age, and inflammation in subjects with impaired glucose tolerance. In that study, vascular reactivity was measured using high-resolution ultrasound imaging of the brachial artery. Subsequently, two reports on the negative correlation of serum omentin-1 with carotid IMT have suggested cardioprotective and anti-atherosclerotic roles for omentin-1[52,53]. Liu *et al*[53] demonstrated that the serum omentin-1 level was independently correlated with carotid IMT in metabolic syndrome patients, and Shibata *et al*[52] showed similar results in apparently healthy men. Recently, El-Mesallamy *et al*[54] examined the level of circulating omentin-1 in an Egyptian population with type 2 diabetes, with or without ischemic heart disease. Although they did not detect clear differences in serum omentin-1 levels between patients with type 2 diabetes with or without ischemic heart disease, multiple regression analysis showed that the IL-6 level was an independent risk factor influencing serum omentin-1 level. This suggests that omentin-1 is regulated by inflammation. Therefore, omentin is regarded as a novel link between insulin resistance, inflammation, and cardiovascular disease, suggesting its possibility as a novel therapeutic target for the cardiovascular diseases.

CHEMERIN

Chemerin was identified as a chemoattractant that promotes the recruitment of immature dendritic cells and macrophages to lymphoid organs and sites of tissue injury[55]. Goralski *et al*[56] first reported a high level of chemerin expression in mouse and human adipocytes. They also reported that loss of chemerin expression almost completely abrogated adipogenesis in 3T3-L1 cells, and modified the expression of genes important in glucose and lipid metabolism, such as GLUT4, leptin, and adiponectin[56]. After that, Ernst *et al*[57] reported that exogenous administration of chemerin exacerbated glucose intolerance, lowered serum insulin levels, and decreased tissue glucose uptake in a mouse model of obesity and diabetes. Growing evidence from human data supports a linkage between chemerin, obesity, and metabolic syndrome. A study of a Mexican-American population showed that circulating chemerin levels were significantly higher in obese subjects compared with non-obese controls. Plasma levels of chemerin were correlated positively with body mass index (BMI), fasting glucose, fasting insulin, and triglycerides levels, and negatively correlated with high-density lipoprotein (HDL)-cholesterol level[58]. Bozaoglu *et al*[58,59] demonstrated that serum chemerin levels were closely correlated with BMI, fasting serum insulin, triglycerides, and HDL-cholesterol in non-diabetic subjects. Sell *et al*[60] reported that in patients who had undergone bariatric surgery for weight reduction, the serum chemerin levels were significantly reduced after surgery, indicating that chemerin might mediate the metabolic alterations in obesity.

Although chemerin is a well-known secreted protein with an established role in immune function, recent experimental data indicate that chemerin might provide a link between obesity and chronic inflammation[61]. Recently, Sell *et al*[62] reported that chemerin activated the NF-κB pathway and impaired glucose uptake in primary human skeletal muscle cells. Moreover, TNF-α treatment of 3T3-L1 adipocytes increased bioactive chemerin levels, suggesting that inflammatory cytokines contribute to the up-regulation of chemerin in obesity[63]. Thus, adipocyte-derived chemerin might be involved in the pathogenesis of obesity-related inflammatory disorders, including atherosclerosis. Although Becker *et al*[64] showed that the expression of chemerin did not significantly alter the extent of atherosclerosis in low-density lipoprotein cholesterol receptor knockout mice, they hypothesized that chemerin might affect early atherosclerotic plaque development and morphology rather than the extent of the atherosclerotic lesion area. Hart *et al*[65] showed that chemerin rapidly stimulated the adhesion of macrophages to the extracellular matrix protein, fibronectin, and to the adhesion molecule, vascular cell adhesion molecule-1, suggesting that chemerin might promote the progression of atherosclerosis. Furthermore, Kaur *et al*[66] demonstrated the novel presence of a G-protein coupled chemerin receptor 1 in human endothelial cells and its significant up-regulation by pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6). Thus, the altered expression of chemerin and its receptors during an inflammatory process might cause dysregulated angiogenesis, leading to the development of cardiovascular disease.

However, there have been very few clinical studies that examined the influence of circulating chemerin on the atherosclerotic process. Lehrke *et al*[67] showed that circulating chemerin was positively correlated with the atherosclerotic plaque burden, as assessed by multi-slice computed tomography angiography, but that the association was lost after adjusting for established cardiovascular risk factors. Very recently, we showed that the circulating chemerin level was an independent risk factor for arterial stiffness even after adjusting other cardiovascular risk factors[68].

CONCLUSION

Various adipokines have been reported to directly modulate the atherogenic environment of the vessel wall by regulating the function of endothelial, arterial smooth muscle, and macrophage cells. Therefore, the identification of a novel adipokine that regulates the atherosclerotic process might provide new opportunities for developing more effective approaches for preventing cardiovascular disease.

Abstract

Adrenomedullin (ADM) is a peptide hormone widely expressed in different tissues, especially in the vasculature. Apart from its vasodilatatory and hypotensive effect, it plays multiple roles in the regulation of hormonal secretion, glucose metabolism and inflammatory response. ADM regulates insulin balance and may participate in the development of diabetes. The plasma level of ADM is increased in people with diabetes, while in healthy individuals the plasma ADM concentration remains low. Plasma ADM levels are further increased in patients with diabetic complications. In type 1 diabetes, plasma ADM level is correlated with renal failure and retinopathy, while in type 2 diabetes its level is linked with a wider range of complications. The elevation of ADM level in diabetes may be due to hyperinsulinemia, oxidative stress and endothelial injury. At the same time, a rise in plasma ADM level can trigger the onset of diabetes. Strategies to reduce ADM level should be explored so as to reduce diabetic complications.

Key words: Adrenomedullin; Diabetes; Diabetic complications; Hyperglycemia; Therapeutics

Core tip: Adrenomedullin (ADM) is a peptide hormone with vasorelaxing and hypotensive properties. It also plays multiple roles in the regulation of hormonal secretion, glucose metabolism and inflammatory response. A major observation is the elevation of plasma ADM level in diabetes, and is associated with diabetic complications in both type 1 and 2 diabetes. The increase could be resulted from oxidative stress, hyperinsulinemia and endothelial injury. This raises the potential application of ADM as a marker in diabetes, and strategies aimed at reducing ADM level could be explored so as to alleviate diabetic complications.

INTRODUCTION

Adrenomedullin (ADM) is a peptide recently discovered with multiple functions. Its characteristic actions include vasorelaxing effect and hypotensive properties. Given its widespread expression and production in different organs, ADM can also act as an autocrine, endocrine or paracrine mediator in various biological systems. The prospects of ADM as a potential disease modulator comes from the observation of increased levels in plasma in various disease states. For instance, increased plasma ADM levels were observed in cardiovascular diseases and diabetes[1-3]. However, different from the observations in cardiovascular diseases, the explanation and significance for such an increase is not clear. Since then, research progress has been made in the association between ADM

and diabetes. For instance, ADM plays a role in glucose metabolism and insulin balance[4]. These evidence may provide clue on the involvement of ADM in diabetes.

In this review, we summarized the current knowledge on ADM based on research progress in the recent decade and provided an account on the role of ADM played in the context of diabetes. This would help us understand better on the clinical application of ADM in diabetic patients.

DISCOVERY OF ADRENOMEDULLIN AS A REGULATORY PEPTIDE

ADM was initially discovered by Kitamura in 1993, extracted from pheochromocytoma in humans by monitoring the elevated 3',5' cyclic adenosine monophosphate (cAMP) production in human platelets[5]. It was later found that the peptide had a potent hypotensive and vasorelaxing effects. It forms a ring structure by 52 amino acid residues held by a disulfide bond. Since the peptide was abundantly found in the adrenal medulla, therefore this accounts for the name. The peptide is classified as a member of the calcitonin gene-related peptide (CGRP) superfamily. Although high level of ADM was identified in the adrenal medulla[6], circulating ADM was the most abundant in vascular wall[7].

BIOSYNTHESIS AND DISTRIBUTION

ADM has a very high tissue distribution. Its biosynthesis has been studied by applying radioimmunoassays, and by detecting tissue ADM mRNA[8]. Immunoreactive ADM is detected in cardiovascular, respiratory, renal, endocrine, reproductive, neurological, intestinal and immune system[9,10]. Among these systems the highest ADM concentrations were detected at the adrenal glands. ADM mRNA is also detected in various peripheral tissues[11]. Such wide distributions indicate the multi-facet roles of ADM.

In the cardiovascular system, ADM is synthesized in both atria and ventricles in heart and blood vessels. Within the vasculature, ADM is actively manufactured and secreted by both the endothelial and the vascular smooth muscle cells[7,12]. It is also demonstrated that the vasculature had much higher ADM mRNA expression than the adrenal glands. This was further supported by the finding of a low ADM precursor ratio in the total ADM immunoreactivity in blood vessels[11].

Besides, ADM is synthesized in the lung[13], brain as well as in the pancreatic islets[14,15]. The widespread ADM expression suggests its diverse role in the regulations of cell functions. Since ADM is mainly produced by vascular endothelial and the smooth muscle cells, its regulatory function of vascular tone has become a major target for investigation.

ADM production is controlled by various humoral factors and physical factors. Inflammatory cytokines such as tumor necrosis factor (TNF)-α, TNF-β, interleukin (IL)-1α and IL-1β all are known to stimulate ADM production and secretion[16]. While mechanical factors like sheer stress and hypoxia are involved in the up-regulation of vascular ADM mRNA expression[17].

In healthy individuals, circulating plasma ADM level is as low as in the picomolar range, similar to the atrial natriuretic peptide, and its level changes in order to compensate for the vasoconstrictive effects. It is reported that in various pathological conditions, the increase in plasma ADM level correlates with severity of disease states. For instance, elevated plasma ADM level has been associated with heart failure, hypertension, artherosclerosis and diabetes mellitus[18].

RECEPTOR SIGNALING

Specific binding sites for ADM were identified in many different places in rat and in human models[19,20]. In humans, the binding sites are most abundant in the microvascular endothelium[20]. The biological actions of ADM are exerted mainly through CGRP receptors and the specific ADM receptors, which share a common molecular component of a G-protein coupled receptor called calcitonin receptor-like receptor (CRLR)[21]. The specificity of CRLR depends on different subtypes of another associated proteins, namely the receptor-activity-modifying proteins (RAMP1, 2 and 3)[22]. Co-expression of CRLR with different subtypes of RAMPs will form different ADM receptors. The specificity brought about by the RAMPs involves glycosylation and transport of the receptor-RAMP complex.

PHYSIOLOGICAL EFFECTS

ADM can act as both a hormone and a cytokine to regulate the regional blood flow, vascular tone, leukocyte migration and differentiation, electrolyte balance, cardiac function, glucose uptake and hormone secretion[18]. It plays an important role in cardiovascular system[23]. ADM imposes a potent vasodilatory effect in humans and increases blood flow to various organs[24,25]. For instance, increased ADM expression could enhance hepatic and renal circulation[26]. In systemic circulation, vasodilation could be resulted from either endothelium-dependent[27], or endothelium-independent mechanisms[28], through ADM and CGRP receptors. In addition, the endothelium-derived vasodilation could be mediated by cAMP and nitric oxide[29,30].

Previous studies have identified the role of ADM in inflammation and immunity. ADM possesses anti-microbial properties against bacteria[31]. *In vitro* and *in vivo* study has demonstrated that ADM secretion and expression are up-regulated upon pathogenic exposure[32]. ADM expression also increases during local inflammation and sepsis[33] In particular, ADM levels in lung, heart and vasculature[34], liver and kidney[26], all increase upon endotoxin administration[35]. Macrophages could also augment ADM expression in inflammation[33].

The role of ADM in the inflammatory process var-

ies after the onset of inflammation. ADM can activate and modulate cytokine production, while it can also inhibit overproduction of pro-inflammatory cytokines[36]. It plays a crucial role in initiating inflammatory response by stimulating the release of migratory inhibitory factor and IL-1β, while activate anti-inflammatory response by suppressing TNF-α production and up-regulating IL-6 production, as the latter is anti-inflammatory and inhibit lipopolysaccharide-induced TNF-α production[37-39]. Such co-ordinated functions of ADM suggest that it is associated with injury, infection and inflammation. Apart from inflammation, ADM expression in immune cells serves diverse functions. ADM can be detected in macrophages in the atherosclerotic plaques[40], where it may play a role in reducing inflammation and thereby exerting an anti-atherosclerotic effect.

While circulating ADM in plasma contributes to a large part of its physiological functions, ADM also serves as a local regulator of cellular functions. The paracrine effect of ADM can be demonstrated in the kidney, as it has been shown that ADM is histochemically localized in renal tubules, and recently mesangium was suggested to be one source of ADM in the kidney[41]. The local ADM modulates mesangial proliferation and is regulated by different growth factors and cytokines. This suggests that regulation of renal function by ADM may operate in an autocrine/paracrine manner. Another example of the localized effect of ADM is in the vascular smooth muscle cells, where its biosynthesis is regulated through a feedback loop. In one study, stimulation of ADM mRNA levels was observed together with a decrease in the immunoreactive ADM peptide secretion resulted from glycolytic inhibition[42]. As ADM could inhibit vascular smooth muscle cell migration and proliferation in response to growth factors[43], a decreased ADM secretion might stimulate its migration and growth locally, and lead to remodeling upon vascular injuries.

ADRENOMEDULLIN AND PANCREATOLOGY

ADM is deeply involved in pancreatic endocrinology, mainly in insulin secretion[44]. It is known that ADM, CRLR and RAMPs are both expressed in the islets of the pancreas[45]. Previous findings demonstrated that exogenous ADM added to freshly isolated rat islets led to a dose-dependent inhibition of insulin secretion by 78% at 1 μmol/L ADM, and was accompanied by cAMP elevation[3]. Oral glucose tolerance tests have illustrated injection of ADM lowered insulin levels in blood by 2 folds 20 min after glucose administration, accompanied by an increase in circulating glucose[4]. This supports a role of ADM in insulin regulation in pancreas, and implies that ADM is associated with hyperglycemia[46].

Another function of ADM is inhibiting amylase secretion in pancreatic acini[47]. As ADM receptors were not identified in the acini, this suggest that such inhibition is mediated through other receptors[45].

ADRENOMEDULLIN AND DIABETES

As suggested above, ADM inhibits insulin release after an oral glucose load. Therefore, it can be expected that ADM contributes to diabetes and even leads to the development of diabetic complications[48].

Diabetes is characterized by hyperglycemia. It is resulted from dysregulation of insulin secretion or peripherial resistance. Diabetes mellitus causes retinopathy, neuropathy, nephropathy, and atherosclerosis. These complications are the results of prolonged hyperglycemia, altered metabolic pathways and non-enzymatic glycation of proteins[49].

There have been advances in the understanding of the relationship between ADM and diabetes. Plasma ADM level is elevated in patients with poorly controlled diabetes than in normal subjects, which suggests a direct effect of glucose on ADM release[1]. The effect of hyperglycemia on ADM expression is mediated through protein kinase C in vascular smooth muscle cells[50]. The observation that ADM expression in aorta, but not in adrenal gland, was raised in diabetic rats (plasma glucose = 567 ± 167 mg/dL) compared to control (plasma glucose = 94 ± 10 mg/dL), suggests that ADM expression in the vasculature could be the source of plasma ADM in diabetic patients[50]. In the streptozotocin-diabetic rat, there were increases in ADM synthesis in the ventricles and possible ADM secretion in the ventricles, atria and the thoracic aorta[51]. On the other hand, ADM may reduce the levels of inflammatory cytokines and endothelin in the adipose tissue and the skeletal muscle and hence increase glucose uptake[37].

However, another study examining the relationship between plasma ADM level and clinical parameters of diabetes demonstrated contradictory results. It showed no significant difference in plasma ADM level between diabetic patients without nephropathy and normal individuals, despite a significant higher level of HbA1c and plasma glucose in patients with diabetes[52]. Therefore, patients with renal impairment should be excluded when examining the relationship between plasma ADM level and blood glucose level, since patients with renal impairment might demonstrate an increase in the plasma ADM levels. Despite the direct effect of circulating glucose on plasma ADM level has not been well established, a positive association between plasma ADM level and the mean blood pressure has been demonstrated in the same study. Given the high plasma ADM levels in various disorders[53], the elevated ADM levels in diabetes might suggest that it has a protective role. Earlier research also showed an elevated plasma ADM level in patients with hypertension and chronic renal failure, particularly a 3-fold elevation in plasma ADM level associated with more severe renal failure. The elevation in ADM may help to prevent blood pressure increase and body fluid retention[54], and represent a compensatory mechanism for diabetic

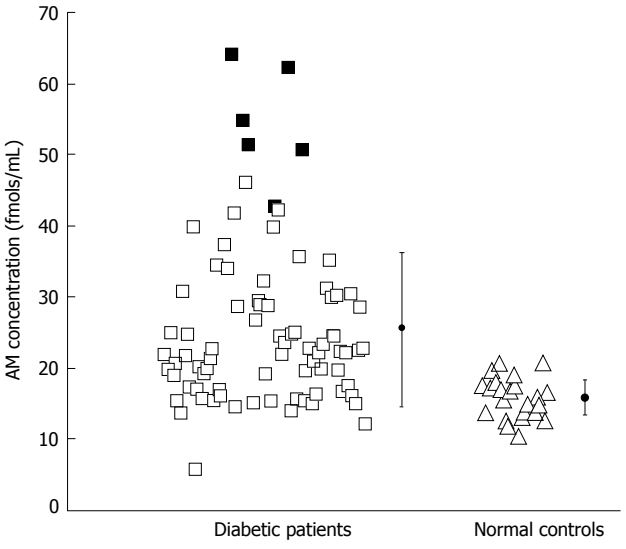

Figure 1 Adrenomedullin concentrations in blood serum from type 2 diabetic patients (in squares) and normal controls (in triangles), shaded squares are outliers. Reprinted from [63].

complications.

ADM AND TYPE 1 DIABETES

One characteristic of type 1 diabetes is the destruction of β-cells in the islets of Langerhans which produces insulin. Previously there was a report investigating the association of ADM and type 1 diabetes. ADM and cAMP levels were compared between type 1 diabetes patients with various complications and healthy individuals[55]. According to the data, increased plasma ADM level was identified only in patients having renal insufficiency, while patients with other complications had normal ADM level. A significant inverse correlation was also found between ADM levels and the creatinine clearance by multiple regression analysis. This suggested that when the kidney function was impaired, clearance of ADM was possibly decreased and resulted in an increase in the plasma level. Such hypothesis deserves further confirmation because most of the circulating ADM was shown to be cleared in the lungs instead of the kidneys[56]. In the same analysis, the relationship between the plasma ADM and the disease duration suggested the change in ADM level is resulted from the endothelial dysfunction.

Despite the uncertainty of the origin of plasma ADM, a recent study postulated that the selective dilation of glomerular capillaries in type 1 diabetes was attributed to the up-regulation of ADM and RAMP2 expression in the afferent arterioles and glomeruli, through the induced release of nitric oxide[57]. This may provide a hint that locally produced ADM can elicit vasodilatation action by paracrine control, independent of any changes in plasma ADM levels. ADM is also involved in the pathogenesis of retinopathy[58]. Since ADM is produced in the vasculature, endothelial activation caused by vessel damage may explain the increase in plasma ADM level. Another possibility is that ADM acts as a factor for survival of the endothelial cells[59], so plasma level of ADM increases upon endothelial injury. A significant positive association between ADM and cAMP in diabetic patients further supported the hypothesis that ADM plays a counter-regulatory role to prevent excessive vasoconstriction and vessel damage, and promotes natriuresis[54,60,61].

All these findings suggested an increase in plasma ADM level is the consequence rather than the cause of type 1 diabetes, since there are insufficient findings to demonstrate the direct link between ADM and the disease states. This can be further supported by the comparison of hypoglycemic- and hyperglycemic-patients in the same study in which no difference in the plasma ADM level was found.

ADM AND TYPE 2 DIABETES

Several studies have been carried out in an attempt to explain the rise in plasma ADM level and its implications in diabetic complications. One study showed that plasma ADM level was elevated in type 2 diabetes but did not correlate with glucose level in circulation[62]. Instead, increased ADM level was correlated with various diabetic complications, and the severity of diabetic nephropathy and retinopathy. Other parameters like serum creatinine level, systolic blood pressure, and urinary protein excretion were found to be related to ADM levels as well. ADM levels might therefore be related to the development of microangiopathy.

Another study examined a group of patients with a common feature of hyperglycemia development. The group had recent onset of diabetes induced by a drug treatment[63]. Results showed that the group can be characterized by a subset of patients with extremely high

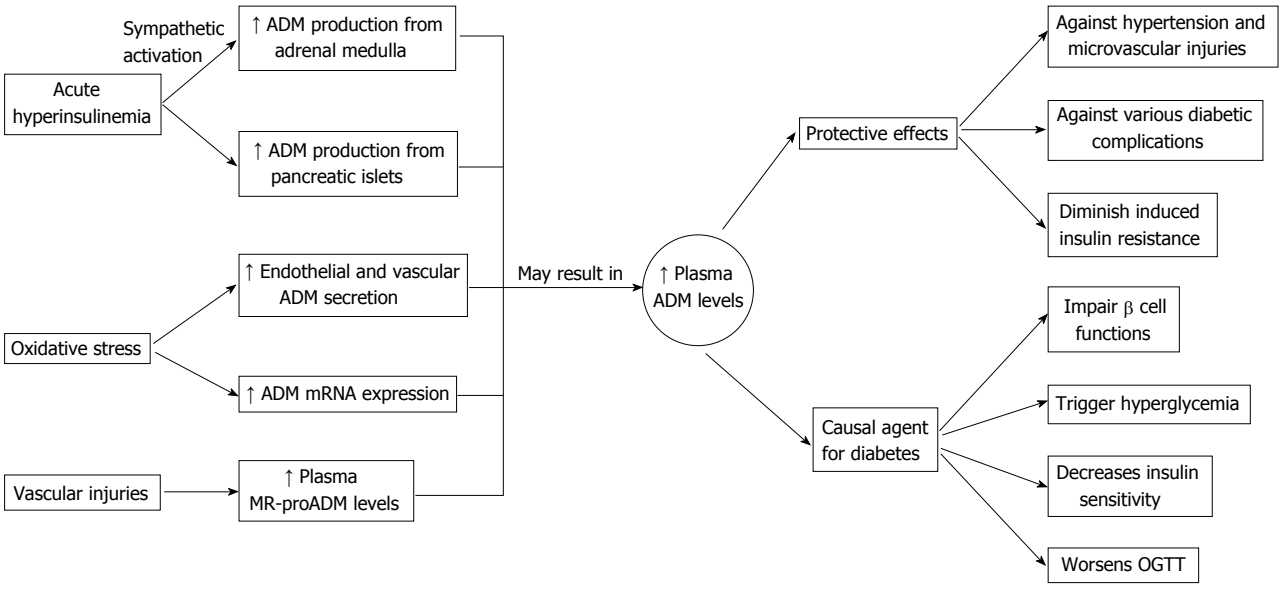

Figure 3 Effects of different disease stresses on subsequent adrenomedullin production and plasma adrenomedullin levels, and the possible roles of increased adrenomedullin levels in type 2 diabetes. ADM: Adrenomedullin.

ADM levels (Figure 1). Even though the source of such excessive ADM is unknown, the results suggested that hyperglycemic patients are characterized by higher circulating ADM levels. In the same studies, the influence of ADM in blood glucose modulation was studied using an obese SHR rat model mimicking human type 2 diabetes. Synthetic ADM, blocking monoclonal antibody against ADM or saline were injected into the animals, and then glucose tolerance tests were carried out. In support to a previous study[4], ADM injection increased blood glucose level more significantly in diabetic rats, while application of antibody effectively reduced blood glucose level to even lower than saline control and improved postprandial recovery in diabetic rats (Figure 2). All these data raise the possibility that ADM is a causative factor in type 2 diabetes and has a negative impact on glycemic control.

To further explore the role of ADM incausing type 2 diabetes, the effect of ADM on insulin secretion has to be considered. There are studies addressing the association of ADM with insulin balance. There is a positive association between insulin resistance and plasma midregion pro-adrenomedullin levels[64]. The link between acute hyperinsulinemia and ADM has been proposed, in which plasma ADM levels increased in acute hyperinsulinemia[65]. There was a concomitant increase in plasma ADM levels with increasing insulin production, and a significant positive correlation between serum insulin levels and plasma ADM was seen in type 2 diabetic patients. The authors speculated that the increased insulin-stimulated ADM production from the pancreatic islets compensated for the diminished vasodilatory effect of insulin, hence this protects against arterial hypertension.

In the recent decade the effect of oxidative stress on ADM expression has been suggested. One study evaluated such relationship by measuring plasma levels of 8-epi-prostaglandin F2α (8-epi-PGF2α, a marker of oxidative stress) and ADM in normal and hypertensive subjects[66]. Both plasma levels were elevated in the hypertensive group ($P < 0.05$ for 8-epi-PGF2α and $P < 0.02$ for ADM respectively), and the data showed that 8-epi-PGF2α was associated with ADM in hypertensive patients with type 2 diabetes ($r = 0.696$, $P < 0.01$). It is known that oxidative stress could stimulate ADM mRNA expression and secretion from endothelial and vascular smooth muscle cells[67]. Sustained ADM deficiency increased oxidative stress and led to insulin resistance *via* impaired insulin signaling, which is supported by an angiotensin (Ang)-Ⅱ treated mouse model[68]. Ang-Ⅱ could induce oxidative stress and hypertensive conditions, and it was shown that Ang-Ⅱ reduced insulin sensitivity in ADM-knockout heterozygous mice more than wild type mice. This suggests that endogenous ADM may act against insulin resistance induced by oxidative stress and offer protection from organ damage through its anti-oxidant action.

The interactions between ADM and diabetic complications are dynamic and complex. While conflicting arguments have been put forward to the link between poor metabolic control and increased ADM levels[64], it is generally accepted that plasma ADM levels are positively linked to oxidative stress[66], acute hyperinsulinemia[65], and other risk factors causing endothelial injury (Figure 3). This leaves much ground for further research about the causes and significance for the plasma ADM level increase.

CONCLUSION

There are two main questions that have to be answered in order to establish a link between ADM and diabetes: Firstly, what are the causes for the increase in plasma ADM levels in diabetic patients, and what are the sources for the elevated circulating ADM? What kind of

stress or stimulation are involved? Secondly, what is the implication for the elevated level? Would it further worsen the glycemic condition and result in various diabetic complications?

Based on the above questions, numerous studies have been commenced. Research has demonstrated the association between diabetic complications and the increase in plasma ADM level. Plasma ADM levels were mainly associated with renal failure and retinopathy in type 1 diabetes. However, the correlation with hyperglycemia is still not clear and requires further investigation.

On the other hand, plasma ADM levels in type 2 diabetes patients are linked to a wider range of complications. The rise may be attributed to acute hyperinsulinemia, oxidative stress and endothelial damage. These stimuli increases ADM production from pancreatic islets and vascular endothelium. Such a rise may represent a causative factor triggering the onset of disease and insulin resistance. If this assumption holds, a controlled reduction in ADM levels may improve hyperglycemia. To understand the casual role of ADM in diabetes, genetic variants could be a potential variable to study using Mendalian randomization, since it is unlikely to be confounded by environmental factors. Our recent study has demonstrated a positive link between a single nucleotide polymorphism (SNP) of ADM gene and development of dysglycemia[69]. Our other studies also demonstrates that plasma ADM level is associated with one of its SNP, IL-6 and adiponectin SNPs[70-72]. In the future regulation of ADM level could be a key in controlling glycemia in people with diabetes and this warrants further investigation.

Abstract

Both diabetes mellitus and cancer are prevalent diseases worldwide. It is evident that there is a substantial increase in cancer incidence in diabetic patients. Epidemiologic studies have indicated that diabetic patients are at significantly higher risk of common cancers including pancreatic, liver, breast, colorectal, urinary tract, gastric and female reproductive cancers. Mortality due to cancer is moderately increased among patients with diabetes compared with those without. There is increasing evidence that some cancers are associated with diabetes, but the underlying mechanisms of this potential association have not been fully elucidated. Insulin is a potent growth factor that promotes cell proliferation and carcinogenesis directly and/or through insulin-like growth factor 1 (IGF-1). Hyperinsulinemia leads to an increase in the bioactivity of IGF-1 by inhibiting IGF binding protein-1. Hyperglycemia serves as a subordinate plausible explanation of carcinogenesis. High glucose may exert direct and indirect effects upon cancer cells to promote proliferation. Also chronic inflammation is considered as a hallmark of carcinogenesis. The multiple drugs involved in the treatment of diabetes seem to modify the risk of cancer. Screening to detect cancer at an early stage and appropriate treatment of diabetic patients with cancer are important to improve their prognosis. This paper summarizes the associations between diabetes and common cancers, interprets possible mechanisms involved, and addresses implications for medical practice.

Key words: Diabetes mellitus; Cancer; Association; Mechanism; Medical practice

Core tip: The diabetes-cancer link is summarized and discussed in detail and it may potentially be attributed to hormonal disorders, chronic inflammation and metabolic alterations. Besides, implications for medical practice are also addressed.

INTRODUCTION

The prevalence of diabetes mellitus (DM) is increasing worldwide. According to the estimates by the International Diabetes Federation, the global prevalence of type

2 diabetes mellitus (T2DM) is 8.3%. The prevalence of T2DM varies by country and area. The highest rate is 10.5% in North America, 8.7% in South-East Asia, 6.7% in Europe and 4.3% in Africa. It is predicted that 552 million people worldwide will develop diabetes by 2030[1].

DM and cancer are frequently diagnosed in the same individual[2]. DM is reported to be associated with an increased risk of different types of cancer, including pancreatic, liver, breast, colorectal, urinary tract, gastric, and female reproductive cancers. The relative risk ranges from 2.0 to 2.5 for liver, pancreatic and endometrial cancers, and 1.2 to 1.5 for breast, colon and bladder cancers associated with DM[3]. It is worth noting that DM is a growing health problem worldwide. Even if the increased risk in cancer incidence and mortality due to DM is small, the consequence would be significant at the population level[4].

The mechanism of DM associated with cancer remains uncovered and needs to be examined in further studies. The mechanism for the diabetes-cancer link has been hypothesized to be mainly related to hormonal [insulin and insulin-like growth factor (IGF)-1], inflammatory or metabolic (hyperglycemia) characteristics of the DM and even to certain treatments[5]. Anti-diabetic medications may have effects on the risk for cancer. Increasing evidence shows that insulin sensitizers such as metformin and thiazolidinediones (TZDs) are associated with prostate cancer[6] and HER2-positive breast cancer[7] among diabetic patients. The diabetic patients who are treated with insulin or insulin secretagogues are more likely to develop cancer than those with metformin[8-11].

In this paper, we summarize the associations between diabetes and cancer in epidemiologic studies, possible mechanisms and implications for medical practice.

POSSIBLE BIOLOGIC LINKS BETWEEN DIABETES AND CANCER RISK

Insulin resistance

Insulin resistance is very common in T2DM, in which circulating insulin level is frequently increased. The insulin/IGF axis plays an important role in diabetes-associated increased risk and progression of cancer. The cancer cells overexpress insulin and IGF-1 receptors[2].

Hyperinsulinemia is a hallmark of insulin resistance. The mechanisms whereby hyperinsulinemia could link diabetes and cancer have been extensively investigated and discussed. Hyperinsulinemia may influence cancer development through ligand by binding with the insulin receptor (IR) and/or indirectly through increasing circulating IGF-1 levels[12]. Insulin signal transduction is mediated through two IR isoforms: IR-A and IR-B[13]. IR-A recognizes insulin and IGFs, with a higher affinity for IGF2 than IGF1, and IR-B is insulin specific and is mainly involved in glucose homeostasis. Insulin binds with IR-A and exerts a direct pro-growth mitogenic effect. When elevated, insulin can increase the hepatic expression of IGF-1 and then activate the IGF-1 receptor, further stimulating cell growth through this mechanism[14,15]. IR-A and IGF-1 receptor are expressed primarily in fetal tissues and cancer cells[16].

The independent role of the IR is confirmed by the observation that down-regulation of IRs in LCC6 cells reduces xenograft tumor growth in athymic mice and inhibits lung metastasis[17]. Besides, blockade of the IGF-1 receptor has been associated with decreased growth of breast cancer cells[18,19]. Hyperinsulinemia also results in decreased levels of IGF binding protein-1 and thus increased levels of bioactive IGF-1[20,21].

Multiple downstream signaling pathways are activated after IRs or IGF-1 receptors interact with their ligands. By phosphorylation of adaptor proteins, two major pathways are involved: (1) the phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt)/mammalian target of rapamycin (mTOR), PI3K/Akt/forkhead box O, and Ras/MAPK/extracellular signal-related kinase 1/2 pathway which plays important roles in cancer cell growth and carcinogenesis[22,23] is activated; and (2) the inhibitor of the oncogenic β-catenin signaling (glycogen synthase kinase 3β) is inactivated, through the PI3K/Akt signaling pathway, resulting in β-catenin signaling activation that has been related to cancer stem cells and chemoresistance[24].

Hyperglycemia

Hyperglycemia has been classically considered as a subordinate whereas hyperinsulinemia as a primary causal factor for cancer[25].

Several large cohort and case-control studies have found a positive relationship between hyperglycemia and the risk of cancer[26-29]. In a tumor-prone animal model, it was found that the number and size of liver tumors increased and apoptosis was reduced in insulin-deficient hyperglycemic mice compared with insulin-sufficient mice. This phenomenon was reversed by insulin therapy[30]. However, *in vivo* studies showed that T1DM, which is characterized by hyperglycemia, reduces the tumor growth. This finding does not support that hyperglycemia increases tumor growth, at least in the setting of insulin deficiency[31]. A recent research found that tumors continue to consume high amounts of glucose, regardless of plasma glucose levels[32]. A recent meta-analysis confirmed this finding that improved glycemic control does not reduce cancer risk in diabetic patients[33]. Hyperglycemia may be an independent risk factor for cancer. Further studies are needed to evaluate the relative roles of insulin and glucose.

The possible mechanisms of hyperglycemia increasing cancer risk include "indirect effect" and "direct effect"[34]. The "indirect effect" is the action that takes place at other organs and will later on influence tumor cells by inducing production of circulating growth factors (insulin/IGF-1) and inflammatory cytokines. The "direct effect" is the effect that is exerted directly upon tumor cells by increasing proliferation, inducing mutations, augmenting invasion and migration and rewiring cancer-related signaling pathways. Recently, Wnt/β-catenin signaling has been suggested as a key cancer-associated pathway and

Table 1 Combined relative risk and 95%CI in meta-analyses of cohort studies of cancer risk in different organs of diabetic patients

high glucose enhances this signaling pathway by allowing nuclear retention and accumulation of transcriptionally active β-catenin independently of hyperinsulinemia, adipokines or inflammation[35,36].

Chronic inflammation

The deregulated metabolism in poorly controlled diabetes causes a long-term pro-inflammatory condition characterized by increased levels of interleukin-6 (IL-6), tumor necrosis factor-alpha (TNF-α), C-reactive protein, and other markers of chronic inflammation. Emerging evidence suggests that persistent inflammation can promote genetic instability and chronic inflammation is associated with increased cancer risk[37-40]. This finding is also supported by the classical evidence that non-steroidal anti-inflammatory drugs can reduce the risk of certain cancers[41-44].

Tumor-promoting mechanism of inflammation in diabetic patients is not much clear. Chronic inflammation and chronic oxidative stress go hand-in-hand. Oxidants affect almost all stages of the inflammatory response process, including the release of inflammatory cytokines, the sensing by innate immune receptors from the families of Toll-like receptors and the nucleotide-binding oligomerization domain-like receptors, and the activation of signaling initiating the adaptive cellular response to such signals[40]. Reactive oxygen species can cause damage to lipids, protein and DNA, and then initiate carcinogenesis[45-47]. Meanwhile, chronic inflammation is associated with high levels of TNF-α, which would strongly activate nuclear factor-kappa B (NF-κB) and further induce downstream signaling transduction to promote the development and progression of many tumors. NF-κB is involved in the proliferation and survival of malignant cells, promotes angiogenesis and metastasis, subverts adaptive immunity, and mediates responses to hormones and/or chemotherapeutic agents[48-50]. Therefore, continued exposure to chronic inflammation and oxidative stress puts susceptible cells at risk of progression toward malignant transformation[31].

IMPACT OF DIABETES ON CANCER

Evidence from animal studies

DM is mainly characterized by insulin resistance, hyperinsulinemia, hyperglycemia, and dyslipidemia. The independent role of diabetes and obesity in caner development has been difficult to distinguish since obesity is also related to inflammation and hyperinsulinemia. Studies in transgenic diabetic mice might shed light on the relative contributions of these factors. In a transgenic model of skin and mammary carcinogenesis, non-obese diabetic mice (A-ZIP/F-1) developed more tumors than wild-type controls[51]. In MKR mouse models of mammary carcinogenesis, female mice with T2DM showed accelerated mammary gland development and breast cancer progression independent of obesity and inflammation[52]. Hyperinsulinemia promoted the growth of primary mammary tumor and subsequent metastasis to the lung[53]. Tumor progression was abrogated with the decreased level of serum insulin after treatment with anti-insulin drugs[54]. Taken together, findings from animal studies support that diabetes plays interconnected roles in the development of cancer.

Epidemiologic findings

The findings from a meta-analysis of 12 cohort studies showed that diabetes increased the risk of all-cancer incidence for overall subjects, with a pooled adjusted RR of 1.14 (1.06-1.23) for men, and 1.18 (1.08-1.28) for women[55]. Diabetes is reported to be associated with several types of cancer, including pancreas, liver, breast, colorectal, urinary tract, gastric, and female reproductive cancers. Meta-analyses on the associations between diabetes and site specific cancer are summarized in Table 1.

Liver cancer: In various studies examining the link between DM and cancer, the highest risk has been seen for liver cancer. A meta-analysis demonstrated that individuals with diabetes had a 2.0-fold increased risk of developing hepatocellular carcinomas (HCC), compared with non-diabetics. And this link was observed in both men and women[56]. The liver is exposed to high concentrations of endogenously produced insulin transported *via* the portal vein. Hyperinsulinemia stimulates the production of IGF-1, which further promotes cellular proliferation and then inhibits apoptosis in the liver. The important role of hyperinsulinemia and IGF-1 in hepatic carcinogenesis has been demonstrated by *in vitro*, *in vivo*, and epidemiologic studies[57,58]. Liver steatosis, hepatitis,

and cirrhosis are more frequent among diabetic patients and are well known risk factors for HCC. Insulin resistance stimulates the release of multiple pro-inflammatory cytokines and consequently promotes the development of hepatic steatosis and inflammation and subsequent cancer in the liver[59]. A causal relationship was also reported by Jee *et al*[60], who found that fasting glucose and liver cancer risk had a dose-responsive relationship. Besides, T2DM-induced hyperglycemia induces the release of TNF-α and IL-6 in patients with hepatic steatosis and enhances the pathogenesis of cancer[61].

Colorectal cancer: A meta-analysis comprising 30 cohort studies showed that diabetes was associated with an increase in the risk of colorectal cancer, with a combined RR of 1.27 (1.21-1.34). This association was consistent for both men and women[62]. Our previous retrospective cohort study showed that a significant association of diabetes was found with colon cancer and not with rectal cancer[63]. This finding indicated that there was a subsite specific association of T2DM with colorectal cancer. General factors like hyperinsulinemia and IGF-1 have contributed to intramucosal adenocarcinomas. Diabetic patients have slower bowel peristalsis and more common constipation and thus increased exposure to bowel toxins (*i.e.*, elevated concentrations of fecal bile acids) and potential carcinogens[64]. Animal models have demonstrated that increased concentrations of fecal bile acids could induce colorectal carcinogenesis[64,65].

Breast and other female cancers: A meta-analysis including 20 cohort studies found an association between diabetes and breast cancer with a summary RR of 1.23 (1.12-1.34)[66]. A meta-analysis including 15 cohort studies reported an increased risk [RR = 1.81 (1.38-2.37)] of endometrial cancer in diabetic women[67]. Hyperinsulinemia could increase the levels of bioactive estrogens by reducing the concentration of circulating sex hormone binding protein in diabetic women. It is well known that bioactive estrogens are the risk factors for malignancies of female reproductive organs[68,69]. Increased bioactive estrogen will stimulate the proliferation of breast and endometrial cells and the inhibition of apoptosis to increase cancer risk.

Kidney and bladder cancers: A meta-analysis including eleven cohort studies showed that diabetes was significantly associated with an increased risk of kidney cancer [RR = 1.39 (1.09-1.78)]. The association was slightly stronger in women [RR = 1.47 (1.18-1.83)] than in men [RR = 1.28 (1.10-1.48)][70]. Hypertension and late stage renal disease, two common comorbidities of DM, contribute to the increased incidence of kidney cancer[71,72]. Impaired renal function results in higher circulating levels of carcinogens and toxins and immune inhibition and thereby renders the kidney susceptible to carcinogens and tumor growth. Findings from a meta-analysis of 29 cohort studies suggest that individuals with DM display an increase in the risk of bladder cancer [RR = 1.29 (1.08-1.54)]. The positive association is only observed in men [RR = 1.36 (1.05-1.77)][73]. In addition to general factors, the frequent infections of the urinary tract in diabetic patients might also be involved[74].

Pancreatic cancer: In a 3-year follow-up study[75], subjects with new-onset DM had a higher risk of pancreatic cancer with a RR of 7.94 than the subjects without DM. A meta-analysis of 35 cohort studies showed that DM was associated with an increased risk of pancreatic cancer in both men and women[76]. However, the question arises about whether diabetes is a risk factor or the consequence of the pancreatic cancer (so-called "reverse causality"). Pancreatic cancer might induce a diabetic status because of impaired pancreatic beta cells. *In vitro* studies show that blockage of insulin receptors and impaired insulin action and glucose transport in a model of pancreatic cancer led to insulin resistance[77]. However, the new onset of pancreatic cancer induced DM depends on the peripheral insulin resistance rather than on the impaired pancreatic beta cells. On the other hand, in patients with T2DM exocrine pancreatic cells are exposed to very high insulin levels because of their proximity to insulin secreting islets. Insulin stimulates the growth of cancer cells. Thus, hyperinsulinemia might account for the risk of developing pancreatic cancer in T2DM.

Prostate cancer: Prostate cancer risk appears to decrease in patients with diabetes. An inverse association was observed between diabetes and risk of prostate cancer in the studies from the United States but not in the studies from other countries, as shown by an updated meta-analysis[78]. The protective effect of DM was also observed in different grades or stages of prostate cancer in another meta-analysis[79]. One possible explanation is that low testosterone levels have been shown in diabetic men. The conversion of testosterone to dihydrotestosterone promotes prostate cell growth[80].

Other cancers in diabetes: A 20% increased gastric cancer risk in diabetic patients was found in a meta-analysis. A positive association was observed in female diabetic patients, whereas it was not the case in diabetic men[81]. The IGF/IGF-IR axis interacts with the vascular endothelial growth factor/vascular endothelial growth factor receptor system in gastrointestinal malignancies[82,83]. It is also possible that reactive oxygen-dependent DNA damage further enhances the effect of *Helicobacter pylori* on epithelial cell proliferation[84]. A meta-analysis of large prospective cohort studies has shown a moderate increase of non-Hodgkin's lymphoma in diabetic patients, whereas stratified analysis by gender shows no significance based on the studies with reported cancer incidence by gender[85]. The immune dysfunction related to impaired neutrophil activity and abnormalities in cellular and humoral immunity in diabetes may contribute to cancer development[86].

MORTALITY

A meta-analysis suggests that preexisting diabetes is as-

Table 2 Pooled HRs and 95%CI of all-cause mortality in cancer patients with and without preexisting diabetes mellitus

Cancer	Ref.	No. of cohort studies	HR (95%CI)	HR (95%CI) male	HR (95%CI) female
Pancreas	Barone *et al*[87], 2008	4	1.09 (0.70-1.69)	NA	NA
Liver	Wang *et al*[56], 2012	3	1.56 (1.30-1.87)	1.84 (1.34-2.51)	1.31 (1.06-1.61)
Breast	De Bruijn *et al*[66], 2013	20	1.38 (1.20-1.58)	NA	1.38 (1.20-1.58)
Endometrium	Zhang *et al*[67], 2013	6	1.23 (0.80-1.90)	NA	1.23 (0.80-1.90)
Colon-rectum	Jiang *et al*[62], 2011	11	1.20 (1.03-1.40)	1.26 (1.04-1.52)	1.18 (0.98-1.41)
Kidney	Bao *et al*[70], 2013	8	1.12 (0.99-1.20)	NA	NA
Bladder	Zhu *et al*[73], 2013	11	1.33 (1.14-1.55)	1.54 (1.30-1.82)[1]	1.50 (1.05-2.14)[1]

[1]Based on the studies reported by gender. NA: Unavailable.

sociated with a higher risk of all-cause long term cancer mortality compared with non-diabetic individuals HR = 1.41 (1.28-1.55)[87]. Mortality among diabetes was significantly increased for liver, breast, and bladder cancers, with pooled RRs of 1.56 (1.30-1.87)[56], 1.38 (1.20-1.58)[66], and 1.33 (1.14-1.55)[73], respectively. Similar but mild results are also seen in gastric cancer[88] and colorectal cancer[62]; with 29% and 20% increased all-cause mortalities, respectively (Table 2). Non-significance is found for the cancers of the pancreas[87], prostate[87], kidney[70], endometrium[67], and non-Hodgkin's lymphoma[89] (Table 2).

Several possible explanations might elucidate the increased risk of cancer death in DM. Impaired immune function and pro-inflammatory condition in diabetes may make the cancer more aggressive, favor cancer growth by making host organism less resistant to cancer progression, and strengthen the metastatic potential of cancer. Hyperglycemia may be an important risk factor. There is evidence that poor glycemic controls can lead to poorer outcomes. Survival rates in cancer are decreasing linearly with declining glycemic controls[90]. Diabetic patients may have a worse response to chemotherapy with a higher occurrence of adverse effects compared with non-diabetic individuals.

Diabetes patients are more often poor candidates for surgery. Preexisting diabetes was associated with increased odds of postoperative mortality across all cancer types [OR = 1.51 (1.13-2.02)][91].

IMPLICATIONS FOR MEDICAL PRACTICE

Cancer screening is required for patients with preexisting diabetes

As shown by the above studies, patients with DM have a higher risk of developing certain types of cancer. A healthy diet, physical activity, and weight management could decrease the risk and improve outcomes of DM and some types of cancer. This was supported by a consensus report of the American Diabetes Association and the American Cancer Society[2]. In order to improve the prognosis, early screening of DM-related cancers is important for T2DM patients. Cancer screening tests of proven benefit for malignancies (breast, colon, endometrial cancer, *etc.*) in at-risk individuals/populations should begin relatively earlier than the general population. Future cancer screenings should be based on current existing recommendations. However, specific DM-related cancer screening recommendations remain to be made.

The impact of anti-diabetic treatments on cancer risk

The major classes of DM drugs function to replace circulating insulin and reduce hyperglycemia by different mechanisms or to reduce the associated obesity[92]. Insulin sensitizers, including metformin and TZDs, are oral antidiabetic drugs that decrease insulin resistance by altering signaling through the AKT/mTOR pathway[93,94].

Metformin has been used with confidence in the treatment of T2DM[95]. Emerging evidence from research on humans and from the preclinical setting suggests that metformin has an anti-cancer effect. A meta-analysis of 17 randomized controlled trials showed a clinically significant 39% decreased risk of cancer with metformin use in patients with or at risk for diabetes, compared to no use of metformin[96]. Metformin can decrease cell proliferation and induce apoptosis in certain cancer cell lines[97,98]. In a recent retrospective cohort study, metformin use is not associated with improved survival in subjects with advanced pancreatic cancer[99]. Whereas metformin use was also reported to be associated with a lower risk of colon, liver, pancreas, or breast cancers, it was not associated with the risk of prostate cancer[100,101]. In a meta-analysis by Colmers *et al*[102], TZD-based therapy has been associated with a potential cancer risk, primarily pioglitazone with bladder cancer, as well as a protective role in breast, lung, and colorectal cancers. In combination, the majority of studies showed that metformin therapy decreases and insulin and insulin secretagogues slightly increase the risk of certain cancers in T2DM. Nonetheless, it is premature to prescribe metformin and TZDs solely for those as yet unproven indications for cancers.

Managing diabetic patients with cancer

Managing diabetes can be a daunting task for patients with cancer. Diabetes may negatively impact both cancer risk and outcomes of cancer treatment. It is clear that comorbidities may play a role in clinical outcomes in patients with cancer. Clinicians who treat cancer patients with T2DM should pay more attention to comorbidi-

ties. Thus, rigorous and multifactorial approaches should be adopted to control diabetes for patients undergoing treatment for malignancies. Poor glycemic control increases morbidity and mortality in patients with cancer. Therefore, hyperglycemia management in patients with cancer is important. Monitoring symptoms of both hyperglycemia and hypoglycemia is necessary. DM patients with cancer and their family members should monitor these symptoms and render suitable medical treatment once these symptoms occur. For hospitalized patients with acute concurrent complications, aggressive glycemic management should be taken to improve the prognosis.

CONCLUSION

Previous evidence provides strong support for an increase of both cancer risk and mortality in diabetic patients and more evidence for certain site-specific cancers. The molecular mechanisms for the association between diabetes and cancer development are still uncovered. As underlined in this review, mechanisms on hormonal (insulin and IGF-1), inflammatory and metabolic (hyperglycemia) characteristics have been proposed to elucidate this association. Guidelines specific for diabetic patients should include both treatment in medical practices and mass screening for specific cancers according to the risk factor profile of each patient.

Abstract

Obesity, sleep apnea, diabetes and cardiovascular diseases are some of the most common diseases encountered by the worldwide population, with high social and economic burdens. Significant emphasis has been placed on obtaining blood pressure, body mass index, and placing importance on screening for signs and symptoms pointing towards cardiovascular disease. Symptoms related to sleep, or screening for sleep apnea has been overlooked by cardiac, diabetic, pulmonary and general medicine clinics despite recommendations for screening by several societies. In recent years, there is mounting data where obesity and obstructive sleep apnea sit at the epicenter and its control can lead to improvement and prevention of diabetes and cardiovascular complications. This editorial raises questions as to why obstructive sleep apnea screening should be included as yet another vital sign during patient initial inpatient or outpatient visit.

Key words: Obstructive sleep apnea; Diabetes; Obstructive sleep apnea screening; Obstructive sleep apnea; Cardiovascular complications

Core tip: Obesity, diabetes, cardiovascular disease and obstructive sleep apnea are one of the most common chronic diseases involving population globally. Efforts have been directed towards prevention and public education about the disease process of each of this condition separately. Though these diseases are interlinked, but educational efforts are failing short to address them together.

Surani SR. Diabetes, sleep apnea, obesity and cardiovascular disease: Why not address them together? *World J Diabetes* 2014; 5(3): 381-384 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/381.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.381

OBSTRUCTIVE SLEEP APNEA

Should obstructive sleep apnea (OSA) screening be included as yet another vital sign during the patient first visit? Obesity and metabolic syndromes are emerging as major public health issues. One point one billion adults population worldwide are overweight, and approximately 312 million of them are obese[1]. Obesity is highly prevalent in United States but the prevalence is increasing in China, Southeast Asia, Middle East and Pacific Island[2]. The increasing incidence of childhood obesity and its association with the cardiovascular disease is also becoming a major public health concern[3,4]. The number of individuals inflicted with diabetes worldwide is approximately 285 million, but is expected to increase to 439 million by 2030[5]. 17 million deaths out of 57 million total worldwide deaths are attributable to cardiovascular disease[6]. The prevalence of OSA is between 4%-7% and increasing[7].

Obesity and OSA seem to be an epicenter for most of the chronic disease catastrophe. OSA is one of the most common diseases, with a high incidence and preva-

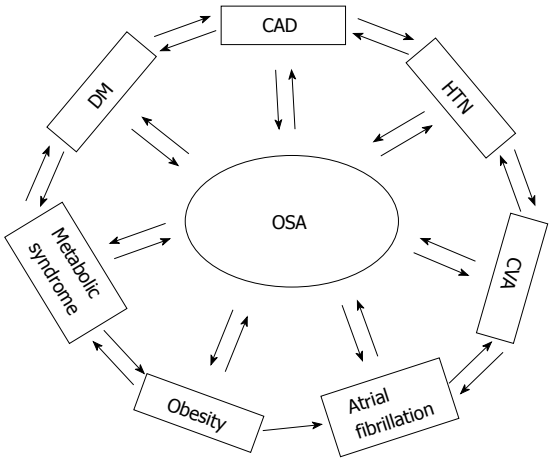

Figure 1 Showing the relationship of obstructive sleep apnea to cardiovascular diseases, diabetes, metabolic syndrome and obesity. CAD: Coronary artery disease; HTN: Hypertension; CVA: Cerebrovascular accident; DM: Diabetes mellitus; OSA: Obstructive sleep apnea.

lence rate that parallels with increasing obesity globally. OSA can be seen in non-obese patients with craniofacial abnormality and children with enlarged tonsils and adenoids too[8-10]. The growing prevalence of obesity and the increasing population body mass index has created major public health challenges[11]. Obstructive sleep apnea has been independently linked with hypertension, atrial fibrillation, cardiac disease, worsening of diabetes, insulin resistance, peri-operative and postoperative complications and coronary artery disease (CAD), to name the few[12-16]. In other words, the data links obstructive sleep apnea to a majority of chronic illnesses. In addition to the illness, untreated OSA increases the health care utilization, impairs work place efficiency, occupational injuries and increase healthcare utilization leading to billions of dollars in economic burden worldwide[17]. OSA if recognized can be adequately treated by an armamentarium of several different treatment modalities. Despite that 85% of the patients with clinically significant and treatable OSA have never been diagnosed, in other word the data has not made to the bedside[18].

OSA involves partial or complete collapse of the upper airway, despite respiratory efforts alternating with normal breathing. It affects 4%-7% of the population[7] and its prevalence in patients with cardiovascular disease is very high. Apnea is defined as a decline in peak signal excursion by $\geqslant$ 90% of their pre-event baseline for $\geqslant$ 10 s. Hypopnea is defined as a drop in the signal excursion by $\geqslant$ 30% of their pre-event baseline for $\geqslant$ 10% and $\geqslant$ 3% arterial oxygen desaturation or accompanied by an arousal[19]. OSA severity is based on Apnea-hypopnea index/h (AHI/h) It can be divided into mild OSA (AHI 5-15/h), Moderate OSA (AHI 15-30/h), and severe OSA (AHI > 30/h). The pathophysiology of obesity and OSA is intimately linked together. Obesity is a major risk factor for OSA. In obese patients there is an enlargement of soft tissue structures in the upper airway, leading to airway obstruction, especially during rapid eye movement sleep when there is atonia. In addition to obesity, there is an increase in fat deposition under the mandible, macroglossia, and palate, which can then lead to narrowing of airway and lead to apnea and hypopnea[20,21]. Obesity has been linked as the central and reversible cardiovascular risk factor that positively influences OSA, diabetes mellitus (DM), metabolic syndrome, hypertension, and lipid metabolism[17]. Children are not immune to the obesity, as the prevalence of obesity among children aged 2-5 is 10% and 6-19 years old is 15%[22].

OSA affects an estimated 15 million adult Americans, especially patients with hypertension, Atrial fibrillation (A-Fib), CAD, and congestive heart failure (CHF) where it is pervasive and levels are very high[23]. Additionally, OSA treatment has also been shown to improve atrial fibrillation incidence, coronary stent reclogging, and improvement of CHF and improvement in blood glucose and insulin resistance[24-29]. Recent evidence directly links OSA and obesity to CAD, heart failure, cardiomyopathy, A-Fib and DM and they are interrelated too as shown in Figure 1. The rise of obesity and DM has been an increased threat to the health of the global population, which has been catalyzed and compounded by the increased occurrence of OSA. In a recent study by Sleep AHEAD Research Group, OSA (AHI $\geqslant$ 5) was found to be in 86% of the population, whereas the pervasiveness of all forms of cardiovascular disease was 14%[30]. On the other hand, individuals who have DM and metabolic syndrome have an increased risk of cardiovascular disease and stroke[31].

The screening for OSA for commercial drivers has been suggested by several societies as American College of Chest Physician, American College of Occupational and Environmental Medicine, and National Sleep Foundation. The International Diabetes federation also recommends screening patients for possible OSA[32]. This screening among the commercial drivers has been successfully implemented, on the other hand, peri-operative screening has been suggested but not implemented in majority of the hospitals despite the availability of simple screening tools as STOP-Bang Questionnaire[33], Berlin Questionnaire[34], neck size, airway, morbidity, Epworth Sleepiness Score, snoring (NAMES) criteria, all with the sensitivity ranging from 80% to 86%[35].

This data has been in literature now for several years, indicating the associations of OSA with almost any disease as glaucoma, end stage renal disease, chronic obstructive pulmonary disease, polycystic ovarian syndrome, metabolic syndrome, cardiovascular disease, stroke, depression, obesity and DM. Moreover, the treatment has led to improvements in the underlying condition[36-38]. The screening test carries high sensitivity, but also has a low specificity. This can result in a plethora of false positive diagnosis and may increase the health care cost. There is high relationship between OSA, hypertension, cerebrovascular disease, CAD and A-Fib. Early diagnosis and treatment of OSA will help in preventing the increase morbidity and mortality associated with those conditions. Studies have shown the improvement in ejection fraction, carotid intimal thickening and benefits in

coronary artery disease, maintenance of sinus rhythm from A-Fib after cardioversion and improvement in insulin resistance. Moreover untreated OSA is also associated with increased risk of death[39-46]. The question arises, if it is the prime time to push for OSA screening for every patient walking in outpatient clinic or hospital? Or do we have to adjust the cutoff of points of our screening test so we can compromise with a decrease in sensitivity to have better specificity to avoid excess healthcare cost as a result of high false positive tests. It is the opinion of the author that Stop-Bang questionnaire, Berlin or NAMES questionnaire can be utilized as the screening tool. In the presence of symptoms, patient should undergo formal sleep study with home sleep study or overnight in lab polysomnography[33-35]. Regardless, one thing is clear: that every physician, nurse and midlevel provider needs to educate patients on risk prevention and education regarding the causes, signs and symptoms of diabetes, sleep apnea, obesity prevention and cardiovascular disease prevention. It is about time that health care providers take the responsibility of preventative education of such diseases as a package rather than fragmentation of education of diabetes in diabetic clinics, sleep apnea in sleep clinics, and cardiovascular disease in heart clinics, as these diseases are interrelated. I will leave the debate open as to if it is about time to push for screening of OSA as one of the vital signs on every patient initial visit.

Abstract

Protein kinase C-β (PKCβ), a member of the lipid-activated serine/threonine PKC family, has been implicated in a wide range of important cellular processes. Very recently, the novel role of PKCβ in the regulation of triglyceride homeostasis *via* regulating mitochondrial function has been explored. In this review, I aim to provide an overview of PKCβ regarding regulation by lipids and recently gained knowledge on its role in energy homeostasis. Alterations in adipose PKCβ expression have been shown to be crucial for diet-induced obesity and related metabolic abnormalities. High-fat diet is shown to induce PKCβ expression in white adipose tissue in an isoform- and tissue-specific manner. Genetically manipulated mice devoid of PKCβ are lean with increased oxygen consumption and are resistant to high-fat diet-induced obesity and hepatic steatosis with improved insulin sensitivity. Available data support the model in which PKCβ functions as a "diet-sensitive" metabolic sensor whose induction in adipose tissue by high-fat diet is among the initiating event disrupting mitochondrial homeostasis *via* intersecting with $p66^{Shc}$ signaling to amplify adipose dysfunction and have systemic consequences. Alterations in PKCβ expression and/or function may have important implications in health and disease and warrants a detailed investigation into the downstream target genes and the underlying mechanisms involved. Development of drugs that target the PKCβ pathway and identification of miRs specifically controlling PKCβ expression may lead to novel therapeutic options for treating age-related metabolic disease including fatty liver, obesity and type 2 diabetes.

Key words: High-fat diet; Signal transduction; Obesity; Mitochondrial function; Insulin resistance

Core tip: Nutrition has important long-term consequences for health. It is one of the lifestyle factors that contribute to the development and progression of obesity (increased fat accumulation), diabetes, and cardiovascular diseases. In fact, obesity rates are increasing dramatically worldwide and obesity amplifies the risk of developing various age-related chronic diseases, such as type 2 diabetes and cardiovascular disease. The prevention or management of chronic diseases is a global priority since they constitute a serious strain on health care systems and account for more than half of the deaths worldwide. Although correct lifestyle remains the mainstream solution to this problem, pharmacological strategies are also being actively seeked. Current antiobesity strategies have not controlled increasing epidemic of obesity and obesity-related disorders. We hope that a better knowledge of the molecular players and biochemical mechanism linking dietary fat to fat accumulation and development of glucose intolerance are critically needed. This review examines a way of metabolizing dietary fat into heat instead of storing them as fat, and the possibility that the "browning" of white fat is regulated by a diet-inducible kinase Protein kinase C-β (PKCβ) may help us explore new translational approaches to combat obesity, improve insulin sensitivity and potentially increase longevity. Finally, attenuation of inflammation in fat by PKCβ inhibition

could have profound clinical consequences because of the large size of the fat organ and its central metabolic role.

INTRODUCTION

Protein kinase C (PKC) family is the largest serine/threonine-specific kinase family known to comprise approximately 2% of the human kinome[1]. PKCs are broadly conserved in eukaryotes, ranging in complexity from a single isoform in budding yeast (Saccharomyces cerevisiae) to 5 isoforms in Drosophila melanogaste and 12 in mammals[2,3]. Three distinct subfamilies can be identified according to their dependency on three combinations of activators: conventional (α, βⅠ, βⅡ, γ) require phosphatidylserine, diacylglycerol, and Ca^{2+}; novel (δ, ε, η, θ) need phosphatidylserine (PS) and DAG but not Ca^{2+}; atypical PKCs (λ/ι, ζ) are insensitive to both DAG and Ca^{2+}. PKC isoforms differ in primary structure, tissue distribution, subcellular localization, *in vitro* mode of action, response to extracellular signals, and substrate specificity. The role of individual PKC isoform is thought to be determined through sub isoform-specific activation processes or isoform-specific substrates in the region downstream of the PKC pathway[4]. Specific role of each isoform is beginning to be understood using isoform-specific transgenic and knockout mouse models. PKCs have been extensively discussed in the literature, and the aim of this review is to focus on the functions of PKCβ in the context of obesity and related metabolic syndromes.

REGULATION OF PKCβ ACTIVITY AND EXPRESSION BY LIPIDS

PKCβ is unique among all PKC isoforms in that a single gene locus encodes two proteins, PKCβⅠ and PKCβⅡ, which are generated by alternative splicing of C-terminal exons and are shown to be physiologically relevant[5]. The difference between these two isoforms resides in the C-terminal V5 domains, which still exhibit a moderate homology (45%) at their amino acid sequences[6,7]. PKCβ is highly expressed in the brain and adipose tissue, and widely expressed at a lower level in multiple tissues including liver, kidney, and skeletal muscle. Analysis of the primary structure of PKCβ reveals the presence of four domains conserved across PKC isoforms (C1-C4) and five variable domains that are divergent (V1-V5). Two functional domains have been described: an amino terminal regulatory domain and a carboxyl terminal catalytic domain. The regulatory domain (V1-V3) contains the so-called pseudosubstrate site which is thought to interact

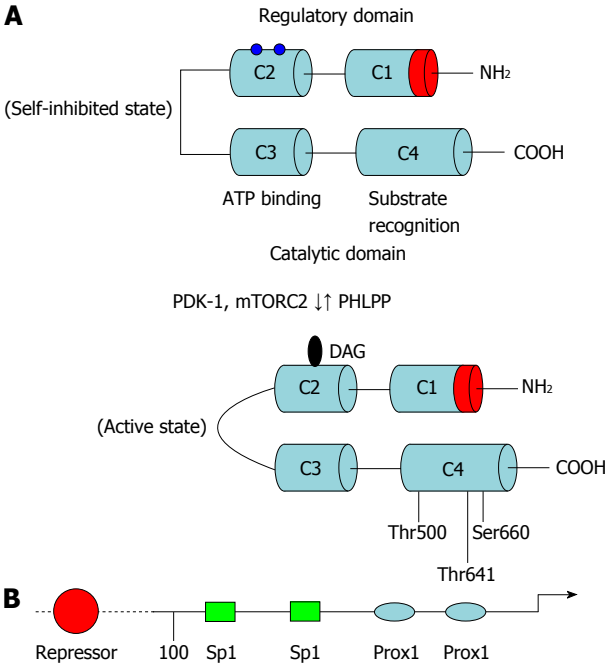

Figure 1 Domain composition of protein kinase C-β and its regulation at the transcriptional and posttranscriptional levels. A: Membrane-targeting modules (C1 and C2), pleckstrin homology domain, the pseudosubstrate region, the kinase core and the C-terminal tail; B: Schematic representation of promoter structure of protein kinase C-β gene. Approximate locations of known regulatory regions are indicated. with the catalytic domain to retain PKCβ in an inactive conformation. The regulatory domain also contains sites for the interaction of PKC with PS, DAG/phorbol ester, and Ca^{2+}. The Ca^{2+} dependency is mediated by the C2 region, while phorbol-ester binding requires the presence of two cysteine-rich zinc finger regions within the C1 domain. The catalytic domain contains two conserved regions, C3 and C4, which are essential for the kinase activity and the binding of adenosine-5'-triphosphate (ATP)/substrate (Figure 1).

In addition to the above specific inputs, other regulatory processes influence the function of PKCβ, including phosphorylation and interaction with specific binding partners. PKCβ is processed by three distinct phosphorylation events before it is competent to respond to the coactivators and is phosphorylated at three conserved serine/threonine residues in the C-terminal domain[8]. Phosphorylation at the activation loop (Thr^{500}) is generally proposed to be first and to be followed by two ordered phosphorylations at the C-terminal tail, the turn motif (Thr^{641} in PKCβⅡ) and then the hydrophobic motif (Ser^{660} in PKCβⅡ). The phosphorylation of the turn motif depends on the mTORC2 complex; this phosphorylation triggers autophosphorylation of the hydrophobic motif[9,10]. The fully-phosphorylated "mature" PKCβ is in a closed conformation in which the pseudosubstrate occupies the substrate-binding cavity, thus autoinhibiting the kinase. Signals that cause hydrolysis of phosphatidylinositol-4,5-bisphosphate result in trans-

location of PKCβ to the membrane by a low-affinity interaction where it binds DAG *via* the C1 domain. Engaging both the C1 and C2 domains on the membrane results in a high-affinity membrane interaction that results in release of the pseudosubstrate, allowing downstream signaling. The membrane-bound conformation is highly phosphatase-sensitive, so that prolonged membrane binding results in dephosphorylation of PKCβ by pleckstrin homology domain Leucine-rich repeat protein phosphatase and PP2A, and subsequent degradation[11]. Binding of Hsp70 to the dephosphorylated turn motif on the C-terminus stabilizes PKCβ, allowing it to become rephosphorylated and reenter the pool of signaling-competent PKC. PKCβ that is not rescued by hsp70 is ubiquitinated by E3 ligases such as the recently discovered RINCK and degraded[12].

PKCβ is also responsive to oxidative stress[13-15]. Why is PKCβ sensitive to oxidative stress? In the PKCβ structure, two pairs of zinc fingers are found within the regulatory domain. They are sites of DAG and phorbol ester binding. Each zinc finger is formed by a structure that is composed of six cysteine residues and two zinc atoms. The high level of cysteine residues renders the regulatory domain susceptible to redox regulation[16,17]. The oxidant destroys the zinc finger conformation, and the autoinhibition is relieved, resulting in a PKCβ form that is catalytically active in the absence of Ca^{2+} or phospholipids[18].

Besides the lipid activation at the post-transcriptional level, PKCβ expression also fluctuates in response to high-fat diet intake. It is shown that feeding high-fat diet (HFD) for 12 wk induces adipose PKCβ expression in an isoform and tissue-specific manner[19]. The molecular mechanism(s) underlying transcription induction have yet to be elucidated but previous studies have cloned and sequenced PKCβ promoter[20-22]. A putative 5'-promoter region for PKCβ is identified and suggested that there is heterogeneity in the active promoter region dependent upon the cellular context. Analysis of the 5'-promoter of PRKCB revealed that a region between -110 bp and -48 bp contains two Sp1 binding sites which are important for basal expression of *PKCβ* gene. In addition two PROX1 sites are also present 3' to Sp1 sites and are involved in inhibiting Sp1-mediated basal transcription of PKCβ promoter[23]. In fact, an inverse relationship between PROX1 and PKCβ levels exist in colon cancer cell lines. It was also found that treatment with a demethylating agent, 5-aza-2'-deoxycytidine, restored PKCβ mRNA expression in PROX1-expressing cells, suggesting that the 5'-promoter of PKCβ is methylated in these cells[23]. Actually, a CpG island in this region, in particular a CpG site within the distal Sp1 site is identified in this study, leading to downregulation of PKCβ transcription. Hypermethylation of PROX1 sites inhibits direct Sp1 binding to this region in PROX1 overexpressing cells. Finally, previous studies have also identified a repressor region located upstream of -110 bp in the PKCβ promoter and the identity of the nuclear factor(s) binding to this region has not been characterized.

NOVEL ROLE OF PKCβ IN LIPID HOMEOSTASIS

A significant conceptual advance in our understanding of the importance of PKCβ signaling in obesity has come from realization that mice deficient in PKCβ express higher levels of genes that regulate fatty acid oxidation and proteins involved in energy dissipation, highlighting its role as a corepressor and in controlling the balance between energy consumption and energy expenditure[24]. On the contrary, genes involved in FA synthesis and gluconeogenesis seem to be downregulated in the absence of PKCβ[25,26]. As a consequence, PKCβ mice are lean, with a significant reduction of body fat and body weight compared to WT mice and are resistant to HFD-induced obesity and hepatic steatosis so that these mice maintain their insulin sensitivity[19]. Moreover, PKCβ levels are shown to be elevated in adipose tissue of leptin-deficient (ob/ob) mice and deletion of PKCβ in ob/ob mice attenuates obesity syndrome of these mice[26]. An important mechanistic insight is the revelation that in PKCβ-deficient mice white adipose tissue (WAT) express genes characteristic of BAT including peroxisome proliferator-activated receptor-gamma coactivator-1alpha (PGC-1α), fatty acid transporter carnitine palmitoyltransferase, and uncoupling protein-1 (UCP-1). Targeted disruption in mice of several genes directly involved in energy metabolism and fat accumulation also leads to lean phenotype with a marked increase in UCP-1 expression in adipocytes, particularly in white fat depots[27-29]. Thus total energy consumption is increased significantly in PKCβ-null mice, presumably as a consequence of energy dissipation in WAT resulting from the expression of UCP-1 and increased mitochondrial activity. The ability of white and brown adipocytes in each depot to reversibly switch into one another has been reported, but the extent to which this occurs and the precise mechanisms involved are not fully understood. The search for regulators that could mediate conversion of white adipocytes (energy storing) into brown adipocytes (energy consuming) has led to the identification of PGC-1α, FOXC2 and positive regulatory domain-containing 16 as transcriptional regulators that have been found to promote a brown fat genetic program, while retinoblastoma protein and RIP140 have been described to favor a white adipose phenotype[27-30]. Another important aspect of these studies relates to possible connection between PKCβ and β-adrenergic receptor levels in WAT. Results presented argue strongly in favor of an inverse relationship between PKCβ and β3-adrenergic receptor expression[26]. The proposed relationship is consistent with earlier reports showing that sustained PKC activation suppressed β-ARs expression at the transcriptional level[31-33]. The net consequence of PKCβ-mediated adipose dysfunction could have profound clinical consequences because of the large size of the fat organ and its central metabolic role. Interestingly, in agreement with the above animal studies, adipose

PKCβ activation is subsequently linked to obese side effects of antipsychotic drugs in humans[34]. Moreover, in agreement with its role in energy homeostasis, PKCβ is shown to be required for adipocyte differentiation[35], PKCβ inhibition promotes insulin signaling in adipocytes[36,37], and PKCβ promoter polymorphism is associated with insulin resistance in humans[38].

The role of PKCβ in obesity is further supported by its potential involvement in angiogenesis. To ensure a sufficient supply of nutrients and oxygen and to transport fatty acids and adipokines, an extended microvasculature is mandatory for adipose tissue. Adipogenesis and angiogenesis are two closely related processes during adipose tissue enlargement, as shown in animal studies and *in vitro* models[39,40]. As adipocyte hypertrophy endures, local adipose tissue hypoxia may occur due to hypoperfusion since the diameter of fat cells overgrows the diffusion limit of oxygen. As a result, hypoxia-inducible transcription factors are expressed triggering the expression of angiogenic factors [vasuclar endothelial growth factor (VEGF), hepatocyte growth factor, plasminogen activator inhibitor-1]. In view of role of PKCβ/HuR in regulating VEGF expression at the post-transcriptional level, simultaneous induction of PKCβ is expected to promote VEGF expression[41,42].

Finally, specific overexpression of a constitutively active PKCβ Ⅱ mutant in mouse skeletal muscle demonstrated that this splice variant of PKCβ not only induces insulin resistance, but also affects the levels of several genes involved in lipid metabolism[43]. Thus impairment in the expression of PGC-1α, acyl CoA oxidase and hormone-sensitive lipase, but enhanced expression of the lipogenic transcription factor sterol response element-binding protein 1c in skeletal muscle, were associated with decreased lipid oxidation and increased intra-myocellular lipid deposition. In addition to these direct effects in muscle, these animals showed defects in insulin action in the liver and brain, as well as hepatic lipid accumulation similar to that seen in fat-fed animals.

POTENTIAL ROLE OF PKCβ IN MITOCHONDRIAL FUNCTION

Several studies have emphasized the association between enhanced mitochondria-derived H_2O_2 and insulin resistance, particularly in the context of excessive nutrient intake that results in metabolic imbalance[44-47]. Oxidative stress has also been described clinically, as well as in WAT of many additional mouse models of obesity, such as the KKAy and db/db mice. Systemic markers of oxidative stress increase with adiposity, consistent with the role of reactive oxygen species (ROS) in the development of obesity-induced insulin resistance. Available data suggest that an increase in ROS significantly affects WAT biology and leads to deregulated expression of inflammatory cytokines such as tumor necrosis factor-α, interleukin-6, and macrophage chemoattractant protein-1, and insulin resistance, which could contribute to obesity-associated diabetes and cardiovascular diseases[47]. Moreover, oxidative stress induced by ROS stimulates fat tissue development both *in vitro* and *in vivo*. H_2O_2-induced oxidative stress is shown to facilitate the differentiation of preadipocytes into adipocytes by accelerating mitotic clonal expansion[48]. Antioxidants such as flavonoids and N-acetylcysteine inhibit both adipogenic transcription factors C/EBP-β and PPAR-γ expression, as well as adipogenic differentiation in 3T3-L1 preadipocytes[49,50]. N-acetyl cysteine (NAC) was also shown to reduce ROS levels and fat accumulation in a concentration-dependent manner[50]. Moreover, animals on a HFD with the antioxidant NAC exhibited lower visceral fat and body weight[51]. Finally, ROS scavenging is associated with fat reduction in obese Zucker rats[52].

Recent studies have highlighted a novel, unexpected signaling pathway bridging the oxidative challenge of a cell to the activation of PKCβ/$p66^{Shc}$-controlled mitochondrial lifespan[53,54]. PKCβ activated by oxidative stress is shown to be required for phosphorylation of the Ser36 of $p66^{Shc}$ and the effect of PKCβ overexpression on mitochondrial Ca^{2+} signaling was not observed in $p66^{Shc-/-}$ cells. Importantly, the mitochondrial consequences of hydrogen peroxide are blocked by hispidine, a specific PKCβ inhibitor. The pathway emerging from these studies is the following: during oxidative stress PKCβ is activated and induces $p66^{Shc}$ phosphorylation, thus allowing $p66^{Shc}$ to be recognized by Pin1, isomerised and imported into mitochondria after dephosphorylation by type 2 protein serine/threonine phosphatase. The $p66^{Shc}$ protein translocated into the appropriate cell domain, can exert the oxidoreductase activity, generating H_2O_2 and inducing the opening of MPTP. This event in turn perturbs mitochondria structure and function. Identification of a novel signaling mechanism, which is operative in the pathophysiological condition of oxidative stress, may open new possibilities for pharmacologically addressing the process of organ deterioration during aging. The above studies are among the first to dissect the downstream target genes and regulatory properties of the PKCβ protein, and therefore make an important contribution to our understanding of the molecular basis to the lean phenotype exhibited by $PKCβ^{-/-}$ mice. Based on a very recent demonstration that PKCβ/$p66^{Shc}$ mitochondrial axis inhibits autophagy[55] and the evolving role of autophagy in energy homeostasis[56-61], it is possible that a combination of adipose PKCβ activation, mitochondrial dysfunction and insufficient autophagy may contribute to the development of diet-induced obesity. In addition to mitochondrial effects, PKCβ is an upstream regulator of NOX but this signaling axis actively produces superoxide across the membranes of neutrophils and phagosomes[62-65]. Accumulating data so far implicates mitochondria as the main source for regulation of autophagy by ROS production in adipocytes[66], whereas NOX contributes to activation of selective, bacterial autophagy[67] (Figure 2).

Although biological function of PKCβ in energy

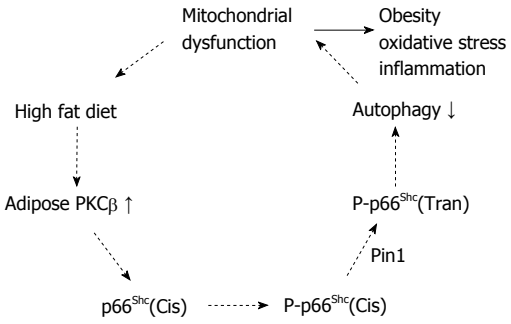

Figure 2 Proapoptotic signals, including reactive oxygen species, activate protein kinase C-β, which in turn phosphorylates p66^{Shc} at serine 36. Phosphorylated p66^{Shc} translocates to the inner mitochondrial membrane and acts as a redox enzyme to amplify oxidative stress by generating H_2O_2. Increased H_2O_2, in turn, causes opening of the mitochondrial permeability transition pore and apoptosis. Protein kinase C-β (PKCβ) activated by reactive oxygen species further induces p66^{Shc} phosphorylation. This event in turn perturbs mitochondria structure and function.

homeostasis appears to be mostly linked with events occurring at the mitochondria, however, increasing evidence has implied a role for this kinase in nuclear functions, suggesting this may be a pathway to communicate signals generated at the plasma membrane to the nucleus. For example, Goss *et al*[68] first showed that PKCβ translocates to the nucleus at G2/M, concomitant with the phosphorylation of lamin B1. Subsequently, a considerable number of nuclear proteins have been identified which are *in vivo* and/or *in vitro* substrates for PKCβ. These proteins include: histone H3, DNA topoisomerase I and Ⅱa, DNA polymerase α and β, cyclic AMP-response element-binding protein, retinoblastoma protein, and vitamin D receptor[69-73]. It has even been shown that PKCβ I co-localizes with androgen receptor and lysine-specific demethylase 1 on target gene promoters and phosphorylation of histone H3 at threonine 6 by PKCβ I is the key event that prevents lysine-specific demethylase 1 from demethylating histone H3 lysine 4[69]. Finally, activated PKCβ indirectly can affect other signaling cascades, including PI3-kinase/Akt pathway, extracellular signal-regulated kinase, and p38 pathway which can impact nuclear events[74-79]. It is thus clear that characterization of PKCβ downstream signaling in the nucleus and its relevance to energy homeostasis is another facets that requires in-depth investigation.

The above findings are applicable to the pathogenesis of obesity and type 2 diabetes since mitochondrial loss in WAT correlates with the development of obesity and type 2 diabetes[80,81]. Indeed, mitochondrial DNA copy number, mitochondrial mass, and mitochondrial activity are all decreased in the white adipose tissue of mouse models of obesity, such as ob/ob and db/db mice[82,83]. Similarly in patients with insulin resistance, type 2 diabetes, and severe obesity, the abundance of mitochondria and the expression of key genes pertinent to mitochondrial function are significantly reduced in white adipose tissue, in concert with decreased adipocyte oxygen consumption rates and ATP production[84,85]. The mitochondrial dysfunction, which could impair substrate oxidation in adipose tissue, is thought to participate in metabolic impairment capacity, thereby accentuating the development of obesity and associated pathologies, such as type 2 diabete. As a result, WAT mitochondria are emerging as highly attractive organelles for therapeutic interventions with the potential to impact upon systemic metabolism. Interestingly, the insulin-sensitizing effects of thiazolidinediones are closely matched by robust increases in adipose tissue mitochondrial biogenesis[86].

CONCLUSION

We have reviewed recent advances pertaining to the potential role of PKCβ in regulating energy homeostasis and contribution to the development of metabolic syndrome. Evidence gathered recently point to an essential role for PKCβ in diet-induced obesity. As a signaling pathway, PKCβ is highly sensitive to changes in environment and fluctuations in lipid supply activate adipose PKCβ, which in turn appears to promote fat accumulation *via* modulating mitochondrial function. A positive loop between oxidative stress and PKCβ/p66^{Shc} is promising and may be the major mechanism underlying contribution of PKCβ activation in generating oxidative stress observed in the obese state. The main gap in our understanding today lies in the specific, molecular and chemical mechanisms of PKCβ-mediated energy homeostasis. What are the mitochondrial and nuclear targets of PKCβ physiologically relevant to energy homeostasis? How is the dietary lipid signals transmitted to the PKCβ promoter? Is PKCβ regulatory signaling network dysregulated in metabolic disease states? Can PKCβ inhibition be adopted to prevent human obesity? These important questions should be the target of future studies. The manipulation of PKCβ levels, activity, or signaling might represent a therapeutic approach to combat obesity and associated metabolic disorders.

Abstract

Diabetic nephropathy (DN) is the leading cause of end-stage renal failure worldwide. Besides, diabetic nephropathy is associated with cardiovascular disease, and increases mortality of diabetic patients. Several factors are involved in the pathophysiology of DN, including metabolic and hemodynamic alterations, oxidative stress, and activation of the renin-angiotensin system. In recent years, new pathways involved in the development and progression of diabetic kidney disease have been elucidated; accumulated data have emphasized the critical role of inflammation in the pathogenesis of diabetic nephropathy. Expression of cell adhesion molecules, growth factors, chemokines and pro-inflammatory cytokines are increased in the renal tissues of diabetic patients, and serum and urinary levels of cytokines and cell adhesion molecules, correlated with albuminuria. In this paper we review the role of inflammation in the development of diabetic nephropathy, discussing some of the major inflammatory cytokines involved in the pathogenesis of diabetic nephropathy, including the role of adipokines, and take part in other mediators of inflammation, as adhesion molecules.

Key words: Diabetic Nephropathy; Inflammation; Albuminuria; Adhesion molecules; Cytokines

Core tip: In recent years, new pathways involved in the development and progression of diabetic kidney disease have been elucidated; accumulated data have emphasized the critical role of inflammation in its pathogenesis. Expression of cell adhesion molecules, growth factors, chemokines and pro-inflammatory cytokines increased in renal tissues of diabetic patients, and serum and urinary levels of cytokines and cell adhesion molecules, correlated with albuminuria. We review the role of inflammation in the development of diabetic nephropathy, discussing some of the major inflammatory cytokines involved in its pathogenesis, including the role of adipokines, and other mediators of inflammation, as adhesion molecules.

INTRODUCTION

Diabetes mellitus (DM) is the leading cause of chronic renal failure in development countries and is increasing as a cause of morbility and mortality worldwide. Both type 1 and 2 diabetes, but principally the last one, plays an important role in this problem because of the impact of its complications[1-4].

Among all these complications, diabetic nephropathy (DN) has become the principal cause of end-stage renal failure and cardiovascular mortality, this condition appears after many years of diabetes beginning[3,5].

It is well understood that type-2 DM is not an immune disease but at this time we could consider that there is evidence that the combine of immunologic and inflammatory mechanisms play a pivotal role in its presentation, development and finally its progression.

The DN take place nearby one-third of patient with type 1 DM and 25% approximately of patients with type 2[4,6].

In México, it is described that the main cause of chronic renal failure is type 2 DM, nevertheless we know that not all diabetic patients develop DN, moreover glucose control is not a warranty of a life free of microangiopathic complications[7].

It has been found that despite all pharmacologic therapies available for DN treatment, some patients develop kidney damage, that is why the need of complete understanding of molecular, metabolic and environmental factors that lead to DN and their interaction between them.

Among diverse factors that could interact actively in pathogenesis and progression of DN have been studied the age, gender, smoking, hypertension and hyperuricemia, all of them with suggestive results of correlation with renal disease[2].

In this paper we review the inflammatory factors that lead to the development and progression of DN.

PHYSIOPATHOLOGY

DN is characterized by glomerular hypertrophy, thickness of basement, tubular and glomerular membranes and accumulation of extracellular matrix in these membranes that finally cause tubulointerstitial and glomerular fibrosis and sclerosis[2,6,8]. As we can see several kidney structures are susceptible to hyperglycemia, and this metabolic change cause organ damage due to several cellular *via* including genetic activation and expression, advanced glycation end products generation, polyol pathway activation, abnormal protein kinase activation (PKC), raise of oxidative stress and the molecules that act as growth factors, transcription factors and others[4,8].

There is a response for hyperglycemia from the system, the transcription factors regulate the gene encoding some cytokines like transforming growth factor β (TGF-β), chemokine C-C motif ligand 2, fibronectin, osteopontin, decorin, thrombospondin, aldose reductase and plasminogen activator inhibitor 1, all these molecules involved in inflammation, extracellular matrix synthesis and its degradation are increased in type-2 DM[4].

Some other factors in relation to DN, it is known that some metabolic *via* activated by hyperglycemia are not enough to cause the kidney complication. The family predisposition to disease, race and other environmental factors interact with hemodynamic changes producing, as a result, advanced glycation end products, glucose reduction and sorbitol accumulation into the cell, overproduction of reactive oxygen species and activation of signaling *via* as PKC and mitogen-activated protein kinase[2].

Diabetic patients then could have albuminuria since early phases or stages of organ damage, it is also considered as a very sensible marker of kidney disease progression. As a result there are many glomerular abnormalities including podocyte structure alteration, reduction of nephrin expression and increase of filtration rate, a hallmark of DN[9].

Many mechanisms were investigated in this process, for a better understanding these are divided in mechanisms of immune cell infiltration of kidney, molecules involved in progression and intracellular pathways activated in DN.

Role of inflammation

Now we know that activation of the immune system and chronic inflammation are both involved in pathogenesis of DM and as a result DN. Some studies have demonstrated that cytokines, chemokines, growth factors, adhesion molecules, nuclear factors as well as immune cells as monocytes, lymphocytes and macrophages are all involved in DM pathogenesis and of course play an important role in DM complications[1,5].

IMMUNE CELLS

Macrophages

Macrophages are recognized as the principal inflammatory cell involved in kidney damage, their accumulation relates with severity of DN in experimental models[3].

These cells are responsible of the calling "renal remodeling", so therapeutics proposed to inhibit their accumulation may help to stop progression.

Two subtypes are mainly involved in DN, M1 macrophages activated by Th1 cells, that are able to increase inflammatory response by cytokines expression [interleukins, tumor necrosis factor (TNF) and interferon γ]; and M2 macrophages activated by Th2 cells that promote tissue repairmen, remodeling and neovascularization by antiinflammatory cytokines expression[3]. Is in this way that investigations are working, it is known that the macrophage subtype levels related with recruitment of circulating monocytes from vascular space to glomerular tissue.

Meanwhile M1 macrophages enhance inflammatory response by upper production of reactive oxygen species (ROS), this point will be reviewed later.

As to activated M2 macrophages, they help in inflammation ending with the participation of interleukin 10 (IL-10), TGF-β1, both with anti-inflammatory functions. Besides they produce proinflammatory factors as chemokines, cytokines and superoxide anions[3].

Many investigations are directed to show that statins are capable to block M1 macrophage actions but at the same time improve M2 functions. It will be helpful as one of the strategies used in the treatment of DN directed to this point.

T lymphocytes

T lymphocytes play a determinant role in early kidney damage in DN, they have cytotoxic effects besides macrophages tissue activation[3].

The first contribution of the studies was about the increase in local accumulating T cells in diabetic experimental models. Xiao *et al*[10] and Moon *et al*[11] showed an increase in CD4 and CD8 lymphocytes in diabetic mouse, these changes were observed in glomeruli and interstice.

In type 1 DM there is an increase of T lymphocytes

in juxtaglomerular tissue that results in a disturbance in albumin glomerular excretion and a decrease of renal filtration. Many other studies have shown at this time that T lymphocytes systemic, specifically circulating CD8, correlated with albuminuria[6].

Lei *et al*[6] demonstrated with a multiple regression analysis a positive association between lymphocytes CD8 and albuminuria in type 2 DM patients and the cell activation could be a systemic response.

Several metabolic and genetic *via*, may activate systemic T lymphocytes. In type 2 DM those cells may be activated by hemodynamic, environmental and metabolic changes. The most important activation seen due to hyperglycemia, that activates nuclear factor κB and this results in an over stimulation of lymphocytes by specific cytokines as IL-12 produced by macrophages, and then, production of interferon further lymphocyte activation[6].

CHEMOKINES

These molecules are active components of inflammatory cells recruitment in kidney and are present in every phase of kidney damage[8].

Many chemokines are involved in the inflammatory response in DN, monocyte chemoattractant protein (MCP-1) was first described in its role in early phases of atherosclerosis[12].

MCP-1

MCP-1 can promote transformation of monocytes in macrophages, the last ones produce diverse cytokines as IL-6 and TNF-α, both induce atherosclerosis changes in vascular walls that results in illness progression. Because of its expression is as high in the atherosclerotic plaques than in impaired plaques, systemic MCP-1 was measured in many studies in order to show an association between this chemokine and DN markers. Takebayashi *et al*[12] found that patients with urinary albumin excretion presented higher circulating levels of MCP-1 than patients without this alteration.

All these findings could suggest that MCP-1 plays an important role in pathogenesis of DN as the protein produced not only in vascular wall, atherosclerotic plaques but also in tubular epithelial cells.

CYTOKINES

Cytokines are molecules with a wide spectrum of physiological actions, many of them due to their pleiotropic actions. They have capacity to combine actions in order to amplify their effects and then induce synthesis or expression of other cytokines if needed.

In 1991 it was suggested for the first time the participation of cytokines with inflammatory actions in the development of DN, by demonstration of high production of these molecules from macrophages in glomerular membranes from diabetic rats, but not from non-diabetic rats[5].

At this time we now that inflammatory cytokines play an important role in DN, but cytokines have been involved in the development of other microangiopathic complications of DM[1].

Interleukins

Interleukins are a group of cytokines produced by many cells in different tissues. According to their physiologic actions, they are classified as antiinflammatory and proinflammatory molecules[3].

IL-1

Many studies have shown that IL-1 promotes an increase of adhesion molecules in glomerular endothelium as well as expression of these molecules in other kidney structures[1].

Mesangial cells and renal tubular epithelium overexpress intercellular adhesion molecule-1 (ICAM-1) and E-selectin, additionally, IL-1 induces prostaglandin E2 synthesis in mesangial cells, this fact cause alterations in the glomerular hemodynamics[1].

Moreover, IL-1 stimulates hyaluronan synthesis, leading to cell proliferation in DM patients, this facts contributes to development of DN. It is known that this proinflammatory cytokin is increased in experimental models with albuminuria and at the same time with macrophages accumulation[1]. According to these pathological changes, IL-1 modifies vascular permeability and increase expression of chemokines that as a result leads proliferation and synthesis of extracellular matrix in mesangium[3].

IL-6

IL-6 is another molecule that has been studied in DN due to its pleiotropic effects. Many authors showed that IL-6 concentration is increased in DN. IL-6 has a direct effect in glomerular and infiltrating cells, this effect modified extracellular matrix dynamics affecting membrane thickening in renal glomeruli[1,3].

IL-6 is a cytokine that can enhance proliferation, overexpression of extracellular matrix and affect vascular permeability; these actions lead to DN progress[1].

It has been shown that serum IL-6 is increased in patients with type 2 DM with nephropathy[3].

IL-18

The principal actions of this inflammatory cytokine are; to enhance the production of other inflammatory cytokines by mesangial cells, and upregulation of ICAM-1. Its serum concentration is increased in DN as well as other interleukins and has a determinant role in endothelium apoptosis[1].

IL-18 has several sources in the diabetic kidney as infiltrating, T-lymphocytes, macrophages, monocytes as well as proximal tubule cells. There is a direct correlation between IL-18, albuminuria and albumin excretion rate, so it's relationship with nephropathy has been identified[13].

TNF-α

This is an inflammatory cytokine with many determinant

actions in inflammatory response by several tissues and pleiotropic effects. TNF-α is produced by infiltrating cells, as monocytes, macrophages and T lymphocytes, as well as kidney cells. Previous reports shown that TNF-α can be stored as a proactive form[1].

Its actions are widely known as systemic and in many cases direct cytotoxic effect in kidney cells principally. Nevertheless actions as activation of second messengers, transcription factors (TF), growth factors, cell adhesion molecules, express or synthesis of cytokines and others are recognized as variable biological effects of this molecule, of course all of them playing a determinant role in DN pathogenesis[1].

When TNF-α binds to the receptors, several signaling pathways are activated and a cascade of molecules begin their expression in renal cells, many of this actions results in apoptosis and necrosis[5].

The negative effects have been described in experimental models and in humans[1]. Those effects were manifested as DM nephropathy, hypertension, nephritis and glomerulonephritis, this fact could be demonstrated with the correlation found by Navarro-González *et al*[5]. in 2005 between renal TNF-α and albumin excretion in diabetic mice. This observation demonstrated that this inflammatory molecule is directly involved in pathogenesis of DN by leading cell and tissue damage; moreover albuminuria has been related to a enhanced stimuli for overexpression of TNF-α[3].

TNF-α alters glomerular hemodynamics and promotes increased vascular endothelium permeability. Infiltration by inflammatory cells, neo-formation of extracellular matrix, production of ROS and blood flow disturb are others recognized effects of TNF-α in renal structures[1].

TGF-β1

TGF-β1 is a cytokine member of TGF-β1 superfamily considered also as a transcription factor related to development of renal damage by promoting renal fibrosis. Its activity is recognized as inflammatory and fibrogenic, with two isoforms, TGF-β2 and TGF-β3, all produced by kidney cells, the union between this cytokine and its receptor phosphorylate the Smads. Smads are intracellular proteins that transduce extracellular signals from TGF-β ligands to the cellular nucleus and activate downstream gene transcription. This family is considered to be involved in development of inflammation and fibrosis in the kidney[4,8,13].

That is why TGF-β1 is recognized as one of the principal mediators of structural changes seen in DN, its concentration is higher in DM patients with urinary albumin excretion than in normal individuals[8].

The upregulation of TGF-β1 promotes extracellular matrix proliferation and at the same time inhibits the degradation, so that is why actually overexpression of this factor is directly associated with severe forms of glomeruloesclerosis and glomerulonephritis[8]. Some other changes are favored by TGF-β1, for example the induction of transforming epithelial cells of tubules into fibroblasts; this process is responsible of renal fibrosis, a result of persistent inflammation.

TGF-β1 is considered too as a cytokine which principal function in inflammation is to inhibit this process. Letterio *et al*[14] discovered that experimental models with impairment in *TGF-β1* gene are highly susceptible to several inflammation resulting in autoimmune diseases and even death[15,16].

El Mesallamy *et al*[8] correlated TGF-β1 concentrations with Connective tissue growth factor level; their findings showed that between these two molecules there is a closed interaction in DN. So as we can see, TGF-β1 is a molecule that can regulate not only its own release and its actions but also it has the ability to modulate other molecular releases and their interactions in signaling pathways.

It seems like TGF-β1 has a complex role in renal inflammation, we know that this protein is present as active and as a latent forms, the first one is related to mediator of renal fibrosis that can progress according to many other factors. The second form is a protective factor for the development of renal damage. Some mechanisms for these findings are not well understood yet[17].

TF

Proteins known as TF bind themselves to some gene specific regions to activate or inhibit nuclear transcription process[4].

TF were classified according to its main action, they can be constitutively active or regulatory factors and they can be activated by several metabolic and environmental stimuli in many cellular sites. Due to this last point we can subclassify TF in nuclear factors, cytoplasmic factors and steroid receptor superfamily[4].

Several TF are involved in DN development, here we have the most relevant.

Upstream stimulatory factors 1 (USF1) and USF2 are a part of Myc family and encoded by two different genes.

USF1 and USF2 are involved in some glucose genes responses in many types of cells including kidney cells. It has been shown that overexpression or increase in concentration of these TF are related with albuminuria development and even more the upregulation of many other molecules with proved actions in DN pathogenesis[4].

Smads

Smads conform a transcription factor family that regulates the expression of certain genes. Three classes are known: the receptor-regulated Smads (R-SMAD) which include SMAD1, SMAD2, SMAD3, SMAD5 and SMAD8/9; the common-mediator Smad (co-SMAD) which includes only SMAD4, which interacts with R-SMADs to take part in signaling and the antagonistic or inhibitory Smads which include SMAD6 and SMAD7, they block the activation of R-SMADs and co-SMADs[17].

As mentioned before this family is closely involved with TGF-β1, which phosphorylate Smad 2 and Smad 3 to form a complex with Smad 4, all this process leads to regulate gene in cell nuclei[17].

Smad 4 is the most related with inflammation, if there is an abnormality of this protein, the inflammatory response is more intense and leads a higher concentration of diverse cytokines and adhesion molecules.

There is another relationship that leads the process to be functional for kidney, this happens when TGF-β1 regulates Smad 7 transcription by Smad 3 and Smad 4 binding, so, when Smad 4 is impaired we can see and exaggerated inflammatory response for reduction of Smad 7 expression, activation of Nuclear Factor κB and fibrosis inhibition[17].

Smad 4 seems to be a key point in regulation of TGF-β1 and its different functions media the conjunction with Smad 7 and Smad 3 expression in kidney.

The case of Smad 7 is quiet interesting, it acts in an inhibitory way and regulates the active function of Smad 2 and Smad 3 but by a negative feedback.

The Smad 7 expression is enhanced by TGF-β1 that in normal condition has a negative feedback inhibit the action of Smad and at the same time degrade this transcription factors. When Smad 7 gets degraded then kidney fibrosis begins. If Smad 7 decline renal inflammation persists and as a result begins fibrosis *via* TGF-β and Smad 3.

In as much as the pivotal role of Smad 7 some investigators decided to study therapeutic effects of this factor in experimental models. When Smad 7 was transferred to kidney they found that if there is an overexpression of Smad 7, inflammation and fibrosis decrease.

Adhesion molecules

ICAM-1 and vascular adhesion molecule-1 (VCAM-1) are involved in the attachment of leukocytes to the vascular wall and penetration into the intima, once there, leukocytes can produce proteolytic enzymes that lead to tissue and organ damage, or differentiate into foam cells that lead to the atherosclerotic process[15].

Several animal models have shown that mice deficient in ICAM-1 are resistant to nephropathy in experimental models of diabetes, while treatment with anti-ICAM-1 monoclonal Ab prevents mononuclear cell infiltration into diabetic glomeruli[3].

Our group has shown that the levels of VCAM-1 correlate with the severity of albuminuria in diabetic hypertensive patients[15]. In addition, Seron *et al*[16] reported that VCAM-1 expression is increased in kidney biopsies from patients with DN, they also found a correlation between levels of VCAM-1 and numbers of infiltrating immune cells[18].

ADIPOKINES

Adiponectin and resistin were first described as adipocyte-secreted hormones (adipocytokines) that modulate insulin action. Both; hypoadiponectinemia and hyperresistinemia are associated with inflammation[19].

Hypoadiponectinemia has been reported as a risk factor for the development of albuminuria in mice[19], whereas in humans, resistin is mainly a monocyte-macrophage product. In humans hyperresistinemia promotes the expression of adhesion molecules[20], and is involved in the pathways that lead to albuminuria and renal damage[21].

WHICH INFLAMMATORY MOLECULE?

Certainly, inflammation is an important player in the pathogenesis of DN, However, because of multiple pathways that joint inflammation with diabetic complications, it looks unlikely that one single molecule be sufficient for the development of DN. It is also true that the blockade of the principal mediators could be useful in the prevention of this complication; several studies have been designed in order to indentify therapeutic targets.

The evidence suggest that TNF-α, MCP-1 and adhesion molecules have a prominent role in the development of DN, and all these mediators may be considered therapeutic targets for the prevention and treatment of DN, as we will discuss in the next section.

PERSPECTIVES

Microinflammation is the most important mechanism for development and progression of DN. Our knowledge related to signaling pathways involved in its pathogenesis has not been elucidated at all.

There are several pivotal mediators of inflammation, and their interactions are determinant in the process.

We have reviewed not only biological actions of these mediators, but also their possible therapeutic effects in experimental models.

The Smad family plays a very important role in inflammation and fibrosis in renal disease, its different actions among all molecular mediators leads to open several optional researches in DN.

A very interesting advanced is that if levels of Smad 7 could be restored in sick kidneys we could balance inflammatory responses in patients with renal diseases.

But not only Smad family could be a therapeutic option for DN patients, at this time it is very important take into a count that gene polymorphisms encoding several molecules in this patients have to be modified. Is in this way that investigations are aimed, looking to stop the progression of the disease, and not just for uncontrolled DM but also for other diseases involving the kidney.

Many options for interfering in transcription factors activation have been proposed, first blocking TF binding and second blocking TF pathways for activation. For these conditions there were used by both TF and experimental molecules.

Several studies are needed for interfering with signaling pathways not just for treatment of an abnormal condition as DN but also to prevent it.

Experimental studies have shown that inhibition of TNF-α (with the use of soluble TNF-α receptor fusion proteins, monoclonal antibodies or pentoxifylline) might be an efficacious treatment for renal disease secondary to diabetes mellitus, being pentoxifylline equivalent in efficacy and safety to captopril, and the addition of than drug to inhibitors of the renin-angiotensin system increases

their antiproteinuric effect[1,5].

Our group found that the reduction of urinary albumin excretion with the use of the fixed dose combination trandolapril-verapamil, depends not only from its antihypertensive effect, but also from its action on VCAM-1 adhesion molecules levels[22].

CONCLUSION

Inflammation plays an essential role in the development of DN, this participation involves increased chemokine production, infiltration of inflammatory cells to the kidney, pro-inflammatory cytokine production and tissue damage.

Several components of the diabetic milieu, as hyperglycemia, renin-angiotensin system and oxidative stress can activate the inflammatory process in the kidneys, which results in the infiltration of the organ by monocytes and lymphocytes, which secrete injurious molecules, such as proinflammatory cytokines and reactive oxygen species.

This leukocyte activity amplifies the inflammatory response and promotes cell injury and the development of fibrosis. Better understanding of the inflammatory response in diabetic kidneys is expected to identify novel anti-inflammatory strategies for the potential treatment of human DN.

Abstract

Canagliflozin (CFZ) is a member of new class of glucose lowering agents, sodium-glucose co-transporter (SGLT) inhibitors, which got approval by food and drug administration. It has insulin independent action by blocking the transporter protein SGLT2 in the kidneys, resulting in urinary glucose excretion and reduction in blood glucose levels. In clinical trials, CFZ significantly decreased HbA1c level when administered either as monotherapy or as combined therapy with other anti-diabetic drugs. Intriguingly, it showed additional benefits like weight reduction and lowering of blood pressure. The commonly observed side effects were urinary and genital infections. It has exhibited favorable pharmacokinetic and pharmacodynamic profiles even in patients with renal and hepatic damage. Hence, this review purports to outline CFZ as a newer beneficial drug for type 2 diabetes mellitus.

Key words: Type 2 diabetes mellitus; Sodium-glucose co-transporter 2; Canagliflozin; Clinical trial; Safety profile

Core tip: This review article focuses upon the current pharmacokinetic, pharmacodynamic and clinical trial data on the newly introduced sodium-glucose co-transporter 2 inhibitor, canagliflozin, for the treatment of type 2 diabetes mellitus. It also discusses briefly about the safety profile and future prospective of canagliflozin.

INTRODUCTION

Diabetes mellitus (DM) is a metabolic disorder characterized by insulin resistance, hyperglycemia and progressive pancreatic β-cell dysfunction. Poorly controlled hyperglycemia leads to irreversible microvascular and macrovascular complications like visual impairment and blindness, kidney failure, peripheral neuropathy, myocardial infarction, stroke and lower limb amputation. In 2012, worldwide > 371 million people suffered from diabetes. Out of which 4.8 million people died due to its complications. This global burden is estimated to increase to 552 million by 2030[1]. This implies that the available drugs for DM are not able to maintain or achieve good glycemic control. Potential adverse events like gastrointestinal disturbances (with biguanides like metformin, α-glucosidase inhibitors like acarbose, glucagon-like peptide-1 agonists like exenatide, amylin agonists like pramlintide), hypoglycemia (with insulin, secretagogues like sulfonylureas and meglitinides), weight gain (with insulin, secretagogues like sulfonylureas and meglitinides, thiazolidinediones like pioglitazone) and risk of cardiovascular disease (with thiazolidinediones like pioglitazone) limit their dosage; and ensuing β-cell failure limits their effectiveness. Current guidelines recommend a target HbA1c value of < 7.0%, with patient-centered

approach allowing some flexibility in terms of the actual target, and treatment with lifestyle changes and drugs for better glycemic control in diabetics. But the target HbA1c is rarely achieved with a single anti-diabetic agent and in only about half of adult patients with diabetes taking combination therapy[2,3]. Hence, there is ongoing hunt for newer efficacious and safer treatment strategies.

Kidney plays a pivotal role in maintaining glucose homeostasis through specialized transporters-sodium-glucose co-transporter (SGLT)1 and SGLT2-present in the proximal convoluted tubule (PCT). Together, they absorb almost all of the glucose filtered in the glomerulus. SGLT1 is a low capacity, high affinity transporter present mostly in small intestine, some in S3 segment of PCT in kidney, and in heart. It is responsible for approximately 10% of glucose reabsorption in the kidney. While SGLT2 is a high capacity, low affinity transporter present almost exclusively in S1 segment of PCT, responsible for approximately 90% of glucose reabsorption[4,5]. But kidney was never the target for treatment of diabetes until phlorizin was discovered. Phlorizin was isolated from the apple trees in 1835 and was initially tested for fever, infectious diseases and malaria. It was noticed that high doses caused glycosuria and chronic administration in dogs caused polydipsia and polyuria with normoglycemia. Subsequent detection of SGLT1 and SGLT2 in kidney, their role in glucose reabsorption and confirmation of inhibitory action of phlorizin on these transporters in animal studies paved way to consider phlorizin in the treatment of type 2 diabetes mellitus (T2DM). However, phlorizin was not clinically developed due to its poor pharmacokinetics and side effects attributed to SGLT1 inhibition such as glucose-galactose malabsorption, dehydration and diarrhea[6,7]. Later on T-1095 was discovered, a derivative of phlorizin which had comparatively better pharmacokinetic profile. Nevertheless, it was discontinued in the Phase-Ⅱ clinical trial[8]. Meanwhile, it was observed that there was upregulation of SGLT2 and increase in maximum tubular transport of glucose in diabetic patients[9]. The underline defect in patients with familial renal glycosuria is also attributable to SGLT2 gene mutation. The patients with gene defect excrete increased amount of glucose in urine and are clinically asymptomatic[10]. These two observations with SGLT2 transporter, *i.e.*, the upregulation of SGLT2 in diabetes and its role in familial renal glycosuria, triggered research that ultimately led to the discovery of specific SGLT2 inhibitors viz. sergliflozin and remogliflozin. Unfortunately, these drugs too exhibited unfavorable pharmacokinetic profile, efficacy and side effect and hence did not progress in clinical trials[11].

Dapagliflozin is the first SGLT2 inhibitor that came to the European market in 2012. Food and drug administration (FDA) approved dapagliflozin on 8th January, 2014[12]. It was initially rejected by FDA due to serious concerns about bladder and breast cancer[13]. Canagliflozin was the first of its kind to get approval from FDA on March 29, 2013. Currently it is in phase-Ⅱ trial for the treatment of obesity in the United States and Europe[14]. Ipragliflozin, empagliflozin and many other SGLT2 inhibitors are under different phases of clinical trials.

This article reviews the available data on the pharmacokinetics, the pharmacodynamics and the therapeutic potential and safety of canagliflozin (CFZ).

SEARCH METHODOLOGY

PubMed, ClinicalTrials.gov and Google scholar databases were used for mining the data. Following Medical subject headings words were used in the above mentioned databases: canagliflozin, canagliflozin and SGLT2, canagliflozin and diabetes, canagliflozin and pharmacokinetics, canagliflozin and pharmacodynamics and canagliflozin and adverse events. Up to date information was included till 31st March 2014.

PHARMACOKINETIC PROPERTIES

When CFZ is taken orally it gets rapidly absorbed from gastrointestinal tract in a dose dependent manner with the dose range of 50-300 mg and mean oral bioavailability of approximately 65%. Median $t_{1/2}$ is 1-2 h and steady state concentration is achieved after 4 to 5 d of daily intake of 100 mg and 300 mg. Maximum plasma concentration is not altered in renal injury. It accumulates in the plasma up to 36% following multiple doses of 100 and 300 mg. The plasma protein binding is 99%, which is constant irrespective of its plasma concentrations or hepatic or renal damage[15,16]. It is metabolized into two inactive O-glucuronide metabolites (M5 and M7). Major O-glucuronidation is by UDP glucuronosyltransferase (UGT)1A9 and UGT2B4, while CYP3A4 mediated oxidative metabolism accounts for only 7%. Single oral radioactive [^{14}C] CFZ to healthy subjects demonstrated 41.5%, 7.0% and 3.2% of administered radioactive dose in feces as CFZ, a hydroxylated metabolite and an O-glucuronide metabolite, respectively. The amount of CFZ excreted in urine in unchanged form is less than 1%, whereas the urine excretion of its metabolites namely M7 is 21%-32% and M5 is 7%-10%. Studies conducted so far have shown no clinically significant effect of age, sex, BMI/weight and race on pharmacokinetics of CFZ[15,16].

PHARMACODYNAMIC PROPERTIES

CFZ primarily inhibits SGLT2 in kidney and is responsible for increased urinary glucose excretion and reduction in blood glucose levels. It also inhibits SGLT1 in intestine and its potency on SGLT1 is 160 times lesser as compared to SGLT2[15,16]. It reduces glucose absorption by 31% in first hour and 20% by next hour of food intake. So, when given before meal, it reduces postprandial glucose excursions[15,17]. This insulin independent action is unique and differentiates CFZ from other available antidiabetic agents. Moreover, there is dose dependent reduction in the renal threshold for glucose excretion (RT_G)

with maximal suppression of RTG from 240 mg/dL to approximately 70-90 mg/dL at the dose of 300 mg. Unlike other oral hypoglycemic drugs, CFZ is tolerated well in mild to moderate hepatic and renal failure patients. However, it is contraindicated in patients with estimated GFR (eGFR) < 30 mL/min per 1.73 m^2, end stage kidney disease and patients on dialysis[15].

DOSAGE AND ADMINISTRATION

The recommended starting dose of CFZ is 100 mg once daily to be taken before the first meal of the day. If patients with eGFR of ⩾ 60 mL/min per 1.73 m^2 tolerate CFZ 100 mg once daily and require additional glycemic control, then dose can be increased to 300 mg once daily. Volume depletion has to be corrected in patients prior to the initiation of CFZ to compensate for CFZ induced increased urination[15].

DRUG INTERACTIONS

UGT inducers (*e.g.*, rifampin, phenytoin, phenobarbital, ritonavir) increase the metabolism of CFZ, thereby reducing active CFZ levels in the blood. Thus, the dose of CFZ may be increased from 100 to 300 mg in such patients. On the other hand, CFZ increases Area Under the Curve for digoxin and hence patients on digoxin treatment should be monitored[15].

THERAPEUTIC POTENTIAL

CFZ has shown promising results in many preclinical and clinical studies of T2DM. A study in Zucker fatty rats and Zucker diabetic fatty rats with CFZ (3-30 mg/kg) decreased renal threshold for glucose and increased urinary glucose excretion (UGE). This resulted in decreased blood glucose, HbA1c, weight gain, dose dependent increased fatty acid metabolism, *de novo* lipogenesis and improved insulin sensitivity in these animals[18].

Table 1 lists the published clinical trials on CFZ use as monotherapy and combined therapy. The CANagliflozin Treatment And Trial Analysis (CANTATA Trials) evaluated CFZ as monotherapy or as an add-on therapy to metformin, metformin and sulphonylurea and metformin and pioglitazone. These trials were randomized; double blind, placebo-or active-controlled with primary endpoint of finding the change in HbA1c at the end of 26 or 52 wk from baseline. In a trial using CFZ as monotherapy, both the doses 100 mg and 300 mg produced a statistically significant decrease in HbA1c ($P < 0.001$), body weight (-2.8% by 100 mg and -3.9% by 300 mg *vs* placebo, $P < 0.001$) as well as systolic blood pressure (-3.7 mmHg by 100 mg and -5.4 mmHg by 300 mg *vs* placebo, $P < 0.001$)[19]. Similar significant results were obtained in combined therapy trials viz. CANTATA-D (Dual therapy trial-CFZ compared with Sitagliptin)[20] and CANTATA-MP (CFZ compared with metformin and pioglitazone)[21].

The CANTATA-SU (CFZ compared with Sulphonylurea) trial established reductions in HbA1c in the glimepiride and CFZ 100 mg groups but greater reductions occurred in CFZ 300 mg group. CFZ 100 mg was reviewed as non-inferior where as CFZ 300 mg group was considered as superior to glimepiride arm. There was greater reduction in body weight, blood pressure (BP) and greater rise in high density lipoprotein (HDL) levels in CFZ group[23]. CANTATA-MSU (CFZ compared with metformin and sulphonylurea) results also demonstrated statistically significant reductions ($P < 0.001$) in HbA1c, fasting blood glucose (FBG) and body weight[24]. In another CANTATA-D2 (Triple therapy trial-CFZ compared with Sitagliptin) trial, at the end of 52 wk, it was showed that CFZ 300 mg was superior to sitagliptin 100 mg when added to sulphonylurea and metformin, in reducing HbA1c, FBG, body weight and systolic blood pressure. There was also significant increase in HDL ($P < 0.001$) in CFZ groups as compared to sitagliptin 100 mg[25].

CANTATA trials have unveiled various interesting clinical observations of CFZ use in the management of T2DM patients. CFZ improved glycemic control without a concomitant increase in the occurrence of hypoglycemia. It lowered RTG but lowering of RTG remained above the hypoglycemic threshold (60-70 mg/dL) and since UGE occurs below the RTG, the incidence as well as risk of hypoglycemia with CFZ was minimal[19,26]. Further, the amplified UGE of 80-120 g/d accounted for net loss of calories (approximately 400 kcal/d) that contributed to the weight loss, which was maintained over the trial period of 52 wk[24,26]. This weight loss was predominantly from loss of fat mass rather than lean body mass[22]. The reversal of glucotoxicity and weight loss together helped to improve beta cell function as indicated in improvement in Homeostasis Model Assessment estimating steady state beta cell function in percentage[19,21,24,26]. The mechanism for increased low-density lipoprotein-C with CFZ is not known, however, improvement in HDL-C and triglycerides was likely to be due to improved glycemic control and weight loss associated with CFZ[19,21,22]. Mild reduction in BP was also observed in the trial participants. This was due to the mild osmotic diuretic response to UGE and natriuretic effect of CFZ[24]. Thus, in nutshell, CFZ can reduce blood glucose levels and has the least risk of producing hypoglycemia as compared to other anti-diabetic agents. In addition, it can also modify the insulin resistance, reduce weight and BP and increase HDL-C. These diverse effects are specific to CFZ and would explain the better outcome with CFZ treated patients as compared to other anti-diabetic agent treatment groups. The CANTATA trials have concluded that CFZ could be taken as an initial drug for T2DM patients whose glycemic control is not achieved with diet and exercise; and also as an effective alternative to sulphonylurea, sitagliptin or pioglitazone in dual therapy with metformin.

CFZ was also studied as an add-on to insulin therapy in a 28-d trial. Participants were T2DM patients not optimally controlled with insulin and receiving up to one oral

Table 1 Summary of clinical trials of canagliflozin

References/trial name (*n* = sample size)	Study population and duration of the study	Study drugs	Change in HbA1c from the baseline (in percent)	Change in FBG from baseline	Change in body weight from baseline	Other parameters (least square mean change)
Stenlöf *et al*[19] (*n* = 584)	T2DM patients on diet and exercise with inadequate glycemic control Duration of the study = 26 wk	CFZ = 100 mg/300 mg OD *vs* PL	-0.77% to -1.03% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	-27 mg/dL to -35 mg/dL (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	% Body weight reduction -2.8% to -3.9% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	ΔPPBG = -43 to -59 mg/dL (CFZ 100 mg/300 mg) ΔSBP = -3.3 to -5.0 mmHg (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL) ΔDBP = -1.7 to -2.1 mmHg (CFZ 100 mg/300 mg *vs* PL) ΔHDL = CFZ 100 mg = 11.2% ($P < 0.001$ *vs* PL) CFZ 300 mg = 10.6% ($P < 0.01$ *vs* PL) ΔLDL = 2.9% to 7.1% (CFZ 100 mg/300 mg *vs* PL) ΔTG = 2.5% to -2.3% (CFZ 100 mg/300 mg *vs* PL) HOMA-%B = 9.9% to 20.3% (CFZ 100 mg/300 mg *vs* PL)
CANTATA-D[20] (*n* = 1284)	26-wk extension study T2DM patients with inadequate glycemic control on protocol specified MET-IR monotherapy with HbA1c: 7.0% to 10.5%, FBG < 270 mg/dL	CFZ = 100 mg/300 mg OD + MET-IR *vs* PL + MET-IR for first 26 wk	At the end of 26 wk -0.79% to -0.94% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk -27.3 mg/dL to -37.8 mg/dL (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk % Body weight reduction -3.7% to -4.2% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk ΔPPBG = -47.9 mg/dL to -57.1 mg/dL (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL) SITA = -49.3 mg/dL ΔSBP = -3.84 mmHg to -5.06 mmHg (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL), SITA = -1.83 mmHg ΔTG = CFZ 100 mg = 1.6%, $P = 0.7$ *vs* PL, CFZ 300 mg = -1.4%, $P = 0.2$ *vs* PL, SITA = 1.0% ΔHDL = 10.4% to 12.1% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL), SITA = 5%
		CFZ = 100 mg/300 mg OD + MET-IR *vs* SITA 100 mg + MET-IR for next 26 wk	SITA = -0.82%	SITA = -20.2 mg/dL	SITA = -1.2%	
			At the end of 52 wk -0.73% to -0.88% (CFZ 100 mg/300 mg)	At the end of 52 wk -26.2 mg/dL to -35.2 mg/dL (CFZ 100 mg/300 mg, $P < 0.001$ *vs* SITA)	At the end of 52 wk -3.8% to -4.2% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* SITA)	At the end of 52 wk ΔSBP = -3.53 mmHg to -4.65 mmHg (CFZ 100 mg/300 mg, $P < 0.001$ *vs* SITA) SITA = -0.66 mmHg ΔTG = CFZ 100 mg = 1.9%, $P = 0.46$ *vs* SITA CFZ 300 mg = 2.7%, $P = 0.32$ *vs* SITA SITA = -0.4% ΔHDL = 11.2% to 13.3% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* SITA), SITA = 6.0%
			SITA = -0.73%	SITA = -17.7 mg/dL	SITA = -1.3%	
Guthrie *et al*[21] Forst *et al*[22] CANTATA-MP (*n* = 344)	26-wk extension study T2DM patients currently treated with PPAR gamma agent (PIO or ROSI) and MET with HbA1c: 7%-10.5% and FBG < 270 mg/dL	CFZ = 100 mg/300 mg OD + MET + PIO *vs* PL + MET + PIO for first 26 wk CFZ = 100 mg/300 mg OD + MET + PIO *vs* SITA 100 mg + MET + PIO for next 26 wk	At the end of 26 wk -0.89% to -1.03% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk -26.8 mg/dL to -33.2 mg/dL (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk -2.8% to -3.8% (CFZ 100 mg/300 mg, $P < 0.001$ *vs* PL)	At the end of 26 wk ΔSBP = CFZ 100 mg = -5.30 mmHg ($P = 0.005$ *vs* PL) CFZ 300 mg = -4.70 mmHg ($P = 0.016$ *vs* PL) ΔTG = CFZ 100 mg = 3.2% ($P = 0.034$ *vs* PL) CFZ 300 mg = -1.7% ($P = 0.003$ *vs* PL) ΔHDL = CFZ 100 mg = 7.2% ($P = 0.01$ *vs* PL) CFZ 300 mg = 8.9% ($P < 0.001$ *vs* PL) HOMA-%B = 15.19% to 18.14% (CFZ 100 mg/300 mg, $P < 0.01$ *vs* PL)
			At the end of 52 wk -0.92% to -1.03% (CFZ 100 mg/300 mg)	At the end of 52 wk -26.7 mg/dL to -31.5 mg/dL (CFZ 100 mg/300 mg)	At the end of 52 wk -2.7% to -3.7% (CFZ 100 mg/300 mg)	At the end of 52 wk ΔSBP = -3.4 to -3.7 mmHg (CFZ 100 mg/300 mg) ΔDBP = -2.5 to -2.7 mmHg (CFZ 100 mg/300 mg) ΔHDL = CFZ 100 mg = 7.0% CFZ 300 mg = 11.4% ΔLDL = 10.9% to 14.3% (CFZ 100 mg/300 mg) ΔTG = 4.7% to -0.6% (CFZ 100 mg/300 mg)

Cefalu *et al*[23] CANTATA-SU (*n* = 1450)	T2DM patients with HbA1c: 7%-9.5% on stable MET therapy ⩾ 1500 mg/d, BMI = 22-45kg/m^2, FBG ⩽ 270mg/dL Duration of the study = 52 wk	CFZ = 100 mg/300mg OD + MET *vs* GLIM 6 mg/8 mg OD + MET	-0.82% to -0.93% (CFZ 100 mg/300 mg) GLIM = -0.81%	-1.35 mmol/L to -1.52 mmol/L (CFZ 100 mg/300 mg) GLIM = -1.02 mmol/L	-4.2% to -4.7% (CFZ 100 mg/300 mg, *P* < 0.001 *vs* GLIM) GLIM = 1%	ΔSBP = -3.3 to -4.6 mmHg (CFZ 100 mg/300 mg) GLIM = 0.2 mmHg ΔDBP = -1.8 to -2.5 mmHg (CFZ 100 mg/300 mg) GLIM = -0.1 mmHg ΔTG = CFZ 100 mg = -3.7% CFZ 300 mg = 2.3% GLIM = 9.5% ΔHDL = CFZ 100 mg = 7.9% CFZ 300 mg = 9.0% GLIM = 0.3% ΔLDL = 9.6% to 14.1% (CFZ 100 mg/300 mg) GLIM = 5%
Wilding *et al*[24] CANTATA-MSU (*n* = 469)	26-wk extension study T2DM patients currently treated with MET and SU with HbA1c: 7%-10.5% and FBG < 270 mg/dL	CFZ = 100 mg/300 mg OD + MET + SU *vs* PL + MET + SU	At the end of 26 wk -0.85% to -1.06% (CFZ 100 mg/300 mg, *P* < 0.001 *vs* PL)	At the end of 26 wk -18.2 mg/dL to -30.5 mg/dL (CFZ 100 mg/300 mg, *P* < 0.001 *vs* PL)	At the end of 26 wk -2.1% to -2.6% (CFZ 100 mg/300 mg, *P* < 0.001 *vs* PL)	At the end of 26 wk ΔSBP = CFZ 100 mg = -4.89 mmHg (*P* = 0.07 *vs* PL) CFZ 300 mg = -4.27 mmHg (*P* = 0.2 *vs* PL) ΔTG = CFZ 100 mg = 5.4% (*P* = 0.256 *vs* PL) CFZ 300 mg = 8.5% (*P* = 0.57 *vs* PL) ΔHDL = CFZ 100 mg = 5.7% (*P* = 0.153 *vs* PL) CFZ 300 mg = 6.5% (*P* = 0.056 *vs* PL)
Schernthaner *et al*[25] CANTATA-D2 (*n* = 755)	T2DM patients currently treated with MET and SU with HbA1c: 7%-10.5% and FBG < 300 mg/dL Duration of the study = 52 wk	CFZ = 300 mg OD + MET + SU *vs* SITA = 100 mg OD + MET + SU	CFZ 300 mg = -1.03% (*P* < 0.001 *vs* SITA) SITA = -0.66%	CFZ 300 mg = -29.9 mg/dL (*P* < 0.001 *vs* SITA) SITA = -5.85 mg/dL	CFZ 300 mg = -2.5% (*P* < 0.001 *vs* SITA) SITA = 0.3%	ΔSBP = CFZ 300 mg = -5.06 mmHg (*P* < 0.001 *vs* SITA) SITA = 0.85 mmHg ΔTG = CFZ 300 mg = 9.6% (*P* = 0.554 *vs* SITA) SITA = 11.9% ΔHDL = CFZ 300 mg = 7.6% (*P* < 0.001 *vs* SITA) SITA = 0.6%
Devineni *et al*[26] (*n* = 29)	T2DM patients not optimally controlled on insulin and up to one oral AHA with BMI: 25-45 kg/m^2, FBG: 3.3-5.5 mmol/L, HbA1c: 7%-10.5% and serum creatinine: < 132.6 mmol/L for males and < 123.8 mmol/L for women Duration of the study = 28 d	CFZ 100 mg OD/300 mg bid + Insulin + upto one AHA *vs* PL + insulin + upto one AHA	-0.73% to -0.92% (CFZ 100 mg/300 mg)	-2.11 mmol/L to -2.35 mmol/L (CFZ 100 mg/300 mg)	-0.73 kg to -1.19 kg (CFZ 100 mg/300 mg)	ΔUGE = 71.9 g/d to 129.2 g/d
Rosenstock *et al*[27] (*n* = 451)	T2DM patients under stable MET monotherapy (⩾ 1500 mg/d) with HbA1c: 7%-10%, BMI: 24-45 kg/m^2, serum creatinine: < 1.5mg/dL for males and < 1.4 mg/dL for females Duration of the study = 12 wk	CFZ = 50/100/200/300 mg OD or 300 mg bid + MET *vs* PL + MET *vs* SITA 100 mg OD + MET	CFZ 50 mg = -0.79% 100 mg = -0.76% 200 mg = -0.70% 300 mg = -0.92% 300 mg bid = -0.95% SITA = -0.74%	CFZ 50 mg = -16.2 mg/dL 100 mg = -25.2 mg/dL 200 mg = -27.0 mg/dL 300 mg = -25.2 mg/dL 300 mg bid = -3.4 mg/dL SITA = -12.6 mg/dL	CFZ 50 mg = -2.3% 100 mg = -2.60% 200 mg = -2.70% 300 mg = -3.40% 300 mg bid = -3.4% SITA = -0.60%	ΔSBP = -3.3 to -5 mmHg (CFZ 100 mg/300 mg) SITA = -0.8 mmHg ΔDBP = -1.7 to -2.1 mmHg (CFZ 100 mg/300 mg) SITA = -0.6 mmHg ΔTG = CFZ 100 mg = 2.5% CFZ 300 mg = -2.3% ΔHDL = CFZ 100 mg = 11.2% CFZ 300 mg = 10.6% ΔLDL = 2.9% to 7.1% (CFZ 100 mg/300 mg) HOMA-%B = CFZ 50-300 mg OD = 6% to 18% CFZ 300 mg bid = 16% SITA = 10%

ClinicalTrials.gov identifier: NCT01064414[28] (*n* = 272)	26-wk extension study T2DM patients with or without AHA, on regular diet and exercise with moderate renal impairment	CFZ = 100 mg/300 mg OD with or without AHA *vs* PL with or without AHA	At the end of 26 wk -0.33% to -0.44% (CFZ 100 mg, *P* = 0.01 *vs* PL, CFZ 300 mg, *P* < 0.001 *vs* PL)	At the end of 26 wk CFZ 100 mg = -14.9 mg/dL, *P* = 0.02 CFZ 300 mg = -11.7 mg/dL, *P* = 0.06	Information was not available	Information was not available

OD: Once daily; FBG: Fasting blood glucose; PL: Placebo; CFZ: Canagliflozin; ΔSBP: Change in systolic blood pressure from baseline; ΔDBP: Change in diastolic blood pressure from baseline; ΔHDL: Change in blood HDL level from baseline; ΔLDL: Change in blood LDL level from baseline; ΔTG: Change in blood triglycerides level from baseline; ΔPPBG: Change in postprandial blood glucose from baseline; MET: Metformin; SU: Sulphonylurea; SITA: Sitagliptin; PIO: Pioglitazone; ROSI: Rosiglitazone; AHA: Antihyperglycemic agent; IR: Immediate release; GLIM: Glimepride; HOMA-%B: Homeostasis Model Assessment estimating steady state beta cell function in percentage; LDL: Low-density lipoprotein; T2DM: Type 2 diabetes mellitus; PPAR: Peroxisome proliferator activated receptor.

antihyperglycemic agent. Both the CFZ doses (100 mg and 300 mg) showed greater reduction in HbA1c, body weight and FBG[26].

The effects of various doses of CFZ (50, 100, 200, 300 mg OD and 300 mg BD) have also been assessed in a 12-wk trial in T2DM patients under stable metformin therapy. CFZ demonstrated greater reduction in FBG and body weight at all doses as compared to sitagliptin[27].

Three studies conducted trials in special patient population. One study was on adults with T2DM aged 55 to 80 years, not controlled on diet and exercise together with an antihyperglycemic agent. This trial showed that CFZ is equally effective in this age group[15]. In the second study, CFZ showed significant reduction in HbA1c in T2DM patients with or without an antihyperglycemic agent, on regular diet and exercise with moderate renal impairment[29]. The third trial done on T2DM patients with stage 3 chronic kidney disease (CKD) established the safety and efficacy of CFZ in these patients as well[28].

SAFETY PROFILE

Overall, CFZ is well tolerated. The distinctive concern is about increased risk of genital mycotic infections and urinary tract infections (UTI). The data from the four pooled 26-wk placebo-controlled trials including monotherapy trial and three add-on combination trials with metformin, metformin and sulfonylurea or metformin and pioglitazone; demonstrated female genital mycotic infections in 3.2% of patients in placebo, 10.4% in CFZ 100 mg and 11.4% of patients in CFZ 300 mg groups. The incidence of genital mycotic infection was less in males with rates of 0.6% in placebo, 4.2% in CFZ 100 mg and 3.7% in CFZ 300 mg groups. UTI presented at the rate of 4% in the placebo, 5.9% in 100 mg dose and 4.3% in the 300 mg dose groups[15].

Other common adverse events reported were increased urination, vulvovaginal pruritus, thirst, constipation and nausea. The risk of hypoglycemia in patients with CFZ was generally low. Volume depletion-related adverse reactions such as dizziness, hypotension and dehydration were higher in elderly patients, 65 years or older, particularly with the 300 mg daily dose, in comparison to younger patients. There were mild and transient changes in eGFR, albumin-creatinine ratio and blood urea nitrogen in early phase of the study in stage 3 CKD patients. However, 26-wk treatment caused return of these parameters to baseline; there was also an increase in serum potassium and magnesium in these patients[15,29]. Some studies showed increase in LDL-C and hematocrit[15]. These short-term studies have shown no significant changes in vital signs or electrocardiogram finding with CFZ use. A long term prospective study to evaluate the efficacy and adverse effect profile of CFZ is already underway[30]. The summary of adverse events of CFZ is depicted in Table 2.

CONCLUSION

Clinical trial data for CFZ reveal that its glucose lowering efficacy is superior to usual gold standard drugs with the added benefit of weight loss. FDA has already approved CFZ monotherapy in adjuvant to diet and exercise. So far, none of the serious concerns which surround dapagliflozin are seen in CFZ trials. Furthermore, its insulin independent action is an important advantage as this essentially means that its glucose-lowering efficacy should not decrease significantly with progression of diabetes. CFZ is also compatible with other anti-diabetic therapies, including insulin, and might therefore be of value at any stage in the natural history of T2DM. CFZ with its multi dimensional properties can be beneficial in the disease cluster of obesity, hypertension and diabetes. Further, there is a low propensity to cause hypoglycemia in patients as glucose is reab-

Table 2 Summary of adverse events observed in the canagliflozin clinical trials

S. No	ClinicalTrials.gov identifier	Adverse events	Ref.
1	NCT01081834	Increased incidence of AEs in CFZ groups Serious AEs and AE related discontinuations similar in all groups Increased incidence of UTI, genital mycotic infections and osmotic diuresis related AEs in CFZ groups Moderate increase in BUN, serum creatinine and decrease in serum uric acid	Stenlöf *et al*[19]
2	NCT01106677	AEs similar across all groups Higher incidence of pollakiuria in CFZ groups -5.71% with 100 mg CFZ and 2.72% with 300 mg CFZ *vs* 0.55% of PL	[20]
3	NCT01106690	Vulvovaginal mycotic infections: 2.65% to 5.26% *vs* 0% of placebo Pollakiuria: 6.14% to 9.42% *vs* 0.87% of placebo Increased rate of hypoglycemic event with CFZ 300 mg (5.26% *vs* 1.74% of PL)	Guthrie *et al*[21]
4	NCT00968812	Osmotic diuresis related AEs in 3% of CFZ groups as compared to < 1% in placebo groups Genital infections and increase in LDL cholesterol more in CFZ groups	Cefalu *et al*[23]
5	NCT01106625	Superficial genital mycotic infection: 16.0% to 21.0% *vs* 5% in women and 3.4% to 6.6% *vs* 1.3% in men More subjects treated with CFZ had ⩾ 1 hypoglycemic episodes	Wilding *et al*[24]
6	NCT01137812	Genital mycotic infections: 9.2% of CFZ 300 mg *vs* 0.5% of SITA Osmotic diuresis related AEs: 2.4% of CFZ 300 mg *vs* 1.3% of SITA Higher incidence of increased TG in CFZ groups	Schernthaner *et al*[25]
7	Not available	Similar rate of AEs and discontinuations across all groups No serious AEs	Devineni *et al*[26]
8	NCT00642278	Non dose dependent increase in incidence of genital infections (3%-8% *vs* 2% of SITA) and UTI (3%-9% *vs* 2% of SITA) in CFZ groups Low incidence of hypoglycemia Small increase in LDL cholesterol in CFZ groups	Rosenstock *et al*[27]
9	NCT01064414	AEs similar across all groups Increased incidence of hypoglycemic events in CFZ groups -14.44% with 100 mg CFZ and 11.24% with 300 mg CFZ *vs* 4.44% of PL	[28]

AEs: Adverse events; CFZ: Canagliflozin; UTI: Urinary tract infections; SITA: Sitagliptin; LDL: Low-density lipoprotein; PL: Placebo; TG: Triglycerides; BUN: Blood urea nitrogen.

sorbed by SGLT1 in kidney. In addition to the reported side effects of CFZ like UTI, genital mycotic infections, volume depletion and hypotension, the high cost of CFZ may prove to be a limiting factor in its wide spread use. However, for the time being CFZ has been proven to be safe and well tolerated and it is for the further long term studies to establish it more firmly as a major breakthrough in the clinical armamentarium for patients with diabetes.

Abstract

AIM: To assess the effectiveness of the Chronic Disease Self-Management Program (CDSMP) on glycated hemoglobin A1c (HbA1c) and selected self-reported measures.

METHODS: We compared patients who received a diabetes self-care behavioral intervention, the CDSMP developed at the Stanford University, with controls who received usual care on their HbA1c and selected self-reported measures, including diabetes self-care activities, health-related quality of life (HRQOL), pain and fatigue. The subjects were a subset of participants enrolled in a randomized controlled trial that took place at seven regional clinics of a university-affiliated integrated healthcare system of a multi-specialty group practice between January 2009 and June 2011. The primary outcome was change in HbA1c from randomization to 12 mo. Data were analyzed using multilevel statistical models and linear mixed models to provide unbiased estimates of intervention effects.

RESULTS: Demographic and baseline clinical characteristics were generally comparable between the two groups. The average baseline HbA1c values in the CDSMP and control groups were 9.4% and 9.2%, respectively. Significant reductions in HbA1c were seen at 12 mo for the two groups, with adjusted changes around 0.6% ($P < 0.0001$), but the reductions did not differ significantly between the two groups ($P = 0.885$). Few significant differences were observed in participants' diabetes self-care activities. No significant differences were observed in the participants' HRQOL, pain, or fatigue measures.

CONCLUSION: The CDSMP intervention may not lower HbA1c any better than good routine care in an integrated healthcare system. More research is needed to understand the benefits of self-management programs in primary care in different settings and populations.

Key words: Type 2 diabetes; Self-management; Chronic Disease Self-Management Program; Glycemic control; Glycated hemoglobin; Chronic disease

Core tip: Diabetes is a serious chronic disease. One of the most studied evidence-based behavioral or self-care programs targeting chronic conditions including diabe-

tes is the Stanford Chronic Disease Self-Management Program (CDSMP). Although the CDSMP has been studied extensively, its impact on glycemic control has not been thoroughly evaluated in a randomized controlled trial to date. To the best of our knowledge, this is the first study to evaluate the effectiveness of the CDSMP in a randomized controlled trial. Our finding that the CDSMP intervention may not lower hemoglobin A1c any better than good routine care in an integrated healthcare system calls for further research.

Impact of chronic disease self-management programs on type 2 diabetes management in primary care. *World J Diabetes* 2014; 5(3): 407-414 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i3/407.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i3.407

INTRODUCTION

Diabetes is a serious chronic condition affecting millions of people worldwide. According to estimates by the World Health Organization, about 350 million people have diabetes globally[1]. Diabetes has a severe and significant health and economic impact on all nations. It is the 6th leading cause of death in Canada and the 7th leading cause of death in the United States, costing an estimated $174 billion[2,3]. The bulk of this cost is attributable to the serious long-term complications associated with the condition including limb amputations, blindness, coronary health disease, stroke, and kidney disease[3]. Type 2 diabetes accounts for 90%-95% of all diabetes[3]. Although type 2 diabetes is more prevalent among people aged 40 years or older, the prevalence among younger populations is increasing dramatically because of the rise in obesity and physical inactivity in children and the youth[4].

Supportive programs to enhance patient self-care have been touted as a pre-requisite to diabetes management in spite of differences in individual needs to cope with this debilitating condition[5]. The traditional didactic models of care that involved teaching patients to improve the knowledge of their health condition are giving way to the current models that focus on behavioral or self-care approaches aimed at providing patients with the skills and strategies to promote and change their behavior[6]. In fact, several national organizations including the American Diabetes Association and the American Association of Diabetes Educators consider self-care an essential component of effective diabetes management[7-9].

One of the most studied evidence-based behavioral or self-care programs targeting chronic conditions is the Chronic Disease Self-Management Program (CDSMP). Developed at the Stanford University, the program offers the potential to improve overall health of individuals with chronic conditions, while preventing further decline in their general health status[10-12]. Designed as a 6-wk, community-based self-care education program, CDSMP focuses on assisting participants to gain confidence or self-efficacy and acquire skills to better manage their chronic conditions. It is taught by trained leaders using a structured protocol.

The CDSMP has been found to be highly effective in improving general health and lowering hospitalization rates[10]. It has therefore been implemented worldwide for several chronic conditions such as heart disease, lung disease, arthritis, and diabetes as well as evaluated in various settings including the United States, Canada, United Kingdom, Australia, New Zealand, Bangladesh, China, Hong Kong, and The Netherlands[13-20]. While the original CDSMP validation study found improvements in general health status, health behaviors, and healthcare utilization[10], the findings of more recent studies from a variety of self-management programs have been inconsistent[5,21-27]. A recent literature review of randomized controlled trials comparing self-management support interventions for general chronic diseases *vs* usual care revealed mixed results. While positive findings were found regarding self-efficacy, less positive ones were found for quality-of-life measures[5]. Also although the CDSMP has been studied extensively, its impact on glycemic control has not been thoroughly assessed. In particular, its effectiveness on glycemic control has not been evaluated in a randomized controlled trial in the United States to date. A recent study concluded that the CDSMP is a useful and appropriate program for lowering glycated hemoglobin A1c (HbA1c) among those out of control[28]. However, this was a longitudinal study with no comparison group. Another related study found the CDSMP to improve lifestyle behaviors among patients with type 2 diabetes[23,29]. But again this was a single-group design.

The aim of this study was to assess the effectiveness of the CDSMP on glycemic control and selected self-reported measures among patients with type 2 diabetes in a large integrated healthcare organization in central Texas that serves large racially/ethnically diverse populations.

MATERIALS AND METHODS

Design

This study was a comparison of one intervention arm, the CDSMP, and the control arm from an open-label, 4-arm randomized controlled trial that was designed to evaluate the effectiveness of two different type 2 diabetes mellitus (T2DM) self-care interventions (implemented singly and in combination) on glycemic control. Designed with the acknowledgment that both patients and researchers would be aware of the random assignment, the study protocol consisted of screening potential subjects for eligibility, randomizing them to one of four study arms, and following them over a 24-mo period. However, the primary end-point was change in HbA1c from randomization/baseline to 12 mo of follow-up. The current study reported here focuses on participants in two of the four original study arms.

The study protocol was approved by the Institutional Review Boards (IRB) of Scott and White Healthcare System and Texas A and M Health Science Center. All quali-

fied participants accepted the conditions of the study and gave informed written consent at enrollment/orientation. Enrollment occurred between January 2009 and June 2011 and data collection was completed in July 2012. We adhered to the CONSORT protocol[30] and registered the trial with clinicaltrials.gov (NCT01221090).

Setting, participants, and recruitment

Participants represent a subset of subjects that were recruited from seven participating clinics of a large integrated healthcare system, a university-affiliated, multispecialty group practice associated with a 250000-member Health Maintenance Organization in central Texas. Potential participants were identified through electronic medical records if they: (1) had a diagnosis of T2DM; (2) were ≥ 18 years; (3) had a lab assessed HbA1c value ≥ 7.5% (≥ 58 mmol/mol) within the last six months; and (4) were able to communicate in English. Subjects were excluded if they: (1) had documented reports of alcoholism or drug abuse; (2) were pregnant or planning to become pregnant within 12 mo; or (3) were unwilling to sign an informed consent. Recruitment was solicited by physicians within the seven clinics who agreed to invite their patients to participate in the study.

Physicians were provided with IRB approved invitation-to-participate letters and a list of their T2DM patients meeting the threshold HbA1c level at their last visit. Contact was initiated with potential subjects through physician-sent letters, describing the study and requesting a completed screening enrollment card if interested. Subjects who returned a screening enrollment card were contacted by project coordinators, who provided additional information and screened them to determine eligibility. To verify the inclusion and exclusion criteria, subject permission was obtained to review their medical records. Other recruitment strategies included oral referrals by physicians and patient educators and posting messages in waiting areas of study clinics.

Lab assessments were continuously monitored at each phase of the study recruitment to ensure that enrolled participants had HbA1c values ≥ 7.5% (≥ 58 mmol/mol) within the last six months since individuals who previously met this criterion may no longer fulfill that requirement at orientation. A follow-up telephone interview was conducted to determine participation interest. Lab results were screened to ensure that the participant met qualifying HbA1c and if needed, tests were scheduled.

Intervention

Participants randomized to the CDSMP arm were invited to attend a 6-wk, classroom-based program for diabetes self-management. The effectiveness of the CDSMP has been described elsewhere[10]. With the goal of increasing self-efficacy to ultimately decrease chronic disease related symptoms and avoidable healthcare utilization, the CDSMP teaches participants techniques to facilitate enhanced decision making, action planning, and effective communication. CDSMP workshops were hosted in clinical environments and community-based settings. While fidelity to the individual classes was not monitored, CDSMP license requires that lay leaders use pre-scripted materials and that experienced master trainers/lay leaders (who attend a required four-day training program) lead the workshops.

Participants randomized to the control arm did not receive any treatment other than their usual clinical diabetes care, along with some publicly available Texas Diabetes Council patient education materials.

Data collection

Study measures were obtained at orientation/baseline, 6 mo, and 12 mo of follow-up. Participants received monetary compensation in the form of a gift card for travel expenses and time, consisting of $20 at orientation and at the 12-mo follow-up visit.

At orientation, a questionnaire was administered to obtain several pieces of information including: (1) demographics such as age, gender, and race/ethnicity; (2) diabetes self-care activity monitoring (number of days, 0-7, that any specific self-care activity was performed in the past week) as measured by the Summary of Diabetes Self-Care Activities instrument; (3) self-reported health-related quality of life (HRQOL) measures (*e.g.*, number of days physical/mental health was not good); and (4) pain and fatigue measures (on a scale of 1-10, 1 indicating none and 10 severe). Questionnaires were administered every 6 mo. However, as our primary end point was 12 mo, analyses were only conducted for this time period.

Anthropometric data were obtained at orientation and at subsequent follow-up visits. Height in inches was measured without shoes. Weight was measured in pounds on a balance beam scale or an electronic scale without shoes. Body mass index (BMI) was computed from height and weight measurements. Blood pressures were recorded with either a mercury sphygmomanometer or a validated automated device. Participants who were unable to come in for their follow-up appointments had their height, weight, and blood pressure data abstracted from electronic health records (EHRs). Measures recorded fell within the range of 10 d prior to and 45 d after participants' scheduled follow-up dates. This was done to obtain participant visits as close to their target dates as possible, but also allow for enough time after the target date to accommodate for scheduling errors (*i.e.*, missed appointments, rescheduling).

Measures of HbA1c were collected from EHRs dating back 6 mo prior to orientation to the last day of study participation (45 d after the 12-mo follow-up period). If a participant did not have any HbA1c value within the EHR for any particular follow-up visit, a lab test was scheduled to obtain a measure. Of the HbA1c collected 6 mo prior to orientation, the value measured closest to the orientation date was considered as the baseline HbA1c value. HbA1c values that were measured on dates preceding the baseline HbA1c were not included; *i.e.*, HbA1c values included in the analysis were those collected since the baseline HbA1c and until the last day of study participation.

Definition of a completed follow-up participation

A participant was considered to have completed a follow-up if there was an available HbA1c within the designated follow-up period, *i.e.*, within the cut-off dates, defined as within 45 d after the scheduled follow-up dates. For the 6-mo follow-up measure, if at least one HbA1c was available after baseline and before the 6-mo cut-off, the participant was considered to have completed a follow-up. For the 12-mo follow-up measure, the designated range was between the 6-mo cut-off date and the 12-mo cut-off date. Participants who were unable to complete an assessment at one time period were not excluded from future assessments. For instance, if a participant did not have any HbA1c measured within the specified time period for their 6-mo follow-up but had one available for their 12-mo follow-up, he/she was considered to have completed the 12-mo follow-up, but not the 6-mo.

Outcome measures

The primary study outcome measure was change in HbA1c from randomization to 12 mo of follow-up. Secondary outcome measures included BMI and blood pressure, along with several self-management behavioral measures (*e.g.*, foot care) from randomization to 12 mo of follow-up.

Statistical analysis

Analysis was based on intent-to-treat. Descriptive statistics were used to describe baseline demographic, anthropometric, and clinical characteristics by study arm. Analysis of variance as used to compare average changes in self-management behaviors between study arms. To determine whether the treatment had an effect on the rate of change in HbA1c level over time, we used linear mixed models that included time as a continuous variable. A spatial power covariance structure with time as the distance measure accounted for the time-series correlation among repeated measurements on each subject. Forward selection was utilized, in which powers of time were added one at a time to the base model including treatment group effects only. Time and treatment effects were then added gradually and evaluated with likelihood ratio tests to assess any effect modification. The final mixed model included time, time squared, treatment group, and the interaction between time and treatment group as fixed effects. HbA1c values included in the analysis were those falling within the time frame of 6 mo prior to orientation until the 12-mo follow-up cut-off point.

RESULTS

Subject enrollment, participation and retention

The flow diagram of participant enrollment and disposition in the trial has been described elsewhere[31]. Of the subjects randomized, 101 entered the CDSMP arm and 95 entered the control arm. Of the participants assigned to the CDSMP, 75.6% attended 4 of 6 sessions required for successful completion.

Demographic data and baseline comparison of study population

Demographic and baseline clinical characteristics were generally comparable between the two groups (Table 1). The mean age of participants was 57.6 ± 10.9 years. Slightly more than a third (36.4%) was of minority status, self-reporting as either African American or Hispanic. The majority of participants had received post-secondary education; 40% had attended some college or vocational school, 20% were college graduates, and 13% had completed higher forms of education. Approximately one-third reported annual incomes greater than $50000, while almost 40% reported annual incomes between $25000 and $49999.

An overwhelming majority (92.9%) of the participants were either overweight or obese, with a mean BMI of 34.3 ± 7.4 kg/m^2. While measures of systolic blood pressure were comparable between study arms, with a mean of 134.8 ± 19.3 mmHg, measures of diastolic blood pressure were significantly different ($P < 0.002$). The mean baseline HbA1c for participants was 9.3% ± 1.6% and did not differ significantly between the two groups.

Table 2 summarizes participants' diabetes self-care activity (DSCA) monitoring, HRQOL measures, and pain and fatigue measures at baseline. Participants in the control arm reported checking their feet more frequently than those in the CDSMP arm ($P = 0.04$). Although participants in the control group reported inspecting the inside of their shoes more frequently and also tended to report fewer unhealthy physical days and experience less limited days due to physical and mental health, these did not reach statistical significance ($P \geqslant 0.05$).

Changes in HbA1c from baseline to 12 mo

There were modest but statistically significant reductions in HbA1c from baseline to 12 mo of follow-up. The results of the linear mixed model are presented in Table 3. The adjusted reductions in HbA1c over the 12 mo of follow-up for the CDSMP and control groups were 0.559% and 0.576%, respectively ($P < 0.0001$). However, the interaction term of the treatment group and time was not statistically significant ($P = 0.885$), implying no significant difference in HbA1c reductions by treatment assignment.

Changes in DSCA monitoring, HRQOL measures, and pain and fatigue measures

The mean difference in the number of days (within the last 7 d), from baseline to 12 mo of follow-up, that participants reported using specific diabetes self-care activity features were compared between the CDSMP and control arms (table not shown). While there were no differences on 12 of the 14 self-care indicators, participants in the control arm had a higher rate of change in checking their feet than those in the CDSMP arm (increase of 0.28 d/mo *vs* 0.20 d/mo; $P = 0.02$). Similarly, participants in the control arm reported an increase of 0.15 d/mo eat-

ing 5 or more servings of fruits and vegetables compared to an increase of 0.01 d/mo reported by those in the CDSMP arm (P = 0.02).

DISCUSSION

In this study, we sought to assess the effectiveness of the CDSMP on HbA1c and selected self-reported measures among patients with type 2 diabetes who were out of control. We found no significant differences between the CDSMP intervention and usual care in this integrated healthcare system. To the best of our knowledge, this is the first study to evaluate the effectiveness of the CDSMP in a randomized controlled trial in the United

States. It is also one of the first studies to evaluate and compare these interventions in a racially/ethnically diverse population in a practice setting outside of testing done by the original program developers. It therefore provides important exploratory data, shaping our knowledge and understanding of factors which may be important to minority and ethnic populations in adopting diabetes self-management techniques.

Our results corroborate the findings of others that participation in the CDSMP may be associated with better glycemic control[28]. However, a comparison with the control group indicates that usual care might do equally well. Therefore, our study findings need to be tempered due to the possibility of methodological confounds such as unaccounted group demographic and health differences at baseline, relatively small sample sizes, and better awareness among those in a clinical trial or high quality routine diabetes care that emphasizes the importance of glycemic control. For example, participants in this study were, on average, younger than those studied in other recent CDSMP studies[23,29]. Additionally, the controls in this study appeared slightly healthier and better educated than their counterparts in the CDSMP intervention which might have made them more receptive to both clinical and community-based diabetes self-management and obesity prevention messages. It should be noted that Scott and White Health System employs diabetes educators for their patients with diabetes. Scott and White also employs dedicated endocrinologists and their usual care for diabetes exceeds the recommendations set by the Texas Diabetes Association.

Other study limitations need to be noted. First, our subjects were selected from a randomized controlled trial with three interventions, restricting the numbers available in any one group. Second, post-hoc analysis showed that we were somewhat under-powered: we only had 60% power to detect a difference of 0.5% HbA1c reduction between the two groups at the current sample size. Other future analyses should focus on randomizing a larger number of participants in the treatment arm being investigated. Third, there were notable differences between the intervention and control groups, with the control group appearing to be healthier at baseline. Fourth, there was attrition in terms of treatment completion for the intervention group (75.6% attended 4 of 6 sessions required for successful completion) as well as differential research attrition between the two groups (14.9% or 15% participants in the treatment group and 23.2% or 22% participants in the control group did not have 12 mo data). Finally, this study was conducted in only one integrated health care system, limiting generalizability to other settings and populations.

There is also a debate in the self-management field regarding whether generic *vs* disease-specific self-management is more beneficial[24,32]. While our view was that a generic program would be valuable for patients experiencing several comorbidities including diabetes, more positive results might have been observed if the diabetes specific CDSMP was utilized (which was not evidence-based at the time of initial program selection for English speaking patients)[33].

In conclusion, we found in this study that although a behavioral intervention such as the CDSMP can result in some modest improvements in glycemic control, the same improvements may be found among participants that receive usual care. The reduction in HbA1c levels found in our control group that received usual care suggests that good routine care in an integrated healthcare system can also lead to better glycemic control. More research is needed to understand the benefits of self-management programs both independently and in conjunction with primary care. For example, are there settings where self-management programs might be especially needed, *e.g.*, in medically underserved areas? What kinds of participants might improve most with self-management programs? Such knowledge is important for providing better tailoring diabetes care to patients.

We thank Dawn Begaye and Janet Helduser for study coordination, Ann Robertson for data abstraction, and Phyllis Davis for administrative duties.

COMMENTS

Background

The Stanford Chronic Disease Self-Management Program (CDSMP) represents one of the most studied evidence-based behavioral or self-care programs for chronic diseases including diabetes.

Research frontiers

The CDSMP has been found to be highly effective in improving the general health of people with several chronic conditions such as heart disease and arthritis. Recent evidence indicates that the CDSMP is a useful and appropriate program for lowering glycated hemoglobin A1c (HbA1c) among people with type 2 diabetes who are out of control.

Innovations and breakthroughs

This study demonstrated that the CDSMP may not lower HbA1c among people with type 2 diabetes any better than good routine care in an integrated healthcare system.

Applications

Findings from this study show that people with type 2 diabetes managed with good routine care in an integrated healthcare system can also have good glycemic control. Nonetheless more research is needed to understand the benefits of self-care programs in primary care.

Peer review

The study by Forjuoh *et al* aimed to assess the effectiveness of the CDSMP on the metabolic control. This is an interesting investigation from a practical point of view.

Abstract

The accumulation of fat in the pancreatic gland has been referred to using various synonyms, such as pancreatic lipomatosis, fatty replacement, fatty infiltration, fatty pancreas, lipomatous pseudohypertrophy, non-alcoholic fatty pancreatic disease and pancreatic steatosis We believe that pancreatic steatosis is the best description of fat accumulation in the pancreatic gland without fat replacement, and this term also describes the possibility that the fat accumulation is a reversible process. A review of the existing literature was carried out, and it was found that there was notable evidence from both the pathological and the imaging point of view that pancreatic steatosis is an increasing problem due to the increasing incidence of obesity. The conclusion was that pancreatic steatosis was easily detectable using modern imaging techniques, such as ultrasonography, endoscopic ultrasonography, computed tomography and magnetic resonance imaging. Pancreatic steatosis was not due to the presence of diabetes mellitus but was highly associated with the metabolic syndrome. The possible presence of steatopancreatitis should be better evaluated, especially regarding the inflammatory cascade, and additional studies are needed which are capable of assessing whether non-alcoholic steatopancreatitis really exists as does non-alcoholic steatohepatitis. Finally, the presence of exocrine pancreatic function should be extensively evaluated in patients with pancreatic steatosis.

Key words: Computed tomography; Endoscopic ultrasonography; Magnetic resonance imaging; Metabolic syndrome; Pancreatic steatosis; Pathology; Type 2 diabetes mellitus; Ultrasonography

Core tip: Pancreatic steatosis is easily detectable using modern imaging techniques, such as ultrasonography, endoscopic ultrasonography, computed tomography and magnetic resonance imaging. It is not due to the presence of diabetes mellitus but is highly associated with the metabolic syndrome. The possible presence of steatopancreatitis should be better evaluated, especially regarding the inflammatory cascade, and additional studies are needed which are capable of assessing whether non-alcoholic steatopancreatitis really exists as does non-alcoholic steatohepatitis. Additional studies regarding the exocrine pancreatic function in patients with pancreatic steatosis are needed.

Pezzilli R, Calculli L. Pancreatic steatosis: Is it related to either obesity or diabetes mellitus? *World J Diabetes* 2014; 5(4): 415-419 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i4/415.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i4.415

INTRODUCTION

Obesity has become a major problem of social and psychological dimensions and it affects all age and socioeco-

nomic groups. It was calculated that, in 1995, there were approximately 200 million obese adults worldwide and another 18 million children under five classified as overweight. In 2000, the number of obese adults increased to over 300 million, and there are also obese subjects in developing countries; it has been estimated that over 115 million people suffer from obesity-related problems[1]. Due to the worldwide presence of this problem, the term "globesity" has been coined by the World Health Organization[2].

Obesity is associated with an elevated number of diseases, and the top 10 obesity-related diseases are high blood pressure, diabetes, heart disease, brain disease, cancer, infertility, back pain due to injury to the most vulnerable parts of the spine, skin infections, gastric ulcers and gallstones.

In the livers of obese patients, a bright liver is seen at ultrasound along with increased levels of hepatic enzymes, such as alanine aminotransferase, aspartate aminotransferase or γ-glutamyltransferase; their prevalence increases progressively with increasing body mass index (BMI)[3]. At liver biopsy, subjects with moderate or severe fatty change, lipogranulomas, focal necroses or parenchymal inflammation are significantly more obese than patients without these changes[4]. Two key components of the metabolic syndrome, glucose and triglycerides, are overproduced by a fatty liver, and the liver is a key determinant of metabolic abnormalities[5]. The effects of the metabolic syndrome on the exocrine pancreas have been less investigated than that of the liver. Thus, we have reviewed the existing data in the literature regarding the effects of obesity and diabetes mellitus on the exocrine pancreas.

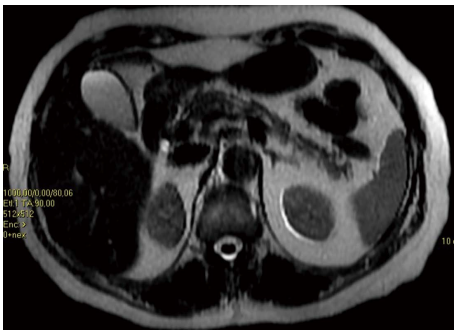

Figure 1 Magnetic resonance imaging using force sensitive resistor T2 sequence, showing the presence of fat infiltration in body and tail of the pancreas. The fat present is hyperintense (white) as the abdominal fat, while the pancreatic normal tissue is hypointense.

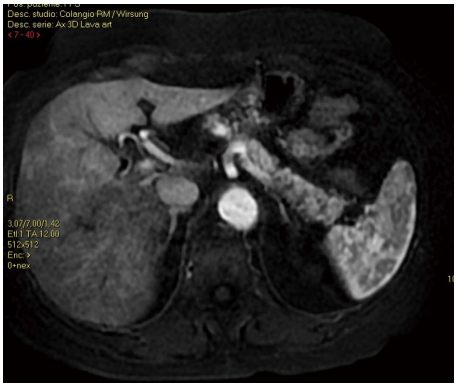

Figure 2 Magnetic resonance imaging during the arterial phase showing the presence of diffuse fat infiltration in the body and tail of the pancreas. The fat present in the pancreatic gland is black using LAVA sequence (LAVA combines contrast-enhanced, multi-phase imaging of the abdomen with high resolution, large coverage and uniform fat suppression).

DEFINITION OF PANCREATIC STEATOSIS

The accumulation of fat in the pancreatic gland (Figures 1 and 2) has been referred to using various synonyms, such as pancreatic lipomatosis, fatty replacement, fatty infiltration, fatty pancreas, lipomatous pseudohypertrophy, non-alcoholic fatty pancreatic disease and pancreatic steatosis[6]. According to the well-written paper of Smits *et al*[6], we believe that pancreatic steatosis is the best description of fat accumulation in the pancreatic gland without fat replacement, and this term also describes the possibility that fat accumulation is a reversible process.

HISTOLOGICAL ASPECTS OF EXOCRINE PANCREATIC STEATOSIS: THE ERA OF AUTOPTIC STUDIES

The first extensive study on this topic was that of Ogilvie who evaluated the exocrine pancreas of 19 obese patients (17 of whom were females, having a mean age of 52 years with a range from 27 to 67 years) and in 19 non-obese subjects (11 of whom were female, having a mean age of 48.5 years with a range from 19 to 67 years)[7]. He found that all pancreatic glands in the controls and in the majority of obese patients showed varying degrees of adiposity, and that the degree of adiposity was higher in obese patients (mean 17.1%, range 0-48.5) than in the controls (mean 9.3%, range 2.5-23.6). Regarding the endocrine pancreas, Ogilvie found hypertrophy of the islet of Langerhans in obese patients with respect to the controls. After the study of Ogilvie, the problem of a fatty pancreas was neglected for several years and, in 1978, Olsen[8] evaluated the presence of a fatty pancreas in 394 autopsies. He graded the pancreatic fat into four categories: Grade 1 sections with few scattered fat cells in the exocrine parenchyma, Grade 4 with the partial or total replacement of exocrine lobules with fatty tissue, and Grades 2 and 3 with a number of fat cells between Grades 1 and 4. The cadavers were divided into three groups: those having below normal weight, those having normal weight and those having above normal weight. He found a relationship between the content of fatty pancreatic cells and age, and between the presence of fat in the pancreas and being overweight. However, in these two studies, the presence of fat in the pancreas was related to the presence of obesity, but not to the presence of diabetes mellitus.

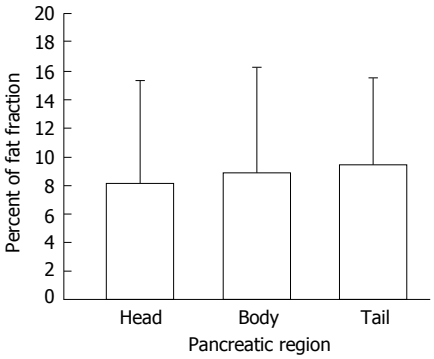

Figure 3 Percent of fat fraction according to three pancreatic regions; data are reported as mean and standard deviation (modified from reference[13]).

More recently, it has been demonstrated in postmortem material collected from 80 patients that interlobular and total pancreatic fat were both related to the non-alcoholic fatty liver disease activity score in patients without steatogenic medication but, when corrected for body mass index, no relationship was found. Thus, total pancreatic fat was a significant predictor of the presence of non-alcoholic fatty liver disease, and the presence of intralobular pancreatic fat was related to non-alcoholic steatohepatitis whereas total fat was not; this relationship seemed to be mediated by general obesity[9].

IMAGING ASPECTS OF EXOCRINE PANCREATIC STEATOSIS: THE ERA OF "*IN VIVO*" AUTOPTIC STUDIES

With the introduction of increasingly refined imaging techniques into clinical practice, it is possible to perform increasingly sophisticated imaging studies which are, in some ways, similar to autopsies carried out "*in vivo*".

The most largely used technique is ultrasonography; Lee *et al*[10] used this technique to evaluate the fat content of the pancreas. They used the increase echogenicity of the pancreatic body over kidney echogenicity as the index of a fatty pancreas, and they found that a fatty pancreas is related only to the metabolic syndrome. These data were also confirmed using an endoscopic ultrasonography in a study comprising 60 patients and 60 controls[11]; in this latter study, hepatic steatosis, alcohol use and an increased BMI were predictors of pancreatic steatosis fat[11].

In one study, the pancreatic volume from birth to advanced age (100 years old) was evaluated in a retrospective study[12]; the authors studied by computed tomography 133 subjects with under 20 years of age, 1721 adults over 20 years of age and 165 patients having type-2 diabetes, and in these patients, the fat within the pancreatic gland was also evaluated. What were the results? The pancreas volume increased relatively rapidly in childhood, changed little from 20 to 60 years of age and then declined in subjects over 60 years of age; the pancreatic volume was 16%-32% greater in obese patients as compared to non-obese patients, and the increase in the volume of the pancreas in obese patients was similar in males as compared to females[12]. The fat volume was also increased in obese patients, and this effect remained so until the age of 70 years[12]. Of importance, both the total and the parenchymal pancreatic volume were decreased in diabetic patients, and there was no difference in fat volume between patients with type-2 diabetes and non-diabetics; in addition, in cadavers in whom an autopsied pancreas was available, the pancreatic fat was similar between diabetic and non-diabetic subjects but, in non-diabetic patients, the fat increased with obesity and age[12].

The best imaging technique for evaluating the presence of fat in the pancreas is magnetic resonance imaging (MRI). There are at least three methods utilized to measure the fat in the pancreas using MRI; the most common is to utilize the frequency shift between the water and the fat resonances to generate in-phase and opposed-phase images in which the signal of the water and fat net magnetization vectors are at a maximum or a minimum. The Dixon method which visualizes the water and fat fractions by the post-processing of the in-phase and opposed-phase spin echo images and leads to water- and fat-selection. The last method, called the spectral-spatial excitation technique, combines chemical shift selectivity with simultaneous slice-selective excitation in gradient-echo imaging sequences. Schwenzer *et al*[13] found that the fat content calculated from images recorded with the fat-selective spectral-spatial gradient-echo sequence correlated well with the fat fraction determined with in-phase/opposed-phase imaging. In addition, the fat percentage increased from the head to the tail of the pancreas as shown in Figure 3. Finally, in another study, the pancreatic fat increased with BMI only in non-diabetic patients[14], confirming the previously published data of[12,15-17].

RELATIONSHIPS BETWEEN INSULIN AND PANCREATIC STEATOSIS

Insulin secretion increases parallel to insulin resistance in order to maintain normal glucose homeostasis in obese patients; the patients that are predisposed to diabetes fail to compensate adequately for the greater insulin requirements[18]. Fat accumulation in the pancreatic islets leads to a decreased insulin secretion and might explain why insulin resistant people cannot encounter the higher demands of insulin and then develop type 2 diabetes mellitus[19-24]. In addition, a greater proportion of pancreatic fat was associated with increased insulin levels in obese nondiabetic subjects. This may indicate that the toxic effect of pancreatic fat accumulation might require a long time before manifesting in impaired β-cell function and it has been assessed that pancreatic β-cell damage is present for more than a decade before diabetes is diagnosed[25].

PANCREATIC STEATOSIS AND EXOCRINE PANCREATIC FUNCTION

Exocrine pancreatic insufficiency has been reported in 14.3% of patients with type 2 diabetes mellitus; it is usu-

ally only of a mild to a moderate degree and does not lead to clinically overt steatorrhea in the majority of diabetics[26]; however, in patients with pancreatic steatosis the data are scarce and are mainly based on case reports. Lozano *et al*[27] have reported two adult patients with weight loss and massive steatorrhea in whom abdominal computed tomograms demonstrated severe pancreatic steatosis; oral pancreatic enzyme replacement in association with cimetidine led to a marked reduction of steatorrhea and weight gain in both patients. Using computed tomography, So *et al*[28] found a pancreas completely replaced by fat in a 57-year-old woman having a 22-year history of chronic diarrhea. Aubert *et al*[29] reported two cases of diffuse and primitive fat replacement of the exocrine pancreas associated with chronic diarrhea and steatorrhea in whom the administration of pancreatic extracts improved symptoms. Thus, pancreatic functional studies are necessary to establish the degree of fat replacement capable of determining exocrine pancreatic insufficiency.

CONCLUSION

Pancreatic steatosis is easy detectable using modern imaging techniques, such as ultrasonography, endoscopic ultrasonography, computed tomography and magnetic resonance imaging. Pancreatic steatosis is not due to the presence of diabetes mellitus but is highly associated with the metabolic syndrome. The possible presence of steatopancreatitis should be better evaluated, especially regarding the inflammatory mediators involved, and additional studies are need capable of assessing whether non-alcoholic steatopancreatitis really exists as does non-alcoholic steatohepatitis. Finally, the presence of exocrine pancreatic function should be extensively evaluated in patients with pancreatic steatosis.

Abstract

The major malfunction in diabetes mellitus is severe perturbation of glucose homeostasis caused by deficiency of insulin. Insulin deficiency is either absolute due to destruction or failure of pancreatic β cells, or relative due to decreased sensitivity of peripheral tissues to insulin. The primary lesion being related to insulin, treatments for diabetes focus on insulin replacement and/or increasing sensitivity to insulin. These therapies have their own limitations and complications, some of which can be life-threatening. For example, exogenous insulin administration can lead to fatal hypoglycemic episodes; islet/pancreas transplantation requires life-long immunosuppressive therapy; and anti-diabetic drugs have dangerous side effects including edema, heart failure and lactic acidosis. Thus the need remains for better safer long term treatments for diabetes. The ultimate goal in treating diabetes is to re-establish glucose homeostasis, preferably through endogenously generated hormones. Recent studies increasingly show that extra-pancreatic hormones, particularly those arising from adipose tissue, can compensate for insulin, or entirely replace the function of insulin under appropriate circumstances. Adipose tissue is a versatile endocrine organ that secretes a variety of hormones with far-reaching effects on overall metabolism. While unhealthy adipose tissue can exacerbate diabetes through limiting circulation and secreting of pro-inflammatory cytokines, healthy uninflamed adipose tissue secretes beneficial adipokines with hypoglycemic and anti-inflammatory properties, which can complement and/or compensate for the function of insulin. Administration of specific adipokines is known to alleviate both type 1 and 2 diabetes, and leptin mono-therapy is reported to reverse type 1 diabetes independent of insulin. Although specific adipokines may correct diabetes, administration of individual adipokines still carries risks similar to those of insulin monotherapy. Thus a better approach is to achieve glucose homeostasis with endogenously-generated adipokines through transplantation or regeneration of healthy adipose tissue. Our recent studies on mouse models show that type 1 diabetes can be reversed without insulin through subcutaneous transplantation of embryonic brown adipose tissue, which leads to replenishment of recipients' white adipose tissue; increase of a number of beneficial adipokines; and fast and long-lasting euglycemia. Insulin-independent glucose homeostasis is established through a combination of endogenously generated hormones arising from the transplant and/or newly-replenished white adipose tissue. Transplantation of healthy white adipose tissue is reported to alleviate type 2 diabetes in rodent models on several occasions, and increasing the content of endogenous brown adipose tissue is known to combat obesity and type 2 diabetes in both humans and animal models. While the underlying mechanisms are not fully documented, the beneficial effects of healthy adipose tissue in improving metabolism are increasingly reported, and are worthy of attention as a powerful tool in combating metabolic disease.

Key words: Adipose tissue; Diabetes; Insulin-independent; Transplantation; Subcutaneous; Adipokines; Metabolic disease

Core tip: Diabetes mellitus is characterized by perturbation of glucose homeostasis due to insulin deficiency, either absolute or relative. Traditional treatments over the past century have focused on insulin replacement and/or enhancing insulin sensitivity. Ultimate goal in treating diabetes is to re-establish glucose regulation. Recent studies increasingly show the ability of extra-pancreatic hormones, particularly of adipose tissue origin, to compensate for insulin. Adipose tissue is a versatile endocrine organ which, under appropriate circumstances, can exert numerous metabolic benefits and may maintain glucose regulation entirely independent of endocrine pancreas. This review discusses such alternative therapies based on beneficial effects of healthy adipose tissue.

INTRODUCTION

Diabetes is one of the most serious and widespread metabolic diseases today, affecting 10%-15% of the United States population and 371 million people worldwide. The major characteristics of diabetes mellitus include defects in insulin secretion at the pancreatic β cell level, and defects in insulin sensitivity at the peripheral tissue level. Depending on which of these defects is primary, diabetes is broadly classified into types 1 and 2. Type 1 diabetes (T1D) is associated with absolute deficiency of insulin due to auto-immune mediated destruction of pancreatic β cells, while T2D results in relative or functional insulin deficiency due to gradually progressing resistance to insulin in peripheral tissues. Such resistance leads to initial compensatory hyperinsulinemia and overexertion of β cells, which may progress into absolute insulin deficiency through eventual β cell failure. T1D accounts for 5% of cases, affecting over 2 million Americans and 11-22 million people worldwide, with 78000 new cases diagnosed each year. Characterized by absolute deficiency of insulin resulting in severe hyperglycemia, T1D is fatal if untreated. Available therapies for diabetes, directed at insulin replacement and/or improving insulin sensitivity in peripheral tissues, have various limitations, some of which could be life-threatening. Recent studies demonstrate the ability of healthy adipose tissue to complement or compensate for the function of endocrine pancreas, independent of insulin. Adipose tissue related therapies show promise in overcoming many of the limitations/complications associated with traditional treatments for diabetes.

AVAILABLE THERAPIES

Both type 1 and 2 diabetes are associated with β cell failure due to different mechanisms. Insulin replacement is necessary in all cases of T1D and many cases of T2D. Treatments for T1D primarily focus on insulin replacement, either directly or through transplantation of insulin-secreting tissue such as pancreas or pancreatic islets. Whole pancreas transplantation is currently the most successful means available for achieving long-term insulin independence for T1D patients, and is also helpful in specific cases of T2D associated with significant insulin deficiency[1-3].

Traditional insulin replacement therapies, either direct or through islet/pancreas transplantation, have certain limitations. Direct insulin replacement does not cure the disease and requires repeated administration. A major concern with administration of exogenous insulin is possible overdose, requiring precise monitoring of dosage and blood glucose to avoid fatal hypoglycemic episodes. Whole pancreas transplantation, when successful, provides insulin independence for many years. However it is an invasive surgical procedure not to be undertaken lightly, and carries the risks and complications associated with any major surgery[1,4-7]. Islet transplantation, although a safer and less invasive procedure, is limited by low success rate in the long term due to apoptosis, rejection or poor vascularization of islets. Other concerns include the necessity of large numbers of donor islets and specific complications associated with portal vein cannulation such as portal vein thrombosis and portal hypertension[6-12]. The need for life-long immune-suppressive therapy is also a concern with both islet and pancreas transplantation. Thus, the need remains for better therapies aimed at establishing long-term glucose regulation with fewer complications.

Xenotransplantation of porcine and non-human primate islets has been proposed as a means to overcome the limitations in availability and preservation of human islets. A major challenge with xenotransplantation is hyperactive rejection. Methods proposed to circumvent this problem include encapsulation of islets, and local immunosuppression through genetic manipulation. While long-term graft survival and insulin independence have not yet been achieved, early studies show great potential[13-15]. Recent advances on insulin replacement include generation of insulin-producing cells from embryonic stem cells; transdifferentiation, *i.e.*, generation of endogenous β-cells from non-β-cells using transcription factors that govern pancreatic development; and engineering endogenous surrogate β-cells by tissue-specific insulin gene delivery[15-17]. Stem cell therapy is promising, except for some limitations such as the inability to generate adequate numbers of insulin-producing cells, generation of unnecessary cell types, and harmful side effects such as teratoma formation. In addition to replacing or regenerating insulin-producing cells, another intriguing potential in stem cell therapy is to prevent further destruction of beta cells by appropriately controlling the autoimmune

response. Recent studies describe the potential of stem cell educator therapy for reversal of T1D[18-20]. Human cord blood-derived multipotent stem cells modulate autoimmune responses through altering regulatory T cells and human islet β-cell-specific T cell clones. While suspending the immune response results in significant improvements of glucose regulation, insulin dependence remains an ongoing concern.

Management of T2D includes various agents that improve insulin sensitivity in peripheral tissues, in combination with agents that increase insulin secretion at β cell level. With advancing β cell failure, these treatments have to be combined with insulin replacement or even pancreas transplantation[21-23]. Drugs that improve peripheral insulin resistance include thiazolidendiones and biguanides. While effective in improving insulin sensitivity at varying degrees, these drugs are limited by a number of dangerous side effects including edema, hypertension, heart failure, bone fractures, lactic acidosis and cognitive impairment[21-26]. Complementary strategies include alpha-glucosidase inhibitors which reduce blood glucose by preventing digestion and absorption at gut level. Drugs that increase insulin secretion at β cell level such as sulfonylureas and meglitinides have the same risk of hypoglycemia unawareness as insulin therapy. With progressive β cell failure in T2D the effectiveness of these drugs eventually decreases[23].

A common limitation among all aforementioned approaches is the ongoing need for insulin, and the difficulty of maintaining physiologically appropriate levels and function of insulin after exogenous delivery or endogenous production following different treatments. Studies in the past decade point to the intriguing possibility of insulin-independent glycemic regulation. Although insulin is the major physiological regulator of glucose, numerous extra-pancreatic hormones also exert a powerful influence on glucose homeostasis. Such hormones primarily originate from the gut and adipose tissue[27,28]. While many of these hormones enhance insulin function, some have glucose-lowering actions entirely independent of insulin.

Glucagon-like peptide-1 (GLP-1) is an incretin secreted from entero-endocrine cells in response to food intake. In addition to glucose-dependent augmentation of insulin secretion, GLP-1 has a variety of beneficial effects throughout the body[28-33]. These include insulin-independent effects on glucose metabolism such as direct suppression of glucagon, decrease of hepatic glucose output, decreased absorption *via* delayed gastric emptying and increased glucose uptake by muscle. GLP-1 is also reported to decrease inflammation[29,33,34], decrease cardiovascular risk factors in human patients[35-37], and promote insulin-independent glucose uptake into brown adipose tissue (BAT) in mouse studies[38]. Due to their hypoglycemic effects, analogs of GLP-1 and inhibitors of dipeptidyl peptidase-4 (DPP-4) (enzyme that metabolizes GLP-1) are now widely used as therapeutic agents for T2D[28,29,39-42]. Direct administration of GLP-1 produces acute hypoglycemia and suppression of glucagon in T1D as well[43,44], and GLP-1's anti-inflammatory effects are believed to be potentially therapeutic in correcting insulitis and enhancing beta cell regeneration in T1D[45]. Despite these beneficial effects, incretin therapy also involves risks such as fatal pancreatitis[46,47].

DIABETES AND ADIPOSE TISSUE

Adipose tissue, believed to be merely a storage organ in the past century, is now widely known for its far-reaching metabolic and endocrine functions. Adipose tissue is classified into white and brown fat based on their morphology, embryonic origin and basic function. White adipose tissue (WAT), the large energy reserve distributed all over the body, stores and accumulates fat, whereas BAT localized into a few small depots, metabolizes fat, generates heat and increases overall metabolism. WAT and BAT have distinct embryologic origins and appear at different stages of development. While WAT is believed to originate from mesodermal stem cells, BAT originates from dermatomyotomal precursor cells in common with skeletal muscle, and has an interchangeable developmental relationship with skeletal muscle rather than WAT[48-50]. Due to its function in energy metabolism, BAT is highly vascularized and innervated compared to WAT, giving it the characteristic "brown" appearance. Brown adipocytes contain small multilocular lipid droplets as opposed to the large unilocular droplets found in white adipocytes.

WAT is broadly classified into subcutaneous and visceral fat depots which are then further subdivided according to their specific location[51,52]. Healthy WAT is a versatile endocrine organ that secretes a range of hormones which influence physiological functions at all levels, including nutrient metabolism, satiety signaling, immune/inflammatory response, and angiogenesis[27,52-55]. The major adipokines of importance in metabolic homeostasis are adiponectin and leptin. Adiponectin, well known for its insulin-sensitizing effects on peripheral tissues, is secreted from WAT in micromolar quantities and acts on several receptors such as AdipoR1, AdipoR2, and T-cadherin, enhancing AMP-activated protein kinase and the peroxisome proliferator-activated receptor-α pathway in the liver and skeletal muscle. Adiponectin levels are inversely proportionate to insulin resistance, obesity and diabetes. In addition to insulin sensitization, adiponectin directly increases fatty acid oxidation; inhibits gluconeogenesis; enhances glucose uptake into adipocytes; and exerts anti-inflammatory and anti-atherosclerotic effects, which collectively enhance overall health[27,55-62]. Leptin, long known for its central effects on decreasing appetite and food intake, also increases fat oxidation in many peripheral tissues including liver, adipose tissue and skeletal muscle. Obesity is associated with increased leptin levels and resistance to leptin action, whereas enhanced sensitivity to leptin results in leanness and protection from diet-induced obesity. Non-metabolic effects of leptin include enhancing immune response, pro and anti-inflammatory effects, and angiogenesis[27,53-55,63]. Numer-

ous other hormones of WAT origin, including but not limited to angiopoietin like proteins, apelin, insulin-like growth factor-1 (IGF-1) and visfatin, also have direct or indirect effects on glucose homeostasis through influencing functions such as insulin sensitivity, insulin secretion at beta cell level, glucose uptake in peripheral tissues, lipogenesis/lipolysis, and inflammation[27,52-55,64-68].

Under normal healthy conditions, these extra-pancreatic hormones actively complement endocrine pancreas in overall glucose regulation. However, WAT can exert a beneficial influence only as long as it remains healthy and un-inflamed. Inflammation results in conversion of WAT from a beneficial to harmful organ, which then secrets increasing amounts of hyperglycemic adipokines such as resistin and retinol binding protein 4, and pro-inflammatory cytokines such as tumor necrosis factor alpha (TNFα) and interleukins 1 and 6[54,55,69-73]. Such compounds increase inflammation and exacerbate hyperglycemia, leading to a vicious cycle of insulin resistance and T2D. While obesity is generally associated with adipose tissue dysregulation, recent studies show that it is the metabolic dysfunction of adipose tissue which primarily leads to insulin resistance, regardless of the presence of obesity[70]. Such metabolic dysfunction is also associated with decreased sensitivity to leptin and resultant hyperleptinemia. Although leptin generally improves metabolism and leanness, pro-inflammatory properties of leptin would lead to further perturbation of adipose tissue function. One of the primary functions of insulin is lipogenesis and maintenance of adipose tissue. Absence of adequate amounts of insulin results in lipolysis and necrosis of adipocytes. In T1D absolute insulin deficiency results in extensive loss of adipose tissue. Even though T2D tends to be associated with obesity, the adipose tissue in T2D patients is unhealthy, and inflamed with extensive cell death and macrophage infiltration[69-73]. T1D is also characterized by generalized inflammation particularly affecting adipose tissue[74,75]. Thus diabetes is associated with progressive dysfunction of adipose tissue.

Considering the strong correlation between adipose tissue inflammation and metabolic disease, maintaining adipose tissue in a healthy state is critical in preventing metabolic disease, and decreasing inflammation is a promising approach to improve and correct such disorders. A major mechanism of insulin-sensitizing agents such as thiazolidinediones is to reduce inflammation in adipose tissue[76-78]. When human T1D patients are treated with insulin replacement, either directly or through transplantation of insulin secreting tissue, there is recovery of adipose tissue[79,80]. While it is generally believed that insulin is necessary for the maintenance of adipose tissue, our recent research shows that it is feasible to generate and maintain healthy adipose tissue in the absence of insulin, and that healthy adipose tissue can compensate for the function of endocrine pancreas[81-83]. Transplantation of embryonic BAT in the subcutaneous space of diabetic mice results in remarkable regeneration of WAT, decrease of WAT inflammation, and reversal of diabetes.

ADIPOSE TISSUE RELATED THERAPIES FOR T1D

The ultimate cure for T1D is to establish permanent and long-term physiological glucose homeostasis. Considering the limitations associated with insulin replacement, and the remarkable influence of non-pancreatic hormones on glucose regulation, establishing glucose control without insulin is an intriguing and increasingly plausible solution.

Insulin-independent amelioration of T1D includes mono-therapy with specific hypoglycemic adipokines, first reported in the past decade. There is a strong negative correlation between diabetes and plasma adiponectin levels[53-58]. Adiponectin gene expression and plasma levels are increasingly used as predictors of metabolic disease in human patients[84-88]. Administration of adiponectin *via* gene therapy has been long known to improve metabolism in T2D in swine and rodent studies, and a few reports indicate similar results with T1D as well[89-95]. Adiponectin gene therapy with hydrodynamic injection into streptozotocin-diabetic mice resulted in improved glucose homeostasis[90], while long-term central infusion of recombinant adiponectin in normal and pancreatectomized rats resulted in improved metabolic homeostasis through several mechanisms including increase in insulin sensitivity and fat oxidation, and decreases in visceral adiposity, hepatic glucose output and beta cell death[91]. The ability of leptin to correct T1D independent of insulin is now well-documented. As first demonstrated in 2008 by Yu *et al*[96], hyperleptinemia produced by adenoviral transfer results in long-term reversal of T1D in mice. Leptin is now well known to correct T1D independent of insulin in rodent models, primarily through suppression of the hyperglycemic effects of glucagon[96-99]. In both chemically and genetically induced T1D models, leptin administration can produce long-lasting normoglycemia within days of initiation of therapy.

Mono-therapy with other adipokines is also reported to alleviate T1D. Apelin can alleviate complications of T1D in mice, and prevent loss of beta cell mass and alleviate ER stress, major pathogenic mechanisms of T1D[100,101]. In human T1D patients IGF-1 is shown to significantly decrease insulin requirement as well as plasma glucose and HbA1c when used as an adjunct to insulin therapy[102]. Incretin therapy, primarily used in T2D, is shown to have significant benefits in T1D as well. Direct administration of GLP-1 produces acute hypoglycemia and suppression of glucagon in human T1D patients[43,45], and the anti-inflammatory effects of GLP-1 and DPP-4 inhibitors are potentially therapeutic in correcting insulitis and enhancing β cell regeneration in T1D in both rodents and humans[103-106].

While these reports demonstrate the remarkable ability of alternate hormones to complement and/or compensate for insulin, mono-therapy with individual hormones still carries the same complications associated with insulin mono-therapy. Another major barrier in its

applicability to human patients is administration. Gene therapy and adenoviral transfer, as has been used in rodent studies of successful adiponectin and leptin monotherapy, are not viable options due to adverse effects. In addition, adverse effects associated with large supraphysiological doses of these hormones should be kept in mind, including carcinogenesis as has been reported with leptin[107,108]. In addition to the pro-inflammatory and immunogenic properties of leptin, other potential adverse effects include hypertension and thrombosis, and hypoglycemic risk due to excessive suppression of glucagon[63].

Considering the anti-diabetic properties of the aforementioned adipokines when administered alone, it is predictable that a combination of beneficial adipokines at physiological levels would perform better through additive and/or complementary effects, with fewer adverse reactions caused by supraphysiological doses. The feasibility of such an approach is demonstrated in our recent study, where replenishment of healthy WAT following subcutaneous BAT transplants led to reversal of T1D without insulin[81-83]. Transplantation of embryonic BAT into T1D mouse models, chemically or autoimmune induced, results in fast and long-lasting euglycemia accompanied by weight gain, proliferation of subcutaneous WAT, and remarkable decrease of WAT inflammation. These effects are independent of insulin, as indicated by consistently subnormal levels of plasma insulin and drastically low pancreatic insulin content post-mortem. Reversal of diabetes is associated with significant increases of adipokines including adiponectin, leptin and IGF-1, as well as suppression of glucagon. Thus it appears that glucose homeostasis is achieved through a chronic equilibrium of alternate hormones originating from newly replenished healthy WAT[81-83]. Both the severe loss of WAT and inflammation of WAT associated with T1D are corrected by BAT transplants, presumably due to adipogenic and anti-inflammatory factors arising from the transplant. BAT is long known to protect against inflammation as well as improve metabolism[109,110].

Use of BAT transplants to reverse T1D without insulin is a promising step towards simpler and safer therapies for this serious disease. This approach bypasses the serious limitations associated with traditional insulin replacement therapy, such as hypoglycemia unawareness and the need for invasive surgery and/or immunosuppresive therapy. The subcutaneous site is superficial and easily accessible, and can be used for repeated transplants if necessary. Since glycemic regulation is achieved by a physiological combination of endogenously-generated hormones, this approach avoids all limitations in monotherapy with other hormones as well. In addition to the underlying mechanisms being as yet unknown, the major limitation in this technique is the need for embryonic tissue which is currently not applicable in clinical situations. Work in progress include attempts to reproduce the results with adult adipose tissue transplants with appropriate modifications.

ADIPOSE TISSUE RELATED THERAPIES FOR T2D

Metabolic diseases such as insulin resistance, obesity and T2D are characterized by unhealthy adipose tissue, deficient in beneficial adipokines such as adiponectin, and with excess of harmful or inflammatory factors[53-55,69-73]. Recovery from such metabolic disease, through drug therapy, lifestyle changes or surgical intervention, is associated with decrease of inflammation and improved functionality of adipose tissue, including increased secretion of beneficial adipokines[111-118].

Many studies report alleviation of T2D through administration of individual adopokines. Adiponectin gene therapy or hydrodynamic delivery have normalized the metabolic perturbation associated with diet-induced obesity, insulin resistance and T2D in several different animal models including rats, mice and swine[89-95]. In diet-induced diabetic swine, a single injection of purified recombinant human adiponectin resulted in acute decrease of basal blood glucose levels associated with an increase of insulin sensitivity but independent of insulin secretion[89]. Long-term central infusion of recombinant adiponectin in normal rats and pancreatectomized high fat fed rats, a T2D model, resulted in improved metabolic homeostasis through several different mechanisms, including increase in insulin sensitivity and fat oxidation, and decreases in visceral adiposity, hepatic glucose output and beta cell death[91]. Adiponectin gene therapy is also known to ameliorate hypertension associated with obesity in mouse models[92-94]. While there is promise in adiponectin mono-therapy, so far the glycemic regulation has been either transient or not followed for an adequately long period, and administration remains a problem with clinical applications. Mouse studies show that Angiopoietin like proteins improve glucose and lipid homeostasis and alleviate metabolic disease such as T2D, obesity and cardiovascular disease[64,65,119]. IGF-1 administration resulted in remarkable improvement of glucose regulation and insulin sensitivity in human patients with T2D or T1D, even though this therapy is limited by a number of undesirable side effects[102,120]. Leptin is demonstrated to reverse T1D independent of insulin in rodent models[96-99], and recent reports show promising effects on T2D as well[121-123]. However on short term human trials have not yielded positive results so far[121].

As with T1D, transplantation/regeneration of healthy adipose tissue is a potential approach for correction of T2D, insulin resistance and obesity. Several studies on rodent models show improvement of glucose tolerance following transplantation of healthy WAT, in both normal and diabetic subjects[124-130]. Lipoatrophic diabetes, characterized by hyperglycemia and hyperinsulinemia combined with severe loss of adipose tissue, is corrected by transplantation of WAT from healthy donors in a dose-dependent manner[125]. Subcutaneous transplantation of gonadal fat pads from healthy donors into leptin-deficient obese *ob/ob* mice resulted in decrease of obesity,

normalization non-fasting insulin levels and insulin tolerance, and restoration of fertility in females. The results were long-lasting, and dependent on the age and length of leptin deficiency of recipients, and the dose of WAT transplanted[126]. Transplantation of human WAT into leptin-deficient mice resulted in significant improvements in body weight and hepatic steatosis in a dose-dependent manner, associated with increased plasma levels of donor-origin leptin[127]. The importance of the source of WAT is demonstrated in several studies where the removal of visceral fat and replacement with subcutaneous fat, or transplantation of subcutaneous fat from healthy donors, is shown to alleviate or prevent metabolic dysregulation[128-130]. Intra-abdominal and peritoneal transplantation of epididymal WAT prevented the development of age-induced insulin resistance in rats, while transplantation of visceral adipose tissue from normal healthy donors prevented the spontaneous development of T1D and severe fat loss in BB/OK rats in a sex-dependent manner[129,130].

WAT transplantation, while promising, has not yet been successful in complete reversal of metabolic disease. Possible reasons include the inability of WAT transplants to transform inflamed WAT of recipients to a healthy state, as BAT transplants can. In addition there are ongoing problems with transplant rejection and immune response, and maintenance of adipose tissue grafts may be problematic in T1D where adequate insulin is not available to prevent lipolysis. Considering BAT transplants lead to replenishment of WAT without insulin, it is possible that specific factors arising from BAT and/or embryonic tissue may help maintain WAT grafts. Once identified, BAT-derived messengers may prove useful in maintaining WAT transplants. While complete reversal of T1D without insulin has been achieved only with embryonic BAT so far, recent studies show promise in adult BAT transplants in alleviating T2D and obesity. Glucose tolerance in diet induced obese mice is significantly improved through transplantation of inguinal fat pads from healthy donors into the subcutaneous space of recipient mice[131]. High fat diet induced obesity and insulin resistance in mice were reversed by visceral or subcutaneous transplantation of healthy adult BAT, in addition to improvements in glucose tolerance, insulin sensitivity and fat mass[132,133]. Mechanisms include increased glucose uptake into peripheral tissues, increased sympathetic activity and elevated levels of BAT-derived signaling molecules such as FGF21 and interleukin 6.

Another technique to improve the health of adipose tissue is to increase the content of endogenous BAT. There is a well-documented relationship between BAT content and nutritional homeostasis[109,110,134]. Recent studies show that human adults have BAT depots, and that the content of BAT is inversely proportionate to obesity and metabolic disease[135-139]. BAT deficiency in mice results in progressive obesity without hyperphagia, and selective stimulation of β-3 adrenergic receptors, abundantly expressed in BAT, leads to increased energy expenditure and weight loss without affecting food intake[109]. Induction of brown fat lipoatrophy in mice results in increased visceral adiposity associated with excessive secretion of pro-inflammatory cytokines such as TNFα, followed by vascular insulin resistance and vascular dysfunction[139]. Methods such as stimulation of β-3 adrenergic receptors, administration of compounds such as thyroid hormone or atrial natriuretic peptide, and specific BAT-derived messenger molecules, are known to increase endogenous BAT content[140-146]. Thyroxine therapy on a patient with extreme insulin resistance was reported to produce full remission from T2D preceded by proliferation of BAT[140]. Specific transcriptional factors arising from BAT such as PRDM16 are now known to impart BAT-like properties to WAT, *i.e.*, cause "browning" of WAT, which results in overall increase of energy expenditure, decrease of weight gain and improvement of glucose homeostasis as reported in rodent studies[141,142,146]. Another recently identified messenger molecule originating from skeletal muscle, irisin, also improves energy expenditure in mice with no changes in movement or food intake, leading to improvements in obesity and glucose homeostasis[143]. Induction of BAT in WAT depots can also be accomplished with other stimuli, such as cyclo-oxygenase 2 or cardiac natriuretic peptides, leading to increased energy expenditure[144-146]. These studies demonstrate the benefits of increasing endogenous BAT content with various techniques, and overt adverse effects are not yet reported.

CONCLUSION

Taken together, the aforementioned studies demonstrate the powerful global influence of adipose tissue as an endocrine organ, and its strong potential in combating metabolic disease. Adipose tissue is unique in generating a large number of hormones influencing metabolism and inflammation, which may compensate for the function of other endocrine organs upon their malfunction. Recent studies demonstrate the ability of adipose tissue to replace the function of endocrine pancreas under appropriate circumstances. Once the underlying mechanisms are documented such therapies would be applicable to other metabolic disorders as well. Specific characteristics of adipose tissue such as its abundance, accessibility, and extensive ability to regenerate, make it a very useful and convenient source for transplantation.

Abstract

Diabetes mellitus entails significant health problems worldwide. The pathogenesis of diabetes is multifactorial, resulting from interactions of both genetic and environmental factors that trigger a complex network of pathophysiological events, with metabolic and hemodynamic alterations. In this context, inflammation has emerged as a key pathophysiology mechanism. New pathogenic pathways will provide targets for prevention or future treatments. This review will focus on the implications of inflammation in diabetes mellitus, with special attention to inflammatory cytokines.

Key words: Diabetes; Diabetic nephropathy; Diabetic kidney disease; Inflammation; Cytokines; Oxidative stress

Core tip: Diabetic kidney disease is the main cause of renal insufficiency. This complication results from interactions of genetic and environmental factors that trigger a complex network of pathophysiological events. Inflammation has emerged as a key pathophysiology mechanism with important implications from a therapeutic perspective.

INFLAMMATION IN DIABETIC KIDNEY DISEASE

Diabetes mellitus (DM) is one of the most significant health problems worldwide. According to the projections, the number of adult diabetic patients will be higher than 430 million in 2030. Diabetic kidney disease (DKD) is one of the most prevalent complications, and is now the leading cause of end-stage renal disease (ESRD) in developed countries[1,2]. In the general population, ESRD rate increases due to the rise of diabetes mellitus. However, a recent study by Burrows *et al*[3] found that the incidence of ESRD in the diabetic population had shown a reduction, suggesting that the strategies for controlling DKD, including early diagnosis, adequate control targets and follow-up, early initiation of therapy, and the use of

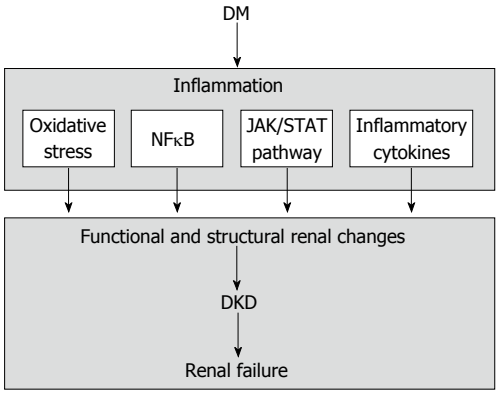

Figure 1 Schematic representation of inflammatory-mediated renal injury in diabetic kidney disease. DM: Diabetes mellitus; NFκB: Nuclear factor κB; DKD: Diabetic kidney disease; JAK/STAT: Janus kinase/signal transducers and activators of transcription.

effective renoprotective therapies, may be efficacious. However, it might be premature to state a real decline in ESRD in diabetes, since other reasons may be possible, such as the lack of enough time to develop ESRD in a large proportion of new diabetic subjects diagnosed in the last 20 years. In addition, the change of the diagnostic criteria for diabetes by the ADA in 1997, may have derived in the diagnosis of diabetes in a earlier stage of the disease, with a much less organ damage, and therefore, when diabetes have a more prolonged evolution, it is possible that this trends in the incidence of ESRD secondary to diabetes may reverse. Finally, another factor is the longer survival of diabetic patients, and thus, these subjects would have an increased risk of developing renal damage and ESRD.

Although kidney biopsy is required to definitively establish the diagnosis of DKD, in clinical practice this is unusual, since the careful screening of patients allow to identify people with DKD. The main criteria to diagnose DKD is the presence of an increased urinary albumin excretion (UAE), which is divided arbitrarily into microalbuminuria and macroalbuminuria, which is associated with an increased risk of decline in glomerular filtration rate (GFR) and a high risk of kidney failure.

DKD has been classically considered as the consequence from the interaction between hemodynamic and metabolic factors. However, renal damage is not completely explained by these factors. Current knowledge indicates that this represents only a partial view of a much more complex scenario. Clear evidence indicates that the pathogenesis of DKD is multifactorial, with the interaction of both genetic and environmental factors that trigger a complex network of pathophysiological events[4,5]. Clinical observations and epidemiological studies in different ethnic groups have indicated that there is familial aggregation of DKD. Although this information does not allow clearly establishing a model of transmission, diabetic nephropathy has been widely considered as a polygenic disease. There may be many genes, and each has a cumulative genetic effect and interacts with environmental factors in the development of DKD. The challenge in genetic studies of diabetic nephropathy is to dissect its genetic complexity. Researchers have searched for the genes involved in susceptibility, resistance or progression to DKD. The aim of genetic studies is to provide useful information for better understanding the pathogenesis and further developing novel therapeutic approach in this disease. Genome wide linkage analyses, candidate gene population association, family-based association and genome wide association studies have been used for the identification of the genes in DKD.

In this context, inflammation has become a cardinal pathophysiological mechanism in the development and progression of DKD. This review will focus on the implications of inflammation in DKD, with special attention to inflammatory cytokines.

INFLAMMATION IN DIABETES MELLITUS

Growing evidence indicates that pathogenesis of diabetes mellitus is widely related to the activation of the innate immune system and the presence of a chronic subclinical low-grade inflammatory state[6,7]. Many studies suggest that individuals who developed DM present characteristics of inflammation several years before the diagnosis of DM[8,9]. Population-based studies have shown that diverse inflammatory markers, such as cytokines, are strong predictors of the development of diabetes[10-12]. In addition, inflammatory cytokines have been involved in the pathogenesis of microvascular diabetic complications, including DKD[13-18].

DKD: AN INFLAMMATORY-BASED COMPLICATION

DM is associated with multiple deviations from normal homeostasis, including hemodynamic and metabolic alterations that produce the activation of diverse transduction pathways in the kidney. At the present time, inflammation is recognized as an important mechanism in the pathogenesis of this complication, through oxidative stress, transcription factors, including nuclear factor κB (NFκB), janus kinase/signal transducers and activators of transcription (JAK/STAT) pathway, and inflammatory cytokines[13,14] (Figure 1).

OXIDATIVE STRESS

There is solid experimental evidence of a key role for reactive oxygen species (ROS) and oxidative stress and their interplay with the renin-angiotensin-aldosterone system (RAAS) and inflammation, in the pathogenesis of DKD. There is a disproportionate production of ROS secondary to hyperglycemia by different renal cells[19-25]. Nuclear factor erythroid 2-related factor 2 (Nrf2) is a transcription factor that participates importantly in the regulation of the cellular antioxidant response[26,27]. Nrf2 appears to counteract renal damage in diabetes, possibly through inhibition of transforming growth factor-β1 (TGF-β1).

In both *in vitro* and *in vivo* experimental studies, Nrf2 ameliorated streptozotocin-induced renal damage. Nrf2(-/-) mice produced greater amounts of ROS and suffered more severe oxidative renal damage compared with wild type mice[28].

NFκB

NFκB is a transcription factor that controls the expression of genes involved in different processes, such as the immune response, cell differentiation and development, apoptosis, cycle progression, inflammation, and tumorigenesis. Importantly, this factor is activated by many stimuli related to DKD[29]. Many of the signalling molecules that produce the activation of NFκB may be potential targets for the inhibition of this factor, some of them acting within a network of signals leading to the activation of NFκB.

NFκB is continuously present in cells in an inactive state. In resting cells, NFκB dimers are cloistered by inhibitors of NFκB (IκBs), which prevents the translocation of NFκB to the nucleus. Triggering of the NFκB signalling cascade results in degradation of IκBs, allowing the liberation of NFκB, and thus, this factor translocates to the nucleus and induces transcription. IκB can be classified into several groups: classical IκB (IκBα, IκBβ and IκBε), NFκB precursors (p105 and p100) and nuclear IκB (IκBζ, Bcl-3 and IκBNS). All of them have a central ankyrin repeat domain (ARD), which permits the interaction with NFκB. The activation process of NFκB needs the phosphorylation of IκB, which results in polyubiquitination, a sign for destruction of the IκB by proteasome. The Ser/Thr-specific IκB kinases (IKKs) are the main points for the activation of NFκB. The IKK holocomplex incorporates IKKα or IKKβ, and the protein NEMO (IKKγ or FIP-3). IKK turning on occurs with phosphorylation of the activation loop Ser residues in the canonical MAP kinase kinase consensus motif SxxxS in the kinase domain. NEMO is crucial for the turning on of IKK since in cells without this protein, IKKα and IKKβ cannot be activated by any of the conventional NFκB activators. IKKβ is a key factor for turning on of the canonical NFκB pathway secondary to inflammation, whereas IKKα has a critical function in the non-canonical NFκB pathway through the phosphorylation of p100.

Different extracellular signals initiate the activation of NFκB. After entering the nucleus, this factor interacts with specific sequence motifs (κB sites) on their target genes, resulting in transcriptional turning on. The particular DNA-binding site characteristics of diverse NFκB dimers for a group of related κB sites, and the specific protein-protein binding at target promoters explain the specificity of NFκB signaling. In the majority of instances, turning on of NFκB is temporary and cyclical under the existence of a continuous inducer. This cyclical characteristic is secondary to recurrent destruction and production of IκB and the resulting turning on and inactivation of NFκB, respectively.

NFκB regulates a huge variety of target genes, including those coding for adhesion molecules, chemokines, inflammatory cytokines, nitric oxide synthase, and other molecules related to inflammation and proliferation, all of them involved in the pathogenesis of DKD[30]. NFκB is activated by a wide variety of stimuli[31] such as cytokines, oxygen radicals, inhaled particles, ultraviolet irradiation, bacterial or viral products, and metabolic abnormalities. High glucose may produce the activation of NFκB in diverse cells, including endothelial and vascular smooth muscle cells, and cells of the proximal tubule[32,33]. NFκB is central in the interplay among the different factors, molecules and pathways resulting in structural alterations and functional abnormalities observed in DKD, such as activation of the RAAS, advanced glycation end-products accumulation, and NADPH-dependent oxidative stress[34]. In experimental models of DKD, it has been established the activation of NFκB in the renal cortical tissue[35]. Moreover, in human DKD, proteinuria itself, is an important activator of NFκB and it's an important pro-inflammatory stimulus for tubular cells. Chemoattractants and adhesive molecules for inflammatory cells are upregulated by excess ultrafiltered protein load of proximal tubular cells *via* activation of NFκB-dependent and NFκB-independent pathways[36].

NFκB represents a central factor in inflammation, with the generation of intrincated regulatory circuits that include a huge variety of cellular mediators, such as adhesion molecules, intracellular second messengers, microRNA, growth and transcription factors, and cytokines. NFκB system is critical for the flow of biological messages from DNA information to protein synthesis. In addition, these elements have important pathogenic and pathophysiologic roles in human disease, including DKD.

JAK/STAT PATHWAY

In animal models and in clinical studies in DKD, it has been demonstrated the enhanced activation of JAK/STAT pathway in the glomeruli and tubulointerstitial cells. The JAK proteins are intracellular, non receptor tyrosine kinases that transduce cytokine-mediated signals. Secondary to the binding of the ligand to the cytokine receptor, the JAK proteins associated with the intracellular domain of the receptor, phosphorylate and activate each other. The autophosphorylation of the JAK proteins induces a conformational modification, allowing the transduction of the intracellular signal by further phosphorylating and activating the STAT transcription factors. The activated STAT molecules dissociated from the receptor and form dimers and translocate to the cell nucleus, where they activate many target genes. The JAK/STAT signaling route is a major connecting system between the receptors located at the cell surface and the transcriptional events occurring within the cell nucleus.

It has been demonstrated the great importance of the JAK/STAT pathway in the pathogenesis of DKD through its participation in several processes, such as the

hypertrophy of mesangial cells induced by angiotensin Ⅱ (Ang Ⅱ), and the synthesis of TGF-β, collagen Ⅳ and fibronectin. In addition, the high levels of glucose stimulate the production of ROS within the cells, which in turn activates the JAK/STAT pathway.

Although there are several types of JAK proteins, the one primarily studied in renal and vascular tissue is JAK2[37]. Experimental studies in animal models of diabetic nephropathy have showed that hyperglycemia is able to turning on the JAK2/STAT pathway in renal cells[38-42]. Moreover, clinical studies in patients with early of advanced stages of DKD have showed an increased expression of JAK/STAT mRNAs and JAK2 protein in the glomerular and tubulointerstitial compartment, with an inverse correlation between JAK2 mRNA levels and estimated GFR in these patients[43].

The intimate mechanism by which hyperglycemia promotes JAK2 activation has been related to the interaction between JAK2 and ROS caused by high glucose. ROS enhance the activity of JAK2, whereas the use of an inhibitor of ROS formation (diphenylene iodonium) resulted in a marked inhibition of Ang Ⅱ-induced activation of JAK2. These facts reveal that ROS act as an intracellular activator of the JAK-STAT pathway, and that ROS also act as a second messenger for the regulation of JAK2 activation by Ang Ⅱ. One of the leading causes of the increased JAK2 tyrosine phosphorylation is the alteration of tyrosine phosphatases (SHP-1 and SHP-2). SHP-1 phosphorylation is abolished under hyperglycemia, whereas SHP-2 phosphorylation is increased under basal and Ang Ⅱ stimulation, suggesting that JAK2 sustained activation under hyperglycemia is partly due to decreased SHP-1 and increased SHP-2 phosphorylation. In addition, these effects are due to hyperglycemia and not to hyperosmolarity, since no alterations in the tyrosine phosphorylation of both SHP-1 and SHP-2 have been observed under conditions with elevated osmolarity without hyperglycemia[38-41].

INFLAMMATORY CYTOKINES

Cytokines are low molecular weight polypeptides with autocrine, paracrine and juxtacrine effects, and very complex activities. The classic function of cytokines is related to the regulation of the inflammatory process, but they are also crucial effectors of the immune system. Cytokines often have multiple target cells and multiple pleiotropic actions, and thus a particular cytokine may activate diverse reactions based on the type of cell, the time of action, and the situation and ambience. Moreover, cytokines may share receptor subunits and intracellular signalling pathways, and they can act synergistically in many contexts[44].

The first studies suggesting that inflammatory cytokines were engaged in the pathogenesis of DKD were published more than 20 years ago by Hasegawa *et al*[45,46]. The authors reported that glomerular basement membranes (GBM) obtained from rats after the induction of diabetes, were able to induce the production of significantly higher quantity of the inflammatory cytokines tumor necrosis factor (TNF)-α and interleukin 1 (IL-1) when were incubated with peritoneal macrophages, as compared with the production of those cytokines when the macropages were cultured with membranes from normal rats. Later works showed that all types of resident renal cells, as well as infiltrating cells (monocytes, macrophages and lymphocytes) are able to synthesize proinflammatory cytokines[47,48]. Nowadays, the results of numerous studies support the notion that cytokines play a transcendent role in the pathogenesis of microvascular complications of DM[13,49,50]. The renal effects of cytokines in DKD are associated with different actions, including intrarenal hemodynamic alterations, modifications of the renal structure with changes in extracellular matrix and basement membranes, abnormalities in the expression of diverse molecules, cellular necrosis and apoptosis, modification in the permeability of glomerular endothelium, and increment in the production of ROS[50-54].

IL-1

In experimental models of DKD, renal expression of IL-1 is elevated[55,56], which has been associated with changes in the expression of molecules related to chemotaxis and cellular adhesion. Specifically, IL-1 augments the production of intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 by different renal cells, including endothelial, mesangial and tubular epithelial cells. In addition, IL-1 also stimulates the expression of endothelial-leukocyte adhesion molecule 1[57,58].

IL-1 produces abnormalities of intraglomerular hemodynamics. These effects are secondary to modifications in the synthesis of prostaglandins by mesangial cells. Experimental *in vitro* studies have shown that glomerular mesangial cells incubated with recombinant human IL-1 are stimulated to produce prostaglandin E2 and delivery phospholipase A2[51]. Futhermore, these cells present an increased secretion of prostaglandin E2 in response to Ang Ⅱ[52], whereas the permeability of vascular endothelial cells is enhanced[59]. Finally, this cytokine raises the production of hyaluronan by epithelial cells of renal proximal tubule[60], which has been related with the development of hypercellularity in experimental models of diabetes[61].

IL-6

Clinical studies have shown that IL-6 levels are significantly higher in patients with DKD in comparison with DM patients without nephropathy[62]. In addition, the histopathological analysis of human renal samples by immunohistochemistry has demonstrated an increased expression of mRNA encoding IL-6 in cells infiltrating the mesangium, interstitium and tubules, with a positive relationship with the severity of mesangial expansion[63]. Other functional and structural abnormalities related to DKD and progression of renal damage have been associ-

ated with IL-6, including abnormalities in the permeability of glomerular endothelium, expansion of mesangial cells and enhanced expression of fibronectin[54] and increase in the thickness of the GBM[64,65]. Our experimental studies have demonstrated an increase in the mRNA levels of IL-6 in the renal cortex of diabetic rats, which is positively associated with the urinary concentration of this cytokine[56]. In addition, in animal models of diabetes, wet kidney weight, a marker of renal hypertrophy and an early phenomenon in kidney involvement in DM[66], has been reported to be enhanced, which was related to mRNA gene expression levels and urine concentration of this cytokine[56].

IL-6 signals through a cell surface receptor, which is formed by the ligand-binding IL-6 receptor (IL-6R)-α chain (CD126) and the signal-transducing component CD130, also called gp130. In addition to the membrane form of the IL-6R, there is a soluble form which is produced by cleavage of the membrane-bound form. These soluble form of the IL-6R comes to the circulation and is able to control the activity of this cytokine. Regarding this regulatory process, it is important to differentiate the actions of soluble CD126 and CD130. In plasma, soluble CD126 binds to IL-6 and results in the increase of the complex half-life, amplifying the bio-activity of this cytokine to tissues that express the membrane form of CD130. On the contrary, soluble form of CD130 in the circulation functions as an IL-6 antagonist. Recent studies have shown that the soluble form of the IL-6R is closely implicated in the evolution from the initial to the final stages of the inflammatory reaction. IL-6 has many biological properties, including the activation of the STAT3 transcription factor, and the induction of the expression of adhesion molecules and other inflammatory cytokines.

IL-18

IL-18, a potent inflammatory cytokine that belongs to the IL-1 superfamily[67,68], is implicated in different actions, including the release of interferon (IFN)-γ[69] (which stimulates functional chemokine receptor expression in human mesangial cells)[70], the synthesis of other molecules involved in the inflammatory reaction, such as IL-1 and TNF-α, the increase in the expression of ICAM-1, and the apoptotic process of endothelial cells[71-73]. Tubular renal cells show an increase in the expression of IL-18 in patients with DKD[74], which has been related to the triggering of mitogen-activated protein kinase (MAPK) pathways secondary to the action of TGF-β[75]. Many other cells may also produce this cytokine, such as infiltrating monocytes, macrophages and T cells[67,68]. High levels of IL-18 has been found in serum and urine of patients with DKD, with an independent relationship with UAE[76-78]. In addition, serum IL-18 levels are associated with the urine concentration of β-2 microglobulin, a low-weight protein that is used as a marker of tubular dysfunction[77]. In a recent longitudinal study in patients with type 2 diabetes, serum and urinary levels of IL-18 were direct and independently associated with UAE. In addition, the concentrations of this cytokine in serum and urine were also significantly associated with changes in albuminuria during the evolution of the study[77].

TNF-α

TNF-α is a cytokine with prominent proinflammatory effects. It is mainly produced by monocytes, macrophages and T cells, but also intrinsic kidney cells[47,79-81]. TNF-α exists in the cells as a precursor of the active form. This precursor is transformed in the active form through the action of the TNF-α-converting enzyme[82]. There are two specific TNF-α receptors: the TNF-α receptor 1 (TNFR1), an epithelial-cell receptor also named p55, and the TNFR2, which is an myeloid-cell receptor (p75). The exact roles of the receptors are not yet completely understood and may differ depending on the organ type[83]. While TNFR1 modulates the immune response (IL-6 synthesis) and apoptosis (apoptotic signaling kinase 1 and NFκB of mesangial cells), TNFR2 has been recognized as one of the proinflammatory mediators in glomerulonephritis[84,85]. After binding to these receptors, the intracellular transduction cascade is activated, leading to the final biological actions of this cytokine[86], with a potential role in the pathogenesis of DKD. Experimental studies in animal models of diabetes have showed that TNF-α levels and mRNA encoding TNF-α are enhanced in renal glomeruli and tubules[47,56,80,87-89].

TNF-α may cause direct cytotoxicity to renal cells, inducing direct renal injury[90], apoptosis and necrotic cell death[91,92]. It can also produce alterations of intraglomerular blood flow and reduction of glomerular filtration as consequence of the disequilibrium between factors promoting vasoconstriction and vasodilation[93], in addition to changes in the permeability of endothelial cells. Other actions of this cytokine are the modification in the location of molecules involved in the adhesion process among cells, such as the endothelial-cadherincatenin complexes, as well as the alteration of normal endothelial permeability due to alterations of cellular junctions secondary to the lack of F-actin stress fibers[94]. In addition, TNF-α is able to directly induce the formation of ROS by renal cells[95]. Experimental researches has shown that TNF-α induces the activation of NADPH oxidase in isolated rat glomeruli through the activation of the intracellular pathways protein kinase C/phosphatidylinositol-3 kinase and MAPK[96]. Thus, TNF-α prompts local ROS production, independent of hemodynamic mechanisms, resulting in alterations of the glomerular capillary wall and consequently increased albumin permeability[53].

An increase in renal size (kidney hypertrophy) and glomerular filtration rate (hyperfiltration) are early and relevant findings of DKD, which are significantly related to TNF-α[88,89]. *In vitro* studies demonstrated that TNF-α stimulates the solute uptake in proximal tubular cells secondary to the activation of sodium-dependent cotransporters[97], whereas *in vivo* studies in diabetic rats found an enhanced urinary excretion of TNF-α excretion, which was related to sodium retention and renal hypertrophy.

All these effects could be blocked by the use of a soluble TNF-α receptor fusion protein[89,97]. In the renal distal tubule TNF-α activates the epithelial sodium channel resulting in an increased reabsorption of sodium, which can be abrogated by blockers of this renal channel, such as amiloride, and inhibitors of extracellular signal related protein kinase. The increment in renal sodium reabsorption might induce the expression of TFG-β, with the development of renal hypertrophy[98].

Expression mRNA levels in the renal cortex and urinary TNF-α excretion show a positive and independent correlation with albuminuria[56,87]. Moreover, microdialysis studies showed that the concentration of TNF-α in the kidney interstitial fluid is elevated, as well as in the urine, with no data of cellular renal infiltration. These findings are observed previously to the detection of an increase in UAE. In addition, there is an elevation in the levels of TNF-α in urine after the increase in UAE, which suggest that the rise of albuminuria has a stimulatory effect in the production of TNF-α by the kidney[99]. These findings support the intimate relationship between proteinuria and inflammation. Current data indicates that proteinuria per se is an important factor in the development of tubulointerstitial damage, but also by the capacity of activate an inflammatory cellular response *via* chemoattractants, adhesive molecules and proinflammatory cytokines. These changes lead to the renal infiltration by blood circulating cells, with the subsequent damage to renal cells, damage of tubular and interstitial structures, and finally, to the development of renal fibrosis and scarring[100].

Finally, many clinical studies in patients with DKD have reported that the serum and urinary concentrations of TNF-α are elevated as compared with non-diabetic individuals or with diabetic subjects and kidneys, and that these concentrations increase concomitantly with the progression of DKD. These findings indicate a potential relationship between the elevated levels of this inflammatory cytokine and the development and progression of renal injury in DM[76,101,102].

In addition to TNF-α, also TNF-α receptors have been related to DKD. In an observational study in type 1 diabetic patients, the serum levels of TNFR1 and TNFR2 were linked with renal function with independence of other variables, such as albuminuria, supporting the important participation of this cytokine in DKD[103]. In addition, this involvement has also been found in type 2 DM (T2DM). Thus, after more than 10 years of follow-up, the Nurses' Health Study showed that increased concentrations of the soluble TNFR2 were a powerful predictor of the loss of renal function in these patients[104].

Finally, are also important the findings derived from studies focused on another cytokine within the TNF superfamily, the TNF-α-related apoptosis-inducing ligand (TRAIL). TRAIL participates in diverse cellular processes, including apoptosis, cell expansion and maturity[105]. Clinical studies in patients with diabetes have shown that the renal expression of this cytokine is enhanced, and more importantly, the grade of expression is directly related with the seriousness of kidney injury[106]. Regarding the cell types that express TRAIL, immunohistochemistry studies demonstrated that the renal expression of this cytokine was maximal in tubular epithelial cells. However, it is important to highlight that the expression of TRAIL has been also observed in podocytes[106,107]. It has been suggested the participation of TRAIL in the pathogenesis of DKD based on the finding that the magnitude of renal tissue staining for this cytokine was directly associated with the grade of tubulointerstitial inflammation, scarring and degeneration.

INFLAMMATION IN DKD: A THERAPEUTIC OPPORTUNITY

Established therapeutic strategies for prevention and treatment of DKD focus on blood pressure and glucose control, RAAS blockade and anti-thrombotic/-inflammatory treatment with aspirin. However, these therapies are insufficient[108] and new approaches are required[109].

Oxidative stress

In experimental models, the administration of different antioxidant drugs (tempol, thiol, kallistatin)[110-112] improved oxidative stress-induced renal injury, decreasing albuminuria and fibrosis. Triterpenoids, synthetic analogues of oleanolic acid with potent anti-inflammatory and antioxidant properties, activate the ARE-Keap1-Nrf2 pathway.

The renoprotective action of bardoxolone methyl, a triterpenoid that reduces oxidative stress and inflammation through Nrf2 activation and inhibition of NFκB, has been recently explored in humans. A large multicenter double-blind, randomized trial (BEAM study), including 227 patients with moderate-severe CKD and T2DM, showed that administration of bardoxolone was associated with significantly improvement of GFR at 24 wk, but some adverse events were found (mild reversible increase of albuminuria, decreased serum magnesium, muscle spasms, nausea and loss of body weight)[113]. Later, the BEACON trial, a multinational, multicentric and double-blind randomized, placebo-controlled Phase 3 trial, was designed to determine whether bardoxolone would have beneficial effects on the progression of renal injury and the hazard of ESRD in subjects with T2DM and severe stages of renal disease. Regrettably, the increased risk of heart failure and cardiovascular events observed in the bardoxolone arm of the BEACON study led to the premature ending of this trial[114].

The most commonly reported serious adverse event in the bardoxolone group was heart failure. The mechanism linking bardoxolone methyl to heart failure is unknown, although some aspects deserve consideration. Firstly, body weight declined significantly in the bardoxolone methyl group, which may suggest a situation of hemodilution secondary to fluid retention, since a reduction in the serum albumin and hemoglobin concentrations was observed. Secondly, it was observed an increase in

blood pressure in the bardoxolone arm, which might result in an elevation of cardiac afterload. This fact, together with the increase in heart preload secondary to fluid retention, combined with a rise in heart rate, result in a situation likely to trigger heart failure. This hypothesis is congruent with the increase in the concentration of B-type natriuretic peptide with bardoxolone methyl, which may reflect an elevated left ventricular wall stress.

NFκB

The renoprotective effects conferred by blockade of RAAS, provides pleiotropic and anti-inflamatory issues through the suppression of NFκB-dependent pathways, beyond the control of blood pressure and proteinuria[115]. In addition, the beneficial effects on the kidney showed by other drugs, such as thiazolidinediones, have been also associated to a suppressive effect on the activation of this transcription factor[116,117]. In addition, recent experimental studies indicates that suppression of NFκB activation by various agents, such as 1,25-dihydroxyvitamin D3[118], cilostazol[119], and curcumin[120], could lead to amelioration of DKD, suggesting the importance of NFκB as a therapeutic target of DKD.

JAK/STAT pathway

Studies in experimental animal models of DKD have reported that the use of AG490, a specific tyrosine kinase inhibitor of JAK2, was able to abrogate the elevation of systolic blood pressure[121] and the increase of UAE[122]. On the other hand, recent studies have highlighted the role of suppressors of cytokine signaling (SOCS) proteins, a group of molecules that bind and interfere with initiating JAK proteins, and act as intracellular negative regulators of JAK/STAT activation in DKD[37]. Ortiz-Muñoz *et al*[123] demonstrated that high concentrations of glucose were associated *in vitro* with activated JAK/STAT/SOCS in human mesangial and tubular cells. Overexpression of SOCS reversed the glucose-induced activation of this pathway, expression of STAT-dependent genes and cell proliferation. On the other hand, the inoculation of recombinant SOCS1 and SOCS3 adenovirus to diabetic rats resulted in an improvement of renal function at 7 wk, and renal lesions such as mesangial expansion, fibrosis or influx of macrophages were also reduced. However, further research into JAK inhibitors, SOCS expression or SOCS mimetics is required, given the critical immunomodulatory role of this pathway, with possible adverse effects[37].

Inflammatory cytokines

Experimental works using animal models of both types of DM have revealed probable benefits from the use of immunosuppressive drugs. Mycophenolate mofetil (MMF), an immunosuppressive agent with anti-inflammatory properties, was able to avoid the initiation and progression of glomerular damage and albuminuria in rats with streptozotocin-induced diabetes[124]. Subsequent works demonstrated that MMF produced a marked reduction of proteinuria, as well as the amelioration of both renal glomerular and tubulointerstitial scarring[125]. All these renoprotective effects did not have any relationship with beneficial changes of hemodynamic or metabolic determinants, suggesting that the benefits probably resulted from its immunosuppressive and anti-inflammatory actions. Thus, it was demonstrated that MMF is able to reduce glomerular and tubulointerstitial inflammatory cell infiltration[126] and abrogate different processes related to the action of TNF-α, such as the expression of ICAM1, the adhesion of neutrophils to the endothelium, as well as the production and discharge of inflammatory cytokines (IL-6 and TNF-α)[127-129]. Despite these promising experimental results, immunosuppressive treatments actually are not a current clinical therapeutic option in patients with DKD.

Modulation of inflammatory cytokines, mainly TNF-α, has been evaluated in experimental works, as well as in studies with diabetic patients. In experimental studies, the use of etanercept, a recombinant human soluble TNF-α receptor, was associated with the reduction of the urinary excretion of this cytokine and the avoidance of initial kidney structural injury and renal hypertrophy in experimental models of DKD[88]. Similarly, the use of the monoclonal anti-TNF-α antibody infliximab on rats with DKD led to a significant reduction in the urine excretion of TNF-α and albuminuria[130]. At the present time, the use of soluble TNF-α receptors or monoclonal antibodies as therapy for DKD have been not tested in clinical trials. However, pentoxifylline (PTF), a drug used in the treatment of peripheral vascular disease, possesses modulating effects on TNF-α, with significant anti-inflammatory properties that has potential clinical applications as a therapy for DKD.

PTF, a methylxanthine derived with non-specific phosphodiesterase activity, possess significant anti-inflammatory properties: this drug is able to abrogate the transcription of the *TNF-α* gene and hamper the augmentation of TNF-α mRNA[131,132], regulate IL-1, IL-6 and IFN-γ, and lessen diverse cell actions related to inflammation, such as activation, adherence and phagocytosis[133,134]. PTF is able to reduce the generation of profibrotic factors (fibronectin and TGF-β) in human mesangial cells caused by elevated glucose levels, and also it protects these cells from the harmful effects of angiotensin Ⅱ on matrix proteins[135]. Furthermore, in animal models of DKD, PTF significantly decreased the width of the GMB, the plastering of podocyte foot processes, and the disappearance of the fenestrations of glomerular endothelium[136]. In addition, PTF prevents the increased renal expression of the inflammatory cytokines TNF-α, IL-1 and IL-6 secondary to diabetes, resulting in a reduction of UAE, the urinary concentration of these cytokines, as well as a decrease of renal hypertrophy and sodium retention[56,87,88].

Beyond the results from experimental works, a number of clinical studies have showed that PTF is effective to reduce albuminuria and has potential beneficial effects on renal function in diabetic patients[137-143]. The antipro-

teinuric action of PTF has been straightly associated with its anti-TNF-α activity. This effect has been demonstrated to affect molecules with a high and a low molecular weight, such as IgG, ceruloplasmin, transferrin, albumin, and α 1-antitrypsine, lysozyme and β2-microglobulin, respectively[144]. The reduction of proteinuria after PTF administration has been confirmed in various prospective, controlled, randomized clinical studies[144-146]. Furthermore, PTF has showed beneficial effects on the urinary excretion of markers of tubular damage, such as N-acetylglucosaminidase[145]. The effectiveness of PTF to reduce urinary protein excretion has been compared with that of angiotensin-converting enzyme inhibitors (ACEI) in T2DM, and the results reveal that PTF is similar to captopril[144,145]. Moreover, the use of PTF on top of blockade of the RAAS with ACEI or angiotensin Ⅱ receptor blockers, provide a supplementary and synergistic decrease of albuminuria[147,148], an effect not related to blood pressure and metabolic control, but positive and directly related with a lowering in the urinary concentration of TNF-α[147].

The capacity of PTF to reduce UAE in subjects with DKD has been confirmed by a recent meta-analysis, which highlighted that the anti-inflammatory properties of this drug, with a decrease in the generation of proinflammatory cytokines, was the main potential mechanism to explain its antiproteinuric effect[149]. A prospective, randomized clinical trial is now ongoing to evaluate the effects of PTF on the renal function of patients with DKD[150], and new definitive trials (multicentre, adequately powered, prospective, placebo controlled) are needed to give definitive evidence for the use of PTF as a real option for the treatment of DKD.

CONCLUSION

Diabetes mellitus is a major global health problem. DKD is one of the most important complications and constitutes a challenge for physicians. Conventional treatments provide incomplete protection for the development of renal failure. Therefore, new approaches and therapeutic targets are needed. Based on the results of recent studies, nowadays inflammation is acknowledged as a key factor in the development and progression of DKD. Future therapies will focus on modulation of inflammatory pathways, including targets such as inflammatory cytokines, oxidative stress, JAK/STAT pathway, or NFκB. In addition, further research is needed to understand how inflammatory pathways interact with other pathogenic factors in the context of diabetes.

Abstract

Diabetes mellitus is a chronic condition that occurs when the body cannot produce enough or effectively use of insulin. Compared with individuals without diabetes, patients with type 2 diabetes mellitus have a considerably higher risk of cardiovascular morbidity and mortality, and are disproportionately affected by cardiovascular disease. Most of this excess risk is it associated with an augmented prevalence of well-known risk factors such as hypertension, dyslipidaemia and obesity in these patients. However the improved cardiovascular disease in type 2 diabetes mellitus patients can not be attributed solely to the higher prevalence of traditional risk factors. Therefore other non-traditional risk factors may be important in people with type 2 diabetes mellitus. Cardiovascular disease is increased in type 2 diabetes mellitus subjects due to a complex combination of various traditional and non-traditional risk factors that have an important role to play in the beginning and the evolution of atherosclerosis over its long natural history from endothelial function to clinical events. Many of these risk factors could be common history for both diabetes mellitus and cardiovascular disease, reinforcing the postulate that both disorders come independently from "common soil". The objective of this review is to highlight the weight of traditional and non-traditional risk factors for cardiovascular disease in the setting of type 2 diabetes mellitus and discuss their position in the pathogenesis of the excess cardiovascular disease mortality and morbidity in these patients.

Key words: Type 2 diabetes mellitus; Cardiovascular disease; Dyslipidaemia; Blood pressure; Obesity; Microalbuminuria; Inflammation; Insulin resistance; Postprandial Hyperglycaemia; Homocysteine

Core tip: The objective of this review is to highlight the importance of traditional and non-traditional risk factors for cardiovascular disease in the setting of type 2 diabetes mellitus and discuss their position in the pathogenesis of the excess cardiovascular disease mortality and morbidity in these patients.

INTRODUCTION

Diabetes mellitus (DM) is a chronic condition that occurs when the body cannot produce enough or effectively use of insulin, and are induced by a genetic predisposition coupled with environmental factors[1].

Three hundred sixty six million people have DM

in 2011; half of these (183 million people) are undiagnosed[2]. The number of people with DM worldwide is increasing and by 2030 this will have risen to 552 million[2].

DM is a well-established risk factor for cardiovascular disease (CVD). People with type 2 diabetes mellitus (T2DM) have a higher cardiovascular morbidity and mortality, and are disproportionately affected by CVD compared with non-diabetic subjects[3]. Diabetic vascular disease is responsible for two-four-fold rise in the occurrence of coronary artery disease (CAD) and stroke, and two-eight-fold improve in the risk of heart failure[4]. It has been described that patients with T2DM and no previous history of CAD have the similar risk for cardiac events as subjects with a prior myocardial infarction[5]. However, subsequent studies have revealed variable results[6], which more indication that diabetes status may not be a CVD equivalent in all conditions, thus highlighting the necessity for multivariate approach as an suitable basis for risk stratification for CVD prevention in persons with diabetes[7]. The CVD risk follows a gradient, and taking this gradient depends on the combination of numerous risk factors[7]. Most of this excess risk is it associated with an improved prevalence of well-known risk factors such as hypertension, dyslipidaemia and obesity in these subjects. During the recent decade, conclusive evidence has been gathered that treatment of traditional risk factors is of immense importance for patients with T2DM in the reduction of CVD risk[8,9]. The poor control of the majority of cardiovascular risk factors observed in the diabetic population[10] supports the need for more aggressive arrangement of modifiable cardiovascular risk factors, especially in patients with previous CVD. However the improved cardiovascular disease in T2DM patients cannot be attributed solely to the higher prevalence of traditional risk factors. Therefore other non-traditional risk factors may be important in people with T2DM[11] (Table 1). Very few studies have shown prospectively the association of non-traditional risk factors in T2DM, independent of traditional risk factors[12]. Moreover therapies that are currently used in the management of T2DM such insulin-sensitizers and statins have a variety of effects on many of these non-traditional risk factors[13,14]. The relative magnitude of these risk factors has been widely reviewed in the literature[15].

Several studies have aided elucidate the mechanisms underlying the vascular dysfunction that leads to cardiovascular outcomes in DM. This vascular dysfunction is related with visceral adiposity, insulin resistance (IR) and changes in the levels of a diversity of circulating factors[16]. The atherogenesis begins as an endothelial cell dysfunction when various noxious insults as dyslipidaemia, hypertension, diabetes, smoking, *etc.* induce deficits of nitric oxide (NO) and prostacyclin. Next, mononuclear cells such as monocytes and T lymphocytes binding to the endothelium; this process is mediated by adhesion molecules present on the endothelial surface, such as vascular cell adhesion molecule (VCAM), intercellular adhesion molecule (ICAM) and E-selectin. Monocyte migrates into the sub endothelial space, matures into a resident macrophage and takes up lipid through certain scavenger receptors such as SR-A and CD-36, becomes a foam cell. Later, smooth muscle cells migrate to the surface and form the fibrous cap of the lesion, and lastly lipid-laden macrophages release matrix metalloproteinase' s causing plaque rupture and acute coronary syndromes such as myocardial infarction and unstable angina. Oxidative stress (OE) play an important role in atherogenesis, especially in DM[17,18], by proatherogenic role of oxidized low-density lipoprotein and its "*in vivo*" existence[19,20]. Elements that may promote increased OE in DM comprise antioxidant deficiencies, increased production of reactive oxygen species and the process of glycation and glycoxilation[20]. Increased plasma levels of nitrotyrosine, a marker of protein oxidation[21,22], elevated both plasma and urine levels of F2-isoprostane, a marker of OE[21-23] also the evidence of oxidative damage to DNA[24], was observed in patients with T2DM.

Table 1 Cardiovascular risk factors in diabetes mellitus

Traditional	Nontraditional
Dyslipidaemia	Insulin resistance and Hyperinsulinemia
Hypertension	Postprandial Hyperglycaemia
Obesity	Glucose variability
Abdominal obesity	Microalbuminuria
Physical exercise	Haematological factors
Cigarette smoking	Thrombogenic factors
	Inflammation C-reactive protein
	Homocysteine and vitamins
	Erectile dysfunction
	Genetics and Epigenetics

In summary, CVD is elevated in T2DM due to a complex combination of various traditional and non-traditional risk factors, that have an important role to play in the beginning and the evolution of atherosclerosis over its long natural history from endothelial function to clinical events[25]. The clustering of vascular risk observed in association with IR has led to the view that cardiovascular risk appears early, before the development of T2DM, whereas the solid interactions between hyperglycaemia and microvascular disease suggests that this risk is not appear until frank hyperglycaemia appears. These notions highlight the progressive nature of both T2DM and related cardiovascular risk which propose specific challenges at diverse stages of the life of a subject with DM[26]; but do diabetic patients have specific risk factors which could explain the observed increase in CVD, or have all cardiovascular risk factors, traditional and non-traditional, the same strength?

The objective of this review is to highlight the weight of traditional and non-traditional risk factors for CVD in the setting of T2DM and debate their position in the pathogenesis of the excess CVD mortality and morbidity in these patients. It is essential to know that these risk factors do not act in isolation. Risk factors occur simultaneously[27], compounding the risk for a cardiovascular event, although such interactions are difficult to quantify

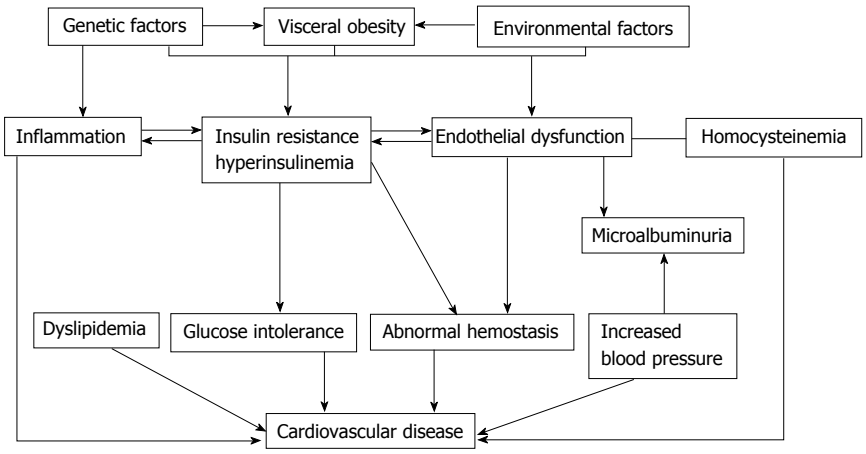

Figure 1 Interactions of traditional and non-traditional risk factors in diabetes mellitus.

(Figure 1). Many of these risk factors may be common history for both DM and CVD, reinforcing the postulate that both disorders come independently from "common soil"[28].

TRADITIONAL RISK FACTORS

Dyslipidaemia

In T2DM, IR increases the mobilization of free fatty acids from adipose tissue. There are three mechanisms across which there is increased very low-density lipoproteins hepatic production: an increased lipogenesis, an exacerbation of substrate availability, and decreased apolipoprotein B-100 (ApoB) degradation. These changes carry to a lipid profile marked by low high-density lipoprotein cholesterol (HDL-C), high triglycerides (TGs), increased ApoB synthesis and small dense LDL particles[29]. This LDL subtype is more inclined to oxidation, playing an important role in atherogenesis. Stronger than LDL cholesterol, a low HDL-C or lonely elevated TGs, atherogenic dyslipidaemia (Low HDL-C and ApoA, Elevation of both fasting and post-prandial TGs, Elevation of small dense LDL particles, Elevation of ApoB) is in T2DM patients a self-determining predictor of cardiovascular risk. The protective function of HDL may be lost in type 2 diabetics owing to alterations of the protein, resulting in a pro-oxidant, inflammatory phenotype[30].

Association between dyslipidaemia and cardiovascular risk in T2DM: A causal association exists between elevation of TGs-rich particles and their remnants, low HDL-C and cardiovascular risk[31,32] as is shown in large data from case-control, genetic, and large observational studies. Still in patients with a normal LDL-C levels, results from statin trials confirm the place of low HDL as an independent cardiovascular risk marker[33,34]. Cardiovascular event rates were significantly greater in those with dyslipidaemia: LDL-C > 2.6 mmol/L, HDL-C ≤ 0.88 mmol/L and TGs ≥ 2.3 mmol/L[35,36], as is proved in the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study and in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study. The FIELD study[37] defined the following variables as best predictors of cardiovascular events during a five year monitoring: lipid ratios non-HDL/HDL-C and total/HDL-C. Ratio of ApoB/ApoA is also associated to CVD outcomes, but this ratio wasn't superior to conventional lipid ratios. Data from the Emerging Risk Factor Collaboration (ERFC) study[38] with 302430 persons with no history of cardiovascular disease, demonstrated that Apo B and non-HDL-C each had very similar association with coronary heart disease (CHD) regardless of the existence of diabetes. The ERFC study showed that an increase of 0.38 mmol/L or 15 mg/dL in HDL-C was associated with a 22% reduction in risk of CHD. Non-HDL-C was the best tool to define the risk linked with TGs rise in clinical practice[38].

Management of dyslipidaemia, significance in the prevention of CVD in T2DM: As the development of atherogenic dyslipidaemia precedes the onset of overt glycaemia and the clinical diagnosis of diabetes, early effective intervention is recommended to reduce the risk of premature CVD.

In T2DM large data exists on action mechanism and efficacy of statins in the prevention of CVD events[39]. The Collaborative Atorvastatin Diabetes Study assessed the benefits of a statin in T2DM patients and at least one of the following risk factors: albuminuria, retinopathy, hypertension or current smoking[40]. In this study, 2838 type 2 diabetics were randomized to placebo or atorvastatin 10 mg/d. The study was finished ahead of time, because to a 37% reduction (P = 0.0001) in the primary endpoint (first acute CHD event). In the Heart Protection Study, simvastatin (40 mg/d) reduced the composite primary endpoint by 33% (P = 0.0003)[41]. This study was performed with 2912 patients (mainly T2DM) without pre-existing CVD. Also, atorvastatin 10 mg decreased the rate of major CVD events in 23% in the Anglo-Scandinavian Cardiac Outcomes Trial subgroup. Diabetic patients were free from CVD[42].

Residual risk in people on LDL-lowering therapy: Patients with T2DM at the LDL-C target are still at a

Table 2 Recommendations for blood pressure control in diabetes

Recommendations	Class	Level
Blood pressure control is recommended in patients with diabetes mellitus and hypertension to lower the risk of cardiovascular events	I	A
It is recommended that a patient with hypertension and diabetes mellitus is treated in an individualized manner, targeting a blood pressure of < 140/85 mmHg	I	A
It is recommended that a combination of blood pressure lowering agents is used to achieve blood pressure control	I	A
A RAAS blocker (ACE-I or ARB) is recommended in the treatment of hypertension in diabetes mellitus, particularly in the presence of proteinuria or microalbuminuria	I	A
Simultaneous administration of two RAAS blockers should be avoided in patients with diabetes mellitus	III	B

ACE-I: Angiotensin converting enzyme-inhibitors; ARB: Angiotensin receptor blockers; RAAS: Renin angiotensin aldosterone system; Class: Class of recommendation; Level: Level of evidence.

significant risk of CVD events[31]. This residual risk is associated to several factors as increased on TGs-rich proteins, decreased HDL-C and small, dense LDL particles. Data of FIELD study demonstrated that fenofibrate therapy did not decrease the primary endpoint (non-fatal myocardial infarction and CAD-related death), but total CVD events were decreased from 14% to 12.5% (P = 0.035)[35,43]. However, a subgroup analysis of dyslipidaemic people (TGs > 2.3 mmol/L and HDL-C ≤ 0.9 mmol/L) in this study showed a 27% reduction in CVD risk[35]. In the ACCORD trial, 5518 patients were allocated to fenofibrate plus simvastatin (20-40 mg daily) or placebo without any additional effect on the primary endpoint. In a pre-specified subgroup analysis of people with TGs > 204 mg/dL and HDL-C < 34 mg/dL, cardiovascular risk was decreased in 31% in the fenofibrate-plus-simvastatin group[44]. In both ACCORD and FIELD, treatment with fenofibrate was related with a strong reduction of TGs (22%), whereas increase of HDL-C remained less than expected (2% and 2.4%, respectively). The clinical benefits of fibrates on major CVD events have been confirmed in meta analyses; but not on cardiovascular mortality[43,44]. The effects seem to be appeared to an improvement in TGs[45].

Blood pressure

Arterial hypertension is present in more than 60% of T2DM patients[46]. This is directly linked to: (1) increased renin-angiotensin-aldosterone system activity; (2) hyperinsulinemia associated to increased renal reabsorption of sodium; and (3) increased sympathetic tone[47]. Aging, obesity, and the onset of renal disease also promote an increase in the prevalence of hypertension. Hypertension and DM are additive risk factors for CVD. While the diagnosis of diabetes doubles the cardiovascular risk in men and more than triples the risk in women, hypertension quadruple cardiovascular risk in diabetic patients[5,48].

Treatment targets: Lowering blood pressure (BP) under 140 mmHg systolic and 85 mmHg diastolic (Table 2) have shown positive effects on cardiovascular outcomes in randomized controlled trials[49-52]. The United Kingdom Diabetes Prospective Study (UKPDS) showed that strict (mean 144/82 mmHg), compared with less strict (mean 154/87 mmHg) control decreased macrovascular events by 24%. DM-related mortality decreased 15% with each 10 mmHg drop, down to a systolic BP (SBP) of 120 mmHg, with no indication of further decrease, as it was shown in a post-hoc observational analysis of the UKPDS trial[53]. Later, the ACCORD trial doesn't support a decrease of SBP below 130 mmHg[50].

Recent evidence suggests visit-to-visit variability in SBP and masked hypertension are predictors of cardiovascular disease in T2DM.

Effects of visit-to-visit variability in SBP on CVD in T2DM patients[54]: Using the data from ambulatory BP monitoring, previous studies reported that short-term or circadian variability of BP was an important prognostic factor of cardiovascular outcomes[55-58]. Similarly, a number of observational studies have investigates the impact of long-term or visit-to-visit BP variability on the risks of cardiovascular outcomes[59-63]. In the Blood Pressure-Lowering Arm of the Anglo-Scandinavian Cardiac Outcomes Trial, Rothwell *et al*[59] reported that visit-to-visit SBP variability was a strong predictor of CVD among patients with transient ischemic attack or stroke and among hypertensive patients. In the Action in Diabetes and Vascular Disease (ADVANCE) Trial, which included 8811 patients, visit-to-visit SBP variability was clearly associated with myocardial infarction and cardiovascular death. Another new and important finding of this analysis was that visit-to-visit variability of SBP clearly predicted the future development of major microvascular complications among patients with T2DM[54].

Risk associated with masked hypertension in T2DM patients[64]: Masked hypertension (MH) is defined as an ambulatory hypertension with a normal conventional BP (CBP).

The International Database on Ambulatory BP (ABP) in relation to Cardiovascular Outcomes[65], which contain a great number of diabetic patients, many of whom have MH, detected a higher prevalence of MH in DM than in non DM, and this finding was even more remarkable in treated *vs* non treated diabetics. Currently is not known the mechanism by which antihypertensive treatment is linked with a higher prevalence of MH. Cardiovascular risk in diabetic patients who are not receiving antihypertensive treatment and presenting with MH was significantly higher than in their normotensive comparator group. In contrast, antihypertensive-treated diabetics with MH had cardiovascular risk that was identical to treated stage 1 and stage 2 hypertensive subjects. This suggests that a significant percentage of these subjects had real hypertension that simulated MH in the presence of elevated

ABP and normalized CBP[65].

Nevertheless, currently, there aren't credible studies in diabetics with MH to evidence the benefit of antihypertensive therapy or to indicate how low to go with the reduction in ABP to achieve optimal reduction in cardiovascular risk. We may have to balance the potential advantage of further reduction in systolic ABP and CBP values with the increased cardiovascular risk of lower diastolic ABP and CBP.

Obesity and abdominal obesity

Generalised obesity assessed by the body mass index (BMI), and abdominal obesity determined by the waist circumference (WC), are related with a variety of CVD risk factors. Clinical guidelines do not indicate whether BMI or the WC measurements have identical utility in predicting cardiovascular risk in individuals with T2DM compared to non-diabetic patients[66,67].

The impact of obesity on both atherogenesis and in novel procoagulant and prothrombotic cardiovascular risk factors is of particular interest in cases of T2DM, as they contribute to increased CVD mortality in these individuals[68-72].

In diabetic patients the coexistence of multiple variables such as diabetic duration, glycaemic control and the drugs used for achieving it, lipid profile, BP or the existence of risk behaviours such as smoking or alcohol use may confound the impact of obesity on the risk of CVD[73].

The Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) study[73] was designed to establish the association between indexes of obesity and atherothrombotic risk factors in patients with T2DM and document CVD. By only taking into account this study's baseline it was possible to evaluate among this group of patients if a higher BMI or higher WC was associated with specific cardiovascular risk factors, and whether a higher WC was related with cardiovascular risk factors independent of diabetic patient's BMI. The review of the study baseline results showed, on the one hand, that patients with BMI $\geqslant$ 40 experienced more cases of heart failure. However, a history of myocardial infarction was less common in patients with BMI $\geqslant$ 35 (26%-30%) than in those with BMI $\leqslant$ 29.9 (34%-36%), possibly because patients with BMI $\geqslant$ 35 reported fewer years smoking than those with BMI of $\leqslant$ 29.9. Smoking was proportionally, inversely related to BMI. Furthermore the BMI, independent of the WC, had a strong association with SBP, the plasminogen activation inhibitor type 1 (PAI-1), the C-reactive protein (CRP) and fibrinogen, whereas WC had robust associations with the HDL-C and TGs levels.

It is well known that CVD is among the most frequent causes of mortality for diabetics and obese individuals. Studies have established the mortality risk in obese T2DM subjects taking the age into account. The data obtained from a study conducted in Verona with 3398 T2DM patients who were followed up for 10 years showed that in patients > 65 years a moderate excess weight predicted longer survival, whereas obesity was a negative prognostic factor in patients < 65 years[74].

On the other hand, the ADVANCE study compared the association between cardiovascular risk and BMI, WC, and the waist to hip ratio in 11140 T2DM patients, and reached the conclusion that the waist to hip ratio is the best predictor of cardiovascular events and mortality in diabetics[75].

Physical exercise

Regularly practicing physical exercise is correlated with a lower risk of cardiovascular morbidity and mortality, both in primary and in secondary prevention. However it should be taken into account that this type of evidence is often subject to other lifestyle changes that take place together with exercise (for example stopping smoking, a balanced diet, *etc.*)[76,77].

Multiple observational studies, conducted in diabetic patients, support that stated above. One such case is an American prospective cohort study of 2896 T2DM adults which showed that those who walked at least two hours per week had lower frequency of CVD mortality compared with inactive patients (HR = 0.66; 95%CI: 0.45-0.96; 1.4% *vs* 2.1% per year, respectively), and that the risk was even lower for those who walked 3 or 4 h a week. In this study the protective effect of exercise was independent of gender, age, race, BMI, diabetes duration, coexisting comorbidities and physical limitations. The authors estimated that one death per year would be prevented for every 61 individuals with diabetes who were persuaded to walk at least two hours per week[78]. The same occurred in a Finnish study, with 3316 diabetic patients, who showed that physical activity at work and during leisure time was linked with a decrease in cardiovascular mortality and total mortality[79].

It is important to note that patients with T2DM have a reduced capacity for exercise due to age, the high BMI and the frequent presence of left ventricular dysfunction[80]. Exercise improves insulin sensitivity in diabetic patients in the same way as it does in non-diabetic patients[81-83]. Patients with diabetes have greater IR which can be mediated by different defects in the glucose metabolism, and some of which would improve with physical exercise. These defects include not only a decreased number of insulin receptors and glucose transporters, but also a reduction in the intracellular enzymes activity (pyruvate dehydrogenase and glycogen synthase) and reduced oxygenation during exercise. Increased physical activity achieves higher mitochondrial enzyme activity and increases insulin sensitivity; however the number of muscle capillaries in diabetic patients with microvascular complications does not increase or is practically negligible[84-86].

Multiple studies have shown physical exercise to improve cardiovascular risk factors (dyslipidaemia, hypertension and body composition) in patients with T2DM[87]. Although it is not all kinds of physical activity exert the same influence on this risk. Aerobic exercise only or

Table 3 Suggested mechanisms for the influence of smoking on risk of type 2 diabetes

Direct effects due to inhalation of smoke from tobacco products
Impaired insulin sensitivity based on influence of haemodynamic dysregulation in capillary vascular bed
Impaired insulin sensitivity due to increase in inflammatory markers secondary to bronchitis and pulmonary infections caused by smoking
Impaired beta-cell function due to toxic effects of tobacco smoke
Lipotoxicity due to influence of increased triglyceride levels
Hypercortisolaemia and increase in abdominal fat tissue
Elevated sympathetic nervous activation
Indirect effects on glucose metabolism
Unhealthy lifestyle in smokers (poor diet, lack of physical activity)
Increased alcohol consumption (toxic effects on beta cells)
Psychosocial stress and impaired sleep associated with smoking
Impaired fetal growth in smoking pregnant women, associated with increased diabetes risk in offspring in adult life

Table 4 The strategic "five As" for smoking cessation

A-ASK:	Systematically inquire about smoking status at every opportunity
A-ADVISE:	Unequivocally urge all smokers to quit
A-ASSESS:	Determine the person's degree of addiction and readiness to quit
A-ASSIST	Agree on a smoking cessation strategy, including setting a quit date, behavioral counseling, and pharmacological support
A-ARRANGE	Arrange a schedule for follow-up

combined with resistance exercise improves glycaemic control, BP, the amount of TGs and WC. But resistance exercise alone does not have a clear impact on cardiovascular risk factors.

In prospective cohort studies, exercise was associated with improved CVD and reduced cardiovascular mortality and total mortality in patients with T2DM[88]. Results from the Nurses' Health Study[89] reported that 5125 women with T2DM who exercised for at least 4 h per week had a 40% lower risk of developing CVD (comprising heart disease and stroke) compared to those who did not. This risk improvement remained after adjustments for smoking, BMI, and another cardiovascular risk factors.

Smoking

Smoking is linked with deterioration in metabolic control in diabetic patients[90,91], which is associated with an increased risk for development of macrovascular and microvascular complications and mortality in DM[92,93].

The suggested mechanisms for the influence of smoking on risk of T2DM are summarized in Table 3. Administration of nicotine rise the circulating levels of insulin-antagonistic hormones (growth hormone, catecholamines and cortisol)[94-97], and also has been proved to affect the autonomic nervous system[98,99]. Nicotine, *via* these and possibly also other mechanisms, decreases insulin sensitivity, directly or indirectly. Also smoking increases circulating free fatty acid levels[95], and this is an additional negative factor for the insulin-mediated glucose uptake[100].

Smoking and macrovascular complications in T2DM: CVD is responsible for the main proportion of mortality associated with T2DM. There is evidence that smoking improves the risk of CAD in T2DM. Based on data from 4540 patients with T2DM followed in the UKPDS, smoking was shown to rise the risk of CHD[101] in males and females with T2DM. The expected RR incidence of a fatal or non-fatal myocardial infarction or sudden death attributable to smoking was 1.350 (95%CI: 1.11-1.59). This study reveals that smoking is an independent and significant risk factor for stroke[102] and peripheral vascular disease[15].

However, it was proved that smoking is significantly related with an augmented risk for CHD, but not for stroke, in T1 and T2DM patients in the London cohort of the prospective (8-year follow-up) World Health Organization Multinational Study of Vascular Disease in Diabetics[93].

In a prospective cohort of female nurses with T2DM[103], cigarette smoking was found to be robustly associated with the risk of CHD, and this risk improved with the number of cigarettes smoked per day. Compared with the nurses who had never smoked, the RR for CHD was 1.21 (95%CI: 0.97-1.51) for past smokers; 1.66 (95%CI: 1.10-2.52) for current smokers of up to 14 cigarettes per day; and 2.68 (95%CI: 2.07-3.48) for current smokers of 15 cigarettes per day or more.

A relatively large prospective study examined the effects of smoking cessation on cardiovascular risk in diabetic patients[104]. Data from this study reveal that stopping smoking decreases mortality risk in diabetes, but risks keep increased some years after stopping and are highly dependent on the duration of smoking.

Diabetic patients who are current smokers should be proposed a planned smoking cessation program that includes pharmacological treatment if is necessary. Detailed instruction should be provided according to the five A principles (Table 4) as is developed in the 2012 Joint European Prevention Guidelines[105].

NON-TRADITIONAL RISK FACTORS

Insulin resistance and hyperinsulinemia

IR is a principal characteristic of T2DM and it develops in multiple organs involving the skeletal muscle, liver, adipose tissue and the heart. The onset of hyperglycaemia and diabetes is often preceded by several years of IR. Obesity plays a major role in this phenomenon and provides an important link between T2DM and the accumulation of fat[106]. A significant section of the population with T2DM is obese[107].

The hyperinsulinemia, as a result of IR, occurs even before the onset of DM, and could be, by chance, related to vascular disease[108-111].

The IR, measured by the hyperinsulinaemic-euglycemic clamp, or surrogate methods such as the HOMA

index, the frequently-sampled intravenous glucose tolerance test or the insulin suppression test, appears in more than 76% of subjects, and is accompanied by compensatory hyperinsulinemia[112]. Although molecular mechanisms of IR are not yet entirely understood, abnormalities in insulin signalling have been explained[113]. Under normal conditions, insulin starts its action by binding to its specific cell surface receptor in peripheral tissues such as liver and skeletal muscle. The conformational changes of the insulin receptor induced by insulin binding to the extracellular alpha-subunit of the insulin receptor, causes the dimerization of neighboring receptors and the activation of the tyrosine kinase domain of the intracellular beta-subunit. Autophosphorylation of the beta-subunit itself, promoted by the onset of tyrosine kinase activity of insulin receptor, and the rapid phosphorylation of docking proteins, such as insulin receptor substrates -1, -2, -3 and -4, and some other proteins, comprising collagen homology proteins (shc) and SRC homology 2 (SH2), activates consecutively multiple intracellular signalling intermediates. In their phosphorylated forms, these proteins develop points of anchoring for intracellular proteins containing complementary SH2 domains, playing an important regulatory function in the insulin-signalling cascade. Specifically, the activation of Akt or protein kinase B, which plays an essential role in the mechanism of insulin action on GLUT-4 translocation, glucose transport, and the activation of NO synthase ("metabolic signalling pathway"), is determined by the interaction between insulin receptor substrate-1 proteins and phosphatidylinositol (PI) 3-kinase. On the contrary, the activation of Ras (predominantly through shc and, to a lesser degree, insulin receptor proteins), Raf, and mitogen-activated protein kinases (MAPK) ("growth signalling pathway") are implicated in the mitogenic, nonmetabolic, pro-inflammatory and proliferative effects of insulin[114]. A decreased activation of insulin signalling *via* the insulin receptor substrate-1/PI3-kinase (PI3K), can be showed in insulin-resistant animals and *in vitro* models. This reduction leads to a decreased glucose uptake, diminished NO synthesis, and reduced glucose utilisation in insulin target tissues pathway. Similar decrease in glucose transport is detected in the pancreatic beta cells, which induces a compensatory rise in insulin secretion. In spite of this, the MAPK-mediated insulin pathway persists unaffected. Under these conditions of hyperinsulinemia, this selective imbalance of the two signal transduction pathways can lead to a disproportionate proliferative/growth-promoting signal, while the normal transport of glucose and glucose homeostasis is conserved. Compensatory hyperinsulinemia stimulates in vascular smooth muscle and endothelial cells, an increased production of endothelin, PAI-1, proinflammatory cytokines and an augmented surface expression of adhesion molecules[115-118].

Homeostasis of blood vessels is conserved through the activation of endothelium-derived NO, stimulated by insulin. By rapid posttranslational mechanisms, which are mediated through PI3K/Akt signaling pathway, insulin augments the endothelial NO production by activating endothelial NO synthase Ⅲ (endothelial NOS)[119]. In IR states, the selective inhibition of the PI3K/Akt pathway detected in skeletal muscle from obese people and subjects with T2DM[120], and in the vasculature and the myocardium of obese Zucker rats, leads to endothelial dysfunction, with a consequent rise in the interaction between endothelial cells and leukocytes, an increase in vascular tone and BP, and a prothrombotic state. In this selective state, largely due to the ability of insulin to increase NO production, its physiological anti-atherogenic effects become proatherogenic[121].

Postprandial hyperglycaemia and glucose variability

Postprandial hyperglycaemia has been appeared to be related with an augmented risk of cardiovascular events in patients with and without T2DM[122-125]. Postprandial glucose excursions, especially when accompanied by increased postprandial TGs levels, are pathophysiologically related to augmented OE, systemic inflammation and endothelial dysfunction, all of which are associated to increases in atherosclerosis and cardiovascular events[126,127]. Postmeal hyperglycaemia is also linked to retinopathy, cognitive dysfunction in old people and specific cancers[128]. Relevantly, even in the setting of controlled fasting glucose levels, postprandial spikes in glucose powerfully improve both atherogenesis and cardiovascular events[122-125,129].

Two studies have examined the predictive strength of postprandial glycemia on cardiovascular events. The Intervention Diabetes Study[130], a prospective population-based multicentre trial, conducted in 1139 subjects, aged 30-55 years, newly diagnosed of T2DM, followed up for 11 years; showed that postprandial blood glucose was an independent predictor for death. However, this study did not consider HbA1c. On the other hand, the San Luigi Gonzaga Diabetes Study[122], conducted in 505 T2DM patients followed up for 14 years, indicated that both postprandial blood glucose and HbA1c predict cardiovascular events and all-cause mortality, showing the independent predictive power of postprandial glycemia on cardiovascular events after correction for HbA1c.

It has been shown that intensive control of hyperglycemia prevents macrovascular events and all-cause mortality in individuals with T2DM. A meta-analysis of 5 randomized controlled trials showed that, in T2DM subjects, intensive glycaemic control considerably decreases coronary events without an increased risk of death [131]. However, the specific effect of postprandial blood glucose control on cardiovascular events and mortality, is less clear. The following evidence is available: (1) Intervention with acarbose, a drug that diminish postprandial blood glucose excursions by delaying carbohydrate digestion in the small intestine, can prevent myocardial infarction and CVD in T2DM patients[132]. Moreover, in patients with impaired glucose tolerance, in Study to Prevent Non Insulin Dependent Diabetes Mel-

litus, acarbose was associated with a 49% relative risk reduction in the development of cardiovascular events[133]; (2) Nateglinide, a drug that lowers postprandial blood glucose by stimulating insulin secretion from the pancreas, was incapable in the Nateglinide and Valsartan in Impaired Glucose Tolerance Outcomes Research trial[134] to diminish cardiovascular events among persons with impaired glucose tolerance and established CVD; however, patients on Nateglinide presented an increase of 2-h postchallenge blood glucose[134]; and (3) The Hyperglycemia and its Effect after Acute myocaRdial infarcTion on cardiovascular outcomes in patients with T2DM trial, planned to compare the effects of prandial *vs* fasting glycemic control on risk for cardiovascular outcomes in subjects with T2DM after acute myocardial infarction, revealed that treating diabetic survivors of acute myocardial infarction with two distinct insulin regimens (prandial *vs* basal) achieved differences in fasting blood glucose, less-than-expected differences in postprandial blood glucose, and no difference in risk for future cardiovascular event rates[135].

Therefore, the role of postprandial glycemia as a predictor of cardiovascular events, and its importance as a treatment target, are issues to discuss.

These assessments had led to the concept of glucose variability. Recently, it has been suggested that blood glucose variability may contribute, even more than HbA1c, to the development of diabetes complications. However, the lack of consensus on the best approach to define the glucose variability, and difficulty of measuring it, are still unsolved problems. The relationship between glucose variability and OE, is an important physiopathological element for the development of the cardiovascular complications of diabetes. Glucose variability, thus, looks set to become the main target for future treatments for diabetes, aimed to reaching better efficacy in the metabolic control of diabetes and the prevention of complications related to it[136].

Microalbuminuria

The term microalbuminuria (MA), a urinary albumin excretion between 30 and 300 mg/24 h, has been introduced to identify subjects at increased risk of early cardiovascular death and progressive renal disease. In individuals with T2DM, MA is a prematurely clinical sign suggestive of vascular damage to the glomerulus. MA has also been currently reported as an important risk factor for CVD and remains the main and most widely used marker of diabetic renal damage in clinical practice. It is also a marker of organ dysfunction, and has been appeared to be associated with an increased risk of cardiovascular morbidity and mortality in T2DM patients[137]. At present, an increased albumin excretion is considered to be a renal symptom of generalized endothelial dysfunction[138]. According to different studies, the prevalence of MA is up to 19% in T2DM[139-142].

The epidemiology of MA shows a close association with systemic and glomerular endothelial dysfunction and with vascular disease. Damage to glycocalyx, a protein rich surface layer on the glomerular endothelium, probably represents the initial step in the development of diabetic MA[143].

MA is a marker for diabetic nephropathy. It also signifies CVD as well as nephropathy in T2DM. MA may precede T2DM, and forms one of the components of the IR/metabolic syndrome which confer a particularly high risk of cardiovascular deaths. Therefore, MA accounts for the increased risk of vascular disease in subjects with metabolic syndrome[144]. Other indicators of cardiovascular risk, such as markers of inflammation, are related with MA in population of patients with and without diabetes[145]. The existence of MA in people with T2DM is the most important early sign that we alert us to the onset of a systemic vascular disease, and associated target organ damage to the heart, the brain and the kidney. Their presence serves to recognize patients at risk of early cardiovascular death and advancement of kidney disease[146].

Patients with MA are at very high vascular risk and should share identical objectives of a vascular risk factor control as patients with overt CVD[147]. MA in patients with T2DM positively correlates with the severity of coronary atherosclerosis[148]. Reinhard *et al*[149] showed that half of asymptomatic patients with T2DM and MA, which received an intensive multifactorial treatment for cardiovascular risk diminution, had significant atherosclerosis in at least one vascular territory. They observed a higher prevalence of coronary atherosclerosis than carotid disease[149]. On the other hand, MA was higher in T2DM patients with silent myocardial ischemia[150].

The presence of MA also indicates that a low-level inflammatory process is ongoing. In hypertensive individuals, with or without diabetes, increasing MA is related with augmented levels of inflammatory markers, endothelial dysfunction and platelet activation[151]. Elevated plasma osteoprotegerin, a cytokine receptor, is an independent predictor of the presence of CVD in asymptomatic T2DM patients with MA[152], and CRP, a marker of inflammation, was an independent risk factor for development of nephropathy in T2DM patients[153]. Finally, D-dimer, a fibrin degradation product, is associated with MA in T2DM patients; this suggests that glomerular dysfunction is in part mediated by hypercoagulability[154].

Duration of diabetes[139], diabetes severity[139], uncontrolled hypertension[139,141,153,155-157], baseline levels of urinary albumin excretion > 12 mg/24 h[153], BMI[139,157], central obesity[139,140,155], high HbA1c[139,141,157], smoking habits[140,155,157], age of the patients[156], creatinine[141], CRP > 3 mg/L[153], as well as TGs and HDL-C[136,156] were independent risk factors for the development of MA in T2DM patients. These risk factors were independently associated with established MA. Population of normotensive subjects with T2DM and MA, female sex, was related with elevated risk of fatal and nonfatal CVD, independent of the traditional cardiovascular risk factors, the severity of nephropathy or existence of retinopathy, or health

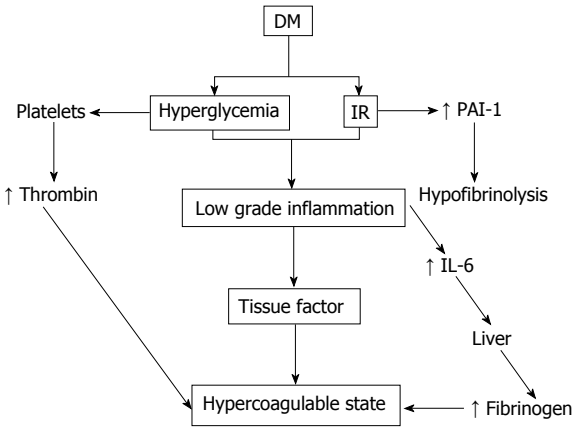

Figure 2 Prothrombotic mechanisms in diabetes mellitus. The hypercoagulable state related with diabetes mellitus is consequent to improved thrombin generation by platelets, impaired fibrinolysis due to increased levels of plasminogen activator inhibitor type 1 (PAI-1), and low-grade inflammation, that rise circulating levels of interleukin-6 (IL-6), fibrinogen, and tissue factor expression in vascular cells. DM: Diabetes mellitus; IR: Insulin resistance.

care utilization[158]; and a decreased estimated glomerular filtration rate and the occurrence of MA were each related with a near doubling of the prevalence of CVD, independently of classical cardiovascular risk factors and glycaemia control in subjects with T2DM[159].

Carotid stiffness, quantified by quantitative carotid stiffness, a local functional measurement of the arterial wall, is augmented in T2DM patients with MA[160]. MA is also independently linked with arterial stiffness and vascular inflammation in individuals with newly diagnosed T2DM[161], but not with carotid intima-media thickness[161,162], with emphasizes the significance of proactive clinical investigations for atherosclerotic complications in subjects with MA in newly diagnosed DM. On the other hand, patients with MA have more severe angiographically detected CAD than those without MA[163]. Thus relative is independent of other risk factors and is particularly evident in patients with T2DM[164].

In conclusion, MA is a marker for diabetic nephropathy. It also signifies CVD in T2DM. MA is predictive, independent of classical risk factors and all causes of mortality in T2DM individuals. Determination of MA has been shown to be helpful to recognize patients with T2DM at high risk of renal and CVD. MA is correlated with higher cardiovascular mortality, especially in diabetics, but the direct relationship between MA and vascular wall properties is still not clear.

Haematological and thrombogenic factors

Atherothrombosis, defined as the formation of a thrombus on a pre-existing atherosclerotic plaque, is the leading cause of mortality in the Western world. Diabetes has been recognised as an independent risk factor and atherothrombosis accounts for the 80% of deaths in these patients[165,166]. It is the result of the progression of atherosclerosis, and its major manifestations are sudden cardiac death, myocardial infarction, stroke and peripheral arterial ischemia[167].

Diabetes is related with a hypercoagulable state, which is more pronounced during the postprandial period. Hyperactivated platelets at injured endothelial interfaces act, together with an improved availability of thrombotic precursors, decreased coagulation inhibitors and diminished fibrinolysis[168]. The UKPDS clearly showed that macrovascular events in patients with T2DM accounted for more than 50% of total mortality[169]. Atherosclerosis develops more quickly and aggressively in diabetes, and leads more frequently to thrombotic events due to the interaction between the vascular wall and hypercoagulability[170,171].

In DM, the activation of the intrinsic coagulation pathway occurs more easily and fibrinolysis diminishes[172]. The increased platelet activity signifies increased adhesion and aggregation in diabetic patients (Figure 2). Individuals with various stages of diabetes were showed to have increased numbers of CD62P-positive and CD63-positive platelets (activated platelets) compared to healthy subjects. This increase in circulating activated platelets is not associated with glycaemic control improvement thereby intensifying insulin therapy. Surprisingly this increase in CD62P-positive platelets can also be found in healthy, first-degree relatives of patients with T1DM. Additionally, significant increments in basal thromboxane B[164] are seen in the platelets of both type T1 and T2DM, both in patients with an absence of vascular complications, as well as those with good diabetic control.

Flow cytometry has revealed that a large, hyperactive platelet subpopulation circulates in patients with DM, at a similar level to patients who have experienced a myocardial infarction. This suggests that the increased aggregation potential of these platelets lowers their activation threshold, thus contributing to the augmented incidence of acute cardiovascular events in DM[173].

Apart from platelet hyperactivity, DM also predisposes the coagulation system to other disorders[174]. Fibrinolysis is a natural defence system against thrombosis. Under physiological conditions, there is a balance between plasminogen activators and inhibitors; however, an imbalance can be caused by a reduction in the tissue plasminogen activator levels or an increase in the PAI-1 levels. This prethrombotic state in diabetic patients has been explained by multiple hypotheses. One such hypothesis is based on various studies showing the high levels of PAI-1 found in diabetic patients[175,176]. High concentrations of PAI-1 have been implicated with an increase in cardiovascular morbidity and mortality with age. A search was made for the relation of PAI-1 with various factors such as age, gender and ethnicity in subjects with T2DM and stable CAD enrolled in the BARI 2D study. The results of this study concluded that in subjects with T2DM and stable CAD, the levels of PAI-1 antigen and its activity were paradoxically lesser with advancing age; and in contrast, D-dimer ($P < 0.0001$) was increased, revealing elevated fibrinolysis. These results may indicate a protective phenomenon resulting in an improved survival in some older people with DM that endowed them with longevity enough to permit them to participate in the

BARI 2D study[177].

Another hypothesis in this prethrombotic state is that hyperglycaemia permits the protein glycosylation process, such as the fibrinogen, which affects the clot's physiological structure, and thus it is more resistant to plasmin degradation.

DM is also associated with increased plasma fibrinogen, which is considered as another cardiovascular risk factor[12,178]. This increase in fibrinogen is also associated with other vascular risk factors such as old age, increased BMI, smoking, total cholesterol and TGs. Fibrinogen has been extensively studied by many researchers, and a connection between the amount of fibrinogen and fibrin present in the vascular wall, the fibrinogen plasma concentration and the severity of atherosclerosis has been established. This association has been shown to be more evident in patients with diabetes[179,180]. Furthermore, an elevated concentration of fibrinogen has been found in diabetic patients with albuminuria. Some authors believe that the increased levels of fibrinogen, factor Ⅶ and von Willebrand factor which have been found in DM patients serve as predictors of coronary atherosclerosis and cardiovascular risk factors[181]. This association supports the fact that diabetic patients develop cardiovascular complications more frequently than the healthy population.

Inflammation: C-reactive protein

Atherosclerotic CHD and other forms of CVD are the main cause of mortality in T2DM, as well a major contributor to morbidity and lifetime costs. When diabetes occurs in subjects with established CAD, absolute risk for future events is very high. Inflammation has been involved in the pathogenesis of CVD, T2DM, and cancer. Different biochemical parameters may be utilised for the evaluation of CVD risk in T2DM patients of different age[182]. CRP is an acute-phase protein produces in the liver; its release is stimulated by cytokines (interleukin 6 and tumour necrosis factor alpha). Increased levels of it are related with the presence and severity of CAD and renal impairment in individuals with T2DM[183]. Although the determination of high-sensitivity CRP (hs-CRP) level represents an interest in the screening of CVD in T2DM patients[184].

Increased concentrations of hs-CRP are associated with IR, T2DM and the development of CVD. In particular, inflammation strongly linked with endothelial dysfunction is accepted as one of the cardiovascular risk factors clustering in the IR syndrome or metabolic syndrome. Moreover, low-grade inflammation might play an important role in the pathobiology of the metabolic syndrome[185,186]. The exact mechanism linking IR and inflammation remain unclear. Several studies have drawn attention to the finding of increased levels of hs-CRP in T2DM patients with features of the metabolic syndrome[187-190]. The elevation of hs-CRP was strongly correlated with BMI, serum lipids, fasting glucose and WC[191-197], features of the metabolic syndrome, indicating potential roles of obesity and abdominal obesity in the development of inflammation associated with the metabolic syndrome in T2DM patients. The strong association between IR and inflammation in atherogenesis insinuates that therapies that address both parameters, such thiazolidinediones may have benefits in decreasing diabetes-related macrovascular complications[198].

Serum concentration of hs-CRP is a good biomarker of chronic low-grade inflammation and is an established prognostic marker in acute coronary syndrome. In subjects with DM, the presence of high plasma levels of hs-CRP are predictive for fatal and non-fatal CHD[199,200]. Although suffering from an acute CAD, patients with T2DM have a poor outcome compared with non-diabetic patients, in part explained by a persistent endothelium-dependent dysfunction and inflammatory activity in these patients after acute myocardial infarction[201]. Finally, hs-CRP was related with silent myocardial ischemia, and might help to detect silent myocardial ischemia in diabetic patients[202].

On the other hand, in T2DM patients hs-CRP was an independent risk factor for CHD deaths[203]. In a case control study including 60 T2DM subjects with normal lipid profile and 60 age and sex-matched healthy controls, hs-CRP was an independent cardiac risk predictor even with normal lipid profile and can help measure additional risk[204]. Moreover the Diabetes Heart Study (DHS) documents the utility of hs-CRP in predicting risk for all-cause mortality in 846 European Americans with T2DM, and supports its use as a screening tool in risk prediction models[205]. However, in acute coronary syndrome few studies found no significant differences in hs-CRP between patients with and without diabetes[206]. Khatana *et al*[207] have found that hs-CRP may not be suitable to predict changes in cardiovascular risk among diabetic patients, and should not be a surrogate for achieving evidence based goals in traditional cardiovascular risk factors; in the Prospective Evaluation of Diabetic Ischaemia Heart Disease by Coronary Tomography Study, there was a negative association between coronary artery calcification score, obtained by electron beam tomography, and CRP in T2DM patients[208]; and the Irbesartan Diabetic Nephropathy Trial with baseline data obtained from 722 diabetic nephropathy patients showed a lack of association between hs-CRP and specific established or emerging cardiovascular risk factors[209].

Diabetic patients with MA and hypertension had more frequent association with increased marker of inflammation such hs-CRP[210]. The correlation found between hs-CRP levels and albuminuria in T2DM patients[211] suggest that the inflammatory process plays a role in diabetic nephropathy patients. However, in these patients CRP does not add predictive information above and beyond that offered by traditional established risk factors[212].

Several large prospective studies have proved that baseline levels of hs-CRP are an independent predictor of cardiovascular events among apparently healthy individuals. However, prospective data on whether hs-CRP predicts cardiovascular events in diabetic patients

are limited so far. The Prevention of Renal and Vascular End stage Disease study, a prospective population-based cohort study in the Nederland's, including 8592 participants[213] show that elevated hs-CRP, has added value to the present metabolic syndrome defining variables in predicting new onset CVD. In a prospective cohort study, baseline hs-CRP level is associated with increased first cardio-cerebral vascular event in the population with DM[214]. In the Casale Monferrato Study[215], hs-CRP measurement is independently related with short-term mortality risk in T2DM patients, even in normoalbuminuric individuals, and in those without a prior diagnosis of CVD; and in the Chennai Urban Rural Epidemiology Study (CURES)[216], an ongoing population-based study conducted on 150 subjects selected from the CURES, hs-CRP demonstrated a solid association with CAD and diabetes even after adjusting for age and gender. Finally, in a prospective study a cohort of 746 American men aged 46-81 years who were free of CVD at the time of blood collection in 1993-1994 were followed[217]. In this study elevated plasma levels of hs-CRP were related with an improved risk of incident cardiovascular events among diabetic men, independent of currently established lifestyle risk factors, blood lipids and glycaemic control.

On the other hand, in the recent ADVANCE study[218], the authors deduce that interleukin-6 levels but not CRP or fibrinogen levels, add significantly to the prediction of macrovascular events and mortality in patients with T2DM who have baseline CVD or risk factors.

In conclusion, the serum levels of hs-CRP, which is a marker of systemic inflammation and a mediator of atherosclerotic disease, have been correlated with the risk of CVD in T2DM patients. The determination of it is very important as screening of CVD in T2DM patients.

Homocysteine and vitamins

Homocysteine (HC) is a sulphur-containing essential amino acid derived from methionine. Vitamins B6, B12 and folic acid act as coenzymes in the metabolism of methionine and HC, and individual deficiency may cause hyperhomocysteinemia (HHC)[219]. Therefore, a negative correlation exists between HC plasma levels and vitamins B6, B12 and folic acid levels[220]. The HC plasma levels are higher in men, in women they increase after the menopause, and in both sexes they rise with aging[219]. An increase in HC levels has also been described in chronic kidney disease through a mechanism that is still not entirely understood, although it has been related to decreased renal clearance and metabolism and/or a descent in the extrarenal metabolism resulting from retained inhibitory substances[221].

In T2DM subjects, elevated HC levels have been related with a rise in the risk of suffering from cardiovascular events, independent of other risk factors[222,223], such as age and renal function[223]. The close relation between HC and CVD confirms the atherosclerotic role in the same[224]. For some authors, higher HC levels are consistent not only with aging and the male gender, but also in line with the development of DM[225]. HC levels do not appear to be related with anthropometric indices such as weight, BMI, percentage of fat mass and triceps skin fold[226].

On the other hand, the HC could play an etiologic role in the pathogenesis of T2DM, promoting OE, systemic inflammation and endothelial dysfunction[227]. HC seems to be the cause of increased mortality in T2DM subjects[223], and some authors consider it as a predictor of mortality[228]. The highest HC levels have been found in diabetic patients who have suffered several cardiovascular events[222].

The role of HC as a cardiovascular risk factor in DM is unclear. The poor metabolic control of the T2DM patients appears to have a predominant role. There exists a positive correlation between the HC levels and those of HbA1c, and a negative correlation with those of insulin[229]. On the other hand, a decline in HC levels has been observed in diabetic patients with a high cardiovascular risk and an elevated intake of foods high in folate, and vitamins B6 and B12[230]. Furthermore, an important predictor of cardiovascular risk in T2DM is arterial compliance which may not only be associated with age, but also with HC levels and renal function parameters[231].

The HHC as a cardiovascular risk factor includes CHD, both in the general population and in the diabetic population, although the role it plays on T2DM is unknown. However, the HHC in plasma is closely related to the development of CAD[232]. Thus, elevated HC levels have been found in patients with CHD, closely correlated with the occurrence of the same in the presence of decreased levels of folic acid and HDL-C[233].

Silent myocardial ischemia is one of the most frequent causes of mortality in the United States and it not only affects the diabetic population. Traditional risk factors have been identified such as T2DM itself, hypertension, dyslipidaemia and smoking, but there are also a series of novel factors such as lipoprotein (a), CRP and HC that can help improve the evaluation of patients with this disease[233]. In patients with T2DM, silent myocardial infarctions have been associated with these novel cardiovascular risk factors such as increased HC[234]. The HHC is related with increased mortality in T2DM patients suffering from CAD, without, however, being a predictor factor of cardiovascular mortality[235].

MA is a predictor of CVD and shows a close relationship with HC. The reason for this association is unknown; however it could be in the origin of MA. There are studies that show a relationship between HC and MA, irrespective of T2DM and hypertension[236]. In T2DM subjects with a high prevalence of peripheral arterial disease and nephropathy, there exists a relationship between the levels of HC and those of MA[226]. Finally, HHC is considered as a risk factor for the development of peripheral arterial disease in T2DM individuals over 65 years of age[237].

HHC is linked with the risk of developing peripheral

and autonomic neuropathy. In T2DM, HC is associated with neuropathy developing through an ischemia. The rise of HC appears to be independently associated with autonomic neuropathy, showing no association with peripheral diabetic neuropathy. For each increase in HC, there is a 7.1% increased risk of developing autonomic neuropathy[238].

In a study of T2DM subjects *vs* non diabetic control subjects, HC levels were found as elevated as those found with preproliferative retinopathy and glaucoma, suggesting that HC was a risk factor for the development of microvascular lesions in these subjects[239]. Small HC elevations in patients with diabetic retinopathy have been associated with capillary and endothelial dysregulation, in which the HHC could be an important risk factor for the development of a macular oedema[240].

An increase in HC levels has been described together with a decrease in levels of folic acid and vitamin B12[241]. However, taking folic acid, and vitamins B12 and B6 supplements with the aim of reducing HC levels does not decrease the risk of developing CVD[237]. Vitamin B12 deficiency together with an elevation of HC will predispose towards an augmented risk of cardiovascular morbidity and mortality in T2DM subjects. Vitamin B12 supplementation in these patients will not reduce the cardiovascular risk[242].

As regards vitamin A, it is capable of affecting the inflammatory mechanisms and the immune function and therefore be associated to CVD. However, there does not appear to be a relation to the cardiovascular risk, as variations of the same are not found in T2DM[243,244]. Neither has an association been found between the zinc levels and cardiovascular risk with the HbA1c levels in T2DM patients[244].

The actions of vitamin D are mediated by binding to a specific nuclear vitamin D receptor (VDR)[247]. Allelic variations of the *VDR* gene are related with improved risk of CAD in T2DM patients[245]. The hypothesis that vitamin D might protect against vascular disease, comprising atherosclerosis and endothelial dysfunction, is postulated since it has been observed that the VDR is also expressed in the vasculature[246]. An increased production of NO, the inhibition of macrophage to foam cell formation, or a decreased expression of adhesion molecules in endothelial cells, might mediate the vascular protective actions of vitamin D[247-249]. Both endothelial dysfunction and increased arterial stiffness[246,250], and more recently cardiovascular risk factors including T2DM[251], and an elevated risk of CVD[252] are related with low vitamin D levels. Of published observational studies, most have shown that lower levels of vitamin D are related with a high incidence of cardiovascular events and mortality[253-257]. Even asymptomatic CAD was associated with lower vitamin D levels in high risk T2DM patients, as observed in a recent observational study[258]. On the other hand, in T2DM patients, severe vitamin D deficiency predicts improved risk of all-cause and cardiovascular mortality, independent of urinary albumin excretion rate and conventional cardiovascular risk factors[259], and vitamin D deficiency appears to be a significant risk factor for T2DM severity and associated cardio-metabolic risk[260]. Furthermore, in a double-blind, parallel group, placebo-controlled randomized trial, a single large dose of 100000 IU vitamin D2 improves endothelial function in patients with T2DM and vitamin D insufficiency[261]; and in a prospective study, vitamin D supplementation (2000 IU/d) in patients with T2DM on different therapeutic regimens, those patients on insulin in combination with other drugs was the group that benefited the most as compared with other groups in terms of improving cardiovascular risk[262]. Thus, we can conclude that in T2DM vitamin D deficiency is an independent cardiovascular risk factor, but whether vitamin D supplementation can significantly improve cardiovascular outcomes is yet largely unknown. However, early intervention may be considered to improve prevention of T2DM related cardiovascular complications.

It has been believed for years that caffeine, one of the substances most used worldwide and included in coffee, tea, energy drinks and chocolate, increases coronary risk, hypertension and HC concentrations. However their high consumption could modulate insulin sensitivity and blood glucose levels, and in the long term it may reduce the incidence of T2DM[263]. Therefore caffeine would not have any adverse cardiovascular effects, as it demonstrates an antioxidant capacity, and presents an inverse risk association with regard to T2DM[264].

Chronic alcoholism may produce an HC plasma increase due to nutritional deficiencies associated with the said habit[265,266]. An association between alcohol and the development of atherosclerosis has been observed in patients with T2DM. Alcohol consumption and HHC together could explain the occurrence of atherosclerosis in diabetic subjects[267].

Finally, regarding treatments for T2DM, metformin appears to reduce folic acid levels in the blood, which in the long-term would raise HC levels. Folate management in these patients would reduce the levels of the same[268].

Erectile dysfunction

Men with DM have a higher prevalence of erectile dysfunction (ED) compared with the general population[269]. In these individuals, the prevalence of ED augments with age and duration and severity of disease[269,270]. ED and atherosclerosis are frequent complications of DM[271]. There are close relations between ED and atherosclerosis in patients with T2DM, and ED might serve as a clinical marker for coronary, peripheral, or cerebrovascular diseases in these subjects[272]. Several studies have found a positive correlation between ED and the risk of cardiovascular events[273,274]. The total cardiovascular risk increases severity of ED in T2DM patients without having overt CVD[275]. A cohort study concluded that the presence of ED in men with T2DM and without clinically overt CVD predicted CHD[276], and another study indicates that ED appears to be robustly and independently

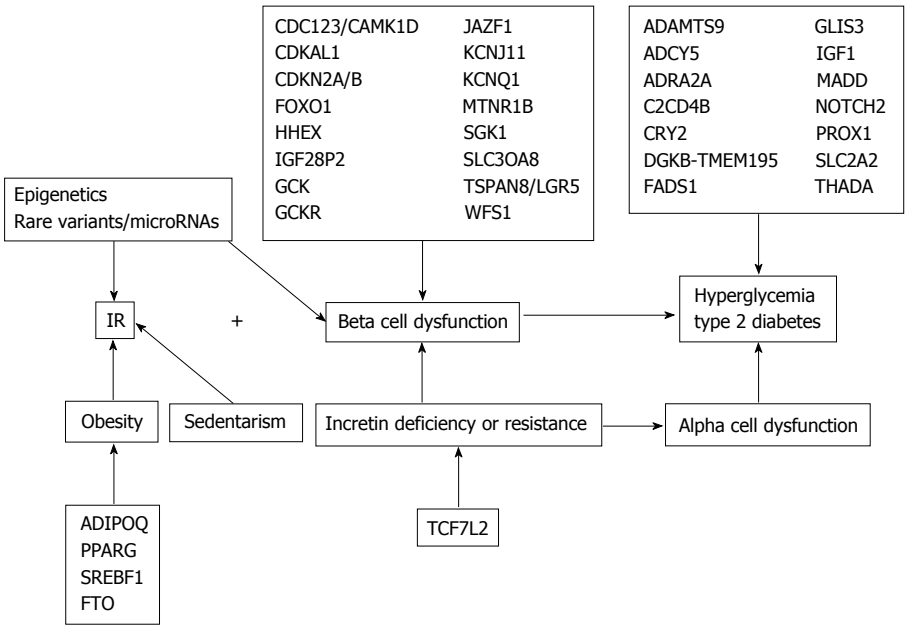

Figure 3 Possible mechanisms of confirmed and potential risk single-nucleotide poly morphisms in type 2 diabetes. Many single-nucleotide poly morphisms (SNPs) affect pancreatic beta-cell function. Gene symbols represent SNPs in or near these gene loci. Likely epigenetic alterations microRNAs and/or rare genetic variants also have a critical role. The mechanisms by which some genes increase the risk of diabetes are not yet know. related with silent CAD in apparently uncomplicated T2DM subjects[272]. Moreover, a meta-analysis of observational studies concludes that the presence of ED was related with an elevated risk of cardiovascular events in diabetic men[277].

Finally, a recent paper suggests that vitamin D deficiency is closely related with both ED and CVD, and the authors postulate that optimizing serum vitamin D levels through vitamin D supplementation helps delay the onset of ED[278].

Genetics and epigenetics

T2DM is an independent risk factor for developing CVD with the relative risk of CVD mortality of 4.9 in women and 2.1 in men, relative to non-diabetics subjects[165,279]. Genetic and environmental factors contribute to this risk. In the past decade, genome-wide association studies had elevated the number of common single-nucleotide polymorphisms, which confirmed the relationship between T2DM and CVD (Figure 3).

Haptoglobin polymorphisms and CVD in T2DM: Haptoglobin (HP) has been involved in both T2DM, and T2DM related CVD[280,281]. HP binds to ApoA1 in the same location as lecithin-cholesterol acyltransferase (LCAT); this lead to a decrease LCAT activity and consequently limiting HDL maturation. This inhibits reverse cholesterol transport causing HDL to become proatherogenic[282].

Several studies have investigated HP polymorphisms and CVD risk in T2DM. In 2002 Levy *et al*[283] reported an OR of CVD events in diabetes five times greater with the HP 2-2 phenotype, than with HP 1-1 in a study that involved 206 CVD patients and 206 CVD controls (146 and 93 were affected by T2DM, respectively, as part of the Strong Heart Study). In 2004, a subsequent study by Levy *et al*[284] involved 3273 subjects in the Framingham Heart Study, however only a subset of 433 patients were affected with T2DM, and of these, only 86 had a history of prevalent CVD. Finally, a 2003 study in patients with acute myocardial infarction reported that individuals with T2DM and the HP2 allele had improved mortality following acute myocardial infarction, compared to subjects with T2DM and the HP 1-1 genotype (included only 224 T2DM affected patients)[285]. The DHS is a study of the genetic and epidemiological causes of CVD in patients with T2DM. In a sub-study of 1208 subjects from the DHS, the HP 2-2 genotype was associated with

increased carotid intima-media thickness[286].

Apolipoprotein E gene polymorphism and risk of CVD in T2DM: ApoE plays an important role in lipid metabolism as a ligand for many cell-surface receptors comprising the LDL receptor, LDL-receptor related protein and VLDL receptor[287]. Human ApoE is genetically controlled by three alleles (e2, e3, and e4) at a single gene locus in chromosome 19; these code for three isoforms (E2, E3, and E4) and thus determine the six genotypes (e2/2, e4/2, e3/2, e3/3, e4/3, and e4/4)[287]. ApoE ε2 allele has been reported to be related with higher plasma levels of ApoE, reduced plasma levels of LDL-C and lower risk of CAD[288], while ApoE ε4 is related with lower plasma level of ApoE, elevated plasma levels of total cholesterol, LDL-C, VLDL-C, and greater risk of CAD when compared to ApoE3 homozygotes[289]. In diabetic population, Apoe4 allele is related with the risk of CAD[290,291], augmented occurrence of exercise-induced silent myocardial ischemia[292], impairment of endothelium-dependent artery dilation[293], and CAD death[294].

Genetic factors in the overproduction of Apolipoprotein C-Ⅲ and the risk of CVD in T2DM: Apolipoprotein C-Ⅲ (ApoC-Ⅲ) plays an important role in regulating the metabolism of TGs-rich lipoproteins (TRLs). ApoC-Ⅲ is an inhibitor of lipoprotein lipase and of TRLs remnant uptake by hepatic lipoprotein receptors. Elevated ApoC-Ⅲ, may cause accumulation of plasma TRLs lead to hypertriglyceridaemia (Figure 4).

The APOC3 gene exists in a gene cluster with the *ApoAIV* and *ApoA I* genes on chromosome 11q23[295]. ApoC-Ⅲ expression is down-regulated, in part, by insulin *via* the promoter insulin response element on the *APOC3* gene[296]. This indicates that ApoC-Ⅲ expression can be regulated by insulin sensitivity[297]. IR may blunt the sensitivity to the normal insulin-mediated suppression of *ApoC-Ⅲ* gene expression. The transcription of *APOC3* gene is also mediated by peroxisome proliferator activated receptors (PPAR)[298]. The induction of PPAR, principally the PPAR-α form, decreases *APOC3* gene expression[299,300].

Several studies reveal that naturally occurring sequence variation in APOC3 genes affects plasma ApoC-Ⅲ (and TGs) concentrations in humans. The APOC3 promoter variants at positions -455 and -482 have been studied more extensively because they relate to responsiveness to insulin. Moreover, there is increasing evidence showing the possibility of interactive effects between the *APOC3* gene variant and other environmental factors such as dietary intakes or smoking[301,302].

Epigenetics and the risk of CVD in T2DM: There is evidence linking epigenetic factors to various diseases such as DM and CVD[303]. Epigenetic factors could be an important mediator between DM, CVD and chronic inflammatory response, and, by different types of reactions such as acetylation and methylation, could mediate the interaction between genes and environment resulting in activation, repression or silencing the genetic transcription (Figure 5). In particular, DNA methylation has been linked to several cardiovascular-related biomarkers, including HC and CRP[304]. Hyperglycaemia may induce epigenetic changes of genes involved in vascular inflammation. Poor glycemic control increases nuclear transcription factor-κB (NF-κB), which regulates the expression of genes involved in inflammatory diseases, including atherosclerosis and diabetic complications[305], activity in monocytes and gene expression of inflammatory cytokines[306,307]. Moreover, in human aortic endothelial cells, the excess of reactive oxygen species resulting from a transient exposure to hyperglycaemia (16 h) can induce monomethylation of lysine from histone 3, increasing the expression of the subunit p65 of NF-κB[308], responsible for the increased transcription of VCAM-1, monocyte chemoattractant molecule 1, and some inflammatory proteins like interleukin-6, ICAM-1, and NOS, that are associated to hyperglycaemia-induced arterial pathology[307]. Epigenetic changes in the NF-κB p65 promoter induced by transient hyperglycaemia, which persist for 6 d during culture at normal glucose levels, can be regulate for two histones: a histone methylase and a histone demethylase[309]. In fact, the hyperglycaemic memory could be explained by epigenetic changes induced by transient hyperglycemia. Epidemiological studies insinuate that hyperglycemia may induce epigenetic changes of proinflammatory genes, which subsequently regulate gene expression and thereby the development of vascular inflammation[310].

PERSPECTIVES AND CONCLUSIONS

The complex interaction of risk factors in T2DM make it necessary to apply a holistic approach to the management of this chronic disorder, and a comprehensive care plan should therefore include modification of all cardio-

vascular risk factors. Targeting multiple markers of CVD risk hopefully offers the best chance of improving CVD outcomes.

There are consistent evidences that optimal glycaemic control, along with control of hypertension, dyslipidaemia, smoking cessation, and weight loss are necessary for reducing cardiovascular risk in T2DM patients. Cardiovascular benefits are obtained if the control of traditional cardiovascular risk factors begins early in subjects with short duration of DM and low cardiovascular risk. On the contrary, in elderly subjects with long duration of DM, exposed to hyperglycemia for a long time, and high cardiovascular risk, the same is not true. This beneficial or harmful effect could be explained by the hypothesis called as metabolic memory, in which the effect of the early glycemic exposure environment is imprinted in target organs, resulting in long-term protective or deleterious long-term effects.

In recent years there have been major advances of the influence of non-traditional risk factors for CVD in DM. This knowledge should gradually lead to the development of more effective therapeutic strategies to prevent cardiovascular events. Currently there is no evidence that routine monitoring of these risk factors in diabetic patients leads to better diagnostic and therapeutic results. Nor is there solid evidence to justify screening for subclinical atherosclerosis in asymptomatic subjects with DM.

Further work is needed to understand the impact of epigenetic changes of complications of T2DM, which can lead to the development of new therapeutic strategies for these patients. Research should focus on the factors that lead to dysfunction and failure of islet, particularly those acquired at an early age because they can be prevented. Epigenetic regulation of metabolic genes may be one of the fields of research.

Abstract

Diabetes mellitus type 2 (T2DM) is a global pandemic that will affect 300 million people in the next decade. It has been shown that early and aggressive treatment of T2DM from the onset decreases complications, and the patient's active role is necessary to achieve better glycemic control. In order to achieve glycemic control targets, an active attitude in patients is needed, and self-monitoring of blood glucose (SMBG) plays a significant role. Nowadays, SMBG has become an important component of modern therapy for diabetes mellitus, and is even more useful if it is performed in a structured way. SMBG aids physicians and patients to achieve a specific level of glycemic control and to prevent hypoglycemia. In addition, SMBG empowers patients to achieve nutritional and physical activity goals, and helps physicians to optimize the different hypoglycemic therapies as demonstrated in the St Carlos study. This article describes the different ways of using this educational and therapeutic tool from the medical point of view as well as from the patient's perspective.

Key words: Structured self-monitoring of blood glucose; Educational; Therapeutic; Tool; Management; Diabetes mellitus type 2

Core tip: Structured self-monitoring of blood glucose (SMBG) has recently become an important component of modern therapy for diabetes mellitus due to its educational and therapeutic role. SMBG aids physicians and patients to achieve a specific level of glycemic control and to prevent hypoglycemia. It empowers patients to achieve nutritional and physical activity goals, and helps physicians to optimize the different hypoglycemic therapies as demonstrated in the St Carlos study.

INTRODUCTION

Diabetes mellitus is known by a number of syndromes that are a consequence of a lack of insulin secretion or by a defect in its hypoglycemic action. Hyperglycemia is the common feature in all of these syndromes, and if it is present for a long period of time it can cause vascular damage. Despite the significant development in hypoglycemic drug therapies over the past two decades, diabetes remains the leading cause of new cases of blindness, kidney failure, and limb amputations not related to accidents or injury in adults. Moreover, the incidence and prevalence of this disease continues to increase, as a result of an unhealthy and sedentary lifestyle in developed coun-

tries, and is nowadays considered a pandemic disease. According to the International Diabetes Federation (IDF), in the next decade it will affect more than 300 million people worldwide. The incidence and severity of complications depend mainly on metabolic control and time to disease progression. Therefore, an early and individualized approach to achieve strict glycemic control is needed along with the management of other cardiovascular risk factors. To achieve this aim, it is essential that patients with diabetes assume an active role in their care, and self-monitoring of blood glucose (SMBG) plays a significant role.

In the early 1990s, the first meter for self-monitoring capillary blood glucose was released. In many researchers' opinion it was the greatest research after that on insulin. SMBG increases life expectancy and improves diabetic patients' quality of life. The Diabetes Control and Complications Trial[1] showed that its use as an educational and therapeutic tool significantly reduced complications and delayed existing complications in type 1 diabetes mellitus (T1DM). To date, the intensive treatment of diabetes consists of multiple daily injections of insulin, however, later this concept was extended to include multiple glucose capillary determinations conducted by the patient in order to perform multiple self-treatment adjustments (including oral drugs and insulin). In T2DM, the results have been more controversial, especially in patients not treated with insulin. However, our group showed that the use of SMBG in an educational program increased the regression rate in newly diagnosed type 2 diabetic patients and led to changes in lifestyle and weight loss[2].

The success of this technique is due to the empowerment that SMBG provides to patients. SMBG shows variations throughout the day facilitating decision-making on changes in hypoglycemic treatment as well as lifestyle at particular time points. These features make SMBG not only a good tool for glycemic control, but also a good tool to prevent hypoglycemia, to improve the quality of life of diabetic patients and for better management of economic resources.

TARGETS OF GLYCEMIC CONTROL

Both patients and health care staff need to jointly agree on the terms and use of SMBG. This can change depending on lifestyle and the pharmacological treatment provided. It is recommended that targets are set by individual steps. The main objective is to achieve normal glycemia values or very close to the normal standards with hemoglobin A1c (HbA1c) levels below 7%. These targets decrease micro-vascular complications as shown in different studies[2,3]. A stricter regime (*i.e.*, level below 6.5%) can be considered for specific patients (as long as it does not result in adverse effects or severe hypoglycemia) with a high life expectancy rate and short disease evolution. A higher glycemic objective (below 8%) may be appropriate for patients with a limited life expectancy, comorbidities and complications, and for those with severe hypoglycemic risk[4]. For this reason, it is necessary to individualize the treatment in line with the patient's "biological" age[5]. We should bear in mind that the HbA1c parameter for glycemic exposure for the last three months might not be as relevant as is currently believed. Other parameters, such glycemic variability, are becoming a significant risk factor involved in the pathogenesis of diabetes complications[6,7]. For example, patients with similar levels of HbA1c can show variability in cardiovascular risk, which indicates that there are unknown factors involved. For this reason, it should be common practice to carefully consider SBMG, as it shows real-time variability of blood glucose.

With regard to glycemic objectives, the ADA and EASD recommendations for glycemic targets[4,8] are shown in Table 1.

Our working group has assumed the same targets as those in the St Carlos study[9]. When objectives in at least 60% of the registered capillary blood tests are not achieved, it is time to take action, either drug titration or introducing new drugs (this theme is further developed in the following section: glycemic assessment and then taking action).

SELF-MONITORING BLOOD GLUCOSE: WHAT IS IT?

This self-analysis is defined as the self-measurement of capillary blood glucose by the patient using an accurate device, digital or battery-operated, that measures capillary glucose in real time. The aim of SMBG is to collect detailed information on glucose levels at many time points during the day in order to implement various strategies to fit the patient's lifestyle. It can be used to guide a new regimen, and it can help people day-to-day to adjust their food intake, physical activity, and their dose of insulin to improve glycemic control.

This useful tool represents the highest level of patient participation. The best decision-making occurs when patients reach a higher level of knowledge and skills to

adhere to changes in lifestyle; similarly, they make proper use of hypoglycemic drugs. Thus, SMBG should be established from the onset to guide initial treatment to ensure better glycemic control.

SMBG could complement HbA1c testing, however, the following factors should be considered: it distinguishes between fasting, before meals, and postprandial hyperglycemia. Glycemic excursions are detected early. It identifies hypoglycemia and its resolution by providing immediate feedback on food choices, activity and different medications.

Methodology of SMBG

The test involves pricking a finger with a lancet device to obtain a tiny blood sample and apply this on a test strip. Subsequently, the blood glucose concentration is determined by inserting the strip into a reflectance photometer for automatic reading. Thus, subjects with diabetes are taught to learn from the results and make corrections by changing their intake of carbohydrates, by changing their physical activity or by changing the dose of medication.

Advantages of SMBG

To perform SMBG the patient does not require help and it can be carried out anywhere. SMBG provides immediate accurate data, which can help patients and their relatives in the daily management of diabetes and can teach them to face new future events. The other important advantages of SMBG should be highlighted. SMBG informs patients whether their treatment is working and guides the health care team on whether to continue with the same treatment regimen or if another treatment is needed. The structured SMBG strategy may help patients in their daily routine to maintain a blood glucose level as normal as possible with proper food choices (with a low or high amount of carbohydrates) and with proper life-style choices. It should also be pointed out, that SMBG improves recognition of either severe hyperglycemia or hypoglycemia. This increases the understanding of hypoglycemia and helps reduce anxiety regarding hypoglycemia. Moreover, SMBG is important for the performance of hazardous tasks which could be influenced by high or low glycemic levels, such as driving or operating machinery.

Disadvantages of SMBG

The disadvantages of SMBG are mainly related to the patient who may have a lack of motivation for testing or does not have enough education on how to interpret his own results or does not know when they should be performed. In this case, the following disadvantages may outweigh the potential benefits. SMBG may increase anxiety regarding glycemic control which is closely related to state of health. Other negative aspects to bear in mind are as follows: the pain derived from finger prick and the cost of testing supplies, whether they have to be self-funded or not.

Obviously, a single system of SMBG does not meet the needs of all people with T2DM, thus it must be adapted according to different patients' characteristics. For instance, meters in elderly patients should be simple and manageable and in blind patients they should incorporate sound alarm systems.

FREQUENCY OF SMBG

The frequency of SMBG is a critical point in treatment efficiency, therefore, SMBG protocols should be individualized according to patient characteristics, needs and changes in lifestyle and treatments. The frequency of SMBG also depends on the availability and expertise of the health care team. The program should intensify in frequency in cases of suboptimal glycemic control and changes in lifestyle or treatment. When possible, the fewest determinations should be carried out to allow appropriate adjustment of treatment. In addition, it is important to emphasize that not only patients should collect and interpret the results, but the health care team should also interpret the glucose readings and act accordingly.

As mentioned previously, glycemic targets must be agreed by the patient and their physician. Ideally, patients should achieve goals of glycemic control as close as possible to the value of those without diabetes. Determinations should be performed before each meal and 2 h after eating, and whenever there is risk of hypoglycemia, especially at night (which is the time with the highest risk of hypoglycemia). Therefore, a complete profile will include the identification of at least 6 points if three meals a day are consumed.

Based on the St Carlos study[9], in patients with newly diagnosed T2DM, the following strategy was proposed: The profile consisted of six points if three main meals were consumed daily. The frequency may vary depending on the stability of the patient, as shown in Table 2. It is noteworthy that the strategy proposed by our group has also been adopted in several European consensus documents[10,11] which have subsequently been published. Therefore, the role of the structured SMBG in the management of diabetes has been confirmed.

At the onset of disease, the frequency of this strategy (six point profile) should be twice a week and evaluated every five complete profiles to adopt changes in treatment. This frequency must be maintained to achieve stability. Stability is achieved when no changes in three consecutive visits are observed, thus, the frequency can be reduced to one profile once every two weeks in order to maintain adherence to the treatment plan. When there is a risk of suboptimal glycemic control, intercurrent diseases or changes in lifestyle, the frequency should increase and self-testing should be performed as many times as necessary. However, if the patient is treated with continuous subcutaneous insulin infusion he will require at least a four point profile daily, although a seven point profile is recommended, based on the frequency of food intake.

It is important to inform patients that these profiles, if they are not carried out during their everyday lifestyle,

Table 2 Frequency of self-monitoring of blood glucose

	Breakfast		Lunch		Dinner		Night	Periodicity
	Before	After 2 h	Before	After 2 h	Before	After 2 h		
At the onset of T2DM	a	a	a	a	a	a		2-3 d/wk
Suboptimal control of T2DM	a	a	a	a	a	a		2-3 d/wk

may not be as useful as they could be for the health team to make decisions on therapy. Thus, we do not recommend SMBG during medical consultation, as this is probably not a usual day in the patient's life. Recently, a structured program was proposed, which consists of three consecutive profiles prior to the medical visit to make decisions on treatment[12]. This strategy has proven to reduce absolute values of Hb1AC by 1.2%.

SMBG IS A THERAPEUTIC TOOL TO IMPROVE GLYCEMIC CONTROL

Although the benefits of SMBG have been demonstrated in T1DM[1] and insulin-treated T2DM[13-15], findings from SMBG studies in non-insulin-treated T2DM[16-20] have been inconsistent. As a result of this, the IDF has recently published a guide for SMBG in non-insulin treated subjects with diabetes[21]. In this guide, the IDF recommends that SMBG should be implemented only when patients and/or their physicians have the knowledge, skills and willingness to incorporate self-analysis into their routines in order to achieve the agreed objectives of treatment. This emphasizes the need for collaboration between the patient and the treating medical team to act jointly.

The study conducted by Evans *et al*[22] demonstrated a statistically significant correlation between the number of daily SMBG tests performed and HbA1c levels. It was observed that patients who performed SMBG more than once per day showed a reduction in HbA1c of 0.7%. Furthermore, to reduce HbA1c levels below 7% it was necessary to carry out SMBG at least six times a day[22]. The results of the St Carlos study were similar. Newly diagnosed T2DM patients were randomized to either a structured SMBG-based intervention (n = 130) or an HbA1c-based control group (n = 65) and were followed for 3 years. The primary endpoint was the regression rate of T2DM. Diabetes regression was observed to be 4.5 times more likely in the intervention group, and that this was associated with greater adherence to dietary and physical activity recommendations. Moreover, a greater weight loss of 4 kg was 3.6 times more likely in the intervention group. The study included a three-year follow-up period, and indicated that the benefits of a structured SMBG program are maintained long-term[2]. Results from the ROSSO[23] and the PRISMA studies[24] support our results.

Therefore, SMBG is not a treatment, but a tool which provides data to adjust treatment. Changes in therapy can be made as soon as the values for SMBG are obtained and before they have an effect on HbA1c. Consequently this useful and efficient tool must be accessible in both primary care and diabetes care centers.

SMBG AS AN EDUCATIONAL TOOL

The active participation of subjects with diabetes in the control and treatment of their disease is an essential component of diabetes care. To that purpose, it is necessary that those with diabetes have an adequate level of knowledge and skills to make proper decisions on their treatment. Through an educational program, diabetics can gain the necessary knowledge, skills and motivation to modify, adopt and maintain healthy behaviors and positive attitudes toward self-management.

Within this context, SMBG is a very handy tool which helps patients understand the disease. In particular, SMBG shows variations in blood glucose in a single day, for instance during exercise, meals, physical and emotional stress. This tool encourages self-management of diabetes[25], allowing patients to measure the impact of their behavior (the effect of eating reflected in postprandial glucose, *etc*.) thus promoting greater adherence to dietary and exercise advice in their daily lives.

In addition to its educational role, SMBG is a powerful motivating factor. It provides positive feedback on the success or failure after making self-adjustments. This can lead to increased confidence in patients to be more self-sufficient, more responsible and can make them more involved in the disease.

However, the DiGEM study[26], did not observe benefits from SMBG in patients with non-insulin-treated T2DM. There are several noteworthy aspects in this study which were crucial in obtaining these data. All treatment changes were performed by physicians, regardless of the

Table 3 Nutrition and activity score

team of nurse educators. In addition, the patients had experienced more than 3 years of diabetes progression when they entered the study, so they were less receptive to this educational tool due to apathy. Thus, we believe that this tool is very helpful from disease onset to provide a greater educational effect, and it is at this point that it is crucial to apply an integrated program based on SMBG. This may explain the conflicting results with our study.

GLYCEMIC ASSESSMENT AND THEN TAKING ACTION

Currently, only invasive procedures, such as subcutaneous continuous glucose monitoring and SMBG, can provide accurate information on the daily profile of blood glucose levels.

The magnitude of the variation in glucose has proved to be the most reliable factor associated with the increased risk of severe hypoglycemia[27] and has been associated with subsequent microvascular and macrovascular complications[28-31]. Hence, the concept of glycemic variability is very important as it is one of the major features of T2DM. SMBG is recorded in real time, but HbA1c is not. Thus, this tool provides information for both patients and doctors, and on lifestyle changes if needed, in order to achieve better glycemic control. Furthermore, it also allows the physician to make adjustments to the different doses of oral hypoglycemic drugs or insulin, depending on the levels registered, to avoid hypoglycemia and hyperglycemia.

To take action, we should take into account that each determination of capillary glucose is explained by previous events. Each determination assesses previous events, such as, the effect of food ingested previously, exercise performed earlier and the dose of drug administered previously. Glycemic variability is explained in more than 90% of cases by food intake. For this reason and in order to achieve targets, it would be advisable to wait at least 3 out of 5 profiles performed in similar conditions to make changes to the diet, or to make changes in hypoglycemic drugs if needed. Therefore, therapeutic changes are required if more than 60% of blood glucose levels are off target, both above and below. In addition, the patient should determine possible reasons for these values. It is recommended that these interpretations should be transcribed into the book of patients' profiles and later discussed during the medical visit with the health care team, both the physician and diabetes educator. Therefore, we stress the importance of correct collection of self-analysis, as data which are not transcribed cannot be evaluated in order to make changes.

Glycemic assessment conducted by the medical team: A proposal of changes in lifestyle and changes in therapy and dose of hypoglycemic drugs

After establishing the diagnosis of T2DM, the physician and the patient must agree therapeutic targets as well as changes in the patient's lifestyle. After 3-6 mo of non-response, pharmacological treatment should be initiated[4,8]. To achieve success, patients must be informed regarding a healthy lifestyle (Table 3).

Interventions in lifestyle include: smoking cessation, dietary and exercise prescription and diabetes education to change negative attitudes and promote healthy lifestyles. All these recommendations are in order to reduce cardiovascular morbidity and mortality in patients with T2DM.

Before adjusting treatment the following factors should be determined: (1) If in three out of five profiles the fasting blood glucose or the postprandial blood glucose values remain within target the patient should remain on the same treatment recommendations; (2) If the target levels are above the objective levels in 60% of cases (3 of 5) the following are recommended: lifestyle recommendations should be intensified. The patient should assess his intake (focused on carbohydrates) and if possible try to decrease the amount of carbohydrates in order to control postprandial glycemia. Another option might be to recommend an increase in physical activity before meals as exercise increases insulin sensitivity; with regard to hypoglycemic drugs, these should be titrated or a new drug added. We first add insulin sensibilizator Should this be sensitizing drugs (metformin or pioglitazone) at the maximum tolerated doses. If the targets are not reached we add drugs based on secretory insulin action (sulfonylurea, glinides, gliptins, glucagon-like peptide-1 agonists or insulin); and (3) If glucose levels are below 70 mg/dL, there are two options: ask the patient to adjust carbohydrate

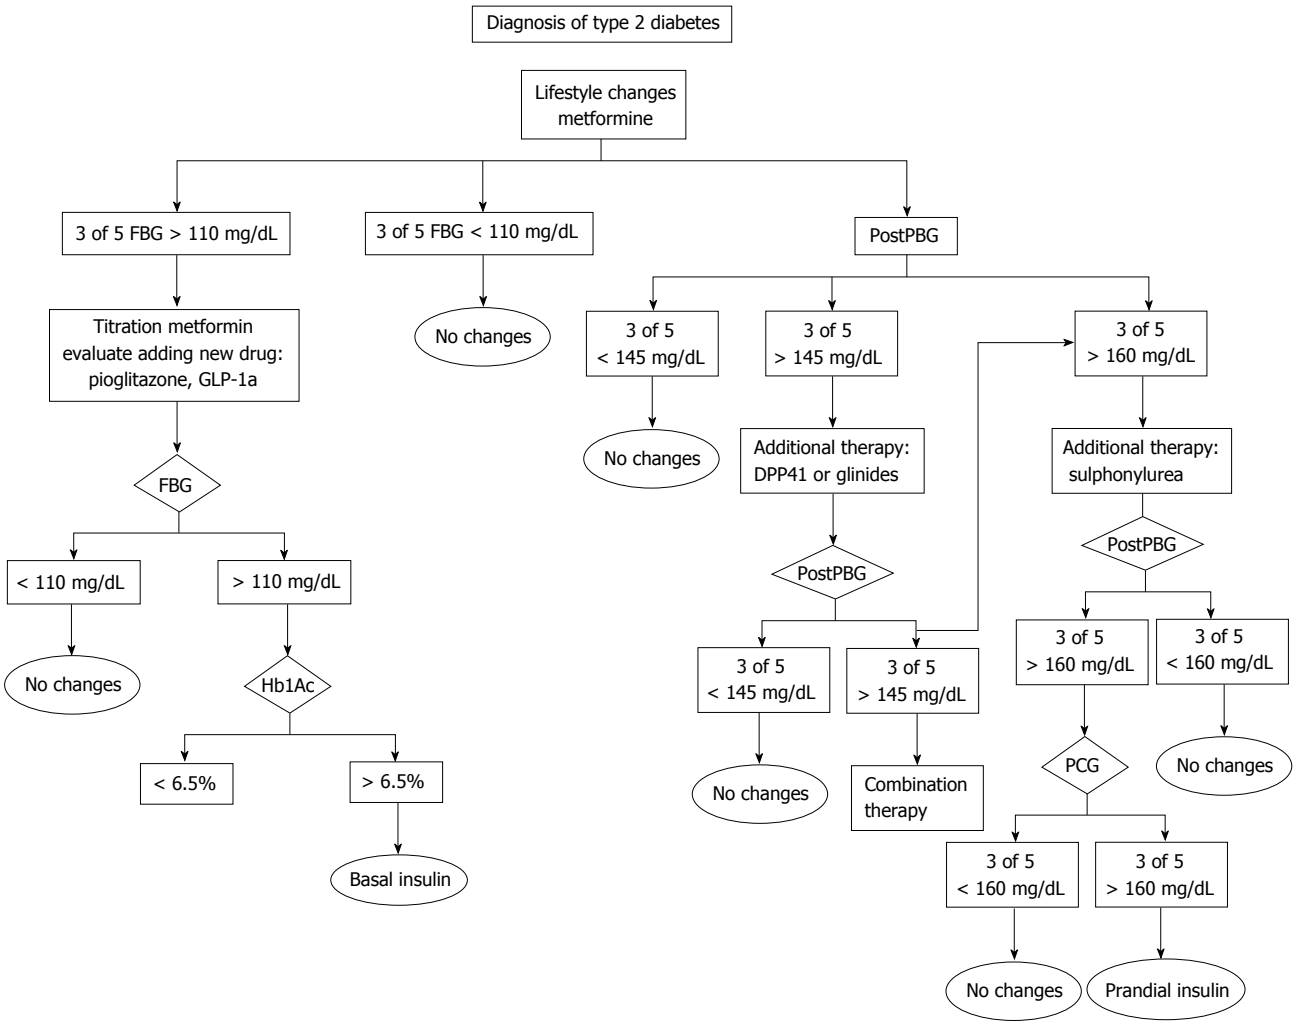

Figure 1 Decision algorithms based on self-monitoring of blood glucose from the diagnosis of type 2 diabetes mellitus as proposed in the St Carlos study. FBG: Fasting blood glucose; GLP-1a: Glucagon-like peptide-1 agonists; PostPBG: Postprandial blood glucose; FBG: Fasting blood glucose; PCG: Titration sulphonylurea.

intake or reduce the dose or the number of drugs prescribed. Figures 1-4 show different algorithms for adjusting diabetes treatment.

Glycemic assessment conducted by patients: Changes in lifestyle and adjustment of doses of hypoglycemic drugs

Due to the educational role of SMBG, patients can be self-sufficient, adequately responding to glycemic fluctuations under different situations, and achieving results very close to the agreed targets.

Fasting glucose assessment: Fasting glucose is the existing glycemia prior to breakfast or eight hours after fasting. This type of glycemia shows minimal pharmacological and intake interference, and shows the effect of gluconeogenesis.

The main causes of fasting hyperglycemia are related to the following: (1) medical prescription errors: the prescribed medication dosage is too low, timing of administration may be inappropriate, or the medication does not effectively target fasting pre-prandial glycemia. Our recommendation is to increase the dose of drugs if hyperglycemia persists for three consecutive days in the daily profile. For instance, if basal insulin is administered during the afternoon or in the evening, patients should increase their usual dose of basal insulin as recommended by their physician without waiting for medical consultation. To do so, patients must be adequately trained; and (2) patient behavior: incorrect medication administration (dosage errors, inappropriate timing), failure to take medication, *etc*. Frequently, we observe a wrong tendency in patients of making changes based only on the registered glycemia (high or low). This is known as rescue therapy. This attitude would be valid only to correct an unforeseen specific situation and to avoid the consequences of sustained hyperglycemia or hypoglycemia. However, this attitude should not be allowed to continue, and an analysis of previous events should be carried out to make appropriate changes if needed. To improve a patient's skills it is essential to have a good team of diabetes educators in order to improve knowledge and glycemic control.

Pre-prandial glucose assessment: Pre-prandial glycemia evaluates previous food intake, which means:

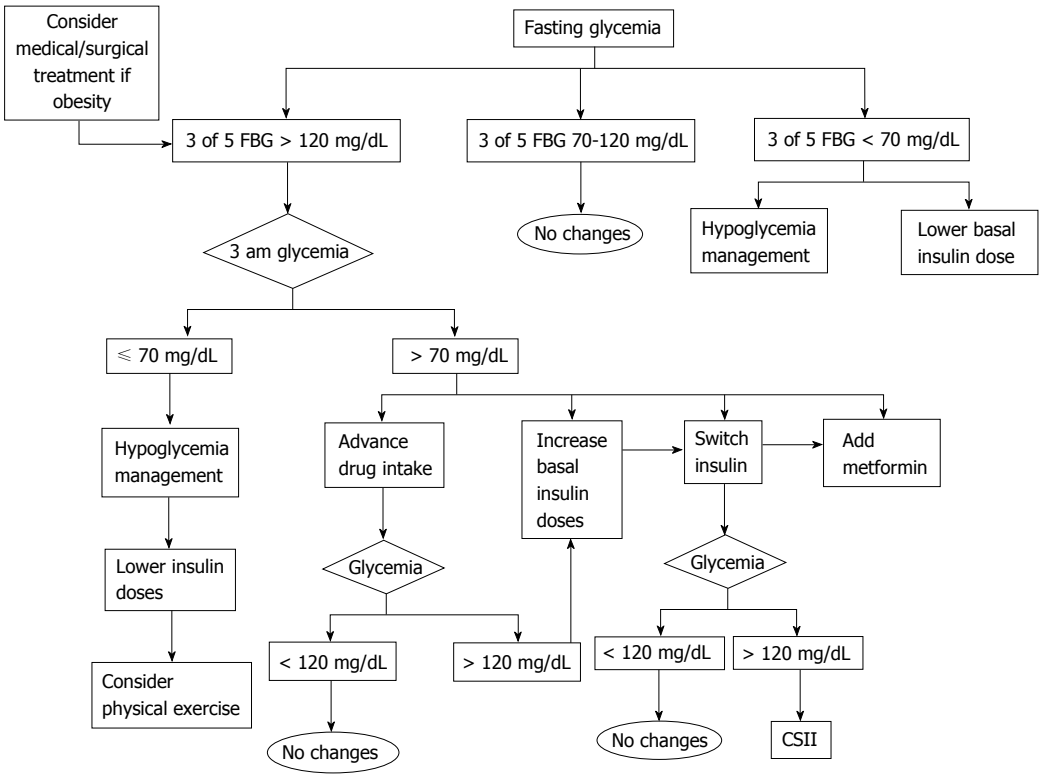

Figure 2 Decision algorithms based on fasting self-monitoring of blood glucose in the evolution of type 2 diabetes mellitus as proposed in the St Carlos study. FBG: Fasting blood glucose; CSII: Continuous subcutaneous insulin infusion.

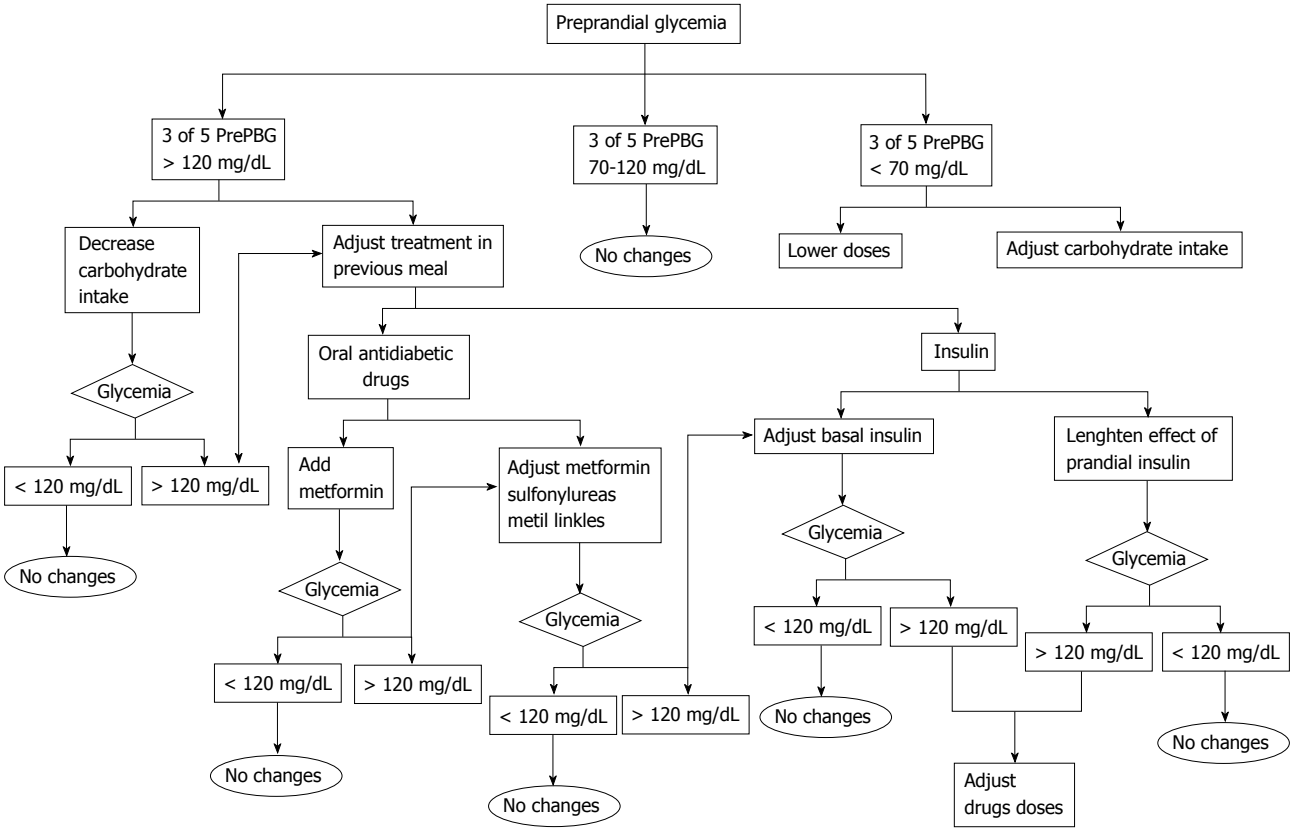

Figure 3 Decision algorithms based on preprandial self-monitoring of blood glucose in the evolution of type 2 diabetes mellitus as proposed in the St Carlos study. PrePBG: Preprandial blood glucose.

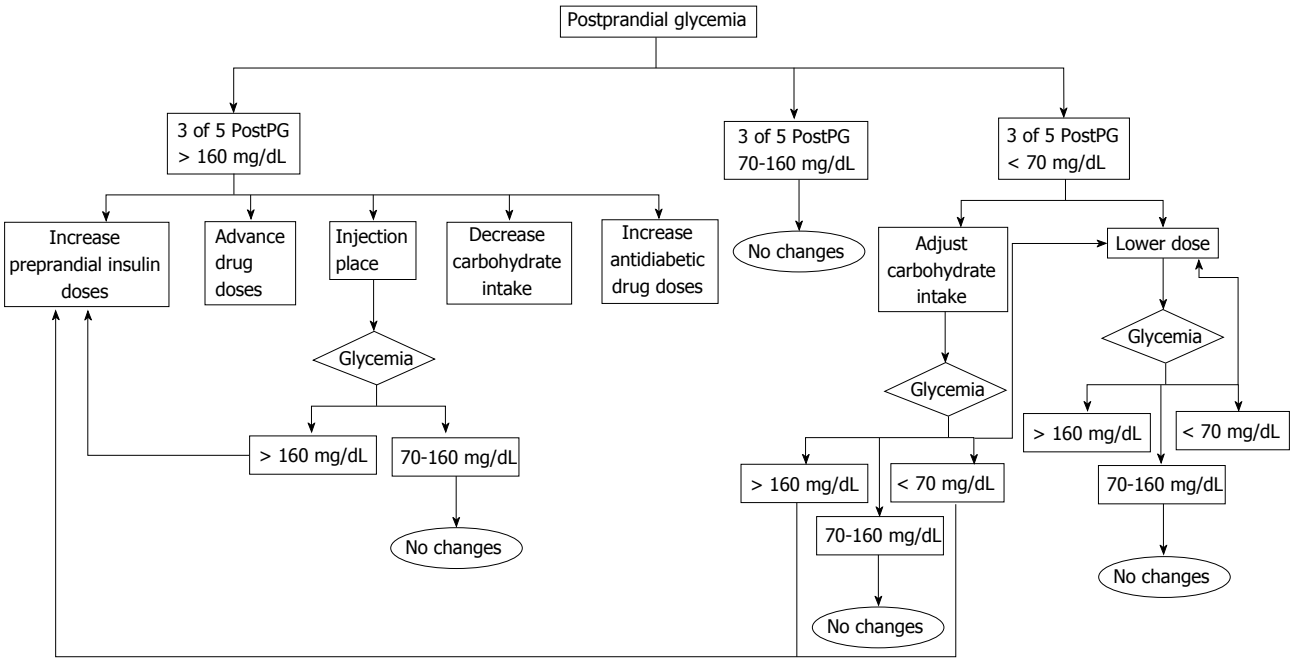

Figure 4 Decision algorithms based on postprandial self-monitoring of blood glucose in the evolution of Type 2 diabetes mellitus as proposed in the St Carlos study. PostPG: Postprandial blood glucose.

mid-morning or afternoon snack, as well as any physical activity conducted before the analysis. A nutritional recommendation might be to decrease the intake of meat (sausage, bologna, ham, salami, *etc.*), cheese, all types of manufactured products, French fries, *etc.* Our recommendation is to substitute those snacks for a limited intake of nuts. Nuts such as almonds, walnuts and hazelnuts have a lower glycemic index and substantially reduce unhealthy fats and they provide mono and polyunsaturated fats (fatty acids oleic, linoleic and omega 3 fatty acids) with high benefits shown in previous reviews[32]. In addition, nuts satiate the appetite and improve microbiota. In addition, promoting physical activity at this point will improve insulin sensitivity.

Postprandial glucose assessment: We evaluate glucose two hours after breakfast, lunch and dinner: (1) in general terms, if glycemia is above the target, we propose one of the following options: reduce the amount of carbohydrate intake, substitute common foods for lower glycemic foods (*i.e.*, white bread for wholewheat bread), modify antidiabetic treatment (*i.e.*, increase prandial insulin) and perform physical activity after food intake; and (2) in those cases with hypoglycemia (< 70 mg/dL), patients are recommended to put into practice the protocol advised in order to resolve hypoglycemia. They will also have to analyze what triggered that specific glycemic level (*i.e.*, insufficient intake of carbohydrates, too much exercise or inadequate drug doses).

The following three questions may be useful in analyzing postprandial glycemia and in understanding the root of the problem in order to act accordingly: (1) what did the patient eat? The patient must analyze what he ate two hours previously, identify foods with high glycemic index and avoid them or substitute them for other foods with a low glycemic index in the coming days; (2) when did the patient eat it and when was the self-analysis performed? The patient should record when he carried out the self-analysis so that the results regarding glucose intake can be put into context. If capillary glucose levels are low after two hours or more, two options are available: increase the intake of slow-absorption carbohydrates or bring forward the next meal; and (3) how did the patient eat it? We know that the way food is cooked is the key to its absorption, for this reason it is important that the patient is informed regarding this. For instance, for the same amount of potatoes, fried potatoes significantly increase the glycemic index, whereas, boiled potatoes show a lower postprandial increase.

Postprandial glucose assessment after breakfast: Postprandial glycemia after breakfast provides information on the foods which are rich in carbohydrates. In cases where glycemia is high we can choose any of the options mentioned above. Recently it was shown that juices, even natural juices, have a high glycemic load, so they are not as healthy as expected. For this reason, we, as professionals, need to educate the diabetic population, that juice intake is inappropriate. Breakfast might also be a good time to evaluate the response to biscuits, including wholewheat biscuits, many of which contain saturated fats. To ensure a healthy breakfast we recommend substituting juice for a piece of fruit, wholewheat bread instead of white bread, and the addition of olive oil to bread instead of ham or butter.

Postprandial glucose assessment after meals: Postprandial glycemia after meals provides information on the

foods rich in carbohydrates and the way food has been cooked. Similar to breakfast time, in those cases where glycemia is high, we can choose any of the options mentioned above to decrease the level of glycemia (Ⓐ). High levels of glycemia are mostly associated with cereal intake, basically white bread and white rice and food containing potatoes (*i.e.*, French fries, Spanish omelet). For this reason, it is advisable to introduce salads and vegetables as starters, and a piece of fruit for dessert. These are recommended daily foods with limited glycemic load and they also lead to satiation. These foods are also recommended when body weight has become a significant issue.

Glycemic assessment during illness

During the presence of disease it is required that patients increase self-analysis, and adjust the treatment according to the results. For instance, during vomiting patients must consume sugar-containing fluids (juices, milk, isotonic drinks *etc.*) to avoid hypoglycemia. If this is not controlled, patients should look for assistance.

QUALITY OF LIFE AND SMBG

The St Carlos study[9] also assessed treatment satisfaction regarding interference with quality of life (family, social and labor). Initially, patients in the intervention group showed greater interference and stated that it was an added challenge to correctly perform SMBG. However, after a year of follow-up, they reported a greater degree of independence in the three different areas (family, social and labor) and a greater degree of satisfaction with the treatment plan compared to the control group. These data persisted after three years of follow-up.

The explanation for this appears to be simple. When SMBG is integrated into the treatment plan, it can tailor treatment to the patient's lifestyle. In addition, patients who do not know about this tool have to change their lifestyle in order to adapt it to the treatment plan, significantly reducing their index of satisfaction.

Not all patients attain self-sufficiency, including most elderly people with social, family or cultural constraints, and some T2DM patients on conventional treatment. Other studies suggest that this tool produces increased stress in the patient associated with the determination of glycemia and frustration over poor results, especially if the patient does not know how to respond.

Therefore, SMBG when integrated into a comprehensive educational program most likely improves the quality of life of patients by allowing them to self-sufficiently manage their daily lives.

COST IMPLICATIONS OF SMBG, PROS AND CONS

Due to the relatively high cost of SMBG, particularly the use of test strips, it would be remiss to ignore the economic implications. Therefore, it is necessary to balance the benefits of SMBG against its costs.

The implementation of this tool from the onset of disease has benefits for glycemic control that will lead to a decrease in chronic diabetes complications. SMBG is costly in the short-term, but may not be so costly in the long-term, as it helps to reduce the treatment costs of the chronic complications of diabetes through improved glycemic control. Accordingly to a recently published Spanish study[33] conducted in the autonomous community of Madrid, the average cost of T2DM complications per patient was estimated to be 4121.54 Euros (66% due to macrovascular complications), whereas the cost of the test strips only accounted for 2% of the expenditure. Thus, SMBG it is an efficient tool in the treatment of diabetes.

CONCLUSION

SMBG is an essential tool in insulin-treated T2DM, and as shown in this article, in non-insulin treated T2DM. SMBG should be an integral part of the treatment in newly diagnosed T2DM patients. It enables patients to adapt their lifestyle more effectively to achieve better glycemic control and provides insights into patients and clinicians concerning the effectiveness of therapies in glycemic control. Despite this, none of the current guidelines include SMBG in their algorithms, and it is necessary to change this point of view. We advocate the implementation of structured-SMBG in newly diagnosed T2DM, as SMBG is a key element for decision-making in hypoglycemic therapy (lifestyle changes and drugs).

Abstract

Type 2 diabetes is characterized by a decreased ability of insulin to facilitate glucose uptake into insulin sensitive tissue, *i.e.*, skeletal muscle. The mechanism behind this is at the moment unresolved. It has been suggested that increased amount of lipids inside the skeletal muscle (intramuscular triglyceride, diacylglycerol and ceramides) will impair insulin action in skeletal muscle, but data are not consistent in the human literature. It has also been hypothesized that the impaired insulin sensitivity is due to a dysfunction in the mitochondria resulting in an impaired ability to oxidize lipids, but the majority of the literature is not supporting this hypothesis. Recently it has been suggested that the production of reactive oxygen species play an essential role in skeletal muscle insulin sensitivity. It is well accepted that physical activity (endurance, strength and high intensity training) improves insulin sensitivity in healthy humans and in patients with type 2 diabetes. Whether patients with type 2 diabetes have the same beneficial effects (same improvement) as control subjects, when it comes to regular physical activity in regard to mitochondrial function, is not established in the literature. This review will focus only on the effect of physical activity on skeletal muscle (mitochondrial function) in patients with type 2 diabetes.

Key words: Mitochondria; Exercise; Type 2 diabetes

Core tip: It is well described that exercise interventions improves insulin sensitivity and maximal oxygen uptake in patients with type 2 diabetes as well as in control subjects. When it comes to adaptations in mitochondrial function after an exercise intervention the literature is more sparse especially in patients with type 2 diabetes. Furthermore the medication that patients with type 2 diabetes are using, are often not described well in the papers, and it is known that the different medication (statins and antihypertensive agents) have a major effect on mitochondrial function and insulin sensitivity.

Larsen S, Skaaby S, Helge JW, Dela F. Effects of exercise training on mitochondrial function in patients with type 2 diabetes. *World J Diabetes* 2014; 5(4): 482-492 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i4/482.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i4.482

INTRODUCTION

The pathophysiology of type 2 diabetes involves the secretion and the action of insulin. The prevailing view[1] is that an inability of insulin to exert its action on the central target tissues, skeletal muscle (mediate glucose uptake initialized by the binding of insulin to its receptor), adipose tissue (mediate glucose uptake and inhibit lipolysis) and hepatic tissue (inhibit glucose output), results in increasing concentrations of glucose in the blood. In response, insulin secretion from the pancreatic beta-cells

is increased, and hyperinsulinemia prevails. Only in those patients in whom the enforced production of insulin from the pancreas fails, hyperglycemia develops and overt type 2 diabetes becomes apparent. The mechanism for the failing pancreatic insulin production is not resolved, while the development of impaired insulin action (insulin resistance) is linked to the development of obesity (in particular visceral fat) and a physical inactive lifestyle and the molecular mechanism is being unraveled these years[2]. Type 2 diabetes is also frequently seen in a cluster of pathologies, including hypertension, endothelial dysfunction, and obesity. Complications to type 2 diabetes include macrovascular complications (atherosclerosis), but also microvascular complications such as neuropathy, nephropathy, retinopathy and angiopathy are known to occur in these patients.

In the past decade mitochondrial dysfunction in skeletal muscle has been linked to insulin resistance[3-7], but an agreement has not been reached and the majority of data does not support this notion[8-17]. It has been shown that patients with type 2 diabetes have 30% lower mitochondrial content in their skeletal muscle compared to healthy control subjects[12,18], and yet the intrinsic mitochondrial function (*i.e.*, respiratory rates normalized for mitochondrial content) is similar in these two groups[12-14]. As such the suggested scenario with insulin resistance being induced by mitochondrial dysfunction *via* accumulation of lipids and lipid intermediates, interfering with insulin signaling[19], is probably only partly correct. It is a consistent finding that lipids accumulate in insulin resistant muscle[3,20] and this is not a qualitative phenomenon (impaired mitochondrial respiration), but rather a quantitative phenomenon (decreased mitochondrial mass). The obvious question is therefore why the mitochondrial mass seems to be lower in the patients with type 2 diabetes? One explanation could be that the matching of the subjects is not optimal in the studies[12,18,21] where a lower mitochondrial content was reported. If the healthy control group and the patients with type 2 diabetes are carefully matched for physical activity level and maximal oxygen uptake, no differences exist in mitochondrial content, or intrinsic mitochondrial function[16]. Another question is the likelyhood of a marked decrease in mitochondrial content in the skeletal muscle of patients with type 2 diabetes. If a 30% decreased mitochondrial mass was indeed present in type 2 diabetes with a marked effect on respiratory capacity at rest (*ex vivo*), then one would expect that the in vivo exercise capacity would be severely impaired, because the mitochondrial respiratory rates increases more than tenfold with the transition from rest to exercise. Although there may be some exercise intolerance in patients with type 2 diabetes[22], most can be explained by altered oxygen uptake kinetics[23,24] on the background of impaired peripheral blood flow distribution/microvascular function. If a reduction in the mitochondrial content in the exercising skeletal muscle was a major limitation, then one would expect that skeletal muscle arterio-venous oxygen extraction would be impaired in type 2 diabetes. This is not the case[25].

It is well known that physical exercise increases skeletal muscle insulin sensitivity in patients with type 2 diabetes[26]. Furthermore, it has been reported that improvements in insulin sensitivity is accompanied by improvements in *in vivo* mitochondrial function[27]. It has been suggested that insulin resistant people may have an attenuated response to exercise training, compared with healthy control subjects[28]. Furthermore it has been reported that the response to an acute bout of exercise is attenuated in insulin-resistant compared with lean control subjects[29], when investigating genes coding for mitochondrial biogenesis (PGC-1α mRNA and protein abundance), which could explain the lack of a training effect in patients with type 2 diabetes in some studies[30-32]. It has been reported that different molecular signals in the skeletal muscle are responsible for the activation of mitochondrial biogenesis after exercise. These signals include elevated levels of cytosolic Ca^{2+}[33,34], AMP[33] and reactive oxygen species (ROS)[35]. All these studies are conducted in animals or cells, and have to our knowledge never been performed in patients with type 2 diabetes after an acute bout of exercise. An increased ROS production has also been linked to type 2 diabetes, but few human studies have actually investigated this and with conflicting results[8,10,36,37]. It has been reported in bovine aortic endothelial cells that hyperglycemia (30 mmol/L) increases ROS production[38].

This review will focus on adaptations in skeletal muscle mitochondria in patients with type 2 diabetes and healthy control participants after different exercise modalities (endurance, strength, high intensity training or a combination). Furthermore, we will attempt to clarify if the pharmacological treatment in patients with type 2 diabetes may blunt the training adaptations seen in non-diabetic people.

EFFECT OF MEDICATION ON EXERCISE ADAPTATIONS

Patients with type 2 diabetes are often treated with other medication to prevent high cholesterol and/or hypertension. In Denmark approximately 75% of all patients with diabetes are treated for hypertension, and approximately 64% are treated for hypercholesterolemia primarily with statins[39]. In Denmark approximately 90% of patients with type 2 diabetes are treated with metformin[39].

Antidiabetic agents

If a lifestyle intervention (diet and exercise) is not sufficient, metformin is the first drug of choice in the newly diagnosed patient with type 2 diabetes. Sulfonylurea may be added, and with poor glycemic control insulin treatment may be initiated. The adaptations to exercise are inadequately investigated when combined with these different medications. The mechanisms behind the glucose lowering effect of metformin is not known in detail, but a decrease in hepatic glucose production[40] and an

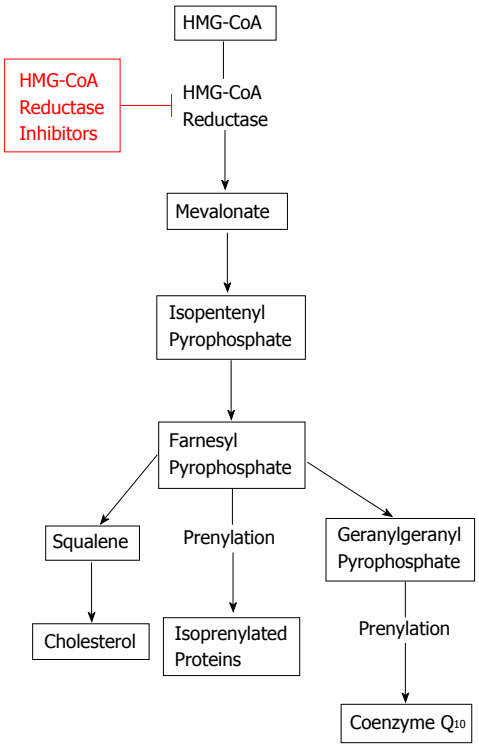

Figure 1 Effect of HMG-CoA reductase inhibitors (statins) on cholesterol and coenzyme Q10. HMG-CoA: 3-hydroxy-3-methylglutaryl-coenzyme A.

increase in glucose disposal in skeletal muscle *via* activation of AMPK[41] contributes to this. Metformin does not stimulate insulin secretion. In contrast, the hypoglycaemic effect of sulfonylureas is mediated *via* activation of the insulin producing beta cells[42], and these drugs have no direct effect on liver or skeletal muscle.

It has been suggested that the glucose lowering effect of metformin takes place *via* an inhibition of complex I in the electron transport chain in the mitochondria[43-45]. One study conducted in patients treated with metformin (2000 ± 200 mg/d) reported no effect on complex I in the electron transport chain[15]. A therapeutic dose of metformin of 1000 mg in humans corresponds to a plasma metformin concentration of approximately 0.1 mmol/L[46,47], and the peak metformin concentration in skeletal muscle is much lower than in the plasma[48]. In the studies were an inhibition was seen on complex I after metformin treatment, the concentrations used were high and supraphysiological[43-45].

It has been investigated whether metformin has an effect of exercise adaptations in young healthy subjects. One study measured maximal oxygen uptake in a double-blinded, placebo-controlled, cross-over study in healthy men and women and found a 2.7% reduction in maximal oxygen uptake after 7-9 d of treatment[49]. The authors suggest that this is unlikely to cause any individual impairment in exercise tolerance. Whether the same reduction is seen in patients with type 2 diabetes needs to be investigated. Even though 2.7% is not a major reduction, it could be argued that patients with type 2 diabetes would suffer more from this, due to a potential lower starting point. However, this finding was not confirmed in a similar study, where solely males participated[50]. Rosiglitazone (thiazolidinedione) is another antiglycemic agents, which has been reported to increase maximal oxygen uptake after 4 mo of treatment[51], the mechanisms behind the improvement is unknown.

A large proportion of patients diagnosed with type 2 diabetes have other co-morbidities, such as obesity, hypertension and dyslipidemia, *i.e.*, components of the metabolic syndrome. The pharmacological treatment of these may interfere with skeletal muscle and mitochondrial adapation to exercise training, and the literature regarding this issue will briefly be reviewed.

Lipid-lowering agents (statins)

Is has recently been reported that statins impairs the beneficial adaptations (increased maximal oxygen uptake and mitochondrial content) normally gained after a training intervention[52]. Different studies (longitudinal and cross-sectional) have reported an impaired mitochondrial function after statin therapy[53,54], which may compromise the OXPHOS capacity of the skeletal muscle. This would, in turn, further cause exercise intolerance. It has been suggested[54] that the culprit behind the impaired mitochondrial function, maybe a reduced coenzyme Q10 content in the skeletal muscle (Figure 1). It must be mentioned that not all studies have found a negative effect of statin therapy in combination with exercise[55]. In the study by Meex *et al*[55] many different statins were used, which could influence the result, since it is known that statins differs in lipophilicity[56], and thereby the ability to cross cell membranes. Is has also been reported that statins impaires complex I respiration in the electron transport chain[57]. Another group reported that simvastatin increased ROS production in human skeletal myotubes in combination with an impaired mitochondrial respiratory capacity[58]. To make it even more complex, it has been demonstrated that statins have opposite effects on mitochondria from cardiac and skeletal muscle[59]. Furthermore, studies have reported that statins have an effect (impairment or improvement) on insulin sensitivity (for review see[60]).

Antihypertensive agents

Diuretics, beta-blockers, calcium antagonists, ACE-inhibitors and angiotensin receptor blockers (ARBs) are all suitable for the initiation and maintenance of antihypertensive treatment, either as monotherapy or in combination therapy.

There are different kinds of β-blockers known as selective or nonselective. The selective can either block β_1 (cardiac) or β_2 (skeletal muscle) receptors, the nonselective ones blocks both receptors. The adaptations to exercise training can be influenced by using either kind[61]. Ades *et al*[62] investigated 10 wk of endurance training (4 times a week) in hypertensive patients, taking either metoprolol (β_1 selective β-adrenergic blocker), propranolol (β_1 nonselective β-adrenergic blocker) or placebo. They reported an improvement in maximal oxygen uptake

and an increase in mitochondrial content (succinyl dehydrogenase activity) in the placebo and the metoprolol group, whereas no improvements after training was seen with propranolol[62]. Another group investigated 6 wk of endurance training in healthy young subjects[63]. The subjects were randomized to either a selective (atenolol) or nonselective (nadolol) β-adrenergic blocker or placebo. Subjects receiving placebo improved maximal oxygen uptake to a higher extent than the two groups receiving medication, but all groups improved maximal oxygen uptake from baseline. Furthermore mitochondrial content increased in all three groups after training, but again the placebo-group improved to a higher extent[63]. Similar results were reported by Svedenhag *et al*[64] in young healthy subjects after 8 wk of endurance training.

Drexler *et al*[65] investigated the short- and long-term effect of ACE inhibition on patients with congestive heart failure at rest and during exercise. They reported an improvement in oxygen extraction of the working muscle after ACE inhibition, and they speculate that this could be due to an increased mitochondrial content, but unfortunately muscle biopsies were not obtained to elucidate this[65]. In addition, studies have investigated the effect of ACE inhibitors on insulin sensitivity and found divergent results, with either no effect[66] or an improvement[67].

It has previously been reported that Angiotensin Ⅱ receptor blockers (ARBs) have a positive effect on reactive oxygen species production and mitochondrial function in animals (for review see[68]). It has been reported that ARBs have different effects on glucose homeostasis in hypertensive patients with the metabolic syndrome[69]. Patients treated with telmisartan showed an improvement in HOMA-IR and HbA1c (surrogate measures of insulin sensitivity[70]), whereas patients treated with losartan showed no improvement[69]. Whether these improvements can be explained by improvements in mitochondrial function is at the moment impossible to say.

These results highlight the importance of controlling the medication when mitochondrial function and insulin sensitivity are measured before and after a training intervention. Otherwise the results obtained will be hard to explain. Furthermore, the interaction between the different drugs is also unknown, and would off course also be a confounding factor when results are interpretated.

MUSCULAR ADAPTATION TO DIFFERENT TRAINING MODALITIES IN PATIENTS WITH TYPE 2 DIABETES

It is well known that exercise interventions improve maximal oxygen uptake, mitochondrial content and insulin sensitivity in healthy subjects[71-75].

Different training modalities have been investigated in patients with type 2 diabetes and control subjects, to see if the training adaptation is similar in patients compared with control participants. Unfortunately many of the studies investigating the effect of exercise in patients with type 2 diabetes are lacking a healthy matched control group, which makes it impossible to compare the response between patients and control participants. Furthermore, the medication used is often not described in detail. In this review we primarily report the studies that have measured maximal oxygen uptake, mitochondrial function and insulin sensitivity (clamp, OGTT, HbA1c or fasting glucose and insulin concentrations).

Endurance training

Hey-Mogensen *et al*[8] investigated if 10 wk of endurance training affected mitochondrial function, maximal oxygen uptake and insulin sensitivity. The patients with type 2 diabetes in this study were treated with either metformin or sulfonylurea, other kinds of medication were not mentioned in the manuscript. A similar improvement in VO_{2max} was seen in patients (12%) and control participants (16%). Insulin sensitivity was significantly increased after training in both control participants (22%) and patients (13%). Mitochondrial OXPHOS capacity and intrinsic mitochondrial function was measured in isolated mitochondria, with no differences between patients and control subjects, except for the increased capacity to oxidize long chain fatty acids after training in patients with type 2 diabetes which was not apparent in the control participants. This finding is in contrast to the hypothesis about reduced ability to oxidize lipids in patients with type 2 diabetes[76,77], and therefore it indicates that impaired insulin sensitivity is not caused by a reduced mitochondrial capacity for lipid oxidation. Furthermore, CS activity also increased similarly in the groups. Interestingly no differences were seen in PGC-1α (mRNA) after training in either patients or control participants. PGC-1α is a major regulator for mitochondrial biogenesis[78]. Mitochondrial ROS production was similar in the two groups and did not change significantly with training. An increased UCP3 protein content was seen, but only in the control participants[8]. It has previously been suggested that UCP3 is acting as a protective mechanism against ROS production[79]. No difference was seen in intrinsic mitochondrial respiratory function between patients and control participants in this study (both before and after training)[8], this finding is contradictory to another study (cross-sectional) from the same group, where a lower intrinsic mitochondrial function was seen in patients with type 2 diabetes[4]. Another study investigated the effect of a combination of endurance and strength training (12 wk)[17] and similar to the study by Hey-Mogensen *et al*[8] no information is available in the manuscript regarding other kinds of medication except for the glucose lowering agents (metformin or sulfonylurea). An increased VO_{2max} was seen after training in the patients with type 2 diabetes, where only a tendency was seen in the control participants. An increased mitochondrial content (mtDNA) was seen after training in both groups, accompanied by a similar intrinsic mitochondrial function before and after training in both groups[17], indicating that mitochondrial OXPHOS capacity was increased to a similar extent

in both groups (data not shown in the manuscript). It has recently been reported that mtDNA is not a good marker for mitochondrial content, at least not in healthy young subjects[80]. Phielix *et al*[5] has previously reported impaired intrinsic mitochondrial function in patients with type 2 diabetes, a finding that contradicts their own finding from 2010[17]. Meex *et al*[27] used the same training protocol as Phielix *et al*[17] with a combination of endurance and strength training for 12 wk. Again only glucose lowering medication is mentioned in the manuscript and thus not the pharmacological specification. Mitochondrial function was measured by magnetic resonance spectroscopy, and a difference was seen before training between the two groups with no difference present after training. Mitochondrial content was measured as complex I -V protein content (average of the complexes), both groups increased the average of the five complexes, but the increase tended to be more pronounced in the patients with type 2 diabetes. Maximal oxygen uptake increased significantly with training in both groups, whereas only patients with type 2 diabetes improved insulin sensitivity (clamp) after training[27]. Mogensen *et al*[81] conducted another study in which the effect of endurance training on skeletal muscle was studied. Again they showed a similar response in regard to maximal oxygen uptake, insulin sensitivity and mitochondrial content CS activity, where both groups improved in all parameters after training[81]. Nine months of aerobic training (150 min/wk at 50%-80% of VO_{2peak}) in patients with type 2 diabetes did surprisingly not improve either mitochondrial content, maximal oxygen uptake or insulin sensitivity, but an increased lipid oxidation was present after training[31]. The patient's medical records were not included in the manuscript, and no healthy control group was included. So the lack of improvement in mitochondrial content after 9 mo of aerobic training could be explained by the medication used (statins most likely). The study was an ancillary study to the HART-D study where the patients medical records are included, and a high percentage of the patients were in statin therapy[82]. Shaw *et al*[83] investigated 6 mo of endurance exercise (corresponding to approximately 77% of VO_{2peak}), they found an increased maximal oxygen uptake and mitochondrial content (COX activity), but no difference in insulin sensitivity. They did not report the medication used, but states that medication was stopped three days prior to the test days, indicating that the patients were on medication during the training period, and in addition an appropriate control group was not investigated. Another group investigated lean, obese and patients with type 2 diabetes before and after 10 d of 60 min exercise at 70% of VO_{2peak}[32]. No differences were seen in muscle oxidative capacity between groups before and after training, which is quite intriguing taking into consideration that the lean subjects had a higher maximal oxygen uptake (approximately 50%) compared with the two other groups. Insulin sensitivity was unfortunately not measured[32]. Mitochondrial volume (by TEM) was investigated after 10 wk of endurance training (approximately 70% of VO_{2max}) and a similar increase in mitochondrial volume was seen in patients with type 2 diabetes and control participants, accompanied by improvements in maximal oxygen uptake and insulin sensitivity (clamp)[84]. Table 1 gives an overview over the published literature in regard to endurance training.

High intensity training

The last five to ten years a renewed interest has been directed towards a different training method, where high intensity training is performed for shorter durations. It has been reported that high intensity training (HIT) leads to similar metabolic adaptations compared to regular endurance training when it comes to improvement in maximal oxygen uptake and increase in mitochondrial content in healthy human skeletal muscle[72,73]. This has not been investigated thoroughly in patients with type 2 diabetes.

Two weeks of HIT has been reported to increase mitochondrial content (CS activity) and improve 24 h blood glucose profile (measured 48-72 h after last training

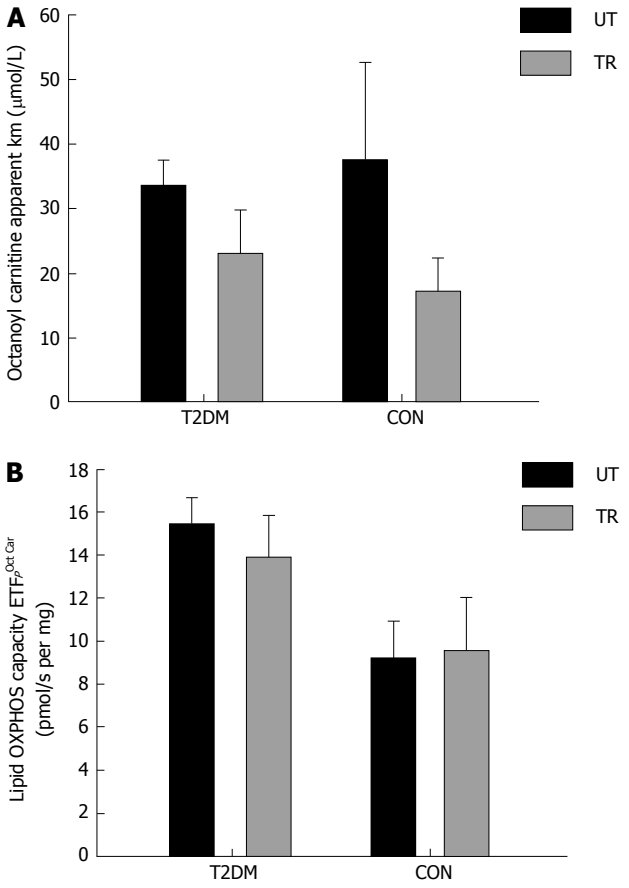

Figure 2 Patients with type 2 diabetes (*n* = 5) and healthy control subjects (*n* = 5) performed eight sessions of one-legged high intensity training in two weeks. Each session consisted of ten one-minute exercise bouts at 60% of one-legged maximal oxygen uptake and > 80% of maximal heart rate, interspersed by one min rest. After completion of the training muscle biopsies (vastus lateralis) were obtained from the untrained (black bars) and the trained (grey bars) leg. The measurement mitochondrial OXPHOS capacity and substrate sensitivity was performed with malate, ADP and octanoyl carnitine (titration: 5-2000 μmol/L). A: Apparent Michaelis Menten constant Km for octanoyl carnitine; B: Maximal OXPHOS capacity with the mentioned substrates. T2DM: Type 2 diabetes; CON: Control subjects; UT: Untrained; TR: Trained.

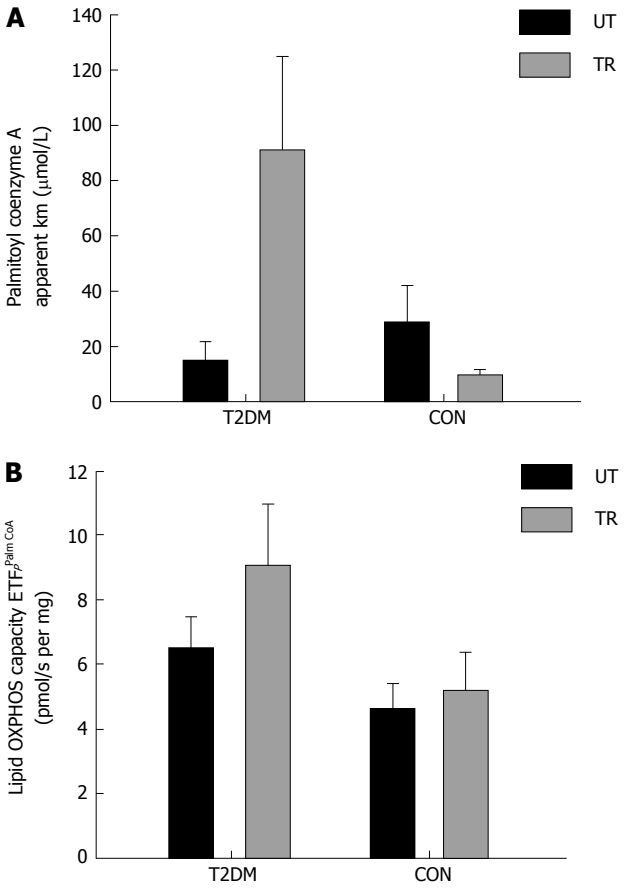

Figure 3 Patients with type 2 diabetes (*n* = 5) and healthy control subjects (*n* = 3) performed eight sessions of one-legged high intensity training in two weeks. Each session consisted of ten one-minute exercise bouts at 60% of one-legged maximal oxygen uptake and > 80% of maximal heart rate, interspersed by one min rest. After completion of the training muscle biopsies (vastus lateralis) were obtained from the untrained (black bars) and the trained (grey bars) leg. The measurement mitochondrial OXPHOS capacity and substrate sensitivity was performed with malate, ADP and palmitoyl coenzyme A (titration: 5-100 μmol/L). A: Apparent Michaelis Menten constant Km for palmitoyl coenzyme A; B: Maximal OXPHOS capacity with the mentioned substrates. T2DM: Type 2 diabetes; CON: Control subjects; UT: Untrained; TR: Trained.

bout)[85] in patients with type 2 diabetes. Unfortunately no control group was included by Little and colleagues[85], but in another study a similar improvement in CS activity was observed in overweight women using the same training protocol[86].

We have recently investigated mitochondrial substrate sensitivity in patients with type 2 diabetes and control participants after two weeks (eight training sessions) of one legged HIT [pilot study (type 2 diabetes; *n* = 5-7; control subjects; *n* = 3-5)]. Each training session consisted of ten one minute bouts of high intense one-legged bicycle exercise interspersed with one minute recovery. The training load corresponded to minimum 60% of the maximal workload obtained during a one-legged maximal oxygen uptake test. Due to the low number of subjects investigated we did not perform any statistical analysis on the dataset. We used high resolution respirometry and measured the mitochondrial ability to use either octanoyl carnitine (medium chain fatty acid), palmitoyl coenzyme A (long chain fatty acid, using carnitine palmitoyltransfer ase I (CPT I) to enter the mitochondrion) and palmitoyl carnitine (long chain fatty acid, using CPT Ⅱ to enter the mitochondrion). The results from the pilot study (respirometric measurements) are provided in Figures 2-4. The method we used has been described previously[12,16]. No differences were seen in mitochondrial substrate sensitivity for octanoyl carnitine between the groups and both groups increased their sensitivity for octanoyl carnitine in the trained leg (Figure 2A). It has been reported previously that no differences are present in mitochondrial subtrate sensitivity with octanoyl carnitine between patients with type 2 diabetes and obese participants[16]. No effect was seen after training in regard to maximal mitochondrial oxidative capacity with octanoyl carnitine as a substrate, but is seems as the patients with type 2 diabetes have a higher capacity to oxidize medium chain fatty acids (Figure 2B). Mitochondrial substrate sensitivity for palmitoyl coenzyme A (Figure 3A) and palmitoyl

Sparks *et al*[31]	T2DM	ST	9 mo (3 times/wk)	→ T2DM	↑ T2DM	→ T2DM

CON: Control participants; IS: Insulin sensitivity [or surrogate measures of insulin sensitivity (HbA1c, HOMA)]; VO_{2max}: Maximal oxygen uptake; Mito: Mitochondrial function (mitochondrial respiratory capacity, mitochondrial content); ND: Not determined; ST: Strength training; T2DM: Patients with type 2 diabetes.

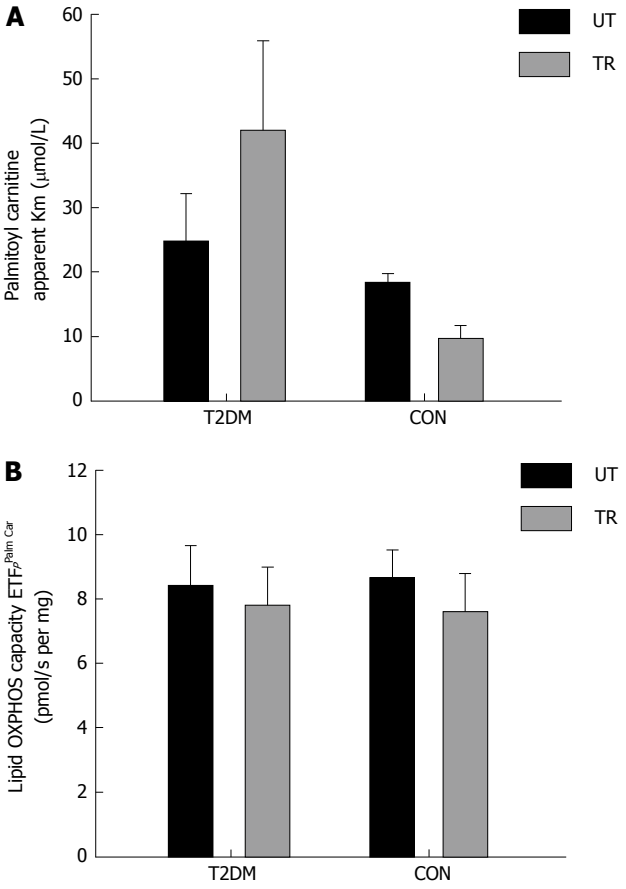

Figure 4 Patients with type 2 diabetes (n = 7) and healthy control subjects (n = 5) performed eight sessions of one-legged high intensity training in two weeks. Each session consisted of ten one-minute exercise bouts at 60% of one-legged maximal oxygen uptake and > 80% of maximal heart rate, interspersed by one min rest. After completion of the training muscle biopsies (vastus lateralis) were obtained from the untrained (black bars) and the trained (grey bars) leg. The measurement of mitochondrial OXPHOS capacity and substrate sensitivity was performed with malate, ADP and palmitoyl carnitine (titration: 5-200 μmol/L). A: Apparent Michaelis Menten constant Km for palmitoyl carnitine; B: Maximal OXPHOS capacity with the mentioned substrates. T2DM: Type 2 diabetes; CON: Control subjects; UT: Untrained; TR: Trained.

carnitine (Figure 4A) showed the same tendency where patients with type 2 diabetes had a decreased (apparent Km increased) sensitivity for long chain fatty acid (palmitoyl coenzyme A and carnitine) and control participants an increased (apparent K_m decreased) sensitivity after training. No major differences were seen in maximal mitochondrial oxidative capacity with palmitoyl coenzyme A (Figure 3B) or palmitoyl carnitine (Figure 4B) between the groups and after the training intervention. From these pilot data, it seems as if no differences are present between patients and control participants in regard to maximal mitochondrial oxidative capacity with fatty acids as substrate either at baseline or after the training intervention. The improved sensitivity for CPT I and CPT II in the control participants, could be explained by an increased activity of CPT I (and maybe CPT II) which have been reported previously[87]. Why patients with type 2 diabetes show an opposite adaptation is difficult to explain, but it has been reported that CPT I activity is reduced in skeletal muscle from obese compared to lean participants[88]. To our knowledge the effect of training on CPT I and II activity has never been investigated in patients with type 2 diabetes, and it is thus impossible to say whether this can explain our results. Little *et al*[85] gives an overview over the published literature in regard to high intensity training.

Strength training

Is has been suggested previously that strength training represents an attractive training modality, due to the fact that many patients with type 2 diabetes are obese and have difficulties performing endurance exercise.

Few studies have been performed where adaptations in skeletal muscle have been investigated. Holten *et al*[30] investigated 6 wk (3 times per week) of leg strength training (one leg, other leg served as control) and found improvement in the trained leg in both groups regarding insulin sensitivity (clamp technique). Maximal oxygen uptake was not measured, but mitochondrial content (by CS activity) showed no difference between the legs in the patients but an increase was observed in the control participants. Nine months of resistance training increased mitochondrial content in patients with type 2 diabetes, but no difference was seen in maximal oxygen uptake and HbA1c[31]. This study contradicts the findings by Holten *et al*[30], and this may be due to a difference in duration and application of different methods to evaluate insulin sensitivity. Table 2 gives an overview over the published literature in regard to strength training.

CONCLUSION

From the literature currently available it is difficult to recommend a training intervention to patients with type 2 diabetes where success is well documented when it comes to improvement in mitochondrial function. The problem with many of the studies available is that medicine usage

is not reported, and therefore potential significant medication effects on the outcome can not be excluded, when adaptations to physical activity are investigated. Furthermore, many of the studies lack a real control group, making it impossible to determine if adaptations are the same in patients and control participants.

The literature is at current lacking well conducted controlled longitudinal studies investigating the effect of exercise on mitochondrial function, where medication is controlled and an appropriate control group is included. These studies are difficult to conduct given the ethical problem in how you control the medication without compromising and disrupting the health of the patients. One approach could be to recruite newly diagnosed patients, where medication is not started yet. A study like this needs to be conducted in the future where mitochondrial function is investigated.

Abstract

Diabetes mellitus is a combined metabolic disorder which includes hyperglycemia, dyslipidemia, stroke and several other complications. Various groups all over the world are relentlessly working out the possible role of a vast number of genes associated with type 2 diabetes (T2DM). Inflammation is an important outcome of any kind of imbalance in the body and is therefore an indicator of several diseases, including T2DM. Various ethnic populations around the world show different levels of variations in single nucleotide polymorphisms (SNPs). The present review was undertaken to explore the association of cytokine gene polymorphisms with T2DM in populations of different ethnicities. This will lead to the understanding of the role of cytokine genes in T2DM risk and development. Association studies of genotypes of SNPs present in cytokine genes will help to identify risk haplotype(s) for disease susceptibility by developing prognostic markers and alter treatment strategies for T2DM and related complications. This will enable individuals at risk to take prior precautionary measures and avoid or delay the onset of the disease. Future challenges will be to understand the genotypic interactions between SNPs in one cytokine gene or several genes at different loci and study their association with T2DM.

Key words: Type 2 diabetes; Cytokines; Single nucleotide polymorphisms; Disease susceptibility; Association studies

Core tip: Diabetes is the third most widespread disease after heart disease and cancer. Cytokines are mediators of inflammation, namely interleukins (IL)-1β, -1Ra, -18, -4, -6, -10, tumor necrosis factor-α and adiponectin, which cause immune responses in disease pathogenesis, including type 2 diabetes. In the present study, the association of cytokine gene polymorphisms in different ethnic populations is reviewed. Such single nucleotide polymorphism analyses and association studies in different populations will benefit individuals belonging to a particular group.

INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a group of metabolic disorders characterized by high blood sugar levels, which results from defects in insulin secretion or action or both, leading to complications[1]. Diabetes mellitus has now

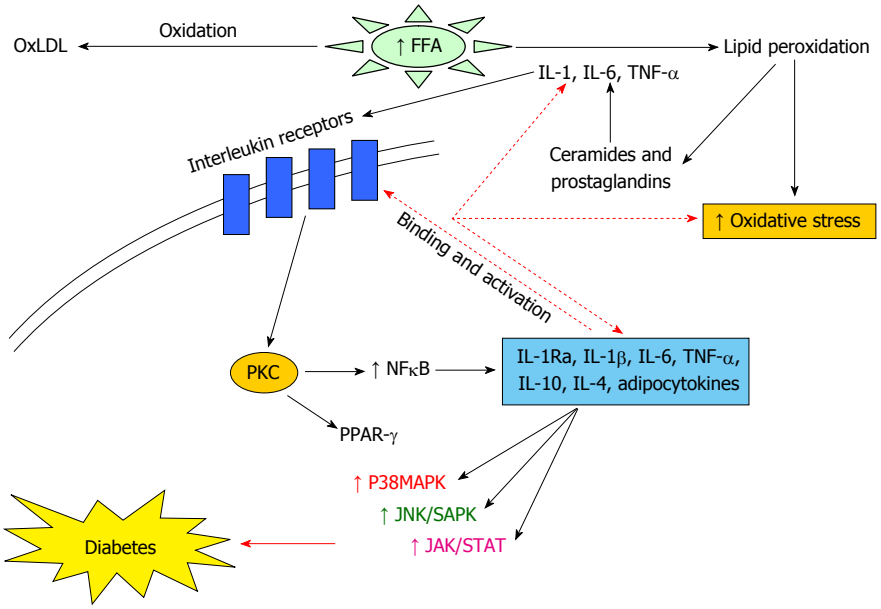

Figure 1 A schematic diagram showing the involvement of various cytokines in diabetes[3]. IL: Interleukin; TNF: Tumor necrosis factor.

been associated with the development of a long term organ disease. T2DM has changed from a mild disorder of old age to a serious cause of morbidity and mortality in young and middle-aged people. The Diabetes Atlas estimates have shown that 371 million people suffer from diabetes worldwide, with India alone having 63.0 million affected individuals and the number is expected to rise to 101.0 million by 2030[2-4]. This alarming figure has instigated several workers worldwide to undertake genetic studies and contribute to the understanding and early detection of the disease.

A predisposition to T2DM or "Adult Onset Diabetes" is probably inherited as an autosomal recessive trait[5]. T2DM is treated initially by diet control, either alone or in combination with orally administered anti-diabetic drugs. It is described as a syndrome on the basis of clustering of many abnormalities, like resistance to insulin-stimulated glucose uptake, hyperinsulinemia, hyperglycemia, increased very low density lipoprotein (VLDL), increased triglycerides, decreased high density lipoproteins (HDL) cholesterol, high blood pressure, micro albuminuria, hyperuricemia, fibrinolytic and coagulation abnormalities, *etc*[3].

Evidence has shown that T2DM is associated with chronic inflammation that can be attributed to dysregulation of the innate immune system and this is a potential link between metabolic syndrome, diabetes and atherosclerosis[6]. A large and diverse family of small, low molecular weight cell signaling proteins mediating complex interaction are called "cytokines", which include interleukins and interferons[7] secreted by white blood cells and various other cells in response to a number of stimuli. The cytokines and their receptors exhibit a very high affinity for each other. Another subgroup of low molecular weight cytokines called chemokines affect leukocyte behavior. Cytokines are of two types, namely pro-inflammatory [*e.g.*, interleukins (IL)-1, -6, tumor necrosis factor (TNF)-α, transforming growth factor (TGF)-β] and anti-inflammatory (*e.g.*, IL-1Ra, -4, -10, -13), which function opposite to each other. The release of adipocytokines by adipocytes, such as leptin, resistin, adiponectin and visfatin, as well as some of the classical inflammatory cytokines like TNF-α, IL-6, MCP-1 (CCL-2) *etc*., help to achieve this. Studies have shown that it is the fat tissue that exerts the endocrine and immune functions. Macrophages and T cells are found in abundance in adipose tissue which develops into an organized immune organ[8]. Inflammation resulting from an imbalance between pro- and anti-inflammatory cytokines leads to T2DM and its complications (Figure 1).

Mediators of inflammation, such as IL-1β, -1Ra, -18, -4, -6, -10, TNF-α and adiponectin (ADIPOQ), have been proposed to be involved in causing T2DM. Elevated blood levels of certain acute phase markers such as IL-6 can characterize the immune response[9], while IL-1 regulates the basic metabolic rate, blood glucose levels, blood pressure, iron metabolism and bone remodeling. Adiponectin levels and its gene variants have also been confirmed to be associated with increased risk of T2DM[10]. To date, more than 1240 gene loci are associated with diabetes in humans[3]. The susceptibility to complex forms of T2DM is associated with frequent polymorphisms that influence the expression of genes belonging to the same or different causal pathways[7]. It is important to understand the nature and actions of these adipocytokines in order to find their association with diseases like T2DM, atherosclerosis, other metabolic and vascular diseases (Figure 2). Studies have reported that Asian Indians are a unique population for carrying out genetic studies due to their greater susceptibility to T2DM and increased insulin resistance[11,12]. This review is an attempt to put together certain important cytokine gene polymorphisms and their association with T2DM in

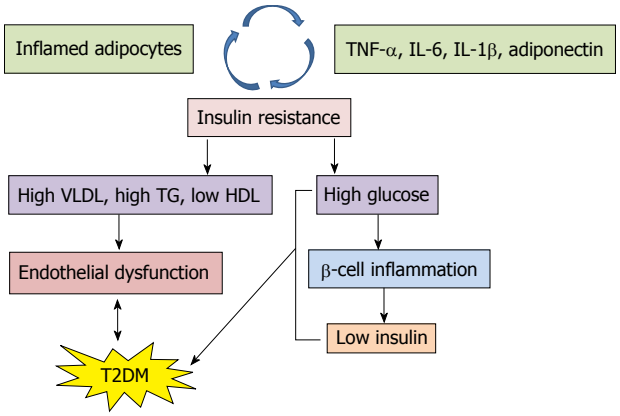

Figure 2 A schematic diagram showing the metabolic defects and biochemical effects of cytokines leading to type 2 diabetes. T2DM: Type 2 diabetes; IL: Interleukin; TNF: Tumor necrosis factor.

different populations around the world.

CYTOKINE GENE POLYMORPHISMS AND T2DM

Certain chemokines/cytokines, like IL-1β, -1Ra, -18, -4, -6, -10, TNF-α, *etc.*, and some members of the adipocytokine family, namely adiponectin, leptin and resistin, are important mediators in inflammation/disease and glucose metabolism and may be involved in the pathogenesis of T2DM. They can be used as biological markers for diabetes and are related to obesity and hypertension. The single nucleotide polymorphisms (SNPs) present in the regulatory regions of cytokine genes often have an impact on their expression levels and can be disease modifiers. The degree of inflammation is controlled, thereby leading to the progression of various immunological diseases, including T2DM[13-20]. The polymorphisms in cytokine genes lead to interindividual differences in their production, leading to variations in immune responses[21].

IL-1α, -1β and -Ra

The IL-1 family consists of two pro- and one anti-inflammatory cytokines, namely 1α, 1β and the IL-1 receptor antagonist (IL-1Ra), respectively. While IL-1α and -1β enhance inflammation and host defense, IL-Ra counteracts their function. A variety of cell types like monocytes/macrophages and keratinocytes are known to produce these cytokines. All three secreted glycoproteins bind to IL-1 receptors[22].

The *IL-1* genes (*IL-1α*, *-β* and -Ra) are located on chromosome 2q12-21. All *IL-1* genes are polymorphic and several are associated with inflammation and disease conditions[7,23]. "Autocrine apoptosis" results from prolonged exposure of human islets to high glucose which triggers IL-1β production, leading to activation of nuclear factors and upregulation of Fas signaling[24]. IL-1β and IL-1Ra play important roles in tissue remodeling, are potent mediators of chronic inflammation[25] and are therefore implicated in the pathogenesis of T2DM and associated complications[7]. The *IL-1* gene variants studied in various groups are shown in Table 1.

IL-18

IL-18, a unique IL-1 family cytokine is expressed in macrophages, keratinocytes, osteoblasts, synovial fibroblasts, dendritic, Kupffer, adrenal cortex, intestinal epithelial and microglial cells[43-50]. IL-18 shares structural homology with IL-1β. It is produced as a 24-kDa inactive precursor, Pro-IL-18, which is cleaved by IL-1β-converting enzyme (ICE; caspase-1) to a mature 18-kDa molecule[51]. The extracellular binding of IL-18 is mediated by IL-18R, a heterodimer complex containing α chain (IL-1Rrp) and β chain (AcPL)[52-54].

Insulin-producing islet β-cells secrete IL-18 and induce IFNγ in T cells[55]. IL-18 is highly expressed in atherosclerotic plaques with a role in plaque destabilization[56]. Elevated levels of plasma IL-18 were reported in T2DM patients and children[57-59]. However, obesity and insulin resistance showed no correlation with IL-18

plasma level[60]. The *IL-18* gene in humans is located on chromosome 11q22.2-22.3, where a diabetes susceptibility locus, Idd2, resides[61]. Studies reporting *IL-18* gene polymorphisms are shown in Table 1.

IL-4

One of the hematopoietic cytokines, IL-4 regulates key events during Th2-dominated immune response and also stimulates T cells, leading to the production of other cytokines. It causes β-cell isotype switching from IgM to IgE and stimulates IgE production in allergic sensitization. IgE stimulation during allergic reactions and infections is the natural defense mechanism. It also plays a crucial role in the pathophysiology of T2DM[62]. The heterodimerization of high-affinity transmembrane receptor α-chain (IL-4Rα) is mediated by IL-4 in a sequential cascade. Several candidate genes have been identified, including the gene for *IL-4Ra* which is situated on chromosome 16p and is known to contain a number of polymorphisms. IL-1Ra and IL-4 are major anti-inflammatory cytokines[63] and have been proposed to be involved in events causing T2DM. The IL-4Ra subunit forms part of the signalling complex for IL-4. In humans, the gene for *IL-4* maps to chromosome 5q31. The polymorphisms in *IL-4* gene and their relationship with T2DM have been studied by various groups (Table 2).

IL-6

IL-6 is secreted by immune cells, adipose tissue and muscles and is able to accelerate or inhibit the inflammatory processes[66,67]. The direct affect of IL-6 may be on glucose homeostasis and metabolism or it might act indirectly by action on adipocytes, pancreatic β-cells, *etc*[68]. In humans, the gene for *IL-6* maps to chromosome 7p15-p21. *IL-6* mRNA expression and insulin resistance were found to have a significant correlation[69] and increased plasma IL-6 levels with higher risk of T2DM[6,70,71], making it an appealing candidate gene. One of the common polymorphisms in the *IL-6* gene promoter (C-174G) was found to regulate transcription in response to inflammatory stimuli, such as lipopolysaccharides or IL-1[72-74]. IL-6 promoter SNPs were considered as risk factors for T2DM development, as reported by other groups[75,76] (Table 3).

IL-10

IL-10 is also a Th2 mediated cytokine that downregulates inflammatory responses of pro-inflammatory cytokines[102]. The serum concentrations of TC, LDL, TGL, glucose and HbA1c gradually decreases and HDL increases with an increase in IL-10 production. These observations implied that low IL-10 production was associated with hyperglycemia and T2DM[68,103]. IL-10 promotes the proliferation and differentiation of B-lymphocytes by stimulating antibody production[104]. The *IL-10* gene is located on chromosome 1q31-q32 and several variants have been identified in its promoter region[105-106]. The presence of IL-10 is protective against T2DM and

inflammation due to its humoral immunity responses and prevention of pancreatic beta cell destruction[4,107]. The association of *IL-10* gene polymorphisms is shown in Table 4.

TNF-α

TNF-α is released by monocytes/macrophages and has an initial role in β-cell damage of the islets. It is reported that TNF-α is a possible mediator of insulin resistance and diabetes since it decreases the tyrosine kinase activity[116]. Furthermore, TNF-α inhibits insulin signaling[117] and impairs its secretion[118]. TNF-α interacts with IL-6, regulating its expression and downregulating itself[73]. In humans, the gene for *TNF-α* maps to chromosome 6p21. 3. One of the SNPs in *TNF-α* gene showed a two-fold increase in transcriptional activity[119,120]. Various groups showed an association of *TNF-α* SNPs with T2DM (Table 5).

Adiponectin

An endocrine effect leading to the clinical expression of T2DM and cardiovascular disease was attributed to the cytokines secreted by adipocytes[135,136]. Since the role of classical cytokines and adipocytokines in metabolic syndrome and associated disease conditions came to light, several workers have shown the role of activated innate immunity in the pathogenesis of T2DM[70,137]. Adiponectin levels in the plasma remain constant throughout the day and are not affected by food intake, unlike insulin and leptin.

Adipocytes secrete a plethora of cytokines, including adiponectin, resistin, leptin, IL-6, TNF-α, visfatin, RBP4, as well as free fatty acids, which alter insulin action and hepatic glucose production[138-140]. Adiponectin is a serum protein produced and secreted exclusively by adipose tissues, also known as adipocytes complement-related protein of 30 KDa (147 amino acids) (Acrp30). It is involved in the homeostatic control of circulating glucose and lipid levels[141]. Reduced adiponectin levels are documented in obese, insulin resistant and T2DM patients[116]. Adiponectin regulates glucose/lipid homeostasis *via* phosphorylation and activation of adenosine monophosphate activated protein kinase[142,143]. Another important function of adiponectin is to prevent the atherosclerotic vascular damage by suppressing interaction of monocytes/endothelial cells and adhesion molecules[144,145]. Therefore, high adiponectin levels are associated with reduced risk of T2DM[70]. In humans, the gene for *ADIPOQ* maps to chromosome 3q27. The SNPs in ADIPOQ studied by other researchers are shown in Table 6.

CONCLUSION

The greater tendency to diabetes in Indians may result from some genetic factors in addition to environmental and dietary factors. It is reported that the severity of diabetes (T2DM) in patients, from chronic to newly diagnosed, is related to certain biochemical and pathological examinations. The risk factors include lipid metabolism abnormalities (VLDL, HDL, LDL, TGA *etc.*) and re-

lationship to body mass index, WHR, food habits and family history. Different correlation with lipid profile and response to anti-diabetic drugs are additional indications of a genetic predisposition. SNPs in specific genes which show considerable levels of variation amongst ethnic groups around the world have been implicated in the pathogenesis of diabetes. Therefore, identification of polymorphic variants of cytokine genes in different populations and the genotypic associations between SNPs and gene-gene interactions will have clinical importance as indicators of T2DM susceptibility. Association studies of cytokine genes will help in the development of prognostic markers to identify individuals at risk. The prognostic regimens arising from such genetic studies will alter and ease out treatment strategies for T2DM and related complications. Individuals at risk will be able to take prior precautionary measures and avoid or delay the onset of the disease.

Abstract

Ever since its first appearance among the multiple forms of diabetes, latent autoimmune diabetes in adults (LADA), has been the focus of endless discussions concerning mainly its existence as a special type of diabetes. In this mini-review, through browsing important peer-reviewed publications, (original articles and reviews), we will attempt to refresh our knowledge regarding LADA hoping to enhance our understanding of this controversial diabetes entity. A unique combination of immunological, clinical and metabolic characteristics has been identified in this group of patients, namely persistent islet cell antibodies, high frequency of thyroid and gastric autoimmunity, DR3 and DR4 human leukocyte antigen haplotypes, progressive loss of beta cells, adult disease onset, normal weight, defective glycaemic control, and without tendency to ketoacidosis. Although anthropomorphic measurements are useful as a first line screening, the detection of C-peptide levels and the presence of glutamic acid decarboxylase (GAD) autoantibodies is undoubtedly the sine qua non condition for a confirmatory LADA diagnosis. In point of fact, GAD autoantibodies are far from being solely a biomarker and the specific role of these autoantibodies in disease pathogenesis is still to be thoroughly studied. Nevertheless, the lack of diagnostic criteria and guidelines still puzzle the physicians, who struggle between early diagnosis and correct timing for insulin treatment.

Key words: Latent autoimmune diabetes in adults; Type 1 diabetes mellitus; Type 2 diabetes mellitus; Autoantibodies; Glutamic acid decarboxylase 65

Core tip: A unique combination of, immunological, clinical and metabolic characteristics has been identified in latent autoimmune diabetes in adults (LADA) patients. Even so, the current definition of LADA fails to capture in one snapshot insulin resistance and autoimmunity, this very special pathognomonic characteristic of LADA. Addressing this dual facet of LADA would undoubtedly provide insight into disease pathogenesis and help in the immediate identification and prompt insulin therapy.

INTRODUCTION

As early as in the end-1970s, Irvine identified a group of patients with diabetes who although treated with oral hypoglycaemic agents, they possessed islet cell antibodies

(ICA)[1]. Not only had these ICA-positive patients higher prevalence of other organ specific autoantibodies, they showed a significant tendency to progress faster towards insulin deficiency as well. Interestingly, in these patients persistence of ICA for more than five years from diabetes diagnosis was associated with coexistent of organ specific autoimmune disease and with human leukocyte antigen (HLA)-B8, A1 1. The autoimmune signature in these patients lead to be classified as type 1 diabetes (T1D)[2,3].

Subsequently, a unique combination of immunological, clinical and metabolic characteristics has been identified for this group of patients, namely persistent ICA, high frequency of thyroid and gastric autoimmunity, HLA-DR3 and DR4, progressive loss of beta cells, adult disease onset, normal weight, defective glycaemic control, lower initial levels of C-peptide and impaired response after glucagon stimulation compared to T2D patients, and without tendency to ketoacidosis[4-8]. But, the idea of latent autoimmune diabetes mellitus in adults has been only recently introduced[9]. More specifically, in 1994 Paul Zimmet *et al*[10] and Tuomi *et al*[11] introduce the term latent autoimmune diabetes in adults (LADA) for LADA and 5 years later the 3 criteria that define LADA are suggested, which are (1) GABA-synthesizing enzyme, glutamic acid decarboxylase (GAD) antibody positivity (> 5 RU); (2) age of diabetes onset > 35 years; and (3) insulin independence at diagnosis (at least 6 mo). However, the current definition of LADA fails to capture in one snapshot insulin resistance and autoimmunity, this very special pathognomonic characteristic of LADA[12].

On the other hand, the World Health Organisation diabetes classification does not differentiate LADA as a distinct entity[13]. In fact, the concept of LADA is strongly debated since many researchers question whether LADA is a definite form of diabetes and propose instead that LADA represents slowly evolving T1D which should be regarded as a continuum[14-16]. Even so, LADA can nicely describe patients with features of both T1D and T2D and provide with a better understanding on the grey zone between these two types[17-19]. Addressing this dual facet of their disease would undoubtedly facilitate treatment option and therefore benefit LADA patients.

IMMUNOLOGICAL CHARACTERISTICS

Bottazzo was the first to describe the presence of ICAs in T1D patients having also an endocrine disorder of autoimmune etiology. These antibodies were detected by indirect immunofluorescence on pancreatic cryosections and they were named as such because they targeted unknown elements of islet cells[20].

Nowadays, commercial available kits using pancreas of primate origin are used at routine basis for the determination of ICAs. To facilitate communication among different laboratories and give the possibility of comparable ICA assays, the results should be given in Juvenile Diabetes Foundation units. On the other hand, one should bear in mind that the limitations of ICA assay are the demanding standardization and challenging interpretation of the results. Despite those restrictions, in the 4th International ICA Workshop it was reported that ICA diagnostic test has exceptional specificity and acceptable concordance among the different laboratories[21].

There is a bunch of studies addressing the ICAs relevance to T1D. It is now clear that more than 70% newly diagnosed T1D patients are ICA-seropositive[22]. With a specificity of about 97%, their presence has been reported in less than 4% of healthy subjects[23]. It should be mentioned that in contrast to general population where ICAs higher than 20 JFD is not of clinical relevance, in the first degree T1D relatives this finding is highly prognostic of T1D[24,25]. Finally, it is important for clinicians to closely follow up ICA-positive patients who are receiving oral hypoglycaemic agents, since their presence in this population is strongly predictive of switching to insulin dependency[26].

Anti-insulin autoantibodies (IAAs) were the first specific ICAs to be identified and this was done in 1983 by Palmer *et al*[27] who performed seminal studies in this area using serum from patients who have not been challenged by exogenous insulin at the time of sample collection. Subsequent research have addressed the insulin levels after glucose challenge and it was concluded that insulinopenia was more prevalent in subjects possessing both, ICAs and IAAs, compared to those being positive just for ICAs[28]. However, this marker has a relatively low sensitivity, being even less than 40%[29].

At the 4th International Workshop regarding standardization of IAAs assays it was suggested that RIA should be the method of choice for IAAs determination[30]. However, in the routine laboratory practice their presence can be also assessed by the enzyme-linked immunosorbent assay (ELISA). A reasonable concern would be how the available assays can distinguish between endogenous and exogenous insulin, but this is feasible through distinct idiotypes[31].

Notably, IAAs prevalence is actively influenced by both, sex and age. In detail, in young patients there is an equal incidence of IAAs in both sexes which is skewed at 2 males: 1 female in ages greater than 15 years old[32]. Additionally, these antibodies are inversely correlated with age and since their prevalence sharply drops with age, it is not surprising that they are of low diagnostic value for LADA[33].

The second ICAs specific target to be identified was the GABA-synthesizing enzyme, GAD, a molecule with a size of 64.000 M(r)[34]. Two forms of GAD exist in humans, each transcribed by different gene, termed according to their molecular mass GAD65 and GAD67, and the former being the antigenic target for T1D[35]. Noteworthy, anti-GAD65 autoantibodies are the most typical and prevailing antibodies connected with ICA reactivity[23]. An interesting proposed aspect on anti-GAD65 autoantibodies is that they are present in healthy individuals but they cannot be detected by conventional methods since they are masked by anti-idiotypic antibodies[36].

Anti-GAD65 autoantibodies are detected by commercial available RIAs as well as ELISAs and interestingly enough recent ELISAs offer comparable specificity with RIAs and even better sensitivity[37]. These autoantibodies are positively correlated with age and in the female population are found in greater levels. Serum conversion for these antibodies, from negative to positive, peaks after T1D diagnosis and usually they can be detected even when ICAs becoming gradually undetectable[23]. Since GAD65 is an intracellular antigen, we speculate that during disease progression islet cells could release GAD65, explaining partially the fact that they can be detected after disease onset. For the aforementioned reasons, anti-GAD65 autoantibodies have major role in the management of diabetes in adults. In fact, their positive predictive value in mid-aged population has been reported to be 50%[38].

As regard GAD65 autoantibodies in LADA, the Non-Insulin Requiring Autoimmune Diabetes (NIRAD) nationwide survey has shown that anti-GAD65 titres are useful to categorise patients with adult-onset autoimmune diabetes in two different distinct groups with characteristic clinical picture, autoimmune features, and genetic signature. In detail, patients with higher anti-GAD65 titres can be described by a more profound autoimmunity, quite marked dependency on insulin, higher levels of serum A1C, and lower both body mass index (BMI) and metabolic syndrome prevalence and, regarding genetic traits, decreased frequency of HLA-DRB1*0403 and HLA-DQB1*0602 and an increased for HLA-DRB1*03 and HLA-DQB1*0201 characterises the patients with higher anti-GAD65 titres[39]. Furthermore, studies from the same nationwide survey revealed that in LADA, the variant PTPN22 1858T is strongly associated with high titres of anti-GAD65 autoantibodies while the low levels are correlated to the T2D genetic variant of susceptibility, TCF7L2[40,41]. It has also been suggested that the presence of high anti-GAD65 titres and/or anti-GAD65 autoantibodies directed against the C-terminal and not the middle epitopes of the protein can group a LADA subphenotype with many similarities with classic T1D and a high probability to develop insulin deficiency[42].

On the other hand, other groups do not rely entirely on high anti-GAD65 titres, in order to predict the progression of LADA. Instead, strong predictors are considered the co-existence of positive autoantibodies and both HLA-DRB1 and HLA-DQB1, while, traits including female gender and low BMI and are highly likely to predict insulin requirement within 4 years post-diagnosis[43].

In mid-1990s, two independent groups will add an additional T1D specific autoantigen to the ICAs reactivity panel, the insulinoma antigen 2 (IA-2), a transmembrane molecule belonging to the family of protein tyrosine phosphatases[44-46]. IA-2 is a ubiquitous molecule expressed by neuroendocrine cells, including islet cells of the pancreas, and is localised in the membranes of secretory granules[47].

Within the framework of T1D diagnostic approach, antibodies against IA-2 can be detected by RIA or ELISA commercial kits, with both methods giving comparable results[37]. As a T1D-specific biomarker, anti-IA-2 autoantibodies have a sensitivity of about 60%, meaning that they are less sensitive compared to anti-GAD65 autoantibodies, but when compared to IAA they have higher sensitivity[29]. In contrast to IAA and ICA, anti-IA-2 AAbs show no variation with age and thus, when anti-GAD65 autoantibodies are also evaluated, an autoimmune signature of the diabetes can be defined[23].

Recently, antibodies against the IA-2 (256-760) fragment were shown to be a reliable marker in LADA patients and they were positively correlated with higher frequency of autoimmunity and susceptible HLA haplotypes[48].

Patients with autoimmune diabetes are likely to be presented with an additional autoimmune condition of endocrine (thyroid and adrenal glands) or non-endocrine organs (thyroid and adrenal glands)[23]. Regarding endocrine organ-specific autoimmune conditions, anti-TPO (thyroid peroxidase)/anti-thyroglobulin (anti-Tg) antibodies, marker for autoimmune thyroid disease can be detected in about one fifth of patients with T1D, while anti-adrenal autoantibodies, marker for Addison's disease are rather less common in T1D, being found in less than 2%[49,50]. Regarding non-endocrine organs, autoimmune gastritis, characterised by the presence of anti-parietal-cell antibodies can be found in about one tenth of patients with autoimmune diabetes, while celiac disease, characterised by an immunological signature of anti-endomysial, anti-Tg and anti-gliadin antibodies, with a prevalence of 11% is consider to be common in T1D[50,51].

Regarding organ specific autoantibodies in LADA, the recent NIRAD study 6 suggests a higher frequency of organ-specific antibodies in subjects with high anti-GAD65 titres[52]. They additionally recommend considering that the risk for the presence of other specific antibodies in LADA depends on both, GAD65 titre and gender, and thus, knowledge of the specific odd ratio can be helpful during screening[52].

CLINICAL AND METABOLIC CHARACTERISTICS

First and foremost, the mean age at onset is a highly important hand tool for the clinician, who has to decide upon the different type of diabetes and consequently on the appropriate treatment for the patient as quickly as possible. According to study groups, the age of older than 25 years at onset is a supportive finding towards LADA[19,53]. Furthermore, in comparison to T2D, stimulated as well fasting C-peptide is lower in LADA[5]. Additionally, the level of insulin secretion in LADA is believed to be intermediate between T1D and T2D 5. Importantly, a fast decline in both insulin secretion and stimulated C-peptide secretion occurs rather fast, namely within a few years after LADA diagnosis[54]. In patients over 35 years old at diagnosis and duration of diabetes less than 5 years, the presence of diabetes-specific antibodies is related to lower fasting C-peptide, less often neuropathy

and blood pressure closer to the normal values (56). On the other hand, only patients with more than 1 antibody have reduced residual beta-cell function, and only these patients tend to be leaner[55].

A review by Fourlanos *et al*[54] concludes that patients with LADA are indeed insulin resistant based on homeostasis model assessment, while 50% of insulin secretory failure occurs within the first 4 years. Furthermore, although controversial, in agreement with our observation, LADA patients are presented with lower BMI, blood pressure and triglyceride levels compared to T2D[56].

Regarding treatment policy in LADA patients, time to insulin treatment is based on clinical judgement, with GAD autoantibodies being of upmost importance[57]. Interestingly, Stenström *et al*[58] have suggested that insulin treatment in LADA patients should start as soon as possible. Factually, guidelines on LADA treatment do not exist and is controversial whether sulphonylurea, insulin, vitamin D or alternative therapies such as GAD65, can influence the beta-cell loss progression and metabolic control[59]. Since LADA patients are presented not only with gradually developing insulin deficiency, but also with insulin resistance, a unique treatment strategy should be designed, in order to treat hyperglycaemia and to preserve b-cell function[60].

CONCLUSION

There is adequate evidence that LADA constitutes a special form of diabetes, with a unique immunological, metabolic and clinical signature, while its pathognomonic characteristic can be described as latent autoimmunity, combined with glucose resistance. The lack of a consensus amid diabetes experts hampers the uniformity of the studies and perplexes results interpretation. The need of a clear definition, fulfilling the metabolic and immunologic characteristic of the disease, is unambiguously required. Even better, diagnostic criteria and guidelines would facilitate disease management and pave the way for LADA understanding.

Abstract

The Src homology 2B (SH2B) family members (SH2B1, SH2B2 and SH2B3) are adaptor signaling proteins containing characteristic SH2 and PH domains. SH2B1 (also called SH2-B and PSM) and SH2B2 (also called APS) are able to form homo- or hetero-dimers *via* their N-terminal dimerization domains. Their C-terminal SH2 domains bind to tyrosyl phosphorylated proteins, including Janus kinase 2 (JAK2), TrkA, insulin receptors, insulin-like growth factor-1 receptors, insulin receptor substrate-1 (IRS1), and IRS2. SH2B1 enhances leptin signaling by both stimulating JAK2 activity and assembling a JAK2/IRS1/2 signaling complex. SH2B1 promotes insulin signaling by both enhancing insulin receptor catalytic activity and protecting against dephosphorylation of IRS proteins. Accordingly, genetic deletion of SH2B1 results in severe leptin resistance, insulin resistance, hyperphagia, obesity, and type 2 diabetes in mice. Neuron-specific overexpression of SH2B1β transgenes protects against diet-induced obesity and insulin resistance. SH2B1 in pancreatic β cells promotes β cell expansion and insulin secretion to counteract insulin resistance in obesity. Moreover, numerous SH2B1 mutations are genetically linked to leptin resistance, insulin resistance, obesity, and type 2 diabetes in humans. Unlike SH2B1, SH2B2 and SH2B3 are not required for the maintenance of normal energy and glucose homeostasis. The metabolic function of the SH2B family is conserved from insects to humans.

Key words: Obesity; Type 2 diabetes; Leptin resistance; Insulin resistance; Glucose intolerance; Hypothalamus; Energy balance; Food intake; Hyperphagia; Nonalcoholic fatty liver disease

Core tip: The Src homology 2B (SH2B) family members mediate cell signaling in response to a variety of hormones, cytokines, and growth factors. In the brain, SH2B1 enhances leptin signaling and leptin's anti-obesity action. In peripheral tissues, SH2B1 cell-autonomously enhances insulin signaling. In pancreatic islets, SH2B1 is required for compensatory β cell expansion in response to insulin resistance and β cell stress. SH2B1-deficiency results in severe leptin resistance, energy imbalance, obesity, and type 2 diabetes. SH2B1 mutations are linked to leptin resistance, insulin resistance, obesity, and type 2 diabetes in humans. Thus, SH2B1 is a critical metabolic regulator in mammals.

INTRODUCTION

The Src homology 2B (SH2B) family contains three members (SH2B1, SH2B2 and SH2B3) in mammals. All members contain a characteristic pleckstrin homology (PH) domain and SH2 domain. SH2B1 (also called SH2-B and PSM) was initially identified as a high affinity

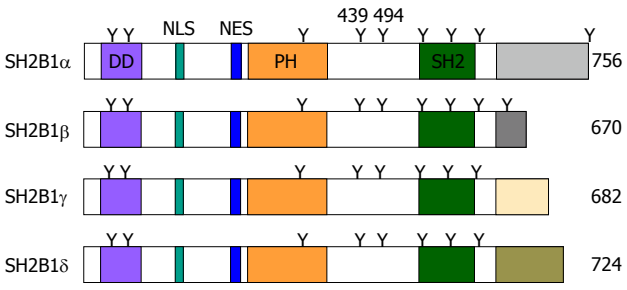

Figure 1 A schematic representation of SH2B1 isoforms. DD: Dimerization domain; PH: PH domain; SH2: SH2 domain; Y: Tyrosine; Numbers: Amino acid numbers.

immunoglobin E receptor (Fc RI) binding protein in the yeast tribrid screen in 1995[1]. SH2B2 (also called APS) was identified as a c-Kit-binding protein by the yeast two-hybrid system in 1997[2]. SH2B3 (also called Lnk) was identified as a SH2 domain-containing, tyrosyl phosphorylated protein in rat lymph node lymphocytes in 1995[3]. The SH2B family is evolutionarily conserved from insects through humans. Unlike mammals, insects have only one *SH2B* gene (also called Lnk)[4,5]. Deletion of SH2B1, but not SH2B2 or SH2B3, results in obesity and metabolic diseases in mice, whereas deletion of either SH2B2 or SH2B3, but not SH2B1, impairs immune function[6-11]. Therefore, individual SH2B1 family members have distinct function in mammals. In this review, I will mainly discuss mammalian SH2B1 and SH2B2.

METABOLIC FUNCTION OF SH2B1

Structure, subcellular localization, posttranslational modification, and tissue distribution of SH2B1

The *SH2B1* gene generates four SH2B1 isoforms (α, β, γ, and δ) through mRNA alternative splicing[1,12-14]. All isoforms have an identical N-terminal region (amino acids 1-632), but differ at their C-termini after the SH2 domain (Figure 1).

SH2B1 structure: All four isoforms have identical dimerization (DD), PH, and SH2 domains (Figure 1). The DD domain mediates SH2B1 homodimerization or its heterodimerization with SH2B2[15-17]. The SH2 domain binds to the phospho-tyrosine motifs of its binding partners (*e.g.*, JAK2 and insulin receptors)[12,18]. The function of the central PH domain remains unclear.

SH2B1 subcellular localization: SH2B1 is located mainly in the cytoplasm, but a subset shuttles between the cytoplasm and the nucleus[19]. SH2B1 contains a nuclear localization sequence (NLS) (KLK^{150}KR) which is required for its nuclear translocation[20]. SH2B1 also contains a nuclear export sequence (NES) (GERWTHRFERL^{231}RLSR) (Figure 1), and replacement of the conserved Leu^{231} and Leu^{233} with Ala increases its nuclear localization[19]. SH2 domain-defective SH2B1β(*R555E*) mutant is also excluded from the nucleus[20]. Therefore, the NLS, NES, and SH2 domain all are involved in the regulation of SH2B1 trafficking between the cytoplasmic and nuclear compartments. SH2B1 is also translocated to the plasma membrane[21]. A N-terminal polybasic region (S^{145}KPKLKKRF), which overlaps the NLS, is required, but not sufficient, for SH2B1β translocation to the plasma membrane[22].

SH2B1 posttranslational modification: SH2B1α and SH2B1β contain nine Tyr residues, and SH2B1γ and SH2B1δ have eight (Figure 1). Tyr^{439} and Tyr^{494} are conserved in all four isoforms, and are able to be phosphorylated by JAK1 and JAK2[23]. Src tyrosine kinases also phosphorylate all four isoforms[24]. Additionally, insulin, insulin-like growth factor (IGF-1), and nerve growth factor (NGF) also stimulate tyrosine phosphorylation of SH2B1 *via* their cognate receptor tyrosine kinases[14,18,25].

SH2B1 contains numerous Ser and Thr residues. NGF stimulates SH2B1 phosphorylation on multiple Ser/Thr residues[21]. Mitogen-activated protein kinase (MAPK) directly phosphorylates Ser^{96}[21], and protein kinase C phosphorylates both Ser^{161} and Ser^{165} residues[22,26]. However, the physiological consequence of SH2B1 phosphorylation remains unknown.

SH2B1 tissue distribution: SH2B1 is ubiquitously expressed in both peripheral tissues and the central nervous system, including adipose tissue, skeletal muscle, liver, pancreas, heart, spleen, hypothalamus, and other brain areas[27]. SH2B1 expression is regulated by neuronal, hormonal, and nutritional signals. The mRNA levels of hypothalamic SH2B1 are 20-fold higher in fed mice than in fasted mice[28]. The expression of hypothalamic SH2B1 in rats is downregulated by high fat diet (HFD) feeding[29]. Chronic overexpression of bovine growth hormone (GH) increases the levels of hepatic SH2B1 protein in GH transgenic mice[30]. The molecular steps, which control the activity of the SH2B1 promoter and the stability of SH2B1 mRNA and protein, remain completely unknown.

SH2B1 regulates cell signaling in response to multiple hormones, growth factors, and cytokines

In cultured cells, SH2B1 acts as an adaptor to couple upstream activators to downstream effectors, to assemble a multiple-protein signaling complex, and/or to enhance the catalytic activity of its bound enzymes.

SH2B1 mediates/modulates leptin signaling: Leptin is an adipose hormone identified by Friedman and his colleagues using positional cloning[31]. Leptin deficiency results in morbid obesity in *ob/ob* mice[31], and recombinant leptin fully corrects obesity and metabolic disorders in *ob/ob* mice[32-34]. Leptin exerts its biological action by binding to and activating its long form receptors (called LEPRb)[35-38]. LEPRb binds to JAK2, a cytoplasmic tyrosine kinase which also mediates GH, prolactin, erythropoietin (EPO), and other cytokine signaling[39,40]. Leptin stimulates tyrosine phosphorylation and activation of JAK2 which activates multiple downstream signaling

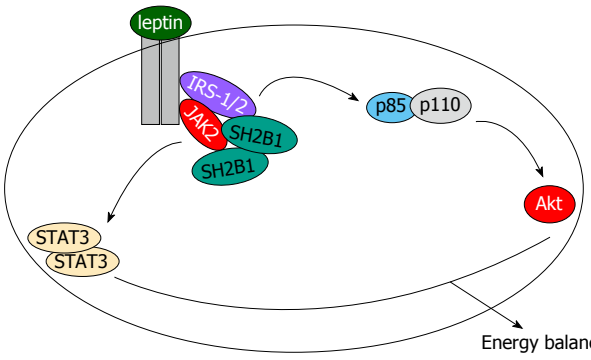

Figure 2 A model of Src homology 2B1 regulation of leptin signaling. The Src homology 2B1 (SH2B1) homodimers bind to JAK2, IRS1, and/or IRS2. SH2B1-JAK2 interaction increases JAK2 kinase activity, thus globally enhancing leptin signaling. JAK2 phosphorylates STAT3 which subsequently homodimerizes, translocates into the nucleus, and activates its target genes. SH2B1-IRS1/2 interaction allows JAK2 to phosphorylate IRS proteins which subsequently activate the PI 3-kinase pathway. Both the STAT3 and the PI 3-kinase pathways are required for leptin to control energy balance and body weight. JAK2: Janus kinase 2; IRS1: Insulin receptor substrate-1; STAT3: Signal transducer and activator of transcription 3.

pathways, including the signal transducer and activator of transcription 3 (STAT3) and the PI 3-kinase pathways[39,40]. Both the STAT3 and the PI 3-kinase pathways are required for leptin's anti-obesity action[39,40]. Impaired leptin signaling and action (leptin resistance) are believed to be the primary risk factor for obesity[39,40].

We reported that leptin stimulates activation of JAK2 which subsequently autophosphorylates on Tyr^{813}[41]. SH2B1 binds *via* its SH2 domain to phospho-Tyr^{813}[41]. This physical interaction markedly increases JAK2 catalytic activity, thus enhancing activation of leptin signaling pathways downstream of JAK2[41-43]. In agreement, leptin-stimulated activation of hypothalamic JAK2 is dramatically attenuated in SH2B1 knockout mice[10]. Leptin sensitivity has been well documented to be negatively regulated by protein tyrosine phosphatase 1B (PTP1B) and SOCS3[39,40]. Overexpression of SH2B1 reverses PTP1B-induced inhibition of leptin stimulation of tyrosine phosphorylation of STAT3[10]. Therefore, cellular leptin sensitivity is likely to be determined, at least in part, by the ability of endogenous SH2B1 to counteract negative regulators such as PTP1B and SOCS3.

Leptin stimulates tyrosine phosphorylation of insulin receptor substrate-1 (IRS1) and IRS2, and IRS proteins subsequently bind to the p85 regulatory submit of PI 3-kinase and activate the PI 3-kinase pathway[39,40,44]. Genetic deletion of IRS2 in LEPR-expressing cells results in leptin resistance and obesity in mice[45]. SH2B1 directly binds to both IRS1 and IRS2 in addition to JAK2[46]. In response to leptin, SH2B1 recruits IRS proteins to JAK2, thus allowing JAK2 to phosphorylate IRS proteins on tyrosine residues[46]. Accordingly, in SH2B1 knockout mice, leptin is unable to stimulate tyrosine phosphorylation of hypothalamic IRS2[10]. SH2B1 is likely to mediate leptin stimulation of the PI 3-kinase pathway by coupling JAK2 to IRS proteins (Figure 2).

SH2B1 C-terminal SH2 domain binds to phospho-Tyr^{813} in JAK2 as discussed above; in contrast, its N-terminal region binds to different sites on JAK2 in a tyrosine phosphorylation-independent manner[43]. Similarly, SH2B1 binds to phospho-tyrosine(s) of IRS1 or IRS2 *via* its SH2 domain, and binds to other sites on IRS proteins *via* its PH domain-containing regions in a tyrosine phosphorylation-independent fashion[46]. SH2B1 forms homodimers or oligomers *via* its N-terminal domains[15-17]. Each individual SH2B1 molecule is able to bind to JAK2 and/or IRS proteins; therefore, SH2B1 dimers or oligomers are predicted to assemble a large signaling complex containing multiple copies of JAK2 and IRS proteins (Figure 2). Physical proximity allows JAK2 to transphosphorylate and activate each other in this complex, contributing to SH2B1 stimulation of JAK2 activation and leptin signaling. Additionally, this highly-organized SH2B1/JAK2/IRS complex may also provide a permissive condition for JAK2 to efficiently phosphorylate IRS proteins and activate the PI 3-kinase pathway in response to leptin.

SH2B1 enhances insulin and IGF-1 signaling: SH2B1 was reported to bind to insulin receptors (IRs) *via* its SH2 domain[18]. Insulin stimulates the binding of SH2B1α to phospho-Tyr^{1158}, Tyr^{1162} and/or Tyr^{1163} within the IR activation loop, and IRs subsequently tyrosyl phosphorylate SH2B1α[13,47]. Overexpression of SH2B1β markedly enhances the ability of insulin to stimulate tyrosine phosphorylation of IRS1 and IRS2[9]. In contrast, SH2B1β(R555E), which has a defective SH2 domain, acts as a dominant negative mutant to inhibit insulin signaling[9]. Moreover, deletion of SH2B1 impairs insulin signaling in the skeletal muscle, adipose tissue, and livers of SH2B1 knockout mice[9].

Mechanistically, SH2B1-IR interaction markedly increases IR catalytic activity and IR-mediated tyrosine phosphorylation of IRS proteins[48]. Replacement of IR Tyr^{1158} with Phe disrupts IR binding to SH2B1, and completely blocks the ability of SH2B1β to stimulate IR kinase activity[48]. SH2B1α similarly increases IR catalytic activity[49]. Additionally, SH2B1β directly binds to tyrosyl phosphorylated IRS1 and IRS2 and protects IRS proteins against dephosphoarylation, thus prolonging the ability of IRS proteins to activate their downstream pathways[48]. Accordingly, overexpression of SH2B1α delays dephosphorylation of IRS proteins in cells[50]. SH2B1 homodimers and oligomers are predicted to simultaneously bind to both IRs and IRS proteins and assemble a large, highly-organized signaling complex, thereby increasing insulin signaling specificity and efficiency.

SH2B1 also binds *via* its SH2 domain to IGF-1 receptors[14], and is predicted to promote IGF-1 signaling in a similar fashion.

SH2B1 enhances TrkA, TrkB and TrkC signaling: Amino acid sequence analysis reveals that like IRs, Trk family members (TrkA, TrkB and TrkC) contain potential SH2B1-binding site(s) within their activation loops. NGF

stimulates both the binding of SH2B1 to NGF receptor TrkA and phosphorylation of SH2B1 on Tyr/Ser/Thr residues in PC12 cells[21,25]. NGF also stimulates the binding of TrkA to both SH2B1 and SH2B2 in primary neurons[51]. SH2B1-TrkA interaction is mediated by the SH2 domain of SH2B1 and phospho-Tyr^{679}, -Tyr^{683} and/or -Tyr^{684} within TrkA activation loop[21,25,51]. Additionally, SH2B1α binds *via* its proline rich regions (amino acids 394-504 between the PH and SH2 domains) to Grb2, contributing to NGF-stimulated activation of the MAPK pathway[51]. Overexpression of SH2B1β also enhances NGF-stimulated activation of Akt in PC12 cells[52].

Brain-derived neurotrophic factor (BDNF) or neurotrophin-3 (NT-3) similarly stimulates the binding of SH2B1 to TrkB or TrkC, respectively, and they also stimulate tyrosine phosphorylation of SH2B1[51,53,54]. Unlike JAK2 and IRs, TrkB kinase activity is not enhanced by SH2B1[53].

SH2B1 regulates GH, prolactin, and EPO signaling: JAK2 binds to GH receptors and mediates GH signaling[55]. GH stimulates the binding of SH2B1 to JAK2 and robust tyrosine phosphorylation of SH2B1 by JAK2 in 3T3-F442A fibroblasts[12]. GH stimulates JAK2-mediated phosphorylation of SH2B1 on Tyr^{439} and Tyr^{494} residues[56]. Like leptin, GH stimulates phosphorylation of JAK2 on Tyr^{813} which binds to the SH2 domain of SH2B1[57]. SH2 domain-phospho-Tyr^{813} interaction markedly increases JAK2 activity, thus enhancing GH signaling (*e.g.*, phosphorylation and activation of STAT5B)[42,43].

JAK2 also mediates prolactin signaling[58]. Like GH, prolactin stimulates tyrosine phosphorylation of SH2B1[59]. Overexpression of SH2B1β enhances prolactin signaling, including tyrosine phosphorylation of JAK2[59].

Unlike GH, EPO stimulates the binding of SH2B1 to EPO receptors rather than to JAK2[60]. SH2B1 constitutively binds to unphosphorylated EPO receptors under basal conditions, and EPO stimulates phosphorylation of EPO receptors on Tyr^{343} and Tyr^{401} which subsequently bind to the SH2 domain of SH2B1[60]. EPO rapidly stimulates phosphorylation of SH2B1 on Ser/Thr residues[60]. Knockdown of SH2B1 increases EPO-stimulated tyrosine phosphorylation of EPO receptors, JAK2, and ERK1/2, raising the possibility that SH2B1 may negatively regulate EPO signaling[60].

SH2B1 binds to JAK1, JAK2 and JAK3, but it only stimulates JAK2, but not JAK1 and JAK3, kinase activity[61]. Both JAK1 and JAK2 are able to phosphorylate SH2B1 on Tyr^{439} and Tyr^{494}, but Tyr^{439}/Tyr^{494} phosphorylation does not affect the ability of SH2B1 to stimulate JAK2[23]. The JAK family members mediate cell signaling and action in response to numerous hormones and cytokines in addition to GH, prolactin, and EPO, so it is conceivable that SH2B1 may mediate or modulate cellular responses to these hormones and cytokines through interacting with JAK family members.

SH2B1 regulates additional receptor tyrosine kinase signaling: SH2B1 binds *via* its SH2 domain to tyrosyl phosphorylated platelet-derived growth factor (PDGF) receptors in response to PDGF-BB stimulation[62]. PDGF-BB stimulates phosphorylation of SH2B1 on Tyr/Ser/Thr residues[62]. PDGF-BB is able to stimulate tyrosine phosphorylation of all four isoforms of SH2B1[14]. PDGF receptors directly phosphorylate SH2B1 on Tyr^{439} residue[23].

Glial cell line-derived neurotrophic factor (GDNF) stimulates the binding of SH2B1β to GDNF receptor RET through SH2B1β SH2 domain and RET phospho-Tyr^{981} motifs[63,64]. This interaction increases RET kinase activity, RET autophosphorylation, and RET-mediated tyrosine phosphorylation of STAT3[64].

SH2B1 directly interacts with fibroblast growth factor receptor 3 (FGFR3) and is tyrosyl phosphorylated by FGFR3[65]. The SH2 domain of SH2B1 binds to phospho-Tyr^{724} and phospho-Tyr^{760} of FGFR3, and the interaction increases the ability of FGFR3 to phosphorylate and activate STAT5[65].

SH2B1 regulates multiple cellular responses

In cultured cells, SH2B1 has been demonstrated to regulate multiple cellular processes, including migration, proliferation, and differentiation.

SH2B1 regulates actin cytoskeletal reorganization and cell motility: SH2B1 is able to regulate cell morphology, adhesion, and motility through modifying actin cytoskeletal reorganization in cultured cells. SH2B1β is detected in membrane ruffles, filopodia, and focal adhesions[26,59], and is colocalizated with filamentous actin (F-actin) in membrane ruffles[66]. SH2B1β binds *via* both its N-terminal (amino acids 150-200) and C-terminal regions (amino acids 615-670) to F-actin, and promotes actin filament cross-link[59]. SH2B1 directly binds *via* its amino acids 200-260 to the actin-binding protein filamin A[67]. Additionally, SH2B1 binds *via* its amino acids 85-106 to Rac, a critical regulator of actin cytoskeletal reorganization[68].

SH2B1 mediates GH regulation of cell adhesion and migration. GH increases the cycling of SH2B1 into and out of focal adhesions[26], and promotes SH2B1 colocalization with F-actin in membrane ruffles[66]. Overexpression of SH2B1β, but not SH2 domain-defective SH2B1β(R555E), enhances the ability of GH to stimulate both membrane ruffles in 3T3-F442A fibroblasts[59,66] and macrophage migration[56]. In fact, SH2B1β(R555E) blocks GH-induced lamellipodia dynamics in 3T3-F442A cells[68]. Both the N-terminal region (amino acids 85-106) and the SH2 domain of SH2B1β are required for GH stimulation of cell motility[68]. Additionally, SH2B1β mutants lacking Tyr^{439} and Tyr^{494} phosphorylation sites are unable to enhance GH-stimulated membrane ruffling in 3T3-F442A fibroblasts[23] and GH-stimulated motility of RAW264.7 macrophages[56]. SH2B1-Rac interaction is involved in mediating GH-promoted actin cytoskeletal reorganization and cell motility[68].

Overexpression of SH2B1β similarly enhances prolactin-stimulated membrane ruffling[59]. SH2B1 directly binds to filamin A, which appears to mediate prolactin stimulation of membrane ruffling and cell motility[67].

SH2B1 promotes neuronal survival and neuronal differentiation: Overexpression of SH2B1β markedly enhances the ability of NGF to stimulate neurite outgrowth in PC12 cells[25], and both SH2B1α and SH2B2 are able to promote NGF/TrkA-induced neuronal differentiation[51]. In contrast, overexpression of SH2 domain-defective SH2B1(R555E) blocks NGF-induced neuronal differentiation of PC12 cells[25]. SH2B1β mutants lacking either the NES or the NLS also are unable to enhance NGF-induced neuronal differentiation[19,20]. Overexpression of a N-terminal (amino acids 1-499) truncated SH2B1 mutant, which lacks both NES and NLS, induces axon degeneration in NGF-treated primary sympathetic neurons[51]. Moreover, neutralization of endogenous SH2B1 with anti-SH2B1 antibody decreases the survival of primary sympathetic neurons[51]. These observations suggest that the SH2 domain, NES, and NLS all are required for SH2B1 to mediate NGF stimulation of neuronal differentiation and survival.

SH2B1β also enhances GDNF/RET-induced neuronal differentiation of PC12 cells[63,64]. However, the molecular mechanisms, by which SH2B1 promotes neuronal survival, differentiation, and neurite outgrowth, remain largely unknown.

SH2B1 promotes mitogenesis and transformation: All four SH2B1 isoforms are able to increase the mitogenic response to epidermal growth factor, IGF-1, and PDGF-BB[14,69]. SH2B1 increases the ability of RET to promote transformation of NIH 3T3 cells[64]. SH2B1 is abnormally expressed in non-small cell lung cancer (NSCLC) tissues and NSCLC cell lines[70]. SH2B1 overexpression is associated with increased tumor grade, tumor size, lymph node metastasis in NSCLC patients[70].

Neuronal SH2B1 regulates body weight and nutrient metabolism in mice

We reported that genetic deletion of SH2B1 results in severe obesity and type 2 diabetes in mice[9,10].

Central SH2B1 regulates energy balance and body weight: We disrupt the *SH2B1* gene to generate SH2B1 knockout (KO) mice by DNA homologous recombination[9]. Exons 1-6, which encode the N-terminal region of all four isoforms of SH2B1, are replaced by a neo cassette[9]. SH2B1-null mice are hyperphagic and morbidly obese[10]. Both *SH2B1* KO males and females gain more body weights than wild type (WT) littermates after 7 wk of age[10,71]. White adipose tissue mass and fat content are much higher in *SH2B1* KO mice in either C57BL/6 or 129Sv/C57BL mixed congenic background, and the size of individual white adipocytes is also larger in *SH2B1* KO mice[10].

SH2B1 KO mice are extremely hyperphagic, causing obesity[10]. Surprisingly, energy expenditure, as estimated by O_2 consumption and CO_2 production, is also higher in *SH2B1* KO mice than in WT littermates[10]. Accordingly, in the pair-feeding paradigm in which each individually-housed mouse is fed the identical amount of food daily, *SH2B1* KO mice gain less body weights and become leaner than WT littermates[10].

Food intake is controlled largely by the brain, particularly the hypothalamus[72], so we generate SH2B1 transgenic (Tg) mice in which a rat SH2B1β transgene is expressed specifically in neurons under the control of neuron-specific enolase promoter[27]. SH2B1β Tg mice are crossed with *SH2B1* KO mice to generate TgKO mice which lack endogenous SH2B1 in all cell types but express recombinant SH2B1β specifically in neurons[27]. Neuron-specific restoration of SH2B1β into *SH2B1* KO mice fully rescues the hyperphagic and obese phenotypes in TgKO mice[27]. Energy expenditure, which is abnormally higher in *SH2B1* KO mice, is normal in TgKO mice[27]. Furthermore, SH2B1β Tg mice, which contain homozygous SH2B1β transgenes and overexpress recombinant SH2B1β in the brain, resist HFD-induced obesity[27]. These observations indicate that central SH2B1 is a key regulator of energy balance and body weight. Multiple brain areas and neural circuits are involved in the control of energy metabolism and body weight[72]; however, SH2B1 target neural circuits remain unknown.

Surprisingly, Ohtsuka *et al*[11] reported that disruption of SH2B1 did not cause obesity, insulin resistance, and glucose intolerance; however, their subsequent studies show that their *SH2B1* KO mice indeed display insulin resistance and glucose intolerance as we observed in our *SH2B1* KO mice[9,73]. Since *SH2B1* KO mice have high energy expenditure[10], a slight disturbance of food intake is expected to lead to reduction in body weight. Thus, variations in house conditions and other environmental factors may contribute to body weight discrepancy between these studies.

SH2B1 KO mice have relatively normal somatic growth, indicating that SH2B1 is not required for GH stimulation of body growth[9,11,71]. Nonetheless, it is still possible that SH2B1 may modulate GH regulation of metabolism and/or other physiological processes.

Central SH2B1 regulates glucose and lipid metabolism: Obesity is the primary risk factor for insulin resistance and type 2 diabetes[39]. As expected, obese *SH2B1* KO mice develop hyperglycemia, hyperinsulinemia, glucose intolerance, and insulin resistance[9,71]. Insulin signaling is impaired in the skeletal muscle, adipose tissue, and livers of *SH2B1* KO mice[9]. *SH2B1* KO male mice display frank type 2 diabetes after 7 mo of age[9]. Moreover, *SH2B1* haploinsuffiency predisposes to HFD-induced insulin resistance[9]. *SH2B1* KO mice develop the symptoms of metabolic syndrome, including hyperlipidemia, hepatic steatosis, and lipid accumulation in skeletal mus-

cle[10]. Moreover, neuron-specific restoration of SH2B1β reveres obesity, type 2 diabetes, and metabolic syndrome in TgKO mice[27]. These observations indicate that central SH2B1 is absolutely required for the maintenance of normal glucose and lipid homeostasis in mice.

Central insulin and leptin are able to regulate systemic glucose and lipid metabolism independently of their action on energy balance and body weight[39,40,74-77]. SH2B1 positively regulates both leptin and insulin signaling, so central SH2B1 may regulate peripheral glucose and lipid metabolism independently of its action on energy balance and body weight.

Central SH2B1 positively regulates hypothalamic leptin sensitivity: Central SH2B1 controls food intake and body weight at least in part by enhancing leptin sensitivity in the brain. SH2B1 cell-autonomously enhances leptin signaling by promoting JAK2 activity and activation of pathways downstream of JAK2[41]. SH2B1 also mediates leptin-stimulated activation of the PI 3-kinase pathway by binding to IRS1/2 and recruiting IRS proteins to JAK2[46]. *SH2B1* KO mice display severe hyperleptinemia, a hallmark of leptin resistance[10]. Hyperleptinemia develops prior to the onset of obesity, suggesting that leptin resistance is a causal factor for obesity progression in *SH2B1* KO mice[10]. In agreement, exogenous leptin is unable to suppress food intake and weight gain in *SH2B1* KO mice, and has reduced ability to stimulate phosphorylation of hypothalamic JAK2, STAT3 and IRS2 in these mice[10]. Furthermore, neuron-specific expression of recombinant SH2B1β in SH2B1-null mice reverses hyperleptinemia, leptin resistance, hyperphagia, and obesity in TgKO mice[27]. However, neuron-specific expression of SH2B1β(R555E) is unable to rescue leptin resistant, hyperphagic, and obese phenotypes in SH2B1-null mice[78], suggesting that the SH2 domain of SH2B1 is required for its anti-obesity action. Like *SH2B1* KO mice, SH2B1β(R555E) transgenic mice develop obesity, insulin resistance, hyperglycemia, and glucose intolerance[78], suggesting that SH2B1β(R555E) blocks the action of endogenous SH2B1 as a dominant negative mutant.

Orexigenic agouti-related protein (AgRP) neurons and anorexigenic proopiomelanocortin (POMC) neurons in the arcuate nucleus are key leptin targets[39]. Leptin suppresses the expression of AgRP and neuropeptide Y (NPY) but stimulates POMC expression[72]. The expression of hypothalamic AgRP and NPY is higher in *SH2B1* KO mice[10], and neuron-specific expression of SH2B1β in *SH2B1* KO mice normalizes AgRP and NPY expression[27]. By contrast, the expression of hypothalamic POMC is normal in *SH2B1* KO mice[10]. Since *SH2B1* KO mice develop severe hyperleptinemia[10], leptin-stimulated expression of POMC may still be impaired in SH2B1-null mice.

Leptin promotes energy expenditure[39]; therefore, increased energy expenditure in *SH2B1* KO mice cannot be explained by leptin resistance. It is likely that central SH2B1 regulates energy metabolism by an additional leptin-independent mechanism. SH2B1 is able to mediate or modulate cell signaling in response to multiple factors as described above. These pathways may be involved in central regulation of energy balance and body weight. For instance, SH2B1 enhances BDNF signaling[51,54]. Central administration of BDNF suppresses food intake and weight gain; conversely, haploinsufficiency of BDNF or TrkB leads to hyperphagia and obesity in mice[79-83]. Mutations in either BDNF or TrkB are associated with obesity in humans[82,84]. Therefore, neuronal SH2B1 may regulate energy metabolism and body weight by enhancing TrkB signaling in addition to LEPRb signaling in the brain.

Peripheral SH2B1 regulates glucose and lipid metabolism in mice

SH2B1 is expressed in both central and peripheral tissues[27], and peripheral SH2B1 also regulates nutrient metabolism.

Peripheral SH2B1 regulates insulin sensitivity and glucose metabolism: TgKO mice, which lack endogenous SH2B1 in all tissues but express SH2B1β transgenes in the brain, have relatively normal blood glucose, plasma insulin, and glucose tolerance[27]. These observations suggest that peripheral SH2B1 is not required for the maintenance of insulin sensitivity and glucose metabolism in mice fed a normal chow diet. We feed TgKO mice a HFD for 16 wk to induce metabolic stress. TgKO mice develop more severe HFD-induced hyperglycemia, hyperinsulinemia, insulin resistance, and glucose intolerance, even though they have similar body weight and fat content as WT mice[48]. Insulin signaling in skeletal muscle, adipose tissue, and the liver is impaired to a greater extent in HFD-fed TgKO mice[48], and these mice display more severe hepatic steatosis[85]. Thus, peripheral SH2B1 promotes insulin signaling and glucose and lipid metabolism under obesity conditions.

SH2B1 in pancreatic β cells promotes β cell expansion and insulin secretion: Pancreatic β cells express high levels of several SH2B1 isoforms[86]. To examine the role of β cell SH2B1, we generate pancreas-specific *SH2B1* KO (PKO) mice, using the *Pdx1-cre*/loxp system[86]. PKO mice have normal body weight, blood glucose, insulin sensitivity, and glucose tolerance; however, they develop more severe HFD-induced glucose intolerance[86]. Pancreatic insulin content, β cell mass, and glucose-stimulated insulin secretion are significantly lower in PKO than control mice fed a HFD, and PKO islets have more apoptotic cells and less mitotic cells[86]. These observations indicate that SH2B1 in β cells is required for HFD-induced compensatory β cell expansion to counteract insulin resistance in obesity.

SH2B1 appears to directly promote β cell expansion by both promoting proliferation and inhibiting apoptosis[86]. In a rat INS-1 832/13 β cell line, silencing of SH2B1 decreases, whereas overexpression of SH2B1β

increases, β cell toxin streptozotocin (STZ)-induced apoptosis[86]. In line with these findings, PKO mice are more susceptible to STZ-induced β cell destruction, insulin deficiency, and glucose intolerance[86]. Mechanistically, SH2B1 directly enhances insulin and IGF-1 signaling in β cells[86], and both insulin and IGF-1 potently increase β cell survival and proliferation[87-91]. Therefore, β cell SH2B1 cell-autonomously promotes β cell survival, proliferation, and expansion under stress conditions at least in part by enhancing insulin and IGF-1 signaling in β cells.

Hepatic SH2B1 regulates liver triacylglycerol content and very low-density lipoprotein secretion: SH2B1 is also highly expressed in the liver[27], so we generate hepatocyte-specific *SH2B1* KO (HKO) mice using the *albumin-cre*/loxP system[85]. Surprisingly, somatic growth, body weight, insulin sensitivity, and glucose metabolism are similar between HKO and control mice fed either a normal chow diet or a HFD[85]. Adult-onset deletion of SH2B1 in the liver also does not alter insulin sensitivity and glucose metabolism in mice fed a HFD[85]. These data indicate that hepatic SH2B1 is dispensable for the maintenance of systemic insulin sensitivity and glucose metabolism in mice. However, adult-onset deletion of liver SH2B1 decreases liver triacylglycerol content in mice fed a HFD[85], suggesting that hepatic SH2B1 regulates hepatocyte lipid metabolism. Liver-specific deletion of SH2B1 alone does not alter very low-density lipoprotein (VLDL) secretion; however, deletion of liver SH2B1 in SH2B2 knockout mice decreases VLDL secretion[85]. These observations suggest that liver SH2B1 and SH2B2 act redundantly to promote VLDL secretion.

SH2B1 regulates reproduction in mice

SH2B1 is highly expressed in testes and ovaries, and systemic deletion of SH2B1 severely impairs fertility in both male and female mice[11]. Ovary size and follicle number are lower in *SH2B1* KO females; similarly, testis size and sperm number are also lower in *SH2B1* KO males[11]. SH2B1 deficiency impairs both follicle-stimulating hormone and IGF-1 signal transduction in ovaries, which may contribute to impaired fertility in *SH2B1* KO mice[11].

Metabolic function of SH2B1 in humans

SH2B1 rs7498665, the first human *SH2B1* single nucleotide polymorphism (SNP), was reported in 2007[92]. It is associated with hyperleptinemia, increased body weight, increased total fat, and increased waist circumference in a United Kingdom white female cohort[92].

Human SH2B1 is a candidate obesity gene: In 2009, two groups independently reported that *SH2B1* rs7498665 is genetically linked to human obesity in genome-wide association studies (GWAS) on large populations[93,94]. Since then, *SH2B1* rs7498665 has been reported to be associated with human obesity in Swedish adults[95], Belgian adults[96], children of European ancestry[97], Chinese women[98], Hong Kong Chinese[99], Japanese adults[100], the MONIKA/KORA cohort[101], a Mexican cohort[102], and a African-American cohort[103]. *SH2B1* rs7498665 risk allele is associated with increased visceral adiposity in Japanese[104] and German[105]. *SH2B1* rs7498665 is also associated with increased fat intake in Dutch females[106].

Several additional *SH2B1* SNPs have been described since 2009. In GWAS, *SH2B1* rs7359397 is associated with obesity in 249796 adult individuals of European ancestry[107] and in Danish adults[108]. *SH2B1* rs4788102 is associated with obesity in Chinese girls[109] and in Japanese populations[100]. *SH2B1* rs4788099 is associated with increased body mass index (BMI) in individuals of European ancestry[110], and is linked to more servings of dairy products[111]. *SH2B1* rs8055982 is associated with severe obesity in children of European ancestry[97].

Aside from *SH2B1* SNPs, chromosomal 16p11.2 deletion is associated with severe obesity in European cohorts[112-115]. The deleted region contains the *SH2B1* gene. In contrast, chromosomal 16p11.2 duplication is associated with underweight in humans[116].

Several *SH2B1* non-synonymous variants have been identified. *SH2B1* rs7498665 risk allele encodes a non-synonymous substitution of Thr484Ala[92]. However, Thr484Ala substitution alone is not sufficient to cause obesity[117], raising the possibility that other unidentified *SH2B1* mutations, which co-segregate with rs7498665, may increase risk for obesity. Several *SH2B1* missense mutations (P90H, T175N, P322S and F344LfsX20) were reported to be genetically linked to obesity and insulin resistance in mixed European descents[118]. *F344LfsX20A* mutation causes a frameshift, resulting in production of a C-terminally-truncated SH2B1 variant lacking the entire SH2 domain[118]. A separate study reported that *SH2B1* g.9483(C/T) missense mutation, but not Thr175Asp non-synonymous variant (rs147094247), is linked to obesity[119]. *SH2B1* g.9483(C/T) mutation results in generation of non-synonymous SH2B1β(Thr656Ile) and SH2B1γ(Pro674Ser) variants[119]. Four additional rare non-synonymous variants (G131S, V209I, L293R, M465T, and W649G) have been identified in Chinese populations[120]. V209I and M465T variants are detected in obese children, whereas G131S, L293R and W649G variants are observed in lean children[120].

None of the above human SH2B1 variants has been verified in animal models to be a causal factor for obesity or obesity-associated metabolic syndrome. We reported that neuron-specific expression of SH2 domain-defective SH2B1β(R555E), which is functionally similar to F344LfsX20A variant, is sufficient to cause obesity and insulin resistance in mice[78]. These findings raise the possibility that F344LfsX20A non-synonymous variant may be a causal factor for obesity in humans.

***SH2B1* mutations increase risk for type 2 Diabetes in humans:** Obesity is the primary risk factor for insulin resistance and type 2 diabetes[39], so *SH2B1* risk alleles

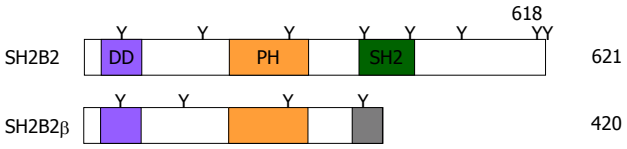

Figure 3 A schematic representation of SH2B2 isoforms. DD: Dimerization domain; PH: PH domain; SH2: SH2 domain; Y: Tyrosine.

are expected to be associated with type 2 diabetes in humans. *SH2B1* rs7498665 is associated with type 2 diabetes in both United Kingdom[92] and French populations[121]. Heterozygous carriers of a P90H, T175N, P322S, or F344LfsX20 non-synonymous variant develop severe early-onset obesity as well as insulin resistance and type 2 diabetes[118].

We reported that peripheral SH2B1 regulates insulin sensitivity and glucose metabolism independently of its action on body weight in mice[48]. SH2B1 in pancreatic β cells directly promotes β cell expansion and insulin secretion in mice[86]. Hepatic SH2B1 regulates liver lipid levels and VLDL secretion[85]. In agreement, *SH2B1* rs4788102 is associated with type 2 diabetes after adjustment for BMI in Japanese[100]. *SH2B1* rs7498665 is associated with increased risk for type 2 diabetes independently of BMI in middle aged Danes[122]. *SH2B1* rs7359397 is associated with insulin resistance after adjustment of BMI in Sweden men at 71 years of age[123]. Thus, SH2B1 also regulates nutrient metabolism by a body weight-independent mechanism.

SH2B1 may regulate multiple physiological processes in humans: Chromosomal 16p11.2 deletion, which results in loss of *SH2B1*, is associated with cognitive deficits, developmental delays[112-115], and autism[115]. Chromosomal 16p11.2 deletion is also linked to abnormal renal and enteric development in humans[124]. *SH2B1* rs4788102 (G/A) is associated with increased circulating triacylglycerol levels in the Northern Swedish Population Health Study cohort[125], and is linked to myocardial infarction[126]. *SH2B1* rs7498665 G allele is linked to increased bone mineral density in Japanese women[127]. However, none of these potential functions have been verified in animal models.

Metabolic function of SH2B1 is evolutionarily conserved

We reported that insulin stimulates the binding of *Drosophila* SH2B (also called Lnk) to Chico, a homologue of mammalian IRS proteins[5]. Almudi *et al*[128] showed that Drosophila SH2B binds to both Chico and insulin receptors in Drosophila cells. SH2B-deficient flies display defects in insulin/IGF signaling, developmental delay, small size, and female sterility[4,5]. Like SH2B1 null mice, SH2B-deficient flies accumulate abnormally-high levels of lipids in their fat bodies[4,5,129].

Interestingly, loss of SH2B increases resistance to oxidative stress as well as lifespan in flies, suggesting that SH2B may regulate aging and longevity[5,129]. However, SH2B1-null mice have a shorter lifespan compared with WT littermates[5]. Obesity and obesity-associated diseases may contribute to early death of SH2B1-null mice. Thus, the role of mammalian SH2B family members in aging remains unclear.

METABOLIC FUNCTION OF SH2B2

SH2B2 was originally identified in 1997[2], and the amino acids of its SH2 and PH domains are 78% and 63% identical to that of SH2B1, respectively.

SH2B2 structure

Crystal structure analysis reveals that the N-terminal region of SH2B2 mediates its homodimerization *via* a Phe zipper[15]. The C-terminal SH2 domain is also able to form a dimer[130]. SH2B2 dimerization is predicted to induce and/or stabilize dimerization of its binding proteins, including JAK2, insulin receptors, or IGF-1 receptors, thus promoting activation of these kinases[15,130].

The *SH2B2* gene also generates an additional C-terminally-truncated isoform (named SH2B2β) through alternative mRNA splicing[131]. SH2B2β contains N-terminal DD and PH domains but lacks C-terminal SH2 domain (Figure 3). SH2B2β binds to both SH2B1 and SH2B2 *via* its DD domain and acts as an endogenous dominant negative variant to inhibit SH2B1 and SH2B2 signaling[131].

SH2B2 regulates insulin signaling and glucose metabolism

Like SH2B1, SH2B2 binds *via* its SH2 domain to phospho-Tyr^{1158} in the activation loop of insulin receptors[130,132,133]. Insulin stimulates phosphorylation of SH2B2 on Tyr^{618} residue in adipocytes[132-134]. Insulin stimulates tyrosine phosphorylation of SH2B2 to a higher level than that of SH2B1[50]. IGF-1 and IGF-Ⅱ also stimulate tyrosine phosphorylation of SH2B2[135]. Additionally, insulin also stimulates Akt-mediated phosphorylation of SH2B2 on Ser^{588} residue[136].

The role of SH2B2 in insulin action is complex. SH2B2 overexpression prolongs insulin-stimulated tyrosine phosphorylation of insulin receptors and IRS proteins[50]. Phospho-Tyr^{618} binds to the tyrosine kinase-binding domain of c-Cbl and promotes c-Cbl phosphorylation by insulin receptors[134,137,138]. Accordingly, knockdown of SH2B2 inhibits insulin-stimulated tyrosine phosphorylation of c-Cbl[139]. SH2B2 also enhances insulin-stimulated phosphorylation of Cbl-b on Tyr^{665} and Tyr^{709} residues[140]. SH2B2 directly binds to SHIP2 and increases SHIP2 activity, and SHIP2 in turn negatively regulates insulin-stimulated tyrosine phosphorylation of SH2B2 and its interaction with c-Cbl[141]. Furthermore, SH2B2 mediates insulin-stimulated plasma membrane translocation of both c-Cbl and Cbl-b in adipocytes[140]. SH2B2 also binds to CAP[134,139] and mediates the activation of the CAP/Cbl/Crk/C3G/TC10 pathway in adipocytes[142]. The SH2B2/CAP/Cbl/Crk/C3G/TC10 pathway is believed to be required for insulin stimulation of GLUT4 trafficking and glucose uptake in adipocytes[142];

consistently, overexpression of SH2B2(Y618F) inhibits insulin-stimulated GLUT4 trafficking[134]. However, SH2B2 also promotes c-Cbl-mediated ubiquitination and internalization of insulin receptors, thus inhibiting insulin signaling[138,143]. Additionally, SH2B2 binds to Asb6, a SOCS family member that may negatively regulate insulin signaling[144].

Deletion of SH2B2 increases insulin sensitivity in mice[6]. We reported that deletion of SH2B2 does not affect HFD-induced insulin resistance and glucose intolerance in *SH2B2* KO mice in either 129Sv/C57BL mixed or C57BL congenic background[71]. Deletion of SH2B2 in *SH2B1* KO mice also does not further exacerbate obesity and insulin resistance in *SH2B1* and *SH2B2* double KO mice relative to *SH2B1* KO mice[71]. The metabolic function of SH2B2 remains unclear.

SH2B2 regulates cytokine signaling and immune response

Like SH2B1, SH2B2 binds *via* its SH2 domain to JAK1, JAK2 and JAK3, and is tyrosyl phosphorylated by these kinases[61,145]. SH2B2 binds *via* both its SH2 domain and non-SH2 domain regions to JAK2, and its SH2 domain binds to phospho-Tyr^{813} of JAK2[16,146]. Unlike SH2B1, SH2B2 is unable to activate, or only slightly activates, JAK2[61,146]. Multiple cytokines, including interferon-γ, EPO, leukemia inhibitor factor, granulocyte-macrophage colony stimulating factor, interleukin-5 (IL-5) and IL-3, stimulate tyrosine phosphorylation of SH2B2, presumably through JAK family members[135,145,147]. Stem cell factor stimulates the binding of SH2B2 *via* its SH2 domain to phospho-Tyr^{568} and -Tyr^{936} of c-Kit and subsequent tyrosine phosphorylation of SH2B2[2,148]. SH2B2 binds *via* its SH2 domain to phospho-Tyr^{343} of EPO receptors[145] , and it also binds *via* its phospho-Tyr^{618} motif to c-Cbl and recruits c-Cbl E3 ligase to EPO receptors, thereby inhibiting the JAK2/STAT5 pathway in hematopoietic cell lines[145]. SH2B2 is colocalized with B cell antigen receptors (BCRs) and negatively regulates BCR signaling, and it is tyrosyl phosphorylated in response to BCR activation[2,149,150].

SH2B1 and SH2B2 play different roles in regulating immune cell function. Deletion of *SH2B1* does not affect the development of T and B lymphocytes and mast cells in mice[11]. In contrast, SH2B2-deficient mast cells display augmented degradulation after cross-linking FcRI[151]. SH2B2 is expressed in B cells but not in T cells[150]. Overexpression of SH2B2 in lymphocytes impairs BCR-induced B cell proliferation and reduces B-1 and B-2 cell number in SH2B2 transgenic mice[150]. Conversely, *SH2B2* KO mice have increased B-1 cell number, and SH2B2-deficient B cells display enhanced response to trinitrophenol-Ficoll, a thymus-independent type 2 antigen[149]. SH2B2 appears to be a negative regulator of a subset of immune cells.

SH2B2 regulates multiple signaling pathways in cultured cells

Like SH2B1, SH2B2 binds *via* its SH2 domain to phospho-Tyr^{679}, -Tyr^{683} and/or -Tyr^{684} of TrkA in response to NGF[51]. BDNF and NT-3 also stimulate the binding of SH2B2 to TrkB and TrkC, respectively[51]. NGF, BDNF and NT-3 stimulate tyrosine phosphoryation of SH2B2[51]. SH2B2 promotes NGF-induced neuronal differentiation of PC12 cells[51].

PDGF-BB stimulates the binding of SH2B2 *via* its SH2 domain to phospho-Tyr^{1021} of PDGFRβ, and SH2B2 in turn inhibits PDGF-stimulated phosphorylation of PLC-γ by competing for phospho-Tyr^{1021} site with PLC-γ[135]. Additionally, PDGF-BB stimulates phosphorylation of SH2B2 on Tyr^{618} which binds to c-Cbl, which recruits c-Cbl E3 ligase to PDGFR complex to negatively regulate PDGFR signaling and PDGFR-promoted mitogenesis[135].

FUTURE DIRECTION

Study of the SH2B family is in its early stages, and many important questions remain unaddressed. Central SH2B1 is required for the maintenance of normal energy balance, body weight, and nutrient metabolism; however, SH2B1 target neurons and neural circuits are unknown. It is unclear whether and how central SH2B1 regulates nutrient mobilization, utilization, and metabolism by a body weight-independent mechanism, and whether and how SH2B1 regulates neuronal activity by a leptin- and insulin-independent mechanism. Numerous *SH2B1* mutations are associated with obesity and type 2 diabetes in humans; however, it is unclear whether these mutations are causal factors for the diseases. Does central SH2B1 regulate higher brain function independently of its action on body weight and metabolism? Do posttranslational modifications affect SH2B1 function? Do SH2B2 and SH2B3 play a role in nutrient metabolism? Can we treat obesity and type 2 diabetes by targeting SH2B family members?

Abstract

Digestive diseases play major role in development and complications of other disorders including diabetes. For example, Crohn's disease (CD) is an inflammatory bowel disease associated with Mycobacterium avium subspecies paratuberculosis. The inflammation is a complex process that involves the activity of both innate and adaptive immune responses. CD lesions are primarily due to T cell response, however; innate immune response has a significant role in initiating its pathogenesis. Toll-like receptors and NOD-like receptors promote the activity of nuclear factor (NF)-κB pathway for cytokines production. This results in the production of high levels of tumor necrosis factor-α, interleukin (IL)-1β and IL-6. Moreover, intestinal inflammation of CD is related to increased activity of NMDA receptors and the release of substance P. Imbalanced magnesium homeostasis in CD is a frequent finding in CD, Diabetes and others. The loss of such a major mineral affects many physiological processes in the body including its role as an immunomodulator. This review aims to (1) describe the significance of hypomagnesemia in the release of pro-inflammatory mediators in CD; (2) demonstrate effects of magnesium on pathways like NF-κB; (3) address the role of hypomagnesemia in the activity of CD; and (4) examine possible future research to establish a standard magnesium supplementation strategy; helping patients with CD or other disorders to maintain a sustained remission.

Key words: Diabetes; Crohn's disease; Hypomagnesemia; Inflammatory bowel disease; Mycobacterium paratuberculosis

Core tip: Magnesium is an essential trace mineral, which plays key role as an immunomodulator in many pathways leading to homeostasis. Hypomagnesemia is common in patients with Crohn's disease (CD) and may be the cause of upregulation of pro-inflammatory factors leading to aggravating symptoms. Therefore, understanding the role of magnesium in maintaining a healthy immune response is important for effective treatment of patients with CD.

INTRODUCTION

Inflammatory bowel disease (IBD) generally describes a group of conditions sharing the characteristic of chronic inflammation of the gastrointestinal tract. The two most common conditions in this category are ulcerative colitis (UC) and Crohn's disease (CD)[1]. In both conditions, the immune system is mistaken food particles and normal flora for foreign materials[2,3]. This will induce an immune response attracting the leukocytes to infiltrate the

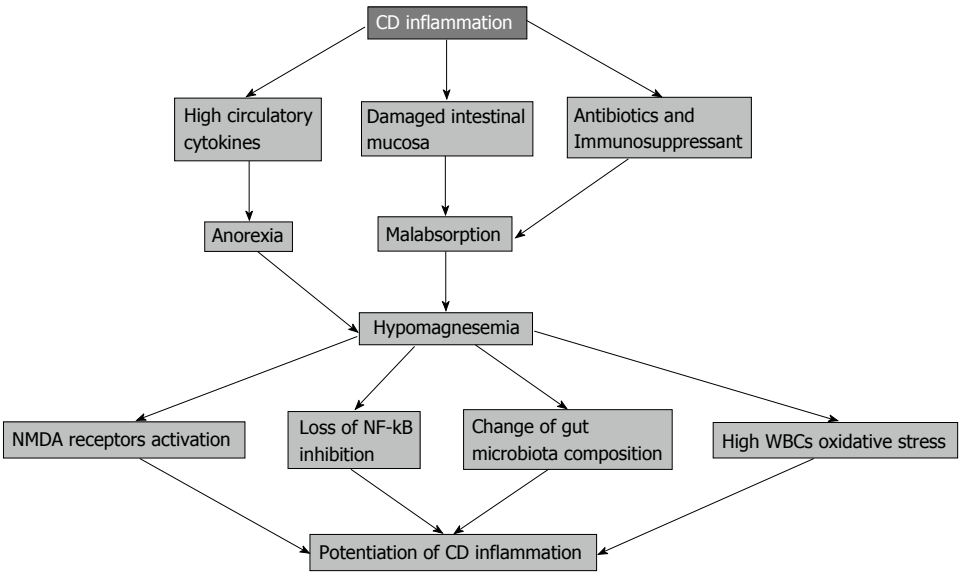

Figure 1 Role of hypomagnesaemia in Crohn's disease complications.

intestine. The result is destruction of intestinal mucosal cells leading to a state of chronic inflammation. Its distribution and involvement varies between UC and CD. UC is usually confined to the colon while CD can affect any site throughout the gastrointestinal tract from mouth to anus[4]. As both conditions progress, continuation of lesions in the colon becomes a characteristic for UC[5], whereas skipping some locations in the gastrointestinal tract or regional enteritis becomes a characteristic for CD[6]. Moreover, small bowels and the beginning of the large bowels are commonly affected in CD[1]. This difference in lesion locations contributes to the variations in the clinical presentation of UC and CD, as well as the severity of complications.

According to the Center for Disease Control and Prevention, both sexes are equally susceptible to IBD[7], with a majority of the affected population in between their 10 to 30 years of age[8]. Among the most susceptible are Caucasian and Ashkenazi Jewish origins[9]. As gold standard diagnosing criteria for IBD are lacking and the condition gets frequently misclassified, precise incidence and prevalence rates are limited. However, both conditions are noted to be at its highest rate of new diagnoses in industrialized North America and Europe for CD and UC, respectively[8]. In the United States, an estimated 1.4 million individuals suffer from IBD[3,7], of which 20.2 per 100000, per person years suffer from CD[8]. Although the etiology for IBD has not been well established, genetic components[4,8], diet, and environmental factors such as smoking[3] are associated with an increased risk of pathogenesis. Nevertheless, the impact of IBD in the United States creates a huge burden in the health care system, especially for CD with an estimated cost of $2.29 billion annually[10].

In particular, the high cost in CD can be attributed to therapeutic management, physician visits, and hospital stays because of the chronic nature and recurrence of the disease[10]. A detailed review of factors that can influence the persistence of CD might lead to establishing therapeutic strategies that can maintain remission for relatively longer periods. One of these factors includes nutritional deficiency due to malabsorption of vitamins and minerals such as magnesium, a frequent finding in CD patients particularly during high activity of the disease[11-15]. Magnesium deficiency or hypomagnesemia is very understudied and underestimated especially when it comes to its relation to CD (Figure 1). This finding encourages further research about the role of magnesium in inflammation and the possibility of linking this to the breakouts of the CD.

This review aims to (1) describe the significance of low magnesium levels in the release of pro-inflammatory mediators like interleukin 1 (IL-1), IL-6, tumor necrosis factor (TNF)-α as CRP levels; (2) demonstrate effects of magnesium on inflammatory response pathways like nuclear factor (NF)-κB; (3) address the role of hypomagnesemia in the activity of CD as one of the associated nutritional deficiencies; and (4) examine possible future research to establish a standard magnesium supplementation strategy to CD patients maintaining remission for relatively longer periods.

INFLAMMATION IN CD: INNATE *VS* ADAPTIVE

CD is primarily a T cell autoimmune disorder[16,17], however; innate immune response has a significant role in its pathogenesis, as we will demonstrate in this paper (Table 1). Traditionally, T helper 1 (Th1) cells were believed to be the main immune cells responsible for most of the intestinal tissue damage in CD[17,18]. Th1-related cytokines like interferon (IFN)γ, which acts as the major inflammatory mediator in CD[19], are released as a response to Th1 stimulation by IL-12 from naïve T cells[19,20]. Therefore, it was plausible to think that it is possible to control CD

Table 1 Key immune effectors for Crohn's disease inflammatory processes

	Role	Ref.
Toll-like receptors	Their overexpression promotes NF-κB pathway leading to immune intolerance to gut normal flora	[17,24,25,28]
IL-1 TNF-α	Stimulation of intestinal stromal cells to release matrix metalloproteinases leading to mucosal damage	[17,20]
Th1 Th17 cells	Secretion of IFNγ, IL-17 and IL-21 activating macrophages (MØ) and stromal cells to release MMPs	[4,17]
NMDA receptors, SP	Intestinal neuronal inflammation	[21,22]

NF-κB: Nuclear factor-kappa B; IL-1: Interleukin 1; MMPs: Matrix metalloproteinases; TNF: Tumor necrosis factor; IFN: Interferon; Th1: T helper 1; NMDA: N-methyl-D-aspartic acid; SP: Substance P.

Table 2 Magnesium and inflammation

	Role	Ref.
NF-κB Pathway	Inhibition of NF-κB p65 phosphorylation and stabilization of IκB protein	[29,39]
NMDA receptors, SP	Low magnesium enhances calcium influx through NMDA receptors	[12,38]
Neutrophilic oxidative stress	Increased levels of superoxide anions and nitric oxide in magnesium deficiency	[12]
Gut microbiota	Low magnesium changes the composition and intestinal permeability	[43]

NF-κB: Nuclear factor-kappa B; SP: Substance P; NMDA: N-methyl-D-aspartic acid; IκB: Inhibitory kappa B.

significantly if antibodies against IL-12 and IFNγ (*Fontolizumab*) are used as a potential therapeutic option[17]; however, this was eclipsed when the administration of these antibodies (anti-IL-12 and anti-IFNγ) showed a limited improvement in cases with active CD[20]. Recently, it was suggested that CD mucosal lesions are not caused only by Th1 cytokines, instead there is a possibility that other cells and mediators are also involved rather than Th1 cells alone as summarized in Table 1[17,20]. Examining mucosa of a terminal ileum from a CD patient before the appearance of lesions showed a large population of Th1 and macrophages releasing IFNγ and TNF-α, respectively; while samples from well-formed lesions presented a relatively equal response from Th1 and another set of cells, Th17, with dominance of their cytokines, IFNγ and IL-17A[17].

As shown in Table 2, this finding suggested a different set of active cells and cytokines presented as the disease progresses from early to late stages. Active lesions in CD are produced after a cascade of steps starting from the antigen presenting cells in the intestine. These cells get activated by luminal antigens triggering the differentiation of naïve T cells into either Th1 cells by IL-12 release or Th-17 cells by IL-6, IL-23, and transforming growth factor beta[4,17,20]. IL-21 from Th-1 and IL-17 from Th-17 will stimulate the release of matrix-degrading proteases from stromal cells[17,20]. Also, IFNγ from Th-1 will further activate macrophages that produce IL-1β and TNF-α, which will further trigger the release of more proteases[20]. Th17 are not stable cells, and as the inflammation continues to progress, they convert to Th-1 releasing more IFNγ during formation of late mucosal lesions[19]. This explains the persistence of high IFNγ levels towards late CD stages[20]. Therefore, it becomes clear that early stages of CD are dominated by Th1 cells, while late stages are mixed in control between Th1 and Th17 (Table 1)[17].

Furthermore, the effects of the adaptive immune system extend to the enteric nervous system. Neuronal inflammation and damage is a well-documented problem in IBD generally and in CD specifically[21,22]. A suggested mechanism for this pathology is explained through high activity of NMDA receptors in enteric neurons (Table 2). Leading to elevated levels of intracellular calcium, as a result, substance P (SP) will be released from these cells acting as a pro-inflammatory mediator increasing release of other inflammatory mediators such as TNF-α, IL-1 and IL-6 from macrophages and neutrophils, which adds to the overall exaggerated immune response in CD[21,22].

SP is a tachykinin peptide that has a high affinity for neurokinin-1 (NK-1) receptors on macrophages, neutrophils and mast cells, and the role of SP as a pro-inflammatory agent was proved when a specific antagonist for NK-1 receptors blocked the release of pro-inflammatory cytokines decreasing inflammation and severity of DSS-induced colitis in rats[22]. On the other hand, release of TNF-α and IL-1β has a role in the re-innervation of smooth muscle of intestine damaged in CD; through activation of NF-κB they were able to increase glial cell line derived neurotrophic factor expression in smooth muscles of intestine, making these cytokines neurotrophic and neurotoxic ones at the same time in a sense[21].

In contrast, the innate immune also plays a role in the pathogenesis of CD. Most of the commensal microbes we have in our bodies are located in the intestine, and this intestinal-microbial interface provides a large surface area for innate and adaptive immune response activities[23]. Cells like DC, M cells, and intestinal epithelial cells have the ability to detect and respond to these microbes[23]. This ability is provided by their surface expression of toll-like receptors (TLR), as well as intracellular NOD-like receptors (NLR), which are molecules that sense microbes through recognition of their PAMP[23-26]. PAMP that stimulates TLRs include bacterial lipoproteins, peptidoglycans and most importantly lipopolysaccharides (LPS)[24]. As shown in several studies[24,26,27], overexpression of TLRs (especially TLR2 and TLR4) is frequently observed in patients with IBD, which contributes to the dysfunction of immune tolerance to gut normal flora.

TLR and NLR promote the activity of NF-κB pathway, a major signaling pathway regulating the immune response through cytokine production and cell survival[24,25,28]. NF-κB molecules are transcription factors

stimulating a group of genes responsible for immune, inflammatory and apoptosis processes[24-26]. NF-κB induces the expression of its repressor IκB that binds to NF-κB molecules preventing their nuclear translocation[25]. Once IκB is phosphorylated, NF-κB becomes free to translocate into nucleus inducing the expression of pro-inflammatory cytokines[25,29]. Significance of this pathway in the inflammatory process of CD was established by the use of triptolide, a potent anti-inflammatory and immunosuppressant extracted from Chinese herb Tripterygium wilfordii Hook F[24]. The study showed that triptolide has down regulated TLR2 and TLR4 expression as well as NF-κB nuclear translocation, resulting in reduction in levels of pro-inflammatory cytokines in CD[24]. This finding suggested triptolide as a possible immunomodulator option for CD, and at the same time showed the strong link between TLR/NF-κB/pro-inflammatory cytokines in CD dysregulated immune response[24].

NUTRITIONAL LOSS IN CD

The inflammation caused by both innate and adaptive immune system leads to progression of CD, causing the loss of a significant functional intestinal area due to villous atrophy, fistulae formation and bacterial overgrowth[30]. These changes in the intestinal structure lead to loss of a variety of proteins, lipids, sugars, as well as vitamins and minerals, which locates the body in a negative nutritional status[13,15]. Other factors contributing to this negative balance in CD include: anorexia, abdominal pain, fasting for different tests, and medications like sulfasalazine used to control the disease or surgeries leading to short bowel syndrome[14,31]. For the same mentioned reasons, magnesium loss is a frequent finding in patients with CD as a result of the imbalanced magnesium homeostasis[13].

MAGNESIUM HOMEOSTASIS

This is maintained by the cooperation between three organs: intestine, kidneys and bones[32]. In the intestine, distal parts of jejunum and ileum are the most common sites for magnesium uptake[12,32]. Approximately 80%-90% of dietary magnesium absorption is achieved *via* paracellular transport, which depends on the permeability of tight junctions[32]. In addition, low expression of claudin 1, 3, 4, 5 and 8 proteins in the jejenum and ileum enables the passage of magnesium ions[33]. This mechanism is passive, allowing a majority of magnesium absorption without energy cost[12,32]. The rest of dietary magnesium is absorbed by the active transcellular transport *via* TRPM6 and TRPM7[12,32]. The latter mechanism allows magnesium to be transported into the blood from intestine through cell membrane[12,32]. Once absorbed, magnesium is stored mainly in bone tissue but traces can be found in muscles, where it acts as a natural calcium antagonist to control muscle contraction[12,32]. Lastly, most of the magnesium excreted from the body is processed by the kidneys, where 90%-95% of filtered magnesium daily gets retrieved *via* passive and active transport mechanisms[12,32].

MAGNESIUM IS NO TRACE ELEMENT: IT IS AN ESSENTIAL GIANT MINERAL

Magnesium is an important mineral in the human body like calcium, potassium and sodium[34,35]. When it comes to physiology, it is truly a "chronic regulator" and a "forgotten electrolyte"[34]. Magnesium is a cofactor for over 300 enzymes catalyzing phosphorylation reactions; it creates the proper conformational changes on their active sites so they fit their specific substrates, which regulates about 30% of total body proteins functions[34]. Regulation of cell cycle and apoptosis is achieved through many magnesium-dependent kinases, adding more weight on the significance of this mineral[34]. Production of the most common second messengers like c-AMP and c-GMP for different signal transduction pathways have magnesium involved in their regulation as well[34]. It is involved in the transport of many other electrolytes including calcium, potassium and sodium through its role in sodium/potassium ATPase activity, which explains the "refractory" nature of their disturbances to conventional treatment if the level of magnesium is low[34,36].

ROLE OF MAGNESIUM IN INFLAMMATION

Several studies have shown the importance of magnesium in inflammation that linked its low levels to many medical conditions such as diabetes type 2[37] (Barbagallo, 2007 #168), obesity, metabolic syndrome, osteoporosis, and cardiovascular diseases (Table 2)[12,38]. Levels of many pro-inflammatory cytokines varies depending on magnesium balance in the body, and among these cytokines, TNF-α IL-1 and IL-6 have the strongest relation[12,29,38]. Also, levels of CRP, a well-studied inflammatory indicator of low-grade and chronic inflammation synthesized by the liver, vary with magnesium status changes as well[12,38]. Effects of magnesium on inflammatory responses and mediators are widely distributed; therefore, it will be discussed separately as follows: (1) Magnesium as an anti-proinflammatory cytokine. Inhibition of NF-κB activity and increasing levels of IκBα are the backbone for this function (Table 2)[29]. NF-κB pathway is stimulated widely in the human body to regulate inflammation, cancer fighting, and cell survival[29]. Expression of cytokines IL-6 and TNF-α is induced during inflammatory responses triggered by TLR and NLR, which stimulates a downstream pathway to translocate NF-κB into nucleus for pro-inflammatory cytokines production[29,39]. IκBα is unstable due to its amino acids composition that is rich in proline, threonine and serine, explaining the constitutive breakdown rate affecting it[29,40,41]. IκBα level in monocytes were tested before and after magnesium sulfate supplementation following stimulation of TLR by LPS and it showed that level of

IκBα is higher in presence of higher intracellular magnesium[29]. The reason was not related to increased IκBα expression and protein synthesis, rather it was increased stability of IκBα, as proved by the use of protein synthesis inhibitor before and after TLR stimulation[29]. On the other hand, phosphorylation of NF-κB p65 is essential for its translocation, as well as its transcriptional effect to induce cytokines production; it was shown to decreased following magnesium supplement in LPS-TLR stimulated monocytes[29]. At the same time, expression of IκBα was decreased in the presence of increased intracellular magnesium sulfate supporting the finding of decreased activation of NF-κB in high levels of cellular magnesium sulfate[29,39]. As a result of inhibition of NF-κB translocation and transcriptional effect and the decreased phosphorylation of NF-κB, levels of TNF-α and IL-6 were significantly lower in LPS-TLR stimulated cells in the presence of high cellular magnesium levels[29,39]. Also, magnesium has preserved and stabilized more IκBα, which led to more suppression in NF-κB related cytokine production following LPS stimulation. In another study, it was shown that IL-8 expression is decreased following the same steps mentioned for LPS stimulation of cytokine production[39]; (2) Oxidative stress and magnesium. In an experiment conducted on magnesium deficient rats, there was a 40% increase in the level of superoxide anions and nitric oxide levels (Table 2)[12]. Also, there were increased levels of neutrophilic basal superoxide anions, as well as prostacyclin, prostaglandin E2, and thromboxane A2[12]. Red blood cells glutathione levels were decreased in the same experiment showing declining body antioxidant potentials in increased oxidative stress as a result of low cellular magnesium levels[12]; (3) Magnesium effect on NMDA receptors. Magnesium is a natural calcium antagonist and this was discussed in role of magnesium in muscle contraction[32]. From another perspective, NMDA receptors have a threshold of activation and it is lowered in states of decreased extracellular magnesium levels[38]. This will lead to an increase in calcium influx into the cell through NMDA receptors, resulting in increased production of pro-inflammatory prostaglandin E2, which was decreased upon blocking NMDA receptors[12,38]. Also, as calcium levels increases intracellular, the level of SP increases as a result stimulating NK-1 receptors leading to production of inflammatory mediators from macrophages, monocytes and neutrophils[38]. It is noteworthy to mention that the increase in NK-1 and substance P are well-known findings in IBD[12]. In addition to that, magnesium binds to the regulatory gates of calcium channels limiting calcium influx into the cell, and low extracellular magnesium levels will enhance the calcium influx triggering a greater inflammatory response[38]; (4) Magnesium, gut microbiota and intestinal permeability. It has been established before that gut microbiota [mainly bifidobacteria; a gram positive, non-motile anaerobic bacteria (Table 2)[42]] are decreased in endotoxemia, high fat mass index and glucose utilization disturbances[43,44]. Similarly, in another experiment, cecal content of bifidobacteria and lactobacilli were decreased in short-term (four days) magnesium deficient rats[43]. On the other hand, prolonged magnesium deficiency (21 d) has actually increased the cecal content of the mentioned bacteria, suggesting an adaptive response by the bacteria and an established demand for magnesium[43]. Bifidobacteria are microorganisms known for their ability to lower intestinal LPS content and thus enhance the mucosal barrier performance[43,45]. As the drop of magnesium levels decreases the cecal bacterial content, it also causes change in intestinal mucosal barrier, where mRNA of two of the junction proteins (ZO-1 and Occ) were noticed to decrease in ileum and proximal colon resulting in increased intestinal permeability for bacterial products and especially LPS to be increased systemically[43]. Accordingly, it was noticed that expression of CD14 receptors that bind LPS was elevated in gut in magnesium deficient mice, as well as increased expression of CD68 supporting the infiltration of monocytes in proximal colon[43]. The overall content of mRNA of TNF-α and IL-6 in proximal colon was increased in magnesium deficient mice[43]. These findings showed the effect of low magnesium on cellular inflammatory stress, which seemed to be limited to proximal colon rather than ileum[43]. Prolonged magnesium deficiency has an impact on the composition of gut microbiota as more bifidobacteria and lactobacilli will be present, and less bacteroids in the intestine[43]; and (5) Magnesium and C-reactive protein. As several studies investigated effects of dietary modification on inflammatory processes, CRP was among the most common inflammation indicators used for evaluation[46]. High levels of CRP were linked to obesity, metabolic syndrome, cardiovascular diseases and IBD[47]. They all share having an inflammatory component in their etiology and CRP was the tested variable in many studies[12]. As levels of IL-1β, IL-6 and TNF-α increase in the plasma, liver will respond by increasing production of CRP[38]. More specifically, serum high sensitive CRP (hs-CRP) has been used frequently due to its stability and easy detection, which has a normal level in plasma of < 3.0 mg/L[48]. Different conditions with low-grade or chronic inflammation states shared the sign of having elevated hs-CRP, indicating the strong inflammatory component they have[46]. CD activity has been strongly correlated to hs-CRP level[49], which is considered to be one of the main laboratory values that increase in relapses. Back to our mineral, magnesium is a significant immunomodulator that affects many inflammatory responses, and therefore its homeostasis is crucial for the overall body homeostasis. Low magnesium levels (< 1.2 mg/dL) were correlated to elevated levels of TNF-α, IL-1β, IL-6 and hs-CRP in plasma[12,38,46]. A study conducted on 5007 children (1999-2002) showed a significant increase in risk of having high CRP (1.94 times more) in children taking less than 50% of magnesium RDI[38]. One of the most interesting findings about magnesium and hs-CRP is that it was developed at University of South Carolina, showing that magnesium is the highest dietary factor in a 42-item dietary anti-inflammatory index they made for the study[46,48].

MAGNESIUM LOSS IN CD

With more than 32% of American people not meeting the daily requirement of magnesium dietary intake (4.5 mg/kg per day for adults), hypomagnesemia became a real concern for many practitioners[14]. Therefore, IBD adds a major cause for developing hypomagnesemia at different rates ranging from 13% to 88% of patients[14]. This deficiency is caused by many factors in CD including anorexia, food avoidance, intestinal surface loss due to diarrhea, fistulae or surgery as well as malabsorption[14]. Intestinal uptake of magnesium is defected dramatically as inflammatory processes of CD result in villus atrophy and fistulae formation, on top of increased bowel movement not allowing the time for magnesium absorption[32]. As the majority of magnesium absorption occurs passively, there will be no sufficient concentration gradient for magnesium uptake in intestine, as well as destructed enterocytes, losing the active transport component of magnesium absorption[32].

Nutritional loss in patients with CD is variable based on the disease activity status. Usually during remission of the disease, the body demand for macronutrient is covered by diet. However, micronutrient loss is frequent and supplementation is usually required even during remission of the disease[15]. Due to the chronic and extensive damage of intestinal mucosal cells, oral magnesium supplement is not recommended and parenteral forms are encouraged since the bioavailability will not be a concern in this case[13].

As CD result in malabsorption and loss of many vitamins, vitamin D in particular has a direct influence on magnesium and its intestinal absorption[32]. Claudin proteins involved in paracellular mechanism of magnesium absorption (the major mechanism) are regulated by active vitamin D, thus in CD, loss of fat soluble vitamins including vitamin D will lead to decreased magnesium absorption and hypomagnesemia[32]. As 75% of CD patients will require surgery at some point due to intestinal disease complications, short bowel syndrome will be a major cause of malabsorption affecting the levels of many nutrients including magnesium as well[14].

Also, magnesium absorption in the intestine is subjected to the amount of protein in diet and this is decreased in CD due to anorexia produced by circulating cytokines and food avoidance by the patients because of abdominal pain[32]. For all of those factors, magnesium will be in negative balance in CD patients (Figure 1).

EFFECTS OF MAGNESIUM ON CROHN'S PATHOGENESIS

By looking back at magnesium significance in the human body, it is obvious that the major effect magnesium can have on CD is from the immunity and inflammation point of views. However, other fields for magnesium influence on CD can be calcium disturbances, intestinal nerve supply and gut microbiota composition.

As established before in this paper, magnesium has the potential to be an effective cytokine antagonist. In different studies magnesium showed immunomodulation capabilities through controlling expression of pro-inflammatory cytokines, oxidative stress and neuronal damage. Through its effect on NF-κB, intracellular magnesium was able to limit NF-κB nuclear translocation as well as p65 phosphorylation activation step. On the other hand, intracellular magnesium preserved and stabilized IκBα limiting its degradation and applying more inhibitory effect on NF-κB pathways. As CD progresses and intestinal lesions develop, exposure of TLR and NLR to LPS will be more likely (Table 2). LPS is a potent TLR stimulator, which will activate NF-κB subsequently leading to production of IL-1, IL-6 and TNF-α. Hypomagnesemia is a frequent finding in CD, which means that the inhibitory effect on NF-κB pathway will be absent allowing more production of IL-6 and TNF-α that will trigger more mucosal damage *via* activation of the release of matrix-degrading proteases from intestinal stromal cells[20].

Among the structural changes that occur to intestinal mucosa due to CD, gut microbiota composition changes are also related to magnesium deprivation[43]. Short-term and long-term magnesium deficiency in mice showed significant changes in intestinal permeability and bacterial adaptation[43]. Low magnesium levels decreased bifidobacteria and increased risk of LPS endotoxemia since bifidobacteria can lower intestinal content of LPS[43]. Down-regulation of junction proteins ZO-1 and Occ mRNA as a result of magnesium deprivation caused an increase in intestinal permeability and this finding alone can describe the significant effect of hypomagnesemia in CD patients[43]. Role of magnesium in alleviating LPS immune response is essential for immune tolerance to gut commensal bacteria.

Among the inflammatory mediators associated with CD, CRP is one of the most sensitive markers of CD activity and relapsing status[50]. Its short half-life made it superior to other markers like ESR and fibrinogen which have longer half-lives and interference with other agents[50]. As demonstrated in many studies[12,38], serum CRP levels are elevated in diabetes type 2, obesity, metabolic syndrome, atherosclerosis, osteoporosis and alcoholism indicating the inflammatory component that links them together in etiology. At the same time, all of these conditions were also associated by hypomagnesemia suggesting a strong relationship between magnesium and CRP and its possible application on CD where levels of magnesium are reduced[12,38].

Calcium influx into neurons is largely regulated by extracellular magnesium[12,38]. Low magnesium levels due to CD will lower NMDA receptors activation threshold allowing more calcium entry into neurons[12,38]. Also, gated calcium channels will lose magnesium regulation over them and will allow more calcium influx, which adds to the overall free intracellular calcium[12,38]. Elevated levels of intracellular calcium are able to increase the release of

inflammatory SP that trigger more production of IL-1, IL-6 and TNF-α resulting in increase in the oxidative stress affecting intestinal sensory innervation causing symptoms like tenesmus (feeling of incomplete defecation) and frequent bowel movements[12].

Hypocalcaemia in CD is characteristic and has more than one cause resulting loss of many calcium functions throughout the body. First, as more vitamin D is lost in the frequent diarrhea associated with CD, calcium absorption at the intestine will be impaired[32]. On the other hand, low magnesium levels associated with CD results in increased calcium influx shifting most calcium into cells and causing calcium levels in plasma to drop even more[12,38].

Role of magnesium in muscle contraction as a calcium antagonist is essential for intestinal smooth muscle function in creating efficient peristalsis. It allows for periods of relaxation following contraction cycles caused by calcium. Also, SP is a regulator of smooth muscle contractility and hypomagnesemia elevates its levels leading to abnormal intestinal smooth muscle function. This function is essential to control bowel movement frequency in CD which is increased as a result of magnesium deficiency[32].

As levels of antioxidant vitamins like vitamin A, vitamin C and vitamin E are decreased in CD due to intestinal loss, oxidative stress effect on different cells increases including intestinal cells as well. Low magnesium levels showed an association with increased oxidative stress in individuals with no CD as levels of lipid peroxidation increase and production of free radicals like superoxide anion and nitric oxide is promoted[12]. These changes in CD with addition of hypomagnesemia augment the load of oxidative stress all over the body.

TARGETS FOR FUTURE DIRECTIONS

The integration of magnesium functions throughout the body is enormous and fields of future studies of that are numerous. However, when it comes to CD association with hypomagnesemia, some targets are very promising for possible maintenance of remission or even a cure of CD.

Most of drugs used to control CD have a long list of side effects and a possible toxicity with chronic use. Magnesium has shown great potentials on affecting the same pathways involved in CD inflammation as many therapeutic agents. On the other hand, magnesium is not expected to be cytotoxic and this hypothesis is very promising if magnesium is tested on specific regimens to block NF-κB signaling pathway in CD patients.

Role of magnesium in controlling calcium entry in neurons is significant in intestinal sensory innervation[12]. Hypomagnesemia leads to more nerve damage following SP activation and this effect carries a potential of modifying intestinal smooth muscle function and innervation in CD if magnesium supplement are tested for that.

Another area that is poorly understood is the role of magnesium in CD as a cofactor for most kinases and the possible changes of this rule during the disease. It is unclear whether this function affects CD activity and if so, in what way this is applied in cases of hypomagnesemia associated with CD.

Possible changes in gut microbiota composition following magnesium level alterations represent a big opportunity to further explore the role of normal flora in developing CD. Other minerals could play a similar role for the short term or long term changes in their levels. As data suggested, certain strains of microbiota like bifidobacteria turned out to have a role in lowering LPS and contributing to the intestinal mucosal barrier function and tolerance. Could other strains have different functions involved in immune responses and tolerance? A hypothesis can be based on the most common commensal strains and their possible role in local and systemic immune responses and possible implications in autoimmune diseases.

Magnesium supplementation for CD patients is strongly suggested by several research data. Maintaining magnesium homeostasis throughout the course of the disease is expected to minimize the inflammatory damage of CD improving the condition of many patients. However, conventional magnesium supplementation itself causes diarrhea which is the main reason magnesium is lost in CD. A therapeutic strategy for magnesium administration is strongly recommended.

CONCLUSION

CD is primarily an innate immunity dysfunction, and this disturbance develops to trigger an adaptive immune response resulting in mucosal intestinal surface damage. Among the numerous functions magnesium has throughout the body, immunomodulation is by the far the most involved function in CD activity and development. Chronic diarrhea among other problems in CD results in long term loss of magnesium, which makes hypomagnesemia a frequent finding in most CD patients. As the data showed, restoration of magnesium levels in CD patients can limit the activity of NF-κB, which is responsible for production of pro-inflammatory cytokines involved in CD inflammation. Additionally, many studies have suggested the disturbances in gut normal flora composition following short and long term hypomagnesemia. These have resulted in loss of immune tolerance to normal flora at the intestinal interface. Involvement of hypomagnesemia in NMDA receptors and SP release creates a direct effect on neuronal function of intestine and smooth muscle activity as well.

This review highlights some of the well-known functions of magnesium and their potential rule in shaping CD activity. It was strongly suggested by data that magnesium could play a significant rule in controlling CD. This review demonstrates a possible mutual effect of CD on magnesium level as well as hypomagnesemia on CD inflammatory processes. Future nutritional studies as well

as medical research are expected to focus more efforts to better understand effects of magnesium and CD on each other. Knowledge of these effects would create a strong basis for development of a potential therapeutic strategy to modulate the vast inflammatory effects CD has on its patients.

Abstract

Type 2 diabetes mellitus (T2DM) and hypertension represent two common conditions worldwide. Their frequent association with cardiovascular diseases makes management of hypertensive patients with T2DM an important clinical priority. Carvedilol and renal denervation are two promising choices to reduce plasma glucose levels and blood pressure in hypertensive patients with T2DM to reduce future complications and improve clinical outcomes and prognosis. Pathophysiological mechanisms of both options are under investigation, but one of the most accepted is an attenuation in sympathetic nervous system activity which lowers blood pressure and improves insulin sensitivity. Choice of these therapeutic approaches should be individualized based on specific characteristics of each patient. Further investigations are needed to determine when to consider their use in clinical practice.

Key words: Diabetes mellitus; Carvedilol; Renal denervation; Insulin resistance; Glucose; Hypertension; Metabolic disorders; Ablation

Core tip: Type 2 diabetes mellitus and hypertension are two common conditions worldwide which increase the risk of cardiovascular disease with resulting disabilities and mortality. Carvedilol and renal denervation are two promising therapies to decrease insulin resistance and lower blood pressure by attenuating sympathetic nervous system activity. This review examines the clinical reports of these novel approaches.

INTRODUCTION

Type 2 diabetes mellitus (T2DM) and hypertension (HTN) represent two common conditions worldwide. They increase the risk for the development of cardiovascular diseases with adverse clinical outcomes including disabilities and mortality[1]. The International Diabetes Federation reports that diabetes kills one person every six seconds and afflicts 382 million people worldwide. The federation estimates that the number of people affected by the disease is expected to climb to 592 million by 2035[2].

DM is a group of metabolic diseases characterized by impairment in glucose, lipid and protein metabolism, resulting from alterations in insulin secretion, insulin action or both. While four types of DM have been classified, T2DM is the most prevalent and accounts for 90% to 95% of all diagnosed cases[3-6]. Its pathophysiology includes an increase in insulin resistance (IR) in tissues with subsequent relative insulin deficiency[7]. A great number of T2DM patients suffer from associated car-

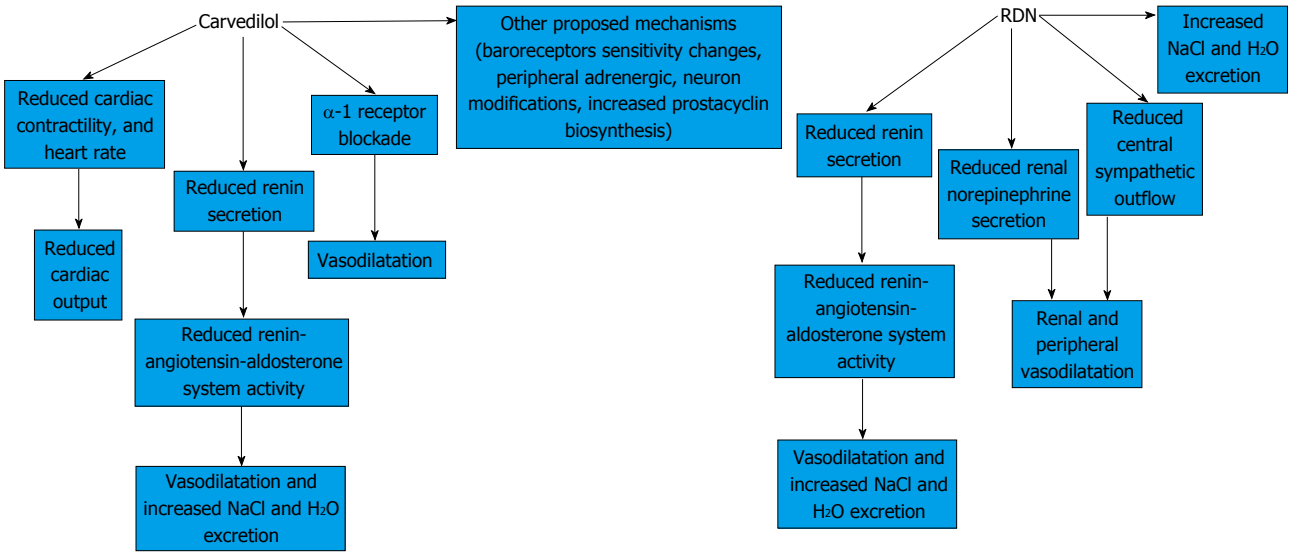

Figure 1 Antihypertensive mechanisms of carvedilol and renal denervation.

diovascular diseases. One of the most common is HTN. Over 60% of patients with T2DM have HTN[8] with resulting four-fold increased cardiovascular risk and death from complications[9,10].

Initial recommended treatment of HTN in patients with T2DM is angiotensin- converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). In the absence of cardiac comorbidity, traditional beta-blockers which increase IR do not constitute an initial choice for the treatment of HTN in patients with T2DM[4]. However, carvedilol which is a third-generation beta-blocker in some studies has demonstrated efficacy to reduce plasma glucose levels and IR[11-13] in patients with and without T2DM. Also in recent investigations, renal denervation (RDN) by catheter using radiofrequency energy has been associated with a decrease in IR in T2DM patients with an improvement in glucose control[14,15]. With both therapies the fall of plasma glucose concentrations and a reduction in blood pressure is likely due to an attenuation in sympathetic nervous system activity. Figure 1 reviews proposed antihypertensive mechanisms of carvedilol and RDN. These observations could open new choices to manage hypertensive T2DM patients with the use of one or both treatments. The benefit of improving patients' blood pressure would be complemented with an IR reduction, decreasing significantly the risk of future complications.

In this article we will review studies which suggest that carvedilol and RDN improve glucose metabolism as well as lower blood pressure in hypertensive patients with T2DM.

STUDIES THAT OBSERVED THAT CARVEDILOL IMPROVED GLUCOSE CONTROL IN HYPERTENSIVE PATIENTS WITH T2DM

It is well recognized that traditional beta-blockers have negative effects on glucose and IR[16]. In contrast, studies have demonstrated that carvedilol stabilizes plasma glucose levels and decreases IR, suggesting a novel therapeutic option in hypertensive patients with T2DM.

Carvedilol is a third-generation, nonselective beta-blocker that also possesses alpha-1 adrenergic blocking, antioxidant and calcium antagonist properties. It is a racemic lipophilic aryloxypropanolamine that causes both precapillary vasodilatation and is devoid of intrinsic sympathomimetic activity[17-20]. Carvedilol is absorbed rapidly after oral administration and it is cleared by aromatic-ring oxidation and glucuronidation in the liver. Compared with traditional beta-blockers, carvedilol has the same pharmacological actions of reducing heart rate and blood pressure[21-23]. Due to these properties, carvedilol has been used in the treatment of heart failure[24,25], angina pectoris[26,27], to improve cardiac function after myocardial infarction[28] and to reduce infarct size following myocardial ischemia and reperfusion injury[29]. Carvedilol is indicated for treating patients with congestive heart failure and after myocardial infarction with ejection fractions less than 40 percent because it has been shown to decrease mortality.

In general, traditional beta-blockers in hypertensive trials have been found to increase IR, facilitate weight gain and raise triglyceride levels. The metabolic benefits of carvedilol administration on plasma glucose reduction in patients with and without DM have been studied over many years and the results are summarized in Table 1 and discussed below.

Ehmer *et al*[30] conducted a study in non-insulin-dependent patients with DM with the aim to compare the antihypertensive effects and the influence on carbohydrate metabolism of carvedilol *vs* metoprolol tartrate. The results after eight weeks showed similar blood pressure reduction and in both groups plasma glucose concentrations remained within normal limits and glycated hemoglobin was unchanged.

Giugliano *et al*[12] compared the metabolic and cardio-

Table 1 Studies which observed glucose reduction carvedilol

Ref.	Study design	Participants	Main results
Ehmer *et al*[30]	Prospective randomized open parallel group trial	49 non-insulin-dependent diabetics with mild to moderate HTN (carvedilol *n* = 25, metoprolol *n* = 24)	Blood glucose concentrations were maintained within narrow limits. Glycated haemoglobin A1 remained unchanged. There was a reduction in blood pressure in both groups
Giugliano *et al*[12]	Prospective single-blind randomized trial	45 patients with non-insulin-dependent DM and HTN (carvedilol *n* = 23, atenolol *n* = 22)	Patients treated with carvedilol had improved glucose and lipid metabolism and reduced lipid perioxidation compared to atenolol. Both reduced blood pressure
Bakris *et al*[11]	Prospective double-blind randomized trial	GEMINI study, 1235 patients with HTN and T2DM (carvedilol *n* = 498, metoprolol tartrate *n* = 737)	The mean glycosylated hemoglobin increased with metoprolol, but not with carvedilol. An improvement of insulin sensitivity was seen with carvedilol but not with metoprolol
Phillips *et al*[32]	Prospective double-blind randomized trial	GEMINI study 1235 patients with HTN and T2DM (carvedilol *n* = 498, metoprolol tartrate *n* = 737)	After and adjustment for age carvedilol was superior than metoprolol reducing baseline glycosylated hemoglobin and also in female patients. In black people carvedilol showed a reduction in IR greater than metoprolol
Kveiborg *et al*[40]	Prospective randomized open parallel group trial	19 patients with T2DM (metoprolol succinate *n* = 10, carvedilol *n* = 9) and 10 controls	Treatment with carvedilol did not change insulin-stimulated endothelial function, whereas it deteriorated with metoprolol
Torp-Pedersen *et al*[46]	Prospective double-blind randomized trial	3029 patients with chronic heart failure and T2DM (carvedilol *n* = 1511, metoprolol tartrate *n* = 1518)	Fewer patients treated with carvedilol developed T2DM than with metoprolol
Wai *et al*[47]	Observational cohort trial	125 patients with T2DM and heart failure (carvedilol *n* = 80, bisoprolol *n* = 45)	Carvedilol significantly improved glycemic control in subjects with heart failure and T2DM
Basat *et al*[48]	Prospective double-blind randomized trial	59 patients with ST-elevation myocardial infarction (carvedilol *n* = 26, metoprolol *n* = 31)	After myocardial infarction, carvedilol added to background therapy improved insulin resistance and lipid profile

T2DM: Type 2 diabetes mellitus; HTN: Hypertension.

vascular effects of carvedilol *vs* atenolol in non-insulin-dependent T2DM hypertensive patients. Reduction in blood pressure was similar with carvedilol and atenolol, but the patients that received treatment with carvedilol had better metabolic responses. Over 24 wk, fasting plasma glucose, insulin and triglycerides levels decreased with carvedilol and increased with atenolol. In addition, an increase in high-density lipoprotein cholesterol level and decrease in lipid peroxidation was seen with carvedilol but not seen with atenolol. By improving glucose and lipid metabolism and reducing lipid peroxidation, the authors suggested that carvedilol may offer advantages in hypertensive patients with T2DM. The benefits of lipid reduction in high cardiovascular risk patients with DM have been demonstrated. In patients with DM the use of simvastatin resulted in a reduction in total mortality (43%), major coronary heart disease events (55%) and all atherosclerotic events (37%) and these reductions were greater than in non-diabetic patients[31]. In most guidelines, traditional beta-blockers are not recommended in hypertensive T2DM patients due to impairment in metabolic control and worsening lipid profile[4]. In contrast, carvedilol lowers blood pressure, improves glucose control and lipid profile, and, thus, is a unique choice in treating hypertensive T2DM patients.

An advance in this field was when researchers published the results of the GEMINI Trial which compared the glycemic and metabolic effects of carvedilol *vs* metoprolol tartrate in patients with HTN and T2DM already receiving renin-angiotensin system blockade[11]. This was a randomized, double-blind study, carried out in 1235 participants. Patients were randomized to receive a 6.25 to 25 mg dose of carvedilol (n = 498) or 50 to 200 mg dose of metoprolol tartrate (n = 737), each twice daily in addition to renin-angiotensin system blockers to achieve blood pressure goal of 130/80 mmHg. After a follow up of 35 wk, the mean of glycosylated hemoglobin increased with metoprolol [0.15% (0.04%); $P < 0.001$] but not with carvedilol [0.02% (0.04%); $P = 0.65$]. Also an improvement of insulin sensitivity was seen with carvedilol (-9.1%; $P = 0.004$) but not with metoprolol tartrate (-2.0%; $P = 0.48$). This study supports the previous benefits observed with the use of carvedilol to improve glucose control in hypertensive patients with T2DM. Particularly in this work, carvedilol associated with simultaneous administration of renin-angiotensin system blockers was superior to metoprolol tartrate to achieve this objective. In patients with diabetes, traditional beta-blockers have been shown to increase fasting glucose, increase hemoglobin A1C, facilitate weight gain and increase triglycerides by approximately thirteen per cent. In the GEMINI Trial, hypertensive diabetic patients receiving renin-angiotensin system blockade and receiving carvedilol demonstrated stabilization of glycemic control, improvement of IR, less effect on triglycerides and less development of microalbuminuria. This study supports earlier investigations suggesting that carvedilol is uniquely different than traditional beta-blockers.

More recently an extension of the GEMINI investigation was published analyzing treatment differences in subgroups on glycemic control comparing carvedilol and metoprolol tartrate in diabetic hypertensive patients

on renin-angiotensin system blockers[32]. Data analyses revealed that both carvedilol and metoprolol patients had significant and similar reductions in blood pressure. After adjustment for age there was a significant treatment benefit favoring carvedilol over metoprolol from change in baseline in glycosylated hemoglobin (0.022% *vs* 0.057%, $P = 0.003$) and IR (-9.09% *vs* -1.76%, $P = 0.015$). Female patients who received carvedilol were favored with a reduction in baseline glycosylated hemoglobin (-0.04% *vs* 0.16%, $P = 0.003$). In regard to race, carvedilol showed better results than metoprolol in African Americans patients from baseline in HOMA IR levels (-17.0% *vs* 8.2%, $P = 0.01$). The fact that carvedilol showed good blood pressure reduction and reduced glycosylated hemoglobin and IR in African American patients has important clinical implications. African Americans represent a special hypertensive group with a poor prognosis and with increased risk to develop additional complications, which are associated with the existence of frequent comorbidities and genetic predispositions[33-36]. African American T2DM hypertensive patients frequently have poor blood pressure responses to renin-angiotensin system blockers[37-39]. The GEMINI results suggest that carvedilol may be useful in the treatment of hypertensive African American patients with T2DM. Carvedilol has the potential of achieving better metabolic control, reducing blood pressure with few side effects, and improve clinical outcomes. This option needs further investigation, but this study should stimulate future work in these patients.

In further support for the unique properties of carvedilol, Kveiborg *et al*[40] examined the effects of carvedilol and metoprolol tartrate on insulin-stimulated endothelial function in patients with T2DM. These results also support the benefit of carvedilol compared with metoprolol observed in earlier studies. Treatment with carvedilol did not change insulin-stimulated endothelial function, whereas it deteriorated with metoprolol. IR is recognized as a pathophysiological cause of glucose disorders in patients with T2DM[7] and there are many reports about the relationship between this metabolic disorder and cardiovascular diseases[41,42]. Since traditional beta-blockers confer negative metabolic effects, carvedilol should be considered in the long term treatment of patients with cardiovascular disease[43-45].

Carvedilol also has been examined in the development of new onset of T2DM in patients with congestive heart failure. A total of 3029 patients with chronic heart failure were randomly assigned treatment with carvedilol or metoprolol tartrate. Fewer patients who received carvedilol were diagnosed with T2DM (119/1151 or 10.3%), compared to the metoprolol group (145/1147 or 12.6%) (HR = 0.78, CI: 0.61 to 0.997; $P = 0.048$)[46]. The results suggest that T2DM and other metabolic disorders could be avoided or at least delayed with administration of carvedilol in patients at risk.

Another study evaluated the use of carvedilol in patients with systolic heart failure[47]. Carvedilol did not affect glycemic control in patients with T2DM and additionally it had a neutral effect on lipid profile and albuminuria status, confirming earlier observations.

Basat *et al*[48] studied 59 patients after a myocardial infarction to compare the effects of carvedilol *vs* metoprolol tartrate on IR and serum lipid. After 12 wk of treatment, carvedilol showed a significantly greater reduction in insulin, C-peptide, total cholesterol and triglyceride levels than metoprolol. The authors concluded than carvedilol could constitute an option to improve IR and lipid profile in patients after myocardial infarction. In patients with coronary artery disease and specifically in those after myocardial infarction, both poor glycemic control and lipid profile are well-known risk factors which increase the number of complications and impair the prognosis[49,50]. Choosing carvedilol in these high risk patients appears indicated because of its unique metabolic advantages compared to traditional beta- blockers.

STUDIES THAT OBSERVED THAT RDN IMPROVED GLUCOSE CONTROL IN HYPERTENSIVE PATIENTS WITH T2DM

RDN has emerged as a promising treatment for HTN[51-55]. Symplicity HTN-1[56] and HTN-2[57] studies demonstrated the efficacy and safety of RDN in patients with resistant HTN. State-transition modeling suggests that RDN is a cost-effective strategy for resistant HTN that can reduce the risk of stroke, myocardial infarction, coronary heart disease, heart failure and end-stage renal disease[58]. Another study suggests that potential lifetime cost-effectiveness ratios may be increased when RDN is performed earlier in patients with resistant HTN[59]. Follow-up of Symplicity patients demonstrate a durable blood pressure reduction out to 36 mo[60].

The principles of catheter-based RDN are based on the influence of afferent and efferent renal nerves in blood pressure physiopathology. As shown in Figure 1, after an ablation of renal nerves there is a reduction in blood pressure, sympathetic nervous system activity and renin-angiotensin system activity and increase in water and salt excretion[61].

Based on these observations, some investigators have examined catheter-based RDN on glucose control. Table 2 describes studies which observed glucose reduction after RDN. These studies were based on the knowledge that sympathetic overactivity can induce IR and hyperinsulinemia. Mahfoud *et al*[14] designed an investigation which enrolled 50 patients with resistant HTN. The group study ($n = 37$) received bilateral catheter-based RDN and the control group ($n = 13$) was assigned to continue medical therapy. Three months after treatment fasting glucose was reduced in the RDN group from 118 ± 3.4 to 108 ± 3.8 mg/dL ($P = 0.039$). Insulin levels were decreased from 20.8 ± 3.0 to 9.3 ± 2.5 μIU/mL ($P = 0.006$) and IR decreased from 6.0 ± 0.9 to 2.4 ± 0.8 ($P = 0.001$). Mean 2-h glucose levels during oral glucose tolerance testing were also reduced significantly by 27 mg/dL

Table 2 Studies which observed glucose reduction after renal denervation

Ref.	Study design	Participants	Main results
Mahfoud *et al*[14]	Prospective, controlled unblinded, randomized study	50 patients with resistant HTN (37 patients underwent catheter-based RDN and 13 patients in a control group	RDN improved glucose metabolism and insulin sensitivity in addition to a significantly reducing blood pressure
Witkowski *et al*[65]	Prospective, nonrandomized, open-label study	10 patients with refractory hypertension and sleep apnea (7 men and 3 women, who underwent RDN)	RDN reduced blood pressure and improved glucose metabolism

HTN: Hypertension: RDN: Renal denervation.

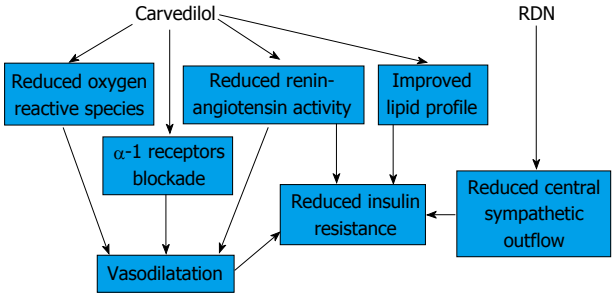

Figure 2 Proposed mechanisms to explain decreased insulin resistance with carvedilol and renal denervation in type 2 diabetes mellitus patients with hypertension.

(P = 0.012) while there were no significant changes in BP or any of the metabolic markers in the control group. These excellent results in metabolic control were accompanied by a significant reduction in blood pressure. This was the first study proving the efficiency of RDN to reduce IR and improve glycemic control. RDN represents one of the most promising non pharmacological strategies to treat HTN, thus, the possibility observed in this research to reduce blood pressure and concomitant IR may open new options for patients.

Guidelines of some societies recommend that patients who receive RDN continue antihypertensive medical therapy after the procedure because the blood pressure often decreases slowly[62,63]. In this study it is suggested that the improvements seen in glucose control are due to a reduction in central sympathetic outflow after RDN. If further studies support this concept in patients with T2DM other conditions with IR like obesity merit study[64].

There is further support for the concept than RDN may benefit glucose control. Other investigators have examined the effects of RDN on blood pressure, sleep apnea course, and glycemic control in patients with resistant HTN and sleep apnea. RDN decreased blood pressure, attenuated sleep apnea severity and decreased two hour post prandial plasma glucose and glycosylated hemoglobin levels[65].

PROPOSED MECHANISMS TO EXPLAIN A PLASMA GLUCOSE REDUCTION FROM CARVEDILOL AND RDN

There are several mechanisms as shown in Figure 2 that may explain improved glycemic control with the use of carvedilol and RDN.

Traditional beta-blockers cause an increase in peripheral vascular resistance due to unopposed alpha vasoconstriction with resultant reduced glucose disposal to skeletal muscles and reduction in glucose uptake[66]. Carvedilol has alpha-1 blocker properties that causes vasodilatation and maintenance of blood flow to skeletal muscles. This difference may explain in part carvedilol's actions on glucose control compared to traditional beta-blockers.

Another mechanism by which carvedilol may improve glucose control is by reducing oxygen reactive species. T2DM is associated with endothelial dysfunction with increased reactive oxygen species and decreased endothelial nitric oxide synthase activity[67]. This phenomenon causes a reduction in oxide nitric availability with resultant vasoconstriction. Giugliano *et al*[12] found an increase in insulin sensitivity with a concomitant reduction in oxidative stress in patients with T2DM treated with carvedilol. Because carvedilol has antioxidant properties it appears to decrease reactive oxygen species and improve endothelial function. Other investigators have also found that carvedilol significantly reduced oxidative stress and C-reactive protein levels in hypertensive patients[68] and increased activity of antioxidant enzymes in diabetic rats[69].

On the other hand there are studies which have demonstrated that IR is related to an increase in sympathetic nervous system activation. An increase in sympathetic nerve activity and HTN in Caucasians with IR has been observed[70]. T2DM and HTN are known to be closely linked with increased sympathetic nervous activity and IR[71,72]. Reflex sympathetic activation has been shown to induce acute IR in the human forearm[73]. Carvedilol causes a significant reduction in cardiac and systemic norepinephrine spillover and this effect was not seen with other beta-blockers like metoprolol[74,75]. The relationship between an increase in sympathetic nervous activity and the development of IR, and the ability of carvedilol to reduce systemic norepinephrine may in part explain the findings of this drug reducing glucose levels. Similar results reducing norepinephrine spillover have been seen with the use of catheter-based RDN[56]. Increased sympathetic nervous system activity in tissues can result in IR. There is evidence of impaired ability of the cells to transport glucose through their membranes due to a decrease in blood flow after a rise in noradrenaline concentration[73]. The mechanism could be related to an

Table 3 Comparison between carvedilol and renal denervation as therapeutic choices to reduce blood pressure and glucose levels in hypertensive type 2 diabetes mellitus patients

Therapeutic method	Mechanism of action	Medical indication	Mechanisms which explain glucose reduction	Contraindications	Side effects
Carvedilol	α1, non-selective β-blocker, antioxidant and calcium antagonist properties[17-20]	Treatment of hypertension[21] heart failure[25] and coronary artery disease[27]	An improvement in insulin sensitivity by a reduction in sympathetic nerve activity[74,75] and free radicals[68,69]	Bronchial asthma, second-third degree atrioventricular block, sick sinus syndrome, severe bradycardia, patients with severe cardiogenic shock and heart failure who use inotropic drugs and hepatic impairement[17-20]	Frequent: edema, dizziness, bradycardia, hypotension, nausea, diarrhea and blurred vision Rare: deterioration of renal and hepatic function[17-20]
RDN	Ablation of afferent and efferent renal nerves[51-55]	Treatment of resistant hypertension[56,57]	An improvement in insulin sensitivity by reduction in sympathetic nerve activity[56,57]	Polar or accessory arteries, renal artery stenosis, prior renal revascularization and glomerular filtration rate < 45 mL/min per 1.73 m^2[56,57,62]	Renal artery dissection, postprocedural hypotension, femoral artery pseudoaneuryn, intraprocedural bradycardia[56,57]

increased distance that insulin has to travel from intravascular compartment to cell membranes due to a reduction of number of open capillaries as a consequence of vasoconstriction by sympathetic overactivity.

Another mechanism by which carvedilol may improve glucose control could be through the positive effects of carvedilol improving lipid profile. There appears to be a direct relationship between free fatty acids and IR. It is not fully understood why high plasma levels of fatty acids can produce IR, but a proposed mechanism is that permanent increases in plasma free fatty acids results in an intracellular accumulation of triglycerides and other compounds involved in triglyceride synthesis. Some of these compounds can activate a novel protein kinase C, and this protein is able to cause IR by decreasing tyrosine phosphorylation of the insulin receptor substrates[76-78]. Thus, the improvement in lipid profile observed with carvedilol[11,12] may in part explain, its ability to increase insulin sensitivity and subsequently improve glucose control.

Both carvedilol and RDN appear to reduce glucose levels by a decrease in IR and this change is associated with a reduction in sympathetic nervous system activity. However, beyond this possible relationship there are other possible mechanisms to explain improved glucose control after administration of carvedilol. Further investigations are needed to understand the metabolic pathways resulting in improved glucose control with the use of carvedilol and RDN.

COMPARISON BETWEEN CARVEDILOL AND RDN TO REDUCE GLUCOSE LEVELS

A comparison between carvedilol and RDN as options to reduce blood pressure and glucose levels in T2DM hypertensive patients is listed in Table 3. While carvedilol is administrated as an oral medication which requires patient's adherence, RDN is an interventional procedure whose safety and durability is still under investigation. Clinical trial data from Symplicity radiofrequency catheter systems have created much interest in the role of the renal nerves in HTN and other conditions such as diabetes mellitus. Furthermore, the attenuation of blood pressure observed has led to the rapid development of alternative methods of RDN by radiofrequency ablation as well as by ultrasound ablation and peri-vascular pharmacologic ablation. Many trials investigating these various innovative approaches to achieve RDN are ongoing. The factors which should be examined when considering carvedilol and/or RDN are the efficacy, safety and cost. Also, physicians need to individualize the recommended treatment because depending on physiological characteristics patient responses (and benefits) will vary.

PERSPECTIVE

Patients with HTN and T2DM require long term therapy. Thus, choice of antihypertensive agents results in long term risks and benefits. Initial recommended treatment of HTN in patients with T2DM is ACE inhibitors or ARBs which have favorable effects on carbohydrate metabolism and insulin resistance. Long-acting dihydropyridines have a neutral effect on glucose metabolism and insulin resistance. In contrast, thiazide-type diuretics can cause hyperglycemia and traditional beta-blockers can increase IR. Furthermore, hypertensive patients with increased cardiovascular risk may require 3-hydroxy-methylglutaryl coenzyme A reductase inhibitors, or statins, which appear (with the exception of pravastatin) to increase the risk of patients developing T2DM. Carvedilol and RDN appear to improve insulin sensitivity and glucose metabolism as well as lower blood pressure. Some guidelines recognize carvedilol's unique metabolic advantages compared to traditional beta-blockers and recommend its use in patients with HTN and T2DM if blood pressure goals have not been achieved using ACE inhibitors or ARBs. Carvedilol has been shown to stabilize HbA1c, improve insulin resistance, and slow development of microalbuminuria in the presence of renin-angiotensin system blockade compared with metoprolol tartrate[11].

Use of carvedilol should be individualized in patients with HTN and T2DM. In general, beta-blockers may mask some of the manifestations of hypoglycemia, particularly tachycardia. Nonselective beta-blockers may potentiate insulin-induced hypoglycemia and delay recovery of serum glucose levels. Patients subject to spontaneous hypoglycemia, or diabetic patients receiving insulin or oral hypoglycemic agents, should be cautioned about these possibilities. Furthermore, beta-blockers can precipitate or aggravate symptoms of arterial insufficiency in patients with peripheral vascular disease. Caution should be exercised in such individuals.

Presently RDN should only be considered in patients with resistant hypertension after causes of secondary hypertension have been excluded, with fairly preserved renal function and eligible renal arterial anatomy. It is not recommended to perform RDN in patients with HTN and T2DM outside of appropriately designed clinical trials.

CONCLUSION

Carvedilol and RDN improve glucose metabolism and insulin sensitivity in parallel with blood pressure reduction. These novel approaches may therefore provide benefit in patients with resistant HTN and T2DM who are at high cardiovascular risk and have not reached recommended goals to improve endothelial function and preserve renal function. An attenuation in sympathetic nervous system activity is the most likely mechanism to explain these actions. There have been no head-to-head comparisons, but RDN appears to have a greater effect on glucose metabolism than carvedilol. Further investigations and follow up are needed to determine the long-term durability of RDN, its efficacy in other diseases such as heart failure, stroke and kidney failure, and its use in stage 1 HTN. Currently, there are no clinical trial data available to indicate that RDN improves cardiovascular outcomes. If further trials confirm blood pressure lowering and improved glucose metabolism with carvedilol and RDN, these approaches represent reasonable choices for the treatment of patients with HTN and T2DM who have not reached guideline goals. These novel approaches could be used together to reach goals. Use of these novel treatments should be individualized in patients taking into account efficacy, safety, and cost.

Abstract

Diabetic foot ulcers are the consequence of multiple factors including peripheral neuropathy, decreased blood supply, high plantar pressures, *etc.*, and pose a significant risk for morbidity, limb loss and mortality. The critical aspects of the wound healing mechanism and host physiological status in patients with diabetes necessitate the selection of an appropriate treatment strategy based on the complexity and type of wound. In addition to systemic antibiotics and surgical intervention, wound care is considered to be an important component of diabetic foot ulcer management. This article will focus on the use of different wound care materials in diabetic foot. From a clinical perspective, it is important to decide on the wound care material depending on the type and grade of the ulcer. This article will also provide clinicians with a simple approach to the choice of wound care materials in diabetic foot ulcer.

Key words: Diabetes; Foot; Wound; Debridement; Topical

Core tip: Diabetic foot ulcers are an important complication of diabetes. There is no conventional guideline regarding the selection of wound care materials in diabetic foot wounds. This article includes fundamental aspects of wound care and management with special emphasis on the selection of appropriate wound care materials depending on the type of wound tissue. Risk factors for foot ulceration, classification and grading of wounds, bacteriology, multidisciplinary team approach, types of debridement, importance of offloading, wound care and choice based on the complexity of the wound and properties of the dressing regime in each category based on clinical experience and practice are discussed.

INTRODUCTION

The increasing prevalence of diabetes has resulted in concomitant illness[1]. The critical effects of hyperglycemia include micro-vascular complications (nephropathy, neuropathy and retinopathy) and macro-vascular complications (coronary artery disease, stroke and peripheral arterial disease). Diabetes is a leading cause of non-traumatic lower extremity amputation, which is often

Figure 1 Wound classification based on the Red-Yellow-Black wound classification system by Marion Laboratories. A: Necrotic tissue; B: Sloughy tissue; C: Granulating tissue; D: Epithelializing tissue.

preceded by a non-healing ulcer. The lifetime risk of foot ulceration in people with diabetes is 15%-20%[2]. More than 15% of foot ulcers result in amputation of the foot or limb[3]. Several other population-based studies indicate a 0.5%-3% annual collective incidence of diabetic foot ulcers. The prevalence of foot ulcers reported varies from 2% to 10%[4]. Approximately 45%-60% of all diabetic foot ulcerations are purely neuropathic, whereas 45% have both neuropathic and ischemic components[5]. It has been estimated that around 15%-27% patients with diabetes require lower limb amputations predominantly (50%) due to infection[6].

DIABETIC FOOT

Definition

Infection, ulceration or destruction of deep tissues associated with neurological abnormalities and various degrees of peripheral vascular diseases in the lower limb (World Health Organization definition, 1995).

Risk factors

Diabetic foot ulcers are a consequence of many factors including loss of protective sensation due to peripheral neuropathy where the feet become numb and the injury goes unnoticed. Also, arterial insufficiency complicates the neuropathic ulcer which leads to poor wound healing. Foot deformity and calluses can result in high plantar pressure, which results in additional risk. Mechanical stress at the wound site is hypothesized to affect wound healing[7]. Many other factors contribute to the risk of foot ulceration and its subsequent infection in patients with diabetes. Uncontrolled hyperglycemia, duration of diabetes, trauma, improper footwear, callus, history of prior ulcers/amputations, older age, blindness/impaired vision, chronic renal disease and poor nutrition have also been demonstrated to play a role in the pathogenesis and progression of diabetic foot ulceration. Infection further deteriorates the diabetic foot resulting in a non-healing chronic wound. Recently, vitamin D deficiency was proposed as a risk factor for diabetic foot infection[8].

Classification

Based on the Red-Yellow-Black[9] wound classification system by Marion Laboratories, wounds can be classified as follows[10]: (1) Necrotic tissue-either dry or infected and usually black or dark green in color as shown in Figure 1A; (2) Sloughy tissue-combination of wound exudate and debris forming a glutinous yellow layer of tissue over the wound which is often mistaken for infection as shown in Figure 1B; (3) Granulating tissue-highly vascularized, red in color and sometimes highly exudating as shown in Figure 1C; and (4) Epithelializing tissue-Epithelium grows over a wound formed by migration of keratinocytes from the wound margins, which looks pink in color as shown in Figure 1D.

Debridement of necrotic tissue is an integral component in the treatment of chronic wounds as they do not heal in the presence of unviable tissue, debris, or critical colonization[11,12] and may be contraindicated in arterial ulcers[13]. Excision of necrotic tissue is necessary for wound healing. Calluses or thickened skin surrounding the ulcer

need to be excised. Necrotic tissue removed on a regular basis can expedite the rate at which a wound heals and has been shown to increase the probability of attaining full secondary closure[14,15].

Grading

Grading can be done using Wagner's or the Texas wound classification system[16]. The most common is the University of Texas wound classification system, which describes the wound with regard to depth, presence or absence of infection or ischemia or both. A description of the wound is important for wound care choice and includes the location, stage, dimension in length, breadth and depth (length and breadth can be measured in centimeters by tracing it on a sterile acetate sheet and depth can be taken by inserting a sterile swab gently into the deepest part of the wound), wound edges (undermining), wound base description, drainage (heavy or low), color, odor, pain and progression, *etc*[17].

Microbiology

Hyperglycemia, impaired immunologic responses, neuropathy, and peripheral arterial disease are the major predisposing factors leading to limb-threatening diabetic foot infections[18-20]. The prevalence of infection in India was 6%-11%, whereas the prevalence of amputation was 3% in patients with type 2 diabetes[21]. Both aerobic and anaerobic bacteria have been shown to infect diabetic foot wounds[22-25]. Fungal infections are also common in diabetic foot[26-28]. Polymicrobial etiology of diabetic foot infections has been widely reported[22-25,29]. However it is not uncommon to have a predominance of mono-microbial infection in diabetic foot[30]. Researchers have shown the predominance of both gram negative[30] and gram positive[26] bacteria in diabetic foot infections. Various studies have reported a high prevalence of *Pseudomonas*[31], *E. coli*[30], and *S. aureus*[26,30] infections in diabetic foot. The pattern of microbial infection in patients with diabetic foot infections is inconsistent and therefore evaluation of microbial characteristics and their antibiotic sensitivity is necessary for the selection of appropriate antibiotics for management of diabetic foot infection.

MANAGEMENT TECHNIQUES

The foot is a complex structure, which acts as a foundation for the whole body, and it is important to prevent progression of diabetic foot problems. The integration of knowledge and experience through a multidisciplinary team approach promotes more effective treatment, thereby improving outcomes and limiting the risk of lower extremity amputation[32,33]. Therefore the following specialists play an important role: (1) Endocrinologist/Diabetologist (optimize blood glucose control); (2) Podiatrist (focus on the foot including prevention and treatment of diabetic foot wounds); (3) Vascular surgeon (manage vascular issues); (4) Microbiologist (look into microbiological etiology and antibiotic selection based on cultures); (5) Orthotist (ensures that therapeutic or custom made footwear aids in minimizing pressure); and (6) Nutritionist (concentrates on diet which helps in the management of diabetes as well as wound healing).

Wound healing is a complex process involving highly regulated responses of specified cell types, which harbor locally secreted growth factors that play a key role in wound healing[34]. Treating a diabetic foot infection requires proper wound care and appropriate antibiotic therapy[19]. The fundamentals of good clinical care includes adequate frequent debridement, offloading, moist wound care, treatment of infection, and revascularization of the ischemic limb[35]. In addition, wound healing can be enhanced by the appropriate choice of a topical regime (mixed range of standard and advanced topical therapies), however, adequate training and significant clinical experience are essential for making this choice. Many factors including assessment of the wound, its classification, and the need for debridement including sharp surgical, mechanical, chemical, *etc*., have to be taken into consideration before proceeding with the appropriate selection of topical regimen.

Debridement

Debridement involves removal of dead, damaged, or infected tissue, which improves the healing potential of the remaining healthy tissues. Depending on the wound tissue type, different debridement techniques are recommended[36,37]: (1) Surgical debridement or sharp debridement-recommended for necrotic and infected wounds. The terms surgical debridement and sharp debridement are often used synonymously, some clinicians refer to surgical debridement as being performed in an operating room, whereas sharp debridement is performed in a clinic setting[38]. Sharp surgical debridement is the most effective and fastest method of debridement; (2) Autolytic debridement-a selective process in which the necrotic tissue is liquefied. A wound covered with an occlusive dressing allows accumulation of tissue fluids containing macrophages, neutrophils, and enzymes, which remove bacteria and digest necrotic tissues. This is achieved by a moist wound healing environment[36]. Autolytic debridement is not advisable for the treatment of infected pressure ulcers[39]; (3) Mechanical debridement-involves removal of unhealthy tissue using a dressing, which is changed regularly by wound irrigation (pressure: 4-15 psi), without damaging healthy/new tissues[40]. Scrubbing the wound aids in removal of exudates and devitalized tissues, however this leads to bleeding as well as pain resulting from wound trauma. This technique is used in the management of surgical wounds and venous leg ulcers. The drawbacks of the method is that it is time consuming and expensive; (4) Enzymatic debridement-a method of debriding devitalized tissue by topical enzymes such as collagenase, fibrinolysin, or papain. Recommended for sloughy, infected, necrotic wounds where surgical debridement is contraindicated[41]; and (5) Maggot debridement-a technique in which maggots or fly larva that

Table 1 Antibiotic recommendation based on the severity of the infection

Site	Severity or extent	Route of administration	Duration of therapy
Soft tissue only	Mild	Topical or oral	1-2 wk may extend up to 4 wk if slow to resolve (outpatient)
	Moderate	Oral (or initial parenteral)	1-3 wk (Outpatient/inpatient)
	Severe	Initial parenteral, switch to oral when possible	2-4 wk (Inpatient, then outpatient)
Bone or joint	No residual infected tissue (*e.g.*, post-amputation)	Parenteral or oral	2-5 d
	Residual infected soft tissue (but not bone)	Parenteral or oral	1-3 wk
	Residual infected (but viable) bone	Initial parenteral, then consider switching to oral	4-6 wk
	No surgery, or residual dead bone post-operatively	Initial parenteral, then consider switching to oral	⩾ 3 mo

are raised in a sterile environment are used. The most commonly used fly is Lucilia sericata, which is used for human wound treatment when conventional treatments fail[42]. Maggots are placed on the wound followed by wrapping with secondary dressing. The larvae feed on the necrotic (dead) tissue and bacteria present at the wound site and secrete antimicrobial enzymes, which help in the wound healing process.

Offloading

Completely or partially relieving pressure from the weight bearing area of the foot by providing mechanical support with the intention of giving rest to the wound area aids in healing. Repetitive trauma and high plantar pressure on the ulcer bed are two primary reasons for the persistence of ulcers once they have developed[43]. Offloading is very important in diabetic wound healing. There are many types of offloading techniques including total contact casts, removable cast footwear, wedge footwear, half shoes, mobilization by wheelchair, *etc*. Total contact casts are considered to be the gold standard method of offloading and treating diabetic patients with neuropathic ulcers[32,44-46].

Wound care

Wound care plays a pivotal role in the management of diabetic foot ulcer, which comprises cleaning the wound with normal saline following aseptic techniques and the use of modern wound care techniques that promote a moist wound healing environment[47,48]. Although topical treatment is an important aspect of wound care, it is always considered secondary to surgical and systemic care[49]. There are numerous topical regimens and devices available for the management of diabetic foot wounds including hydrogels, hydrocolloids, alginates, foam, silver impregnated dressings, growth factors, silicon impregnated atraumatic dressings, vacuum aided devices, hyperbaric oxygen therapy, *etc*. However, before choosing a regime one should consider factors such as the general health of the patient, the process of tissue repair, assessment of the wound by means of grading, description and classification of the wound, local environment of the wound, knowledge on specific properties of the dressing materials and devices as well as their availability, affordability, and accessibility.

The ideal characteristics of a wound dressing are as follows[50,51]: (1) Sterile, easy to use, cost effective; (2) Maintain a moist wound healing environment; (3) Absorb excess exudate; (4) Non-adherent/non-toxic, non-allergic; (5) Not contaminate the wound with foreign particles; (6) Protect the wound from microorganisms; (7) Allow gaseous exchange and control wound odor; and (8) Provide thermal insulation and mechanical protection.

Antibiotic selection

The principle of antibiotic treatment is based on evidence provided by reports on bacteriological culture and sensitivity from different centers worldwide[52,53].

Use of anti-infectives/antibiotics must be guided by appropriate cultures. Inappropriate use of antibiotics could lead to resistance and adverse effects.

Oral and parenteral antibiotics are prescribed for mild soft tissue infections and moderate to severe infections, respectively (Table 1)[54]. Evidence-based regimes should be followed for the management of infection in diabetic foot. Appropriate dosage, optimal duration, identification and removal of the infective focus and recognition of adverse effects should be critically evaluated in all outpatients and inpatients with diabetic foot infections[54-56].

Every hospital should develop an institutional antibiotic policy containing guidelines and protocols for antibiotic use. It is advisable to have different sections for treatment and prophylaxis including surgical procedures as well as how to treat different infections[57].

Three levels of antibiotic prescribing are generally recommended: (1) First line of choice - antibiotics prescribed by all doctors; (2) Restricted antibiotic group - for resistant pathogens, polymicrobial infections, special conditions, and expensive antibiotics. When prescribing antibiotics from this group, the prescriber should discuss with the committee and head of the department; and (3) Reserve antibiotics-for life-threatening infections, to be used after obtaining permission from the committee.

The institutional antibiotic committee should update their policy by collecting surveillance on antimicrobial resistance and data on antibiotic consumption, which will improve clinical and laboratory standards. The committee should monitor implementation of the policy,

Table 2 Choice of wound care materials for necrotic and sloughy wounds

Wound classification	Choice of wound care material	Advantages	Disadvantages
Necrotic wound	Wet to dry	Good debriding capacity and inexpensive	Frequent dressing change Painful if not soaked with saline prior to dressing change
	Topical antibacterial such as metronidazole	Very good antibacterial coverage Maintains a moist wound healing environment by promoting autolysis and controls odor	Chance of maceration Contraindicated in infected necrotic wounds
	Hydrogel	Hydrates the wound by promoting autolysis	Chance of maceration Contraindicated in infected necrotic wounds and is expensive
	Hydrocolloid	Maintains a moist wound healing environment, which helps in autolytic debridement	Expensive Contraindicated in infected necrotic wounds
Sloughy wound	Wet to dry	Good debriding capacity Absorptive, adhesive and cheapest	Frequent dressing change Painful if not soaked with saline prior to dressing change
	Topical enzymes such as collagenase, papain, fibrinolysis	Promotes autolytic debridement by desloughing Can be used in combination with metronidazole or hydrogel	Contraindicated in granulating or epithelizing wounds
	Topical antibiotics such as metronidazole	Very good antibacterial coverage Maintains moist wound healing environment by promoting autolysis and controls odor	Chance of maceration
	Polyurethane Foam	Very effective in desloughing Maintains a moist wound healing environment by promoting granulation	Sometimes painful if not soaked with saline prior to dressing change
	Hydrogel	Hydrates the wound by promoting autolysis	Chance of maceration and is expensive
	Hydrocolloid	Maintains a moist wound environment, which helps in autolytic debridement	Chance of maceration and is expensive

receive feedback information, assess the outcome, and discuss with various specialty doctors. The policy should be reviewed every year based on the experience of prescribers and the susceptibility reports of microbiology and laboratory.

Revascularization

With advances in both vascular and orthopedic reconstructive surgeries, limb salvage has become an option for limbs that previously would have been amputated. Patients with both diabetes and peripheral arterial disease are more prone to ischemic ulceration than those without the disease[58,59]. Several endovascular options, including percutaneous transluminal angioplasty (PTA), balloon-expandable stents, self-expanding stents, and covered stents are now available. The success rate after stent implantation in the iliac arteries is greater than 95%[60]. Revascularization plays a crucial role in the treatment of ischemic lower extremity wounds and should be performed before drainage or debridement[61]. Endovascular techniques such as cryoplasty, drug eluting stenting, plaque debulking lasers, *etc*., are being investigated and are potentially useful adjuncts to PTA. Subintimal angioplasty for arterial lesions below the ankle in diabetic patients could achieve a limb salvage rate of 94.6%[62]. Several retrospective studies report considerably better results of transmetatarsal amputations performed after a revascularization procedure[63,64].

CHOICE OF TOPICAL REGIME

Choice of wound care materials should be based on wound tissue type, complexity, and its properties (Tables 2 and 3).

Wet to dry dressing or simple saline

This dressing has a good debriding action and helps in wound bed preparation. Wet-to-dry dressings are described in the literature as a means of mechanical debridement[65]. It is very absorptive as well as adherent and one of the cheapest dressings used throughout the world, but requires frequent dressing change (twice or thrice a day) based on wound severity. Dressings should be moistened before removal to minimize any chance of bleeding. A gentle cleanser (normal saline or neutral-pH cleanser) will minimize wound irritation and discomfort[66]. When treating a granulating or epithelizing wound one should soak the dressing thoroughly with normal saline for five minutes (based on our clinical experience) to prevent trauma and heavy bleeding.

Antibacterial agents

Used solo or in combination for each category except dry necrotic wounds. Topical antibiotics have broad-spectrum antibacterial coverage which lasts for 12 h and are less toxic. Metronidazole gel [Ornidazole (IP-10 mg and water soluble gel base quantity sufficient)] has good anaerobic coverage and helps in maintaining a moist wound healing environment. By weight, gels are mostly liquid, yet they behave like solids due to a three-dimensional cross-linked network within the liquid. It is the crosslinking within the fluid that gives a gel its structure (hardness) and contributes to its adhesion[67]. Both by

Table 3 Choice of wound care materials for healing/sinus or cavity wounds

Wound classification	Choice of wound care materials	Advantages	Disadvantages
Granulating wounds	Non adherent dressing	Reduces trauma to the healing tissue Maintains a moist wound healing environment	Chance of shearing to new epithelium
	Wet to dry dressing	Promotes healing	Chance of bleeding if not soaked with saline before dressing change
	Polyurethane foam	Maintains a moist wound healing environment Promotes healing process	Chance of bleeding if not soaked before dressing change
	Topical antibacterial such as metronidazole, mupirocin, Tulle, Silver containing ointments, Acetic acid 0.5%-5% and povidone iodine	Maintains a moist wound healing environment, promotes epithelization and controls odor Effective against Gram positive cocci including MRSA. Silver sulfadiazine has broad antibacterial coverage, accelerates epithelization, and is very effective in burns. Acetic acid is very effective against Pseudomonas. Povidone iodine is very effective for gangrene as it hastens demarcation	Silver containing ointments cannot be used in Sulfa allergy patients Povidone iodine is cytotoxic to fibroblasts and delays the healing process
	Platelet derived growth factor	Faster healing and very effective	Expensive
	Hydrogel	Promotes healing	Chance of maceration and is expensive
	Hydrocolloid	Promotes healing Reduces the interval of dressing change	Chance of maceration and is expensive
Epithelizing wounds	Non adherent	Reduces trauma to the healing tissue Maintains a moist wound healing environment	Chances of shearing
	Wet to dry dressing	Promotes faster healing	Soaking of dressing is required prior to dressing change
	Topical antibacterial	As mentioned in granulating wounds	As mentioned in granulating wounds
	Epidermal growth factor	Effective and faster healing	Expensive
	Hydrogel	Effective	Chance of maceration and is expensive
	Hydrocolloid	Effective	Chance of maceration and is expensive
Cavity/Sinus wounds	Alginate	Highly absorbent and non-adherent Maintains a moist wound healing environment	Needs adequate padding and is expensive
	Hydrogel	Effective in promoting granulation tissue	Needs adequate padding and is expensive

weight and volume, gels are mostly fluid in composition and thus exhibit densities similar to those of their constituent liquids, such as hydrogels. Topical metronidazole gel (0.75%-0.80%) is frequently used directly on the wound once per day for five to seven days or more often as needed[68,69], and metronidazole tablets can be crushed and placed onto the ulcer bed[66,70]. There are numerous other articles (case studies or anecdotal experience) reporting the reduction of wound odor with topically applied metronidazole[71-73]. Antibiotics such as Neomycin, Gentamycin, and Mupirocin have good antibacterial coverage when used topically. Silver containing dressings come in different formulations and have very good antibacterial coverage. Silver dressings and polyherbal preparations have shown good results in healing diabetic foot wounds[74]. They are very effective in burn wounds and can also be used in infected or colonized wounds. Sisomycin (0.10%) and acetic acid at concentrations between 0.5% and 5% are effective against *Pseudomonas*, other gram-negative bacilli, and beta hemolytic streptococci wound infections. Povidone iodine solution dressings are very effective in healing sutured wounds and hypergranulating wounds to suppress or hamper further granulation. Povidone iodine soaked gauze is a good dressing for dry gangrene which hastens the process of demarcation. Iodine has been found to be toxic to human cells as well as bacteria and fungi at high doses[75,76]. Also, it should not be used on granulating or epithelizing wounds because it slows down the healing process and is cytotoxic to keratinocytes and fibroblasts.

Tulle dressings

These are gauze dressings impregnated with paraffin, which lowers the dressing adherence, but this property is lost if the dressing dries out. Tulle dressings are mainly indicated for superficial clean wounds and skin grafts. They can be used in granulating and epithelizing wounds. Tulle dressings not only prevent trauma to the new and delicate epithelium during dressing removal, but also provide a good moist environment, which is preferred for epithelial cell proliferation and migration[77]. This concept is well supported by evidence from many previous studies which showed faster re-epithelialization rates when moist environment dressings were compared with traditional dry dressings[77-79]. Evidence shows that gauze-based dressings still have a place in wound care[80].

Polyurethane films

These films are coated with an adhesive (water-proof dressing) and are comfortable. The vapor-permeable films allow diffusion of gases and water vapor which helps in maintaining a moist wound healing environment. Their transparency allows for wound monitoring without dressing removal, but there is a chance of maceration of surrounding skin. They can be used for low exudating wounds.

Polyurethane foam

These dressings are extremely absorbent, non-adherent, and have a semi-permeable backing which allows moisture to escape. Polyurethane foam dressings loosen slough by creating a moist wound environment, assisting in proper wound bed preparation, and promoting wound healing[81]. They maintain a moist wound environment which implies that they can be easily removed without pain. They are also used as outer dressings after application of topical antibiotics, such as metronidazole, or hydrogels. Polyurethane foam is widely used in diabetic foot wounds and is capable of absorbing light to heavy amounts of exudate, thereby preventing maceration, facilitating removal of slough, and promoting the proliferative stage of wound healing[82].

Hydrogel dressings

These dressings consist of cross-linked insoluble starch or carboxymethylcellulose polymers and water (96%). The term hydrogel implies that the material is already swollen in water. Hydrogels donate fluid to dry necrotic and slough wounds and promote autolysis. They apparently debride by rehydrating the wound. These dressings are the best choice for the treatment of dry wounds with necrotic eschar, and the hydrogel reaches a 50% debridement level more quickly than wet-to-dry dressings and are more cost-effective[83-85]. The hydrogel hydrates, cools the wound and provides an analgesic effect.

Hydrocolloid dressing

These dressings are a combination of polymers such as gelatin, pectin and cellulose which form a waterproof adhesive dressing. Exudates produced by the wound are absorbed into the dressing and form a gel. Hydrocolloid dressings are capable of absorbing low to moderate levels of exudate and can be used to promote autolytic debridement of dry, sloughy, or necrotic wounds[86]. They maintain a moist wound healing environment and promote autolytic debridement of necrotic and sloughing tissues. They can be used as occlusive dressings and are very good at absorbing exudate. Hydrocolloid dressings should be avoided on plantar ulcers of the foot, as the periwound skin is susceptible to maceration. Additionally, hydrocolloids have been shown to retain growth factors under the dressing as well as promote granulation and epithelialization[87]. The low pH created by the hydrocolloid is effective for the treatment of wounds infected by *Pseudomonas* species[88].

Alginate dressings

Alginate dressings are highly absorbent and are available in two forms; calcium alginate and calcium sodium alginate. The use of alginate dressings as hemostatic agents was reported both *in vitro* and in clinical studies. The selection of an alginate dressing is usually to manage wound exudate, as it is claimed that they can absorb 15-20 times their own weight in wound fluid[89]. The alginate forms a gel when it comes into contact with the wound surface. It can be used in granulating, epithelializing, and cavity wounds. Cochrane reviews detail the role of alginate dressings in the treatment of diabetic foot ulcers[90,91].

Growth factors

Growth factors such as platelet-derived growth factor (PDGF), insulin-like growth factor, transforming growth factor (TGF)-β, TGF-α, epidermal growth factor (EGF), *etc*., are very effective in diabetic wound healing and have been reported to accelerate the formation of various components of healing. Growth factors stimulate different functions including angiogenesis, enzyme production, cell migration, and cellular proliferation[92]. Diabetic wounds are enriched in proteases and supports the premise that impaired growth factor availability may act as a rate limiting factor in diabetic wound healing[93]. PDGF regulates cell growth and division. It plays a significant role in blood vessel formation (angiogenesis). A recombinant human (rh)-PDGF dressing is an effective modality for facilitating wound healing in patients suffering from diabetes and can be used as an adjunct to the conventional mode of treatment for healing diabetic wounds[94]. It can be used in the granulating stage of the wound. EGF stimulates the proliferation of fibroblasts, keratinocytes, and vascular endothelial cells, which contributes to scar tissue formation. Local injections of rh-EGF offer a favorable risk-benefit balance in patients with advanced diabetic foot ulceration and was significantly enhanced by 75 μg EGF treatment in neuropathic *vs* ischemic ulceration[95].

Honey-impregnated dressings

Proposed to have antimicrobial and anti-inflammatory properties, these dressings can be used for acute or chronic wounds. The antimicrobial properties of honey have been demonstrated in the laboratory, however, *in vivo* evidence is scant, particularly in comparison to the literature on silver antimicrobial dressings[96,97].

Topical enzymes

Collagenase, fibrinolysin, or papain containing ointments help in the enzymatic debridement of sloughy tissues and thus promote granulation formation. Collagenase and papain/urea formulations have been demonstrated to have degrading effects on wound components, such as collagen, fibrin, and elastin both *in vitro* and clinically. Papain-urea and collagenase have proven efficacy in enzymatic wound debridement. Papain-urea (89.2%) is a better enzymatic debriding agent than collagenase (82.2%)[98].

Mechanical device

Vacuum-assisted closure generates a topical negative pressure over the wound bed. Pressure of 125 mmHg is the ideal pressure. Vacuum-assisted closure is extremely effective in removing exudate and reducing edema, while leaving the surface of the wound moist. It is contraindicated in avascular wounds or exposed tendons or bones. Some of the contraindications include untreated osteomyelitis,

non-enteric and unexplored fistula, presence of necrotic tissue, exposed organs or blood vessels, and malignancy in the wound[99]. Vacuum-assisted closure is effective in promoting wound closure in patients with treated osteomyelitis or soft tissue infections[100,101]. Hyperbaric oxygen therapy (HBOT) is another treatment which is used as an adjunct to standard wound care in the treatment of diabetic foot wounds. It has limited side effects, is relatively safe, and is widely used[102].

CONCLUSION

The successful management of diabetic foot wounds requires the multidisciplinary teamwork of specialists. The management of diabetic foot wounds needs timely detection of complications and frequent assessment of the wound. No wound should be treated as simple. It is important to take into account all the related causes, identify the problem, and treat it. There are various topical regimes available, but the choice depends only on the treating physicians, podiatrist, or clinical care nurse. While selecting wound care materials one should bear in mind the properties of the ideal wound care dressing which should maintain a moist wound healing environment, absorb exudates, control infection/odor and be effective in treating diabetic foot wounds. In addition to these wound care techniques, antibiotic therapy and offloading plays a very important role.

Abstract

AIM: To investigate the role of protein tyrosin phosphatase 22 (PTPN22), maternal age at conception and sex on susceptibility and age at onset of type 1 diabetes (T1D) in Continental Italy and Sardinian populations.

METHODS: Three hundred seventy six subjects admitted consecutively to the hospital for T1D and 1032 healthy subjects as controls were studied in Continental Italy and 284 subjects admitted consecutively to the hospital for T1D and 5460 healthy newborns were studied in Sardinia. PTPN22 genotype was determined by DNA analysis. Maternal age at conception and age at onset of disease were obtained from clinical records. χ^2 test of independence, student *t* test for differences between means and odds ratio analysis were carried out by SPSS programs. Three way contingency table analysis was carried out according to Sokal and Rohlf.

RESULTS: The pattern of association between PTPN22 and T1D is similar in Continental Italy and Sardinia: the proportion of *T allele carriers is 13.6% in T1D *vs* 6.7% in controls in Continental Italy while in Sardinia is 7.3% in T1D *vs* 4.4% in controls. The association between T1D and maternal age at conception is much stronger in Sardinia than in Italy: the proportion of newborn from mother aging more than 32 years is 89.3% in T1D *vs* 32.7% in consecutive newborn in Sardinia ($P < 10^{-6}$) while in Continental Italy is 32.2% in T1D *vs* 19.1% in consecutive newborns ($P = 0.005$). This points to an important role of ethnicity. A slight prevalence of T1D males on T1D females is observed both in Continental Italy and Sardinia. PTPN22 genotype does not exert significant effect on the age at onset neither in Continental Italy nor and Sardinia. Maternal age does not influence significantly age at onset in Italy (8.2 years in T1D infants from mothers aging 32 years or less *vs* 7.89 years in T1D infants from mothers aging more than 32 years: $P = 0.824$) while in Sardinia a border line effect is observed (5.75 years in T1D infants from mothers aging 32 years or less *vs* 7.54 years in T1D infants from mothers aging more than 32 years: $P = 0.062$). No effect of sex on age at onset is observed in Continental Italy while in Sardinia female show a lower age at onset of T1D as compared to males (8.07 years in males *vs* 6.3 years in females: $P = 0.002$).

CONCLUSION: The present data confirm the importance of ethnicity on susceptibility and on the age at onset of T1D.

Key words: Type 1 diabetes; Continental Italy; Sardinia; Protein tyrosin phosphatase 22; Maternal age; Age of onset; Sex

Core tip: It is known that the incidence of type 1 diabetes (T1D) is greater in Sardinian than in Italian population. Among the factors considered in this review maternal age only has shown a significant difference between the two populations. Although in both Sardinia and Continental Italy the proportion of mothers aging more than 32 years is higher in children with T1D than in consecutive newborns from the same population, the risk of having a child with T1D in younger women is much greater in Sardinia than in Continental Italy (OR = 17.191 *vs* 2.018).

INTRODUCTION

Type 1 diabetes (T1D) is an autoimmune disorder with severe implications for the health of the patients. In western population the prevalence of T1D is increasing suggesting a role of current changes of cultural and environmental factors[1,2].

The incidence of the disease varies among populations, highest in Finland and Sardinia and lowest in Venezuela and China. This points to an important effect of genetic and environmental factors[3-7]. Positivity for islet antibodies precedes the onset of disease for years and it has been observed that the rate of positivity varies by ethnicity and age[1].

Among genetic factors HLA is the most important predictor, followed by protein tyrosin phosphatase 22 (PTPN22) and by insulin gene. Other genes are involved in susceptibility to T1D and it is likely that genes at present involved in autoimmunity, have been selected positively in the past being adaptive in particular environments[1].

A role of non genetic factors is suggested by the low concordance rate of T1D among monozygotic twins and by the increasing incidence of the disease in younger children and in those with lower risk HLA genotype, pointing to an important role of environment including dietary, viral and bacterial factors. Epigenetic regulation is emerging as an important factor also[1,8,9].

The role of maternal age at conception is well established[10-13]: the incidence of T1D increases with maternal age at conception. It is well known the present tendency in Western populations to conceive in older age as compared to the past: this is an important non genetic cultural factor.

Compared to Continental Italy the population of Sardinia shows a higher incidence of T1D[14]. This prompted us to review our data from Continental Italy and Sardinia concerning the factors that increase the risk of T1D.

In this paper we have studied the role of PTPN22, sex and maternal age on susceptibility to T1D and on age of onset of the disease in the population of Continental Italy and in the population of Sardinia. The survey includes data previous published[13,15,16] and unpublished observations from our data base.

PTPN22 codifies for Lyp, a protein tyrosine phosphatase involved in the regulation of T cell receptor signaling. The gene shows a single nucleotide polymorphism C/T at + 1858 resulting in W620 variant that is associated with autoimmune diseases. The variant is a gain of function of the enzyme that more strong1y inhibit T-cell receptor-mediated signals, and it has been suggested that the increased susceptibility to autoimmune disorders is due to failure to delete autoreactive T cells during intrathymic selection[17]. The association of PTPN22 polymorphism with T1D reported by Bottini *et al*[15] in 2004 have been confirmed in many populations[18-20].

T1D shows a slight prevalence of males over females whereas the opposite is observed for other autoimmune disorders[21].

MATERIALS AND METHODS

We have reviewed data on 376 subjects with T1D and 1032 controls in Continental Italy and on 291 subjects with T1D and 5460 controls in Sardinia. PTPN22, maternal age at conception and age at onset of disease were not determined in all subjects thus the number of subjects is not the same in all tables.

PTPN22 genotype was determined by DNA analysis as previously described[15]. χ^2 square test of independence, Student *t* test for differences between means and Odds ratio analysis were carried out by SPSS programs[22]. Three way contingency table analysis was carried out according to Sokal *et al*[23]. By this analysis is possible to study the effect of the categories of a third variable on the association between two variables: a statistically significant interaction suggests that the third variable influences the association between the other two.

The number of subjects in the tables are different due to the fact that PTPN22 have not studied in all subjects and the role of maternal age on the incidence of T1D have been evaluated in different samples.

RESULTS

Table 1 shows the distribution of PTPN22 genotypes in T1D and controls in Continental Italy and in Sardinia. The proportion of *T allele carriers is slightly higher in Italy than in Sardinia; the positive association between T1D and this genotype is slightly stronger in Continental Italy (OR = 2.19) than in Sardinia (OR = 1.70).

Table 1 Distribution of protein tyrosin phosphatase 22 genotypes in type 1 diabetes and controls in Continental Italy and in Sardinia

	% Proportion of *T allele carriers	Total *n*
T1D		
Continental Italy	13.60%	376
Controls	6.70%	1032
T1D		
Sardinia	7.30%	248
Controls	4.40%	205

T1D: Type 1 diabetes.

Table 2 Maternal age at conception in consecutive newborns and in children with type 1 diabetes in Continental Italy and in Sardinia

	Sardinia		Continental Italy	
	Consecutive newborns	Children with T1D	Consecutive newborns	Children with T1D
% proportion with maternal age > 32 yr	32.70%	89.30%	19.10%	32.20%
Total *n*	5460	187	792	90
χ^2 test of independence				
χ^2	253.705		7.821	
df	1		1	
P	$< 10^{-6}$		0.005	
OR analysis				
OR	17.191		2.018	
95%CI	10.569-24.396		1.234-3.331	

Three way contingency table analysis by a log linear model: x = T1D *vs* controls; y = maternal age (≤ 32 yr *vs* > 32 yr); z = Continental Italy *vs* Sardinia. x, y and z interaction: G = 45.703; *df* = 1; *P* < 0.0001. T1D: Type 1 diabetes.

Table 3 Effect of protein tyrosin phosphatase 22 genotype on age at onset of type 1 diabetes

	Continental Italy	Sardinia
	Age at onset (yr)	
	mean ± SE	mean ± SE
PTPN22 genotype		
*C/*C	8.56 ± 0.28	7.44 ± 0.32
*T carriers	9.85 ± 1.03	7.43 ± 1.33
Student *t* test for differences between means		
	P = 0.100	*P* = 0.540

PTPN22: Protein tyrosin phosphatase 22.

Table 2 shows the effect of maternal age at birth on susceptibility to T1D. In both Sardinia and Continental Italy the proportion of mothers aging more than 32 years is higher in children with T1D than in consecutive newborns from the same population. The association, however, is much stronger in Sardinia than in Continental Italy (OR = 17.191 *vs* 2.018). A three way contingency table analysis indicates that the relationship between maternal age and susceptibility to T1D is dependent on the population.

There is a not statistically significant prevalence of males both in Italy and in Sardinia (data not shown).

Table 4 Maternal age (year) at conception and age at onset of diabetes

		Age at onset of diabetes (yr)			*t* test for differences between means
		mean	SE	total *n*	
Sardinia	Maternal age ≤ 32	5.75	0.89	20	
	Maternal age > 32	7.54	0.31	169	*P* = 0.062
Continental Italy	Maternal age ≤ 32	8.02	0.51	61	
	Maternal age > 32	7.89	0.81	28	*P* = 0.894

Age at onset; Sardinia *vs* Continental Italy. *t* test for differences between means. Maternal age > 32, *P* = 0.720; Maternal age ≤ 32, *P* = 0.028.

Table 5 Effect of sex on the age at onset of type 1 diabetes

	Continental Italy	Sardinia
	Age at onset (yr)	
	mean ± SE	mean ± SE
Sex		
Males	8.50 ± 0.39	8.07 ± 0.40
Females	8.93 ± 0.39	6.30 ± 0.40
Student *t* test for differences between means		
	P = 0.433	*P* = 0.002

Table 3 shows the effect of PTPN22 on the age of onset of the disease. No effect is observed in Sardinia. In Continental Italy the mean age at onset is greater in *T carriers than in *C/*C genotype but the difference is not statistically significant.

The effect of maternal age on the age at onset of disease is shown in Table 4. No significant effect is observed in Continental Italy while in Sardinia a border line significant effect is observed with a lower age at onset in the mother aging 32 years or less.

The effect of sex on the age at onset of T1D is reported in Table 5. No effect is observed in Continental Italy while in Sardinia females show a lower age at onset of disease.

DISCUSSION

The most important result emerging from our analysis regards the role of maternal age at conception on susceptibility to T1D and on the age of onset of the disease. The effect of maternal age at conception on susceptibility and on age of onset of disease is more marked in Sardinian than in Italian population.

The effect of maternal age at conception on the susceptibility to T1D has been observed in many populations[10-12] including Sardinia[13]. In Sardinia this effect is stronger compared to other populations and this may be connected with the high risk of T1D observed in Sardinian population[14,24,25]. Moreover in Sardinia a clear correlation between maternal age at delivery and age at onset of diabetes has been also observed[13]. Changes of hormonal pattern due to maternal aging may be involved in modifi-

cations of maternal-fetal immunological relationship[26-28]. Maternal age could influence the maturation of fetal immune system through modifications of intrauterine environment. T1D (a Th1 mediated disease) is more frequent in children conceived by older women, whereas atopic disorders (Th2 mediated diseases) are more frequent in children conceived by younger women[13,29-31].

The incidence of T1D varies among population and at present the causes of this phenomenon is not yet clarified. The most important predictor is HLA followed by PTPN22 and insulin gene. Other minor genetic factors and epigenetic regulation are probably involved. Maternal and environmental factors could also have an important role[1-13].

Sardinian population differs from the population of the Continental Italy for many genetic factors including HLA, PTPN22 and glucose 6 phosphate dehydrogenase (G6PD). Our review does not show important effect on the susceptibility to T1D due to difference in genotype frequency of PTPN22 between the two populations but points to an important role of maternal age at conception.

In Sardinia there is high incidence of G6PD deficiency. Some studies[32] suggest that G6PD heterozygous women enjoy a more favorable pregnancy outcome compared to normal women suggesting that adaptation to endemic malaria could have involved genetic factors important in human reproduction and in the maternal fetal relationship resulting in a more marked role of maternal age in the susceptibility to T1D. A prevalence of Th1 orientation during pregnancy could have had an adaptive role in the malaria environment: this could explain the stronger effect of maternal age on susceptibility and on age at onset of T1D observed in Sardinian as compared to Continental Italian population.

From a practical point of view from the present analysis emerges the advice to females of Sardinia origin to conceive at young age to reduce the risk of T1D in the offspring.

COMMENTS

Background

The incidence of Type 1 diabetes (T1D) varies among populations, highest in Finland and Sardinia and lowest in Venezuela and China. This points to an important effect of genetic and environmental factors.

Research frontiers

In this paper authors have studied the role of protein tyrosin phosphatase 22 (PTPN22), sex and maternal age on susceptibility to T1D and on age of onset of the disease in the population of Continental Italy and in the population of Sardinia.

Innovations and breakthroughs

The most important result emerging from authors' analysis regards the role of maternal age at conception on susceptibility to T1D and on the age of onset of the disease. The effect of maternal age at conception on susceptibility and on age of onset of disease is more marked in Sardinian than in Italian population.

Applications

From a practical point of view the present analysis suggests to advice females of Sardinia origin to conceive at young age to reduce the risk of T1D in the offspring.

Terminology

PTPN22 codifies for a protein-tyrosin-phosphatase involved in the regulation of T cell receptor signaling. The PTPN22 polymorphism (chromosome 1) has two alleles, *C1858 (encoding the R620 variant, here simply called *C) and *T1858 (encoding the W620 variant, here simply called *T), and has three genotypes, *C/*C, *C/*T and *T/*T. The *T/*T genotype is very rare. The W620 variant is associated to autoimmune disorders.

Peer review

This manuscript describes the role of genetic and non-genetic factors in the development of Type 1 diabetes. It is well wtitten.

Abstract

AIM: To evaluate the impact on glucose variability (GLUCV) of an nurse-implemented insulin infusion protocol when compared with a conventional insulin treatment during the day-to-day clinical activity.

METHODS: We enrolled 44 type 2 diabetic patients (n = 32 males; n = 12 females) with acute coronary syndrome (ACS) and randomy assigned to standard a subcutaneous insulin treatment (n = 23) or a nurse-implemented continuous intravenous insulin infusion protocol (n = 21). We utilized some parameters of GLUCV representing well-known surrogate markers of prognosis, *i.e.*, glucose standard deviation (SD), the mean daily δ glucose (mean of daily difference between maximum and minimum glucose), and the coefficient of variation (CV) of glucose, expressed as percent glucose (SD)/glucose (mean).

RESULTS: At the admission, first fasting blood glucose, pharmacological treatments (insulin and/or anti-diabetic drugs) prior to entering the study and basal glycated hemoglobin (HbA1c) were observed in the two groups treated with subcutaneous or intravenous insulin infusion, respectively. When compared with patients submitted to standard therapy, insulin-infused patients showed both increased first 24-h (median 6.9 mmol/L *vs* 5.7 mmol/L $P < 0.045$) and overall hospitalization δ glucose (median 10.9 mmol/L *vs* 9.3 mmol/L, $P < 0.028$), with a tendency to a significant increase in first 24-h glycaemic CV (23.1% *vs* 19.6%, $P < 0.053$). Severe hypoglycaemia was rare (14.3%), and it was observed only in 3 patients receiving insulin infusion therapy. HbA1c values measured during hospitalization and 3 mo after discharge did not differ in the two groups of treatment.

CONCLUSION: Our pilot data suggest that no real benefit in terms of GLUCV is observed when routinely managing blood glucose by insulin infusion therapy in type 2 diabetic ACS hospitalized patients in respect to conventional insulin treatment

Key words: Glycaemic management; Intensive insulin therapy; Conventional insulin treatment; Acute coronay syndrome; Glucose variability

Core tip: In type 2 diabetic patients hospitalized for acute coronary syndrome no real benefit in terms of reduced glucose variability is observed by intensively managing blood glucose through insulin infusion therapy in respect to conventional insulin treatment

INTRODUCTION

It is well-known that type 2 diabetes and acute coronary syndromes (ACS) are strictly related. Also, patients with type 2 diabetes are more likely than non-diabetic subjects to experience silent or symptomatic myocardial ischaemia as the first presentation of coronary artery disease[1].

The role of admission and fasting glucose level as best indicator of glucose metabolic state in predicting outcome in ACSs remains, however, uncertain[2-4]. Fasting glucose levels have been shown to represent a marker of adverse outcome after ST-segment elevation myocardial infarction (STEMI)[5,6] and elevated blood glucose level at admission for acute myocardial infarction (AMI) is associated with worse outcome in both non-diabetic and diabetic patients[4-7]. On the contrary, the role of high fasting glucose levels in non-STEMI ACSs is less defined. On the other hand, an increased incidence of cardiac events also in patients with a prediabetic state presenting with either STEMI or non-STEMI, compared with non-diabetic patients has been already shown[8].

High coefficient of variation (CV) of blood glucose as an indicator of glucose variability (GLUCV) predicts increased risk of death in intensive care unit (ICU) patients[9] and represents a better discriminator of in-hospital mortality than mean blood glucose in patients with ACS[10]. In this context, epidemiological studies have also shown that beside spontaneous hypoglycaemia, treatment-induced hypoglycemia was associated with higher mortality[11].

Over the last years, glycaemic management in critical care patients has dramatically changed. Emerging evidence seems to indicate that intensive blood glucose control by intravenous insulin infusion may significantly reduce morbidity and mortality in hyperglycaemic patients admitted to ICU[1]. Furthermore, some evidence suggests that diabetic patients with ACS might benefit by intravenous insulin infusion[12,13]. For the above reasons, the European Society of Cardiology/European Association for the Study of Diabetes recommends blood glucose control by intensive insulin treatment (Class I recommendation) in patients with AMI (Class Ⅱ, level of evidence B)[14]. Some schemes of insulin infusion therapy have been proposed for critically ill patients[15-22]; however, among the nurse-implemented insulin infusion protocols available none was specifically tested in patients with ACS during the day-to-day clinical activity of a coronary care unit[21].

Aim of the present pilot study was to compare the impact on GLUCV of a nurse-implemented insulin infusion therapy and conventional insulin treatment for management of diabetic patients affected by ACS in a day-to-day in-hospital clinical activity. In order to avoid potential bias in studied population we decided to enrol only type 2 diabetic patients by considering that type 2 diabetes comprises 90% of people with diabetes in Europe.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. Informed consent was obtained from all patients and the study was approved by the institutional review board of the Hospital.

Patients

All type 2 diabetic patients admitted to the Heart Department of Fondazione CNR/Regione Toscana G. Monasterio from January 2013 to July 2013 with a diagnosis of ACS (*i.e.*, STEMI, non-STEMI or unstable angina) and confirmed by electrocardiographic changes consistent with ACS, increased biochemical markers of cardiac necrosis and/or documented coronary artery disease were potentially eligible.

Additional inclusion criteria were: (1) age 18-80 years; (2) history of diabetes; (3) admission glucose level > 180 mg/dL (*i.e.*, 10 mmol/L); and (4) glycated hemoglobin (HbA1c) > 6.2%.

Exclusion criteria were: (1) stage of chronic kidney disease >3; (2) severe chronic liver, autoimmune diseases; (3) active neoplastic disease; and (4) treatment with corticosteroids.

We enrolled 44 patients, 32 males, 12 females, randomy assigned to standard multidose subcutaneous insulin treatment (n = 23) or continuos insulin infusion protocol (see below) for the first one-three days followed by standard subcutaneous multidose insulin treatment.

Methods

We adopted the nurse-implemented continuous intravenous insulin infusion protocol as proposed by Avanzini *et al*[21] developed also to drive the optimal transition to subsequent subcutaneous insulin therapy[22], with little modifications. In particular targeting glycemic values were 120-180 mg/dL (*i.e.*, 6.6-10 mmol/L) instead of 100-139 mg/dL (*i.e.*, 5.5-7.7 mmol/L), and infusion treatment was stopped in presence of glycemic values below 120 mg/dL (*i.e.*, 6.7 mmol/L) instead of 100 mg/dL (*i.e.*, 5.5 mmol/L)

To facilitate acceptance, during year 2012 all nurses involved in the study were previously trained by a week-long series of 1-h in-service training sessions and all experienced very good compliance with the infusion protocol at the time of the study.

The frequency of blood glucose determinations was guided by the infusion protocol as previously suggested[21]; usually blood samples were withdrawn every 2 h during day-time and every three hours during night-time. Blood glucose was checked at fixed times (*i.e.*, 07:00 am; 10:00 am; 12:00 am; 04:00 am; 06:00 pm; 10:00 pm) in the case of subcutaneous insulin treatment.

glucose levels utilized to determine GLUCV parameters (see below) were based only on measurements obtained at the same timetables in the two mentioned protocols (*i.e.*, 07:00 am; 10:00 am; 12:00 am; 04:00 am; 06:00 pm; 10:00 pm)

Blood glucose levels were measured by a standard hospital glucose meter which was calibrated daily.

Assessment of glucose variability

GLUCV was assessed according to Brunner *et al*[23] using three statistical indicators calculated for the three periods of interest *i.e.*,: (1) during the first 24 h; (2) during the whole hospitalization; and (3) during the pre-discharge day. The first indicator was represented by standard deviation (SD), the second by mean daily δ glucose, assessed as the mean of daily difference between maximum and minimum glucose, and the third indicator was the CV of glucose, express as percent [glucose (SD)/glucose (mean) (%)].

Statistical analysis

Continuous variables were expressed as mean ± SD or median (25th; 75th percentiles) and categorical variables were expressed as percentage. Student Independent *t*-test or Wilcoxon test was used as appropriate to compare continuous and ordinal variable differences between patients. Due to the small number of patients analyzed, the Wilcoxon test is preferred to the *t*-test for comparison of the indices of GLUCV between groups. Comparison between categorical variables was performed by χ^2 test or by Fisher exact test (if an expected cell count was 5). All statistical tests were evaluated with the use of 2-tailed 95%CI, and tests with *P*-value < 0.05 were considered significant. All analyses were performed using Stata, version 10.2.

RESULTS

Baseline characteristics of the 44 studied patients are reported in Table 1. Similar admission, first fasting blood glucose, pharmacological treatments (insulin and/or anti-diabetic drugs) prior to entering the study and basal HbA1c were observed in the two groups treated with subcutaneous or intravenous insulin infusion, respectively. Also, glycaemic control did not differ after three months from discharge between the two groups, as documented by superimposable HbA1c values (Table 1).

In patients submitted to intravenous infusion insulin therapy transition to subcutaneous insulin treatment was, on average, obtained after 3.5 ± 1.5 d.

The effectiveness of the two therapeutic protocols (*i.e.*, infusion *vs* conventional insulin treatment) was assessed with regard to values of several relevant parameters of GLUCV (Tables 2 and 3 and Figure 1). Notwithstanding increased staff's efforts and increased number of glycaemic determinations, patients receiving insulin infusion therapy showed both first 24-h and overall hospitalization increased GLUCV δ associated with a tendency to a significant increase in first 24-h glycaemic CV ($P = 0.059$). Importantly, severe hypoglycemia (*i.e.*, with glycaemic values < 50 mg/dL) was extremely rare (14.3%), but it was observed only in patients receiving insulin infusion therapy (Table 2).

All data, taken as whole, suggest that no improvement is observed in glucose management in day-to-day clinical activity by intensive insulin infusion protocol in diabetic type 2 patients with ACS when compared to standard subcutaneous insulin treatment.

DISCUSSION

An alteration of glucose metabolism which includes

a prediabetic state is frequently observed during acute cardiac events[2,5,8,11,22,24,25]. Furthermore, diabetic patients show an increased mortality and morbidity after both AMI and ACS in general when compared with non-diabetic patients[8]. Also, the relationship of high blood glucose with risk of death or poor outcome after AMI is present for both diabetic and non-diabetic patients[4,26].

A large meta-analysis[27] clearly indicated that new hyperglycaemia *per se* in presence of AMI represents a strong prognostic predictor of short and long-term mortality and progression toward heart failure in both diabetic and non-diabetic patients.

On the other hand, worse outcome in diabetic patients with ACS has not been improved by progressive diffusion of new, more efficacious pharmacological cardiac treatments and interventional procedures thus suggesting the hyperglycemia and glucose toxicity playing a critical role on adverse prognosis in ACS.

Serum GLUCV and in particular SD/CV of glycemic values measured during the first days after acute events including ACS has been demonstrated to represent a good prognostic biomarker of increased death rate[28].

It has been also reported that the relationship between mean serum GLUCV and mortality is described by a "U-shaped" curve, with lower and higher GLUCV values associated with higher death rate[9]. This suggests that preventing both hypo and hyperglycemic states may be an important therapeutical target to minimize changes in GLUCV.

Because hypoglycaemia, hyperglycaemia and high GLUCV are associated with an increased risk of death, an intensive insulin treatment has been proposed as a better strategy than conventional treatment to ameliorate glycaemic control immediately after the acute cardiac event and, consequently patient's prognosis[1]. Data so far reported are somewhat contrasting[1,29,30]; actually, although the DIGAMI study[12] demonstrated the superiority of intravenous insulin infusion when compared with standard care in reducing early and long-term mortality in diabetic AMI patients, the later DIGAMI 2 study did not confirm previous results[31]. Also, a major risk of intensive insulin treatment is the greater appearance of hypoglycaemic episodes which are mainly related to diabetes life span, frequency of previous hypoglycaemic attacks and pre-existing coronary artery disease[29,30] with worsening of prognosis and prolongation of in-hospital stay. Several insulin-infused operational protocols to be adopted in ICUs have been proposed so far[15-22] but no specific guidelines with validate protocols in day-to-day clinical practice and definite glycaemic target values have been provided. Furthermore, an additional concern is represented by a recurrence of hyperglycaemic states during the transition from intravenous to subcutaneous treatment regimen.

With the above premises, in our pilot study we evaluated the superiority of an intensive, nurse-implemented insulin treatment for treating type 2 diabetic patients with ACS in a clinical practice setting. We utilized GLUCV parameters as well-established surrogate markers of early and long-term outcome in ACS patients[30]. Our preliminary results indicate that GLUCV as represented by SD of blood glucose levels and glucose δ variation does not improve by intensive *iv* insulin treatment when compared to conventional approach. A concurrent clear disadvantage is represented by both higher personnel efforts and costs related to the significant increase in number of blood glucose determinations in the case of an insulin-infused protocol.

We do not have definite explanations for our findings. Among the possible causes we may recognize an increased difficulty in: (1) managing the infusion protocol, also by well-trained and compliant nurses, when compared with conventional insulin therapy, in a day-to-day clinical practice of a cardiac ICU; (2) managing the infusion protocol in feeding patients as in the case of ACS; and (3) managing the transition to conventional insulin treatment.

In conclusion our pilot study suggests that no benefit in terms of GLUCV is observed by early insulin infusion therapy in type 2 diabetic ACS in-patients in respect to conventional treatment in a day-to-day clinical practice. Further studies in larger populations and with a longer follow-up are, however, necessary to confirm these preliminary results.

COMMENTS

Background

Glycaemic management in severely ill acute patients is a critical issue and in-hospital glucose variability (GLUCV) represents a good prognostic predictor. Emerging evidence suggests that diabetic patients hospitalized for acute coronary syndrome (ACS) may benefit intensive blood glucose control.

Research frontiers

Some nurse-implemented insulin infusion protocols have been proposed for patients affected by ACS but none was specifically tested in patients during the day-to-day clinical activity. In their pilot study they compared for the first time the impact on GLUCV of a nurse-implemented insulin infusion protocol with a conventional insulin treatment in a group of 44 type 2 diabetic patients with acute coronary syndrome.

Innovations and breakthroughs

Over the last years, glycaemic management in critical care patients has dramatically changed. Emerging evidence seems to indicate that intensive blood glucose control by intravenous insulin infusion may significantly reduce morbidity and mortality in hyperglycaemic patients admitted to intensive care units. Some evidence suggests that diabetic patients with ACS might benefit by intravenous insulin infusion.

Applications

The results of the present pilot study may represent a stimulus to further studies on large populations of diabetic patients with ACS to define the better strategy for glycaemic control during hospitalization.

Terminology

GLUCV was assessed by using three statistical indicators calculated for the three periods of interest during hospitalization: (1) during the first 24 h; (2) during the whole hospitalization; and (3) during the pre-discharge day. The first indicator was represented by glucose standard deviation (SD), the second by mean daily δ glucose, assessed as the mean of daily difference between maximum and minimum glucose, and the third indicator was the coefficient of variation of glucose, express as percent (%) glucose (SD)/glucose (mean).

Peer review

The present manuscript deals with a very interesting topic: comparison between intravenous insulin therapy and conventional insulin treatment. The main criticism arises from the reduced number of participants as the authors point.

Abstract

AIM: To evaluate metabolic control and health-related quality of life (HRQOL) in a type 1 diabetes mellitus (T1DM) population.

METHODS: As part of a prospective cohort study, 283 T1DM patients treated with various insulin treatment modalities including multiple daily injections (MDI) and continuous subcutaneous insulin infusion (CSII) were examined annually. HRQOL was measured using the SF-36 and EuroQol questionnaires. Data regarding HRQOL, glycaemic and metabolic control from baseline and follow-up measures in 2002 and 2010 were analysed. Linear mixed models were used to calculate estimated values and differences between the three moments in time and the three treatment modalities.

RESULTS: Significant changes [mean Δ (95%CI)] in body mass index [2.4 kg/m^2 (1.0, 3.8)], systolic blood pressure [-6.4 mmHg (-11.4, -1.3)] and EuroQol-VAS [-7.3 (-11.4, -3.3)] were observed over time. In 2010, 168 patients were lost to follow-up. Regarding mode of therapy, 52 patients remained on MDI, 28 remained on CSII, and 33 patients switched from MDI to CSII during follow-up. Among patients on MDI, HRQOL decreased significantly over time: mental component summary [-9.8 (-16.3, -3.2)], physical component summary [-8.6 (-15.3, -1.8)] and EuroQol-VAS [-8.1 (-14.0, -2.3)], $P < 0.05$ for all. For patients using CSII, the EuroQol-VAS decreased [-9.6 (-17.5, -1.7)]. None of the changes over time in HRQOL differed significantly with the changes over time within the other treatment groups.

CONCLUSION: No differences with respect to metabolic and HRQOL parameters between the various insulin treatment modalities were observed after 15 years of follow-up in T1DM patients.

Key words: Type 1 diabetes mellitus; Health-related quality of life; Glycaemic control; Insulin treatment; Multiple daily injections; Continuous subcutaneous insulin infusion

Core tip: The results of this study demonstrate that over a period of 15 years, general health-related quality of life is almost stable among patients with type 1 diabetes mellitus. In addition, no differences with respect to metabolic control and general health-related quality of life were observed among type 1 diabetes mellitus patients treated with different insulin regimens (multiple daily injections or continuous subcutaneous insulin infusion).

Fifteen-year follow-up of quality of life in type 1 diabetes mellitus. *World J Diabetes* 2014; 5(4): 569-576 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i4/569.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i4.569

INTRODUCTION

Patients with type 1 diabetes mellitus (T1DM) require lifelong daily insulin to compensate for an absolute endogenous insulin shortage. In many patients, it is possible to achieve adequate or even tight glycaemic control and delay the onset and progression of micro- and macrovascular complications with intensive insulin therapy[1]. At present, multiple daily injections (MDI) and continuous subcutaneous insulin infusion (CSII) are the most common forms of insulin administration in T1DM.

It is likely that T1DM and its therapy impact health-related quality of life (HRQOL)[2]. Previous studies have underlined the importance of this association by revealing a negative association between HRQOL and diabetes prognosis[3-5]. In T1DM, a relevant deterioration of HRQOL and glycaemic control during the disease course has been reported[6,7]. In contrast, reports have also found no association between duration of diabetes and scores on quality of life scales[8,9]. In addition to diabetes duration and clinical and metabolic characteristics, such as body mass index (BMI), the presence of macrovascular complications, hyperglycaemic complaints and personal characteristics influence HRQOL. In addition, insulin treatment with CSII is thought to have a positive effect on HRQOL compared with MDI[2,10,11].

The aim of the present analysis was to assess long-term metabolic control and HRQOL in T1DM patients treated with various therapy modes. Furthermore, we aimed to investigate whether mode of therapy (MDI or CSII) influences long-term clinical and HRQOL parameters in T1DM patients.

MATERIALS AND METHODS

Study design and population

The study was designed as a prospective, cohort study to investigate several disease factors, including oxidative stress and HRQOL, in T1DM. The full study design has been published in detail previously[12]. In brief, from January 1995 to January 1996, consecutive visiting T1DM patients treated at the diabetes outpatient clinic of the Weezenlanden Hospital (currently Isala), Zwolle, The Netherlands, were invited to participate. T1DM was defined as the initiation of insulin therapy within 6 months after the first signs of diabetes and before the age of 30 years or the absence of C-peptide secretion. In total, 293 patients agreed to participate. The main scope was to assess patients treated with MDI or CSII or patients switching from MDI to CSII during the study period. Patients who switched from CSII to MDI and back (n = 3) or from CSII to continuous intraperitoneal insulin infusion (n = 8) or underwent a pancreas and kidney transplantation (n = 1) were excluded from analysis.

Measurement of clinical data and HRQOL

At baseline, a trained physician examined all patients according to a standardised protocol. Data concerning demographics, mode of therapy, height, weight, blood pressure and several laboratory measurements were collected. We adjusted the eGFR MDRD values for differences using the conventional Jaffe creatinine method before 2007 and the isotope-dilution mass spectrometry-traceable enzymatic creatinine method after 2007. HRQOL was assessed annually from 1995 to 2001, and these results were reported previously[12]. From 2001 onwards, HRQOL was assessed in 2002 and 2010. HRQOL was assessed using the SF-36 and EuroQoL. The SF-36 is a widely used, self-administered generic questionnaire with 36 items involving 8 subscales: physical functioning, role limitations due to physical problems, bodily pain, general health perception, vitality, social functioning, role limitations due to emotional problems, and mental health. Scale scores range from 0 to 100, and higher scores indicate better HRQOL. In addition, a physical and mental component summary (PCS and MCS) score can be determined[13]. The EuroQol is a generic measure developed by researchers from 5 European countries, including The Netherlands[14]. The questionnaire has 2 parts. The first part consists of 5 items covering the areas of mobility, self-care, usual activities, pain or discomfort and anxiety or depression (EQ-5D). Each item has 3 levels: no problems, some problems, or extreme problems. EQ-5D scores were converted to a single index value (ranging from 0 for the worst health state to 1 for the best health state) using a value set specific for the Dutch population[15]. The second part consists of a visual analogue scale (VAS) from which a single overall score for self-rated health status can be elicited ranging from 0 to 100 (EQ-VAS).

Ethical considerations

The study was performed in accordance with the Declaration of Helsinki. Informed consent was obtained from all patients, and the protocol was approved by the local medical ethics committee.

Statistical analysis

All analyses were performed using SPSS version 18.0 (SPSS, Inc., Chicago, Il, United States). A (two-sided) P-value of less than 0.05 was considered statistically significant. Q-Q plots were used to determine whether the tested variable had a normal distribution. Where appropriate, paired parametric and non-parametric tests were used to compare outcomes between baseline and follow-up measurements. Linear mixed models with Bonferroni correction were used to calculate estimated values and test differences among the 3 moments in time (1995, 2002 and 2010) and between the 3 treatment modalities

Data are mean (± SD), median (interquartile range) or *n* (%). *P*-values are based on unpaired student *T*-, Mann-Whitney *U*- or χ^2-tests. HRQOL: Health-related quality of life; BMI: Body mass index; BP: Blood pressure; eGFR: Estimated glomerular filtration rate; MDI: Multiple daily injections; CSII: Continuous subcutaneous insulin infusion; MDRD: Modification of diet in renal disease; MCS: Mental component summary; PCS: Physical component summary; ACEi: Angiotensin-converting enzyme inhibitors.

for patients completing follow-up. The observed and estimated values of the clinical and HRQOL parameters were calculated using linear mixed models and reported.

RESULTS

Patients

Of the 281 patients who entered the study, 201 (71.5%) and 113 (40.2%) were available for follow-up measurements of HRQOL in 2002 and 2010, respectively.

The reasons for dropping out of the study were unknown (*n* = 32), moving out of the area or referral to another physician (*n* = 48), death (*n* = 21), lack of interest (*n* = 7) and incorrect diagnosis of T1DM (*n* = 2). Compared with patients who completed follow-up, individuals who eventually dropped out were more often women or patients with increased diabetes duration, a higher HbA_{1c} and total cholesterol, a lower eGFR and more often neuropathy at baseline ($P < 0.05$). In addition, these patients displayed lower HRQOL scores at baseline ($P < 0.05$, Table 1). No differences in baseline characteristics were observed between patients with follow-up until 2002 *vs* 2010.

Data are presented as the mean (SD), n (%) or median (interquartile range). BMI: Body mass index; eGFR: Estimated glomerular filtration rate; MDI: Multiple daily injections; CSII: Continuous subcutaneous insulin infusion; MDRD: Modification of diet in renal disease; MCS: Mental component summary; PCS: Physical component summary.

Therapy mode

Eighty patients remained on the initial treatment mode throughout the follow-up period; 52 were on MDI, and 28 were on CSII. During the follow-up period, 62 patients switched from MDI to CSII, and 33 of these patients completed follow-up. For these patients, the median time between the start of the study and switch in therapy mode was 8.5 years (IQR 4.6). Baseline characteristics of the different treatment groups are presented in Table 1.

Long term follow-up-clinical parameters

In total, 59 macrovascular complications occurred during follow-up. The number of patients completing follow-up until 2010 and experiencing a macrovascular complication was 16 (14.2%). Eight of these patients were on MDI; 5 were on CSII during the complete follow-up period, and 3 switched from MDI to CSII.

The observed course of clinical parameters, categorised per treatment modality, is presented in Table 2. The estimated clinical parameters using linear mixed models are

Table 3 Estimated changes in clinical parameters during follow-up

Data are the mean (95%CI). Mean differences and *P*-values are based on linear mixed models. BMI: Body mass index; BP: Blood pressure; MDI: Multiple daily injections; CSII: Continuous subcutaneous insulin infusion.

presented in Table 3. In total, BMI increased (mean difference: 2.4 kg/m^2, 95%CI: 1.0-3.8; $P < 0.00$) and systolic blood pressure decreased [-6.4 mmHg, 95%CI: -11.4-(-1.3); $P = 0.01$] during the follow-up period.

The BMI increased significantly in the group of patients who switched from MDI to CSII (2.7 kg/m^2; 95%CI: 0.2-5.2; $P = 0.03$), and systolic blood pressure decreased exclusively among MDI users [-9.2 mmHg; 95%CI: -16.4-(-2.0); $P = 0.01$]. In 2010, no differences were observed between the various treatment categories (*i.e.*, MDI, CSII and from MDI to CSII) concerning clinical parameters at the end of the follow-up.

Long term follow-up-HRQOL

The observed course of the summary scores for the SF-36 and the EuroQol are presented in Table 2. The mean values and estimated changes in HRQOL are presented in Table 4. In total, no changes in both SF-36 component scores were observed. At baseline, patients administered MDI displayed the highest MCS. The SF-36 subscales for physical functioning [-8.3, 95%CI: -14.9-(-1.7)], social functioning [-8.9, 95%CI: -16.3-(-1.6)], role limitations due to emotional problems [-15.0, 95%CI: -27.0-(-3.0)] and vitality [-10.0, 95%CI: -18.4-(-1.7)] decreased significantly over time among patients on MDI. In addition, the MCS and PCS for patients administered MDI were significantly lower in 2010 compared with 1995, with a mean difference of -9.8 [95%CI: -16.3-(-3.2)] and -8.6 [95%CI: -15.3-(-1.8)], respectively. The subscale vitality ($\Delta = 12.0$, $P = 0.03$) displayed a more significant decrease over time among patients using MDI compared with patients who switched from MDI to CSII, and a greater decrease was observed with the subscale role limitations due to emotional problems in patients administered MDI compared with CSII ($\Delta = 22.1$, $P < 0.01$) and switchers ($\Delta = 18.0$, $P = 0.02$). MCS and PCS did not differ between the treatment groups.

The EuroQol-VAS decreased among all patients [-7.3; 95%CI: -11.4-(-3.3); $P = 0.001$]. For patients using CSII or MDI throughout the follow-up period, the EuroQol-VAS decreased throughout the follow-up period to -8.1 [95%CI: -14.0-(-2.3)] and -9.6 [95%CI: -17.5-(-1.7)], respectively.

None of the HRQOL component scores differed from baseline among the patients who switched from MDI to CSII throughout the study. No differences concerning HRQOL parameters were observed between the various treatment categories in 2010.

DISCUSSION

This is the first study to describe the long-term natural course of HRQOL among patients with T1DM treated with different insulin treatment modalities. In general, no relevant HRQOL changes were observed after a follow-up of 15 years. Between the treatment modalities, no differences with respect to metabolic and HRQOL parameters were observed during follow-up.

The approximately stable HRQOL reported in the current study is somewhat surprising given the natural decrease in HRQOL in an unselected population after 5

Data are the mean (95%CI). HRQOL: Health-related quality of life; MDI: Multiple daily injections; CSII: Continuous subcutaneous insulin infusion; MCS: Mental component summary; PCS: Physical component summary. Mean differences and *P*-values are based on linear mixed models. [a]$P < 0.05$ at that moment in time *vs* the MDI and from MDI to CSII treatment groups.

years of follow-up and the occurrence of macrovascular and microvascular complications, both of which are known to decrease HRQOL[16-18]. However, this finding can be explained in part by improved clinical and/or metabolic parameters and/or the low number of patients who completed follow-up until 2010[19]. Arguing against the latter explanation, no change in HRQOL was observed after 7 years of follow-up, with 71.5% of the study sample intact.

Regarding the impact of the therapy mode, a decrease in both component scores of the SF-36 and EuroQol-VAS was observed among patients using MDI. One potential explanation for this finding is the relatively high scores of these HRQOL parameters at baseline compared with patients on CSII. Although speculative, this observation can be attributed to a relative short diabetes duration[7].

In a recent Cochrane review, CSII was preferred over MDI with respect to HRQOL[11]. In accordance with our study, the only study among T1DM adults that used the SF-36 questionnaire demonstrated a significant improvement of the general health and mental health subscale in the CSII group compared with stable values in the MDI group after 32 wk of follow-up[20]. The other SF-36 scales, including the component scales, remained unaltered.

In our current study the HRQOL does not differ between modes of therapy, but the patient can choose his or her mode of choice in daily practice to a larger extent. This observation could partially explain the differences found in randomised trials (in favour of the treatment mode under investigation, mainly CSII) and the absence of differences in daily practice.

Although in many cases inadequate metabolic control is the main indication to commence CSII, we did not observe any significant difference regarding HbA_{1c} at the start of therapy, HbA_{1c} at final follow-up or changes in HbA_{1c} over time between patients on MDI and those switching to CSII. Therefore, we conclude that the switch to CSII was initiated in some of the patients for reasons other than poor metabolic control.

Our findings also demonstrate that it is possible in daily practice to maintain moderate to good control of clinical parameters in a T1DM population and even improve these parameters. The reasons for this improvement remain open for discussion. Organisation of care, stricter guidelines, more education, improved pump and pen systems and a more active role of patients themselves may be involved. No definite conclusions can be drawn to explain this finding because not all these data were recorded in this study.

Interpretations of the findings from our study are limited by various factors, including the magnitude of loss to follow-up during the 15-year study period. Therefore, the results of our study should be interpreted with caution, and generalisability may be limited. This rate of loss to follow-up can be partly explained by the relatively young age of our population and the accompanied high relocation rate, which is the reason for approximately half of the loss to follow-up. In addition, 12 patients, mostly woman, moved to a hospital nearby after the departure of one of the diabetologists from our centre. Our results are also limited by the lack of appropriate controls and the use of questionnaires that measure general HRQOL.

In a conclusion, no differences with respect to meta-

bolic and HRQOL parameters between the various treatment modalities were observed after 15 years of follow-up between patients using MDI or CSII or patients switching from MDI to CSII in a setting in which patients, to a large extent, choose the mode of therapy that best suits them.

ACKNOWLEDGMENTS

The results of this study were orally presented during the 49th Annual Meeting of the European Association for the Study of Diabetes in Barcelona.

COMMENTS

Background

Patients with type 1 diabetes mellitus (T1DM) require lifelong daily administration of insulin in order to achieve metabolic control. Multiple daily injections (MDI) and continuous subcutaneous insulin infusion (CSII) are the most common forms of insulin administration. It is likely that T1DM and its therapy have impact on health-related quality of life (HRQOL). At the present, the influence of the mode of therapy (MDI or CSII) on long-term HRQOL and metabolic control is unknown.

Research frontiers

As HRQOL and metabolic control are important outcomes of T1DM management the influence of mode of therapy (MDI or CSII) on both outcomes is of great importance.

Innovations and breakthroughs

In T1DM, relevant deterioration of HRQOL and glycaemic control during the course of the disease have been reported. In contrast, there are also reports which found no association between duration of diabetes and scores on quality of life scales. The present study is the first to describe the long-term natural course of HRQOL among patients with T1DM. In addition, results of the study show no differences with respect to HRQOL and metabolic parameters between the various treatment modalities after 15 years of follow-up between patients using MDI, CSII or patient who switched from MDI to CSII.

Applications

The results of this study show that HRQOL and metabolic control is stable among T1DM patients. In addition, there is no impact of the mode of insulin therapy on HRQOL. Therefore, the findings of this study supports clinical decision making.

Terminology

CSII: continuous subcutaneous insulin infusion, insulin is administered continuously in the SC tissue using an externally placed pump. MDI: multiple daily injections, insulin is administered in the SC tissue using injections.

Peer review

This is a very well done and written clinical 15 year follow-up study considers the evaluation of on long term metabolic control and health related quality of life in type 1 diabetes patients treated with various therapy modes.

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α, β, δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

Abstract

Peripheral arterial disease, manifested as intermittent claudication or critical ischaemia, or identified by an ankle/brachial index < 0.9, is present in at least one in every four patients with type 2 diabetes mellitus. Several reasons exist for peripheral arterial disease in diabetes. In addition to hyperglycaemia, smoking and hypertension, the dyslipidaemia that accompanies type 2 diabetes and is characterised by increased triglyceride levels and reduced high-density lipoprotein cholesterol concentrations also seems to contribute to this association. Recent years have witnessed an increased interest in postprandial lipidaemia, as a result of various prospective studies showing that non-fasting triglycerides predict the onset of arteriosclerotic cardiovascular disease better than fasting measurements do. Additionally, the use of certain specific postprandial particle markers, such as apolipoprotein B-48, makes it easier and more simple to approach the postprandial phenomenon. Despite this, only a few studies have evaluated the role of postprandial triglycerides in the development of peripheral arterial disease and type 2 diabetes. The purpose of this review is to examine the epidemiology and risk factors of peripheral arterial disease in type 2 diabetes, focusing on the role of postprandial triglycerides and particles.

Key words: Peripheral arterial disease; Type 2 diabetes; Postprandial lipidaemia; Apolipoprotein B-48; Ankle-brachial index; Non-fasting triglycerides

Core tip: Peripheral arterial disease is highly prevalent in type 2 diabetes; traditional risk factors contribute to the disease. Interestingly, postprandial lipidaemia is increased in both conditions. However, one study showed that only subjects with both type 2 diabetes and peripheral arterial disease had elevation of postprandial lipids; subjects with type 2 diabetes and a normal ankle-brachial index had a normal postprandial response. Because most of the triglycerides of chylomicrons are extracted in muscle and adipose cells in the legs, the authors speculate on whether arteriosclerosis in the legs may contribute to greater postprandial lipidaemia.

ABI: Ankle-brachial index.

definition encompasses all extracoronary and extracerebral vascular disease. However, the term PAD is usually restricted to involvement of the lower limbs, particularly in the iliac bifurcation, and the iliofemoral and popliteal arteries[1]. The main cause of arterial stenosis in developed countries is atherosclerosis.

The prevalence of PAD in Europe and the United States is estimated to be 27 million persons[2]. The prevalence of PAD increases progressively with age, with most cases starting after the age of 40 years. It is well known that only a very few PAD patients actually have symptoms, around 10%-20%[3]. The use of a standardized questionnaire in the physician's office can increase the detection of claudicant patients[4,5]. Most patients with PAD are identified from non-invasive tests, such as the ankle-brachial index (ABI). Using this widely extended technique in Spain led to the identification of PAD in 8% of individuals aged 55-85 years[6]. In addition to age, the other cardiovascular risk factors also increase the likelihood of developing PAD. Thus, in persons with a low cardiovascular risk the prevalence of PAD is almost inconsiderable[7], whereas it can reach 27% in persons with type 2 diabetes[8].

The prognosis for patients with PAD, both symptomatic and asymptomatic, is poor[9]. Overall mortality is increased and the risk of death is even greater than that in patients who have angina or acute myocardial infarction[10-13]. Data from Spain confirm these findings. An analysis of the FRENA, REACH and AIRVAG registries showed that patients with PAD have a greater frequency of symptomatic multivessel disease and a worse one-year prognosis than patients with single-vessel involvement or cerebrovascular disease[14].

Diabetes and PAD

Diabetes, together with smoking, is the main risk factor for PAD[15]. Of patients who attended an angiology office in Spain due to intermittent claudication and who underwent arterial surgery or had an ABI ⩽ 0.9, 67% had diabetes mellitus[16]. Population-based studies in Spain, undertaken in either the general population or at various levels of care, showed that the presence of diabetes mellitus doubled or even tripled the possibility of having PAD (Table 1)[6,17-23]. The prevalence of an ABI < 0.9 in series of Spanish patients with diabetes ranges from 21% to 60% (Table 1)[8,24,25]. In the autonomous communities of Andalusia and the Canary Islands, 72% of all lower-limb amputations between 1996 and 2006 involved patients with diabetes[23,26,27]. In patients with diabetes, for every 1% increase in haemoglobin A1c there is a corresponding 26% increased risk of PAD[28]. The presence of PAD also increases the risk of death in patients with diabetes mellitus[29,30]. The prognosis for PAD is worse in patients with diabetes than those without diabetes[31].

Diagnosis of PAD in diabetes

The diagnosis of PAD usually depends on the sum of the symptoms, particularly intermittent claudication, plus the physical examination, especially the lack of pulses and the trophic disorders leading to critical limb ischaemia and distal necrosis[32]. However, patients, particularly diabetic patients, commonly have other processes at

the same time that can alter the traditional symptoms of PAD, making them much less specific[33]. Accordingly, the measurement of the ratio of the systolic blood pressures in the ankle and the arm, the ABI, has been recommended as the screening method for asymptomatic PAD and as a form of confirmation in symptomatic PAD[2,34,35]. A finding in one limb of an ABI < 0.9 with the measurement taken at rest under standard conditions is considered diagnostic of PAD, with an ABI between 0.9 and 1.0 considered borderline[36].

One limitation of the ABI, especially relevant in patients with diabetes, is arterial media calcification, which can lead to non-compressible arteries (ABI > 1.4) or false normal values. A recent study showed that individuals with an ABI > 1.4 have a worse prognosis than those with a normal ABI and even those with an ABI < 0.9. The prevalence of diabetes in the group with an ABI > 1.4 was 58%, compared with 18% and 48% in those with a normal ABI or those with an ABI < 0.9[37]. It has long been known that the sensitivity of the ABI to correctly diagnose PAD is considerably reduced in the presence of arterial media calcification and that, clinically, this calcification is associated with the presence of peripheral neuropathy[38,39]. Accordingly, in the presence of peripheral neuropathy it is recommended to use an alternative method, such as flow wave analysis using Doppler colour ultrasound[40,41]. In our experience this limitation is not negligible. In a series of 456 patients with type 2 diabetes, 35 were found to have intermittent claudication (7.6%); only 22 of these had an ABI < 0.9. Of the other 13, 12 underwent colour Doppler ultrasound and in 3 (25%) we obtained a monophasic wave, diagnostic of PAD. Thus, a normal ABI does not rule out PAD in patients with type 2 diabetes, and these patients should therefore undergo complementary tests if they have symptoms suggestive of PAD[8].

The resting ABI should be used as the diagnostic technique for PAD when lower limb arteriosclerosis is suspected. This should be done in persons with one or more of the following: symptoms in the lower limbs after exercise, wounds with delayed healing, and individuals older than 65 years of age or older than 50 years with a history of smoking or diabetes[34]. Given the high prevalence of PAD in patients with diabetes, the ADA recommends screening with the ABI in patients with diabetes who are older than 50 years and who have another risk factor (smoking, hypertension, hyperlipidaemia, or diabetes for more than 10 years)[42].

LIPIDS, POSTPRANDIAL LIPIDAEMIA AND PAD

Fasting lipids in PAD

Lipid abnormalities in PAD have received less attention than in other areas, as for example, in coronary anomalies. Very few prospective studies have focused on the relation between triglycerides and peripheral vascular disease. The most common feature of PAD is raised levels of triglycerides and lower levels of high-density lipoprotein (HDL) cholesterol as compared with age- and sex-matched controls without vascular disease, with similar levels of cholesterol and low-density lipoprotein (LDL) cholesterol[43-47]. The frequency of a cluster of lipid abnormalities of the type of raised triglycerides and small and dense LDL and reduced HDL was 20% in persons with PAD *vs* 0% in the control group[48]. Several studies have also shown that triglyceride levels are a predictive factor for PAD[49-51], though not all[52].

Postprandial lipidaemia: Atherogenic mechanism

Unlike the carbohydrates, which normally only show transitory increases after a meal, the circulating triglycerides show a pronounced increase (postprandial lipidaemia) one hour after the intake of a fat-rich meal (around 30-60 g), and can remain high for 5-8 h after the meal. As most persons regularly consume fatty meals every 4-5 h, the usual state in humans insofar as their triglyceride metabolism is concerned is clearly a continuous postprandial lipidaemic state[53,54].

The large triglyceride-transporting particles, the chylomicrons and the very low-density lipoprotein (VLDL), are too large to cross the endothelium and they therefore don't contribute to the atherosclerosis, but the same does not occur with the chylomicron remnants and the intermediate-density lipoprotein (IDL), which are much smaller particles[55]. Evidence exists that the cholesterol in the postprandial particles, originating in the intestine, contribute to the phenomenon of atherosclerosis, both in animals and in humans[56-59].

Postprandial lipidaemia and cardiovascular disease: Case-control vs prospective studies

Since the seminal work of Zilversmit, many case-control studies have found an association between the magnitude of the postprandial lipidaemia and the presence and severity of coronary artery disease[60,61]; these studies have been reviewed by Lopez-Miranda *et al*[62]. Prospective studies, however, are few and controversial. Reyes-Soffer *et al*[63] followed 69 patients with type 2 diabetes who were free of coronary disease for a mean of 8.7 years; 33 patients remained disease-free. No differences were found in the postprandial parameters at the initial visit between the groups, and the authors concluded that the postprandial triglycerides do not predict the onset of coronary disease in individuals with diabetes. A more recent study involving 514 survivors of an acute coronary syndrome found that the postprandial triglycerides after the oral intake of 75 g of fat predicted the appearance of new events at 18 mo. In the subgroup of patients without diabetes or oral glucose intolerance the relative increase in postprandial triglycerides was an independent predictor of events[64].

Non-fasting triglycerides

Interest in studying postprandial lipidaemia has increased over recent years as a result of studies showing that serum triglyceride levels measured in a non-fasting state have

proved to be better predictors for the risk of vascular disease than fasting triglyceride concentrations, *i.e.*, when they are quantified after 8-10 h of fasting[65-68]. Two meta-analyses also support the association between fasting and postprandial triglycerides and the vascular risk[69,70]. One of the problems encountered when introducing postprandial triglyceride measurements in the clinical setting is the absence of specific recommendations in the clinical practice guidelines and thus the identification of a threshold level above which postprandial hypertriglyceridaemia is recognised. To date, only the American Association of Clinical Endocrinologists has considered the possibility of evaluating the non-fasting triglyceride concentration[71]. Based on evidence from the above mentioned population-based studies, an expert group estimated non-fasting triglyceride levels < 180 mg/dL as desirable[72]. This means that 38% of the men and 20% of the women in the Copenhagen study who had figures above these levels have postprandial hypertriglyceridaemia[73].

Suggestion for the measurement of postprandial lipidaemia

The study of postprandial (hyper)lipidaemia has several inconveniences. The most important at present is the poor clinical yield and the great complexity of the fat test; its prolonged time is uncomfortable for both the patient and the medical personnel, not to mention the lack of standardization for the test. A few years ago, using data from a meta-analysis of 113 studies in healthy subjects by Mihas *et al*[74], an expert group attempted to standardize the test and recommended a fat tolerance test meal consisting of 75 g fat, 25 g carbohydrates and 10 g protein. Furthermore, the fatty test meal should contain mixtures of saturated and unsaturated fatty acids in a digestible form and be easy to prepare. The candidates for the test should have fasting triglycerides of 90-180 mg/dL and the test can be shortened with the measurement of the serum triglycerides at 4 h, with no need to reach a complete postprandial curve of 8 or 12 h[72].

POSTPRANDIAL LIPIDAEMIA AND PAD IN TYPE 2 DIABETES

Little attention has been given to the study of postprandial lipidaemia in patients with PAD. Only the elegant paper by Lupattelli *et al*[75] showed that the magnitude of postprandial lipidaemia, expressed as "the area under the incremental curve for triglycerides," was higher in 16 non-diabetic normolipidaemic claudicant patients with PAD than in 10 normolipidaemic control subjects, suggesting the relevance of postprandial lipoprotein metabolism in the pathogenesis of peripheral atherosclerosis. However, although normolipidaemic, the patients in Lupattelli's study had slightly higher fasting triglycerides than their controls.

In recent years our group has studied the relation between lipids and postprandial particles, PAD and type 2 diabetes mellitus. Firstly, the postprandial triglycerides were more strongly associated with PAD in individuals with type 2 diabetes mellitus than were the fasting triglycerides. A group of 119 patients with type 2 diabetes mellitus treated with just diet and/or oral glucose lowering agents, with no lipid-lowering treatment, were analyzed at fasting and 4 h after a mixed breakfast containing 50 g of fat and 40 g of carbohydrates. Although the patients with cardiovascular disease, most of them with asymptomatic PAD and identified by an ABI < 0.9, had lower fasting HDL cholesterol levels and higher triglyceride levels, only the triglycerides at 4 h post-breakfast were associated in the multivariate analysis with cardiovascular disease, together with the duration of the disease and smoking[76].

The postprandial triglycerides include not only those contained in chylomicron particles and their remnants, but also those contained in VLDL and IDL. In an attempt to further understand the role of postprandial fat in PAD, we undertook a second experiment to analyze the serum concentration of apolipoprotein B48, a protein that is only associated with chylomicrons and their remnants and is not interchanged with any other circulating particle. This second study involved 101 patients with type 2 diabetes mellitus and 73 controls without diabetes, both groups with no known cardiovascular disease. Asymptomatic vascular disease was identified from the ABI and as a marker of postprandial particles we used the apolipoprotein B48, measured with a commercial enzyme-linked immunosorbent assay. Of the patients with type 2 diabetes mellitus, 21 had PAD as defined by an ABI < 0.9, though no control had PAD. The levels of triglycerides and apolipoprotein B48, both fasting and postprandial, were significantly higher in the group of diabetic patients with PAD than in those without PAD and the controls. Curiously, no differences were found between the controls and the patients with type 2 diabetes mellitus without PAD. Of all the lipid and non-lipid parameters studied, only apolipoprotein B48 and smoking were associated with the presence of PAD in a binary logistic regression analysis. Likewise, the presence of PAD was an independent predictor of the levels of apolipoprotein B48, both fasting and 4 h after a mixed breakfast[77].

As the patients with type 2 diabetes mellitus in the previous studies did not receive any insulin or lipid-lowering therapy, we decided to confirm the findings in a larger population with type 2 diabetes mellitus without these exclusion criteria. Again, using an ABI < 0.9 as a marker of PAD, we found in 456 patients with type 2 diabetes mellitus that fasting apolipoprotein B48 was a marker of PAD, independently of the other lipid factors, statin treatment or insulin therapy[78]. Identical results have also been reported by another group[79].

May PAD delay postprandial lipid catabolism?

Taken together, these studies confirm an association between postprandial particles, measured as triglycerides 4 h after breakfast or as fasting and postprandial apolipoprotein B48, and PAD. In the above-mentioned studies, a diabetic status in itself was not associated with a greater

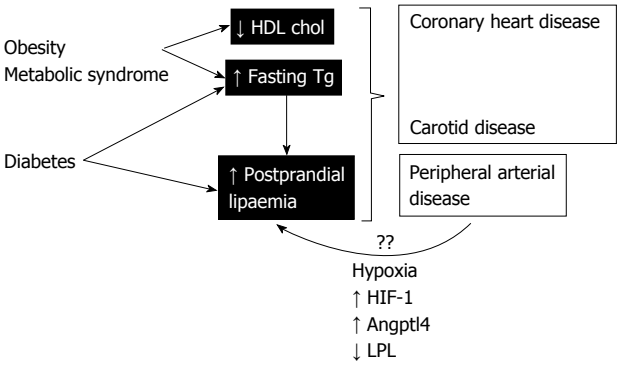

Figure 1 Proposed mechanism linking peripheral arterial disease and worsening postprandial lipaemia. HIF-1: Hypoxia-induced factor 1; Angptl4: Angiopoietin-like protein 4; LPL: Lipoprotein Lipase; HDL: high density lipoproteins.

concentration of postprandial triglycerides or apolipoprotein B48 if there was no PAD. As mentioned earlier, the case-control studies show an association between postprandial lipidaemia and cardiovascular disease, particularly coronary disease.

An explication for this association was provided by Lupattelli *et al*[75]. Somehow, and following the hypothesis of Zilversmit[80], the exposure of the endothelium to greater concentrations of postprandial particles favours the appearance of arteriosclerotic lesions, in our case in the lower limbs. Though this hypothesis is the most plausible, no causality can be deduced from the association studies. Accordingly, it is worth speculating about whether arteriosclerotic disease in the legs could alter chylomicron metabolism, slowing it. With this in mind, consideration should be given to the study by Horton *et al*[81], who showed that men have higher triglyceride concentrations than women because women posses a greater extractive capacity of triglycerides in adipose and muscle tissues in the lower limbs when they undergo a fatty breakfast. For some reason the catabolism of the chylomicrons in the legs is not negligible and an alteration in the circulation in the legs may worsen or slow this metabolism.

The kinetics of lipoproteins are marked by (1) their intestinal production; (2) hydrolysis of their triglycerides by the action of lipoprotein-lipase anchored in the endothelium (but synthesised in adipose and muscle tissue cells); and (3) removal of chylomicron remnants by hepatic receptors. These steps are all modulated by the levels and genetic variants of the apolipoproteins like C-Ⅱ, C-Ⅲ, E, A-5[82,83]. As persons with arteriosclerosis, particularly those with PAD, have a marked endothelial dysfunction[84], it is possible to speculate that the action of an enzyme anchored to the endothelium, as is the case of lipoprotein lipase (LPL), is reduced. Given the great extension of the endothelial surface in the legs (in comparison with coronary arteriosclerosis), established PAD might affect postprandial lipidaemia more intensely than coronary disease.

If this hypothesis were true, what would its mechanism of production be? The consequence of arteriosclerosis is tissue ischaemia. This is usually manifested as intermittent claudication, though the tissues may experience hypoxia in earlier stages. Tissue hypoxia leads to changes in the endothelial cells (where the LPL are anchored) or in the production of LPL (or its associated proteins) by adipose or muscle cells[85]. Cells submitted to hypoxia upregulate the expression of hypoxia-inducible factor 1, a transcription factor that induces changes in innumerable target genes that were reviewed some time ago[86]. Of note among these changes is the raised expression of angiopoietin-like 4 protein (Angptl4) and vascular endothelial growth factor (VEGF). VEGF intervenes in the processes of angiogenesis, much related with chronic ischaemia of the lower limbs and the formation of collateral vessels. Angptl4 is a potent inhibitor of LPL, the enzyme that intervenes critically in the first step of the catabolism of triglyceride-rich particles[87]. A recent experimental animal study showed that mice submitted to cyclic hypoxia experienced inhibition of the catabolism of triglyceride-rich lipoproteins as a consequence of a drastic reduction in adipose tissue LPL activity, coupled with a notable increase in Angptl4[88] (Figure 1).

Taken together, these data suggest that postprandial hyperlipidaemia, a recognised vascular risk factor associated with obesity, the metabolic syndrome and type 2 diabetes, could be aggravated by PAD, further exposing other arterial territories to greater concentrations of postprandial atherogenic particles. Finally, if the hypoxia were an underlying mechanism, it could be improved by percutaneous or surgical revascularization.

Abstract

Hepatitis C virus (HCV) infection and diabetes mellitus are two major public health problems that cause devastating health and financial burdens worldwide. Diabetes can be classified into two major types: type 1 diabetes mellitus (T1DM) and T2DM. T2DM is a common endocrine disorder that encompasses multifactorial mechanisms, and T1DM is an immunologically mediated disease. Many epidemiological studies have shown an association between T2DM and chronic hepatitis C (CHC) infection. The processes through which CHC is associated with T2DM seem to involve direct viral effects, insulin resistance, proinflammatory cytokines, chemokines, and other immune-mediated mechanisms. Few data have been reported on the association of CHC and T1DM and reports on the potential association between T1DM and acute HCV infection are even rarer. A small number of studies indicate that interferon-α therapy can stimulate pancreatic autoimmunity and in certain cases lead to the development of T1DM. Diabetes and CHC have important interactions. Diabetic CHC patients have an increased risk of developing cirrhosis and hepatocellular carcinoma compared with non-diabetic CHC subjects. However, clinical trials on HCV-positive patients have reported improvements in glucose metabolism after antiviral treatment. Further studies are needed to improve prevention policies and to foster adequate and cost-effective programmes for the surveillance and treatment of diabetic CHC patients.

Key words: Hepatitis C virus infection; Type 1 diabetes mellitus; Type 2 diabetes mellitus; Epidemiology; Pathogenesis; Prevention; Treatment

Core tip: Many studies have shown an association between type 2 diabetes mellitus (T2DM) and chronic hepatitis C (CHC) infection. The processes through which CHC is associated with T2DM seem to involve direct viral effects, insulin resistance, proinflammatory cytokines, and chemokines. Few data have been reported on the association of CHC and T1DM. A small number of studies indicate that interferon-α therapy can induce T1DM. Diabetic CHC patients have an increased risk of developing cirrhosis and hepatocellular carcinoma compared with non-diabetics. Clinical trials on hepatitis C virus-positive patients have reported improvements in glucose metabolism after antiviral treatment.

INTRODUCTION

Hepatitis C virus (HCV) infection and diabetes mellitus (DM) are two major public health problems that cause devastating health and financial burdens worldwide[1,2]. Diabetes can be classified into two major types: type 1 (T1DM) and T2DM[3,4]. T2DM is a common endocrine disorder that encompasses multifactorial mechanisms. These mechanisms include resistance to the action of insulin, increased hepatic glucose production, and a defect in insulin secretion, all of which contribute to the development of overt hyperglycaemia[5]. T1DM is an immunologically mediated disease. Prevention and treatment of T1DM are hampered by the fact that the key immunological mechanisms of the pathogenesis of the disease are still under debate[6,7]. However, a Th1 immune response is involved in β-cell destruction[8] and the importance of islet autoantibodies has been highlighted[9-11].

Chronic hepatitis C (CHC) infection has a global prevalence of 2%-3%. Approximately 170 million people are thought to be currently infected (approximately 3% of the world's population), and an additional 3-4 million are infected each year[12,13]. HCV is the main reason for liver transplantation in the developed world and the main cause of liver-related morbidity and mortality in a number of countries, including Italy. This virus is not only a frequent cause of chronic liver diseases, including hepatitis, cirrhosis, and hepatocellular carcinoma (HCC), but it is also involved in the pathogenesis of various autoimmune and rheumatic disorders (*e.g.*, arthritis, vasculitis, sicca syndrome, porphyria cutanea tarda, lichen planus, nephropathies, and lung fibrosis) and in the development of B-cell lymphoproliferative diseases[14,15].

CHC is a multifaceted disorder that is associated with extrahepatic manifestations, including endocrinological disorders, thyroid disorders and diabetes[16,17].

In this paper, we review the increasing evidence linking HCV infection and DM in multiple fields (epidemiology, pathogenesis, clinical aspects, prevention, and treatment).

RELATIONSHIP BETWEEN CHC AND THE DEVELOPMENT OF T2DM

Origins of the hypothesis and epidemiological data in the general population

The liver plays an important role in carbohydrate metabolism, and liver diseases such as chronic hepatitis and cirrhosis are associated with a higher prevalence of disturbed glucose homeostasis, impaired glucose tolerance, and insulin resistance (IR)[18,19], which can eventually lead to DM[20-23]. Asymptomatic, moderate serum aminotransferase elevation has frequently been found in patients with DM, particularly in those with T2DM[24,25]. This phenomenon has often been related to fatty infiltration of the liver without further investigation[26,27]. In particular, steatosis has been related to IR and T2DM, beyond intracellular fat accumulation[28].

Liver fibrosis progression has also long been considered to be responsible for the development of IR and T2DM in patients with chronic liver diseases[29]. However, diabetes often occurs in the early stages of liver disease[30].

The aetiological factors that underlie the development of glucose homeostasis alterations were initially thought to be exclusively related to general long-term hepatocyte damage. However, later studies showed that patients with hepatitis B virus infection have a lower prevalence of T2DM compared with HCV-infected patients[31,32]. Thus, the question is as follows: "Does HCV infection itself have diabetogenic action?"

Since the discovery of HCV in 1989, attention has been paid to the association of CHC with the development of DM. Additionally from 1994[33] until now, several epidemiological studies on the seroprevalence of HCV have shown higher prevalences in diabetic patients than in controls (Figure 1). Moreover, analyses have shown a higher prevalence of DM in patients who are seropositive for HCV than in controls without HCV infection.

To analyse the epidemiological data, we searched for published studies in the PubMed database, covering the period from 1994 to December 2012. The literature search was performed using combinations of the terms "diabetes", "diabetes mellitus", "type 2 diabetes mellitus", "T2DM", "type 2 DM", "non-insulin dependent diabetes", or "NIDDM"; "hepatitis", "hepatitis C", "hepatitis C virus", "HCV", "HVC", or "chronic hepatitis"; and "risk", "risk factor", "case-control", "cohort", "clinical trial", "cross sectional", "epidemiology", "observational", "meta-analysis", "systematic review", or "review". For epidemiological studies, we only searched human studies and publications in English and Italian, the languages understood by the authors.

The data represent a very heterogeneous population regarding gender, age, and ethnic group. Globally, approximately seventy studies are in agreement with an association[18,26,30-96], although not all of them have shown significant data. However, some of the non-significant data may be attributed to small sample sizes and other methodological factors (Figure 1).

Certain negative data that are not in agreement with an association between HCV infection and T2DM have also been reported[97-104]. However, the number of published epidemiological studies that are in agreement with the association between HCV infection and T2DM is higher than the number of studies in disagreement with this hypothesis.

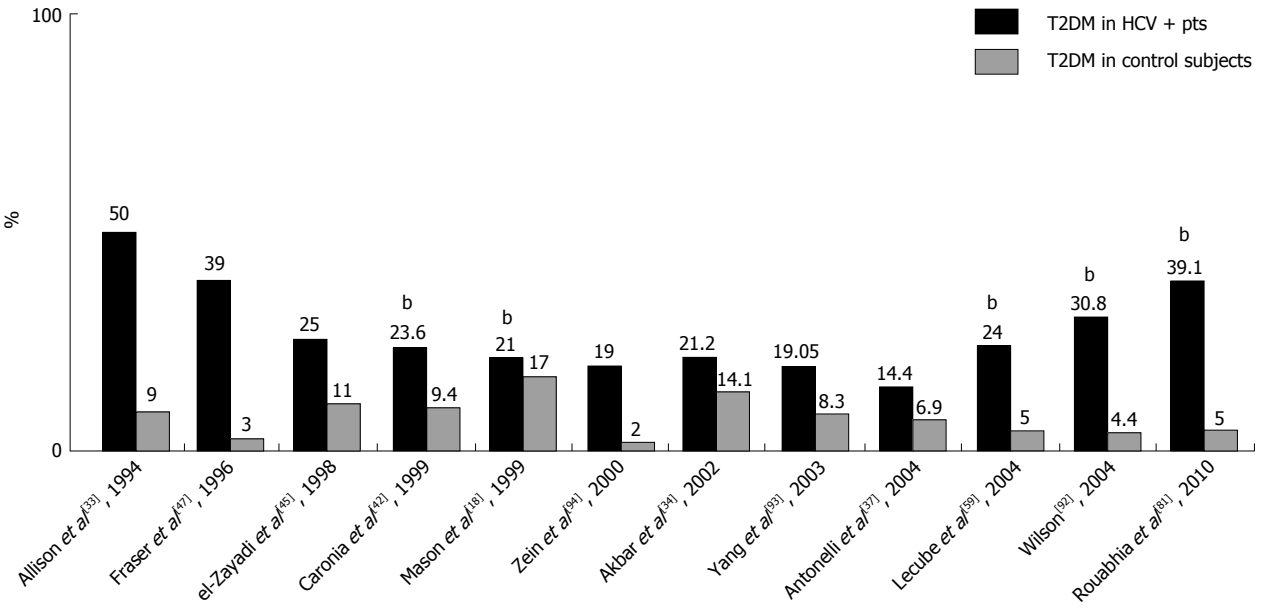

Figure 1 Patients seropositive for hepatitis C virus show a higher prevalence of diabetes mellitus than healthy controls. Twelve representative epidemiological studies demonstrated a relationship between HCV infection and the development of type 2 diabetes mellitus (T2DM). Analyses have shown a higher prevalence of diabetes mellitus in patients who are seropositive for HCV than in controls. $^{b}P < 0.001$, T2DM in HCV+ pts *vs* T2DM in control subjects. HCV+: Hepatitis C virus-infected; pts: Patients.

HCV INFECTION AND T2DM ASSOCIATION: PATHOGENESIS

Direct effects of HCV and IR

HCV is hepatotropic and noncytopathic; nevertheless, its genome has been identified in a number of tissues beyond the liver, including pancreatic acinar cells and epithelial cells of the pancreatic duct[105,106]. Although post-mortem studies have revealed that HCV replicates in the pancreas[107] and animal models have suggested a direct effect of HCV infection on IR in the liver[108], the evidence is scanty.

Of interest are the roles of structural and non-structural HCV proteins. HCV has an RNA genome of 9.6 kb that encodes approximately 3010 amino acids and is translated into structural (core, E1, and E2) and non-structural (NS3-NS5B) proteins. These proteins play a role in the development of IR and oxidative stress *via* reactive oxygen species at the cellular level[109-113]. The HCV core protein, alone or in combination with other viral proteins, increases phosphorylation of insulin receptor substrate-1 (IRS-1), which is the basis of IR[114-116]. Phosphorylated IRS-1 activates phosphatidylinositol 3-kinase (PI3K)[117,118], and the activation of PI3K and one of its downstream targets, Akt, is essential for most of the metabolic effects of insulin[119-126]. Therefore, defects at the level of the association of PI3K with IRS-1 and a lack of PI3K activation may contribute to IR and the increased prevalence of diabetes in HCV-infected patients. Indeed, this mechanism ultimately promotes glucose transporter-4 translocation to the plasma membrane to enhance glucose uptake[127,128]. Within the IR mechanism impairment of the activation of Akt/PKB is the key step that can inhibit glucose uptake[30,129,130].

The detailed molecular events leading to IR in HCV-infected patients are, however, unclear. Recent evidence supports the existence of a significant extrahepatic component of HCV-induced IR. Thus, the molecular pathogenesis of the glucose metabolism disturbances observed in hepatitis C is much more complex than expected[131].

Recently, Eslam *et al*[132] showed that polymorphisms in the IFNL3 (IL28B) region are associated with spontaneous and treatment-induced recovery from HCV infection. Furthermore, circumstantial evidence suggests a link between single-nucleotide polymorphisms in IFNL3 and lipid metabolism, steatosis, and IR in CHC. The emerging picture suggests that the responder genotypes of IFNL3 polymorphisms are associated with higher serum lipid levels and less frequent steatosis and IR[132].

HCV-induced immune responses; cytokines, chemokines-mediated effects

Viral innate immune evasion strategies and human genetic determinants underlie the transition of acute HCV infection into viral persistence and chronic infection. Host genetic factors can influence both the outcome of the infection and the response to antiviral therapy. Recent insights into how HCV regulates immune signalling within the liver reveal a complex interaction of the patient's genetic background with viral and host factors related to the innate immune triggering and control that dictate the outcome of HCV infection and immunity[133].

Beyond the direct effects of HCV on IRS-1/PI3K, the HCV core protein may induce IR indirectly *via* stimulation of the secretion of proinflammatory cytokines[115]. In patients with CHC, most likely due to HCV-induced inflammation, there is hypersecretion of insulin-resistant proinflammatory cytokines such as interleukin (IL)-6 and

tumour necrosis factor (TNF)-α[134-138]. Proinflammatory cytokines also upregulate suppressors of cytokine signalling proteins as part of a negative feedback loop to attenuate cytokine signalling[139,140]. This phenomenon may contribute to increased gluconeogenesis due to a lack of Akt-mediated inhibition of phosphoenolpyruvate carboxykinase gene expression. In this context, it is interesting to note that leptin can modulate the action of insulin in liver cells by antagonising insulin-stimulated IRS-1 tyrosine phosphorylation, increasing phosphoenolpyruvate carboxykinase gene expression, and decreasing glucokinase expression, which results in increased gluconeogenesis[141]. Together with the increase in gluconeogenesis, the enhanced production and accumulation of lipids mediated by inhibition of the AMP-activated protein kinase occur after HCV infection[142]. Additionally TNF-α plays a role in lipid metabolism. Indeed, the lipolysis-stimulating effect of TNF-α leads to increased serum levels of free fatty acids, which reduces insulin sensitivity[143,144].

Cytokines are intercellular mediators involved in viral control and in the liver damage induced by infection with HCV. The complex cytokine network that operates during the initial infection allows the coordinated, effective development of both the innate and the adaptive immune responses. However, HCV interferes with cytokines at various levels and escapes the immune response by inducing a Th2/T cytotoxic 2 cytokine profile. The inability to control infection leads to the recruitment of inflammatory infiltrates into the liver parenchyma by interferon (IFN)-γ-inducible CXC chemokine ligand (CXCL)9, CXCL10, and CXCL11, which result in sustained liver damage and eventually liver cirrhosis. The most important systemic HCV-related extrahepatic diseases (mixed cryoglobulinemia, lymphoproliferative disorders, thyroid autoimmune disorders, and T2DM) are associated with complex dysregulation of the cytokine/chemokine network, involving proinflammatory and Th1 chemokines[145,146].

HCV-INFECTED PATIENTS WITH T1DM

Few data on this association have been reported, and published studies have shown only small proportions of CHC patients positive for one or more markers of pancreatic autoimmunity[18,147-150].

Even rarer are reports on the potential association between autoimmune diabetes and acute HCV infection. Only two cases have been described in the literature[151,152]. Several mechanisms have been postulated to initiate the process. Even if HCV can infect extrahepatic tissue in patients with hepatitis C[16,107,153], no direct involvement of HCV in the onset of T1DM has been clarified yet. Nevertheless, the direct destruction of β-cells by viral infection could be a good explanation. Beyond the undemonstrated direct mechanisms, HCV infection surely initiates an immune reaction against β-cells or causes an acceleration of diabetes onset when an immune reaction against β-cells is already present. Some authors have also suggested the involvement of a process of molecular mimicry as a trigger of HCV-related autoimmunity[154,155]. Indeed, glutamic acid decarboxylase (GAD) 65 shares amino acid sequence similarities with antigenic regions of the HCV polyprotein[156]. Of interest, HCV/self-homologous autoantigenic regions are also mimicked by other microbial agents. Such mimics may give rise to β-cell autoimmunity through a multiple-hit mechanism of molecular mimicry[154,155,157]. Cross-reactive immunity does not exclude the possible involvement of additional factors, such as proinflammatory cytokines, which may act in concert, leading to the development and/or maintenance of pancreatic autoimmunity during acute HCV infection[156]. Another possibility is the induction of antibody reactivity against GAD and the development of full-blown diabetes, mediated by IL-18 and other proinflammatory cytokines. In particular, IL-18 is presumed to play a pathogenetic role in T1DM, specifically because this cytokine appears to be involved in acceleration of the development of overt disease[152,158-160]. IL-18 can induce both Th1 and Th2 responses, depending on the surrounding cytokines[161], and this cytokine plays a pathogenic role in several diseases[161], including acute hepatic injury[162]. Other proinflammatory cytokines, such as TNF-α and IL-1β, which are elevated in patients with acute hepatitis[163], can also induce autoimmune diabetes[164-167].

OTHER IMMUNE ASPECTS OF HCV ASSOCIATED WITH T1DM OR T2DM

Immune aspects have been reported in both T1DM and T2DM, and based on the immunology, it is clear that the lines separating T1DM from latent autoimmune diabetes in adults (LADA) and T2DM are not well delineated[10,11,16,37,145,168-170].

The type of diabetes manifested by patients with CHC is not classical T2DM, and the labelling of HCV patients as having T2DM is purely conventional and possibly inaccurate. The lines separating T1DM from LADA and T2DM are fading away as new pathogenetic information is obtained[170].

Three studies have reported[37,38,171] that HCV patients with T2DM are leaner than T2DM controls and show significantly lower low-density lipoprotein-cholesterol levels and systolic and diastolic blood pressures. Furthermore, patients with HCV-associated mixed cryoglobulinaemia (MC + HCV) and T2DM had non-organ-specific autoantibodies more frequently (34% *vs* 18%, respectively) than did non-diabetic MC + HCV patients[37]. An immune-mediated mechanism for MC + HCV-associated diabetes has been postulated[37], and a similar pathogenesis might be involved in diabetes in HCV patients. This hypothesis is strengthened by the finding that autoimmune phenomena are more common in T2DM patients than previously thought[10]. However, as the prevalence of classic β-cell autoimmune markers is not increased in HCV patients[70], other immune phenomena might be involved[168]. Chemokines could be important in this context. In fact, in children with newly

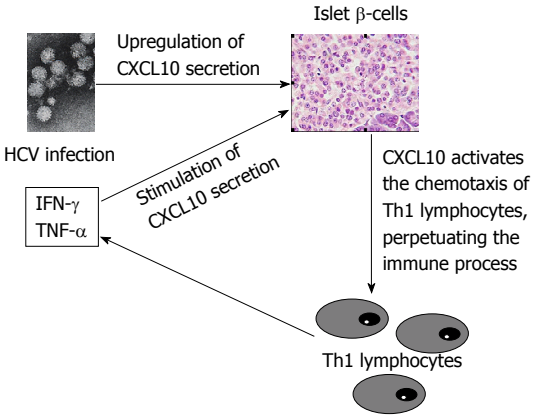

Figure 2 Potential regulation of the endocrine manifestations of hepatitis C virus infection in islet β-cells. Hepatitis C virus (HCV) infection may act by upregulating CXC chemokine ligand (CXCL) 10 gene expression and the subsequent secretion of this chemokine by islet β-cells. These events lead to the recruitment of Th1 lymphocytes that secrete interferon (IFN)-γ and tumour necrosis factor (TNF)-α, which induce chemokine secretion by islet β-cells, thus perpetuating the immune cascade. This cascade may lead to the appearance of autoimmune thyroid disorders in genetically predisposed subjects.

diagnosed T1DM, raised serum CXCL10 and normal chemokine (C-C motif) ligand 2 concentrations signal a predominantly Th1-driven autoimmune process, which shifts toward Th2 immunity 2 years after diagnosis[172].

Based on the abovementioned concepts, HCV infection of β-cells[106] may act by upregulating *CXCL10* gene expression and secretion (as previously shown in human hepatocytes[173]) and recruiting Th1 lymphocytes that secrete IFN-γ and TNF-α, which induce CXCL10 secretion by β-cells and thus perpetuate the immune cascade. This cascade may lead to the appearance of β-cell dysfunction in genetically predisposed subjects (Figure 2). Recently, certain studies have confirmed this hypothesis, demonstrating higher serum levels of CXCL10 in HCV patients with T2DM than in those without[16,169].

T1DM AND T2DM IN HCV-INFECTED PATIENTS TREATED WITH IFN-α

An important research area concerns the relationship between diabetes and IFN-α therapy in HCV-infected patients. In particular, studies have shown a high prevalence of markers of pancreatic autoimmunity in HCV-positive patients after or during IFN-α therapy, most likely due to the immunostimulatory effects of this cytokine. Indeed, IFN-α has antiviral, antiproliferative, and immunomodulatory activities[174]. Thus, in predisposed individuals, IFN-α can either induce a diabetogenic process or accelerate a diabetogenic process that is already underway[18,175,176]. For this reason, islet cell autoantibodies and GADAb should be investigated before and during IFN treatment to identify subjects who are at high risk of developing T1DM[177-180]. A small number of patients can develop *de novo* pancreatic autoimmunity and fall into a group of patients at risk of developing DM. In general, patients who are initially positive for organ-specific autoantibodies (in particular, thyroid- and pancreas-specific autoantibodies) and those who seroconvert seem to be at high risk of developing clinical autoimmune disease after treatment with IFN-α[181]. Timely suspension of IFN-α therapy is rarely accompanied by regression of clinical DM. No correlation has been documented between the response to antiviral therapy and the development of DM.

IFN-α increases HLA class I antigen expression and natural killer cell and T cell activities, and this cytokine may be an important cofactor in the development of a Th1 immune reaction. This reaction can contribute to the development of autoimmune disease by the activation of CD4+ lymphocytes that secrete IL-2, IFN-γ and TNF-β. These cytokines help in the generation of CD8+ cytotoxic T cells[182]. In addition to its immunomodulatory properties, IFN-α can also increase IR and induce hyperglycaemia[183-188]. Fabris *et al*[189] documented the first case of T1DM development during IFN-α therapy. Other studies suggest that IFN-α therapy can stimulate pancreatic autoimmunity and, in certain cases, lead to the development of T1DM[150,175,177,180,181,190-223].

The relationship with T1DM does not account for all of the effects of IFN-α therapy on diabetes. Indeed, from a completely different perspective, antiviral therapy with IFN should also be considered in HCV-positive patients because of its potential role in limiting the progression of this metabolic disturbance (see later discussion).

OUTCOME IN DIABETIC HCV-POSITIVE PATIENTS

CHC is an insidiously progressive form of liver disease that leads to cirrhosis[224-226] and HCC[227-231]. Diabetic HCV-positive patients have increased risk compared with non-diabetic subjects, and DM itself seems to have a selective impact on HCC development[232-251].

The main characteristic of diabetic patients is IR, which plays a crucial role in fibrosis progression and has a negative impact on treatment responses to antiviral therapy in patients with CHC[52,252,253]. Reduced insulin sensitivity is at the basis of compensatory hyperinsulinemia and elevated levels of insulin-like growth factor 1 (IGF-1), which stimulates cell proliferation and inhibits apoptosis. Additionally, this phenomenon has strong mitogenic effects on a wide variety of cancer cell lines[254-256]. At the same time, insulin activates the IGF-1 receptor, which has a growth-promoting effect that includes modulating cell cycle progression. Excess insulin may also indirectly affect the development of cancer by downregulating the level of IGF-binding protein 1, which increases the level and bioavailability of total circulating IGF-1. Additional factors, such as obesity and physical inactivity, also cause hyperinsulinemia and are thus also ultimately associated with accelerated cancer progression[255-258].

Genotype differences in terms of liver disturbance progression have been described as well. Genotype 3a is more strongly correlated with steatosis than other

genotypes[259,260], and the HCV genotype 3 may have a cytopathic effect[261]. Steatosis in genotype 1 infection is instead thought to be an expression of metabolic syndrome caused by the activation of proinflammatory mechanisms as well as underlying obesity and IR[262]. The degree of steatosis in this genotype is independent of the HCV viral load, and antiviral therapy does not improve steatosis in these patients. Similar data have been obtained for genotype 4 infection, whereas few data are available for genotype 2[263].

The presence of HCV infection in patients with DM may also increase the proportion of DM-related chronic nephrologic complications[86,264].

PREVENTION AND TREATMENT

CHC is a complex disease with systemic effects that require a multidisciplinary treatment approach[265].

The potential relationship between HCV infection and the development of DM increases the need for the implementation of prevention measures. Prevention must be directed toward lifestyle changes that can reduce the risk of HCV infection and/or diabetes development[266]; regular diabetes screening for anti-HCV-positive people; and the analysis of other risk factors that can accelerate the progression of both CHC and DM, such as obesity, dyslipidaemia, and alcohol consumption. In these high-risk patients, comprehensive treatment, including lifestyle modifications, must be recommended. Animal models also provide clues regarding the prevention and clinical management of diabetes in the setting of HCV infection[108]. Indeed, identifying patients who are at risk of developing diabetes, and have CHC, reduces liver disturbance progression[267,268], the incidence of HCC and transplant-related morbidity and mortality. Additionally, this identification improves the response to antiviral therapy[269-271], even reducing the side effects of the treatment[270] by encouraging the pretreatment of IR and DM[265].

Moreover, clinical trials on HCV-positive patients have reported improvement in glucose metabolism after antiviral treatment[187]. As discussed earlier, many factors may surely affect the antiviral response that modulates the IFN signalling pathway. Among these factors, the HCV genotype, genetic host factors, and comorbidities have been taken into account. In particular, recent studies have reported obesity[272] and hypercholesterolaemia[273] as potential factors that interfere with a sustained viral response. These observations suggest additional therapeutic options for HCV infection, including dietary changes, anti-diabetic drugs, and statins. Concerning anti-diabetic drugs, it is not currently clear whether the best approach is to use a peroxisome proliferator-activated receptor agonist or a biguanide, such as metformin[274-276]. Concerning statins, these drugs are capable of inhibiting HCV replication *in vitro*[277-279] but not *in vivo*[280].

Further studies are needed to improve prevention policies and to foster adequate and cost-effective programmes for the surveillance and treatment of diabetic CHC patients. The final goal must be to cure two diseases, diabetes and CHC, with one multifaceted treatment.

CONCLUSION

Many epidemiological studies have shown an association between T2DM and CHC. The processes through which HCV is associated with DM seem to involve direct viral effects, IR, proinflammatory cytokines, chemokines, suppressors of cytokine signalling, and other immune-mediated mechanisms. Other factors, such as metabolic syndrome and a family history of diabetes, also seem to be important risk factors for the development of diabetes. Few data on the association of CHC and T1DM have been reported, and reports on the potential association between T1DM and acute HCV infection are even rarer. A small number of studies have indicated that IFN-α therapy can stimulate pancreatic autoimmunity and, in certain cases, lead to the development of T1DM. Diabetes and CHC have important interactions. Diabetic CHC patients have an increased risk of developing cirrhosis and HCC compared with non-diabetic CHC subjects. Additionally, clinical trials on HCV-positive patients have reported improvement in glucose metabolism after antiviral treatment. Further studies are needed to improve prevention policies and to foster adequate and cost-effective programmes for the surveillance and treatment of diabetic CHC patients.

Abstract

Patients with diabetes mellitus are at high risk of developing atherosclerosis, associated with higher rates of micro and macro vascular involvement such as coronary artery disease and renal disease. The role of hyperglycemia to induce synthesis of reactive oxygen species by the oxidation of glucose, leading to an increased production of advanced glycosylation end products, as well as inflammation and oxidative stress has been proposed as a possible mechanism in the pathogenesis of endothelial dysfunction (ED). The interaction between C-peptide - the connecting segment of pro-insulin-and nitric oxide in vasodilation is also discussed. Therefore, endothelial dysfunction has been identified as an early marker of vascular disorder in type 1 and type 2 diabetes mellitus. In some other diseases, ED has been considered an independent predictor of vascular disease, regardless of the method used. Studies have demonstrated the importance of endothelial dysfunction as an useful tool for identifying the risk of vascular complications in patients with type 1 diabetes mellitus, particularly as regards to renal impairment. The aim of this review is to clarify the prognostic value of endothelial dysfunction as a marker of vascular disease in these subjects.

Key words: Endothelial dysfunction; Type1 diabetes; Prognostic; Cardiovascular disease; Pathogenesis

Core tip: This review is divided into two parts: first we discuss aspects related to the pathogenesis of endothelial dysfunction in type 1 diabetes mellitus. In the second, are pointed out and critically discussed the scientific evidence about the important role of endothelial dysfunction, independent of the method used for its diagnosis, as an early marker of cardiovascular and renal complications in this population.

INTRODUCTION

Diabetes mellitus patients have a high risk to develop atherosclerotic disease[1]. The macro- and microvascular complications are the main cause of morbidity and mortality, especially in those with more than five years of disease[2-4]. Endothelial dysfunction (ED) has been identified as an early marker of vascular disease in type 1 diabetes mellitus (T1DM)[5]. In some other conditions, ED has been an independent predictor of cardiovascular risk[6].

This review aims to evaluate the endothelial dysfunc-

tion role as a prognostic factor of vascular complication in patients with T1DM.

PATHOGENESIS OF ENDOTHELIAL DYSFUNCTION IN T1DM

The role of vascular endothelium on the pathogenesis of vascular disease has been better known in the last 30 years. Adequate endothelial function depends on the healthy balance between vasoconstrictor and vasodilator substances that interact in the endovascular environment[7,8]. Nitric oxide (NO), identified by Furchgott *et al*[9], is synthetized from L-arginine by nitric oxide synthase (eNOS) in the presence of oxygen, nicotinamide adenine dinucleotide phosphate and BH4 (tetrahydrobiopterin). This substance produced on endothelial cells diffuses itself into smooth muscle cells and platelets, where it stimulates the activity of the soluble guanylate cyclase and hence production of cyclic GMP promoting, in turn, relaxation of the muscle layer of the vessel and reduces platelet aggregation. On the other hand, NO reduction is associated with increased vascular injury, because it enhances platelet aggregation and increases monocyte adhesion to vascular endothelium; as well it stimulates proliferation of smooth muscle cells[10].

In pathologic situations, as diabetes, numerous mechanisms as: (1) decreased synthesis or inactivation of NO; and (2) increased production and release of vasoconstrictor substances have been proposed to explain the ED. In addition, metabolic changes favoring increased production of free radicals as well as advanced glycosylation end products (AGEs) are able to accelerate the nitric oxide inactivation[10].

Considering that the major metabolic disturbance in diabetes is hyperglycemia, it has been suggested that it may induce the synthesis of reactive oxigen species, by the oxidation of glucose[11], leading to an increased production of AGEs[12], among other mechanisms. On the other hand, a recent study demonstrates that hypoglycemia is also associated with ED, oxidative stress and inflammation. Moreover, worsening of endothelial function was greater in those who went from hypoglycemia to hyperglycemia than those recovered to a state of normoglycemia[13].

Other substances involved in the pathogenesis of endothelial dysfunction in T1DM are insulin and C-peptide. Several studies have shown that the vasodilator effects of insulin depends on the synthesis of nitric oxide, since the use of substances that block eNOS, inhibits the increase of blood flow mediated through the action of insulin[14-16]. Moreover, acute administration of C-peptide-a connecting segment of pro-insulin-is able to increase blood flow in subjects with T1DM after exercise or at rest, but not in normal subjects[17,18]. As well, a prolonged infusion of C-peptide in type 1 diabetic subjects improves kidney function[19] by a mechanism that involves the interaction between nitric oxide activity, and Na^+K^+ATPase[20,21]. So, it is important to understand that the pathogenesis of endothelial dysfunction in T1DM is complex and involves metabolic and hormonal changes; in particular, the role of insulin deficiency that leads to a decreased production of nitric oxide, increased oxidative stress in the vascular milieu with consequent decreased in the ability to promote vessels dilation. Furthermore, it is suggested that a better control of metabolic changes by insulin replacement can decrease the aggression of endothelial cells.

Other aspects of the pathogenesis of vascular abnormalities in diabetic subjects deserve attention. T1DM and T2DM are associated with a reduction in the number of endothelial progenitor cells (EPCs)[22-24]. It is interesting to note that this reduction is related to the severity of peripheral vascular disease which reinforces the importance of EPCs as a marker of vasculopathy in diabetic patients[25]. Moreover, potent vasoconstrictor such as angiotensin II and endothelin promote endothelial dysfunction in the metabolically altered environment of diabetes[26]. This knowledge is relevant since it may allow the emergence of new therapeutic perspectives. It is noteworthy that it has already been demonstrated that oral treatment with bosentan, endothelin receptor antagonist, for 4 wk, improves endothelial function in T2DM[27].

PROGNOSTIC VALUE OF ENDOTHELIAL DYSFUNCTION

The literature clearly suggests that metabolic and hormonal disorders present in T1DM injure the endothelial cells favoring endothelial dysfunction and initiation of the atherogenic process. A longitudinal study published recently suggests that flow-mediated vasodilation is an useful tool to stratify T1DM children according to cardiovascular risk, as well as for the long term follow-up[28]. However, the prognostic value of endothelial dysfunction as a marker of vascular complications should be further analyzed.

A 10-year follow-up prospective cohort study involving young T1DM adults with a mean disease duration of 19 years, evaluated the ability of adhesion molecules in predicting coronary artery disease (CAD) defined by angina, confirmed myocardial infarction, stenosis > 50%, ischemic electrocardiogram, or revascularization. With this purpose, a nested case-control study involving 60 patients who developed CAD and 72 patients without the disease was performed. Dosages of vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule 1 and E-selectin were performed from stored samples prior to the cardiovascular event. Although there was a correlation between adhesion molecules and lipid variables, considered an unquestionable cardiovascular risk factor in type 1 diabetes, only E-selectin was an independent predictor of CAD (HR = 1.07, 95%CI: 1.01-1.15, $P < 0.03$)[29].

Another cross-sectional study that included patients with T1DM without cardiovascular disease and a comparison group of healthy subjects, sought to identify association between endothelial dysfunction [flow-mediated vasodilation (FMD)] and subclinical cardiovascular dis-

ease. It was then observed a strong inverse correlation between FMD and systolic dysfunction (r = -0.70, P < 0.0001), diastolic dysfunction (r = -0.77) and duration of T1DM (r = -0.61,) P < 0.0001 for the three variables[30]. The association between ED and other markers of subclinical CAD, as the carotid intima-media thickness (IMT), was evaluated in a study that included T1DM patients and non-diabetic children-without significant differences in weight, age, blood pressure and gender. This study demonstrated that the T1DM group had lower peaks of FMD response and higher IMT when compared to controls (P < 0.001). Moreover, in the multivariate analysis, there was a strong association between increased IMT and decreased FMD in the group of children with diabetes (P < 0.03). However, the data in the literature are still conflicting. A study involving patients with T1DM and healthy subjects showed no difference between the IMT of the two groups, although endothelial function had been worse in T1DM group and correlated with glycemic control[31].

On the other hand, a recent study that evaluated endothelial function, IMT and ventricular function in 30 children and adolescents with T1DM compared with 30 healthy subjects matched by gender, age, and body mass index, found a lower FMD response, increased IMT and impaired diastolic function with lower early peak flow velocity, decreased E/A ratio, increased early filling deceleration time in T1DM patients. Furthermore, these changes were more evident in patients with poor glycemic control[32].

Several studies have shown the importance of endothelial dysfunction as a marker of renal impairment. In 2005, we demonstrated that FMD had an inverse correlation with microalbuminuria (r = -0.50, P = 0.049) in children and adolescents with a short duration diabetes (2.9 + 1.2 years) calling attention to the value of the endothelial dysfunction as a very early marker of vascular complications[4]. This association was also demonstrated in patients with disease duration > 10 years, with the following features: individuals with proteinuria and chronic renal failure (CRF) had FMD 7% and 4% respectively, while those with normal albumin excretion or microalbuminuria showed FMD > 8%, considered the lower limit of normality for flow-mediated vasodilation in adults[33]. In this study, there was a continuous, progressive and significant increase in the levels of endothelin-1 and C-reactive protein in individuals (1) without microalbuminuria; (2) with microalbuminuria; (3) with proteinuria; and (4) CRF. In addition, the sensitivity coefficient to shear stress endothelium was inversely correlated with glomerular filtration rate (GFR) (r = -0.48, P = 0.03). This aspect can be somewhat reinforced by another recent study that demonstrated that pulse pressure was associated with a decline in estimated GFR (r = 0.26, P = 0.003, adjusted), as well as the higher pressure pulse predicted an increased risk to develop end-stage renal disease: adjusted HR of 1.2 (95%CI: 1.1-1.4, P = 0.011)[34]. In addition, a cohort study of 18 T1DM patients followed for 8 years has shown an association between the expansion of the cortical interstitial volume fraction and PA1-activity and VCAM levels[35].

It is worth noting that changes in endothelial function can be identified regardless of the method used. A sustained hyperaemic stimulation induced by the hand skin heating method, as well as FMD vasodilation, were used to evaluate endothelial dysfunction in T1DM patients with and without microangiopathy and also in healthy controls matched for gender, age and body mass index. It was observed that FMD was lower in the diabetes group compared to controls. Furthermore, the presence of clinical complications was significantly associated with lower FMD and creatinine levels were also negatively correlated with the magnitude of FMD. With regard to the hand skin heating method, it was shown that the radial flow shear stress increased vascular diameter in all groups, however, the amplitude of FMD in diabetic patients were significantly lower than in the control group[36]. This dataset demonstrate the importance of endothelial aggression factors as potential markers of vascular injury.

More recently, longitudinal studies have sought to identify markers of endothelial dysfunction as predictors of long-term cardiovascular events. In a prospective study, T1DM patients with persistent normoalbuminuria and nephropathy, without previous cardiovascular events, were followed for a mean period of 12.3 years. The plasma levels of soluble receptor for advanced glycation end products (sRAGE) and other biomarkers were measured at baseline. High levels of sRAGE as a reflection of RAGE expression, was associated with greater incidence of fatal or nonfatal cardiovascular disease, as well as all-cause mortality. Furthermore, there was a significant association between levels of sRAGE and GRF in patients with nephropathy[37]. These authors, in a prospective study with a similar sample, showed that higher plasma levels of the pro-inflammatory cytokine high -mobility group box 1 was an independent predictor of fatal and non-fatal cardiovascular events and also a high-risk marker for all causes of mortality[38].

According to a recently published review, the mechanisms of endothelial dysfunction and ischemic response in diabetes mellitus is complex, involving inflammation, intercellular signaling peptides and proteins, cell angiogenic potential, among others[39]. It is noteworthy that a prospective study demonstrated a decrease of EPCs in children with T1DM, as well as the association between better glycemic control and increased EPCs after an one-year follow-up, suggesting that knowledge of this mechanism may be a way of mediating the high cardiovascular risk in these patients[40]. Therefore, more knowledge on the balance between vascular homeostasis and cardiometabolic risk factors will certainly improve the monitoring of diabetic patients and reduce vascular complications and consequently morbidity.

CONCLUSION

In summary, the pathogenesis of endothelial dysfunction

in T1DM is complex and involves several mechanisms such as inflammation, oxidative stress, interaction between insulin and C peptide, decreased number of endothelial progenitor cells among others. The prognostic value of assessing endothelial function as a marker of cardiovascular morbidity and risk has been demonstrated by cross-sectional and prospective studies with long follow-up, using various methods to identify subclinical atherosclerosis and endothelial dysfunction. The dataset demonstrate that regardless of the method used, impairment of endothelial function is a predictor of risk for cardiovascular disease and nephropathy. This knowledge suggests that new preventive and therapeutic interventions should be recommended early in order to decrease morbidity in this high-risk population.

Abstract

A re-examination of the mechanism controlling eating, locomotion, and metabolism prompts formulation of a new explanatory model containing five features: a coordinating joint role of the (1) autonomic nervous system (ANS); (2) the suprachiasmatic (SCN) master clock in counterbalancing parasympathetic digestive and absorptive functions and feeding with sympathetic locomotor and thermogenic energy expenditure within a circadian framework; (3) interaction of the ANS/SCN command with brain substrates of reward encompassing dopaminergic projections to ventral striatum and limbic and cortical forebrain. These drive the nonhomeostatic feeding and locomotor motivated behaviors in interaction with circulating ghrelin and lateral hypothalamic neurons signaling through melanin concentrating hormone and orexin-hypocretin peptides; (4) counterregulation of insulin by leptin of both gastric and adipose tissue origin through: potentiation by leptin of cholecystokinin-mediated satiation, inhibition of insulin secretion, suppression of insulin lipogenesis by leptin lipolysis, and modulation of peripheral tissue and brain sensitivity to insulin action. Thus weight-loss induced hypoleptimia raises insulin sensitivity and promotes its parasympathetic anabolic actions while obesity-induced hyperleptinemia supresses insulin lipogenic action; and (5) inhibition by leptin of bone mineral accrual suggesting that leptin may contribute to the maintenance of stability of skeletal, lean-body, as well as adipose tissue masses.

Key words: Insulin; Leptin; Weight regulation; Autonomic; Circadian

Core tip: The novel proposal for the mechanism of body weight regulation deals with all three components of body mass: bone, lean tissue, and fat depots. It attributes the central control of counterbalancing energy expenditure and intake to an autonomic nervous system-circadian clock command center that encompases brain reward substrates, lateral hypothalamic peptidergic circuits and areas of the cortex. The nonhomeostatic character of feeding and locomotion is driven and controlled by the reward circuits and modulated by shifts in insulin sensitivity induced by counterregulation by leptin of insulin as weight deviates between underweight and overweight and alters basal leptin concentrations.

INTRODUCTION

Finding and ingesting food and drink are intermittent behaviors essential for individual and species survival against continuous energy cost of staying alive. Our complex physiological design insures that opportunities to ingest food are not missed and that drive to seek food increases and compensatory processes are deployed to counteract substantial losses of body mass. That this behavior supports both growth of body mass as well as its

maintenance when statural growth has ceased only adds to its complexity and challenges our ability to understand its mechanism. Therefore, the transformation from a system in which food abundance drives the acquisition of body mass during statural growth to a system where energy intake is matched to each finite adult physique requires an explanation that integrates both phenomena. In addition, feeding behavior is coupled to spontaneous variations in movement and locomotion in ways that are imperfectly understood, and the two behaviors and control of metabolic heat production also contribute to regulation of body mass. A satisfactory model for the regulation of stable adult body mass must integrate central neural, autonomic, and endocrine controls of feeding, locomotion, and metabolic heat production. But it also needs to account for the prospect that some humans[1,2] and animals[3] can deviate from body mass stability and predictably become obese[1,2] under conditions providing abundant foods of high energy density and palatability along with limited opportunities and incentives for physical activity.

The quest for understanding what guides intermittent meal-to-meal eating and body mass maintainance as well as increased hunger and food intake responding to substantial losses of body mass, has a long history but no satisfactory closure or consensus. Because of its complexity, and relevance to professionals in disconnected fields of psychology, nutrition, gastrointestinal physiology, endocrinology, exercise science, neuroscience, and physiology among others, the wealth of information about the neural, autonomic, and hormonal mechanism of feeding, physical activity, and thermogenesis in body mass regulation has not been satisfactorily integrated. A prevailing preference for a unitary deductive model of body mass regulation has placed emphasis on the presumed metering and matching of energy consumed to energy expended and to the energy content of body fat mass under both ad libitum and underweight conditions[4-9]. The core feature of this model is operation of a negative feedback exerted by adipokine leptin (and in some variations of the hypothesis, also by insulin) over feeding behavior and energy expenditure in response to changes in body fat mass. This widely accepted hypothesis is not supported by the empirical data under conditions of intact neuroendocrine system, environmental abundance of food, reduced opportunities for physical exertion, and rising levels of body fat. Obesity coexists with high basal concentrations of leptin and insulin. Further, administration of leptin to obese humans is ineffective in suppressing feeding and reducing the body or fat mass[10]. On the other hand, two robust findings regarding leptin actions on feeding and body energy status need to be reconciled with its inability to reduce body fat mass in a negative feedback fashion in neurologically normal obese individuals under the ad-libitum feeding conditions. The first finding is a consistent proportional relationship between distributed body fat mass and basal leptin (and insulin) concentrations in humans and animals first clearly demonstrated in humans by Considine[11] and postulated to exert sustained inhibition over feeding and facilitation of energy expenditure[4-9]. The second finding is capacity of leptin to inhibit pronounced and consistently high hunger and suppress high fat mass in freely feeding humans and animals that lack leptin signaling capacity. This was first reported in humans by Farooqi[12,13] and in animals by Pelleymounter[14].

A unitary mechanism of weight regulation that can account for eating and weight changes leading to obesity and in non-deprivation as well as weight-loss conditions needs to account for (1) central neural coordination of this process; (2) interactions of this mechanism with the biological clock in structuring ultradian and nycthemeral rhythms of intermittent hunger and feeding; (3) opportunistic as opposed to homeostatic control of food intake and locomotion; (4) counterregulation by leptin of insulin secretion and actions to fluctuations of short-term energy availability and deviations in body fat mass; and (5) inclusion of skeletal and lean body masses along with the fat mass in the energy regulatory process. The proposed mechanism accounts for these processes in a novel way that differs from the currently prevailing view[4-9]. Its main propositions are that : (1) the autonomic brain centers activate hunger drive in; (2) a circadian pattern suppressed by intermittent inhibition from gastrointestinal (GI) filling and food processing that coordinate anabolic and catabolic processes to produce weight stability; (3) meal-to-meal eating and spontaneous physical activity represent non-homeostatic behaviors motivated through activation of a common brain substrates of reward that are connected to, and controlled by, the autonomic centers and circadian clock and responsive to short-term variations in the filling of the GI tract with food and fluctuations in body fat reserves and body mass; (4) autonomic nervous system (ANS) controls counterregulation by leptin of insulin secretion and tissue sensitivity to insulin actions to yoke leptin's thermogenesis and catabolic metabolism to insulin's anabolic actions; gastric leptin participates in GI processing of ingested nutrients and thus contributes to defining meal size through both anabolic digestive and restrictive satiating effects. It does so in conjunction with leptin of adipose tissue origin to regulate peripheral tissue and ANS/circadian command center sensitivity in response to body fat and body mass deviations from the adult setpoint; and (5) brain defends skeletal and lean body masses along with body fat mass against losses demonstrating that these body components should be integrated along with the adipose tissue in the regulation of adult mammalian body weight. The proposed postulates of this novel formulation of weight regulatory mechanism reconcile the conundrum of central and peripheral resistance to actions of insulin and leptin in obesity that is inherent in the homeostatic negative feedback view and the dichotomy of absence-of-protection model of energy regulation in non-deprivation eating with the central-resistance model of homeostatic leptin negative feedback[15].

CENTRAL COORDINATING ROLE OF THE ANS IN THE CONTROL OF FEEDING

Coordination of parasympathetic functions of nutrient intake, digestion, absorption, storage, and behavioral quiescence with sympathetic control of behavioral and metabolic energy expenditure has been recognized for over half a century. In 1947, Adolph[16] reported that body weight in rats stabilizes and is defended at a given plateau at the end of the growth period when mature rats with unrestricted access to food eat daily an amount of standard lab chow sufficient to maintain a stable weight plateau. Application of various methods of localized brain damage[17] and transsections of neural pathways[18,19] has revealed that ventromedial (VMH) and arcuate (ARC) hypothalamic lesions result in transient hyperphagia and hyperinsulinemia, permanent hypoactivity, and defective postprandial and cold-exposure thermogenesis. This has been interpreted by some to reflect an imbalanced parasympathetic overactivation because insulin oversecretion[20], hyperphagia, deficient thermogenesis[21,22], and spontaneous hypoactivity[23] were preventable by subdiaphragmatic vagotomy. In support of this interpretation, electrical stimulation of ventromedial hypothalamus[24-27] or administration of sympathomimetics[28,29] to neurologically intact animals elicited fuel mobilization and energy expenditure. After the weight in lesioned animals stabilizes, the same amount of food per unit weight is consumed as in intact rats, and the new weight plateau is defended against weight loss[30] indicating that regulation of stable weight is a consequence of balance between parasympathetic and sympathetic actions that is only reset by lesions to a new plateau by damage to the sympathetic controls or pathways. Although the relatively crude methods of brain lesions and neural tract transection initially singled out the VMH in the medial basal hypothalamus as the source of sympathetic actions[31], other lines of evidence identified the paraventricular hypothalamic nucleus (PVN) as the control center of sympathetic outflow and, by inference, dorsal motor nucleus of the vagus as the site of parasympathetic control of visceral actions other than cardiac function. Interest in the role of parasympathetic nervous system in the control of feeding has taken a back seat compared to the focus on leptin actions in the ARC and VMH nuclei. Nevertheless, pharmacological and denervation approaches have shown that suppression of sympathetic tone reduces thermogenesis[32] and increases parasympathetic functions of white adipose tissue (WAT) cell proliferation and body fat accumulation[33].

THE CENTRAL CLOCK COORDINATES ANS CONTROL OF FEEDING

One of the missing pieces in our understanding of energy regulation is the causative stimulus of hunger and meal initiation. The proposition that ghrelin is the key initiator of hunger and feeding[34-37] is challenged by normal food intake and weight maintenance in animals with deficient ghrelin signaling[38] and by a correlational and transient changes in ghrelin concentration and hunger sensations in the course of a meal[34,39]. On the other hand, the proposition that an autonomic controller coordinated by the circadian master clock regulates meal taking, locomotion, and thermogenesis is supported by a wealth of both behavioral, lesioning, and anatomical evidence.

Meal eating is intermittent in contrast to continuous behavioral and metabolic energy expenditure. Its ultradian and circadian patterning is a universal feature of mammalian feeding behavior. Rodents take meals at ultradian intervals of 3 to 4 h with a circadian segregation of eating to only the waking portion of the day[40]. Humans also eat during their nycthemeral wakeful period at 3-h intervals if snacks are included and at about 6-h intervals if more substantive main meals are considered. Circadian control of feeding in mammals is supported by extensive neuroanatomical evidence. Suprachiasmatic nucleus (SCN), the master circadian clock, has multiple ANS interconnections with structures that are implicated in weight regulation. Neural pathways through which the photo-entrainable SCN controls behavioral, endocrine, and metabolic rhythms related to energy balance include direct projections to subparaventricular zone (SPZ), an anterior hypothalamic region that receives innervation from both the PVN and SCN and is therefore thought to integrate circadian and metabolic information[41]. Additional areas receiving SCN innervation include medial preoptic area and dorsomedial hypothalamic nucleus (DMN)[42,43]. DMN, which is innervated both by the SCN and the SPZ, also controls circadian pattern of feeding, sleep-wakefulness, and locomotor activity. SCN also influences the circadian control of food intake, locomotion, and metabolic energy expenditure through its fibers projecting to the ARC, the VMH, and the ventral part of the lateral hypothalamus (LH), all areas implicated in the control of feeding and energy regulation. Interneurons from the SCN inhibit the PVN through γ-aminobutyric acid neurotransmission to facilitate parasympathetic functions. Consequently, most viscera receive SCN-dependent circadian time cues *via* their parasympathetic and/or sympathetic innervations that reflect metabolic and digestive events at peripheral sites[43]. Besides the obligatory periodicity of meal eating, nycthemeral patterning of feeding is necessary for the maintenance of stable body and fat masses. When the nocturnal part of the circadian sleep-wake cycle in humans is truncated, inappropriate overeating during extended wakeful periods ensues contributing to obesity and associated health risk factors[44,45]. Similarly, a seasonal change in the length of circadian exposure to light produces changes in feeding and body fat accumulation in some mammals[46].

Additional evidence for a functional interaction between the circadian clock and the ANS energy regulatory circuits involves loss of feeding, locomotor, and thermogenic periodicities when either the ANS or SCN circuits are disrupted. Destruction of SCN results in the loss of

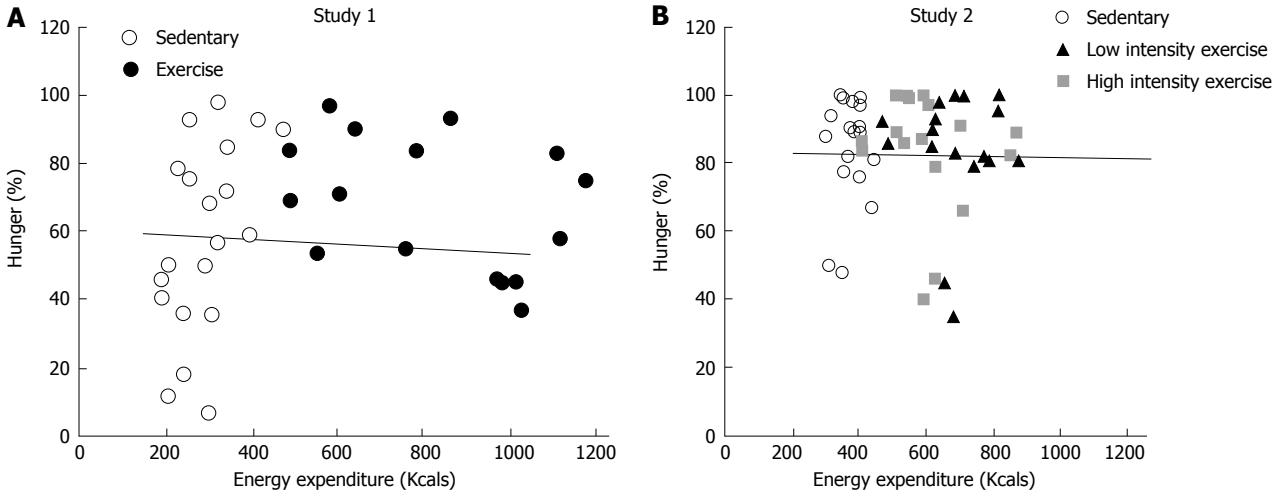

Figure 1 Correlation between energy expenditure and peak hunger in two studies in which exercise energy expenditure of between 2300 and 2500 KJ was inserted between the morning and midday meal (A) or between both morning and midday, and midday and afternoon, meals (B). Correlation coefficient between energy expenditure during overnight fast before the morning meal, and during morning intermeal interval that included exercise on one hand and peak hunger at the next meal was 0.06 in A. In B, the correlation coefficient between intermeal intervals that included exercise and peak hunger at the subsequent meal was 0.0002. Data from Ref. [69].

all bioenergetic circadian responses including circadian pattern of drinking and locomotor activity[47,48]. Destruction of VMH and ARC nuclei within the medial basal hypothalamus disrupts circadian alternation between active and inactive periods of food seeking and eating and results in protracted 24-h extension of meal taking and obesity[49,50]. Postprandial[51] and general thermogenesis also display circadian[52,53] and ultradian[54] rhythms of activation that have an acrophase during the active portion of the day and a nadir during the inactive phase. Metabolic and thermogenic gene expression in brown adipose tissue (BAT) and WAT also follows circadian periodicity[55]. The activation is attributable to stimulation of BAT by sympathetic nerves that originate in PVN, SCN, and DMN[31]. And thermogenesis can be elicited by electrical stimulation of sympathetic nerves to BAT[56], application of sympathomimetics[28,29,57,58] and activation by leptin of sympathetic nerves to BAT[28,29,31,59] when the hormone is applied to DMN, one of key sites involved in circadian components of energy regulation[59]. Leptin itself exhibits a prominent circadian pattern of secretion in humans with an acrophase around midnight and a nadir during mid-day[60-62]. This diurnal pattern is entrained to meal taking and phase shifts by the same number of hours with temporal displacement of meals[62]. In addition to its circadian pattern, leptin secretion is pulsatile with 32 pulses over 24 h, and a mean pulse duration of 33 min[63]. Circadian control of several aspects of energy regulation is seen in circadian changes in postprandial BAT thermogenesis in response to olfactory and gustatory stimulation by hedonic properties of palatable diets. The importance of stimulation of olfactory and gustatory receptors in eliciting postprandial BAT thermogenesis is demonstrated by diet-induced thermogenesis (DIT) attenuation when oral route of food administration is bypassed by tube feeding[64], or by administration of endocannabinoid blocker rimonabant[65,66]. Similarly, overeating palatable diets elicits a greater DIT than does eating diets of lesser olfactory and gustatory appeal[67]. Olfactory responsiveness[68] and hedonic responses to food and associated increases in DIT[67] show a diurnal rhythm with an acrophase during the active portion of the circadian period. The rhythm and the magnitude of thermogenic response are abolished by SCN lesion, sympathetic denervation of BAT[66], or deletion of β_1 receptors in BAT[60]. Endocannabinoid blockade of DIT thermogenesis is more effective during the active that during the inactive phase of the circadian cycle[66].

Circadian influence in human meal eating is evident by comparing the effect of energy expenditure during long nocturnal inter-meal interval (IMI) on morning hunger[69]. We determined that the nocturnal IMI generated expenditure of between 710 and 750 Kcal in healthy postmenopausal women as compared to 340 to 450 Kcal expended during diurnal sedentary 6-h IMIs. Yet hunger rating at the end of 11 to 12-h long nocturnal IMI was only half as large as the hunger rating recorded at the end of individual diurnal IMIs and approximately as low as the evening hunger rating. Even more remarkably, the quantity of food consumed at the end of two mid-diurnal IMIs bore no relationship to the magnitude of preceding energy expenditure (Figure 1). These data support the operation of a circadian control of hunger with an acrophase at mid-day, a presumed nadir in the middle of sleep period, and transitional effects at dawn and dusk. They also indicate that the quantity of food eaten at a meal bears no homeostatic relationship to preceding energy balance but is influenced by time of day.

The universal circadian and ultradian patterning of mammalian feeding behavior suggests the operation of a central circadian meal- and hunger-timing mechanism where the signals related to meal digestion may be entrained to an ultradian gastric-contraction oscillator. The circadian clock restricts the predisposition to seek

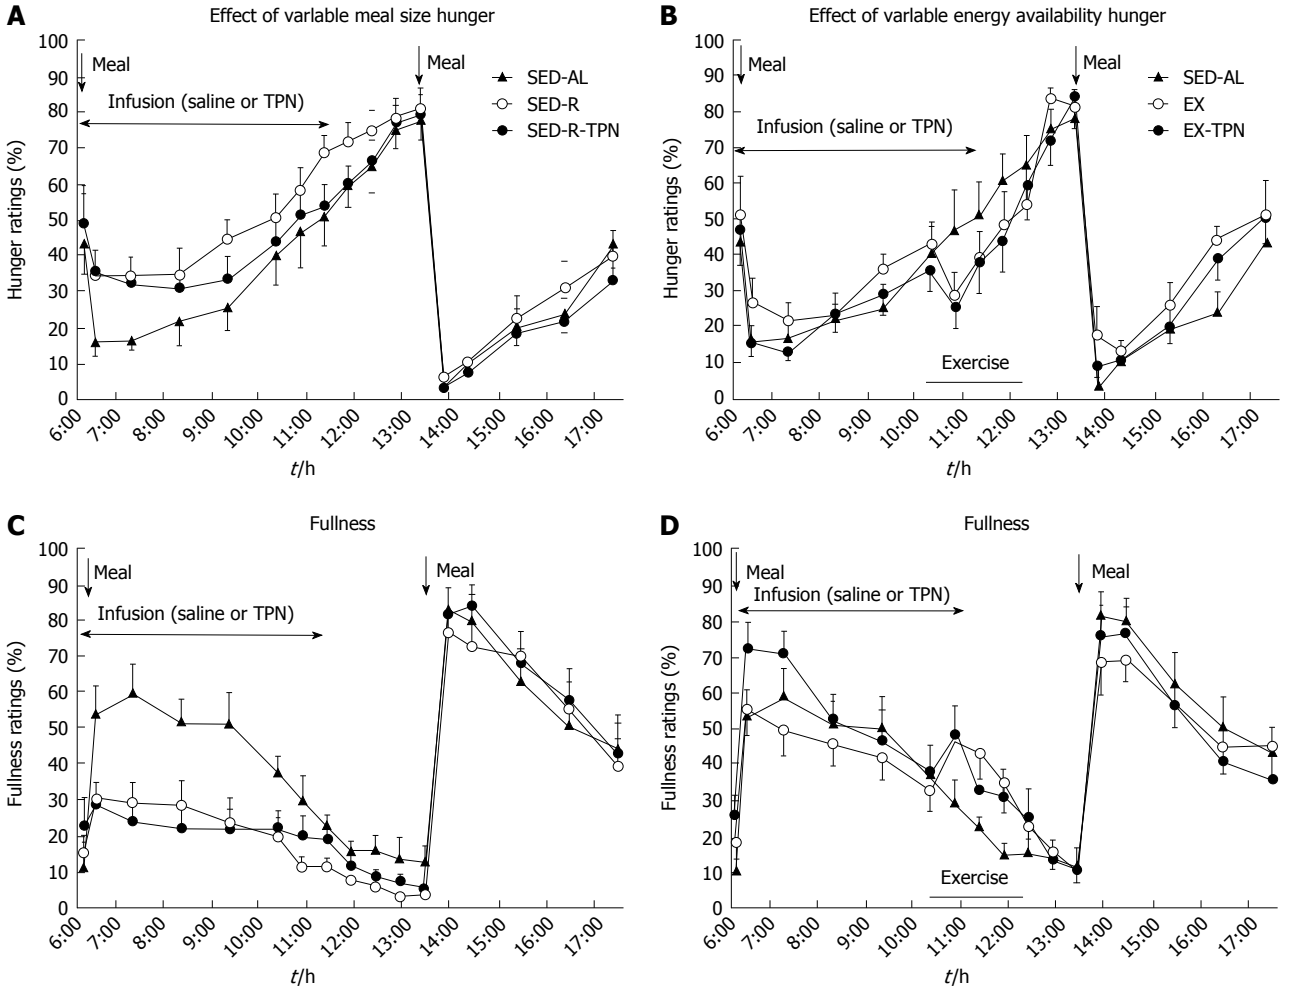

Figure 2 The effects of variable meal size (A) and energy availability (B) on the psychophysical ratings of hunger (A and B) and fullness (C and D) in 10 postmenopausal women subjected to a sedentary trial with a large morning meal (SED-AL), or a small morning meal SED-R, 2 h of moderate intensity exercise after a large morning meal (EX), and *iv* nutrient infusion (TPN) as a replacement of energy withheld from a morning meal (SED-R-TPN) or expended through exercise (EX-TPN). Meal size had a negative effect on hunger ($F_{df4,36}$ = 39.3, P < 0.0001) and a positive effect on fullness ($F_{df4,36}$ = 115.3, P < 0.0001). Exercise energy expenditure had a negative effect on hunger ($F_{df4,36}$ = 25.5, P < 0.0001), and a positive effect on fullness ($F_{df4,36}$ = 42.8; P < 0.0001). TPN had no effect on psychophysical ratings. Data from Ref. [39].

and take food to the active portion of the day when it is interrupted only by the GI signals of fullness and suppresses it during the inactive phase. The uniformity and regularity in the postprandial rise in hunger and attainment of peak hunger regardless of the pre-meal energy balance is consistent with suppression by the GI stimuli of the influence of a central food-seeking command. Energy content of orally taken food appears responsible for partial suppression of hunger when the stomach is incompletely filled (Figure 2A and B). Here, GI nutrient sensing and the rate of stomach emptying according to the energy content of the meal may affect the predisposition for supplementary food intake. Circadian control of hunger and initiation of eating is inferred from low morning and evening hunger and a hunger acrophase between 10 and 19 h[69] that are independent of variations in pre-meal energy availability[39] (Figure 1). An empty stomach and completed GI transit of food generate peak pre-meal hunger during wakeful portion of diurnal cycle (Figure 2A and B) and could do so through removal of gastrointestinal inhibition over the central circadian command guiding the predisposition to eat.

OPPORTUNISTIC AND HEDONISTIC CONTROL OF MEAL-TO-MEAL FEEDING: THE ROLES OF TASTE, OLFACTION, GI NUTRIENT SENSING, AND SOCIAL FACILITATION

In contrast to much of our physiology that operates automatically, we have an innate capacity to consciously detect and prefer foods with sweet and savory taste[70] that leads to predisposition for acceptance and intake of palatable food. Sweet and savory nutrients elicit swallowing even at a fetal stage of development[71], positive facial expressions and sucking in newborn infants[72], and acceptance of palatable foods by children[73]. Sampled nutrients bind to five different populations of taste receptors in the mouth.

Their gustatory properties are signaled in the afferents of facial (VIIth), glossopharyngeal (IXth), and vagus (X th) nerves and are relayed to the rostral two thirds of the nucleus of the solitary tract (NTS) in medulla oblongata[74]. Gustatory information also reaches parabrachial nucleus in the pons[75], ventral tegmental area[76], and several regions of the cortex to elicit hedonic appreciation of the properties of the food. The amygdala and medial and mid-anterior edge of orbitofrontal cortex, and anterior cingulate and insular cortex contribute the emotional component of hedonic responses. The nucleus accumbens (NA) in ventral pallidum contributes to hedonic reinforcement of intake of palatable food through the release of endocannabinoids[76-78]. These innate properties justify the hypothesis that non-homeostatic olfactory and gustatory stimuli provide incentives for non-homeostatic intake of food.

Olfactory and gustatory stimuli complement sensing by the GI tract of food properties and eliciting digestive and absorptive endocrine reflexes[79]. Chemosensory receptors for sugars, amino acids, and fatty acids are located in the neuroendocrine epithelium of the stomach, duodenum, and small intestine. By sensing ingested nutrients, chemosensory neuroendocrine cells in the stomach secrete gastrin from G cells. In the intestine, ghrelin is released from P or X/A cells, somatostatin from D cells, cholecystokinin (CCK) from I cells, serotonin from enterochromaffin cells, glucose-dependent insulinotropic peptide (GIP) from K cells in the proximal small intestine, while glucagon-like peptides (GLPs) and peptide tyrosine tyrosine (PYY) are released from L cells in the distal small intestine. These GI hormones bind to receptors on the afferent vagal fibers that are located in the lamina propria[80]. Stoichiometric GI endocrine responses to energy content of ingested nutrients affect the rate and duration of nutrient digestion and absorption. Some digestive hormones also elicit conscious sensation. Ghrelin increases olfactory salience of food stimuli, decreases olfactory detection threshold, and elicits sniffing[81] as its secretion rises in parallel with pre-meal appetite and declines with meal completion. This action is its most probable contribution to facilitation of the pre-meal appetite[34,35]. Besides their digestive roles in promoting enzyme release and slowing the rate of stomach emptying, CCK[82-85], GLP-1[86-88], and PYY[89], also contribute to the conscious detection of stomach fullness and therefore participate in short-term meal-associated control of post-meal satiation.

Opportunistic characteristic of feeding also is revealed in its responsiveness to the abundance of food and communal food setting. More fluid is consumed if presented in tall, rather than short, glasses[90]. Savory food is consumed in greater amounts from larger platters than from small ones[91]. More food is eaten in company of others[92-96], a social facilitation phenomenon widely shared by mammals[97-99] and even birds[100]. Further, increasing the number of palatable food choices in all-you-can-eat settings leads to overeating in animals[3] and humans[101-103]. In effect, that represents the basis for producing experimental obesity by providing animals fat-enriched, in addition to standard laboratory, diet[3].

A direct test of the homeostatic metering of energy during feeding requires either changing the caloric density of food or the magnitude of pre-meal energy expenditure (EE). Studies manipulating the energy content of food and the meal size indicate that sensations of fullness after the meal and the amount eaten in the subsequent meal are guided by the volume of food eaten rather than its energy content[104-106]. That such non-homeostatic eating bears no direct relationship to the energy content of ingested food also during a longer time frame was suggested by an 11-wk study in which 13 females were provided with either low-fat (20%-25% of energy as fat), or a higher fat, diet (35%-40% fat)[107]. The volume or weight of food eaten daily was comparable on the two diets resulting in a daily energy intake error of 1.22 KJ. Only 35% of this caloric error on a low-fat diet was compensated by the end of 11 wk resulting in a weight loss of 2.5 kg, twice the amount of weight lost on a higher-fat diet.

A more rigorous test of human ability to homeostatically sense energy availability in non-deprived state requires that hunger and food consumption show evidence of caloric compensation when oral, olfactory, and GI sensing is bypassed. Three circumstances that meet that criterion include already mentioned prolonged nocturnal period without food, exercise energy expenditure (EEE), and intravenous supplementation of withheld or expended calories in the form of total parenteral nutrition (TPN). Examination of the effects of between 2300 to 2500 KJ of EEE inserted during morning and afternoon IMIs reveals that this increase in energy expenditure does not influence peak hunger ratings at the onset of the next meal[69] (Figure 1). A similar lack of a relationship between pre-meal energy expenditure and the size of spontaneous meal was previously described in rats[40]. In another study, the search for compensatory changes in food intake was extended to manipulations of EEE, intravenous TPN supplementation for energy withheld in a small meal or for EEE, and the size of meals taken by oral and intragastric route. In this crossover study[39], ten overweight postmenopausal women were provided with a large breakfast containing 2100 KJ in three trials and a small one containing 420 KJ in two trials. The energy supply in the large breakfast in one trial was cancelled by 2270 KJ EEE in another, and EEE was largely replaced by intravenous infusion of 1530 KJ of TPN in the third trial. The low energy content in the small 420 KJ breakfast in the fourth trial, was supplemented with the intravenous infusion of 1530 KJ of TPN in the fifth. The results showed unequivocally that changes in the sensations of hunger (Figure 2A and B) and fullness (Figure 2C and D) were only elicited by the size of the meals taken by oral, and processed by GI, route but not by energy lost exercising or supplemented intravenously. Moreover, the quantity of food eaten, and peak hunger rating at the onset of the next ad-libitum meal is indistinguishable

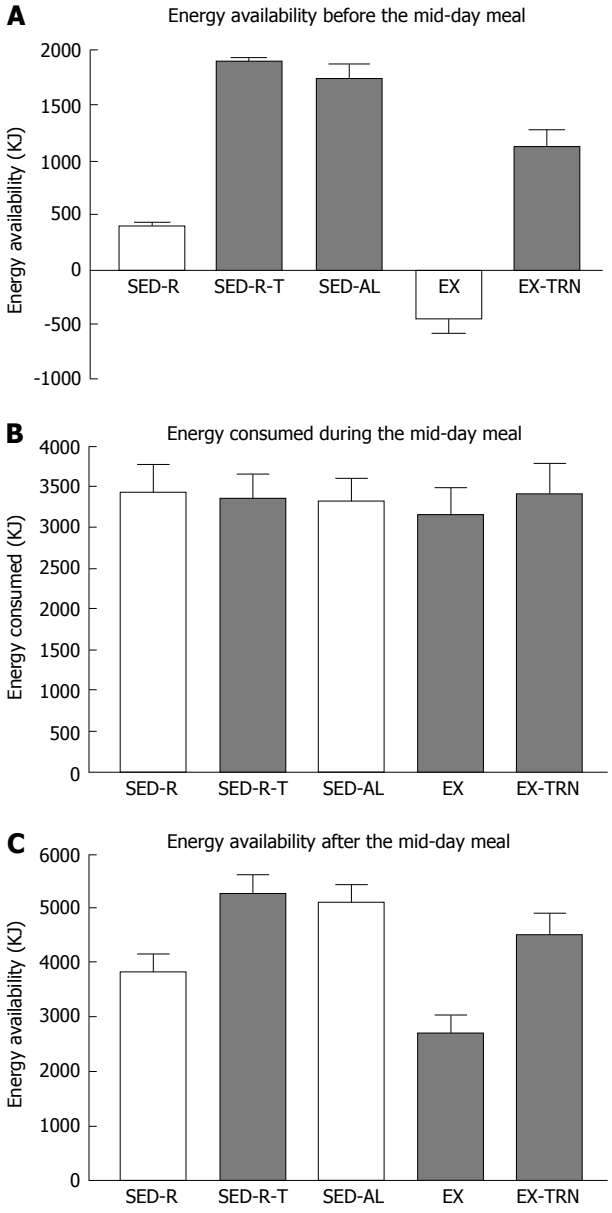

Figure 3 Effect of the morning energy availability (A) on the energy consumed during the midday meal (B) and the residual postmeal energy balance (C) in 10 women subjected to small (SED-R) or large (SED) morning meals, exercise (EX), and TPN (SED-R-T, EX-TPN). Midday meal did not compensate for the significantly lower energy balance in SED-R and EX trials ($F_{df4,45}$ = 77.2; P < 0.0001), which remained uncorrected after the meal ($F_{df4,45}$ = 10.2; P < 0.0001). Data from Ref. [39].

among the five conditions, two of which generated substantial negative energy balance (Figure 3). Furthermore, hormones insulin and leptin tracked accurately changes in energy balance that resulted from unequal meal size, energy lost exercising, and energy supplemented intravenously (Figure 4), but the changes in their plasma concentrations bore no apparent relationship to conscious sensations of hunger and fullness (Figure 2).

Collectively, the above studies support the hypothesis that intermittent meal-to-meal eating under unrestricted access to food is guided by cues provided by oral and GI processing of food. Hunger and fullness ratings, the conscious guides for food intake and meal termination, are affected by the size of the orally ingested nutrients (Figure 2) but not by fluctuation in short-term energy availability caused by intravenous nutrient infusion or by EEE, or by changes in the plasma concentrations of insulin and leptin[39]. Moreover, the peak hunger rating at the onset of the next meal, and the amount eaten during that meal are not responsive to preceding energy imbalance[39,69,104-107]. Stomach filling as a guide to meal size held true in the 11-wk study in which the subjects were largely unresponsive to the energy content of the food[107].

Additional supportive evidence for the role of GI signaling rather than for homeostatic metering of premeal caloric deficit in the control of ad-libitum meal-to-meal eating is available in the singular success of various forms of bariatric surgery in curbing hunger and reducing food intake. A common feature of several variants of bariatric surgery is reduction in stomach capacity to hold food and associated suppression of appetite and hunger[108] or increased nausea and vomiting[109]. The efficacy of stomach fullness as a deterrent for hunger and food intake is also evident in successful application of inflatable balloons to induce weight loss[110,111]. A century ago, Cannon and Washburn[112] demonstrated a striking concordance between episodic bursts of gastric contractions and intermittent sensations of hunger using intragastric balloons as pressure gauges. In addition to Cannon's classic demonstration of the correlation between the ultradian periodicity of empty stomach contractions and hunger, connections of mechanosensitive elements in the smooth muscle of the stomach with the afferent vagus also have been documented more recently[113-115]. Further, these GI smooth muscle mechanoreceptors inhibit eating in response to volume of food introduced into the stomach without regard to its nutritional properties[116,117]. On the other hand, nutrient quality and energy content are sensed by vagal receptors in the intestine and lead to secretion of digestive hormones such as CCK/gastric leptin, GLP-1 and PYY[117]. More recently, pooled data from 8 studies on 67 healthy humans confirmed Cannon and Washburn observation by identifying pyloric pressure waves and peak CCK concentrations as predictors of food intake while finding intravenous nutrient infusions ineffective[118].

In its basic outline, the blueprint of human non-deprivation meal-to-meal eating bears a striking resemblance to the feeding mechanism of a blowfly[119,120]. The insect whose adult body mass is confined within a rigid exoskeleton, accepts sapid solutions whenever its crop is empty. Similar to ad-libitum feeding humans in whom termination of growth imposes a finite body mass, blowfly's food acceptance operates on an opportunistic and hedonic principle, and feeding termination on a GI negative feedback. The fly will ingest to capacity higher concentrations of sweet solutions rather than larger quantities of more dilute solutions. It stops feeding when its full crop inhibits a brain mechanism responsible for predisposition to seek and ingest nutrients whenever the crop is empty. If the recurrent nerve that provides the negative feedback from the crop to the brain is severed, the animal overeats,

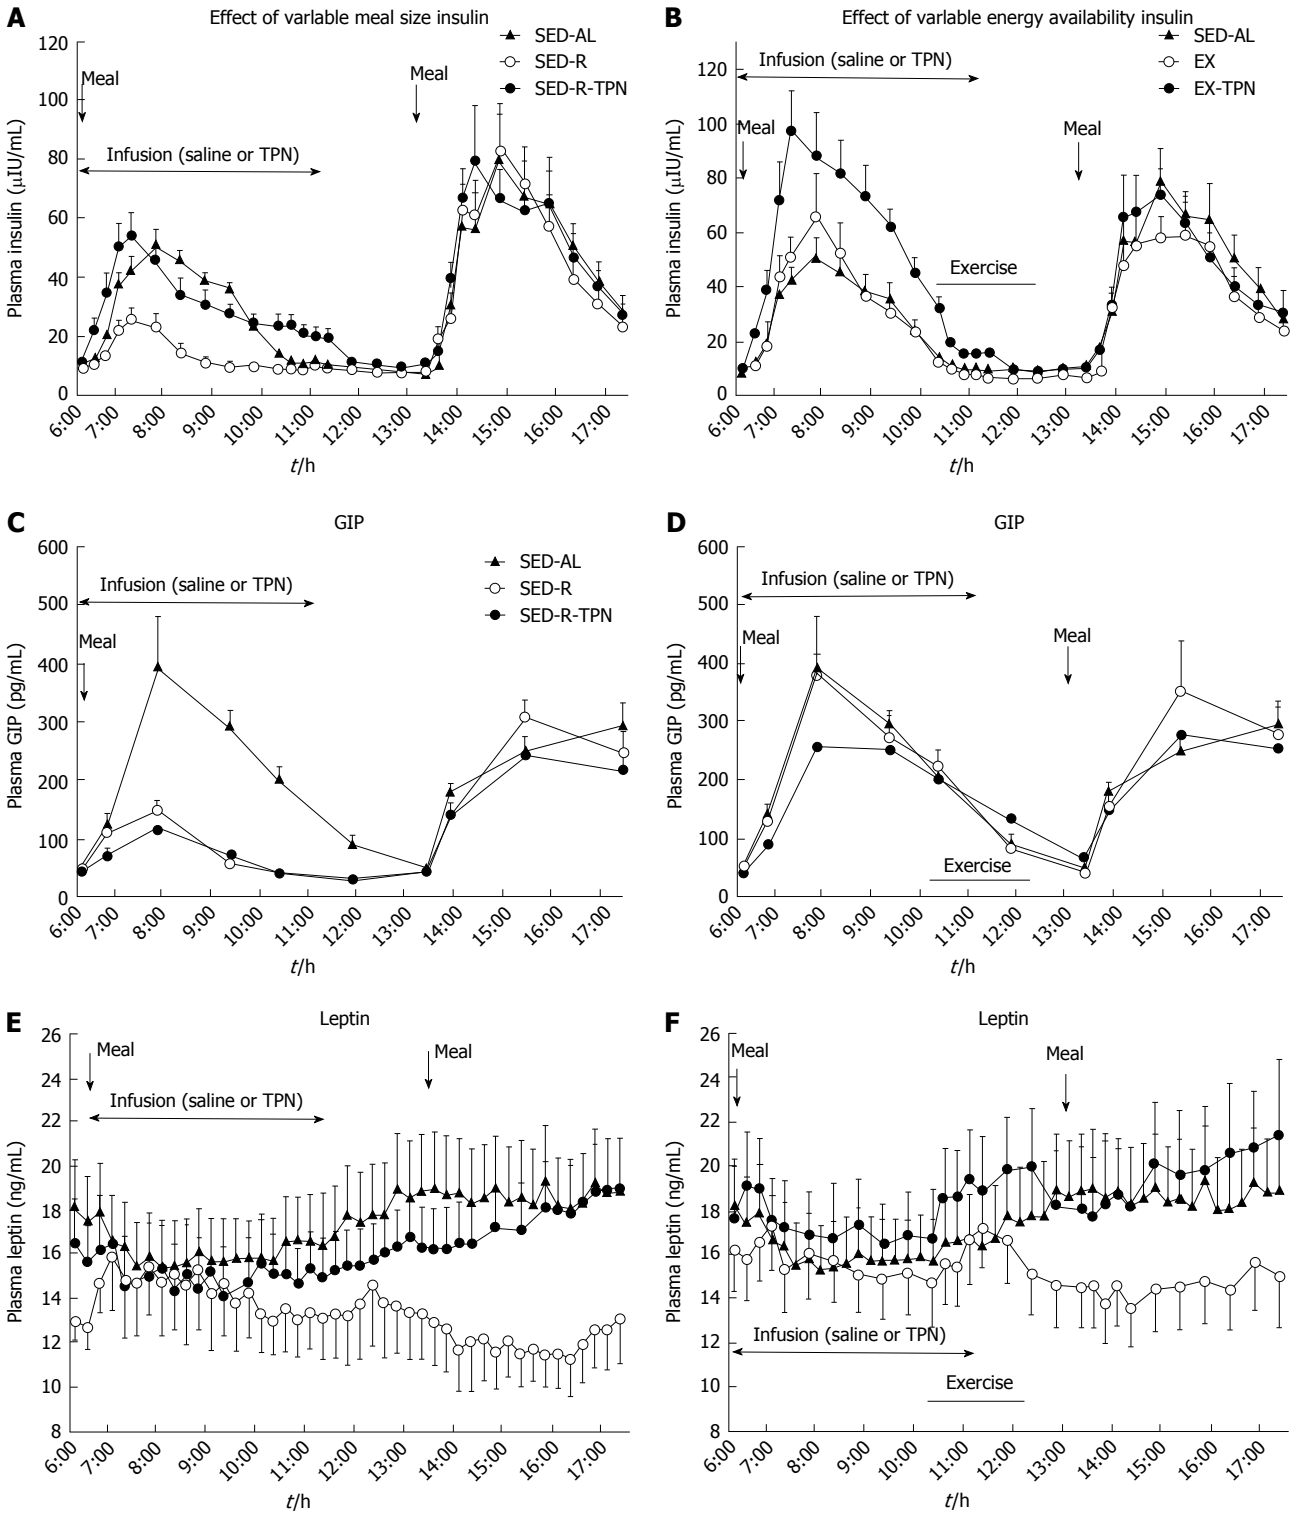

Figure 4 The effects of variable meal size (A) and energy variability (B) on the plasma concentrations of insulin (A and B), GIP (C and D) and leptin (E and F) under the conditions described in Figure 2. Insulin showed significant postprandial increases to meal size (A) and TPN (B) ($F_{df4,45}$ = 25.7; P < 0.0001), whereas GIP responded only to meal size ($F_{df4,45}$ = 42.3; P < 0.0001). Neither insulin nor GIP responded to exercise energy expenditure. Plasma leptin concentration slowly and progressively decreased in response to reduced energy availability caused by small meal ($F_{df4,36}$ = 48.1; P < 0.0001) and exercise ($F_{df4,36}$ = 39.1; P < 0.0001), and this response was abolished by large meal and TPN. Data from Ref. [39].

and with sufficiently high sugar concentrations, will rupture its crop. Presented evidence supports the conclusion that a similar system of nonhomeostatic meal-to-meal eating operates in humans. However, these considerations still leave unanswered the question regarding the signal initiating hunger and food intake. The present reinterpretation of energy regulation proposes that a central ANS command mechanism, given temporal structure by the SCN master circadian clock is responsible for sustained food seeking and meal intake interrupted intermittently

by the inhibition from the signaling of gastric distension as sensations of satiation and fullness associated with GI processing of food. This proposition is consistent with close anatomical connections between SCN and the ANS energy regulatory circuits, circadian and ultradian pattern of meal eating and sympathetic activation of BAT thermogenesis, and disruption of both feeding pattern and thermogenesis and DIT in particular with lesions of either the master clock or the ANS energy regulatory substrates.

COUNTERREGULATION BY LEPTIN OF INSULIN SECRETION, ACTION, AND SENSITIVITY

The key feature of the proposed novel view of body weight regulation is the counterregulation of insulin by leptin under the control of the ANS-circadian command mechanism. Leptin counterregulates insulin in four ways, by (1) acting as a gut peptide signaling satiating fullness and contributing to termination of meals; (2) suppressing insulin secretion; (3) counteracting insulin anabolic actions; and (4) regulating ANS and peripheral tissue sensitivity to insulin in response to downward or upward deflections in the components of body mass. Through these counterregulatory interactions with insulin, leptin matches its sympathetic energy expending actions to the parasympathetic energy conserving actions of insulin.

The sustained stoichiometric relationship between the body fat mass and basal leptin secretion[11] has strongly influenced formulation of a homeostatic lipostatic hypothesis of body fat regulation featuring leptin negative-feedback from WAT to the brain. Integration of short-term secretory responsiveness of leptin to fasting[121-124], meal intake[123,125,126], glucose[127-129], pyruvate[128], insulin secretion[121,130], and insulin-stimulated carbohydrate metabolism[39,127,131-133] with the long-term parallel shifts in plasma leptin concentration and body fat mass has largely escaped scrutiny. To update the understanding about leptin physiology, it should be pointed out that, besides the WAT[134], the hormone also is secreted from the stomach[135-143], placenta[144], and lactating mammary glands[145]. Since leptin of gastric origin is likely to react more rapidly to short-term fluctuations in prandial state than leptin of WAT origin, and both may contribute to short-term changes in circulating leptin concentration, it is useful to briefly review how gastric leptin secretion and appearance in circulation differs from that arising in WAT.

Gastric leptin is rapidly mobilized by cholinergic neurotransmission, nutrient entry into the stomach[139], and release of CCK[135]. Its release is distinctly regulated by these stimuli in contrast to the leptin release from the WAT which is predominantly released in a constitutive fashion[128,134,140,146,147]. Leptin is released into the stomach lumen in exocrine fashion from the chief cells in gastric mucosa. Complexing of gastric leptin with its soluble receptor (LepR) prior to being released from the Golgi apparatus protects it from denaturation by gastric acid[141]. It then is transported to the duodenum where it binds with LepR on the luminal membrane and is transcytozed into the Golgi apparatus of the duodenal enterocyte. There it again binds with LepR and leaves the intestinal mucosa for systemic circulation[139-141].

The first counterregulation of insulin by leptin is clearly of gastric origin and consists of its counteracting the absorptive actions of insulin during a meal. Gastric leptin, mobilized by ingested nutrients and CCK, potentiates the satiating effects of CCK[148,149] and GLP-1[150,151], actions that the two hormones exert in part by slowing the rate of gastric emptying[82-85,88,151], trigerring a sensation of fullness and thus contributing to the termination of a meal. The potentiation by leptin of satiating properties of CCK is mediated by vagal primary afferent neurons selectively responsive to both hormones and to gastric distension and transmitting gastric stretch information to NTS[152] *via* vagal sensory nodose ganglion[153]. Activation of gastric smooth muscle mechanoreceptors is sensitive only to volume of food introduced into the stomach without regard to its nutritional properties[116] while vagal intestinal receptors sense directly the nutrient quality and energy content of ingested food[117]. The potentiation by leptin of CCK satiating effect is activated by nutrient intake while fasting and obesity attenuate vagal afferent stretch signaling[154]. Repeated gastric overstretching, common in overeating and some eating disorders, delays onset of feeding, suppresses leptin concentration and reduces neuropeptide Y levels in ARC and NTS after meal intake as compared to no stomach overstretching[155]. The indirect involvement of leptin in the control of postprandial insulin response and the meal size explains the lack of a relationship between its postprandial concentration (Figure 4C and D) and sensation of fullness (Figure 2C and D). The role of gastric leptin in curtailing postprandial insulin actions may contribute to increased food consumption in free feeding individuals[12,13] and animals[14] who have an inability to produce leptin or leptin receptors. In line with the parasympathetic source of gastric leptin elicitation, the sympathetic actions of leptin suppress cardiac rate by acting on the rostral ventrolateral medullary heart pacer[156,157].

Since leptin of both gastric and WAT origin reaches systemic circulation, it is difficult to distinguish their relative role in the remaining three counterregulations of insulin by leptin. Similar to the responsiveness of gastric leptin to meal ingestion, secretion of leptin from WAT adipocytes also is responsive to short-term fluctuations in prandial state and a number of hormones[160,161]. Feeding increases leptin secretion from WAT cells[134,140,147] and fasting decreases both[147]. Endocrine secretagogues are insulin[128,158,159] and cortisol[158-160], and inhibitors are β-adrenergic stimulation, adrenocorticotropic hormone (ACTH), alpha melanocyte stimulating hormone (αMSH)[161] and testosterone[161,162]. Furthermore, carbohydrate metabolism has to be present for insulin to

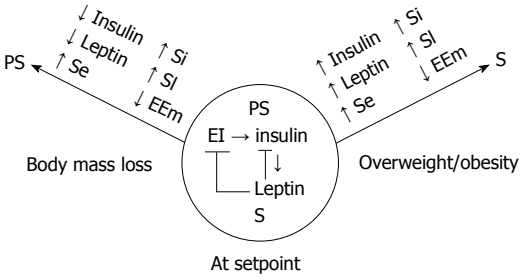

Figure 5 The conceptual model of the autonomic regulation of body weight. Autonomic nervous system regulates the energy flux through the energy conserving actions of insulin that are counterbalanced by the energy expending actions of leptin to match energy intake (EI) and expenditure (EE) and maintain stable body weight (center circle). The counterbalancing is achieved by the upregulation of leptin by the glycolytic energy flux in the WAT stimulated by insulin. Leptin, in turn, inhibits insulin secretion and actions in several organs. If dieting or food scarcity cause weight loss (left arrow), energy conservation is achieved, in part, by reduced Symp activity and EE (EEm). Predominance of Parasymp actions are manifested in reduced fasting insulin and leptin concentrations, increased tissue sensitivities to insulin (Si) and leptin (Sl) along with increased sensitivity in enzymatic nutrient sensing (Se) of energy depletion. In addition, energy is conserved through reduced S activation of metabolism. When overeating and reduced physical activity result in obesity (right arrow), there is a reverse change in fasting insulin and leptin concentrations, tissues become resistant to both hormones as well as to S elicitation of metabolic EE. Due to insulin and leptin resistance, the ineffective compensatory increase in S activity to counteract further body fat, lean body mass, and bone accretion, mainly causes vasoconstriction and hypertension.

increase leptin secretion[129,133], linking the WAT cell responses to short-term metabolic changes. The uncertainty as to the origin of circulating leptin particularly arises when the hormone is being stimulated by systemic administration of insulin in hyperinsulinemic euglycemia. This stimulus applied for longer than 3 to 4 h increases leptin concentration in the plasma[130,163,164] but not if the duration of the clamp[165-170] or of the postprandial period[170,171] is shorter or if hyperinsulinemia is accompanied by hypoglycemia[124].

The second way that leptin counterregulates insulin is by suppressing its secretion in pancreatic β cells[172-176] as shown by insulin oversecretion after deletion of leptin receptors in these cells[176] (Figure 5, circle). Thus, after leptin gene deletion or pharmacological antagonism of leptin action, insulin secretion is supranormal, and leptin administration in *ob/ob* mice that are unable to produce leptin suppresses it[172-177]. Insulin oversecretion results from leptin counterregulation of insulin secretion and not from obesity because it occurs before any significant tissue fat accumulation takes place[176].

The third way that leptin counterregulates insulin is by suppressing its lipogenic and other anabolic actions. While the catecholamines and growth hormone facilitate lipolysis and lipid utilization to systemic signals of energy deficit[178,179] and actually decrease leptin gene expression in WAT[180-182] and its circulating concentration[183-187], leptin binds to adipocytes to selectively counteract insulin-stimulated lipogenesis and activate lipolysis and lipid utilization in WAT[188], especially in its visceral conpartment[189]. It similarly counterregulates insulin lipogenesis in other tissues and thus reduces triglyceride (TG) content in pancreas[190], liver[189-193], and the muscle[190,194-198]. In the liver[192,199], the skeletal muscle[197,200], the BAT[201] and WAT[202], leptin shifts the metabolism from insulin-mediated carbohydrate utilization and TG synthesis toward free fatty acid (FFA) uptake and increased lipid utilization. In the skeletal muscle, leptin activates the enzyme 5'-AMP-activated protein kinase (AMPK) that is capable of sensing metabolic energy depletion[190,194,195]. AMPK in turn inhibits fat synthesis and facilitates FFA entry into the mitochondria for fat oxidation[195-198,203,204]. While some of these metabolic leptin actions result from the hormone binding directly to its receptors in peripheral target organs such as the pancreas[190] the WAT[188,189], the liver[205,206], and the muscle[198,207], the same actions also can be achieved by leptin binding to its receptors in the brain. Suppression by leptin of lipogenic actions of insulin in the WAT[205,208-211] and liver[205,206] is controlled both by the brain, particularly the VMH[208-211] and also is effected at the tissue level[205], particularly in the liver[206].

Leptin counteracts insulin's postprandial anabolic effects by stimulating DIT. It does so by upregulating the thermogenic uncoupling protein UCP1 in BAT by increasing sympathetic nerve activity[123,124,212,213] and norepinephrine turnover in BAT[214]. It also upregulates UCP2 in WAT[215,216], and UCP3 in skeletal muscle[217]. Leptin increases muscle thermogenesis by stimulating substrate cycling[218,219], both lipid and carbohydrate oxidation[200], and expression of genes for anaerobic glycolysis, a metabolic pathway that is bioenergetically less efficient than lipid oxidation[203,204]. While insulin increases postprandial metabolism and thermogenesis through its stimulation of carbohydrate oxidation and sympathetic activation of fat oxidation in BAT[220-222], thermogenic actions of leptin are yoked to postprandial insulin release.

The fourth way that leptin counterregulates insulin action is by controlling the sensitivity of peripheral tissues and the brain to insulin actions as body fat and body masses deviate from the adult plateau. Considering first the peripheral tissues, it is well established that insulin sensitivity increases with body fat and body mass losses, and insulin resistance increases with body fat and body mass gains. Tissues such as the liver, muscle and the WAT display direct autoregulatory increases in numbers of spare receptors, hormone-receptor binding[223], and enzyme sensitivity to nutrients as they are depleted of storage molecules and structural proteins. After glycogen-depleting exercise, activity of glycogen synthase increases in proportion to the magnitude of glycogen depletion which leads to a faster rate of glycogen resynthesis during recovery from exercise[224,225]. As they are depleted of storage nutrients, liver, muscle, and WAT develop direct and autoregulatory increases in sensitivities to the anabolic actions of insulin[191,223,225-227] and catabolic actions of catecholamines[228] some of which are induced by counterregulatory actions of leptin[190-193]. Changes in hormone sensitivities and responses are greater to more rapid rather than to gradual or prolonged reductions in

energy availability. Insulin sensitivity (IS) increases more during the initial weight loss than during maintenance of reduced body weight[229]. Declines in leptin concentration are greater during faster weight loss over a two-day food restriction[230] than to a slower but cumulatively larger energy deficit extended over a 4-[231] or 7-d period[122]. During weight loss, sympathetic activation of metabolic EE is suppressed and only the release of adrenal epinephrine[232] regulates the metabolic shift to predominant lipid utilization[222].

The insulin sensitizing effect of leptin in peripheral tissues becomes manifest as body mass index (BMI) declines below 25 kg/m^2 and fasting plasma leptin concentration drops below 15 ng/dL[233,234]. At its low plasma concentrations, leptin contributes to insulin's parasympathetic actions by increasing muscle glucose uptake[201,235,236] achieved in part by inhibiting the expression of negative regulators of glucose transporter type 4 (GLUT4) translocation to the membrane[237]. By restraining visceral fat accumulation and insulin oversecretion[191-226], leptin preserves insulin sensitivity in the liver[191,226,238] implicating hyperinsulinemia in resistance to insulin action. When the visceral fat is surgically removed[226], reduced glycogenolysis and hepatic glucose production, increased glucose uptake, and reduced insulin requirements to maintain euglycemia are all markers of increased IS. In addition, metabolic gene expression in favor of reduced WAT fat synthesis also results from visceral fat removal[226]. In the oxidative skeletal muscle, leptin counteracts insulin facilitation of intramyocellular triglyceride synthesis and storage by activating AMPK[200]. Through this action, leptin preserves the sensitivity of muscle to insulin leading to increased glucose uptake and glycogen synthesis[175,225]. In addition to being able to exert some of these actions directly in respective tissues studied *in vitro*[175,209], most of leptin actions are contingent on its systemic counteraction of insulin secretion and actions.

The physiological significance of insulin sensitizing actions of low leptin concentrations in weight-reduced state is that it contributes to increased metabolic efficiency that facilitates weight regain and a shift in the ANS balance in favor of the parasympathetic activation[239] (Figure 5, left arrow). A rebound increase in carbohydrate utilization and insulin oversecretion in insulin-sensitive state during post-deprivation overeating in the rats[240,241] is comparable to the postlesion insulin oversecretion after VMH-ARC damage that is prevented by subdiaphragmatic vagotomy[20].

With weight gain at body mass indices above 25 to 27 kg/m^2[233,234] caused by the oportunistic and hedonic design of human meal-to-meal eating where energy intake and expenditure are loosely coupled[242-245], rising basal plasma concentrations of insulin and leptin lead to peripheral tissue resistance to the two hormones[233,234,246,247]. Although adult human adipose tissue retains some capacity to expand both through hyperplasia and hypertrophy[248-250] and is refractory to reductions in adipocyte numbers[251], the parallel rises in obesity and tissue resistance to high plasma leptin and insulin concentrations limit additional body fat and mass accumulation. Resistance to both hormones[246,252] has several causes. An enzymatic resistance to anabolic actions of insulin and counterregulatory actions of leptin[198,207,253] develops in part due to downregulation of respective receptors exposed to prolonged high insulin[173] and leptin[179,181] concentrations. Insulin resistance (IR) also develops due to impaired hormone signaling that results from the action of intermediates of fat biosynthesis driven by high circulating lipid concentrations[253] and accumulation of TG in peripheral organs[200,209,252,253]. Although IR and leptin resistance (LR) increase in parallel with the rise in adiposity, they differ in the timing of their development and their relationship to WAT mass[163,254,255]. Hyperinsulinemia causes hyperleptinemia[163] and both lead to IR and LR. A decline in insulin signaling and IS is a consequence of hyperinsulinemia rather than of IR, since its correction with insulin-lowering diazoxide restores IS and prevents development of obesity while treatment of IR with metformin does not[173]. IR has received a lot of medical attention as a gateway to type 2 diabetes. However, development of IR and LR can also be viewed as an important compensatory processes in autonomic regulation of energy flux in the form of both enzymatic[15,256,257] and sympathetic resistance against additional accretion of body fat. The autonomic resistance to accretion of additional energy storage involves an increase in sympathetic activation of thermogenesis[258] (Figure 5, right arrow), the action of which is rendered ineffective by resistance of enlarged adipocytes to actions of catecholamines[193,228]. The deleterious health consequence of sympathetic overactivation and tissue resistance to hormones in obesity are increased vasoconstriction and hypertension[259-262]. Finally, peripheral LR is possibly dissociable from the resistance of the brain and ANS to leptin actions because of its origin from two different sources, stomach and the WAT, and different routes of accessing the brain, vagal transmission of gastric leptin signals to the NTS, and endocrine signaling of both gastric and WAT leptin to the hypothalamus. This dissociation is suggested by continued effectiveness of leptin when administered intracerebroventricularly at the time dietary obesity has rendered leptin applied intraperitoneally ineffective[263].

Remarkably and importantly leptin controls insulin sensitivity of the ANS energy regulatory command center as body fat and body masses deviate from the norm. The brain substrate that is responsive to changes in body fat and body mass is midbrain ventral tegmental (VTA) dopaminergic and opioidergic projection to the NA in the ventral striatum[76,77] that has rich interconnections with hypothalamic and cortical circuits responsible for activation and inhibition of feeding, voluntary activity, and thermogenesis. The key neurotransmitter mediating behavioral reinforcements is dopamine (DA)[264,265], originating in medial VTA and projecting to ventromedial striatum including medial olfactory tubercle and medial shell of the NA[265]. Activation of these midbrain

DA neural projections to ventral striatum supports nonhomeostatic motivating, rewarding, and incentive properties of food and drives locomotor and eating behaviors[76,77,266-268]. Functional connections between the hypothalamus and this motivational circuitry is illustrated by the LH being the key effective site for behavioral self stimulation with mild electric current[269,270]. LH area also is responsible for arousal and incentive activation of locomotion probably linked to search for food through its component ghrelin[271], melanin concentrating hormone (MCH), and orexin/hypocretin[272-274] neural circuits. LH ghrelin is involved in anticipatory meal-associated increase in locomotion[271] and increases in olfactory stimulus salience during intermeal intervals[81]. MCH neurons regulate olfactory locomotor food-seeking behaviors[272]. In addition to motivating feeding[273], MCH neurons affect energy metabolism[274-277], and their secretion is regulated by gut peptide GLP-1[276], leptin[277], and β_3 adrenergic stimulation[278]. Distinct presympathetic-premotor neurons in LH express both orexin and MCH[279]. Orexin-hypocretin neurotransmission elicits circadian periodicity of locomotion[280], locomotor food seeking, and sequencing of postprandial behavioral satiety and grooming[281,282]. Activation of LH orexin-hypocretin neurons is functionally connected to DA reward circuit[282]. Further, the hyperactivity in anorexia nervosa is hypothesized to be driven in part by increased ghrelin signaling to DA neurons in ventral tegmental area during underweight and hypoleptinemia[283].

At this point, the attention should be brought to the fact that spontaneous locomotion and physical activity levels are, like meal-to-meal eating, under nonhomeostatic control although their interaction brings about the stability of adult body weight[284]. Cross-sectional human data show that total non-basal energy expenditure normalized for body mass is inversely related to body fat[285,286], and that morbidly obese individuals are almost completely inactive[287]. On the other extreme, underweight subjects with anorexia nervosa are known for compulsive running, "drive for activity", and "restlessness"[288,289]. This paradox where overweight and obese subjects reduce locomotor energy expenditure while the underweight ones are hyperactive, defies the homeostatic expectations. Several lines of experimental animal research confirm the inverse relationship between spontaneous physical activity and body fatness. Obesity induced by either VMH lesions in rats[23], rostromedial septal lesions[290] and hippocampal[291] or septo-hypothalamic transections[292] in hamsters, or cafeteria and high-fat diets in neurologically intact animals[3,293,294] reduce spontaneous running activity. On the other hand, severe dietary restriction consisting of only 2-h access to food, leads to weight loss in rats and up to 300% to 500% increase in spontaneous running activity to the point of emaciation[295]. Spontaneous running by rodents in wheels is a motivated behavior amplified by the device challenges[296] and mediated in part by μ opioids[297]. The inverse relationship between body fat and activity levels is associated with neurochemical changes in brain areas where damage produces obesity and hypoactivity[293]. Obesity-inducing brain lesions in hamsters abolish the inverse relationship to body fat[292]. This then indicates a neurochemical link between the nonhomeostatic physical activity and body fat and body mass.

The motivational basis of spontaneous activity can be demonstrated by placing obese and hypoactive lesioned animals on a motor-driven treadmill. Mild electrical shock at the base of treadmill provides external motivation for animals to keep running on the moving track. Compared to neurologically intact animals, obese hypoactive animals can be compelled by such external negative incentive to run on a treadmill as long and as fast as the intact controls[298]. In a similar vein, rats displaying hyperphagia during ad libitum access to food following a weight loss, display reduced willingness to run and need external incentives to increase their activity[241].

So how then do non-homeostatic feeding and non-homeostatic spontaneous physical activity add up to maintenance of stable adult body mass and composition? The evidence presented so far permits a conclusion that the intermittent feeding and locomotor and other physical activities are loosely coupled with continuous body energy drain[244-246,248]. The way they result in stable body mass setpoint is by sharing the same neural substrate which provides variable reward for these behaviors based on the changes in the brain substrate's sensitivity to circulating concentrations of insulin and leptin. The brain substrate that supports motivations to locomote and search and ingest food is richly populated by insulin[299] and leptin[300] receptors and consists of dopaminergic projections from VTA to NA in the ventral striatum, to limbic forebrain structures and to orbitofrontal cortex[265-267]. Endogenous opiates and cannabinoids[301,302] also are components of this DA reward circuitry, with most of NA, but also some of its parts in particular, showing increased hedonic responding to sweets after stimulation of μ opioid receptors[303]. Mu opioids are also implicated in the motivation for spontaneous running[297]. LH circuits responsive to circulating ghrelin and signaling through MCH and orexin-hypocretin neurons[304] also are associated with DA reward system[273,282,283] in supporting behavioral activation and search for food. The basis of changes in incentive value for locomotor search and ingestion of food[76,77,264-268,302] is vested in changes in the brain substrate's sensitivity to changes in the concentrations of the two hormones as body mass undergoes deviations from the adult norm. Withdrawal of leptin during weight loss reduces its counterregulation of insulin actions, increases the sensitivity of the brain reward substrates to locomotor, olfactory, and gustatory rewards and increases the efficiency of insulin actions leading to lipogenesis and recovery of depleted body energy reservoirs. Leptin administration to underweight humans and animals suppresses the motivation to eat[305], insulin metabolic efficiency[203,204,305], and motivation for spontaneous locomotion[306-309]. With body mass loss and declines in leptin and insulin concentration, increased parasympathetic activation and sensitivities of tissues to insulin and leptin action

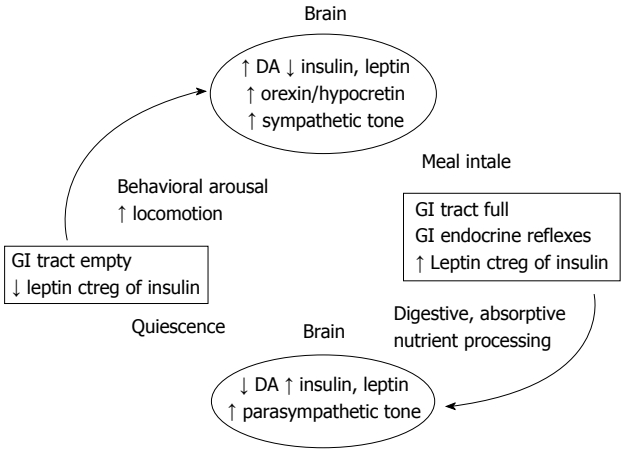

Figure 6 The conceptual model of the linkage between nonhomeostatic meal eating and nonhomeostatic facilitation of physical activity. Completion of gastrointestinal (GI) transit of food removes the inhibitory influence of volumetric and nutritional afferent information mediated by the vagus nerve from reaching nucleus tractus solitaries and DA and opioidergic brain centers of reward.This allows activation of sympathetic actions over fuel mobilization, full operation of behavioral arousal, nonhomeostatic increase in locomotion in quest of food associated with activation of orexin/hypocretin and ghrelin. Completion of nonhomeostatically controled meal results in filling of the stomach, activation of GI nutrient sensing, and increases in postprandial plasma concentrations of insulin and leptin. Vagal projections of this information to the brain reinstate the inhibition over autonomic sympathetic actions and activate parasympathetic control of food digestion and absorption and behavioral quiescence. It is probable that weight loss increases postprandial events linked by the left arrow, and that obesity increases the postprandial events linked by right arrow. Additional consequences of weight loss and weight gain are mediated by changes in tissue sensitivities to leptin and insulin actions altering the prevailing sympathovagal balance and illustrated in Figure 5. DA: Dopaminergic.

facilitate efficient energy storage. Insulin actions are enhanced by reduced leptin counterregulation of its secretion and actions (Figure 5). The parasympathetic dominance in underweight state is reflected in hyperphagia, insulin oversecretion to food intake, and increased efficiency of energy storage that prevail as long as peripheral and central insulin and leptin concentrations remain low and tissue and ANS sensitivity to their actions high.

As increased hunger and metabolic efficiency drive restoration of body fat and body stores to pre-deprivation plateau, the sensitivity of the brain reward circuit declines. The transport of both hormones into the brain also declines[310,311], a process that most likely signals that predeprivation body weight setpoint has been attained. Accrual of excess body fat and body mass along with increases in basal insulin and leptin concentrations leads to reduced motivation to locomote, while feeding is supported in part by palatability of food rather than responsiveness to hunger[76,77]. When excess fat is gained, increased basal concentrations of both insulin and leptin lead to reduced peripheral tissue sensitivity to their actions, and increased activation of sympathetic tone develops as a countermeasure against further body fat and body mass accretion (Figure 5). Thus the brain reward circuit is a component of the autonomic-circadian command center responsible for balancing of sympathetic and parasympathetic processes in part by controlling the secretion of insulin and leptin.

Alternating cycles of famine and feast very likely produced the evolutionary pressure toward coupling of nonhomeostatic search for food opportunities with variable incentive rewards associated with these behaviors[312]. Meal taking and meal processing represent shorter cycles of intermittent refueling of the body that expends energy continuously (Figure 6). Pre-meal behavioral arousal and increased nonhomeostatic locomotion may reflect the activation by the central ANS/circadian command center of lateral hypothalamic neurons responsive to ghrelin, and signaling through MCH and orexin/hypocretin neurons as well as ultradian contractile activity of the empty stomach. The activation of these processes increases locomotor behavior and responsiveness to olfactory gustatory and other signals of food availability. Meal eating inhibits the ANS/circadian command center by GI signals of fullness and satiation. Post-meal grooming in animals and somnolence is induced in part by postprandial insulin secretion[313] and activation of orexin-hypocretin circuits in the LH[280]. The inhibition of the ANS/circadian command center by volumetric and hormonal signals of GI repletion declines progressively as the GI processing of food is completed allowing the sensation of hunger to progressively rise (Figure 2).

REGULATION OF SKELETAL, LEAN AND FAT BODY MASS

Body weight losses or gains along with accumulation of excess fat by either damage to the sympathetic and circadian components of the ANS or cafeteria or high-fat food are viewed by some as a pathological dysfunction of brain substrates where leptin and insulin fail to exert a negative feedback over feeding due to neural inflammation[9]. What this formulation fails to take into account is that weight regulatory mechanism is in full operation at either starvation or obesity extreme of energy balance. Animals rendered obese by medial basal (or in the case of hamsters, septal) lesions or by cafeteria and fat diets defend their new elevated body weight plateau after it has been attained against downward deflections[3,314,315]. The lesions and hedonic nonhomeostatic overeating therefore only raise the plateau at which WAT mass is defended and do not interfere with the body mass regulatory mechanism per se. The clearest demonstration of the integrity of the body mass regulatory defenses after VMH lesions is absence of hyperphagia and hyperinsulinemia (or even presence of hypophagia) if animals are rendered obese by prolonged insulin injections prior to VMH lesion. The change in their feeding behavior lasts until they attain the usual obese body mass plateau characteristic of lesioned animals and thus demonstrate its regulatory defense[316].

The origin of the signal for body mass recovery can therefore not reside exclusively in the size of WAT or adipocyte fat content but requires consideration of the role of the other two body components, the bone and lean tissues. The bone is the probable source of such sig-

nals as its mass changes in parallel with changes in body fat. With each kilogram of body fat gained or lost, 16.5 g of bone mineral is gained or lost[317], and changes in body fat level are accompanied by changes in lean mass. In the hamster, rostral septal lesions[290] and hippocampal[291] and septo-hypothalamic[292] transections increase obesity but also elicit bone and lean body mass growth and an upward displacement of regulated body mass setpoint. Remarkably, increases in body mass setpoint without obesity also can be triggered by voluntary running in this species[318] proving Gordon Kennedy right about the interconnectedness of voluntary activity, weight regulation, and body growth[30,319-321]. The facility of producing upward displacement of body mass setpoint by voluntary running in neurologically intact mature animals provides an exceptional opportunity to examine the location and nature of neural changes responsible for termination of statural growth and initiation of regulatory defenses of the adult body mass setpoint[322,323]. That this is a maturational event is seen by growth acceleration not being possible during animals' natural early rapid growth[323]. The requirement for growth cessation before the defenses of stable adult weight against downward deflections are initiated is shown by the necessity of pituitary gland presence for acceleration of growth by exercise[324], increased pulsatile oversecretion of growth hormone during that growth[325,326], and increased pulsatile growth hormone secretion after the disruption of the brain substrates involved in the maintenance of weight stability in non-growing animals[290-292]. Finally, the permanence of neural changes involved in the defense of the growth-induced upward displacement of body mass setpoint is seen in the phenomenon of catch-up growth[325]. If the hamsters are not given enough food during exercise, their bones and other body components cannot grow as they do when the food is available in unlimited amounts[327]. When the unlimited food is restored, previously exercised hamsters now execute catch-up growth to the approximate body mass plateau they achieve in the absence of food restriction[325]. These data thus demonstrate that exercise has raised mature hamster weight setpoint, and the catch-up growth represents a compensatory process of attaining it.

The supporting inference that leptin is involved in the regulation of lean tissues of the adult body, in particular the bone, should be credited to Gerard Karsenty. He and his research team demonstrated that leptin and sympathetic nerves regulate bone mass in adult mammals by affecting the bioactivity of the bone hormone osteocalcin (OCN)[328]. Although his studies do not include measurements of physical activity, they suggest that signals from the bone osteoblasts influence ANS circuits involved in the regulation of adult body mass. The key finding of Karsenty research was that leptin-induced increase in sympathetic stimulation of the bone suppresses its mineralization and growth. It does so by blocking bioactivity of OCN by activation of an Esp gene in osteoblasts and gamma carboxylation of the hormone. Upregulation of this gene reduces osteoblast numbers and blocks increases in bone mineralization and size. The effect requires β adrenergic receptors on the osteoblasts in the absence of which a high-bone, obese, and hypoactive phenotype is observed similar to that of VMH lesioned animals or mice with deficient leptin signaling (*ob/ob* and *db/db* mice). These findings help explain why with each kg of body fat lost, 16.5 g of bone mineral is lost, and then gained back with body fat regain[317]. Acknowledgment that all three compartments of body mass are regulated extends our understanding of the scope of the roles of leptin and ANS both in short-term nonhomeostatic behaviors and in maintenance of adult weight stability.

The proposed re-interpretation of body weight regulation presents it as a counterpoint between the sympathetic and parasympathetic actions of the ANS/circadian command center in which counterregulation by leptin of insulin secretion and actions and change in tissue sensitivities to the two hormones influence nonhomeostatic locomotor and ingestive behaviors as body fat and body mass are displaced from the stable adult norm. This novel integration offers an opportunity to revise the prevailing homeostatic view of energy regulation and to refocus weight regulation research. The inclusion of body components other than fat stores in body weight regulation expands the scope of study of this mechanism. The proposal that the role of leptin is to counterbalance energy storage associated with insulin secretion as well as help guide lost body mass to pre-deprivation setpoint prompts new hypotheses and research about its possible role in termination of growth and initiation of the maintenance of a stable adult body mass.

Abstract

Diabetes mellitus is a complex condition with far reaching physical, psychological and psychosocial effects. These outcomes can be significant when considering the care of a youth transferring from paediatric through to adult diabetes services. The art of mastering a smooth care transfer is crucial if not pivotal to optimising overall diabetic control. Quite often the nature of consultation varies between the two service providers and the objectives and outcomes will mirror this. The purpose of this review is to analyse the particular challenges and barriers one might expect to encounter when transferring these services over to an adult care provider. Particular emphasis is paid towards the psychological aspects of this delicate period, which needs to be recognised and appreciated appropriately in order to understand the particular plights a young diabetic child will be challenged with. We explore the approaches that can be positively adopted in order to improve the experience for child, parents and also the multi- disciplinary team concerned with the overall delivery of this care. Finally we will close with reflection on the potential areas for future development that will ultimately aim to improve long-term outcomes and experiences of the young adolescent confronted with diabetes as well as the burden of disease and burden of cost of disease.

Key words: Transition; Adolescent; Young adult; Diabetes

Core tip: This manuscript is a comprehensive review of the challenges encountered during the transition of diabetes care from paediatric to adult diabetes services. Further we explore the structured transitional programs that could help in the smooth transition of diabetes care from the youth to early adulthood.

INTRODUCTION

Adolescence is a term derived from the Latin word, "to grow up"[1]. Not only does it denote a transitional phase of physical change and maturation, but also an immense modification of patient psychology. The presence of chronic long term illnesses such as type 1 diabetes may make this vulnerable group even more prone to fall out of the healthcare system and be prone for development of acute or chronic complications.

Diabetes is a complex condition that patients of all

ages often struggle to manage, as it requires many adaptations and modifications to lifestyle. It is often a great challenge when we take into consideration the physical, social and psychological interactions that a young adolescent is often faced with[2]. The scope for development in this area remains vast and the need for a structured framework paramount[3]. The diabetic consultation also changes in a way, from being initially a complex, dynamic parent-led interaction to being a physician-led shortened purpose driven appointment. The lack of this assumed comfortable niche may often leave the adolescent with diabetes feeling abandoned and thus susceptible to poor diabetic control and its complications. The purpose of this article is to highlight the importance of a structured transitional program that could help to alleviate some of the challenges of this turbulent process and help to enable a swift transition from early youth to emerging adulthood.

The key aspects to focus in this review are assessing risks of developing poor glycaemic control during this period, risk of potential complications, acute *vs* chronic as well as possible ways of engaging this at-risk vulnerable cohort of patients. We explore the potential implications of transition from paediatric to adult services and the potential processes that could be considered for service development and also to enhance the patient journey.

THE SCOPE OF THE PROBLEM

The proportion of young adults under the age of 20 years affected by diabetes in 2010 was 0.26%[4]. The "search for diabetes in Youth" study estimated that on average approximately 15000 youth are diagnosed with type 1 diabetes and 3700 with type 2 diabetes annually in the United States[5]. Given the changes in demographics and society, these numbers are projected to increase year on year and henceforth highlighting the need to be vigilant of the problems young teens face and being able to provide a framework to forward the development of this specific aspect of adolescent care[6,7].

The other key feature to be alerted to when accounting for this cohort of patients is the projected increase in the childhood onset of type 2 diabetes[8]. As sedentary lifestyles become more common and fast food more readily available thereby propelling obesity incidence, the emerging numbers of type 2 diabetics is ever more a problem we will encounter in clinical practice[9]. This would therefore cascade down to increasing numbers of adolescents with diabetes who will eventually transition from paediatric to adult care ultimately. The important aspect to be aware of in provision of care for this cohort of patients is to be alert to the changes they will be facing. Thus as any other adolescent will be assuming new roles and changing identities, this is no less apparent in adolescents with diabetes mellitus. The transition services therefore needs to be adapted accordingly and the clinician needs an appreciation of the complexities the youth will be challenged with in general, but more so particularly in the setting of diabetes mellitus.

MODELS OF DEVELOPMENT

There are various psychological models of development that have been put forward to explain the key stages in a young adolescent's life[10]. It is pertinent to be aware of these theories in order to tailor our approach and modify these according to the stages of development. Ignorance of these changes of roles may lead to the provision of sub-optimal care and hence ultimately compromise diabetic control and leave the youth prone to complications, both in the immediate and longer term.

A model of impact of personal change that reflects the changes the young adolescent individual experiences has been previously proposed[10]. The model has a useful analogy to the changes a young adolescent would experience when transitioning of their diabetic care[11]. There is an initial excitement and almost "honeymoon" phase where the young youth is coming of adulthood and excited to be leaving paediatric services, only to gain autonomy of their own care. However this is later followed by a sense of confusion and lack of confidence and almost a crisis stage. Alongside understanding theories of development and change it is also critical to appreciate and understand the corresponding psychosocial changes the youth will be greeted with. This period of emerging adulthood is often the period of most change where young children are assuming new roles of education, moving out of the parental home and progressing towards seeking employment and independence. It is of paramount importance to understand this psychological metamorphosis of a teenager, as it is during this process that the adolescents are most susceptible to run into problems and lack of understanding of this process by the adult care providers acts as a confounding barrier to effective care provision[12]. Care providers and service managers need to acknowledge this and incorporate necessary amendments in their model of care delivery, without which the care could be disruptive, disjointed and not tailored leading to high fall-out rates[13].

In many countries, suboptimal outcomes in the management of diabetes in young adults have lead to centralization of diabetes care. With this the optimization of treatment and outcomes is concentrated in such regional centres and centres of excellence, and subsequently used to reach out to comprehensively improve care in all regions. The need for a multi-disciplinary team, the central role of education and the overlying need for better metabolic control depend on such centres. In developing countries, such centres may develop spontaneously based on perceived need for centralized policies and action. In more comprehensive care systems such as in Europe, marginal outcome data force health care providers to redesign diabetes care, which in some countries is resulting in an orchestrated centre development.

Table 1 Changes in the HbA1c during the transition through the joint transition clinics and the young adult clinics (*n* = 65)

	Joint transition clinic	Young adult clinic
Mean entry age (yr)	17.1	18.5
Number of patients per clinic	2.9	2.7
Mean change HbA1c (DCCT HbA1c %)	0.1	0.2
Mean HbA1c entry (DCCT HbA1c %)	9.8	9.7
Mean HbA1c exit (DCCT HbA1c %)	9.7	9.8
Proportion with > 1% HbA1C (DCCT) improvement	25%	19%
Proportion with improvement in HbA1c	49%	50%

DCCT: Diabetes control and complications trial.

CHALLENGES AND BARRIERS IN THE TRANSITION PROCESS

Delivery of care

Perhaps the biggest change in transition of care is mode of delivery[14]. Initially the child will encounter an aspect of their diabetes care being provided in a very family centered manner, in converse to adult care which is very much assumed and based on the young adult gaining autonomy and identity of their own care, without the parental guidance and support. Different roles and methods have been adopted in the clinical setting to help face and tackle these challenging times[15].

Emerging evidence is gaining credibility that by providing transitional care based on gradual transition is far more successful and advantageous in terms of outcomes, as opposed to offering a simple transfer to care to services[16]. This allows the individual to experience a smooth healthcare experience that is free of plentiful turmoil and change. Certain centers have set up a joint transition clinic whereby paediatricians, adult clinicians and specialist diabetic nurses (DSN) from Paediatric and Adolescent services are directly involved in the delivery of care in this potentially vulnerable period.

We report the model of transition diabetes care in our regional tertiary center where the transition process pans out over 6-8 clinic appointments over a typical 24 mo period, staged through Joint Transition clinic and Young adult clinic. Children with diabetes ready for transition are identified by the paediatric diabetes team and reviewed in the Joint Transition clinics. Majority of these children are between 16 and 18 years of age. During the first two reviews the clinic is led by the paediatric team with the adult diabetes Consultant and a DSN from the adult diabetes team sitting in the joint clinics. The adult team leads the clinic in the subsequent 2 visits after which the care is transferred to a young adult diabetes clinic. Young Adult diabetes clinics are run by the same adult diabetes consultant and adult DSN, provide longer duration of consultation for each appointment, and provide open access to diabetes services through the same named DSN. A telephone reminder service is provided through secretarial staff, to improve attendance rates at these clinics. Each young adult is reviewed 2 to 4 times a year in the Young Adult clinic, for up to 3 years based on clinical needs, before being provisionally transferred to general adult diabetes clinic.

By delivering such a model for transition of care there was an overall significant improvement in attendance rates: 72% attendance rates (of 266 appointments) in the joint transition clinics and 75% attendance rates (of 254 patients appointments) in the young adult diabetes clinic compared to the 45% attendance rate prior to the introduction of this robust pathway.

HbA$_{1c}$ and glycaemic control

The success of a holistic diabetes care can be objectively measured and monitored using glycaemic control as a service indicator. Achievement of target glycaemia in the young adolescent group can be challenging with large studies reporting less than one-third achieving the recommended glycaemic targets[17].

The glycaemic control in the two clinical settings was assessed as part of an internal audit done at our centre. Table 1 shows the changes in the glycaemia as assessed by the HbA$_{1c}$ with the implementation of the transition model at our centre. The HbA$_{1c}$ improved in half of the cohort in the transition model with an significant portion achieving the glycaemic targets of HbA$_{1c}$ < 7.5%.

Loss to follow up

The competing interest of adolescent life along with it inherent psychological changes lead to non-adherence to the service, which can be easily assessed by non-attendance rates to the clinics. There are inevitably adverse short and long term outcomes of patients that are lost to follow up of care[18,19], such as increased risk of acute glycaemia related complications like DKA and severe hypoglycaemia, long term damage to end organs by way of diabetic retinopathy, nephropathy and longer term cardiovascular damage[20]. Patients who are lost to follow up have higher risk of hospitalisation with its huge health care cost implications and increased risk of all-cause mortality[21,22]. Henceforth, various strategies of improving attendance need to be put forward and implemented to improve adherence to the service.

Various centers have devised methods to tackle and approach the above obstacle and have found that use of a simple text reminder service to remind patients of clinic appointments will help them engage with services better thereby helping with improving long term outcomes[23].

At our centre, introduction of a simple telephone service made a significant impact on attendance rates at these clinics. A non-medical staff member of the team (medical secretary) made a phone call 2-3 d prior to the appointment, with the sole purpose of establishing con-

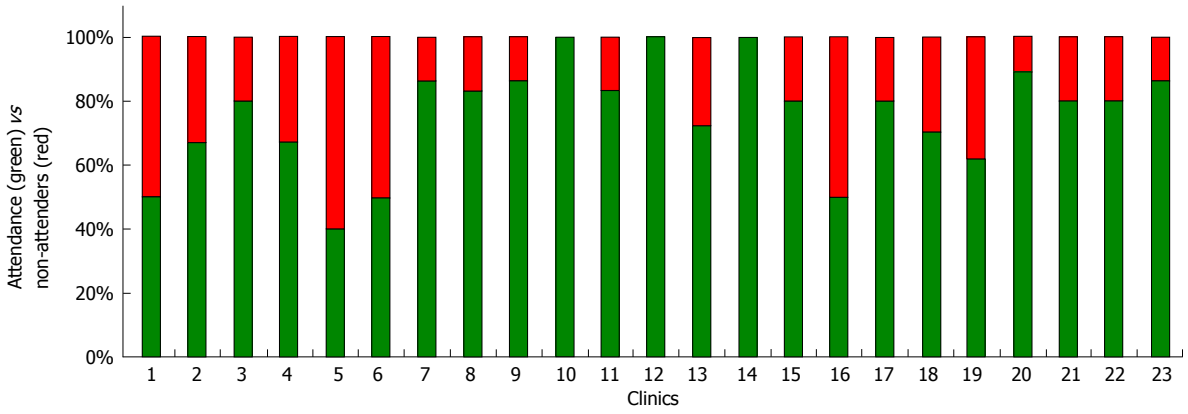

Figure 1 Attendance and non-attendance rates before and after introduction of the telephone service in the young adult clinics[1]. The telephone reminder was 2 d prior to the appointment (clinic 7 onwards, except clinic 16 and 19) significantly improved attendance rates compared to clinics without it.

Table 2 Impact of the telephonic service on the non-attendance rates in the young adult diabetes clinics

Non-attendance rates	Before telephonic intervention (6 clinics)	With telephonic intervention (15 clinics)
Overall non-attendance rate (%)	41	15
New patient (%)	47	8
Follow up patients (%)	30	19

tact and providing a reminder of the forthcoming appointment. The non-attendance rates were reviewed in 23 clinics-6 clinics pre introduction of telephone service and 17 clinics post introduction of the service of which in 2 clinics the service was not used (due to leave of the staff involved and this was effectively a reality check *per se*). There was a significant reduction in non-attendance rate with the introduction of the telephone reminder, both for new and follow-up patients (Table 2). The two of the 17 clinics which did not have this service since the introduction of the process, showed significantly higher non-attendance rates (50% and 38%) thereby internally proving the value of the appointment reminder service and emphasizing how prudent it can be in enhancing attendance to the young adult diabetes clinic (Figure 1). The introduction of a simple telephone service to remind patients of their clinic appointments therefore proved to be a simple addition to improve efficient utilisation of clinic time and in the longer run could demonstrate to be significantly cost effective.

Psychosocial stressors as barriers

Young adults with diabetes are also more likely to face psychological issues hindering their care and management, as evidenced by any patients challenging chronic long-term conditions[24,25]. Thus efficient delivery of care is crucial to allow for this vulnerable patient group in a susceptible period where their lives are simultaneously changing.

Depression in diabetes is a recognised co-morbid factor and will increases mortality and leads to poorer glycaemic control[26]. Up to 33% of adolescent's aged 18-30 years will report depressive symptoms[27]. It is also important to be vigilant of the high risk of eating disorders and substance misuse and insulin misuse, with the risk of misusing insulin for unhealthy weight control measures being quoted to be as high as 57%[28,29].

In our transition clinic setting all patients have access to psychological support from the clinical psychologist embedded in the diabetes team. Some patients are specifically referred to psychology if the teams have any concerns. Authors believe such a model is efficient way of utilization of resources and can be easily replicated across the globe.

Sexual and reproductive health

Unplanned pregnancy remains a major problem in teenagers with co-existing diabetes. The use of contraception has been found to be lower in patients with diabetes (39%) as compared to those without (27%)[30]. Issues around contraception need to be proactively addressed at the young adult diabetes clinics, with emphasis on pre-conception counseling and optimising diabetes care to improve fetal and maternal outcomes[31]. This again highlights the multitude of dimensions that the consultation at the young adult clinic needs to take and address numerous additional challenging issues that young teens will now face.

RECOMMENDATIONS TO IMPROVE MODELS OF CARE

It is therefore prudent that the transition care for children with diabetes should be structured, coordinated with a multi-disciplinary approach with collaboration and communication between the paediatric and adult diabetes teams and making sure the young adult's care is effectively taken over by the adult diabetes team with prior engagement in conjunction with the paediatric team. Despite the clear need for such systematic transition there appears to be lack of a structured approach to this provision and delivery of successful care to provide a service

that is multifaceted and enables the interactions to occur in a step wise fashion allowing the gentle introduction of adult services and gradually stepping away from paediatric input.

Young adults with diabetes, as with any teenage child facing a chronic long term condition, are more vulnerable to the changes of adaptation in care and hence there is greater risk of this care being compromised at a time where they need it most and at a time where the longer term complications (as well as acute) need to be screened and monitored for[32]. One key obstacle identified here is the loss to follow up of these patients. There is evidence to support the use of a simple telephonic calling system in order to aid compliance and concordance with the adult services and ultimately improve outcomes, reduce long-term complications and reduction of end point mortality.

There is evidence that structured transition processes improve health outcomes and quality of life. International organizations including American Diabetes Association, International society for pediatric and adolescent diabetes, Diabetes United Kingdom recommend a structured framework of goals to be outlined and met when transition care of young diabetics to adult services[33-35]. There are no proven uniform strategies to achieve all these goals, although programs that particularly target the young adult with diabetes through education, skills training, specialty transition clinics, or addition of transition coordinators may help towards achieving such goals, for this rising global challenge[36]. It is therefore pivotal that every effort is made to encompass all aspects of their care which will be instrumental in designing and developing a joint care pathway for young adults emerging into adulthood for a well-recognized but less commonly perceived problem in routine clinical practice in the world of diabetes.

Abstract

In recent years the treatment focus for type 2 diabetes has shifted to prevention by lifestyle change and to more aggressive reduction of blood sugars during the early stage of treatment. Weight reduction is an important goal for many people with type 2 diabetes. Bariatric surgery is no longer considered a last resort treatment. Glucagon-like peptide-1 agonists given by injection are emerging as a useful treatment since they not only lower blood sugar but are associated with a modest weight reduction. The role of the oral dipeptidyl peptidase 4 inhibitors is emerging as second line treatment ahead of sulphonylureas due to a possible beneficial effect on the beta cell and weight neutrality. Drugs which inhibit glucose re-absorption in the kidney, sodium/glucose co-transport 2 inhibitors, may have a role in the treatment of diabetes. Insulin treatment still remains the cornerstone of treatment in many patients with type 2 diabetes.

Key words: Type 2 diabetes; Lifestyle modification; Dipeptidyl peptidase 4 inhibitors; Glucagon-like peptide-1 agonists; Insulin

Core tip: Treatment of diabetes is difficult. Initial success in achieving treatment goals is followed by deterioration and the necessity for additional treatments. Exciting new drugs with new modes of action, have stimulated diabetologists to strive for improved control in the knowledge that complications will be reduced or prevented. Obese patients, who loose weight on glucagon-like peptide-1 agonists are usually delighted with these drugs but for those who fail to loose weight changing to oral dipeptidyl peptidase-4 inhibitors would seem a good choice. sodium-glucose transporter-2 inhibitors have the added benefit of being effective even if blood sugar is near to target but uro-genital infection is a concern.

INTRODUCTION

Readers interested in diabetes must be sick and tired reading that diabetes is a global problem of immense size and getting worse by the day with predictions that we will all have the disease one day! I exaggerate of course but it is sad to realise that although we know so much more about the condition we have made little progress in reducing or conquering the disease. A recent history of diabetes in the past 200 years by Polonsky[1] gives an excellent review of the history of discovery of so many mechanisms that are faulty in diabetes and the number of Nobel prize winners who have contributed to such wonderful success, yet more and more people are being diagnosed with the condition/disease and the consequences are immense in terms of suffering and financial cost. One should not forget that before the discovery of insulin 90 years ago

diabetes was a rapidly fatal disease and there was little interest in what we now term type 2 diabetes. Type 2 diabetes now makes up 90% of all diabetes. Insulin resistance rather than insulin deficiency is the major player in the vast majority of type 2 diabetes and type 2 diabetes can be reversed, at least in many patients, with exercise and weight reduction. This is not new information but was highlighted by Taylor's group in Newcastle in 2011[2] when they did a very simple experiment on patients who had diabetes, were obese and managed with tablets. They got 13 patients to do what was common practice and fashionable 40 years ago. They put the patients on an 800 kcal diet, a diet that has been proven beyond doubt to cause weight loss. Indeed there has never been a report of anyone who can maintain their weight on an 800 kcal diet. Compliance was checked by urinary ketones and weight loss. Eleven of the patients succeeded in finishing the eight week diet and lost as much weight as would be expected from bariatric surgery. Just like what happens following bariatric surgery in patients with type 2 diabetes, the diabetes disappeared and blood pressure and lipids improved. Nothing spectacular so far and the study would not have been worthy of reporting since all this is well known and has been done many times before, as Professor Yki-Jarvinen in her leading article in Diabetologia[3] wrote "the only problem is that in medical school and when I was training as an endocrinologist nobody told me how to get patients to follow such a diet". Only 10% of patients are able to follow dietary restriction advice and only the minority take the exercise treatment. Worse, of those who do succeed 90% relapse. Indeed this is why low calorie diets became unfashionable and large type 2 diabetic trials such as the Steino Hospital trial[4] did not include weight reduction as part of their protocol. The Newcastle group[2] converted an unoriginal and mundane study into a really exciting study by demonstrating that liver fat almost disappeared completely within a week and this was associated with a very large improvement in blood sugar and insulin resistance. The rapidity of improvement was interesting and the significance of the reduction of fat around the beta cell, a new finding of uncertain importance. However a plausible theory is that fat in the vicinity of the beta cell and in particular cholesterol, may be easily oxidised and the release of free radicals contributes to damage to the beta cell. In this regard a gene variant Ckal1, a gene associated with protein translation, has been shown to be very sensitive to oxidation and it is associated with a feeble insulin response[5]. Beta cells have the ability to regenerate and early and intensive reduction in blood sugar has been shown to improve beta cell function. Hyperglycaemia creates a vicious circle-the higher the blood sugar the greater the damage to the beta cell and the greater the damage to the beta cell the higher goes the sugar. Hence the drive to prevent hyperglycaemia by intervention in the pre-diabetes phase and to normalise blood sugar in the early stages of diabetes. The final result of the Newcastle group study that made me and many others sit up and take notice was the demonstration that the beta cell recovered, not partially but completely, and even the first phase insulin release returned to normal so the patients really did reverse their diabetes. This article was of such interest that it made headlines in daily newspapers around the world. Patients and their relatives, perhaps for the first time, really understood the damage diabetes does and gained new hope seeing a goal of reversal of diabetes and the possibility of discontinuation of diabetes medications. Beta trophin has been discovered-a hormone expressed mostly in liver and fat that stimulates beta cell proliferation, expands beta cell mass and improves glucose tolerance in a mouse model[6]. Perhaps an exciting new way to help to reverse diabetes in the future?

The July 2012 edition of the Lancet[7] carried on its cover "Physical inactivity: Worldwide", we estimated that physical inactivity causes 6%-10% of the major non-communicable diseases. Physical inactivity seems to have an effect similar to that of smoking or obesity. Min Lee *et al*[8] examined how much disease could be averted if inactivity were eliminated. Diabetes, as expected, is one of the major diseases the authors looked at. They concluded that not only did physical inactivity account for 6%-10% of the major non communicable diseases but this unhealthy behaviour causes 9% of premature mortality. There is good evidence to demonstrate that overweight or obese children who become obese as adults are at increased risk of diabetes whereas overweight or obese children who became non-obese by adulthood are not[9]. More importantly many studies have shown that educational interventions in physical activity have actually been successful and indeed more successful than interventions for obesity. Heath *et al*[10] in the same issue of the Lancet, examined interventions from around the world and demonstrate that the literature is convincing in demonstrating that behavioural and social approaches are effective. The improvements are seen among people of various ages and from different social groups, countries and communities. The authors make the point that although individuals need to be informed and motivated to adopt physical activity, the public health priority should be to ensure that environments are safe and supportive of health and wellbeing.

Since we know so much about the risk of developing diabetes, it should be possible to have treatment to prevent diabetes in many patients. The diabetes prevention program outcome study[11] has been recently published. This ongoing study demonstrated a clear reduction in diabetes incidence in participants randomly assigned to a lifestyle intervention or metformin during the intervention period. The authors end by stating that their data "support early and aggressive measures for long term prevention of diabetes in people at risk". Intensive lifestyle intervention has been shown to slow the decline in mobility in overweight adults with diabetes[12]. A disappointing result has recently come from the Look AHEAD study[13]. The study was designed to test the hypothesis that an intensive life style intervention for weight loss would decrease cardiovascular morbidity and

mortality in over weight patients with type 2 diabetes. More than 5000 patients took part in the study and the median follow-up of the study was for 9.5 years, weight loss was modest in the intervention group (6% *vs* 3.5% at the end of the study). Alas there was no reduction in the rate of cardiovascular events. The study results are perhaps not surprising in that significant weight reduction is unachievable in most patients but does suggest that we as physicians should accept that most patients are unable to loose weight and should not be made to feel guilty about this. On the other hand to continue to engage the patient in meticulous control of blood pressure, lipids and blood sugar, together with cessation of cigarette smoking, a healthy diet and exercise, are of proven benefit.

Casazza *et al*[14] have written an excellent article entitled "myths, presumptions and facts about obesity". The definition of a presumption was a belief in the absence of supporting scientific evidence; a Myth was defined as a belief persisting despite contradictory evidence. Facts were suppositions backed by sufficient evidence to consider them proven for practical purposes. The authors note that sometimes action is taken by policy makers in the absence of strong scientific evidence "This principle of action should not be mistaken as justification for drawing conclusions". The myths examined were: (1) that small sustained changes in energy intake or expenditure will produce large long term weight changes; (2) Setting realistic goals for weight loss is important otherwise patients will become frustrated and loose less weight; (3) Large rapid weight loss is associated with poor long term weight outcomes as compared with slow gradual weight loss; (4) It is important to assess the stage of diet readiness in order to help patients who request weight loss treatment; (5) Physical education courses in their present form play a part in reducing childhood obesity; (6) Breast feeding is protective against obesity; and (7) A bout of sexual activity burns 100-300 cal for each participant.

A stepwise approach to the management of diabetes has become a fashionable concept in recent years with many published paradigms of the steps which are variable and often contradictory or display so many different stairways that they become very confusing. The first step depends on getting the patient at the very beginning of their path, that is in the pre-diabetes stage but even then they may have already suffered from macrovascular and microvascular damage[15-18]. There is little dissention in advising the lifestyle changes but, should metformin also be used or should one wait and see the effect first of the lifestyle changes? Information on this point is available, for example in the trial by Snehalatha *et al*[19] 2009. There seemed to be no advantage to add metformin to life style changes so perhaps metformin should be reserved for those patients who are unable to adhere to life style changes?

Once diabetes has been diagnosed can one wait and see the result of life style changes or should one aggressively control blood sugar? High glucose is toxic to the beta cell. Exciting new information suggests that the beta cell may dedifferentiate under high glucose attack by causing reduction in a key transcription factor, Fox 01. This dedifferentiation results in the production of inactive proinsulin and an increase in glucagon[20]. Intensive insulin therapy at diagnosis of type 2 diabetes has been shown to reverse diabetes. Weng *et al*[21] studied 382 patients and had divided them into 3 groups. Continuous insulin infusion, multiple injections or oral agents were used to achieve rapid normalisation of hyperglycaemia. Treatment was stopped after normoglycemia was maintained for two weeks. After a year 51% and 44% of the insulin treated patients were in remission where as only 26% of the patients in the oral agent group had gone into remission. The evidence to support early and aggressive treatment for type 2 diabetes has not been widely accepted. The reasons are probably due to a shortage of personnel to manage patients. In my country there is a long waiting list to be seen in a diabetic clinic and general practitioners are usually unhappy about starting insulin. The better understanding of the beta cell pathology of diabetes should persuade physicians to adopt a more urgent approach to diabetes management in the future. A systematic review and meta-analysis on short term intensive insulin therapy in type 2 diabetes gives further support for the ability of this treatment to modify disease progression[22].

BARIATRIC SURGERY

Bariatric surgery for obese type 2 diabetes has been refined over the last few years. Laparoscopic surgery has made operation on morbidly obese patients who have diabetes, and indeed those who do not have diabetes, much safer and very often will reverse the diabetes. The operation has been shown to reduce cardiovascular risk. As with all operations the experience of the surgeon and indeed the surgical unit plays a very important part in outcome. A Cochrane review[23] in 2009 concluded that bariatric surgery is more effective than conventional treatment in achieving and in sustaining weight loss in people with obesity. Improvements in health related quality of life and obesity related co morbidities including type 2 diabetes, dyslipidaemia and sleep apnoea are further benefits. A very good review of the subject has recently been written by Dixon *et al*[24].

Mingrone *et al*[25] in 2012 published a single centre non-blinded randomised controlled trial to examine the difference in outcome between surgery as compared to usual medical therapy. Surgery was either gastric bypass or bilio-pancreatic diversion. At the end of 2 years HbA1c was 6.35% in the gastric bypass group and 4.95% in the bilio-pancreatic-diversion group as compared to 7.69% in the medically treated group. Diabetes remission had occurred in 75% of the gastric bypass group and 95% in the bilio-pancreatic diversion group. No patient in the medical group had reversed their diabetes. There were no deaths and almost no complications in the surgical group[25].

In the same edition of the journal Schauer *et al*[26] evaluated the efficacy of intensive medical therapy as compared to medical therapy plus Roux en Y gastric bypass or sleeve gastrectomy in 150 obese patients with uncontrolled type 2 diabetes. The primary end point was the proportion of patients with a glycated haemoglobin level of 6.0% or less, 12 mo after treatment. Twelve percent of the medical group, 42% in the gastric bypass group and 37% in the sleeve gastrectomy group achieved the primary end point. HbA1c was 7.5% in the medical group 6.4% in the gastric bypass group and 6.6% in the sleeve gastrectomy group. No deaths or life threatening complications occurred[26]. An editorial in the same edition by Zimmet *et al*[27] suggests that the bariatric surgery should not be seen as a last resort. More recently Arterburn *et al*[28] did a retrospective analysis to compare rates of diabetes remission, relapse and all cause mortality amongst severely obese adults with diabetes who underwent bariatric surgery *vs* non-surgical treated individuals. At 2 years the surgery subjects had significantly higher diabetes remission rates 73.7% compared to non surgical subjects with 6.9%. The surgical subjects also experienced lower relapse rates with no higher risk of death[28].

NEW INSULINS FOR TREATMENT OF TYPE 2 DIABETES

Many different regimes have been proposed and indeed are in use for the treatment of type 2 diabetes when life style and metformin have failed to control hyperglycaemia. A three year efficacy of complex insulins in type 2 diabetes demonstrated that the addition of a basal or prandial insulin based regimen to oral therapy had better diabetic control than those who added a biphasic insulin regimen[29]. My own feeling is that, as so many patients with type 2 diabetes don't increase their blood sugars overnight, attention should be paid to controlling the post evening meal rise in blood sugar so that the patient goes to bed with a normal blood sugar, long acting insulins being reserved for those patients in whom blood sugars rise overnight. To me it doesn't make sense to give a basal dose of a long acting insulin pre bed with the risk of overnight hypoglycaemia to a patient whose blood sugar has not been shown to rise overnight. Insulin degludec is almost identical to human insulin but with the last amino acid deleted from the B chain and addition of a glutamyl link from LysB29 to a hexadecanoic fatty acid[30]. Two phase 3 studies were reported recently[31,32]. In the first study type 1 diabetic patients (472 subjects) were subjected to insulin degludec and 157 to glargine insulin[31]. Although there was no difference in HbA1c at the end of the study and no difference in overall, confirmed hypoglycaemia; overnight hypoglycaemia was 25% less in the insulin degludec and of course nocturnal hypoglycaemia is what many patients fear most. The second study Garber *et al*[32] reported the effect of the new insulin in type 2 diabetic patients *vs* insulin glargine. Again after 1 year there was no difference between the 2 groups in HbA1c. Overall hypoglycaemia was a little less in the insulin degludec group and nocturnal hypoglycaemia was also a little lower (1.4 *vs* 1.8 episodes per patient-year exposure). The authors conclude that the newer basal insulins with lower hypoglycaemia events may allow more intensive blood sugar lowering treatment. From the results presented in their paper, insulin degludec does not seem to be the answer. An editorial by Tahrani *et al*[33] in the same edition, ends by saying that insulin degludec is not a revolution but an evolution of insulin therapy for patients with both type 1 and type 2 diabetes.

SODIUM GLUCOSE CO-TRANSPORT-2 INHIBITORS

Glycosuria occurs when the blood glucose reaches a threshold of about 10 mmol/L. However some people will excrete glucose at much lower levels of blood glucose (renal glycosuria). The discovery that glucose is transported across the proximal tubule membrane by sodium/glucose co-transport 2 (SGLT2) and that a naturally occurring polymorphism of the gene causes renal glycosuria, paved the way for the development of SGLT2 receptor inhibitors as a way of promoting renal glucose excretion and therefore calorie loss and reduction of blood sugar. Two drugs have undergone clinical trials dapaglifozin and canaglifozin and have been the subject of a meta analysis by Clar *et al*[34]. The drugs both result in blood glucose reduction of about 0.5%-1% with some weight loss. Urinary and genital infections were more common. Hypoglycaemia did not occur any more frequently that placebo. The results of the Cantata-SU trial have recently been published[35]. The trial was a 52 wk study in type 2 diabetes with patients who were inadequately controlled with metformin. Canagliflozin was compared to Glimepiride. 1452 patients were randomised in a phase 3 non-inferiority, double blind, randomised trial. Three hundred mg of Canagliflozin reduced HbA1c from a mean of 7.8% to 6.9% (mmol/L) a reduction of 0.9%. Hypoglycaemia was less common on Canagliflozin and there was a 4 kg reduction in weight with a small reduction in blood pressure. There was a 0.25 increase in LDL cholesterol but also a slight, 0.1% increase in HDL cholesterol and a very slight reduction in triglycerides also of 0.1%. Genital mycotic infections occurred in 8% in men and 14% in women on the 300 mg dose. The study suggests that the benefit of the drug is a useful reduction in HbA1c and weight reduction. The blood pressure reduction is also of benefit but the rise in LDL might be a worry and the mycotic genital infections and urinary tract infections might make the drug unacceptable to many patients who may have presented with these problems when first diagnosed. An editorial in the Lancet where the results were published is entitled "SGLT2 inhibitors for diabetes: turning symptoms into therapy" and makes the point that the place of this class of drugs in the treatment of type diabetes is still to be decided[36]. There has been concern about breast and bladder cancer as well

as long-term cardiovascular adverse effects also making surveillance mandatory. Another recently published study comparing canagliflozin with placebo and sitagliptin produced similar results[37]. A randomised, blinded, prospective Phase 111 study on dapagliflozin as monotherapy in drug naive Asian patients with type 2 diabetes found that with the 10 mg dose HbA1c had fallen from a mean of 8.26% to 7.15% as compared to a fall of only 0.29% for placebo(a difference of 0.82%) Genital infections occurred in 4.5% of patients and Urinary tract infections in 5.3%[38].

The role of these drugs in the treatment of type 2 diabetes is not clear at present but the lack of risk of hypoglycaemia and the weight reduction suggest that there is a place for them in certain patients who are inadequately controlled and in whom an extra 0.5% or more reduction in blood sugar would be of benefit in bringing the patient into the acceptable blood sugar range.

METFORMIN

The reason for metformin as first line pharmacological treatment is based on many studies suggesting that metformin is weight neutral or associated with very modest weight loss as compared with sulphonylureas which cause slight weight gain initially. Also, in experimental conditions reperfusion after myocardial infarction is reduced by sulphonylureas. As long ago as 1971 the University Group Diabetes Program[39] showed that tolbutamide, a first generation sulphonylurea, was associated with an increased cardiovascular risk in diabetes. The UKPDS trial[40] suggested that metformin has a protective effect on mortality. Roumie *et al*[41] examined the comparative effectiveness of sulphonylurea and metformin monotherapy on cardiovascular events in type 2 diabetes mellitius. This was a very large retrospective cohort study examining cardiovascular outcomes. The crude rates of composite outcome were 18.2 per 1000 person years in the sulphonylurea users and 10.4 per 1000 person years in the metformin group. A wonderful editorial in the same edition of the Annals of Internal Medicine by Nissen[42] entitled "Cardiovascular effects of Diabetes Drugs; Emerging from the dark ages", likens the dark ages after the fall of the Roman Empire to the time between the University Group Diabetes Program in 1972[39] which showed that treatment for diabetes with phenformin or tolbutamide was associated with increased cardiovascular risk, and 2012. The article explains why there is still uncertainty about the effect of sulphonylureas and cardiovascular events. Nissen[42] suggests that the study is hypothesis generating rather than definitive and that high quality evidence is still missing "Continued darkness is not an acceptable option" he concludes.

INCRETINS

It has been known for many years that intravenous glucose will not stimulate insulin secretion to the same extent as a similar glucose load given orally. It was discovered that hormones secreted from the intestine in response to a glucose load had the ability to release glucose from the pancreas. These hormones were called incretins and they are responsible for at least 50% of insulin secretion following a meal. In 1971 a peptide was isolated from the intestine which had the ability to inhibit gastric acid secretion and was therefore called gastric inhibitory polypeptide (GIP)[43]. GIP was later found to stimulate insulin secretion. What was very interesting was that GIP would only stimulate insulin secretion in the presence of high blood sugar. This finding has implications in treatment terms since drug that only works with high blood sugar would be much less likely to cause hypoglycaemia. Patients, their families and of course doctors and other health care professionals all fear hypoglycaemia. Garber[44] refers to the many hospital visits caused by hypoglycaemia and suggests that minimisation of hypoglycaemia should be a goal for treatment of type 2 diabetes. I would certainly agree. In a survey insulin accounted for 13.9% of overall admissions to hospital from adverse drug reactions and oral anti-diabetic drugs 10.7%[45].

Another incretin was discovered in 1985 and called glucagon-like peptide-1 (GLP-1)[46]. This hormone was also dependent on high blood sugar level for full action. Both GIP and GLP-1 act by binding to specific receptors and so release insulin. GLP-1 has another action, it inhibits gastric emptying and this has been of benefit in the treatment of diabetic patients because the feeling of satiety leads to weight reduction. Another beneficial effect of the reduction in rate of gastric emptying is to delay absorption of food, a mechanism which improves blood sugar excursion. GLP-1 also regulates appetite and food intake through its effect the hypothalamus. A recent review of the effects of GLP1 on appetite and body weight with a focus on the central nervous system has been published[47].

GLP-1 agonists have been shown to stimulate B cell growth in animals and cell cultures. In humans it is less clear if these drugs can improve insulin output by regenerating the B cell. It seems less likely that the dipeptidyl peptidase (DPP)-4 inhibitors could also have an effect on B-cell re-growth. However an abstract presented at the Annual American Diabetes Association meeting in 2010 suggested that linagliptin was able to restore beta cell function in human isolated islets[48]. Vildagliptin has also been shown to improve beta cell function and glucose tolerance but also to improve the extensive peri-insulitis found in the mouse model examined[49].

A very interesting effect of GLP-1 analogue therapy has been described in obese type 2 diabetic patients. The investigators found a reduction in inflammatory macrophages and a reduction in inflammatory cytokines together with an increase in the adipokine adiponectin. The researchers had previously described a case of psoriasis that was greatly improved by GLP-1 agonist therapy[50]. The new study does suggest an important beneficial effect of GLP-1 analogue therapy that needs further inves-

tigation[51]. A good review on the extrahepatic effects of GLP-1 receptor Agonists has just been published[52].

DEVELOPMENT OF GLP-1 FOR THE TREATMENT OF DIABETES

Exenatide is a GLP-1 receptor agonist. It is a 39 amino acid peptide produced in the saliva glands of the Gila monster lizard[53] it has 53% amino acid homology to full length GLP-1 and it binds with greater affinity than GLP-1 to the GLP-I receptor in GLP-1 receptor expressing cells[54]. DPP-4 cleaves peptides and is responsible for the rapid breakdown of GLP-1. DPP-4 does not denature exenatide because of the slight amino acid differences and in human studies the half life ranges from 3.3 to 4 h[55]. Exenatide (Eli Lilly) is now in clinical use in many countries for the treatment of diabetes. It must be given an hour before meals on a twice a day basis. Many trials have reported that the drugs cause about a 1% reduction in HbA1c and reduction in body weight of 5.3 kg at the end of 3 years of treatment[56]. The dropout rate is about 20%, many patients refusing treatment because of nausea.

EXENITIDE

Attempts have been made to prolong the action of exenatide using a polylactide glycolide microsphere suspension so that the drug can be given weekly. Kim *et al*[57], in a randomised placebo-controlled phase 2 study examined the effect of exenatide long acting release, a long acting release exenatide formulation, found that a weekly dose for 15 wk in patients with type Ⅱ diabetes resulted in a 1.4% reduction in HbA1c, suggesting that once a week formulation may be as good as, if not better than, twice daily injections of exenatide. In particular there were no dropouts in the trial due to adverse events. Liraglutide is a long acting GLP-1 analogue with attachment of a C-16 free fatty acid derivative. The free fatty acid derivative promotes non-covalent binding of liraglutide to albumen thereby increasing plasma half life. A recent study comparing liraglutide once a day with exenatide twice a day found that liraglutide improved HbA1c significantly more (-1.12% *viz* -0.79%) and was generally better tolerated[58]. The study has demonstrated that glycaemic improvement and weight reduction are independent of each other. This fits in with other studies which suggest that the weight loss is not, in itself, the cause of the improved blood sugar control[59].

In a recent paper Derosa *et al*[60] examined the effect of exenatide on beta cell function. The authors used the homeostasis model assessment beta cell function index as well as assessing pro-insulin and insulin with arginine stimulation under clamp conditions. The results suggested that beta cell function was improved by exenatide. However a caveat, HbA1c was significantly better after the 12 mo of exenatide as compared to placebo. It is well known that hyperglycaemia is toxic to the beta cell hence the improved glucose might have been responsible for the beta cell improvement rather than the drug itself. Bunck *et al*[61] showed similar results compared to glargine. In their study combined glucose and arginine stimulated C peptide secretion was 2.46 fold greater after 52 wk of exenatide treatment compared with insulin glargine treatment with a non significant (P = 0.55) 0.8% reduction in HbA1c as compared to a -0.7% reduction in the glargine group. Four weeks after cessation, the beta cell function returned to pre treatment levels.

Exenatide, was compared to glimepiride in patients who were not controlled on metformin alone[62]. About 1000 patients were divided into 2 groups and studied on average for 2 years although some went on for 42 mo. At the end of 3 mo both groups had decreased HbA1c from around 7.4% to 6.8% but by 36 mo the glimperamide group had gone back to a HbA1c of more than 7.3% whereas the exenatide group, although increasing their HbA1c slowly over the 3 years, was significantly lower at a level of just over 7.2%. Body weight fell in the exenatide group by 3.32 kg and rose in the glimperamide group by 1.15 kg. Systolic blood pressure (BP) decreased in the exenatide group by 1.9 mmHg with no change in the Glimpereride group. Less patients in the exenatide group experienced a hypoglycaemic episode. In the first 6 mo 49 patients in the exenatide group discontinued mostly due to gastrointestinal side effects as compared to 17 in the glimepiride group (P = 0.001) Buse *et al*[63] examined whether twice daily exenatide injections reduced HbA1c levels more than placebo in patients receiving Glargine insulin. HbA1c decreased by 1.74% in the exenatide group as compared to 1.04% in the placebo group over a 30 wk period. Hypoglycaemia was similar in the 2 groups and 13 treatment patients and 1 placebo recipient discontinued the study because of adverse events, nausea and vomiting being the main problems.

LIRAGLUTIDE

At the beginning of 2012 the FDA approved the marketing of extended release exenatide (Bydurion). The drug is given weekly by injection. Liraglutide is a human GLP-1 analog given by once daily injection with a good safety record and HbA1 lowering effect similar to the other GLP-1 agonists. A 2-year report on safety, tolerability and sustained weight loss over 5.2 years with once daily liraglutide has been published[64]. Two hundred and sixty eight of 398 people who entered the extension of the original 20 wk trial completed 2 years. Weight loss was 7.8 kg from screening and was maintained. There were improvements in BP and lipids. Patients with diabetes however were excluded from taking part in this trial. The Duration Trial 6[65] reported on a study comparing daily liraglutide to weekly extended release exenatide. This was a 26 wk trial with more than 400 patients in either arm. Liraglutide was associated with a greater change in HbA1c (-0.48% *viz* 1.28%). Nausea was more common in the liraglutide group (21% *viz* 9%) and also vomiting (11% *viz* 4%) 5% of patients allocated to liraglutide discontinued the treatment as compared to 3% allocated to exenatide because

of adverse events. The results suggest that the patient might be allowed to choose whether to have a drug which is injected daily but with no diluting procedure before the injection or a weekly injection with less blood sugar lowering effect but less side effects. Non-alcoholic steatosis has become a problem in type 2 diabetes. The LEAN study is currently examining whether liraglutide will improve non-alcoholic steatohepatitis outcome[66].

LIXISENATIDE

Lixinitide is another potent, selective, once daily GLP-1 agonist. A randomised placebo controlled double blind trial examined lixisentide daily injection in Asian patients with type 2 diabetes insufficiently controlled on basal insulin with or without sulphonylureas[67]. This was a 24 wk study. These patients were not obese body Mass Index 25.3 kg/m^2. Eighty-two percent of patients reached and stayed on the maintenance dose of lixisenatide (20 μg once a day). There was a significant reduction in HbA1c compared to controls. The difference at the end of the trial was 0.88%. There was no significant change in weight compared to controls. The incidence of serious side effects were similar in both groups. Two patients in the lixisenatide group experienced cerebrovascular infarction. Forty-two percent of study drug patients experienced hypoglycaemia as compared to 24% on placebo. Fonseca *et al*[68] examined efficacy and safety of once daily lixisenatide at different doses. HbA1c was reduced by 0.66% compared to placebo. Postprandial and fasting blood sugars were significantly lower in the treatment group. In a study by Kapitza *et al*[69] lixisenatide once daily was compared to liraglutide once daily in patients with type 2 diabetes insufficiently controlled on metformin. This was only a 28 d study but the results showed that liraglutide controlled fasting blood glucose better than lixisenatide but postprandial blood sugar was better controlled by lixisenatide. A review discussing the place of this GLP-1 agonist as an add on therapy to basal insulin has recently been published[70].

TASPOGLUTIDE

Ipsen Roche had another GLP-1 analogue under review called taspoglutide. This is a GLP-1 analogue which has a prolonged action and is in phase Ⅱ trials. The drug has been shown to improve diabetes control and lowers body weight in subjects with diabetes. In a study involving once a week injections in 306 type 2 diabetic subjects who were already on Metformin, 8 wk treatment was associated with a reduction in HbA1c. The highest dose gave an HbA1c reduction of 0.9% and a weight reduction of 1.9 kg as compared to placebo. Nauck *et al*[71] report on a 24 wk study using a 10 mg or a 20 mg dose of Taspoglutide, comparing once a week dosing to daily glargine insulin. One thousand and forty-nine patients were randomised into 3 groups. Withdrawal rates were 21% for each of the Taspoglutide groups and 9% for the glargine group. HbA1c of < 53% was achieved in 39.47% and 32% receiving Taspoglutide 10 mg, 20 mg and HbA1c < 48 in 18%, 24%, and 14% of patients or glargine insulin respectively. Lower fasting blood sugars were achieved by glargine insulin. Serious hypersensitivity reactions occurred in 2 patients on Taspoglutide. However confirmed hypoglycaemia was less with the study drug (0.3%, 0.9% *viz* 3.1%) and weight loss was greater on Taspoglutide (-3.3 and -4.1 kg). Withdrawals due to adverse effects occurred in 9%, 13% on Taspoglutide and in 1% on the glargine insulin. An addendum to the paper states that Roche has now stopped the development of the drug. Ibsen is currently pursuing further investigations. Rosenstock *et al*[72] examined the fate of Taspoglutide once a week *vs* Exenatide for type 2 diabetes. The doses used were again 10 mg or 20 mg as compared to twice daily exenatide 10 μg. Reduction in HbA1c was -1.24 with 10 mg and -1.31 with the 20 mg as compared to exenatide from a starting HbA1c of 8.1%. Withdrawals were higher in the study drug patients and the authors conclude that even though Taspoglutide caused lower blood sugars the level of side effects was unacceptable.

Albiglutide is a long acting subcutaneous albumen-based fusion of GLP-1[73]. In February 2009 Glaxo SmithKline (GSK) began phase 3 studies in type Ⅱ diabetes. Albiglutide is a GLP-1 mimetic generated by genetic fusion of a DPP-4-resistant GLP-1 dimer to human albumin[74]. The formulation was originally developed by Human Genome Sciences (HGS) and named Albugon, GSK having bought the drug in 2004 for all human therapeutic and prophylactic applications of Albiglutide. In 1999 Centeon (now Aventis Berring) granted Principia (now HGS) world wide rights to its recombinant fusion proteins and its related yeast technologies[75].

ANTIBODIES TO GLP-1 AGONISTS

Therapeutic proteins/peptides with structural similarity to endogenous proteins/peptides often have unwanted immunogenicity. Antibodies to the GLP-1 agonists have been described and may inhibit the action of the agonist. The role of antibody formation to the various agonists on the market at present are uncertain. A study by Buse *et al*[76] in 2011 suggested that antibodies to liraglutide did not inhibit efficacy however antibodies to exenitide, if they were high, was associated with a smaller HbA1c reduction. Antialbiglutide antibodies developed in 2.5% of patients in an 8 wk trial.

GLP-1 AND THE CARDIOVASCULAR SYSTEM

Endothelial dysfunction is a common finding in diabetes and an early marker of atherosclerosis. GLP-1 has been shown to improve endothelial dysfunction[77,78]. GLP-1 exerts a cardio-protective effect against ischaemic damage and heart failure. Diabetes is associated with an increased risk of atherosclerosis and myocardial infarction.

Ischaemic preconditioning is a protective mechanism by which the heart may protect itself from prolonged ischaemia. The University Group Diabetes Programme report[39], more than 40 years ago, suggested that tolbutamide might increase myocardial infarction and mortality. Glibenclamide has been shown to affect ischaemic preconditioning but trials have not shown beyond doubt that it is associated with increased myocardial infarction. However drugs that inhibit the K ATP channel opening, such as glibenclamide, are related to loss of ischaemic preconditioning[79-81]. GLP-1 receptors are found in the heart. Increased glucose uptake by the cardiac myocyte is beneficial in protecting the heart from ischaemia changes[82]. Studies in situ and *ex-vivo* suggest a beneficial effect on the heart muscle when under ischaemic stress. Bao *et al*[83] examined the effect of albiglutide in rats after myocardial ischaemia reperfusion injury. They measured cardiac glucose uptake and cardiac metabolic flux. They found enhanced glucose uptake and reduced myocardial infarct size and improved cardiac function. It has yet to be shown if this effect also occurs in humans and if myocardial infarct size and mortality will be reduced by GLP-1 agonists. DPP-4 inhibitors have been less well studied in cardiac ischaemic preconditioning. In a study by Rahmi *et al*[84] rapaglinide, a sulphonylurea like drug, inhibited ischaemic preconditioning as measured by stress testing in patients with type 2 diabetes who already had evidence of coronary atherosclerosis. Vildagliptin, a DPP-4 inhibitor, did not alter preconditioning in 72% of patients whereas 83% of the repaglinide patients had ischaemia earlier in their stress test.

GLP-1 AND THE PANCREAS

Pancreatitis has been described in patients using GLP-1 agonists. A report in 2010 stated that 8 cases during clinical development and 36 post marketing reports are available[85]. A recent report[86] examined a large United States health insurance claims database and could find no increased risk of acute pancreatitis using twice daily exenatide. However there were several limitations to the study and it was a pity that other GLP-1 agonists were not investigated at the same time but the study was funded by Amylin and Eli Lilly. Stimulation of GLP-1 receptors that are found in the exocrine pancreas might lead to overgrowth of the epithelial cells in the small ducts causing pancreatitis through obstruction. A worry has been raised that GLP-1 agonists may induce metaplasia and premalignant changes[87,88].

GLP1 AND THE THYROID

The thyroid contains GLP1 receptors and Gier *et al*[89] also found coincident immunoreactivity for calcitonin and GLP-1 receptors in both medullary thyroid carcinoma and C cell hyperplasia. C cell carcinoma of the thyroid has been seen in animals dosed with GLP-1 agonists and can be explained by the finding of GLP-1 receptors in the thyroid[89]. GLP-1 receptor immuno-reactivity was also found in 18% of papillary thyroid carcinoma. The authors speculate on the consequences of long term stimulation of these GLP-1 receptors. They suggest that prospective studies need to be done to exclude an increase in papillary and medullary carcinoma in the thyroid.

DPP-4 INHIBITORS

These drugs act by inhibiting the enzyme that breaks down GLP-1, thus increasing the level of GLP-1 in the blood stream. They are however not able to raise the GLP-1 levels to levels found after injection of GLP-1 agonists and therefore their hypoglycaemic efficacy is less than that of GLP-1 agonists. Sitagliptin, vildagliptin, saxagliptin and linagliptin have already been approved in the United States and in Europe. An excellent systematic review and meta-analysis has been published in the British Medical Journal in 2012[90]. Compared with metformin, DPP-4 inhibitors were associated with a smaller decline in HbA1c and a lower chance of attaining a HbA1c goal of less than 7%. As a second line treatment DPP-4 inhibitors achieved a smaller decline in HbA1c than the other hypoglycaemic drugs. There was however, no significant difference in attaining an HbA1c of less than 7% when compared to sulphonylureas. They were less effective in lowering body weight when compared to metformin. When added to metformin they had a favourable weight profile compared to metformin and sulphonylureas or pioglitazone but not when compared to GLP-1 agonists. Hypoglycaemia was less common when a DPP-4 inhibitor was added to metformin as compared to a sulphonylurea added to metformin. There is evidence to suggest that the DPP-4 inhibitors are more effective in lowering glucose in Asians than non Asians[91]. A one year follow up of DPP-4 inhibitors *vs* sulfonylureas on top of metformin has been published recently[92]. Patients with prior metformin therapy received a dual combination of metformin with either DPP-4 inhibitor or sulfonylureas. There was no significant difference in either body weight or HbA1c. Hypoglycaemia was significantly less in the patients taking DPP-4 inhibitors. These patients had significantly less transitory cerebral ischaemic attacks whereas other cardiovascular events were of borderline significance.

There are 6 DPP-4 inhibitors (*e.g.*, Sitigliptin, Linagliptin, Vildagliptin, Alogliptin, Saxagliptin, Teneligliptin) on the market minor variation in their chemical composition have not been translated to particular benefit although it should be noted that linagliptin is mostly excreted in pathways other than the kidney and hence dosage does not have to be reduced in moderate renal failure.

Vildagliptin, a DPP-4 inhibitor which increases circulating GLP-1 levels, has been shown to ameliorate the deposition of amyloid beta and tau phosphorylation in a streptozotosin induced animal model of diabetes[93]. A study by Omar *et al*[94] using a high fat diet induced obesity model in mice of advanced age has demonstrated that Vildagliptin confirms other rodent models of diabetes in preserving beta cell mass mainly through inducing beta cell proliferation and reducing beta cell apoptosis[94-96].

Omar *et al*[94] found that Vildagliptin improved glucose secretion in response to oral glucose. Beta cell area was not significantly altered by Vildagliptin treatment in these mice but peri insulitis was prevented by Vildagliptin. Sitagliptin has also been shown to protect against amyloid associated beta cell loss but its effect was not different to that of Metformin[97].

The binding modes of these drugs has recently been investigated[98]. Based on their binding sites the authors divided the drugs into 3 categorise, Vildagliptin and Saxagliptin, Alogliptin and Linagliptin, Sitagliptin and teneligliptin. It is not clear whether these different binding modes have clinical relevance but may help in the development of better inhibitors in the future. Unlike GLP-1 agonists the DPP-4 inhibitors do not pass the blood brain barrier and have no effect on satiety, nor do they effect gastric emptying. Although the different DPP-4 inhibitors have some differences including potency, half lives and metabolism there does not seem to be any meaningful difference in their ability to lower blood sugar and this is probably why there are virtually no head to head studies (one head to head study showed no difference between saxagliptin and sitagliptin when combined with metformin[99]. A good review of the differences has been written by Capuano *et al*[100]. Most of the DPP-4 inhibitors can be administered once daily but Vildagliptin needs to be given twice daily. Saxagliptin is mainly metabolised by CYP3A4/5 isoforms to a major active metabolite 5-saxahydroxygliptin. It is suggested that the dosage of saxagliptin be modified if co administration with CYP3A4/5 inducers such as rifampicin or inhibitors such as ketoconazole.

SITAGLIPTIN

Insulin glargine *vs* sitagliptin another DPP-4 inhibitor was studied by Aschner *et al*[101]. About 250 patients in each group were studied for more than 6 mo. At the start patients were already on metformin which was continued during the study. HbA1c was significantly lower in the glargine group. There were more hypoglycaemic episodes and slight weight gain in the glargine group where as there was slight weight loss in the Sitagliptin group. A recent study compared the effect of sitagliptin or glibenclamide in addition to metformin and pioglitazone on glycaemic control and beta cell function[102]. Body weight reached was lower with sitagliptin. Fasting plasma insulin and homeostasis model assessment of insulin resistance with glibenclamide were significantly increased with glibenclamide and decreased with sitagliptin. Sitagliptin did not change the homeostasis model assessment of beta cell function but the value was significantly increased by glibenclamide. Both glibenclamide and sitagliptin increased C-peptide.

VILDAGLIPTIN

A 24 wk study in elderly patients was recently published[103]. The study investigated the feasibility of setting and achieving individualised targets over 24 wk for elderly patients (over 70 years of age with type 2 diabetes). The patients who were treated with vildagliptin achieved a 0.6% reduction in HbA1c from a baseline of 7.9% as compared with placebo. There were no tolerability issues as compared to placebo, hypoglycaemic events were 2.2% in the vildagliptin arm and 0.7% in the placebo arm. Individualising goal HbA1c is thought to be appropriate particularly in the frail elderly[104]. The benefit of reducing HbA1c by less than 1% in this age group is uncertain. There seems no doubt that in the frail elderly hypoglycaemia is a very serious threat to health[105,106]. Macrovascular disease/events seem to respond better to blood pressure and lipid interventions than to blood sugar lowering at least in the short term[107] but microvascular damage and retinopathy prevention, particularly in patients who already have significant damage, should make the Physician consider carefully the probable benefit of tighter blood sugar control. Under these circumstances one might not choose a DPP-4 inhibitor since they work better in the higher blood sugar range and are less likely to result in the achievement of a HbA1c of 6.5% (48 mmol/L). The efficacy and safety of vildagliptin in patients with type 2 diabetes inadequately controlled on Metformin and sulphonylurea suggests that a mean HbA1c of 8.75% can be improved by about 0.75% as compared to placebo[108]. It is such a pity that the GLP-1 agonists work best at high HbA1c levels and are less effective in reduction of HbA1c as the HbA1c gets near to target. However in this trial 25% more patients reached a target of 7% as compared to controls(38.6% *vis* 13.9%).

SAXAGLIPTIN

The 4-year safety of saxagliptin has recently been published[109]. No new safety issue findings appeared during the 4 years of treatment alone or with metformin and hypoglycaemia did not increase the risk of hypoglycaemia. The cardiovascular safety of diabetic drugs continues to raise concern[109]. Saxagliptin was examined by Scirica *et al*[110]. They randomised 16492 patients with type 2 diabetes who had a history of or who were at risk for cardiovascular events, to receive Saxagliptin or placebo and followed them for a median of 2.1 years. The HbA1c at the beginning of the study was 8.0% and at the end of the study the HbA1c in the Saxagliptin arm had decreased to 7.5% and the placebo arm to 7.8%. A surprising finding was that more patients in the Saxagliptin group were hospitalised for heart failure but otherwise the cardiovascular end point results were similar between the two groups. Hospitalisation for hypoglycaemia occurred infrequently and was similar in the two groups but significantly more patients in the saxagliptin group reported at least one hypoglycaemic event. Thus this 2-year study gives little support for the use of saxagliptin in these patients.

LINAGLIPTIN

Linagliptin is a once a day oral DPP-4 inhibitor. It is an

orally active small molecule which was licensed in United States in 2011. It is mostly excreted in the faeces and there are no clinically relevant alterations in linagliptin pharmokinetics resulting from renal or liver impairment[111]. A recent study has confirmed that renal impairment has no clinically relevant effect on the long term exposure of linagliptin in patients with type 2 diabetes[112].

A 2-year efficacy and safety study of linagliptin compared to glimepiride in patients inadequately controlled on metformin was reported recently[113]. More than 1400 patients were divided into two groups. HbA1c at the end of the study was similar in the two groups but there was less hypoglycaemia and there were significantly less cardiovascular events (1 *vs* 2). Hypoglycaemia is not usually a problem in the treatment of type 2 diabetes but recently has been suggested to be a therapeutic concern. The efficacy and safety of Linagliptin in subjects with type 2 diabetes was analysed by Del Prato *et al*[114]. Pooled analysis of data from 2258 subjects in 324 wk phase 3 studies. Oral linagliptin or placebo as monotherapy added on to metformin or added on to metformin plus a sulphonylurea were the treatments investigated. Although linagliptin was effective the patients had a mean HbA1c of 9.0% and the level of HbA1c only dropped to 8.3% still unacceptably high for many patients. DPP-4 inhibitors unfortunately work less well the lower the starting HbA1c[102]. A study of linagliptin in patients aged over 70 years found that HbA1c was lowered by 0.64% from 7.8% to 7.2% with a safety profile similar to placebo. Whether long term studies in this age group will show benefit in measurable outcome is speculative at this time.

ALOGLIPTIN

Alogliptin seems to have much the same characteristics as the other DPP-4 inhibitors on the market, A useful review has recently been published[115]. Another large study specifically looking at cardiovascular disease in type 2 diabetic patients has been reported[116]. More than 5000 patients who had type 2 diabetes and either an acute myocardial infarction or unstable angina requiring hospitalisation within the previous 15 to 90 d received allogliptin or placebo in addition to existing antidiabetic and cardiovascular drug treatment. HbA1c at the start of the trial was 8.0% and at the end of the study had come down to 7.7% as compared to 7.97% in the placebo group. Hypoglycaemia was similar in the two groups. Again this large study makes one question the value of the addition of the DPP-4 inhibitor which was associated with such a modest drop in HbA1c.

TENELIGLIPTIN

Teneligliptin is another DPP-4 inhibitor which has been recently reviewed[117].

DPP-4 INHIBITORS AND THE HEART

GLP-1 receptors, which are found in the heart increase glucose uptake by the cardiac myocyte is beneficial in protecting the heart from ischaemia changes[118]. Matsubara *et al*[119] examined 44 patients with coronary artery disease and uncontrolled diabetes (HbA1c > 7.4%). Sitagliptin or aggressive conventional treatment was compared after 6 mo. Endothelial function was significantly improved in the sitagliptin group with no difference in fasting blood sugar at the end of the trial but a reduction in HbA1c of 0.6% in each group. C-reactive protein (CRP) reduced significantly in the sitagliptin group with a significant correlation between the CRP and the vascular reactivity but not with HbA1c.

DPP-4 INHIBITORS AND THE PANCREAS

Butler *et al*[120] examined the pancreata of 7 individuals treated with sitagliptin and 1 with exenatide compared with 12 individuals with type 2 diabetes treated with other agents, and 14 non-diabetics. There was an increase in the number of pre-malignant lesions and marked alpha cell hyperplasia with glucagon expressing micro adenomas and a glucagon expressing neuroendocrine tumour in one of the eight. Because the number of diabetics who were not on treatment with DPP-4 based therapy were so few the evidence is insufficient for alarm but the evidence for caution and vigilance in the next number of years is clear and persuasive.

Sero negative polyarthropathy has been recorded with the use of DPP-4 inhibitors. Three patients were described by Crickx *et al*[121] and one case by Ambrosio *et al*[122]. The acute arthritis is not perhaps surprising since DPP-4, also named CD 26 is expressed on many cells involved in the immune process.

CONCLUSION

New treatments for diabetes are coming on line but prevention and treatment of obesity through increased exercise and reduced calorie intake still seems the best option in most patients with type 2 diabetes. Those with insulin deficiency have new options which are exciting as they demonstrate new approaches to treatment but their glucose lowering effects are modest and mostly most effective when blood sugars are high thus of less use when blood sugars are near to, but not at, target in spite of a combination treatment.

Abstract

Diabetes is the most important risk factors for chronic kidney disease (CKD). The risk of CKD attributable to diabetes continues to rise worldwide. Diabetic patients with CKD need complicated treatment for their metabolic disorders as well as for related comorbidities. They have to treat, often intensively, hypertension, dyslipidaemia, bone disease, anaemia, and frequently established cardiovascular disease. The treatment of hypoglycaemia in diabetic persons with CKD must tie their individual goals of glycaemia (usually less tight glycaemic control) and knowledge on the pharmacokinetics and pharmacodynamics of drugs available to a person with kidney disease. The problem is complicated from the fact that in many efficacy studies patients with CKD are excluded so data of safety and efficacy for these patients are missing. This results in fear of use by lack of evidence. Metformin is globally accepted as the first choice in practically all therapeutic algorithms for diabetic subjects. The advantages of metformin are low risk of hypoglycaemia, modest weight loss, effectiveness and low cost. Data of UKPDS indicate that treatment based on metformin results in less total as well cardiovascular mortality. Metformin remains the drug of choice for patients with diabetes and CKD provided that their estimate Glomerular Filtration Rate (eGFR) remains above 30 mL/min per square meter. For diabetic patients with eGFR between 30-60 mL/min per square meter more frequent monitoring of renal function and dose reduction of metformin is needed. The use of sulfonylureas, glinides and insulin carry a higher risk of hypoglycemia in these patients and must be very careful. Lower doses and slower titration of the dose is needed. Is better to avoid sulfonylureas with active hepatic metabolites, which are renally excreted. Very useful drugs for this group of patients emerge dipeptidyl peptidase 4 inhibitors. These drugs do not cause hypoglycemia and most of them (linagliptin is an exception) require dose reduction in various stages of renal disease.

Key words: Chronic kidney disease; Diabetes; Antidiabetic drugs; Metformin; Dipeptidyl peptidase 4 inhibitors; Therapeutic algorithm

Core tip: Chronic kidney disease (CKD) is very often among diabetic persons. In every day clinical practice doctors worldwide have to deal with these patients and help them to achieve their metabolic goals. Despite this, many studies of antidiabetic drugs have excluded people with CKD. So, we lack solid evidence on the effectiveness and safety of these drugs. In this review I propose therapeutic algorithms for diabetic patients in different stages of CKD and clarify some questions about the use of popular antidiabetic drugs as metformin and sulfonylureas.

Ioannidis I. Diabetes treatment in patients with renal disease: Is the landscape clear enough? *World J Diabetes* 2014; 5(5): 651-658 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i5/651.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i5.651

INTRODUCTION

Chronic kidney disease (CKD) affects million of people

worldwide. CKD is becoming a major problem for public health as it leads to increased morbidity and mortality. Patients with end stage chronic kidney disease often need kidney transplantation[1].

The prevalence of chronic kidney disease to the estimated 11% of the United States population. Patients with chronic kidney disease have an increased risk of cardiovascular disease and progression of renal disease in end-stage renal failure. End stage renal failure leads to dialysis or transplantation[2,3].

Diabetes is the most important risk factors for CKD. The risk of CKD attributable to diabetes continues to rise worldwide.

The National Kidney Foundation and the American Heart Association have recently issued guidelines for the management of cardiovascular risk in people with kidney disease by stating emphatically that these individuals are at very high cardiovascular risk.

For diabetic patients with chronic kidney disease, the risk of cardiovascular disease is even higher classifying these individuals in the highest risk group for cardiovascular disease. Diabetic subjects with microalbuminuria have increased risk (2x) of cardiovascular disease than those with normoalbuminuria. Proteinuria and decreased Glomerular Filtration Rate (GFR) contribute synergistically to increase cardiovascular risk. Most diabetic patients with CKD stage 3 will suffer a serious cardiovascular event, possibly fatal before their chronic kidney disease progress to end stage kidney failure.

Diabetic patients need complicated treatment for their metabolic problems as well as for related comorbidities. They have to treat, often intensively, hypertension, dyslipidaemia, bone disease, anaemia, and frequently established cardiovascular disease (CVD). Thus, the problem for the appropriate selection of antidiabetic treatment for patients with diabetes and CKD is usual in every day clinical practice[4,5].

DIABETES TREATMENT: DIFFERENT GOALS AND DIFFERENT DRUGS

Recent guidelines for the treatment of diabetes (ADA, EASD 2012) propose personalization of glycaemic goals. For the majority of diabetic patients the appropriate goal is a haemoglobin A1c (HbA1c) < 7% but for patients with severe comorbidities a goal between 7% and 8% is acceptable. Diabetic subjects with CKD usually belong to this group.

The glycated HbA1c is the most popular and well-accepted biological marker for the assessment of long-term glycaemic control. This also applies to patients with diabetes and renal disease. However, the method has significant limitations in these patients. The measurement is influenced by both renal function and complications of chronic kidney disease such as haemolysis, iron deficiency and metabolic acidosis.

In most cases diabetic subjects with chronic kidney disease must rely more on self-monitoring of blood glucose with usual glucose meters. Patients with diabetes and CKD have usually already established CVD. These patients are also in greater risk of hypoglycaemia. We know from physiology that normal renal function conveys a 30% of neoglycogenesis, which is necessary to avoid hypoglycaemia especially in prolonged fasting periods[6].

Many diabetics with uraemia have also nutritional problems and some times cachexia. The use of insulin as well as of sulfonylureas or glinides (short acting secretagogues) leads to increased rate of hypoglycaemia in this group of patients[7,8].

On the other hand, many drugs have renal metabolism and their metabolites are usually active prolonging their time of action. The use of antidiabetic drugs, especially the new classes, is conflicted. The major problem is that in many efficacy studies patients with CKD are excluded so data of safety and efficacy for these patients are missing. This results in fear of use by lack of evidence[9].

Nevertheless, pharmacokinetics and pharmacodynamics data for many new drugs help us to understand the potential risks and benefits for these subjects. Even if these basic data are reassuring the clinical point remains critical: We cannot use new drugs based only on these evidence! We need results form efficacy studies and then approval from FDA and EMEA[10].

Finally, the use of antidiabetic drugs is more complicated in these patients because many people with kidney disease are often elderly, and have long lasting disease and significant co-morbidities. These people take many drugs and they have high risk of drug interactions.

ESTIMATION OF RENAL FUNCTION IN DIABETIC PATIENTS

For all diabetic subjects we have to estimate their renal function. 1st step: Serum creatinine/annually (or every 3-4 mo in selected patients); 2nd step: Based on serum creatinine we estimate GFR (eGFR). eGFR is usually based on patient characteristics (as age, sex and race) as well as serum creatinine levels. The most popular method of assessment of renal

$$\text{MDRD: GFR} = 175 \times \text{SerumCr}^{-1.154} \times \text{age}^{-0.203}$$

[× 1.212 (if patient is black) × 0.742 (if female)]

function with the greater precision is the Modification of Diet in Renal Disease (MDRD) equation. This equation is based on data of MDRD Study. This equation (MDRD) is especially accurate in GFR < 60 mL/min.

For higher GFR another equation can also be used: Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) method based on data of CKD-EPI.

$$\text{CKD-EPI: GFR} = 141 \times \min(\text{Scr}/\kappa, 1)^{\alpha} \times \max(\text{Scr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ (if female)} \times 1.159 \text{ (if black)}$$

Where Scr is serum creatinine (mg/dL), κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum of Scr/κ or 1, and max indicates the maximum of Scr/κ or 1.

Usually we use friendly calculators to estimate GFR.

Many programs are also free available for smartphones.

The classical formula of Cockcroft-Gault is not used anymore because it overestimates GFR. (Body weight in the formula must be lean weight and not total weight).

METFORMIN

Metformin is globally accepted as the first choice in practically all therapeutic algorithms for diabetic subjects. The advantages of metformin are low risk of hypoglycaemia, modest weight loss, effectiveness and low cost. Data of UKPDS indicate that treatment based on metformin results in less total as well cardiovascular mortality.

Many diabetologists as well as practitioners are fear to use metformin in patients with renal problems even if they have only albuminuria. There is a lot of confusion about the real restriction of its use in patients with CKD[11].

Metformin is slowly absorbed when administered orally. The bioavailability of the drug is low (50%-60%).

Metformin achieves a maximum plasma concentration one to three hours after ingestion, if taken in the form of immediate release or in 4-8 h with the extended release form. Metformin is not connected with albumin or any other protein in plasma. This results in a high volume of distribution up to 1000 even after the first dose[12].

In patients with moderate and severe CKD Cmax is increased 173% and 390%, respectively, compared with patients with normal renal function.

In normal pH metformin remains as hydrophilic cation. Less than 0.01% of the drug is unionized in blood. Lipid solubility of metformin is low. So, metformin can not diffuses through cell membranes. Phenformin, another member of antidiabetic drug class biguanides, which is no longer in the market, is more lipophilic than metformin due to different side chain. Metformin is not metabolized in the liver. Metformin is actively excreted by the urinary tube and found unchanged in the urine. After 24 h, if renal function is normal, metformin is not detected in the blood after administration of a single dose. The half-life of metformin is plasma is about 6 h[13].

The absorption of metformin in the intestine is mediated by a transporter known as plasma membrane monoamine transporter. Several metformin transporters are implicated in its intestinal absorption as well as in its hepatic uptake and renal excretion. These transporters are either Organic Cation Transporters (OCTs) or multidrug and toxin extrusion proteins (MATEs).

The kidneys also actively excrete metformin. Metformin enters renal cells of the renal tubule from circulation. This procedure takes place on the basolateral membrane of the cells and is mediated by OCT2.

Then, metformin is excreted into the lumen. This excretion is facilitated by MATE (1 and 2-K). These extrusion proteins are located in the apical membrane of renal proximal tubule cells.

Metformin is also reabsorbed in renal tubules and this action is mediated by OCT1, which is located also in proximal and distal tubules.

The molecular mechanisms underlying metformin action appear to be complex. Metformin entries into the hepatic cell and facilitate phosphorylation and activation of AMP-activated protein kinase (AMPK). Activation of this key-kinase (energy status sensor) lead to many effects related to metabolism of glucose and lipids. Metformin inhibits hepatic neoglycogenesis also in a direct manner. Metformin inhibits complex I of the mitochondrial respiratory chain. This inhibition, leads to an incretion of AMP:ATP ratio, which activate AMPK. This inhibition leads also to increased anaerobic metabolism of glucose in cytoplasm and the production of lactic acid. Thus, metformin is related with increased risk of lactic acidosis when renal elimination of lactic acid is decreased (renal disease, reduced GFR) or hepatic function is severely damaged (lactic acid is used in hepatocytes to produce glucose-neoglycogenesis-). The risk of lactic acidosis is also increased in patients with tissue hypoxia (shock, severe heart failure, sepsis, surgery related hypotension, *etc.*)[14].

Risk of lactic acidosis was greater with phenformin because it's a more potent inhibitor of mitochondrial respiration. Phenformin has hepatic metabolism with an inactive metabolite. The enzyme CYP2D6 metabolizes phenformin into an inactive metabolite. A small ratio of patients (about 2.8%) has a polymorphism of the enzyme that makes them poor metabolizers. In these patients the risk of lactic acid is even greater (due to higher levels of phenformin).

Nevertheless, analysis of data from may trials (347 comparative trials and cohort studies) from Cochrane Database systematic review in 2010, showed no cases of lactic acidosis in 70490 patient-years of metformin.

Statistical analysis of these data suggested that the upper limit for the incidence of lactic acidosis per 100000 patient-years was 4.3 cases (lower than 5.4 cases in the non-metformin group).

In this analysis also, levels of lactic acid seems to be no different in the two groups.

In most studies however lactic acidosis was not a pre specified end point and there were no data about lactic acid levels.

In the Table 1 we summarize the current recommendations about the use of metformin in CKD.

All diabetic subjects at risk of acute renal failure must discontinue at least temporally metformin. Clinical situations related to increase of acute renal failure includes hepatic insufficiency and use of radiocontrast agents and antimicrobial drugs. Fluid substitution as well as support of cardiac output is useful in certain clinical conditions. Monitoring of urine output and serum creatinine lack sensitivity and specificity in acute renal failure, they remain the most used parameters in clinical practice.

At last, when we change the dose of drugs affecting blood pressure and potentially renal perfusion we have to monitor renal function closely and to reduce the dose of metformin (use of diuretics or increase of their dose,

Table 1 Use of metformin in chronic kidney disease

eGFR (mL/min per 1.73 m^2)	Use of metformin
> 60 (CKD 1 and 2)	No contraindication Check of renal function annually
45-60 (CKD 3a)	Use of metformin-reduce dose (no more than 1.5-2 g daily) Frequent check of renal function (every 3-6 mo)
30-45 (CKD 3b)	Reduce dose (no more than 1-1.5 g daily) No new cases Frequent check of renal function (every 3-6 mo)
< 30 (CKD 4 and 5)	Stop metformin

CKD: Chronic kidney disease; eGFR: Estimate Glomerular Filtration Rate.

start of use of ACEIs and ARBs, unstable heart failure with frequent hospitalizations, *etc.*).

PIOGLITAZONE

Pioglitazone has only and exclusively hepatic metabolism. It does not cause hypoglycemia and it can be given theoretically without dose adjustment at all stages of CKD. Pioglitazone is related with fluid retention, anemia and osteoporosis. These side effects complicate the existing problems with anemia and bone disease in subjects with diabetes and CKD[15,16].

The use of pioglitazone is generally limited in these patients and in decreased dose (usually 15 mg once daily).

SULFONYLUREAS

Sulfonylureas are old drugs widely used worldwide. These drugs ease the secretion of insulin and are related with increased risk of hypoglycemia, which is a major issue for CKD patients.

Glibenclamide

Glibenclamide (glyburide) is metabolized in the liver and excreted by the kidneys equally and intestine. Some metabolites are active and can accumulate in CKD despite the fact that biliary removal partially counteracts the limited renal excretion.

Hypoglycemia may be serious and lasting more than 24 h in CKD.

The use of glibenclamide in subjects with moderate CKD (eGFR 60-90 mL/min) should be limited (reduced dose, frequent monitoring due to increased risk of hypoglycemia). The drug and is contraindicated in stage $\geqslant$ 3 CKD (eGFR < 60 mL/min)[17].

Glimepiride

Glimepiride is metabolized by the liver to two major metabolites each of which has hypoglycemic activity. In renal disease these metabolites summed. Although the half-life is 5-7 h, the drug can cause severe hypoglycemia that lasts more than 24 h. Its use is safe in GFR > 60 mL/min and with a reduced dose of up to 30 mL/min. In CKD stage 4 or 5 the use of glimepiride is dangerous[18].

Gliclazide

Gliclazide is metabolized by the liver to inactive metabolites that are eliminated in the urine. Thus, gliclazide causes less hypoglycemia than other sulfonylureas. In CKD sage 1, 2, 3 (eGFR > 30 mL/min) gliclazide can be used. There are no data in patients with severe CKD but according to its metabolism the use (in reduced dose) of gliclazide is also permitted in these subjects[19].

Glipizide

Glipizide also does not need dose adjustment in severe and moderate renal disease and can be used safely. (The only caution remains the risk of hypoglycemia).

GLINIDES

Glinides, repaglinide and nateglinide, are short acting secretagogues. The short duration of their action means reduced risk of hypoglycemia compared to sulfonylureas. This is an advantage for diabetic subjects with CKD because they belong in the high risk for hypoglycemia group as already mentioned.

Repaglinide is absorbed from the gastrointestinal tract and metabolized in the liver by oxidation and conjugation with glucuronic acid. The major metabolites of repaglinide are M1, M2 and M4. These metabolites are excreted *via* the bile into the feces and have no hypoglycemic activity[20].

Repaglinide can be used even in CKD stages 4 and 5 without dose reduction.

Nateglinide is also rapidly absorbed from the gastrointestinal tract and metabolized in liver to 9 main metabolites (M1-M9). These metabolites have much weaker hypoglycemic activity than the parent compound. The only metabolite that retains high activity is the metabolite M7. The concentration of this metabolite however is low (< 7%), resulting in a hypoglycemic effect, which is attributed mainly to intact nateglinide. The excretion of the drug in urine is unchanged form at 16% and by 84% in the form of metabolites.

In CKD stage 5 we avoid nateglinide, and in stage 4 we adjust the dose (60 mg × 3)[21].

GLIPTINES (DIPEPTIDYL PEPTIDASE 4 INHIBITORS)

Dipeptidyl peptidase 4 (DPP-4) inhibitors (gliptins) constitute a new class of antidiabetic drugs with a very favorable profile: safety, efficacy, and low risk of hypoglycemia and weight neutrality[22].

Gliptins are inhibitors of the enzyme DPP-4. This enzyme degrades and inactivates many active peptides. Among them are incretin hormones. These hormones, namely glucagon like peptide 1 (GLP-1) and glucose dependent insulinotropic polypeptide stimulates glucose

Table 2 Dose adjustment of dipeptidyl peptidase 4 inhibitors in chronic kidney disease

	CKD			
	CKD 1, 2 and 3a (Cl_{cr} > 50 mL/min)	CKD 3b (Cl_{cr} 30-50 mL/min)	CKD stage 4 (Cl_{cr} 15-30 mL/min)	CKD stage 5 (ESRD)

Alogliptin (Nesina)	√ (25 mg × 1)	1/2 dose (12.5 mg × 1)	1/4 dose (6.25 mg × 1)	1/4 dose (6.25 mg × 1)

CKD: Chronic kidney disease; ESRD: End stage renal disease.

dependent insulin secretion by b cells in pancreatic islets. At the same time they suppress glucagon production by a cells in the same islets. Their role in glucose homeostasis seems to be important. These hormones are secreted in low levels when we are fasting but their secretion is rapidly increased after meal consumption. Their action results also in reduced glucagon secretion, which in turns reduces hepatic glucose production.

Vildagliptin, Sitagliptin, Saxagliptin, Linagliptin and Alogliptin belong to this class and are already available in the market. Their place in algorithms for patients with diabetes and CKD is important. We can use them all in CKD but with dose adjustment for the majority of the members of this class. (Only linagliptin does not need dose adjustment in any stage of CKD)[23].

In Table 2 we summarize the dose adjustments for all gliptins in diabetic subjects with CKD.

Sitagliptin

Sitagliptin does not undergo extensive metabolism. In the liver sitagliptin partially metabolized by oxidation in a limited rate by the enzyme CYP3A4. Nevertheless, most of the drug is excreted in the intact form in the urine (more than 80%). Sitagliptin is filtered in renal glomerulus but also is actively excreted by active tubular secretion[24].

Six metabolites are detected in amounts of < 1% to 7%. These metabolites M1 to M6 are products of hepatic metabolism.

Chemically the changes in these metabolites are: M1: N-sulfation, M4: N-carbamyl glucuronidation, M6: hydroxylation followed by either glucuronidation (M3), and oxidative desaturation followed by cyclization (M2 and M5). These metabolites are practically inactive.

In renal disease the elimination of the drug is reduced resulting in 2- or 4-fold increase of the concentration of the drug (for CI_{cr} 30-50 mL/min and < 30 mL/min respectively). The dose adjustment is based on these properties.

In Phase I studies of sitagliptin dosing up to 600 mg daily doe not results to dose-related side effects, at least in the short term (up to 28 d). These data indicates that if we don't adjust the dose in CKD practically it might be safe at least for a short period[25,26].

Vildagliptin

Vildagliptin is absorbed quickly (85.4% of the drug). The maximum plasma level is detected at 1.1-h post dose.

Plasma radioactivity (after the administration of radioactive labeled drug) due to vildagliptin is 25.7% and to its major metabolite M20.7 is 55%. The half- life of vildagliptin is 2.8 h. Eighty-five percent of the drug is excreted in the urine (22.6% as vildagliptin the rest as inactive metabolites) and the remaining 15% in feces (4.54% as vildagliptin). In humans, the main pathway of metabolism of the drug is carboxylation, which results in the form of the active metabolite M20.7. DPP-4 contributes to formation of this metabolite. Other minor metabolites are: M15.3, which results from hydrolysis of amide bonds, M20.2 from glucuronidation of the pyrrolidine ring and M20.9, M21.6 from oxidation of the pyrrolidine ring. All these metabolites are inactive[27].

Hydrolysis takes place in multiple tissues or organs. Exposure to vildagliptin in subjects with type 2 diabetes and renal disease of various stages cannot be accurately predicted because the kidneys play a small role in the removal of the drug while participating in metabolism *via* hydrolysis[28].

In diabetic subjects with chronic kidney disease stage 1 or 2 (eGFR > 50 mL/min per 1.73 m^2), dose adjustment of vildagliptin is not required.

In patients with chronic kidney disease stage ⩾ 3, both vildagliptin and its active metabolite M20.7 are less excreted *via* the kidneys. In these patients a dose adjustment is required. (When eGFR is < 50 mg/mL per 1.73 m^2 the dose is 50 mg × 1).

Saxagliptin

Saxagliptin is primarily hepatic metabolized by the cytochrome P450 3A4/5 (CYP3A4/5). The major metabolite of this drug is also active as also a DPP-4 inhibitor, and retains half of the potency of parent drug.

All the drugs, which are also metabolized in this cytochrome CYP3A4/5, may alter the pharmacokinetics of the drug and its active metabolite. Twenty-four percent of the drug is excreted in the urine as saxagliptin and 36% as its active metabolite. There is also some active renal excretion of the drug. A significant part (more than 20%) can be found in the feces as a sum of excreted in bile drug and unabsorbed drug[29].

In diabetic patients with chronic kidney disease stages 1 and 2 increased concentration of saxagliptin and its active metabolite remains clinically irrelevant and no dose adjustment is needed.

In diabetic subjects with chronic kidney disease stages ⩾ 3 half dose is recommended (2.5 mg × 1 daily) to

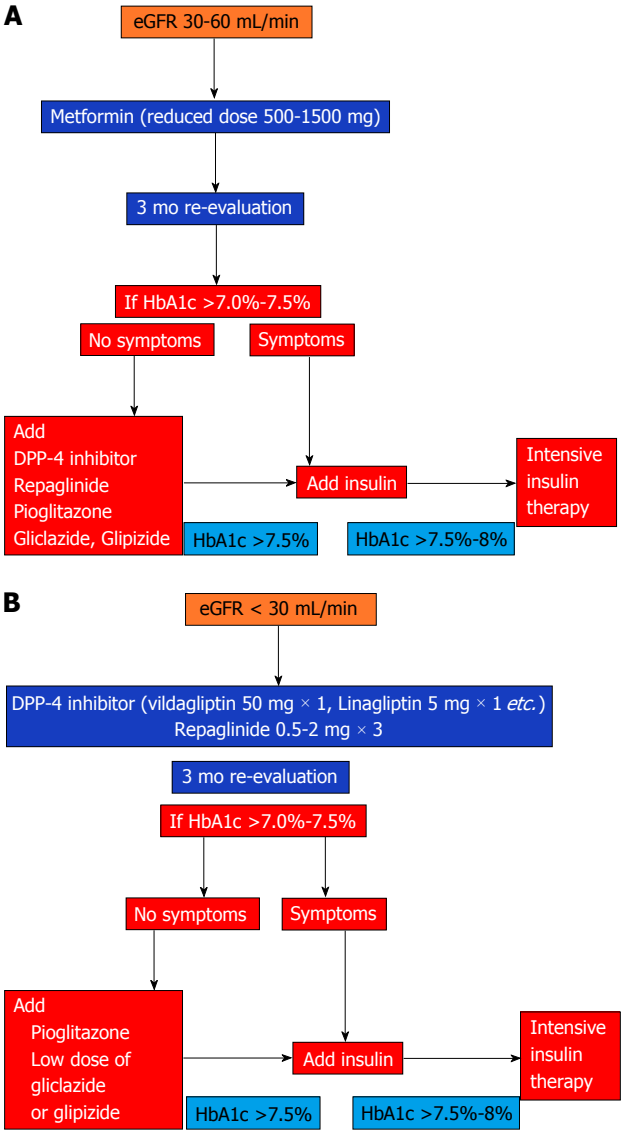

Figure 1 Therapeutic algorithm (A and B). eGFR: Estimate Glomerular Filtration Rate; HbA1c: Haemoglobin A1c; DPP-4: Dipeptidyl peptidase 4.

achieve the same plasma concentrations compared to subjects with normal renal function. The same dose is recommended in patients with end-stage renal disease (requiring hemodialysis).

Alogliptin

This DPP-4 inhibitor is not practically metabolized and is excreted unchanged in the urine. (More than 70% of the parent drug). One minor metabolite named M1 is active but its concentration remains quite low (< 1%)[30]. Alogliptin is excreted by glomerulus filtration as well as by active tubular secretion.

In patients with CKD stage 1 and 2 no dose adjustment is needed (25 mg × 1 daily). In patients with CKD stage 3 (Cr_{Cl} ⩾ 30 to < 60 mL/min), the recommended dose is 12.5 mg once daily and in patients with CKD stage ⩾ 4 the recommended dose is 6.25 mg once daily. The same dose is required in patients with end-stage renal disease requiring dialysis.

Linagliptin

Linagliptin is primarily nonrenally excreted: 80% of the drug is eliminated *via* the bile and gut and only 5% is eliminated *via* the kidney[31]. The drug is not practically metabolized and is excreted unchanged. There is no need of dose adjustment in any stage of CKD (5 mg × 1 for all diabetic subjects).

GLP-1 RA (RECEPTORS AGONISTS)

These drugs are injectable and are potent without risk of hypoglycemia. They have to be used with caution in patients with CKD because their gastrointestinal side effects can induce deterioration of renal disease. (Dehydration due to vomiting or diarrhea).

Exenatide

Exenatide is excreted only by the kidneys and undergoes fragmentation in the renal tubule. It does not metabolized by DPP-4 nor the neutral endopeptidase (NEP). There is no hepatic metabolism of exenatide[32].

In CKD stage 3 dose reduction is needed (5 μg × 2 and close monitoring). In CKD stage 4 and 5 (clearance < 30 mL/min) is not allowed.

Liraglutide

Liraglutide is cleaved *in vivo* by the enzyme DPP-4 that elicits two amino acids at the N terminus of the peptide. NEP also metabolizes liraglutide into several metabolites[33].

Of the administered drug (radioactive labeled) only 26.3% appears in the urine and feces, while breathing excretes 15%. Twenty point one percent of radioactivity is excreted in the urine mainly as water and only 6.3% in substances other than water.

Liraglutide is degraded entirely in the body and is not excreted in urine and feces. These characteristics indicate that we can use in all stages of CKD. Nevertheless we have not yet clinical studies in patients with eGFR < 60 mL/min[34] (there is ongoing studies with preliminary, not yet published, positive results of safety and effectiveness in patients with CKD stage ⩾ 3).

INSULIN

The kidneys carry out one third of exogenous insulin degradation. It is filtered at the glomerulus and is absorbed by the proximal tubule. Sixty percent of the renal clearance is due to glomerular filtration and 40% in the secretion by uptake from peritubular vessels. Reduction in renal filtration is partially counterbalanced by secretion[35]. The dose of exogenous insulin is reduced 25% when eGFR is 10-50 mL/min and 50% when eGFR is < 10 mL/min[36].

CONCLUSION

The landscape is not clear enough in diabetes treatment in CKD. The risk of hypoglycaemia, which is higher in

subjects with both diabetes and CKD, leads to selection of appropriate drugs with low risk of hypoglycaemia such as metformin (reduced dose) and DPP-4 inhibitors. When insulin treatment is appropriate, dose adjustment is usually required especially in CKD stages 4 and 5. Finally, many people with diabetes have a less strict target of glycaemia.

ACKNOWLEDGMENTS

Based on all these data I propose the algorithms as shown in Figure 1.

Abstract

The literature has shown the efficiency of exercise in the control of type 2 diabetes (T2D), being suggested as one of the best kinds of non-pharmacological treatments for its population. Thus, the scientific production related to this phenomenon has growing exponentially. However, despite its advances, still there is a lack of studies that have carried out a review on the acute effects of physical exercise on metabolic and hemodynamic markers and possible control mechanisms of these indicators in individuals with T2D, not to mention that in a related way, these themes have been very little studied today. Therefore, the aim of this study was to organize and analyze the current scientific production about the acute effects of physical exercise on metabolic and hemodynamic markers and possible control mechanisms of these indicators in T2D individuals. For such, a research with the following keywords was performed: -exercise; diabetes and post-exercise hypotension; diabetes and excess post-exercise oxygen consumption; diabetes and acute effects in PUBMED, SCIELO and HIGHWIRE databases. From the analyzed studies, it is possible to conclude that, a single exercise session can promote an increase in the bioavailability of nitric oxide and elicit decreases in postexercise blood pressure. Furthermore, the metabolic stress from physical exercise can increase the oxidation of carbohydrate during the exercise and keep it, in high levels, the post exercise consumption of O_2, this phenomenon increases the rate of fat oxidation during recovery periods after exercise, improves glucose tolerance and insulin sensitivity and reduces glycemia between 2-72 h, which seems to be dependent on the exercise intensity and duration of the effort.

Key words: Metabolic diseases; Hypertension; Nitric oxide; Blood glucose; Oxygen consumption

Core tip: Physical exercise is one of the best kinds of non-pharmacological treatments to prevent and control type 2 diabetes (T2D), being recommended by important medical associations, such as American College of Sports Medicine and the American Diabetes Association. In the literature, studies about the effects of a single exercise session on the population, its changes in blood pressure, glycemia, carbohydrate oxidation, fat oxidation, increase in nitric oxide and others are increasing exponentially. In this review, we report the most recent and important findings in the literature about the ef-

fects of acute exercise in T2D.

Acute effects of physical exercise in type 2 diabetes: A review. *World J Diabetes* 2014; 5(5): 659-665 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i5/659.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i5.659

INTRODUCTION

Physical exercise, along with a proper diet are central factors in the prevention and control of diabetes mellitus (DM), since their effects include appropriate values of blood pressure, glycemia and lipidemia[1]. Several studies have shown the efficiency of exercise programs in the control of DM, being suggested as one of the best types of non-pharmacological treatments to the population in question[2-5]. Aerobic, resistance or combined exercise programs can help in the control of glycemia of diabetes mellitus type 2 (T2D), mainly by the increase of the need of glucose consumption by skeletal muscle in activity and the hypoglycaemic effect after exercise has been performed[1,6-9].

Currently, the guidelines to physical exercise prescription by the American College of Sports Medicine and American Diabetes Association to T2D provide general information, such as exercise daily, accumulate 150 min of exercise in a moderate intensity or 75 min of high intensity exercise per week; resistance exercises should be included at least 2-3 times per week[1]. On the other hand, despite the advances made in discovering the effects of exercise in the treatment and control of T2D and associated diseases, still there is a lack of studies that have carried out a review on the acute effects of physical exercise on metabolic and hemodynamic markers and possible control mechanisms of these indicators in individuals with type 2 diabetes, not to mention that in a related way, these themes have been very little studied today. Mainly concerning the magnitude of different intensities and durations of exercise on glucose uptake, oxidation of macronutrients and blood pressure response after performing only one session of exercise (acute exercise) and biomolecular mechanisms involved in this phenomenon[1]. Hence, the aim of this study was to synthetize the current knowledge pertaining the acute effects of physical exercises in T2D; analyze the implications of exercise and determinate trends to future researches about this topic.

The method used in the present study was a review of the literature. As inclusion criteria and search of scientific articles, the following keywords were used: diabetes and exercise; diabetes and postexercise hypotension; diabetes and excess postexercise oxygen consumption; diabetes and acute effect of physical exercise, in the databases PubMed, Scielo and HIGHWIRE. The studies that have not addressed the acute effects of physical exercise on type 2 diabetes and did not show relevant results on the subject were excluded from the analysis.

ACUTE EFFECTS OF PHYSICAL EXERCISE ON GLYCEMIA AND INSULINEMIA

The control of glycemia is dependent of the activities of the neuroendocrine system. In resting conditions, the glucose uptake by the cells is mainly insulin dependent, where the glucose transporter 4 (GLUT-4) is translocated to the cell membrane, facilitating glucose entrance in the cell cytoplasm[10]. During exercise, an increase in the uptake and utilization of glucose occurs, and it seems to be dependent on the intensity and duration of the effort. The more intense the effort is, more carbohydrate will be metabolized[11,12]. Therewith, exercise promotes a reduction in glycemia, which is initially controlled by glucagon, epinephrine and norepinephrine. Afterwards, with the assistance of growth hormone and glucagon, production and release of glucose by the liver in the bloodstream is increased, thus, regulating again the glycemia[13].

This acute effect of exercise is benefic in euglycemic and T2D individuals. Exercise increases the concentration of GLUT-4 in the cell membrane, which leads to the increase in glucose uptake, even with low insulin levels[14]. On the other hand, the mechanisms surrounding this phenomenon are still inconclusive. Higher expression of key-proteins related to the insulin pathway, such as insulin receptor substrate 1 and phosphatidylinositide 3-kinases, and insulin independent mechanisms, such as the increase in the activity of AMP-activated protein kinase, the activation of the calcium-calmodulim pathway, and the kallikreins-kinins components can be involved in this process[10,15-20].

Furthermore, both exercise models, aerobic and resistance, promote improvements in glucose tolerance, insulin sensitivity and reduction in glycemia between 2-72 h, which seems to be dependent on the intensity and duration of the effort[1,21,22].

Although, there is some knowledge about the benefits of acute exercise in T2D, more studies are still made necessary to elucidate some questions, such as the effects of intense exercise in general population, since the most studies and exercise prescription to this population are of moderate intensity[1].

CARBOHYDRATE AND FAT OXIDATION DURING AND POST EXERCISE IN T2D

Insulin resistance, along with elevated oxidative stress, impairs energy metabolism at rest, as well as during and after exercising in T2D. At rest, the lowest availability of glucose and muscular glycogen in T2D increases the predominance of fat oxidation when compared to euglycemic individuals[1].

Although glucose uptake by insulin dependent pathways are impaired in T2D, exercise increases carbohydrate

oxidation, and this capacity seems to be preserved in T2D, since the glucose uptake during the effort occurs mainly by insulin independent pathways[23]. Nevertheless, T2D demonstrates lower capacity to utilize carbohydrate during exercise when compared to euglycemic individuals[24].

Other peculiarities occur during exercise in T2D, such as the decrease in rate of fatty acids oxidation when compared to euglycemic[25]. However, the effects of different lactate threshold intensities, during and after aerobic exercises, have been little studied and are yet inconclusive.

Ghanassia *et al*[25] observed that the predominance of carbohydrate oxidation in T2D during exercise seems to be independent of the intensity of effort. Nevertheless, the use of carbohydrate as substrate seems to be dependent of intensity, since it is available in the muscle (glycogen) and in the blood (glucose)[1].

Lima *et al*[26] observed an increase in fat oxidation after a cycle ergometer session, when compared to resting values in T2D. Furthermore, high exercise intensities extend this increase, and fat oxidation after exercise was higher in T2D in comparison to euglycemic.

The increase in carbohydrate oxidation during exercise, as well as fat oxidation during the post exercise recovery period can contribute to augment insulin sensitivity, and collaborate to reduce body fat percentage. It is noteworthy that the accumulation of intramuscular fat has a direct relation on insulin resistance, and consequently the appearance of T2D[27,28].

POST-EXERCISE HYPOTENSION IN T2D

Individuals with T2D present other impairments, such as endothelial dysfunction[3,29], increased sympathetic tonus and other cardiovascular diseases, including hypertension[30], which lead to the increase in morbidity and mortality.

One session of aerobic or resistance exercise can promote postexercise hypotension (PEH). The exercise-induced mechanical stress on the wall of the arteries, can increase the release of vasodilating substances by the endothelium (*e.g.*, nitric oxide, bradykinin), augments baroreflex sensitivity, and decreased sympathetic nervous activity in the solitary tract nucleus caused by the release of substance P by skeletal muscles[31-34]. This adaptation can bring benefits to health, because it helps to keep low levels of blood pressure, avoiding and controlling blood pressure increase at rest. However, the magnitude of this effect seems to be diminished in T2D individuals, since this population presents endothelial dysfunction, which collaborates to a decrease in the capacity of nitric oxide (NO) release when compared with euglycemic individuals[35-37]. Increased sympathetic tonus and other cardiovascular diseases are also observed in T2D[30].

Studies have demonstrated that the occurrence of PEH in T2D can be intense depending on the effort. Lima *et al*[4] demonstrated that T2D individuals seem to be more responsive to high intensity exercise sessions, since exercise above lactate threshold (LT) (110% of the LT) resulted in a significant decrease in systolic blood pressure (SBP) values up to 90 min after the session, whereas exercise performed below lactate threshold (90% of the LT) only reduced SBP during 45 min post exercise.

Simões *et al*[38] comparing two resistance training exercise intensities (23% and 43% of 1RM), observed that only the higher session (43%) promoted PEH. Similar results were found by Motta *et al*[29], when studying the effects of a 20 min high intensity cycle ergometer (90% of lactate threshold) in individuals with and without T2D. Both studies only observed significant blood pressure decreases in non T2D individuals.

Although the physiological mechanism responsible by this process still remains inconclusive, it is known that high intensity exercise promotes increases the activity of the kallikrein-kinin system, and consequently, augments the synthesis and release of nitric oxide[29]. However, more studies are still made necessary to elucidate this question.

EXCESS POSTEXERCISE OXYGEN CONSUMPTION IN T2D

Exercise increases oxygen consumption after exercising and during rest, this phenomenon is known as excess postexercise oxygen consumption (EPOC), which has a fast component (2-3 min), and a slow component which can persist for more than 30 min. The duration and magnitude of EPOC depends on the intensity and duration of the effort[39-42].

The need to resynthesize creatine phosphate, restore intramuscular oxygen, body temperature and muscular glycogen, increased activity of the sodium-potassium pump, clearance of lactate, high levels of epinephrine and norepinephrine are factors that can lead to EPOC[40,41].

However, T2D individuals present metabolic impairments, such as lower capacity to utilize carbohydrate, due to lower enzymatic regulation and intracellular signalling and gene transcription[43]. Thus, these modifications can change the pattern of metabolic and respiratory alterations elicited during and after exercise[4]. Therefore, it decreased the benefits of EPOC when compared to euglycemic individuals.

Studies about EPOC in T2D are scarce. Therefore, determining which intensity and duration could be more beneficial to promote this event in T2D is important to increase post-exercise fat oxidation, once the accumulation of intramuscular fat has been associated to the development of T2D[43].

NITRIC OXIDE AND EXERCISE IN TYPE 2 DIABETES

NO is a gaseous, inorganic and colorless free radical, which has seven electrons of nitrogen and eight of oxygen, having an unpaired electron[44]. NO is synthetized from oxidation one of the two guanidine nitrogens of

L-arginine, which is converted to L-citrulline[45].

NO produced by endothelial cells has an essential function in the process of relaxing of blood vessels. In physiological conditions, vascular relaxing occurs when the membrane receptors of endothelial cells are activated by soluble stimulus, which include: acetylcholine, bradykinin, adenosine diphosphate, substance P, serotonin and others, or when there is an increase of friction exerted by circulating cells in the endothelial layer (shear stress), generating the activation of endothelial NO synthases (eNOS) present in these cells, causing an increase of synthesis and release of NO[46].

NO produced by eNOS in endothelial cells spreads out to smooth muscle cells and vascular lumen. In the smooth muscle, NO interacts with the iron from heme group of enzyme guanylate cyclase (GC), causing an alteration in the structure of this enzyme, becoming activated (GCa). GCa catalyzes the departure of two phosphate groups from the molecule guanosine triphosphate, similar to the adenosine triphosphate (ATP), forming the cyclic guanosine monophosphate (cGMP). An increase in the levels of cGMP occurs when NO activates GC inside the cells[47], resulting in: (1) maintenance of vascular tonus; (2) blood pressure regulation; (3) prevention of platelet aggregation (by increase of cGMP and decrease in Ca^{2+}); (4) inhibition in adhesion of monocytes and neutrophils in the vascular endothelium; (5) anti-proliferative effect; and (6) anti-oxidant effect decreasing the production of peroxynitrite anion (ONOO-)[36]. Recent studies have shown that having a physically active lifestyle can contribute to maintain the functional capacity of the vascular endothelium, measured by the preservation of ability to produce NO[48-50].

The acute effects of exercise in the bioavailability of NO in physical performance and health, mainly in endothelial function, have been previously studied. Studies have demonstrated that exercise promotes an increase in NO levels after a single session. This acute effect of exercise in NO can induce positive adaptations in the cardiovascular, hepatic, esqueleto muscle systems and others[35,51].

This effect can influence health parameters, such as the control of blood pressure (BP). Faria *et al*[52] induced spontaneously hypertensive rats to one session of exercise (squat), using vests as load. They observed a decrease in BP, lower vascular reactivity, and endothelium-dependent vasodilatation mediated by the NO after exercising.

Augeri *et al*[53] examined the influence of the T786C gene of eNOS in post-exercise hypotension (PEH) and NO after a low (40% VO_2max) and moderate intensity exercise (60% VO_2max) in the cycle ergometer in prehypertensive individuals. The individuals, who carried the TT genotype, demonstrated less PEH than heterozygous individuals 9 h after exercising.

On the other hand, Long *et al*[54] determined the preventive effects of exercise in the coronary blood flow and macrovascular atherosclerosis in aerobic trained Yucatan pigs, which passed by a high cholesterol and fat concentrated diet. The short aerobic training kept the endothelium independent relaxation (adenosine) and increased the coronary endothelium-dependent relaxation through the action of bradykinin, that is a mediator of NO production, and decreased the developing of atheromatous plaques in the aerobic trained pigs.

In the venous system, Chies *et al*[55] evaluated the effects of angiotensin Ⅱ in the portal vein and vena cava of trained rats. The exposition of trained animals to consecutive sessions of acute aerobic exercise in a treadmill improved the portal vein response in the presence of angiotensin Ⅱ. This upgrading seems to be specific in portal vein, once the researches didn't observe this phenomenon in vena cava. The authors concluded that these adaptations are influenced by NO, endothelin and prostanoids.

Regarding vascular damage, Cubbon *et al*[56] studied the association of NO induced by exercise in the proliferation and mobilization of circulating progenitor cells (CPC), which are potential mediators of cell repair. The mobilization of CPC is critically dependent of NO, and south Asians are associated with low CPC levels. The mobilization of CPC was measured during a moderate-intensity exercise session. Mediators of vasodilatation and CPC were lower in the Asian group than in Europeans. During the exercise, the CPC also was lower in Asians. A decrease in the release of NO can contribute to inappropriate balance between vascular damage and muscular repair in the population.

The acute effects of exercise in NO have also been studied in other tissues. In the skeletal muscle, Lee-Young *et al*[57] observed that in mice without eNOS, ATP is reduced (40%), in sedentary conditions exercise tolerance is markedly impaired during a 30 min session. The researchers observed that a partial reduction of eNOS expression is enough to induce physiological changes in ATP and NO production, and consequently, reducing the tolerance to the effort.

Besides exercise, diet also seems to influence the availability of NO. Bailey *et al*[58] administrated oral L-arginine in nine healthy individuals and performed "step" exercise in two intensities (moderate and high) one hour after ingestion. Plasma nitrite was significantly higher in the group that consumed L-arginine, resulting in a decrease in SBP. Submaximal VO_2max was 7% lower in the moderate intensity exercise, while in the high intensity exercise the slow component was reduced and the time to exhaustion delayed with L-arginine supplementation. As a conclusion, the authors stated that diet with L-arginine showed similar results with nitrite, increasing the bioavailability of NO, and reducing the cost of O_2 in the moderate exercise and time to exhaustion in the maximal exercise.

One exercise session seems to increase the bioavailability of NO, collaborating with the regulation of vascular tonus, balance between damage and muscle repair and preventing diseases such as atherosclerosis and hypertension[59]. Studies related to the bioavailability of NO in different exercise intensities are inexistent. The production

Table 1 Summary of human studies about acute effects of physical exercise in type 2 diabetes

Ref.	Sample	Exercise intervention	Results
Lima *et al*[4]	T2D = 11	20 min of cycle ergometer at 90% and 110% LT, and control session	Higher intensity exercise (110% LT) was more effective than lower intensity (90% LT)
Sriwijitkamol *et al*[5]	Obese T2D = 12 Obese CG = 8 Lean CG = 8	40 min of cycle ergometer at 50% and 70% VO_{2max}	Obese and T2D had attenuated exercise-stimulated AMPK activity and AS160 phosphorylation. T2D had reduced basal *PGC-1* gene expression but normal exercise-induced increases in PGC-1 expression
Borghouts *et al*[12]	T2D = 8 CG = 8	1 h of cycle ergometer at 40% VO_{2peak} and control session	Muscle glycogen oxidation was lower in T2D than in CG. Plasma glucose contributed more to energy expenditure in T2D than CG
Braun *et al*[24]	Insulin-resistant = 6 Insulin-sensitive = 6	50 min of treadmill walking at 45% VO_{2max}	Carbohydrate oxidation and estimated muscle glycogen use were significantly lower in the insulin-resistance group
Ghanassia *et al*[25]	T2D = 30 CG = 38	Increasing exercise intensity in cycle ergometer	Lipid oxidation was lower in T2D. Maximal lipid oxidation point and the crossover point were lower in T2D
Lima *et al*[26]	T2D = 9 CG = 11	20 min of cycle ergometer at 90% LT, increasing exercise intensity and control session	T2D have a better fat oxidation after high-intensity exercise than moderate exercise. T2D had less fat oxidation than CG after moderate exercise
Motta *et al*[29]	T2D = 10 CG = 10	20 min of cycle ergometer at 90% LT and control session	CG presented PEH, but not in the T2D. Plasma kallikrein activity increased postexercise in the CG, but not in the T2D
Simões *et al*[38]	T2D = 10 CG = 10	Resistance exercise circuit at 43% and 23% 1RM (approximately 25 min), and control session	43% 1RM promoted PEH, whereas the 23% did not
Asano *et al*[60]	T2D = 11	20 min of cycle ergometer at 80% and 120% LT, and control session	Exercise above LT (120% LT) increase nitric oxide and decrease SBP post-exercise, but about 80% LT not

T2D: Type 2 diabetics; LT: Lactate threshold; CG: Control group; VO_{2max}: Maximal oxygen uptake; VO_{2peak}: Peak oxygen uptake; PEH: Post-exercise hypotension; 1RM: 1-repetition maximum; AMPK: AMP-activated protein kinase; PGC-1: Peroxisome proliferator-activated receptor gamma coactivator 1-alpha.

of knowledge about this important topic is essential to define better exercise strategies to increase the bioavailability of NO in individuals with T2D after one exercise session.

A summary of acute effects of physical exercise in T2D, along with the reference, number of volunteers and the kind of intervention, can be observed in Table 1.

CONCLUSION

A single session of exercise can promote beneficial effects regarding blood pressure control, glycemia, carbohydrate oxidation during exercise and fat oxidation after exercise. Evidence has shown that exercise, especially at intense domains, can increase the bioavailability of nitric oxide, promoting a decrease in blood pressure after exercising. Furthermore, metabolic stress from exercising is able to increase the oxidation of carbohydrates during exercise, keeping an elevated O_2 consumption after exercising. This, in consequence, increases fat oxidation during at rest and improves glucose tolerance, insulin sensibility and can reduce glucose levels between 2 to 72 h depending of intensity and duration of the effort.

These acute effects of physical exercise are important to T2D, because they help to improve conditions such as high blood pressure, hyperglycaemia and lipidemia.

Abstract

The interplay between glucose metabolism and that of the two other primary nutrient classes, amino acids and fatty acids is critical for regulated insulin secretion. Mitochondrial metabolism of glucose, amino acid and fatty acids generates metabolic coupling factors (such as ATP, NADPH, glutamate, long chain acyl-CoA and diacylglycerol) which trigger insulin secretion. The observation of protein induced hypoglycaemia in patients with mutations in *GLUD1* gene, encoding the enzyme glutamate dehydrogenase (GDH) and *HADH* gene, encoding for the enzyme short-chain 3-hydroxyacyl-CoA dehydrogenase has provided new mechanistic insights into the regulation of insulin secretion by amino acid and fatty acid metabolism. Metabolic signals arising from amino acid and fatty acid metabolism converge on the enzyme GDH which integrates both signals from both pathways and controls insulin secretion. Hence GDH seems to play a pivotal role in regulating both amino acid and fatty acid metabolism.

Key words: Hyperinsulinaemic hypoglycaemia; K_{ATP} channel; Glutamate dehydrogenase; Hyperinsulinism/Hyperammonaemia syndrome; Short-chain-3-hydroxyacyl-CoA dehydrogenase; Glutamine

Core tip: The interplay between glucose, amino acid and fatty acid metabolism is critical for regulated insulin secretion. Mitochondrial metabolism of glucose, amino acid and fatty acids generates metabolic coupling factors (such as ATP, NADPH, glutamate, long chain acyl-CoA and diacylglycerol) which trigger insulin secretion. The observation of protein induced hypoglycaemia in patients with mutations in *GLUD1* [encoding for the enzyme glutamate dehydrogenase (GDH)] and *HADH* genes, has provided novel mechanistic insights into the regulation of insulin secretion by amino acid and fatty acid metabolism. Metabolic signals arising from amino acid and fatty acid metabolism converge on the enzyme GDH which integrates both signals from both pathways and controls insulin secretion. Hence GDH seems to play a pivotal role in regulating both amino acid and fatty acid metabolism.

INTRODUCTION

Glucose, amino acids and fatty acids are the substrates available for metabolic homeostasis and play important roles in insulin secretion. Pancreatic β-cells synthesise and secrete insulin in response to signals generated from glucose, amino acid and fatty acid metabolism but glucose is the prime stimulus for insulin secretion. Regulated insulin release requires tight coupling in the β-cell between glucose metabolism and insulin secretory response. As β-cells are continually exposed to a complex milieu of nutrients and other circulating factors (like incretins), it is important to understand the interplay between glucose metabolism and that of the two other primary nutrient classes, the amino acids and fatty acids. Specific amino acids are now known to acutely and chronically regulate insulin secretion from pancreatic β-cells *in vivo* and *in vitro* and lipid metabolism in the β-cell is critical for the regulation of insulin secretion[1].

The metabolism of glucose, amino acids and fatty acids results in the generation of metabolic coupling factors involved in regulating insulin exocytosis. These metabolic coupling factors generated from the metabolism of glucose, amino acids and fatty acids in the β-cell include ATP, NADPH, glutamate, long chain acyl-CoA and diacylglycerol[2]. Each of these coupling factors plays a key role in regulating insulin secretion. The exocytotic process is closely controlled by signals generated from nutrient metabolism as well as by neurotransmitters and circulating hormones.

Under normal physiological conditions the metabolism of glucose, amino acids and fatty acids is intricately controlled and will result in the regulated secretion of insulin. The secretion of insulin is precisely regulated to keep fasting blood glucose concentrations between 3.5-5.9 mmol/L. In some pathological states the signals generated from glucose, amino acid and fatty acid metabolism cause insulin hyper-secretion or dysregulation of insulin secretion. In these states insulin secretion becomes inappropriate for the level of blood glucose causing hyperinsulinaemic hypoglycaemia (HH).

HH is a major cause of persistent hypoglycaemia in the childhood period[3]. In the newborn and infancy periods HH can be either congenital or secondary to certain risk factors (such as intrauterine growth retardation). Congenital forms of HH are due to defects in key genes (*ABCC8*, *KCNJ11*, *GLUD1*, *GCK*, *HADH*, *HNF4/HNF1A*, *SLC23A* and *UCP2*) involved in regulating insulin secretion[4]. Loss of function mutations in the genes *ABCC8* and *KCNJ11* (which encode for the SUR 1 and KIR6.2, components of the β-cell potassium (K_{ATP}) channel subunits respectively) lead to the most severe forms of HH, which is usually medically unresponsive[5]. Clinically HH presents with fasting hypoglycaemia but in some patients the HH is typically triggered by the ingestion of protein (amino acids). Protein induced HH is observed in patients with gain of function mutations of *GLUD1*[6], loss-of-function mutations of *ABCC8/KCJN11*[7] and loss of function mutations in the *HADH*[8].

This state of the art review article will firstly discuss the molecular mechanisms of glucose, amino acid and fatty acid regulated insulin secretion and then focus on the current understanding of the molecular mechanisms involved in protein induced HH.

GLUCOSE MEDIATED INSULIN SECRETION BY THE PANCREATIC β-CELL

Glucose mediated secretion of insulin is initiated by the uptake of glucose by the β-cells *via* the glucose transporter. Glucose is then phosphorylated to glucose-6-phosphate by islet-specific glucokinase. Further metabolism of glucose increases the cellular ATP: ADP ratio, which closes ATP-dependent K_{ATP} channels in the β-cell membrane, causing membrane depolarization and influx of calcium. Intracellular free calcium then promotes margination of secretory granules, which fuse with the cell membrane before releasing their contents into the extracellular space by exocytosis (Figure 1)[9]. The functional integrity of both SUR 1 and KIR 6.2 proteins is necessary for K_{ATP} channel function and the genes encoding for these two proteins are localized very closely to each other on the short arm of chromosome 11 (11p14-15.1).

Although K_{ATP} channels have an essential role in linking the metabolism of glucose to the secretion of insulin, there is now evidence that there may well be other mechanisms of insulin secretion, the so-called K_{ATP} channel independent pathways of insulin secretion[10]. This pathway leads to augmented insulin release in the presence of raised cytosolic calcium (Ca^{2+}) concentrations. Increases in the intracellular Ca^{2+} concentration in the pancreatic β-cell cause modest increases in insulin secretion, which can be dramatically increased by modulators of protein kinases and phosphatases. This suggests that steps distal to the elevation of cytosolic Ca^{2+} are of greater quantitative importance in controlling insulin secretion. It has also been shown that glucose can cause pronounced insulin secretion in Ca^{2+} depleted islets in the presence of activators of protein kinases A and C[11].

Given the key role of pancreatic β-cell K_{ATP} channels in regulating insulin secretion it is no surprise that genetic defects in the genes regulating the function of these channels lead to severe forms of HH. Recessive inactivating mutations in K_{ATP} channel subunits are the most common cause of HH[5,12]. So far, over 150 mutations have been identified in the *ABCC8* and 25 in *KCNJ11*[13]. These include missense, frame shift, nonsense, insertions/deletions, splice site and regulatory mutations, either present in homozygous or compound heterozygous state. In the Ashkenazi Jewish population, two common (F1388del and c.3992-9G4A) mutations account for 90% of all cases of congenital HH[4].

The molecular basis of recessive inactivating *ABCC8* and *KCNJ11* mutations involves multiple defects in K_{ATP} channel biogenesis and turnover, in channel trafficking

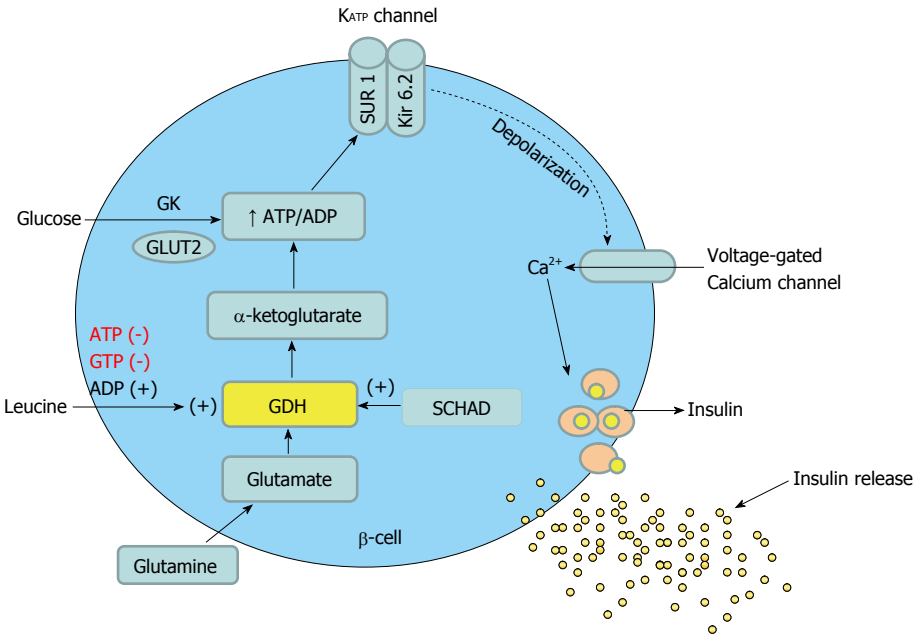

Figure 1 Glucose and protein mediated insulin secretion in the beta cell of pancreas. GDH: Glutamate dehydrogenase; SCHAD: Short-chain 3-hydroxyacyl-CoA dehydrogenase; GK: Glucokinase; SUR: Sulfonylurea receptor; Kir 6.2: Potassium channel inwardly rectifying; GLUT2: Glucose transporter 2.

from the endoplasmic reticulum and Golgi apparatus to the plasma membrane and alterations of channels in response to both nucleotide regulation and open state frequency.

AMINO ACID MEDIATED INSULIN SECRETION

The observations that plasma levels of insulin increase consistently and significantly when healthy subjects ingest protein meals[14] or when intravenous mixtures of amino acids are administered[15], provide fundamental scientific evidence of the relationship between protein metabolism, amino acids and insulin secretion.

Protein metabolism begins when dietary proteins are broken down to amino acids by intestinal enzymes[16]. Large differences in capacity of individual amino acids to stimulate insulin release are noted in both animal and human studies[15,17]. For example, when 30 g each of 10 amino acids in a mixture was administered individually, arginine proved the most effective and histidine the least in stimulating insulin release[15]. Although leucine itself can stimulate insulin secretion, the phenomenon of protein meal or amino acid stimulated insulin secretion does not solely or largely depend on the presence of leucine[14,15].

Amino acids, alone[18] or in combination[19], act synergistically with glucose to potentiate the release of insulin. Synergism was also observed between amino acid pairs, where the synergistic effect was significantly greater with arginine-leucine than with arginine-phenylalanine and their combined effects greater than when amino acids were administered alone[20]. Indeed, the oral ingestion of amino acid mixtures in combination with carbohydrates produce stronger insulinotropic effects compared with carbohydrate-only preparations[21], a phenomenon mediated by the incretin hormones gastric inhibitory polypeptide and glucagon-like peptide-1 (GLP-1)[22]. Amino acids shown to have the highest insulinotropic effect include leucine, valine, lysine, and isoleucine[23]. Metabolism of amino acids can occur either by transamination or by oxidative deamination.

Transamination is an early step in the degradation of most amino acids and involves a chemical reaction between two molecules, an amino acid (with an amine NH_2 group) and a keto acid (with a keto = O group), catalysed by a family of enzymes known as aminotransferases. Different aminotransferases are each specific for an amino acid or a group of chemically similar ones such as branch chain amino acids (BCAA). The keto acid that accepts the amino group is always alpha-ketoglutarate (α-KG), a metabolically important biological compound and key intermediate in the citric acid cycle. For example, alanine transaminase catalyses the transfer of an amino group from alanine to α-KG giving rise to pyruvate and glutamate.

On the other hand, oxidative deamination involves conversion of an amino acid into the corresponding keto acid by removing the amine group as ammonia, which goes into the urea cycle. As glutamate is the end product of many transamination reactions, oxidative deamination occurs primarily on glutamate, generating α-KG[16,24]. The main enzyme involved in oxidative deamination is glutamate dehydrogenase (GDH).

Glutamine and alanine are the most abundant amino acids in the blood and extracellular fluids. Whereas glutamine and alanine require the presence of glucose for insulin secretion, leucine is able to stimulate insulin secretion independently through the allosteric activation of GDH[25-28], generating α-KG. The further metabolism of α-KG is then involved in insulin production in two ways.

First, by entering the TCA cycle, the ATP:ADP ratio is raised causing closure of the K_{ATP} channel and depolarisation of the β-cell. The voltage dependant calcium channel opens leading to an increase in cellular calcium concentration, triggering the release of insulin from storage granules (Figure 1)[29]. Second, α-KG inhibits isocitrate dehydrogenase resulting in increased cytosolic citrate needed for the synthesis of short and long chain acyl-CoA, which are coupling factors closely involved in insulin secretion[30].

LEUCINE

Leucine is one of the most potent insulin secretagogues among the BCAA that facilitates glucose-induced insulin release from pancreatic β-cells[31]. It does so *via* several mechanisms. First, in pancreatic β-cells, leucine and its non-metabolizable analogue 2-aminobicyclo (2.2.1) heptane-2-carboxylic acid, stimulate the secretion of insulin by acting indirectly as a positive allosteric activator of GDH to enhance glutaminolysis. Activated GDH facilitates the oxidation of glutamate to α-KG, which raises the ATP:ADP ratio resulting in closure of K_{ATP} channel, cellular depolarization, influx of calcium and exocytosis of insulin from the storage granules (Figure 1)[32]. Second, the transaminated product of leucine, α-ketoisocaproate (KIC) can cause insulin secretion through direct inhibition of the K_{ATP} channel[33]. Glucose completely blocks the effects of leucine but not of KIC on stimulation of insulin secretion by β-cells[34]. Third, leucine plays an important role in the regulation of the mammalian target of Rapamycin (mTOR) pathway, which was recently recognized as a critical regulator of metabolic response to nutrients and growth factors[35]. Recent data strongly suggest that leucine down-regulates the surface expression of α2 adrenergic receptors in pancreatic islets through activation of mTOR, leading to insulin secretion[36].

GLUTAMINE

As the most abundant amino acid found in the blood, glutamine has both nutritive and non-nutritive effects[37]. Glutamine is physiologically important for maintaining cellular function in tissues of the intestine, kidney, brain and liver[38]. It is an important precursor substrate for the synthesis of peptides, proteins and nucleotides[39], in particular ATP which is central in the β-cell signalling pathway. In SUR 1 knockout (KO) β-cells models, isolated pancreatic islets respond briskly to a physiological mixture of 20 amino acids even though these islets cannot be stimulated by glucose or by leucine. Glutamine played an important role in mediating amino acid stimulation of insulin release as 60% of the insulin response was attributable to glutamine even though it comprised 16% of the amino acid load[7].

Although glutamine itself functions as a key precursor for nucleic acids and nucleotides, in many physiological circumstances it acts to provide glutamate, which promotes a wider array of metabolic functions compared to glutamine. By oxidative deamination of glutamate, GDH liberates free ammonia and the α-KG is then oxidized in the tricarboxylic acid cycle (TCA) cycle, raising ATP levels that close K_{ATP} channels and depolarize the cell membrane to release insulin. Ammonia is added to glutamate by glutamine synthetase to form glutamine, the major inert-organ carrier for ammonia.

Glutamine can be cleaved by glutaminase to yield glutamate and NH3. The mitochondrial carbamoyl phosphate synthetase (CPS 1) then can catalyze the conversion of ammonia to carbamoyl phosphate. The CPS 1 enzyme is allosterically activated by N-Acetyl glutamate (NAG) produced from glutamate by NAG synthase and may thus be indirectly regulated by glutamate concentration. Carbamoyl phosphate thus formed combines with ornithine in the urea cycle. Thus glutamate also aids in ammonia detoxification and promotion of urea synthesis in the liver (Figure 2)[40,41]. However, the exact mechanism of glutamine linked hyperinsulinemia remains less well understood. Glutamine can also potentiate insulin secretion by stimulating enteroendocrine L-cells to synthesise and secrete the incretin GLP-1. This effect is attributable to a triggering pathway that elevates intracellular Ca^{2+} and an amplifying pathway mediated by elevated cAMP[42].

ALANINE

The mechanism of action of alanine as an insulin secretagogue is still unclear. Upon entry into the β-cell cytosol, alanine is deaminated and takes part in the TCA cycle through pyruvate and acetyl-CoA. This results in increase of the cellular content of ATP, closure of the K_{ATP} channel, depolarization of the plasma membrane, activation of voltage-gated calcium channel, increase in calcium influx and insulin exocytosis (Figure 3)[43]. Insulinotropic property of alanine has been reported by Dunne *et al*[44] and McClenaghan *et al*[45] to be the result of co-transport with Na^+, leading to β-cell membrane depolarization and increase in cellular calcium. Current evidence suggests that the mode of action of alanine as an insulin secretagogue involves a combination of increased ATP generation, co-transport with Na^+ and signal transduction[26,46].

ARGININE

The mechanism of insulin release by arginine involves the mCAT2A amino acid transporter which electrogenically transports arginine into the β-cell, leading to increased intracellular calcium[47]. Accumulation of intracellular arginine leads to membrane depolarization, a further rise in intracellular calcium through opening of voltage-gated calcium channels, and insulin secretion[48]. Arginine can also influence insulin secretion by its conversion to glutamate, which allows the generation of metabolic coupling factors[49], however the detailed metabolism of arginine in the β-cell remains to be investigated.

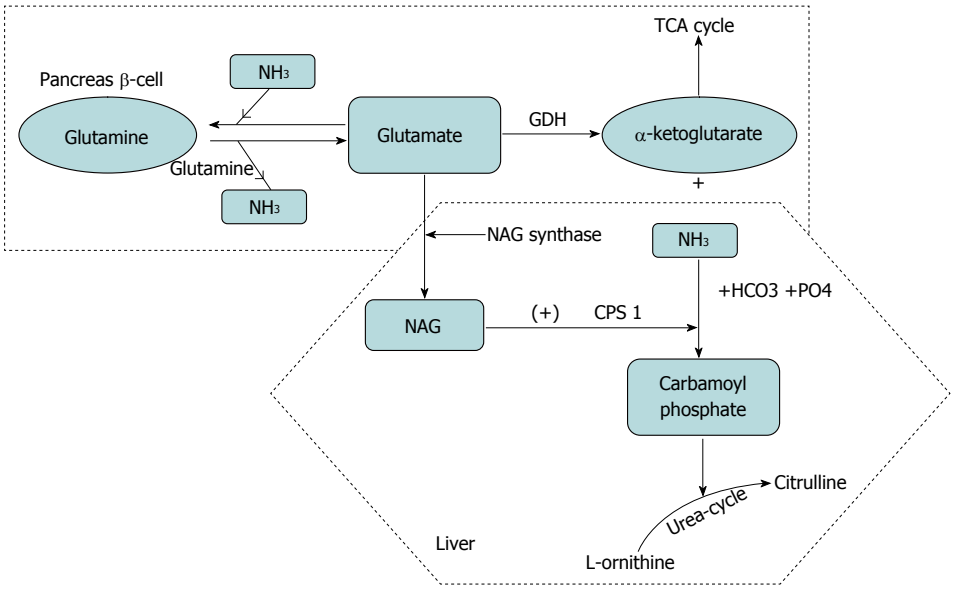

Figure 2 Glutamate metabolism. Oxidation of glutamate by glutamate dehydrogenase liberates free ammonia (NH_3) and alpha ketoglutarate, which enters tricarboxylic acid cycle cycle and generates ATP. In the liver glutamate also generates N-acetylglutamate (NAG), which in turn allosterically activates carbomyl phosphate synthetase (CPS) to regulate ammonia detoxification into urea. Glutamine provides a substrate for ammonia buffering, by adding ammonia to glutamate to form glutamine. TCA: Tricarboxylic acid cycle; GDH: Glutamate dehydrogenase.

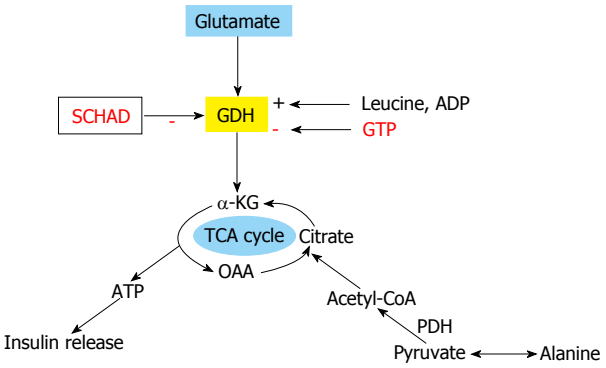

Figure 3 Glutamate and alanine as insulin secretagogues. Protein induced hyperinsulinaemic hypoglycaemia due to loss of function mutation in HADH gene (SCHAD). Alanine is deaminated to pyruvate and pyruvate dehydrogenase (PDH) converts it to acetyl CoA, which can enter TCA cycle to generate ATP for closing KATP channel. TCA: Tricarboxylic acid cycle; α-KG: Alpha ketoglutarate; GDH: Glutamate dehydrogenase; OAA: Oxaloacetic acid.

FATTY ACID β-OXIDATION PATHWAY

During the fasting state fatty acids (FA) are the most important substrates for ketogenesis to provide the brain with an "alternative fuel" source. Triglycerides are broken down to FA and glycerol in the process of lipolysis. β-oxidation of FA occurs in the peroxisomes and mitochondria. Short and medium chain FA can diffuse directly into the mitochondria and are then activated by acyl-CoA synthetase to acyl-CoA in the mitochondrial matrix, whereas long and very long chains FA are activated by acyl-CoA synthetase on the mitochondrial outer membrane. The "carnitine shuttle" allows acyl-CoA to penetrate the outer and inner mitochondrial membranes, catalysed by carnitine palmitoyltransferase- Ⅰ and Ⅱ (CPT- Ⅰ and Ⅱ) respectively, facilitated by the inner membrane exchange transporter, carnitine-acylcarnitine translocase[50].

In the mitochondrial matrix, acetyl-coA is generated by β-oxidation of acyl-CoA *via* a 4-step process involving dehydrogenation, hydration, oxidation and thiolysis (Figure 4)[50]. Acetyl-CoA finally enters the Krebs cycle. The short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD), an intramitochondrial homodimer enzyme is essential for catalysing the penultimate reaction of 3-hydroxyacyl CoA to 3-ketoacyl-CoA. Possible molecular mechanisms involved in the pathogenesis of HH due to deficiency of SCHAD have been reported recently[8,51].

PROTEIN INDUCED INSULIN SECRETION-HISTORICAL PERSPECTIVE

The history of protein induced hypoglycaemia dates back to 1956 when Cochrane described three children with severe hypoglycaemia while on low carbohydrate and high protein diet. Even though amino acid-stimulated insulin secretion by pancreatic β-cells was known for long[52], the molecular mechanisms involved in the dysregulated islet cell function leading to HH due to genetic mutations remain poorly understood. In 1970 researchers reported that amino acids could induce insulin secretion only in the presence of glucose except in case of leucine where the insulin-stimulatory effect is abolished in presence of glucose[53]. Animal studies have suggested that amino acid oxidation and signalling effects are two vital steps in which the amino acid amplifies insulin release from the stored vesicles following β-cell depolarisation and influx of calcium. By early 80's leucine's property to induce insulin secretion by allosterically stimulating GDH was identified[29].

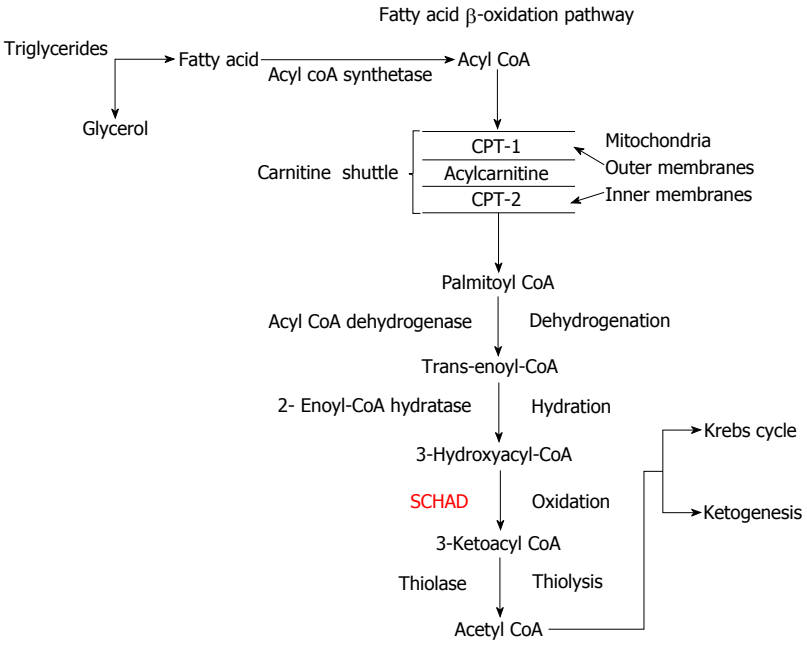

Figure 4 β-oxidation of fatty acids. Acyl-CoA is converted to acetyl-CoA through dehydrogenation, hydration, oxidation and thiolysis. Acetyl-CoA can enter the Krebs cycle or can lead to ketogenesis. CPT-1: Carnitine palmitoyltransferase-1; SCHAD: 3-hydroxyacyl CoA dehydrogenase.

MOLECULAR MECHANISMS OF AMINO ACID INDUCED HYPERINSULINAEMIC HYPOGLYCAEMIA

Amino acids are known to enhance insulin secretion from primary islet β-cell lines under appropriate conditions. Leucine can stimulate insulin release on its own by allosterically activating GDH. In the β-cell mitochondria, GDH can stimulate insulin secretion by oxidative deamination of glutamate by raising α-KG, NADH/NAD and NADPH/NADP ratios. Protein sensitive hyperinsulinaemic hypoglycaemia occurs in three forms; gain-of-function mutations of *GLUD1*[6], loss of function mutations of *ABCC8/KCNJ11*[7] and loss of function mutations in *HADH*[8].

HYPERINSULINISM/ HYPERAMMONAEMIA SYNDROME

Hyperinsulinism/hyperammonaemia syndrome (HI/HA) syndrome is the second most common cause of congenital hyperinsulinism-(CHI), characterized by both fasting and protein sensitive hypoglycaemia together with persistently elevated plasma ammonia levels[6]. HI/HA is likely the disorder described by Cochrane *et al*[52] in 1955, with leucine sensitive hypoglycaemia in a child and her father. Zammarchi *et al*[54] first reported a case of hyperammonaemia with leucine sensitive hypoglycaemia. Activating mutations in the *GLUD1* gene were reported to be the cause of HI/HA syndrome by Stanley *et al*[6,32] in 1998. Children usually present with recurrent symptomatic hypoglycaemic episodes (leucine sensitive) and persistent hyperammonaemia.

Molecular basis of HI/HA

The enzyme, GDH has a complex allosteric regulatory mechanism and is highly expressed in the pancreas, liver, kidney and brain. GDH catalyses the reversible oxidative deamination of glutamate to α-KG and ammonia, using NAD or NADP as co-factors. GDH is allosterically inhibited by GTP and activated by ADP and leucine[55].

In patients with HI/HA syndrome there is impairment of allosteric inhibition of GDH by GTP leading to gain-of GDH function. This causes increased leucine induced glutamate oxidation to α-KG, which explains the leucine sensitivity following a protein meal and postprandial hypoglycaemia. These patients on fasting develop hypoglycaemia following release of alanine and glutamine from skeletal muscle, which can stimulate insulin release mediated through GDH[56]. The mechanism of hyperammonaemia in HI/HA syndrome is still unclear. In liver, increased GDH activity may lead to hyperammonaemia through 2 possible mechanisms: elevated activity of GDH causing increased levels of ammonia from glutamate and excessive depletion of glutamate pool, reducing the availability of N-acetyl glutamate (NAG) *via* NAG synthase reaction. NAG is an allosteric activator of CPS 1 and deficiency of this can impair urea synthesis[32,57]. An alternative hypothesis for hyperammonaemia in HI/HA syndrome is that the excessive ammonia is due to abnormal muscle catabolism[58]. More recently the source of the hyperammonaemia in the HI/HA syndrome is thought to be the kidney[59].

Sirtuins and insulin secretion

Sirtuins are a family of NAD^+ dependant enzymes having a critical role in metabolic adaptation to stress. Sirtuin4 (SIRT4), an intramitochondrial enzyme highly expressed

in pancreatic β-cells, also regulates GDH. SIRT4 repress the activity of GDH by ADP-ribosylation in pancreatic β-cell mitochondria, down regulating insulin secretion mediated through amino acids. In normal glucose states, SIRT4 blunts amino acid-induced insulin secretion by repressing the activity of GDH[60,61]. In contrary GDH is released from the SIRT4-mediated inhibition *via* an undefined mechanism during fasting, thereby enhancing amino acid-induced insulin secretion[61]. In SIRT4 knockout mice, GDH activity is enhanced in β-cells, leading to the enhancement of glucose and amino acid-stimulated insulin secretion[61]. So loss of function mutation of *SIRT4* can present with a phenotype similar to gain of function mutation of GLUD1. However no humans have yet been described with protein induced hyperinsulinism due to *SIRT4* mutations[62].

Clinical presentation of HI/HA

The infants with HI/HA syndrome are usually born at term and not macrosomic. The major clinical feature is recurrent episodes of symptomatic HH after first few months of life. These may occur with fasting or can be provoked by protein feeding. Hypoglycaemia in HI/HA syndrome is not as severe as seen in HH due to KATP channel mutations. Hyperammonaemia, a characteristic biochemical marker of HI/HA syndrome, is typically mild to moderate (up to 3-5 times the upper limit of normal) and is not associated with lethargy, irritability, or coma. The plasma amino acid profile remains normal in HI/HA syndrome in contrast to abnormal profile observed in the other causes of hyperammonaemia[62,63].

Protein diet or blood glucose levels do not affect the plasma ammonia levels in patients with HI/HA syndrome[54,64]. Kapoor *et al*[62] reported some patients who have mutations in GLUD1 with HH but with normal serum ammonia levels and the authors proposed that this could be due to mosaicism for the mutation in the liver, where the mutation is absent or seen in < 50% in hepatocytes. Hyperammonaemia is resistant to detoxification compounds (sodium benzoate and N-carbamylglutamate) or protein-restricted diet[65].

Kapoor *et al*[62] have published the clinical characteristics of patients with HI/HA due to GLUD mutations. Of the twenty patients most of them were appropriate for the gestational age and presented at a mean age of 23.4 wk. Nineteen of them had hyperammonaemia. Thirteen of the 17-screened probands had 7 different heterozygous mutations and three novel mutations were identified (N410D, D451V, P436L). More than 90% cases responded to diazoxide. Seizure was the most common (94%) symptom, 43% of them developed generalized epilepsy with a higher preponderance in cases with mutations in exons 6 and 7 of *GLUD1* gene[62,66].

Earlier in 2004, Stanley *et al*[32,57] has reported that over activity of GDH in the brain decreases the levels of glutamate and glutamine, protecting the central nervous system from the neurotoxicity of its accumulation.

GDH transgenic mice harbouring the human *GDH-HI H454Y* mutation develop a hypoglycaemia phenotype[67] and insulin secretion studies in these mice are associated with increased oxidative deamination of glutamate *via* GDH, this confirming the key role of GDH in amino acid stimulated insulin secretion.

Using a β-cell-specific GDH KO mouse model [βGlud1 (-/-)] islets isolated from these mice showed diminished of insulin release when stimulated by glutamine combined with 2-aminobicyclo (2.2.1) heptane-2-carboxylic acid or l-leucine[68]. Further studies in these mice showed that permissive levels of glutamate were required for the full development of glucose-stimulated insulin secretion and that GDH plays an indispensable role in this process.

Management of HI/HA

Treatment of HI/HA is aimed at correction of fasting and protein induced hypoglycaemia. Diazoxide remains the main stay of treatment and affected patients are well controlled with a dose of 5-15 mg/kg per day[69]. Being a KATP channel agonist, diazoxide prevents β-cell membrane depolarization and inhibits insulin secretion by keeping KATP channels open. Diazoxide is usually combined with hydrochlorothiazide in neonates to counteract its fluid retention side effects. Hypertrichosis seen in infants on diazoxide usually resolves on discontinuation[70]. Recent reports of large symptomatic pericardial effusion in infants on diazoxide, warrants meticulous cardiovascular monitoring while on treatment[71].

Green tea flavonoids and HI/HA

Naturally occurring compounds from green tea, discovered by the Chinese Emperor Shen-Nung in 2737 B.C. has been used as a remedy to treat a number of ailments, including diabetes mellitus[72]. Green tea is a significant source of a type of flavonoid called catechin, which includes epigallocatechin gallate (EGCG), epigallocatechin, epicatechin gallate (ECG) and epicatechin, of which EGCG and ECG have a strong inhibitory effect on GDH function[72,73].

Animal studies have shown that ECG binds to the same site as the allosteric regulator ADP and hijacks the ADP activation site. In pancreatic islet cells of transgenic mice expressing a human HI/HA form of GDH, a hyper-response to glutamine caused by dysregulated GDH is blocked by the addition of EGCG[73]. Above all EGCG has the property to inhibit GTP-insensitive GDH mutations, opening the window of therapeutic potential to treat GDH hyperinsulinism. EGCG also has been shown to block glutamine stimulated calcium influx and insulin secretion in GDH transgenic mice islets[74].

Several novel GDH inhibitors are identified and are under trial[75]. Current evidence support the pathological basis of hyperammonaemia to be due to gain in GDH activity and excessive oxidation of glutamate, reducing the level needed for the synthesis of NAG and thereby slowing the clearance of ammonia (Figure 2). In this context N-carbamylglutamate (Carglumic acid), a carbamoyl

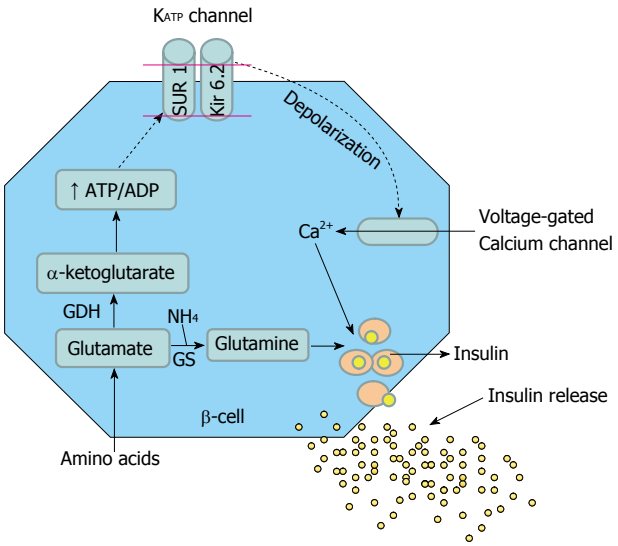

Figure 5 Protein Induced Hypoglycaemia due to defects in KATP channel genes. GDH: Glutamate dehydrogenase; GK: Glucokinase.

phosphate synthetase activator has a potential role in the treatment of hyperammonaemia in HI/HA syndrome[69,76,77]. De novo mutations in GLUD1 have been reported in 70% of GDH-HI cases with the remainder inherited in an autosomal dominant pattern[69].

PROTEIN INDUCED HYPOGLYCAEMIA DUE TO DEFECTS IN KATP CHANNEL GENES

Mutations in the *ABCC8/KCNJ11* genes are the most common cause of CHI[5]. The observation that patients with KATP channel null mutations can develop HH following high protein meal in the absence of leucine sensitivity[78], demonstrates that amino acids can induce HH *via* GDH and KATP channel independent pathways. Patient with GLUD1 mutations show leucine sensitive hypoglycaemia whereas those with *ABCC8/KCNJ11* mutations are not leucine sensitive. Thus, protein-induced HH is not necessarily synonymous with leucine-sensitive HH. The GDH and KATP channel independent mechanism of protein induced HH can be explained through the direct induction of insulin release by glutamine, formed by the ATP-dependent condensation of glutamate with ammonia, catalysed by glutamine synthetase (Figure 5).

Role of glutamine in insulin secretion in patients with KATP channel defects

Glutamine plays a pivotal role in glucose and amino acid stimulated insulin secretion as a signalling molecule, which is followed by β-cell depolarization and influx of calcium and insulin release. Prerequisites for glutamine to function in β-cell include elevated ATP levels and increased cytosolic calcium[7]. Role of glutamine in stimulation of insulin release has been shown in patients with mutations of SUR 1[78]. Animal studies have shown that β-cells of SUR $1^{-/-}$ mice are markedly sensitive to glutamine stimulation[7,67]. Li *et al*[7,67] has shown that β-cells lacking SUR 1 protein were hyper-responsive to glutamine and amino acid mixture but were refractory to glucose stimulation. This amino acid response was reduced by 60% when glutamine was omitted from the amino acid mixture[7]. Two possible mechanisms are considered but still remain unsettled: Metabolism of amino acids is enhanced while glucose is impaired in SUR 1 lacking β-cell which could be the result of persistent elevation of cytosolic calcium and secondly glutamine may be triggering insulin release by a hypothetical novel mechanisms like activation of protein kinase pathways[11,78,79].

PROTEIN INDUCED HYPERINSULINAEMIC HYPOGLYCAEMIA DUE TO LOSS OF FUNCTION MUTATION IN HADH GENE

Mutations causing genetic defects have been described in many of the enzymes involved in mitochondrial fatty acid oxidation. Recently, mutations in the penultimate enzyme in the fatty acid oxidation chain have been described that result in quite different symptoms from those normally seen. Patients with the mutations in *HADH* present with protein (leucine)-induced HH, suggesting a link between fatty acid oxidation, amino acid metabolism and insulin secretion[80].

Short-chain-3-hydroxyacyl-CoA dehydrogenase catalyses the penultimate reaction of the β-oxidation cycle for medium and short chain 3-hydroxy fatty-acyl-CoA's. SCHAD deficiency impairs short chain fatty acid oxidation. First insights into the molecular mechanism involved in SCHAD deficiency came with the observation of Clayton *et al*[8] (2001) that fatty acid beta oxidation defect is associated with HH, supporting the concept of lipid signalling pathway in the control of insulin secretion[81].

Clinical aspects of patients with HADH mutations

Affected children with SCHAD deficiency on fasting as well as following a protein meal, either present with mild late onset hypoglycaemia or severe neonatal hypoglycaemia with raised levels of fatty acid metabolites including plasma hydroxybutyrylcarnitine and urinary 3-hydroxyglutaric acid[82,83]. Most often they present with hypoglycaemic seizures. Kapoor *et al*[84] in 2009 reported for the first time that human mutations of *HADH* gene cause severe dietary protein sensitivity leading to HH and they may have normal acylcarnitine and urinary organic acid profiles. These cases had novel *HADH* gene mutations. The enzymes GDH and SCHAD have a direct protein-protein interaction, which is lost in patients with *HADH* mutations causing leucine induced HH. Leucine sensitivity is evident in patients with *HADH* gene mutations (Figure 3). There is no associated loss of inhibitory effect of GTP on GDH, as seen with *GLUD1* mutations[85].

The interaction between SCHAD and GLUD1

SCHAD has a vital role in insulin secretion, suggested by the high degree of expression of *HADH* gene in β-cells

of pancreas[86]. Hardy *et al*[87], using RNA interference, identified *HADH* gene as one of the 4 essential genes required for normal insulin secretion. FOXA2, a transcription factor encoded by the gene *FOXA2*, is essential for β-cell differentiation and its function has been shown to regulate *HADH* expression[88]. Additionally, severe hyperinsulinism after leucine tolerance testing was reported in all patients having *HADH* gene mutations[85]. Further reports on the loss of protein-protein interaction in human cases between SCHAD and GDH were published[51,83,89]. Heslegrave *et al*[85] made a similar observation of the loss of interaction between SCHAD and GDH in lymphoblasts.

Sund *et al*[90] showed severe HH in FOXA2 β-cell KO mice. Islets from these mice were shown to have reduced expression of both SCHAD and Kir6.2 and had severe HH. Li *et al*[51] showed that HADH KO mice developed a hyperinsulinaemic response following leucine loading and an exacerbation of the same on addition of glutamine and alanine. When glutamine and leucine were removed from the amino acid mixture, KO mice islets failed to induce HH, suggesting the role of GDH activation for abnormal insulin secretion.

Recent studies on HADH KO mice showed an increased sensitivity to amino acid stimulated insulin secretion indicating activation of the glutaminolysis pathway *via* GDH to increase ATP production and thereby insulin. Binding of SCHAD to GDH was also shown in immunoprecipitation experiments. These research works indicate that hyperinsulinism in SCHAD-deficient states is caused by loss of "moonlighting function" (a protein having additional functions in other pathways) of SCHAD protein, which otherwise provides a direct inhibitory regulation of GDH in β-cells[51,91]. So in pancreatic β-cells, mutations resulting in the absence of SCHAD protein leads to abnormal activation of GDH, causing hyperinsulinism.

The activation of GDH in *HADH* gene mutant patients or mouse KO models is limited to pancreatic β-cells and hence deficiency of SCHAD enzyme does not lead to hyperammonemia unlike in HI/HA syndrome[51,92]. Further evidence for protein-protein interaction between enzymes came from Zhang *et al*[93]. They showed the co-precipitation of GDH with SCHAD when anti-SCHAD antibody was used as bait in wild type mouse liver mitochondria, confirming the previous observation that GDH activation in SCHAD deficiency is due to loss of protein-protein interaction.

Diazoxide remains the treatment of choice in HH due to *HADH* gene mutations. This also confirms the intactness of K_{ATP} channel in patients with SCHAD deficiency[8,82,84,92].

CONCLUSION

The interplay between glucose metabolism and that of the two other primary nutrient classes, amino acids and fatty acids is critical for regulated insulin secretion. Protein induced HH is observed in patients with mutations in *GLUD1*, *HADH* and *ABCC8/KCNJ11*. GDH and SCHAD play important roles in integrating amino acid and fatty acid signals for insulin secretion.

Abstract

Atherosclerotic involvements are an essential causal element of prospect in diabetes mellitus (DM), with carotid atherosclerosis (CA) being a common risk-factor for prospective crisis of coronary artery diseases (CAD) and/or cerebral infarction (CI) in DM subjects. From another point of view, several reports have supplied augmenting proof that hepatocyte growth factor (HGF) has a physiopathological part in DM involvements. HGF has been a mesenchymal-derived polyphenic factor which modulates development, motion, and morphosis of diverse cells, and has been regarded as a humor intermediator of epithelial-mesenchymal interplays. The serum concentrations of HGF have been elevated in subjects with CAD and CI, especially during the acute phase of both disturbances. In our study with 89 type 2 DM patients, the association between serum concentrations of HGF and risk-factors for macrovascular complications inclusive of CA were examined. The average of serum HGF levels in the subjects was more elevated than the reference interval. The serum HGF concentrations associated positively with both intimal-media thickness (IMT) (r = 0.24, P = 0.0248) and plaque score (r = 0.27, P = 0.0126), indicating a relationship between the elevated HGF concentrations and advancement of CA involvements. Multivariate statistical analysis accentuated that serum concentrations of HGF would be associated independently with IMT (standardized = 0.28, P = 0.0499). The review indicates what is presently known regarding serum HGF might be a new and meaningful biomarker of macroangiopathy in DM subjects.

Key words: Hepatocyte growth factor; Diabetes mellitus; Carotid atherosclerosis; Macroangiopathy; Biomarker

Core tip: Hepatocyte growth factor (HGF) has been a mesenchymal-derived polyphenic factor which modulates development, motion, and morphosis of diverse cells, and has been regarded as a humor intermediator of epithelial-mesenchymal interplays. The serum levels of HGF in diabetes mellitus (DM) subjects might be assayed by balancing of stimulators (hypertension, atheromatous arteriosclerosis, *etc*.) and suppressors (hyperglycemia, transforming growth factor-, angiotensin Ⅱ, *etc*.). The elevated serum level of HGF might have been regarded as an indicator of the DM involvements seriousness. Accordingly, the concentration of serum HGF might be a new and meaningful biomarker of macroangiopathy in DM subjects.

growth factor, a biomarker of macroangiopathy in diabetes mellitus. *World J Diabetes* 2014; 5(5): 678-688 Available from: URL: http://www.wjgnet.com/1948-9358/full/v5/i5/678.htm DOI: http://dx.doi.org/10.4239/wjd.v5.i5.678

INTRODUCTION

Diabetes mellitus (DM) is a complex metabolic disturbance and one of the principal chronic diseases internationally. The planetary number of diabetic (DM) patients is approximated at 382 million (mill) in 2013, and it is anticipated to be over 592 mill by the year 2035[1]. Close to 5.1 mill the dead in the 20-79 years aged group might be due to DM in 2013, elucidating 8.4% of the global all-cause deathrate[2]. In addition to the effect on the subjects' life quality, the microvascular [diabetic retinopathy (DR), diabetic nephropathy (DN), neuropathy] and macrovascular complicating diseases (coronary heart diseases, peripheral artery diseases, and stroke) of DM also increase the internal healthcare spendings. Approximated planetary healthcare expendings to care and preclude DM and its complicating diseases are anticipated to total leastwise 548 billion USD in 2013. By 2035, this number is proposed to surpass some 627 billion USD[3]. Worldwide, DM is probable to be the fifth leading killer[4].

DM individuals, both type 1 DM (T1DM) likewise T2DM, have an elevated hazard of growing endorgan dysfunction. In a clinical manner, the conception of DM cardiac myopathy is determined as cardiac ventricle damage that arises irrespective of hypertension (HTN) and coronary artery disease (CAD), namely as a discrete primitive disorder course that generates secondarily to a damage of metabolism and leads to morphological and functioning anomalies of the myocardia guiding to heart failure (HF). Human DM cardiac myopathy has been chiefly demonstrated by the damage of diastole, that might introduce the the damage of systole growing[5]. Intriguingly, solely roughly 30% of T2DM and T1DM subjects make grow DN, in contradistinction to DM cardiac myopathy that is existed in half of T2DM subjects and DR investigated in over 90% of T1DM individuals[6,7]. It suggests a distinct timecourse of DM endorgan disorder. Therefore, in a differential manner, respective cell types would be exact to hyperglycemia-caused disturbance possibly for sake of distinct expression or activeness of molecular factors would be in charge of damage activating and progression[8].

Atherosclerotic complicating diseases are an essential causal element of prognosis in T2DM, with carotid atherosclerosis (CA) being a common risk-factor for prospective crisis of CAD and/or cerebral infarction (CI)[9,10]. Some molecules, such as high-sensitivity C-reactive protein (hs-CRP) and interleukin-18, would have been presented to be atherosclerotic biomarkers[11,12]. Preclusion of DM and its involvements, early invention of disease stages, and interventions that would act in the presence of hyperglycemia to avoid, retard or inverse the involvements are the principal concerns. Biomarkers have been investigated for understanding the structures of the evolution and progress of DM involvements[13]. This review presents what is currently known regarding serum hepatocyte growth factor (HGF) level might be a new and meaningful biomarker of DM macroangiopathy.

PLEIOTROPHIC EFFECTS OF HGF

HGF has been a mesenchymal-derived polyphenic factor which modulates diverse cells development, motion, and morphosis and it is thought that HGF would be a body fluid intermediator of epithelial-mesenchymal interplays. HGF has been distinguished as a new element of the family of endothelium-specific growth factors and a topical HGF system, configured HGF and its particular receptor mesenchymal epithelial transition factor (c-MET, MET), would have been presented in blood vessel cells both *in vivo* and *in vitro*[14-17]. Additionally, there is the proof that HGF induces the security and/or restoration of vascular endothelical cells hurt by HTN, with elevated serum HGF concentrations happening dependent on endothelial cell dysfunction[18,19]. HGF has been a polyphenic cytokine related to tissue security and restoration of the vascular endothelia[13-18]. Furthermore, it has been demonstrated that HGF would have in vitro mitogenic action in cultivation systems, and is deemed to be a new angiogenetic growth factor[20] (Figure 1). Some of investigations have demonstrated that HGF/scatter factor (SF) is represented by smooth muscle cells (SMCs) but works on vascular endothelical cells, not SMCs in the artery wall[17]. Nevertheless, different investigations have suggested that SMCs can react to HGF/SF[15,16]. McKinnon *et al*[21] have restudied expression and action of HGF/SF and its receptor MET in artery SMC and vascular endothelical cell cultivations and in total arteries after superficial or deep damage or atherogenicity. High-density cultivations of SMCs brought about HGF/SF but did not express MET, meanwhile SMCs, at the leading-edge of damaged cultivations, expressed both ligand and receptor and displayed a conspicuous motion and development reaction to HGF/SF. In accordance with these outcomes, HGF/SF and MET expression was indiscernible in the media of undamaged carotid arteries but was caused after deep artery damage in areas of SMC migration in the neointima. In addition, strong MET expression was found in the SMCs of the atheromatous arteriosclerotic focuses of homozygous apoE(-/-) mice, meanwhile HGF/SF was expressed by macrophage-derived foam cells. These results showed that MET was caused in migrating and proliferating SMCs and that HGF/SF and MET were key agents of the SMC reaction in atherogenicity[21].

ANTI-APOPTOTIC ACTION OF HGF IN ENDOTHELIAL CELLS

It was focalized that the character of HGF would be a new, element of the angiogenetic proliferators[15,18].

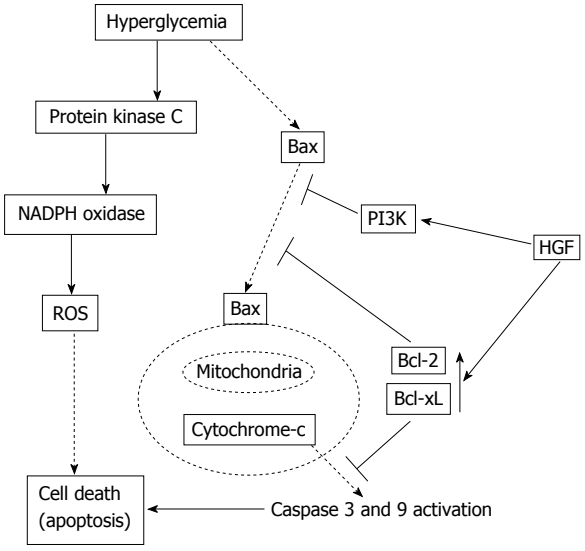

Figure 2 Potential mechanisms of anti-apoptotic effect of hepatocyte growth factor[33]. HGF: Hepatocyte growth factor; PI3K: Phosphatidylinositol 3-kinase; ROS: Reactive oxygen species.

Regional vascular HGF output was reduced by elevated glucose *via* the transforming growth factor-β (TGF-β) activating[22]. It was crucial that genetically modified HGF elevated bcl-2 protein without impacting bax protein and weakened the elevated glucose-caused caspase 3 and 9 activating[23]. The anti-apoptotic effect of HGF by bcl-2 initiation was possibly efficient against not merely elevated glucose conditions, but other stimulus related to activating of the mitochondrial-mediated apoptotic pathway, because HGF weakened caspase 3 activating stimulated by tumor necrosis factor-alpha by the phosphatidylinositol 3-kinase pathway, that was related to Akt activating[24]. These anti-apoptotic effects of HGF are not only unequaled as vascular endothelial growth factor (VEGF) and fibroblast growth factor but also demonstrated such effects. In addition, expression of VEGF and its receptor were reduced in the DM rats myocardia[25], as well as HGF[26]. Nonetheless, an unequalled latent mode of HGF is the capacity of immediate relationship between bcl-2 and MET due to bag-1 protein. The bag-1 protein has been accounted to interplay with the bcl-2 protein and to collaborate with the bcl-2 protein to inhibit apoptosis[27]. Of consequence, the bag-1 protein seems to reduce apoptosis by binding to bcl-2, the raf-1 protein kinase, and MET[28]. Besides, the conjunctive activating of these bcl-2-related genes might take part the apoptosis inhibition by HGF. It has been shown that bcl-2 affects antiapoptotic action by two modes: segregation of the executes of two major caspases-pro-caspase 9 and pro-caspase 8-and suppression of apoptogenic mitochondrial alterations, inclusive of cytochrome c secrete and loss, leading to apoptosis inductive factor secrete from isolated mitochondria[29,30]. In addition, it has been described that HGF could prevent against cell death by the phosphorylation of bad *via* phosphatidylinositol 3-kinase and augment bcl-xL[31], and bax translocation can be modulated by a configurational alteration leading to the exposition of its BH3 domain, and phosphatidylinositol 3-kinase precludes apoptosis by the depression of configurational alteration of the bax BH3 epitope[32]. These findings suggested that vascular endothelical cell death, particularly apoptosis, in hyperglycemia could be weakened by addition of growth factors, which would be potent anti-apoptotic factors (Figure 2)[33].

SERUM HGF CONCENTRATION IN T2DM PATIENTS

The previous studies showed that hyperglycemia reduced

regional HGF output in blood vessel unstriped muscle cells and vascular endothelical cells[22,34], Morishita *et al*[22] postulated that hyperglycemia influences HGF output in diverse apparatuses, such as the renal. If so, the serum level of HGF might be suppressed in DM. In a KKAy mice model of T2DM, the concentration of serum HGF was conspicuously decreased as compared to that in 14 wk of aged control mice[35], while renal and cardiac HGF concentration were remarkably decreased in KKAy mice as compared to those in C57BL mice. In this way, they moreover evaluated their hypothesis in human subjects in order to explore the association between the level of serum HGF and the severeness of T2DM. As supposed, the concentration of serum HGF was remarkably inversely correlated with HbA1c level[35]. In an interesting manner, the concentration of serum HGF in T2DM subjects was remarkably lower than that in non-DM subjects. There was no meaningful divergence in the serum HGF concentration between male and female subjects in either group. It is remarkable that there is a divergence between increased serum HGF in hypertensive (HTN) and decreased serum HGF in T2DM, whereas the tissue HGF levels are decreased in both diseases. The liver, lung and kidney are supposed to be major sources of serum HGF. High blood pressure (BP) in HTN patients does not cause injury to the liver or lung, while high blood glucose is known to influence the liver of such patients. Indeed, activation of serum TGF-β, a strong negative regulator of HGF, has been shown to be increased in T2DM patients[36]. In HTN, on the other hand, because the liver and lung are not injured by high BP, they can secrete HGF into serum in response to HTN damage. It is likely that this difference in the changes of serum HGF level between HTN and T2DM is due to the different influences exerted by high BP and high blood glucose on the major source of circulating HGF. In a contrasting manner, the concentration of serum HGF in T2DM subjects with HTN was markedly more elevated than that in the normal control subjects or that in T2DM subjects with no HTN.

Additionally, the concentration of serum HGF in all T2DM subjects was conspicuously correlated with systolic, but not with diastolic, BP. The concentration of serum HGF in T2DM subjects without HTN complications was markedly more elevated than that in the normal control subjects. The concentration of serum HGF in T2DM subjects with HTN involvements was higher than that in the other subjects. Nishimura *et al*[37] examined the association between the level of serum HGF and proliferative DM retinopathy (PDR), which is characterized by the major characteristic of retinal neovascularization. They found that the serum HGF concentration in T2DM individuals with no DR was more reduced than that in non DM individuals. Serum HGF concentration was elevated in PDR subjects who had not received photocoagulation, but not in those who had received photocoagulation. They concluded that the measurement of serum HGF may be helpful in predicting the presence of PDR in T2DM subjects. Afterwards, they reported that individuals with advanced grades of arteriosclerotic changes had higher serum HGF levels[38]. By contrast, they did not show a positive relationship between HTN and the level of serum HGF. As they included patients treated with antihypertensive drugs, it would be useful to assess the correlation between the level of serum HGF and BP of patients not treated with such drugs. It has also been reported that serum HGF was increased within 3 h after the beginning of pectoralgia in acute myocardial infarction (MI) subjects[39]. Attractively, increased HGF concentrations were conspicuously more common than those of creatine kinase (CK) within 3 h, and the increased level associated well with that of serum CK at 6-9 h after the beginning of acute MI. Therefore, HGF assay is a precise early checkup approach of the presence of arteriosclerotic lesions and acute MI. Serum HGF concentration may be a beneficial biomarker for investigating the cardiovascular disease development.

HGF is a member of the kringle proteins family, distinguished by a triple disulfide loop configuration (kringles) that communicates protein/protein and protein/cell interplay[40]. Consequently, HGF might serve a function in the modulation of thrombi and atheromatous arteriosclerosis. The kringle family to which HGF belongs contains tissue-plasminogen activator (t-PA), plasminogen, apolipoprotein (a) [Lp (a)] and urokinase. The effect of other factors associated with thrombi and atheromatous arteriosclerosis on the serum concentration of HGF was also evaluated, with the outcome that there was no remarkable relationship between the serum concentrations of HGF and total cholesterol. Likewise, the levels of t-PA, plasminogen activator inhibitor 1 and Lp (a) did not demonstrate any relationship with the concentration of serum HGF.

SERUM HGF CONCENTRATION IN T1DM PATIENTS

Nowak *et al*[41] hypothesized that the high level of HGF determined in T1DM subjects might be a significant DR progression biomarker and that the concentration of HGF might be a PDR risk indicator. Average levels of serum HGF in the control subjects were remarkably lower than in the T1DM subjects. They determined a meaning increment in the concentrations of serum HGF in T1DM subjects with PDR in comparison with the control subjects. Average concentrations of serum HGF were conspicuously higher in T1DM subjects with PDR than in T1DM subjects without DR. The concentration of HGF might be elevated in T1DM subjects with PDR, and levels increment with the DR progression, indicating that HGF takes on a role in the etiology of PDR in T1DM patients[41].

HGF AND CI AND CAD

The concentrations of serum HGF are elevated in sub-

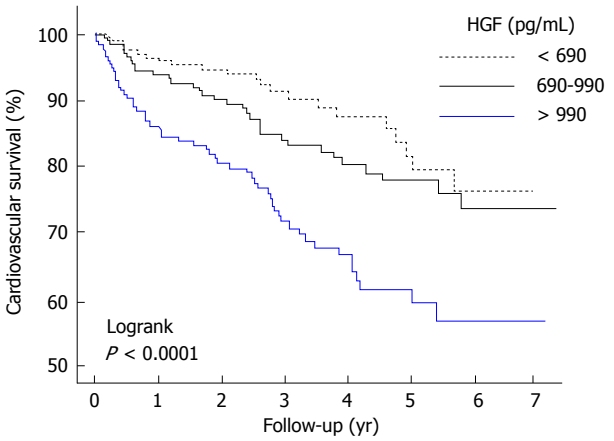

Figure 3 Kaplan-Meier survival curves in accordance with the tertiles of hepatocyte growth factor. The survival curves shows a worsened result for subjects with elevated hepatocyte growth factor (HGF) concentrations[45].

jects with CI and CAD, especially in the acute stage of both damages[39,42]. Besides, Nakamura *et al*[35] have shown that the concentrations of HGF were elevated in T2DM subjects who had HTN involvements such as arteriosclerosis. In addition, it has been described that the serum levels of HGF would be elevated in subjects during the beginning of acute MI and ischemic apoplexy[39,42].

Rajpathak *et al*[43] carried out a nested case-control study to constructively assessed the relationship between plasma HGF and ischemic apoplexy risk within the Women's Health Initiative Observational Study, a cohort of 50 to 79 years aged postmenopausal women. Base line plasma HGF concentrations were associated positively with body mass index (BMI), systolic BP, low-density lipoprotein cholesterol, insulin resistance, and inflammatory markers, such as CRP, and negatively with high-density lipoprotein cholesterol (HDL-C) (all $P < 0.05$). Base line plasma HGF concentrations were more elevated among cases than control subjects (geometric means, 601.8 *vs* 523.2 pg/mL; $P = 0.003$). Circulating plasma HGF levels are correlated with an elevated incidental ischemic apoplexy risk, extraneous to obesity and other cardiovascular disease risk-factors, amongst the 50 to 79 year aged postmenopausal women[43]. The white matter lesions (WML) existence is an essential predictive factor for the apoplexy onset. Increased levels of HGF are correlated with a high T2DM subjects death rate. The BMI was more elevated in the WML-positive subjects than that in the WML-negative subjects. Plasma concentrations of triglycerides were higher while HDL-C was more reduced in the WML-positive subjects than in the WML-negative subjects. Fasting plasma glucose ($P < 0.0001$), insulin levels ($P < 0.0001$), HOMA index ($P < 0.0001$) and HGF ($P < 0.0001$) levels were more elevated in the WML-positive subjects than in the WML-negative subjects. Multiple regression analysis showed that WML was independently prognosticated by the elevated HGF and insulin resistance ($P < 0.0001$ and $P < 0.0001$ respectively). The auxiliary investigation demonstrate that the WML existence was correlated with the increased HGF and insulin resistance in Japanese T2DM subjects[44].

Presently, the utilization of HGF as a biomarker of circulatory system disorder has been in the potent controversy as some reports showed elevated serum HGF level in HF subjects. Lamblin *et al*[45] studied the predictive value of 2 cytokines, HGF and, VEGF in subjects assessed for a decreased left ventricular ejection fraction (LVEF). Nevertheless, elevated concentrations of HGF were powerfully correlated with biomarkers of congestive HF severeness for example more elevated New York Heart Association class and more reduced LVEF, likewise clinical results inclusive of both cardiac and total deathrate (Figure 3). The relationship of HGF with harmful results continued multivariate statistical analysis that integrated latest style of risk-factors for example brain natriuretic peptide (BNP) and peak oxygen consume, a significant stage when evaluating the novel biomarker. Thoroughly, the concentrations of HGF would be more elevated in subjects with a heart trouble [1001 (741-1327) pg/mL] than in the subjects without it [773 (610-1045) pg/mL, $P < 0.000$]. Comparable outcomes would be determined when total deathrate was conceived. The concentrations of HGF would be more elevated in the subjects that deceased of any cause [940 (748-1306) pg/mL] than in subjects that would not. In an important way, the levels of HGF were intensely correlated with age, DM, and all biomarkers of congestive HF severeness. Accordingly, the survival curves suggested a worsened result for subjects with high HGF concentrations. In addition, Lamblin *et al*[46] investigated a first anterior Q-wave MI subjects. It was found that the plasma concentrations of HGF would be positively correlated with left ventricular (LV) volumes, wall motion systolic index, early transmitral velocity to mitral annular early diastolic velocity ratio, and BNP concentrations. Elevated concentrations of HGF would be correlated with more elevated CRP concentrations. Meanwhile, the concentrations of HGF were inversely correlated with LVEF. Multiple regression analysis demonstrated that both CRP and BNP were independently correlated with the concentrations of HGF at 3 and 12 mo. Subjects that deceased or were rehospitalised for HF during follow-up had more elevated concentrations of HGF at 1 mo, 3 mo, and 1 year after MI. Therefore, the circulating concentrations of HGF associated with all markers of LV remodeling after MI and would be correlated with rehospitalization for HF[46].

Susen *et al*[47] investigated the correlation between base line concentrations of the serum angiogenic growth factors, VEGF and HGF, and clinical result in 488 consecutive subjects related to elective percutaneous coronary revascularization (PCR) with no heparin pre-treatment. This primary endpoint, a complex of decease and MI, happened in 44 subjects at a median follow-up of 14.9 mo. At base line, the concentrations of HGF were in relation to CRP concentrations, DM, and late clinical unstability. HGF had a notable positive correlation ($P = 0.003$) with the primary endpoint in the univariate analysis. A same trend was found for VEGF ($P = 0.11$). The only

three variables remarkably correlated with the primary endpoint were HGF (P = 0.004), CRP (P = 0.007), and DM (P = 0.04) in the multivariate Cox model. It is demonstrated that an elevated serum HGF concentration is an independent predictive factor of clinical outcomes during follow-up and is associated with other surrogate markers of the atheromatous arteriosclerosis activeness in subjects, without heparin pre-treatment, related to PCR[47].

HGF would be a magnetic biochemical marker in congested HF subjects therefore it is augmented in the circumstance of cardiac muscle cell apoptosis and active tissue repair, whereby ascertaining patients that are at elevated hazard of harmful clinical results. Nevertheless, based off of obtainable proof, the the heart disorder pathogenesis should be assumed before utilizing HGF as a biochemical marker[48].

HGF AND DM CARDIAC MYOPATHY

The part of HGF/MET signalling in tissue of heart is chiefly attached to ischemic injury and little is recognized about its part in DM cardiac myopathy. Thus HGF brings about the vascular endothelical cells preservation or reparation and reduced serum and tissue concentrations of HGF would be referred for the advance of vascular endothelical cell injury caused by DM[49], the similar would be real for tissue of heart. Generally, elevated HGF would be supposed to be an involvements biomarker. Nevertheless, regional HGF output in blood vessel cells would be presented to be remarkably depressed by elevated D-glucose[50] that indicates reduced regional HGF generation might promote the atheromatous arteriosclerotic blood vessel alterations advance likewise cardiomyocytes damage in DM. Successively, an adaptative increment of HGF in progressed DM might promote the supposition that the levels of serum HGF are increased dependent on diverse apparatus damages.

Nakamura *et al*[49] discovered a serum level of HGF decrement in DM subjects with no HTN but an increment in subjects concerned about both DM likewise arterial HTN. In the latter group, the level of HGF successively elevated with the degree of HTN and it positively associated with systole BP in DM subjects. Furthermore, both clinical and animal experimental result indicated that the serum level of HGF was inversely associated with HbA1c in patients with no involvements, demonstrating that the damage of this vascular endothelical security in line with the DM seriousness. General HGF might affect in anagenesis as a humor intermediator, nevertheless it might be deficient to accelerate anagenesis, due to a decrement in regional HGF generation. Finally, the HGF/MET signalling would play an essential part in heart injury for example DM cardiac myopathy and precise discrimination of this part might ask for a new directions for agent exploitation and to assist better prospective DM care[8].

HGF AND THERAPEUTIC DRUG

Recently, HGF has been shown to be a downstream effector of peroxisome proliferator-activated receptor (PPAR)γ agonists[51]. Sanada *et al*[52,53] demonstrated that HGF exhibited anti-inflammatory and antioxidant effects using HGF transgenic mice. In particular, the fact that HGF has potent antifibrotic effects in both the heart and kidney through blockade of the profibrotic actions induced by angiotensin Ⅱ (Ang Ⅱ) and TGF-β1, and stimulation of degradation of fibrosis *via* matrix metalloproteinase activation is the center of interest[54-56]. In an interesting manner, amongst the accepted angiotensin receptor blockers (ARBs), irbesartan and telmisartan, so-called "metabosartans" [57], were presented to comprise a singular fraction of ARBs that can also be actuating PPARγ[58,59]. Indeed, telmisartan, reduced renal fibrosis and inflammation through the PPARγ-HGF pathway, independently of Ang Ⅱ type 1A receptor (AT1aR) blocking, in a unilateral ureteral obstruction model using AT1aR knockout (AT1aR-KO) mice[60].

Kusunoki *et al*[60] further investigated whether irbesartan has specific-organ protective effects *via* the PPARγ-HGF pathway independent of AT1aR blockade in a mouse fibrosis model, because, in large clinical trials such as the Irbesartan Microalbuminuria Type 2 Diabetes in Hypertensive Patients study and the Irbesartan Type Ⅱ Diabetic Nephropathy Trial, irbesartan demonstrated potent renoprotective effects irrespective of its hypotensive action[61,62].

"Aldosterone breakthrough" found in subjects accepting longterm care with angiotensin blocking is intensely correlated with elevated risk of LV hypertrophy, poor exercise capacity, refractory proteinuria, and decreasing glomerular filtration rate *via* the profibrotic effects of aldosterone. They used salt-sensitive HTN mediated by aldosterone and 1% NaCl infusion in AT1aR-KO mice, as this has been shown to induce severe cardiac fibrosis[63,64]. They demonstrated that irbesartan, which has not merely AT1aR- blockade actions, but PPARγ agonistic actions attended by HGF expression, suppressed organ injury by aldosterone and salt treatment[65]. Second-generation ARBs such as irbesartan, which has the double effects of AT1aR blocking and PPARγ activating, may have clinical merit for the care of HTN subjects with aldosterone breakthrough.

Calcium channel blockers are accounted to have protecting actions on the vascular endothelia *in vivo* and *in vitro*. Notably, nifedipine, amongst numerous calcium channel blockers, was demonstrated to ameliorate vascular endothelical damage in HTN subjects. Yamasaki *et al*[66] investigated the immediate actions of nifedipine on smoke-caused vascular endothelical damage, because tobacco use *per se* is a principal factor in vascular endothelical cells dysfunction, likewise HTN. They studied whether nifedipine would ameliorate endothelial action in 10 normotensive tobacco users with no atheromatous arteriosclerotic risk-factors. Nifedipine did not influence BP and cardiac rate of normotensive tobacco users. They determined forearm blood flow (FBF) by strain-gauge plethysmography after 2 and 4 wk of therapy. Alterations in vasorelaxant reaction to responsive hyperemia were

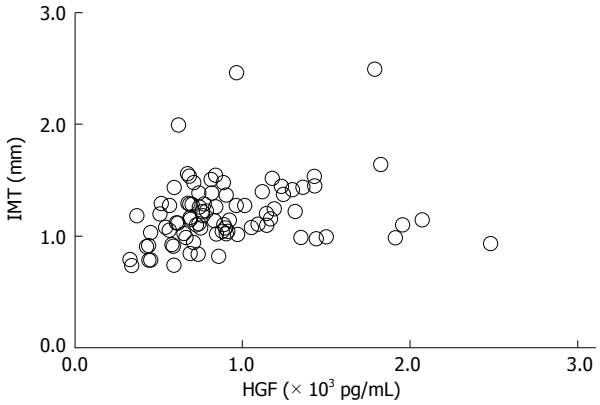

Figure 4 Relationship between serum hepatocyte growth factor and intimal-media thickness in type 2 diabetes mellitus subjects (r = 0.24, P = 0.0248)[69]. HGF: Hepatocyte growth factor.

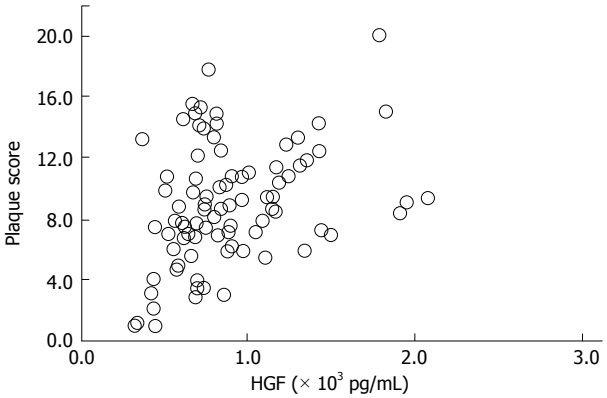

Figure 5 Relationship between serum hepatocyte growth factor and plaque score in type 2 diabetes mellitus subjects (r = 0.27, P = 0.0126)[69]. HGF: Hepatocyte growth factor.

conspicuously ameliorated in nifedipine-treated patients ($P < 0.05$), meanwhile there was no remarkable alteration in FBF reaction in controls. Furthermore, to investigate the machinery of the immediate actions of nifedipine on the endothelium, they focalized HGF, that is a new angiogenic growth factor with an antiapoptotic effect on vascular endothelical cells. Intriguingly, the serum level of HGF in tobacco users cured with nifedipine was markedly increased both at 2 and 4 wk ($P < 0.05$). Generally, these consequences indicated immediate actions of nifedipine in the endothelial damage amelioration in normotensive tobacco users. The increment in the serum level of HGF by nifedipine might bring about the vascular endothelical damage amelioration[66].

Makino *et al*[67] examined the action of calcium antagonist, benidipine, on endothelial mechanism in the essential HTN subjects, which induces endothelial damage. BP was decreased markedly. Endothelial mechanism was investigated applying FBF by strain-gauge plethysmography after 8 wk of therapy. Alterations in vasodilator reaction to responsive engorgement were notably ameliorated ($P < 0.01$), meanwhile the reaction to nitroglycerin was not altered, presenting the amelioration of endothelial mechanism. The level of serum HGF in patients cured with benidipine was grossly increased at 8 wk ($P < 0.05$). Intriguingly, an increment in the level of serum HGF by benidipine might bring about the amelioration of endothelial damage[67].

Takahashi *et al*[68] investigated whether lipid-lowering therapy (LLT) with statins would influence the leptin and angiogenic factors concentrations in CAD subjects. CAD subjects were randomised to 6 mo of intensive LLT with atorvastatin or moderate LLT with pravastatin. The plasma concentrations of leptin, Ang Ⅱ, HGF and VEGF were determined before statin treatment (baseline) and after 6 mo. Base line concentrations of leptin, Ang Ⅱ, HGF and VEGF were more elevated in the CAD subjects than in the non-CAD subjects (all $P < 0.05$). Intensive LLT reduced the concentrations of leptin, Ang Ⅱ, HGF and VEGF, while moderate LLT did not alter these concentrations. Their result displayed that LLT with atorvastatin reduces the leptin and angiogenic factors (HGF, VEGF) concentrations in CAD subjects, conceivably bringing about the favorable actions of LLT with atorvastatin in CAD[68].

HGF AND CA IN PATIENTS WITH T2DM

We conducted a clinical research to investigate the correlation between the serum HGF concentrations and the stage of CA in T2DM subjects[69]. The average level of serum HGF of T2DM patients in this clinical research was 895 +/- 408 pg/mL, a level notably more elevated than the reference values. The serum concentrations of HGF associated positively with both intimal-media thickness (IMT) (r = 0.24, P = 0.0248) and plaque score (PS) (r = 0.27, P = 0.0126) (Figures 4 and 5), indicating a correlation between the elevated HGF concentrations and development of atherosclerotic involvements.

Indeed, this was the first report presenting a notable relationship between the serum HGF concentrations and IMT and PS in T2DM subjects. Nevertheless, we failed to demonstrate a marked association between the concentrations of serum HGF and HbA1c. The clinical study outcome means the serum concentrations of HGF would be a beneficial biomarker of CA in T2DM subjects that is extraneous to entire glycemic control. Morishita *et al*[22] showed the elevated concentrations of glucose decreased the generation of HGF by vascular endothelical cells, conceivably as an outcome of apoptosis, in an in vitro study. In addition, these authors have indicated a inverse association between HGF and HbA1c in DM subjects without involvements[35]. Furthermore, the DECODE study presented that hyperglycemia after meal had an atherosclerotic action in T2DM subjects and impaired glucose tolerance subjects[70]. Collectively, these outcomes indicate additional investigations are certified to reveal the immediate or nonimmediate actions of control the level of blood glucose on both serum concentrations of HGF and the atherosclerotic involvements correlated with T2DM. It is indicated that these investigations should introduce supplemental scales like 1,5-an-

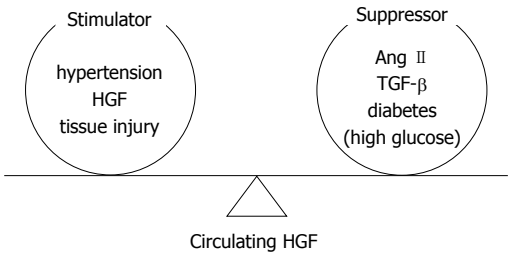

Figure 6 Determination of circulating hepatocyte growth factor level by the balance between stimulators and suppressors[19]. HGF: Hepatocyte growth factor; TGF: Transforming growth factor.

hydroglucitol and glucose level after meal. Nevertheless, using multivariate statistical analyses, we indicated that a positive relationship between the serum concentrations of HGF and IMT (standardized $\beta = 0.28$, $P = 0.0499$), we could not demonstrate any correlation between the serum concentrations of HGF and PS. The PS in the common carotid arteries (CCA) is considered as an indication of regional proliferating damages in large arteries, for instance atheromatic plaques. Since IMT and PS have discrete pathologic importance, we showed that serum HGF is a precise and characteristic biomarker for general endothelial cells proliferation. Although elevated serum concentrations of HGF would have been accounted in HTN subjects with DM[19], we could not show that the relationship was discovered between HGF and systolic BP. Contrarily, both IMT and PS associated positively with systolic BP. These outcomes would show that the concentrations of serum HGF might not be influenced by HTN intrinsically but might elevate as a secondary reaction to endothelial dysfunction that could occur during atherosclerotic progress. Hyperlipidemia, hyperglycemia and tobacco use are authenticated carotid atherosclerotic risk factors. In spite of these intense relationships, we could not show a correlation between the serum HGF concentrations and these three factors. It is potential that no correlation between serum HGF concentrations and hyperlipidemia and tobacco use was this result of the subject group not being classified in line with medical care with oral dyslipidemia therapeutic drugs, such as statin or tobacco use habit disturbance[71]. Many investigations have shown that the atherosclerotic progress in the CCA is a risk-factor for CI or MI[72,73]. IMT in those lacunar stroke subjects was not notably higher than in the no lacunar stroke subjects in our study. Contrastingly, PS in the lacunar stroke subject group was notably higher than in the no lacunar stroke group. It is demonstrated that PS is relevant to the lacunar stroke count[72], with Matsumori *et al*[42] also indicating the serum concentrations of HGF are elevated in CI subjects, especially in the preterm ischemic attack. It was discovered that both PS and IMT in ischemic heart disease (IHD) subjects would be notably more elevated than in those with no IHD. The relationship between CA and IHD has been accounted formerly[73] and moreover, it has been demonstrated that the serum levels of HGF would be elevated in acute MI subjects[39]. Our study of T2DM patients has indicated a positive relationship between the serum level of HGF and IMT and PS of the CCA. Additionally, IMT and PS would be ascertained as risk-factors for general atheromatous arteriosclerosis in both CI and CAD[69].

CONCLUSION

Actually, the serum level of HGF in DM subjects might be specified by balancing of stimulators (HTN, atheromatous arteriosclerosis, *etc*.) and suppressor (hyperglycemia, TGF-, Ang Ⅱ, *etc*.) (Figure 6)[8,19]. Accordingly, the increase of the serum HGF level might be regarded as an indicator of the DM involvements severeness. Therefore, serum concentration of HGF might be a beneficial biomarker of macroangiopathy in DM subjects.

Abstract

Treatment of type 1 diabetes mellitus has always posed a challenge to balance hyperglycemia control with hypoglycemia episodes. The quest for newer therapies is continuing and this review attempts to outline the recent developments. The insulin molecule itself has got moulded into different analogues by minor changes in its structure to ensure well controlled delivery, stable half-lives and lesser side effects. Insulin delivery systems have also consistently undergone advances from subcutaneous injections to continuous infusion to trials of inhalational delivery. Continuous glucose monitoring systems are also becoming more accurate and user friendly. Smartphones have also made their entry into therapy of diabetes by integrating blood glucose levels and food intake with calculated adequate insulin required. Artificial pancreas has enabled to a certain extent to close the loop between blood glucose level and insulin delivery with devices armed with meal and exercise announcements, dual hormone delivery and pramlintide infusion. Islet, pancreas-kidney and stem cells transplants are also being attempted though complete success is still a far way off. Incorporating insulin gene and secretary apparatus is another ambitious leap to achieve insulin independence though the search for the ideal vector and target cell is still continuing. Finally to stand up to the statement, prevention is better than cure, immunological methods are being investigated to be used as vaccine to prevent the onset of diabetes mellitus.

Key words: Type 1 diabetes advances; Insulin analogues; Closed loop system; Continuous glucose monitors; Insulin gene therapy

Core tip: As therapy of type 1 diabetes poses important challenges because of life long insulin dependence,multiple injections, excursions in glucose values and inability to simulate the pancreas, newer modalities of therapy are emerging. Hence, this is the right time to review developments in this front. This review conjures up recent advances in continuous glucose monitors, closed loop systems, insulin analogues, insulin gene therapy, transplantation and immunological vaccination.

INTRODUCTION

The year 1923 is a watershed in the history of diabetes mellitus when insulin was discovered by Banting and Best[1]. Today the world has come a long way from that, but living with type 1 diabetes still remains akin to a tight rope walk, balancing between hyperglycemia and hypoglycemic episodes. Multiple injections, strict control on food and exercise are herculean tasks to deal with, especially in children. Hence, the need for better therapies is warranted and they have thus evolved from nascent stages to actual usage.

The incidence of type 1 diabetes varies among different countries, which reflects the roles played by genetic

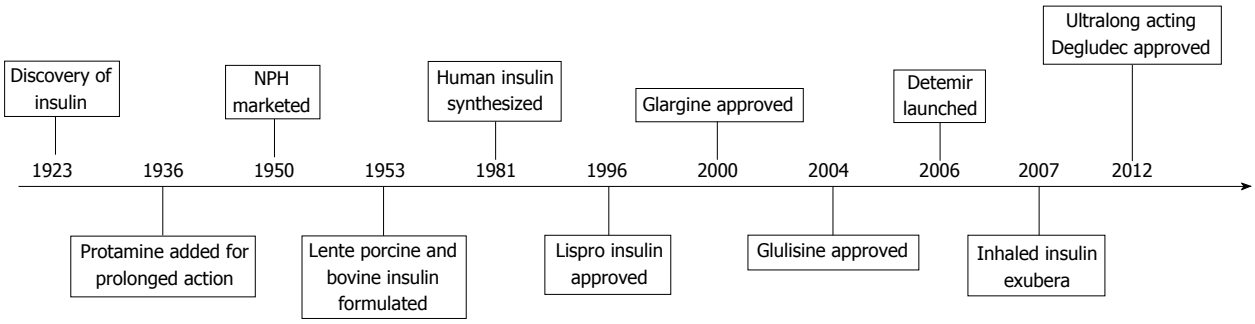

Figure 1 Time line of Insulin and its analogues. NPH: Neutral protamine hagedorn.

and environmental factors in the ultimate expression of the disease. It varies from 57.4 cases/100000 per year in Finland to 0.6 cases/100000 per year in India[2]. The fact that there is a rising trend in the number of children diagnosed to have type 1 diabetes is supported by a number of studies. Whether this can be attributed to an absolute increase in the incidence of the disease is still under speculation because the proportion of children with highest risk human leukocyte antigen haplotypes have decreased and hence, the changing environmental patterns may rather be uncovering the latent genetic factors to cause earlier expression of the disease[3]. The changing epidemiology is bringing more and more children to us to care for. Thus, unveiling newer and better therapies becomes an onus on us.

In this chapter, we shall be presenting a brief overview of the recent advances in the management of type 1 diabetes, including newer insulins, newer insulin delivery options, hypoglycemia prevention through use of technology and lastly, advances in the field of "curing" diabetes through transplant and gene therapy.

ADVANCES IN INSULIN

The quest for the ideal insulin has led to the discovery of a variety of analogues to match the mighty pancreas and yet, many lacunae are left to be filled. The timeline of important events in the history of insulin is presented in Figure 1.

Insulin analogues were designed to overcome the problems of poor stability and erratic absorption profile of the preceding generations of insulin.

Short acting insulin

Insulin lispro: Short acting insulin is necessary to deal with meal time hyperglycemia. Insulin Lispro which was approved in 1996 has rapid onset of action and shorter duration so that post prandial hypoglycaemia can be prevented. The inversion of proline at position 28 with lysine at position 29 allowed insulin to exist more in the monomeric form that is easily absorbed which could counteract meal time hyperglycemia without causing prolonged hypoglycaemia. The modification in the amino acid sequence did not alter the receptor binding and hence, is as effective as regular insulin[4].

Insulin aspart: Substituting proline at position 28 with aspartic acid formed insulin aspart which is also short acting due to absence of hexamer formation. Immunogenicity and teratogenicity profile was similar to regular insulin[5].

Insulin glulisine: This is the newest addition to the list of short acting insulin produced by substituting asparagine at position B3 by lysine and lysine at position B29 by glutamine. It is unique in action by causing phosphorylation of Insulin Receptor Substrate 2. Increased binding to insulin like growth factor (IGF) 1 receptor and mitogenic activity has however, raised concerns over its tumorigenic potential which needs further evaluation[6]. Food and drug administration (FDA) approval has been obtained for use of glulisine in children > 4 years.

Long acting insulin

Isophane, Lente and Ultralente failed to ensure long time control of glucose with minimum variations and hence, they made way for newer long acting insulins.

Insulin glargine: Amino acid alterations brought about a change in pH from 5.4 to 6.7 that made glargine poorly soluble at physiological pH. The stability of its hexameric structure prevents rapid absorption from subcutaneous tissue and its activity is maintained for 11 to 24 h. Glargine also has affinity to the IGF 1 receptor making it mitogenic, but the clinical significance of this finding is still questionable[7]. Safety in the pediatric age group has been established but due to the acidic pH burning sensation has been reported in some children.

Insulin detemir: Detemir binds reversibly to albumin and undergoes a slow release process as only free detemir is biologically active. Onset of action is within 1 to 2 h and lasts for 24 h. Peakless activity ensures stability[8]. Detemir shows more reproducible pharmacokinetics in children than glargine[9]. The United States FDA has approved the use of Detemir and Glargine only in children > 6 years.

Insulin albulin: As the name suggests, insulin albulin has been developed by directly fusing single human insulin gene to human albumin gene that makes this analogue long acting. The peakless effect makes albulin a potential

Figure 2 Dr. Arnold Kadish with the first insulin pump. (Courtesy: www.medscape.com).

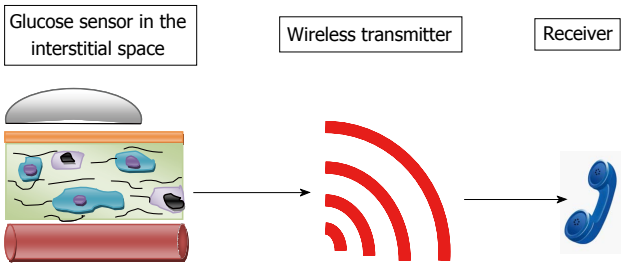

Figure 3 Schematic representation of continuous glucose monitors.

agent for long term glycemic control. The affinity of albulin to IGF 1 receptors is less compared to other analogues which makes albulin less likely to trigger mitogenesis[10]. Insulin albulin still has to evolve to enter clinical application.

Insulin degludec: Approved in 2012, Insulin degludec shows a flat profile upon injection with a half-life of 25 h, enabling once in 3 d injection. The dihexamers associate with each other to form multi hexamers that slowly form monomers and enter the bloodstream. When compared to other long acting insulins, degludec shows much lower variability in day to day glucose levels. Trials investigating degludec have also included children and adolescents. Nocturnal Hypoglycemia, which is the bottle neck in intensive glucose lowering, is reported to be up to 25% lower with degludec[11]. Increase in adverse cardiovascular events is a concern with degludec and use in pediatric age group is not yet approved.

Inhaled insulin

The search for alternative routes of delivery of insulin paved way to the discovery of inhaled insulin Exubera that was approved in 2006, but withdrawn from the market a year later due to poor sales. It was thought that the large surface area of the lungs would facilitate better absorption. However, bioavailability was found to be only 10% and so higher doses were required. Unpredictable absorption patterns that varied with age, respiratory tract infection and smoking form important hurdles for lungs to be the route of choice[12].

Despite the initial enthusiasm with oral insulin which was considered as the "holy grail" for treating diabetes, it remains an enigmatic target due to enzymatic digestion of insulin and inadequate intestinal absorption.

Buccal and skin patches are also candidate routes for delivering insulin that await further research.

INSULIN PUMPS

Parallel to the advancements in insulin, the modes of delivery also underwent considerable changes in the last 50 years. The first pump designed by Dr. Arnold Kadish in 1963 was bulky and had to be worn like a backpack as in Figure 2. It was replaced by the "big blue brick" model which again became obsolete due to inaccuracies. All the early models could only provide a single basal delivery rate and had to be programmed frequently. The technological boom that accompanied the dawn of the 20th century brought about further developments and today we have insulin pumps that are convenient, small, accurate and adjustable.

CONTINUOUS GLUCOSE MONITORS

Fear of hypoglycemia is recognised as the most important road block in the path to achieving good glycemic control. Continuous blood glucose monitoring system is an important aid in the management of type 1 diabetes and an essential prerequisite for closed loop systems. The superiority of Continuous glucose monitors (CGMs) over self-monitoring of glucose in reducing the time spent in hypoglycemia has been proven beyond doubt[13].

The basic structure of a CGM consists of a sensor, wireless transmitter and a receiver as in Figure 3.

Sensor provides real time blood glucose levels and typically consists of a membrane layer, electrode and enzyme matrix. It works on the same principle as the conventional glucose monitors using the glucose oxidase catalysed oxidation of glucose to produce hydrogen peroxide that generates an electric current at the electrode[14]. The membrane layer forms a barrier between the electrode and the surrounding tissues, which mandates adequate permeability to glucose and oxygen. Sensors are inserted subcutaneously and detect glucose concentration in the interstitial compartment. In the earlier versions, blood glucose values were stored and had to be downloaded to view the level of control retrospectively. The present CGMs have sensors that display the glucose values in real time which enables the user to take appropriate steps in case of skewed values. The CGMs are also equipped with systems that would alert the user when values are above or below the set thresholds. The receiver may either be a display device to be worn like a pager or may be connected to an insulin pump.

A drawback that has emerged with CGMs is bioinstability. Sensors become unstable secondary to inflammatory reaction, granuloma formation, blood clots, *etc*[15]. This brings about drifts in glucose values and a need for intermittent calibration with conventional blood glucose

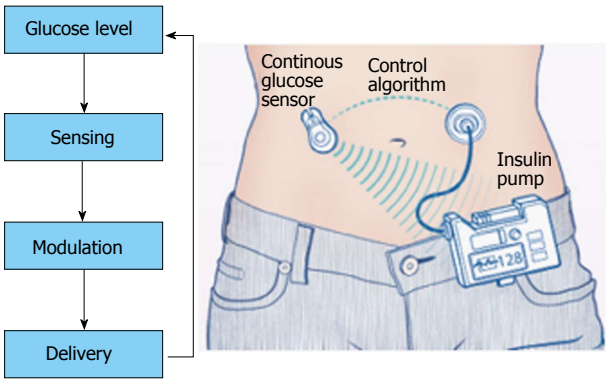

Figure 4 Principle of closed loop system.

measurements. Coating of the membrane layer with silicon oxide nanoparticles containing Polyethylene Glycol has been found to prevent bioinstability of sensors[16]. Further research is ongoing to discover the most appropriate material to coat the sensors. Another innovation that has been successful is replacement of electrochemical sensors with fluorescent sensors. When glucose binds to the receptors, the fluorophore fluoresces brightly. These sensors are highly accurate even with extreme values of glucose[17]. Despite these refinements, there are two important shortcomings with the CGMs. First, the interstitial glucose measurement does not exactly reflect the blood glucose concentration. Second is the time lag due to glucose transport to the interstitium and sensor processing. The CGMs lag behind blood glucose by an average of 4 to 10 min[18].

Another method of blood glucose monitoring that had emerged in 1999 was the Glucowatch Biographer. This device was worn like a wristwatch. It used the process of reverse iontophoresis to stimulate the secretion of subcutaneous fluid, and glucose content was measured using a biosensor unit. There was good correlation with the blood glucose monitoring devices[19]. However, skin irritation and false alarms were obstacles to the widespread clinical use of this device.

A recently developed non-invasive CGM device named HG1c uses the principle of Raman spectroscopy where a painless pulse of monochromatic light is transmitted into the skin, and the scattered light is detected for the determination of glucose levels. This device can be worn on the abdomen like a band and measures blood glucose levels every five minutes. The sensor transmits data to a smartphone which is also enabled with alarms during periods of glucose excursion[20]. A similar iPhone operating system-enabled smartphone-based Wireless Smart Gluco-Monitoring system has also been developed[21].

Many smartphone based glucose monitors and applications are helping to make the life of a diabetic patient easier. These allow the user to enter diabetes related data like carbohydrates and water consumed, insulin dose taken, duration of exercise, *etc*. Based on the information given these apps can also calculate the amount of insulin required. A device named Eyesense is under development which will be able to determine blood glucose level using a small photometer implanted in the interstitial fluid under the conjunctiva[21].

CLOSED LOOP SYSTEMS

The idea of closed loop systems came into vogue as the repeated discrete subcutaneous doses caused fluctuating insulin and in turn glucose levels. Blood glucose concentration stands on a delicate balance between caloric intake and expenditure which is modified by the insulin doses that necessarily do not mimic the original pancreatic secretion. As the CGMs started providing real time feedback of the glucose levels, the extreme variations were uncovered. The concept of artificial pancreas surfaced when CGMs were linked to insulin pumps as Continuous Subcutaneous Insulin Infusion gained acceptance from the 1990s[22]. The principle of closed loop systems is simple as shown in Figure 4.

In contrast to the pre-programmed insulin pumps, closed loop systems modulate insulin delivery at intervals of 1 to 15 min.

The characteristics that are desired in an ideal closed loop system would be the following[23]: (1) Response to glucose levels in a highly specific way; (2) Response within a timescale of minutes; (3) Monitoring within the visceral region; (4) Pulsatile output to avoid desensitization of insulin receptors; and (5) No chemical modification of insulin.

The backbone of the closed loop system is the control algorithm. Control algorithms direct insulin delivery as per glucose levels and account for measurement errors and kinetic delays.

There are two categories of control algorithms: (1) Proportional Integral Derivative (PID); and (2) Model Predictive Control (MPC).

PID

The schema of PID is given in Figure 5. The PID was one of the most initial algorithms developed for artificial pancreas. The proportional component detects deviations from target glucose, integral component measures the area under the curve between the measured and target levels and the derivative component assesses the rate of change of measured glucose levels. However, PID is rather a reactive algorithm which implies that skewed values of glucose cannot be prevented but can only be shortened in duration because the PID responds to observed glucose levels. Adding announced meals to the algorithm or patient directed insulin boluses can overcome hyperglycemia but hypoglycemic episodes may not be prevented.

MPC

This is a proactive algorithm because it can forecast the blood glucose values from the current concentration and is designed in such a way that it brings the forecasted glucose closer to the target glucose values. Based on the current glucose levels further insulin delivery is planned but after the first step is executed the system is reassessed and

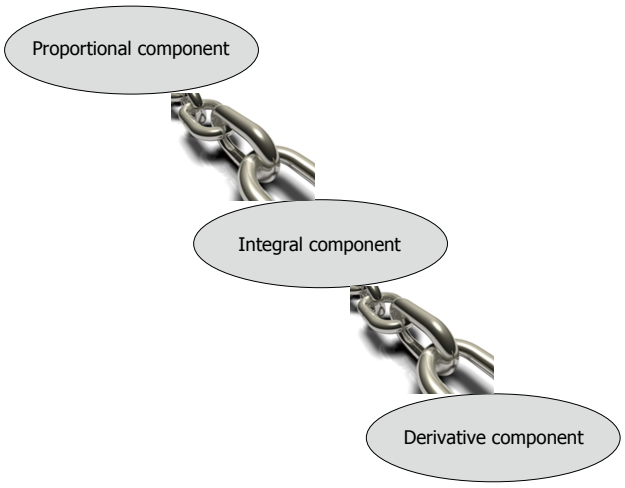

Figure 5 Components of proportional integral derivative.

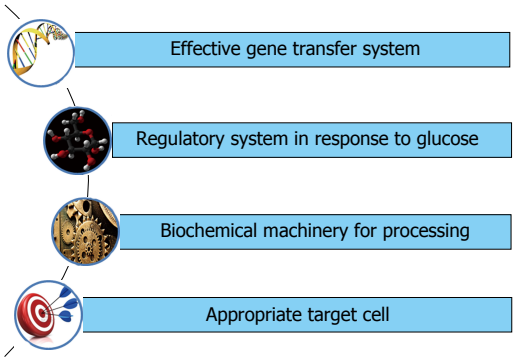

Figure 6 Requirements for insulin gene transfer.

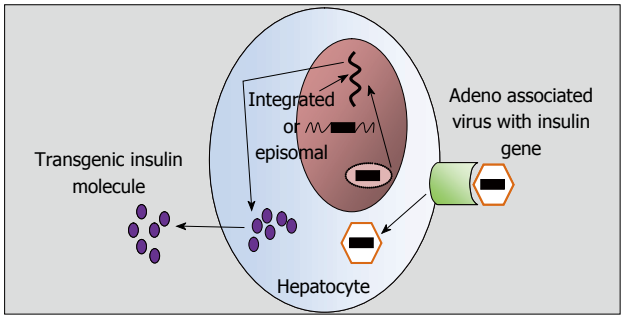

Figure 7 Insulin gene insertion with adeno associated virus.

further delivery is planned. This enables a step by step assessment and reaction, yet in a proactive manner. In this way MPC can prevent hypoglycemic episodes and reduce the time spent in hyperglycemia. MPC can efficiently deal with meals and exercise without any additional inputs[24]. MPC also has capabilities to learn the patient's routine to adjust the insulin delivery based on this information using the run to run control algorithms and also optimize according to circadian fluctuations[25].

Innovations in closed loop system
