duration of the disease as a parameter that should be considered when choosing HbA1c target levels^[4]. Vacante *et al*^[27] suggested combining the current age of the patient with the duration of DM.

LONG-STANDING DIABETES IN THE ELDERLY

As mentioned above, long-standing DM in the elderly has higher morbidity rates compared to new-onset DM. Therefore, the question is whether good glycemic control in elderly people with long-standing DM will influence the course of the disease.

In young and middle-aged diabetic patients, the role of tight glycemic control is crucial, as was proven in the Diabetes Control and Complications Study (DCCT) and United Kingdom Prospective Diabetes Study (UKPDS) in type 1 and type 2 DM, respectively^[28-30]. These two studies confirmed the benefit of intensive glycemic control in reducing microvascular and macrovascular complications^[31]. Nonetheless, these studies included only new-onset diabetic patients and excluded patients ages 65 years and above at the time of enrollment.

Almost 10 years after the publication of the UKPDS study, and 15 years after the DCCT study, 3 large randomized controlled trials examined the influence of intensive glycemic control on microvascular and macrovascular complications in older subjects with long standing DM. The Action to Control Cardiovascular Risk in Diabetes trial^[32] enrolled diabetic patients (mean

age 62.2 ± 6.8 years) 10 years after diagnosis, 35% with previous cardiovascular disease. This trial was terminated after 3 years because of excessive deaths in the intensive glycemic control arm. The Action in Diabetes and Vascular Disease trial^[33], which had also enrolled people with advanced disease (mean age 66 ± 6 years, average duration of diabetes 8 years, 32% with previous major macrovascular disease), showed no significant effect of tight glycemic control on major macrovascular events or death from any cause, but there was significant reduction in nephropathy incidence and as a result, reduction in the incidence of combined microvascular and macrovascular events. This reduction was proven only for patients younger than 65 years, according to a sub-group analysis published as part of the trial. The Veterans Affairs Diabetes Trial trial^[34] enrolled similar diabetic patients (mean age 60.5 ± 9 years, 11.5 years after diagnosis, 41% with major macrovascular disease) and also showed no significant effect of tight glycemic control on major macrovascular events or death from any cause. As one would expect, adverse events related to intensive glycemic control, such as hypoglycemia, were more common in the elderly^[35].

Few studies are directed to glycemic control in the old age. For example, the retrospective diabetes and aging study^[36] enrolled participants above 60 years of age (38% between 70-79 years and 15% age 80 or older); 57% had diabetes for more than 4 years at enrollment. There was a U-shaped relationship between

Table 3 Studies on the role of tight glycemic control in long-standing diabetes mellitus

Study	No. participants	Years since diagnosis	Mean age at enrollment (yr)	Length of follow up (yr)	Population	Results
ACCORD trial ^[32]	10251	10 (median)	62.2 ± 6.8	3.4 (median)	United States and Canada	Terminated after 3.5 yr; excessive deaths in the intensive glycemic control arm
ADVANCE trial ^[33]	11140	8 (mean)	66 ± 6	5 (median)	Asia, Australasia, Europe, and North America (20 countries)	No significant effect of tight glycemic control on major macrovascular events or death; significant reduction in nephropathy incidence
VADT trial ^[34]	1791	11.5 (mean)	60.5 ± 9	5.6 (median)	United States military veterans; 97% males	No significant effect of tight glycemic control on major macrovascular events or death
Diabetes and aging study ^[35]	71092	8.3 (mean)	71 ± 7.4	3.1 (mean)	California, United States	U-shape relationship between mortality and HbA1c, with the lowest mortality rate at HbA1c 6%-8%

ACCORD: Action to Control Cardiovascular Risk in Diabetes; ADVANCE: Action in Diabetes and Vascular Disease; VADT: Veterans Affairs Diabetes Trial.

mortality and HbA1c, with the lowest mortality rate at HbA1c 6%-8%, in all age-groups (Table 3).

The benefit of tight glycemic control for prevention of microvascular complications is not immediate. As proven in the UKPDS studies, the difference in outcome between the tight glycemic control group and the control group only appeared 9 years after randomization^[14,31]. In other words, for patients with life expectancy of 7 years or less, the benefit in this area is doubtful.

The complexities of diabetes care in old age, with benefits alongside potentially serious adverse events, led researchers to quality-adjusted life year (QALY) trials. Vijan *et al.*^[37] compared the QALY gained with intensive glycemic control versus moderate glycemic control, in different age-groups. They concluded that older patients, age 75 years and older, experience smaller benefit from glycemic control compared to younger patients, and their expected gain in QALYs for a 1-point change in HbA1c was minimal, even with the favorable assumption that the benefits of glycemic control extend to the elderly.

The results of the aforementioned studies resulted in changes in the clinical guidelines regarding treatment goals for elderly with long-standing DM. However, the guidelines offer general instructions and leave a large margin for clinical judgment.

The 2014 ADA guidelines^[4] recommend a standard glycemic goal of HbA1c below 7% for adults, and a less stringent goal, such as < 8% for patients with a more complex status, which is defined according to disease duration, life expectancy, important comorbidities, risk for adverse events and existing vascular complications. The International Association of Gerontology and Geriatrics and the European Diabetes Working Party for Older People published similar recommendations^[38].

The consensus report of the ADA and the American Geriatrics Society from 2012^[14], offered 3 levels of glycemic control for the old patient: HbA1c < 7.5% for healthy patients, < 8% for patients with intermediate health status (multiple chronic illnesses, 2+ instrumental impairments or mild cognitive impairment), and < 8.5% for patients with poor health status (end-stage chronic illnesses or moderate-to-severe cognitive impairment or 2+ activities of daily living dependencies). The International Diabetes Federation 2013 guidelines^[39], suggest a similar categorization. They also emphasize that for end-of-life situations, the goal should be merely to avoid symptomatic hyperglycemia (Table 4).

CONCLUSION

This review summarizes the current evidence about glycemic control in the elderly. Similar to young and middle-aged adults with DM, it seems that the elderly patient with diabetes has higher risks for morbidity and mortality compared to a non-diabetic person of the same age. Even so, new-onset DM is less severe in elderly patients compared to young adults and easier to control. The impact of pre-diabetes state on morbidity and mortality risk in the elderly is doubtful, and the role of screening and treatment in these patients is questionable. Finally, the importance of tight glycemic control on long-standing DM in the elderly in not well-established and the preferred level of glycemic control should be considered in the overall context of the patient's health status. The optimal level of control among elderly patient subgroups requires

Table 4 Guideline recommendations for glycemic control in the elderly

further evaluation.

Beyond all the above, the heterogeneity of the elderly population presents a significant challenge in clinical decision making. Old diabetic patients can be healthy or with much comorbidity and the risks of adverse events from medications increases with age. The decision regarding an individual patient's glycemic goal should be made, ideally with the patient himself, after considering all the comorbidities, together with current cognitive state, risk of adverse events, quality of life aspects and life expectancy.

Abstract

The 3-hydroxy-methylglutaryl coenzyme A reductase inhibitors, statins, are widely used in the primary and secondary prevention of cardiovascular diseases to lower serum cholesterol levels. As type 2 diabetes mellitus is accompanied by dyslipidemia, statins have a major role in preventing the long term complications in diabetes and are recommended for diabetics with

normal low density lipoprotein levels as well. In 2012, United States Food and Drug Administration released changes to statin safety label to include that statins have been found to increase glycosylated haemoglobin and fasting serum glucose levels. Many studies done on patients with cardiovascular risk factors have shown that statins have diabetogenic potential and the effect varies as per the dosage and type used. The various mechanisms for this effect have been proposed and one of them is downregulation of glucose transporters by the statins. The recommendations by the investigators are that though statins can have diabetogenic risk, they have more long term benefits which can outweigh the risk. In elderly patients and those with metabolic syndrome, as the risk of diabetes increase, the statins should be used cautiously. Other than a subset of population with risk for diabetes; statins still have long term survival benefits in most of the patients.

Key words: New onset diabetes mellitus; Statins; Hyperglycemia; Cardiovascular risk; Dyslipidemia

Core tip: The use of statins in diabetics has long term benefits in terms of decreasing morbidity and mortality. Recent studies have shown that statins increase the incidence of new onset diabetes. The issue became debatable after Food and Drug Administration released changes to statin safety that they increase glycosylated haemoglobin and blood glucose levels. At the same time statins are beneficial in preventing cardiovascular events. Most of the investigators are of the opinion that the risk of diabetes with statins can be outweighed by the long term benefits in preventing complications. In patients with high risk of diabetes, statins should be cautiously used.

Chogtu B, Magazine R, Baiyy KL. Statin use and risk of diabetes mellitus. *World J Diabetes* 2015; 6(2): 352-357 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i2/352.htm>

INTRODUCTION

Statins, the 3-hydroxy-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, inhibit the rate limiting step of conversion of HMG-CoA to mevalonate and thus limit cholesterol synthesis. Lower hepatic cholesterol levels subsequently increase expression of low density lipoprotein (LDL)-receptors in liver cells. This in turn leads to enhanced clearance of LDL-particles from blood. Lowering of plasma LDL-cholesterol by statins reduce production and increase catabolism of apo B 100^[1]. A range of products like coenzyme Q10, heme-A, and isoprenylated proteins are generated by mevalonate pathway^[2] which have an important role in cell biology and human physiology. The role of statins has been hypothesized to be widespread as in inflammatory markers and nitric oxide (NO)^[3], polyunsaturated fatty acids^[4], immunomodulation^[5], neuroprotection^[6], cellular senescence^[7], *etc.*

STATINS IN DIABETES

Statins are used for primary and secondary prevention of cardiovascular diseases. Other benefits due to statins are not mediated by their lipid lowering properties^[8] but due to its pleiotropic effects. In conditions like heart failure, cardiac arrhythmias, vascular disease and hypertension the non-lipid lowering pleiotropic benefits of statins have been observed^[9]. These pleiotropic effects mediated by statins can be due to inhibition of isoprenoid synthesis which in turn inhibits intracellular signaling molecules Rho, Rac and Cdc42. The predominant mechanism that has been postulated is inhibition of Rho and its activation to Rho kinase^[10].

Type 2 diabetes is characterized by hyperglycemia, insulin resistance and insulin deficiency. The insulin resistance contributes to the abnormal lipid profile associated with type 2 diabetes^[11]. Dyslipidemia contributes to increased cardiovascular events in patients with type 2 diabetes^[12]. A linear relationship exists between cholesterol levels and cardiovascular diseases in diabetics even if we ignore the baseline LDL^[13]. By predominantly lowering LDL-Cholesterol and due to minor effects on other lipoproteins, statins appear to be beneficial^[12]. In Heart Protection Study which was done in diabetics, the decrease in cardiovascular events like first major coronary event, stroke were to the tune of 22% as compared to placebo^[14]. It was recommended by American Diabetes Association that statin therapy should be initiated in individuals with diabetes and other cardiovascular risk factors with target LDL cholesterol of 100 mg/dL^[15]. Investigators are also of the opinion that statin therapy should depend not on the LDL levels but the cardiovascular complications accompanying diabetes^[16]. Other studies which showed

reduced coronary events with statins in patients with diabetes mellitus are Cholesterol and Recurrent Events and Long-term Intervention with Pravastatin in Ischaemic Disease studies of pravastatin^[17,18]. In The Collaborative Atorvastatin Diabetes Study, statins significantly reduced acute coronary events by 36% and stroke by 48%. The beneficial effects of statins were so clear in this study that it was halted two years in advance^[19]. West of Scotland Coronary Prevention Study also showed that the risk of diabetes was reduced by 30% in patients on pravastatin 40 mg/d^[20].

STATINS AND DIABETES RISK

In February 2012, Food and Drug Administration released changes to statin safety label to include that statins have been found to increase haemoglobin (HbA1C) and fasting serum glucose levels^[21]. This release has brought in the debate of using statins in patients with cardiovascular risk factors like diabetes.

In Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin study participants with LDL cholesterol levels of less than 130 mg/dL and elevated high-sensitivity C-reactive protein levels were included. They received rosuvastatin or placebo for a period of two years. It was observed that rosuvastatin significantly reduced the rates of a first major cardiovascular event and death from any cause as compared to placebo. A 54% lower risk of heart attack, 20% lower risk of stroke and 20% lower risk of death from any cause was noted in statin group^[22]. An increase in new onset diabetes, *i.e.*, 3% in statin arm and 2.4% in placebo arm was reported. This was accompanied by increase in median value of glycated haemoglobin and was one of the earlier studies to report the increase in new onset diabetes in patients on statins. Women's Health Initiative trial was a post hoc analysis and included 153840 postmenopausal women without diabetes mellitus. Even after adjustment for potential confounders, statin therapy was associated with an increased risk of new-onset diabetes mellitus^[23]. There was no difference between women with and without overt cardiovascular disease, which could have influenced the risk-benefit ratio of statins^[23]. Authors suggest that statin-induced diabetes mellitus is a medication class effect^[23]. Another study also reported that as compared to placebo, statin group showed a higher risk of physician reported incident diabetes and it was also observed that risk was higher in women as compared to men^[24].

Meta-analysis of randomized controlled trials by Sattar *et al.*^[25] involving 91140 non-diabetic patients showed that statin therapy was associated with 9% increased risk of incident diabetes. After a period of four years during which 255 patients were treated, there was one extra case of diabetes mellitus^[25]. Authors did not find any apparent difference between lipophilic and hydrophilic statins in association with

diabetes risk^[25].

Though some studies put forth this as a class effect, others showed different effects with different statins and at different doses. A number of studies showed dose dependent association between statin administration and incident diabetes. A meta-analysis with 32752 participants was done in which the risk of intensive dose statin therapy was compared with moderate dose statin therapy on incident diabetes. It revealed that intensive dose of statins was associated with high incidence of new - onset diabetes, though it decreased cardiovascular events as well^[26]. In those receiving intensive dose of statins, 18.9 ± 5.2 diabetic cases per 1000 patient years were observed vs 16.9 ± 5.5 cases per 1000 patient years with moderate doses of statin therapy^[26].

In PROVE-IT TIMI 22 trial 3382 patients without pre-existing type 2 diabetes mellitus were included. The levels of HbA1C increased by 0.12% in patients treated with pravastatin 40 mg, while in those receiving atorvastatin 80 mg showed a significant difference and the levels increased by 0.30%^[27]. Another study comparing glycaemic control between diabetic patients receiving atorvastatin 10 mg, pravastatin 10 mg or pitavastatin 2 mg/d showed that it was only the atorvastatin-treated patients in which the blood glucose and HbA1C levels increased^[28]. Treatment with atorvastatin and simvastatin may be associated with an increased risk of new onset diabetes as compared to pravastatin^[29]. Pitavastatin has shown favourable profile in patients with diabetes by improving insulin resistance and minimally impairing glucose metabolism^[30]. Increased incidence of diabetes was seen with atorvastatin in the Anglo-Scandinavian Cardiac Outcomes Trial^[31] and impaired glucose metabolism in some cases of type 2 diabetes^[32]. Increased insulin resistance secondary to statins was demonstrated in a prospective non randomised study in patients with coronary bypass surgery^[33]. So, many studies have reported an increase in new onset diabetes and there is a variation in response depending on the statin administered and the dose of statin.

MECHANISM OF STATINS IN HYPERGLYCEMIA

Statin-induced insulin resistance can be due to inhibition of isoprenoid biosynthesis and downregulating C/EBP α production^[34]. Decreased synthesis of isoprenoids can produce downregulation of GLUT4 expression on adipocyte cells^[35]. It can lead to decrease in insulin-mediated cellular glucose uptake and possibly manifest as intolerance to glucose^[36]. Acceleration of type 2 diabetes can be seen secondary to downregulation of GLUT4/SLC2A4 in adipocytes^[37]. Over-production of NO by inducing cytokines can cause β -cell apoptosis^[38].

On incubating rat pancreatic cells with statin, there was a decrease in insulin secretion due to inhibition of glucose stimulated increase in free cytoplasmic

calcium^[39]. Statins also inhibit the insulin secretion due to reduced production of ATP by suppressing the synthesis of ubiquinone (CoQ10)^[39]. Clinical doses of atorvastatin in animal model of type 2 diabetes led to inhibition of adipocyte differentiation, decreased SLC2A4 expression in both differentiating and mature adipocytes, and impaired insulin sensitivity and post-challenge glucose tolerance^[34]. Animal models have also shown that there is an association between development of insulin resistance and statin-induced myopathy^[40].

Other mechanisms hypothesized for the possible effect of statins on new-onset diabetes are that statins by inhibiting phosphorylation interfere with intracellular signal transduction pathways of insulin, reduce action of small GTPase, decrease peroxisome proliferator activated receptor gamma by inhibiting the differentiation of adipocytes, inhibit β -cell proliferation and insulin secretion by inhibiting leptins^[41]. Atorvastatin, a lipophilic statin, may decrease insulin secretion due to increased HMG-CoA inhibition or cytotoxicity^[42]. The actions of statins on beta cells of pancreas can be summarised^[43] as shown in Figure 1.

RECOMMENDATIONS FOR USE OF STATINS IN DIABETES

Authors have put forth the recommendations from time to time regarding the use of statins in patients with cardiovascular diseases. For patients with cardiovascular risk factors, statins prevent cardiovascular event 8 times more likely than they can cause a case of incident diabetes^[44] shifting the risk-benefit ratio in favour of statin therapy^[44]. Modest increase in blood glucose levels by statins will not be an issue of concern if they decrease morbidity and mortality due to macrovascular and microvascular complications^[45]. In patients with low cardiovascular risk factors, statins should be cautiously used, less aggressive LDL-C-lowering targets should be kept and monitoring of fasting blood glucose levels should be done routinely^[46].

In high risk patients with impaired glucose tolerance and established cardiac risk factors, statins and diuretics increased the risk of new onset diabetes. As both the drugs have a propensity to increase blood glucose levels, there is a need of regular monitoring^[47]. As compared to other cardiovascular medications like thiazide diuretics and beta blockers, statins can three times less likely cause diabetes^[48].

When statins are being used in primary prevention patients at high risk of diabetes, pravastatin should be preferred over other statins^[29]. One of the meta-analysis comparing high-dose statin therapy with moderate dose found that the former is associated with improved cardiovascular outcomes, though at the same time there was a 12% increased risk of new-onset diabetes mellitus^[49]. Such studies have stimulated the controversy about the treatment of patients not attaining target lipid profile on moderate dose of statins^[49].

Figure 1 Actions of statins on beta cell of pancreas^[43]. HMG-CoA: 3-hydroxy-methylglutaryl coenzyme A; NO: Nitric oxide; LDL: Low density lipoprotein.

Increasing age increases the risk of diabetes and benefits secondary to statins can decrease. There is a need to be vigilant in these patients^[50]. Factors like older age, increased weight, and higher blood sugar levels before the use of statins predict that whether a patient will develop diabetes mellitus. The use of statins can unmask diabetes mellitus in patients with other risk factors^[51]. So in obese patients and those with metabolic syndrome these findings may be relevant^[52]. While analysing one of the initial studies which suggested the link between statins and diabetes, it was found that rate of reduction of cardiovascular events outbalanced the risk of incident diabetes even in patients at highest risk for diabetes though the absolute risk increase was small (placebo 1.2%, rosuvastatin 1.5% developed diabetes^[53]). Meta-analysis of individual data of over 170000 persons from 27 randomized trials also put forth the risk benefit ratio in favour of statins^[54]. In patients on statins, there was an improved outcome after cardiac surgery^[55]. Current guidelines recommend use of statins in patients undergoing coronary artery bypass graft^[56]. Statins can reduce cardiovascular complications like atrial fibrillation and MI after cardiac surgery, but at the same time poor glycemic control may lead to deterioration of non-cardiovascular complications like infections and renal complications^[33].

Elevated triglycerides and low HDL-C are associated with type 2 diabetes mellitus. The evidence for drugs targeting this type of dyslipidemia is not as strong as those targeting LDL-C^[57].

To conclude, physicians should be cautious about development of diabetes in patients on intensive statin therapy^[26]. Lifestyle management should be considered in patients with low risk of cardiovascular diseases^[58] and the use of statins should be reconsidered^[58]. In patients with cardiovascular risk factors, the benefits of statins supersede the risk of diabetes^[59]. There is a need

of randomized clinical trials to find the role of statins on microvascular complications as the existing evidence only shows a benefit on macrovascular complications^[60]. Overall evidence at present shows that the risk of new onset diabetes is less as compared to the long term benefits of statins in patients with cardiovascular risk factors. But there is a small subgroup of population in whom a more careful use of statins is mandatory.

Abstract

AIM: To investigate the association of 10 known common gene variants with susceptibility to type 2 diabetes mellitus (T2D) among Omanis.

METHODS: Using case-control design, a total of 992 diabetic patients and 294 normoglycemic Omani Arabs were genotyped, by an allelic discrimination assay-by-design TaqMan method on fast real time polymerase chain reaction system, for the following gene variants: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398), *CDKN2A/B* (rs10811661), *FTO* (rs9939609 and rs8050136), *IGF2BP2* (rs4402960), *SLC30A8* (rs13266634) *CAPN10* (rs3792267) and *HHEX* (rs1111875). T2D patients were recruited from the Diabetes Clinic ($n = 243$) and inpatients ($n = 749$) at Sultan Qaboos University Hospital (SQUH), Muscat, Oman. Adult control participants ($n = 294$) were volunteers from the community and from those visiting Family Medicine Clinic at SQU, for regular medical checkup. The difficulty in recruiting Omani participants with no family history of diabetes was the main reason behind the small number of control participants in this study. Almost all volunteers questioned had a relative

with diabetes mellitus. In spite of the small number of normoglycemic controls in this study, this sample was sufficient for detection of genes and loci for common alleles influencing T2D with an odds ratio of ≥ 1.3 reaching at least 80% power. Data was collected from June 2010 to February 2012.

RESULTS: Using binary logistic regression analysis, four gene variants showed significant association with T2D risk: *KCNJ11* (rs5219, $P = 5.8 \times 10^{-6}$, OR = 1.74), *TCF7L2* (rs7903146, $P = 0.001$, OR = 1.46), *CDKAL1* (rs10946398, $P = 0.002$, OR = 1.44) and *CDKN2A/B* (rs10811661, $P = 0.020$, OR = 1.40). The fixation index analysis of these four gene variants indicated significant genetic differentiation between diabetics and controls {[*KCNJ11* (rs5219), $P < 0.001$], [*TCF7L2* (rs7903146), $P < 0.001$], [*CDKAL1* (rs10946398), $P < 0.05$], [*CDKN2A/B* (rs10811661), $P < 0.05$]}. The highest genotype variation % between diabetics and controls was found at *KCNJ11* (2.07%) and *TCF7L2* (1.62%). This study was not able to detect an association of T2D risk with gene variants of *IGF2BP2* (rs4402960), *SLC30A8* (rs13266634), *CAPN10* (rs3792267) and *HHEX* (rs1111875). Moreover, no association was found between *FTO* gene variants (rs9939609 and rs8050136) and T2D risk. However, T2D risk was found to be significantly associated with obesity ($P = 0.002$, OR = 2.22); and with the Waist-to-Hip ratio ($n = 532$, $P = 1.9 \times 10^{-7}$, OR = 2.4), [among males ($n = 234$, $P = 1.2 \times 10^{-4}$, OR = 2.0) and females ($n = 298$, $P = 0.001$, OR = 6.3)].

CONCLUSION: Results confirmed the association of *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661) gene variants with susceptibility to T2D among Omani Arabs.

INTRODUCTION

Type 2 diabetes mellitus (T2D) is one of the most common non-communicable diseases globally. Insufficient compensatory insulin secretion due to insulin resistance causes T2D. Insulin resistance is, mostly, an early event due to environmental factors, such as obesity. Decline in β -cell function is gradual but generally a late event^[1]. In addition to the environmental factors, there is strong evidence that genetic factors play an important role in the pathogenesis of T2D^[2].

Candidate gene approach identified few T2D susceptibility gene variants: *Pro12Ala* (rs1801282) in the coding region of peroxisome proliferator-activated receptor γ gene and it is the more common proline allele that is associated with T2D^[3]; *E23K* (rs5219) in the coding region of the subunit kir6.2 of the ATP-sensitive potassium channel gene of β -cells (*KCNJ11*)^[4] and a series of polymorphisms and haplotypes (UCSNP-43 or rs3792267; UCSNP-19 or rs3842570 and UCSNP-63 or rs5030952) in the coding region of the cysteine protease calpain 10 (*CAPN10*)^[5].

Genome-wide association studies (GWAS) of T2D susceptibility genes and loci and their meta-analysis identified a large number of gene variants and confirmed the previously discovered ones^[6]. The common intronic variants within the transcription factor 7-like 2 (*TCF7L2*) gene was reported as the strongest genetic risk factor for T2D^[7]. Other loci most consistently associated with T2D risk include variants within or near the solute carrier family 30/zinc transporter (*SLC30A8*), hematopoietically expressed homeobox (*HHEX*), cyclin-dependent kinase 5 regulatory subunit-associated protein 1-like 1 (*CDKAL1*), insulin-like growth factor 2 mRNA-binding protein 2 (*IGF2BP2*), a genomic region between cyclin-dependent kinase inhibitor 2A/B (*CDKN2A/B*) and fat mass and obesity associated protein (*FTO*)^[6,8].

In total, approximately, forty four common T2D susceptibility gene variants and loci have been identified to-date, but all these variants could only explain approximately 10%-15% of the heritability of T2D; which suggests that more variants remain to be discovered^[9]. Rare large-effect mutations have recently been recognized as causes of many complex diseases^[10-12].

According to the international diabetes federation, six out of the world's top ten countries with the highest prevalence (%) of T2D among adults aged 20-79 years, in 2011, are in the Middle East and North Africa region; Kuwait (21.1%), Lebanon (20.2%), Qatar (20.2%), Saudi Arabia (20.0%), Bahrain (19.9%) and

United Arab Emirates (19.2%). Small studies were conducted among Arabs, with a limited number of participants, to investigate genetic susceptibility for T2D^[7,13-24].

The prevalence of diabetes in Oman, in 2011, was estimated to be 10.8%; with a further 9.7% of the population at high risk of diabetes with impaired glucose tolerance, (<http://www.idf.org/diabetesatlas/content/what-is-diabetes>). Oman has a high inbred population and consanguineous marriages are about half of all marriages^[25]. Therefore, genetic factors might play an important role in the pathogenesis of T2D among Omanis.

In the present study, 10 known common gene variants, described previously, were examined for their association with susceptibility to T2D among Omani Arabs using case-control study design. Selection of variants was predominantly based on earlier GWAS studies, which extensively investigated T2D and showed a significant association of those variants with the highest odds ratios (ORs) among all the genes/loci discovered^[4-8,26].

MATERIALS AND METHODS

Sample size

For determining the sample size, we employed the Power Calculator for Genetic Studies developed by Skol *et al.*^[27] (2006) in their Website <http://www.sph.umich.edu/csg/abecasis/CaTS/index.html>. We used a T2D prevalence of 10% in the adult population of the Region as reported previously^[28,29]. We also anticipated disease allele frequencies of ≥ 0.25 , and assumed a multiplicative disease model^[30]. An optimum one-stage sample was deduced from the Power Calculator: 1000 cases and 1000 controls, will guarantee detection of genes and loci for common alleles influencing T2D with an OR of ≥ 1.2 reaching at least 80% power. However, we could not collect the required sample size, and only 992 cases and 294 controls were collected. This sample will guarantee detection of genes and loci for common alleles influencing T2D with an OR of ≥ 1.3 reaching at least 80% power.

Study population

A total of 992 T2D Omani Arab patients and 294 normoglycemic Omani Arab controls were included in this study. T2D patients were recruited from the Diabetes Clinic ($n = 243$) and inpatients ($n = 749$) at Sultan Qaboos University Hospital (SQUH), Muscat, Oman. A history of T2D among patients was ascertained from the diagnosis and medical history deposited in the electronic records of the hospital information system. Exclusion criteria for T2D patients included: patients diagnosed with type 1 diabetes; maturity onset diabetes of the young; positive diabetic antibodies (islet cell antibodies and glutamic acid decarboxylase antibodies) or patients diagnosed with any type of cancer. Adult

control participants ($n = 294$) were volunteers from the community and from those visiting Family Medicine Clinic at SQU, for regular medical checkup. The inclusion criteria for controls were: Omani, age ≥ 35 years, no family history of diabetes (first degree relatives) and with fasting glucose value of < 6.1 mmol/L, according to the World Health Organization 2006 criteria. The difficulty in recruiting Omani participants with no family history of diabetes was the main reason behind the small number of control participants in this study. Almost all volunteers questioned had a relative with diabetes mellitus (DM). Data was collected from June 2010 to February 2012. Participants were informed about the project and written consents were obtained. The study was approved by the Ethics and Research Committee of the College of Medicine, Sultan Qaboos University, Muscat, Oman.

Anthropometric and biochemical parameters

T2D patients and normoglycemic control participants underwent demographic, anthropometric and biochemical investigations, summarized in Table 1. Anthropometric variables measured were: weight, height, waist and hip circumference. Obesity status was defined according to the international classification of an adult's weight (http://apps.who.int/bmi/index.jsp?introPage=intro_3.html), [normal body mass index (BMI): 18.5-24.99 kg/m², overweight: 25.00-29.99 kg/m² and obese ≥ 30.00 kg/m²]. The biochemical investigations included: fasting glucose level and HbA_{1c}. To compare T2D patients and normoglycemic control participants' obesity status, we selected 294 T2D patients; age and sex matched with the normoglycemic control participants ($n = 294$). Waist-to-Hip ratio (WHR) was also calculated among T2D patients and control participants. Health risk based solely on the WHR, was identified according to the ranges specified at waist-to-hip ratio chart (<http://www.bmi-calculator.net/waist-to-hip-ratio-calculator/waist-to-hip-ratio-chart.php>) for males (low risk = 0.95 or below, moderate risk = 0.96-1.0, high risk = over 1.0) and females (low risk = 0.80 or below, moderate risk = 0.81-0.85, high risk = over 0.85).

Genotyping

All participants ($n = 1286$) were genotyped for the following gene variants: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398), *CDKN2A/B* (rs10811661), *FTO* (rs9939609 and rs8050136), *IGF2BP2* (rs4402960), *SLC30A8* (rs13266634), *CAPN10* (rs3792267) and *HHEX* (rs1111875). Genotyping was done by an allelic discrimination assay-by-design TaqMan method on 7500HT fast real time polymerase chain reaction system (Applied Biosystems, United States). Accuracy was achieved by duplicating approximately 10% of the samples.

Statistical analysis

The SPSS statistical package software (v20.0) was

Table 1 Anthropometric and biochemical characteristics of Omani type 2 diabetes mellitus patients and controls

¹Median (range = minimum-maximum) displayed in the table when the variable does not follow a normal distribution pattern. In all parameters, $P < 0.001$ between diabetics and controls, except: NS; ^a $P < 0.05$ between diabetics and controls; ^b $P < 0.01$ between diabetics and controls. NS: No significant difference between diabetics and controls; T2D: Type 2 diabetes mellitus; BMI: Body mass index.

used for statistical analysis of measured parameters. The measured anthropometric and biochemical parameters were tested for normal distribution using one sample Kolmogorov-Smirnov test. Independent sample *t*-test was used to test the significance of the difference in the mean values for the measured anthropometric and biochemical parameters between T2D patients and control participants with a normal distribution, while the Mann-Whitney *U* test was used for variables with skewed distribution.

The frequencies of the risk allele for each gene variant were calculated for T2D patients and normoglycemic control participants. The proportions of the genotypes of the gene variants were tested for departures from Hardy-Weinberg equilibrium (HWE) for both groups using population genetics software GenAEx 6.3 (Genetic analysis in Excel, version 6.3)^[31]. However, in case-control studies, HWE should be applied only to controls because a deviation from HWE in cases may indicate a genetic association^[32,33].

Genotyping data were further analyzed using GenAEx 6.3^[31] and Arlequin 3.1 software^[34]. For each polymorphism, GenAEx was used to calculate fixation index (*F*), heterozygosity (*He*) and *F*_{st}, which provides a measure of genetic differentiation among subpopulations (T2D patients and control populations). Arlequin was used to calculate genotype's % variation among the subpopulations and its level of significance.

Binary logistic regression analysis on the SPSS statistical package was used to test the association between each gene variant and susceptibility to T2D, adjusted for age, sex and BMI. Bonferroni correction was applied for multiple testing and adjusted *P* values were calculated to be 0.005. Beta coefficients, ORs and 95%CI were also estimated. An OR is a measure of association between an exposure and an outcome. It is measured as an exponential function of the regression

beta coefficient value ($e^{\text{beta coefficient}}$).

The association between obesity status of participants and *FTO* gene variants (rs9939609 and rs8050136) was also tested. In addition, obesity and health risk status, based on the WHR, were tested for their association with T2D risk.

RESULTS

Anthropometric and biochemical characteristics of all participants are summarized in Table 1. About 48% of the T2D patients and 41% of the control participants were males. The mean age of T2D patients (56 years) was higher than that of the normoglycemic control participants (45 years). T2D patients had significantly higher weight, BMI, waist circumference, fasting glucose values and HbA_{1c} % levels compared with control subjects (Table 1). Eighty five percent of the T2D Omani patients were overweight to obese in comparison to 78.5% of the control Omani participants. Half of the T2D patients and 39.6% of the control participants were obese. T2D risk was found to be significantly associated with obesity ($P = 0.002$, OR = 2.22); and with the WHR ($n = 532$, $P = 1.9 \times 10^{-7}$, OR = 2.4), [among males ($n = 234$, $P = 1.2 \times 10^{-4}$, OR = 2.0) and females ($n = 298$, $P = 0.001$, OR = 6.3)].

Among control participants, there were no significant deviation in the proportions of gene variant frequencies from HWE except in *SLC30A8* (rs13266634) ($P = 2.35 \times 10^{-4}$, $\chi^2 = 13.5$) gene variant. However, among T2D patients, there were significant deviations in: *KCNJ11* (rs5219) ($P = 4.14 \times 10^{-9}$, $\chi^2 = 34.6$), *CDKAL1* (rs10946398) ($P = 0.008$, $\chi^2 = 6.9$) and *IGF2BP2* (rs4402960) ($P = 0.038$, $\chi^2 = 4.3$) gene variants.

The risk allele frequencies of the tested variants for diabetic and control participants are summarized in Table 2. Using binary logistic regression analysis,

Table 2 Risk allele frequencies for the tested gene variants among Omani type 2 diabetes mellitus patients and control participants

Gene	Gene variant (SNPs)	Risk/non-risk allele	Risk allele frequency (f)		¹ P value	OR	95%CI for OR
			T2D patients (n = 992)	Controls (n = 294)

This provides a measure of genetic differentiation among population; ¹P value: Level of significance; F: Fixation index; He: Heterozygosity; Fst: The inbreeding coefficient within subpopulation, relative to total; T2D: Type 2 diabetes mellitus.

four gene variants out of 10 showed statistically significant association ($P < 0.05$) with susceptibility to T2D: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661), Table 2. After correction for multiple testing, *KCNJ11*, *TCF7L2* and *CDKAL1* gene variants still showed a significant association ($P < 0.005$) with T2D.

Fst values, showed statistically significant genetic differentiation between T2D patients and controls (Table 3), in the following gene variants: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661). These findings confirmed the results obtained using binary logistic regression analysis.

This study was not able to detect an association of T2D risk with gene variants of *IGF2BP2* (rs4402960), *SLC30A8* (rs13266634), *CAPN10* (rs3792267) and *HHEX* (rs1111875). Moreover, no association was found between *FTO* gene variants (rs9939609 and rs8050136) and T2D risk.

DISCUSSION

In this study, four gene variants showed significant association with T2D risk using binary logistic regression analysis after adjustment for confounding factors

of age, sex and BMI: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661). The association of *KCNJ11* (rs5219), *TCF7L2* (rs7903146) and *CDKAL1* (rs10946398) gene variants with T2D risk remained significant after correction for multiple testing. Fst, a measure of genetic differentiation among subpopulations (diabetics and controls), confirmed the significant risk difference between diabetics and controls at the four gene loci [*KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661)]. The highest genetic variation between diabetics and controls was found in *KCNJ11* and *TCF7L2* gene variants (Table 3). However, none of the other gene variants previously reported in GWAS were found to be associated with risk to T2D in Omanis.

KCNJ11 (rs5219) gene variant was found to be associated with T2D risk among Omani Arabs with an OR of 1.74, which is higher than that reported in previous European studies. Our findings were consistent with what was reported among Saudi Arabs (OR = 1.7), although the risk allele frequency was found to be lower among Saudis compared to Omani Arabs^[16]. However, in both Arab studies the association may be overestimated due to the small number of participants included or due to a high-inbred population.

In contrast, no association of this gene variant with susceptibility to T2D was found among Tunisian Arabs^[14]. Large scale studies and meta-analysis of the *KCNJ11* gene variants have shown that the lysine variant of the rs5219 gene loci resulting in a 1.15 times higher risk of developing T2D^[4,35] and GWAS studies confirmed this association^[26,36,37]. The rs5219 variant is located within the N-terminal of the subunit kir6.2 of the ATP-sensitive potassium channel gene of β -cells and can cause spontaneous hyperactivity of pancreatic beta-cells and reduced sensitivity of KATP channels to ATP, resulting in impaired insulin secretion^[38].

Although this study is relatively small, the association of *TCF7L2* (rs7903146) gene variant with T2D risk among Omani Arabs is consistent with previous large GWAS studies^[14,15,22,36,37,39-44]. The association of *TCF7L2* gene variants with susceptibility to T2D was marginal between the rs12255372 gene variant and T2D risk among Emirati Arabs; but not in Saudi Arabs^[13,17]. In contrast, subsequent studies among North African Arabs (Tunisians and Moroccans), Palestinians and Iranians, confirmed the association of *TCF7L2* (rs7903146) gene variant with susceptibility to T2D^[7,14,15,22]. Comprehensive genotyping studies across the *TCF7L2* gene showed that the rs7903146 variant to be consistently associated with T2D among European with an OR of 1.37 (1.28 to 1.47)^[45,46]. Meta-analysis of 27 different studies found a global OR of 1.46 (95%CI: 1.42-1.51)^[7]. The common variants in the *TCF7L2* gene predispose to T2D by reducing beta-cell function and insulin secretion. *TCF7L2* mRNA levels in human pancreatic islets increase with the number of risk alleles and are fivefold higher in T2D patients than in controls pancreatic islets, and over-expression of *TCF7L2* leads to reduced glucose stimulated insulin secretion^[47].

CDKAL1 (rs10946398) gene variant's OR was found to be 1.44 among Omani Arabs, which may be overestimated due to the small number of participants. Variants at *CDKAL1* gene loci showed an association with T2D risk among Caucasians^[26,36,37], Asians^[48,49], African Americans^[50] and Arabs^[22,24]. A recent meta-analysis of *CDKAL1* (rs10946398) gene variant showed a significant association of this variant with susceptibility to T2D risk (OR = 1.12)^[51]. Another study among Russian population showed a significant association of the C allele with higher risk of T2D^[52]. The *CDKAL1* gene encodes cyclin-dependent kinase 5 (CDK5) regulatory subunit-associated protein 1-like 1. The CDK5 is a serine/threonine enzyme that inhibits both Ca^{2+} efflux into the beta-cell and insulin secretion, while inhibition of this enzyme results in enhanced insulin secretion^[53].

The association of *CDKN2A/B* (rs10811661) gene variant with susceptibility to T2D risk among Omanis was also confirmed in this study (OR = 1.40), in agreement with a recent large study among North African Arabs^[22]. In contrast, this gene variant was not found to be associated with T2D risk in other Arab studies^[24,54]. Previous studies among European populations have

shown an association with an OR of 1.20^[26,36,37]. A recent meta-analysis concluded that the T allele of rs10811661 is a risk factor of T2D both in Asians and Europeans^[55]. *CDKN2A* and *CDKN2B* genes encode p16^{INK4a} and p15^{INK4b}, which inhibit CDK4 and CDK5, respectively. CDK4 and CDK5 play an important role in β cell function and regeneration^[55].

FTO gene variants (rs9939609 and rs8050136) have been shown to associate with BMI and obesity^[8,56] and GWAS studies of T2D have also suggested the involvement of *FTO* gene in T2D pathogenesis through obesity^[8,26]. It is surprising, therefore, that we could not detect an association of T2D risk with *FTO* gene variants (rs9939609 and rs8050136). This could be attributed to the fact that both diabetics and controls have similar distributions of body weight. The impact of the *FTO* gene variants on T2D risk through obesity, seen in other populations, was not observed here. Hennig *et al.*^[57] tested the effect of *FTO* variants on measures of BMI in a population of lean Gambians (Africans) and also found no association. However, this study showed a significant association between obesity and T2D risk; and between health risk, based on the WHR, and T2D risk among males and females.

In spite of the small number of participants examined in this case-control study, we were able to confirm the effect of four common gene variants on T2D risk among Omani Arabs. Oman has a homogeneous population due to a high level of inbreeding and the tradition of consanguineous marriages. The difficulty in recruiting Omani participants with no family history of diabetes was the main reason behind the small number of control participants in this study, where, almost everybody has a relative with DM. This might have raised risk allele frequencies of *T2D* gene variants and made it easier to detect.

All previous GWAS identified common gene variants, which could only explain 10%-15% of the heritability of T2D. Large studies with new strategies, other than the classic case-control study design, are required to find the hidden heritability due to rare variants behind developing T2D among Omani and other Arab populations.

Limitation of this study was the lack of oral glucose tolerance test, where we could not run the test among the control group. However, the strength of this study was that the control participants were with no family history of diabetes.

This study confirmed the effect of four common gene variants on T2D risk among Omani Arabs: *KCNJ11* (rs5219), *TCF7L2* (rs7903146), *CDKAL1* (rs10946398) and *CDKN2A/B* (rs10811661). However, we could not detect the association of other known common gene variants with susceptibility to T2D.

ACKNOWLEDGMENTS

We are grateful to the Deanship of postgraduate studies at Sultan Qaboos University, Muscat, Oman

for the PhD grant to SS. We thank Nassra Al Maani and Ranjitha K Sukumaran for their contribution to collection of patients data. Special thanks to Hameeda Al Barwany, Najma Al Kharousi, Zainab Al Hashami, Laila Al Hinai and Sameera Al Harrasy for their help in analyzing samples. We also thank George Khaukha, Mohammed Al Kindi, Mohammed Al Tob, AbdulRahim Al Abri and Taruna Dutt for their support. We are grateful to the staff of the diabetes clinic at SQUH and FAMCO clinic at SQU for their help and support. We also are obliged to the office of educational supervision/Al Seeb, Directorate General of Education in Muscat, for their support and help in controls collection. We are indebted to all subjects who participated in this study.

COMMENTS

Background

Type 2 diabetes mellitus (T2D) is one of the most common non-communicable diseases globally. Insufficient compensatory insulin secretion due to insulin resistance causes T2D. In addition to the environmental factors, there is strong evidence that genetic factors play an important role in the pathogenesis of T2D.

Research frontiers

Oman has a high inbred population and consanguineous marriages are about half of all marriages. Therefore, genetic factors might play an important role in the pathogenesis of T2D among Omanis.

Innovations and breakthroughs

In the present study, 10 known common gene variants were examined for their association with susceptibility to T2D among Omani Arabs using case-control study design. Selection of variants was predominantly based on earlier Genome-wide association studies, which extensively investigated T2D and showed a significant association of those variants with the highest odds ratios among all the genes/loci discovered.

Applications

Large studies with new strategies, other than the classic case-control study design, are required to find the hidden heritability due to rare variants behind developing T2D among Omani and other Arab populations.

Terminology

T2D is one of the most common non-communicable diseases globally, and it is a result of insufficient compensatory insulin secretion due to insulin resistance. Candidate gene approach focuses on associations between genetic variation within pre-specified genes of interest and phenotypes or disease states. Genome-wide association studies scan the entire genome for common genetic variation.

Peer-review

This is a well-written and interesting paper evaluating the association between a variety of gene polymorphisms and the risk for type 2 diabetes mellitus.

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Shan-Dong Ye, MD, Professor, Department of Endocrinology, Anhui Provincial Hospital, No. 17, Lujiang Road, Hefei 230001, Anhui Province, China

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

causing weight loss dependent glucose intolerance, bariatric surgery induces other physiological changes that contribute to the alleviation of diabetes. However, the putative post-surgical neuro-hormonal pathways that underpin the therapeutic benefits of bariatric surgery remain undefined. In a recent report, Ryan and colleagues shed new light on the potential mechanisms that determine the salutary effects of bariatric surgery in mice. The authors demonstrated that the improved glucose tolerance and weight loss in mice after vertical sleeve gastrectomy (VSG) surgery were likely to be caused by post-surgical changes in circulating bile acids and farnesoid-X receptor (FXR) signaling, both of which were also mechanistically linked to changes in the microbial ecology of the gut. The authors arrived at this conclusion from a comparison of genome-wide, metabolic consequences of VSG surgery in obese wild type (WT) and FXR knockout mice. Gene expression in the distal small intestines of WT and FXR knockout mice revealed that the pathways regulating bile acid composition, nutrient metabolism and anti-oxidant defense were differentially altered by VSG surgery in WT and FXR^{-/-} mice. Based on these data Ryan *et al*, hypothesized that bile acid homeostasis and FXR signaling were mechanistically linked to the gut microbiota that played a role in modulating post-surgical changes in total body mass and glucose tolerance. The authors' data provide a plausible explanation for putative weight loss-independent benefits of bariatric surgery and its relationship with metabolism of bile acids.

Abstract

Bariatric surgeries have emerged as highly effective treatments for obesity associated type-2 diabetes mellitus. Evidently, the desired therapeutic endpoints such as rates of weight loss, lower levels of glycated hemoglobin and remission of diabetes are achieved more rapidly and last longer following bariatric surgery, as opposed to drug therapies alone. In light of these findings, it has been suspected that in addition to

Core tip: The report of Ryan *et al*, raises a number of questions with regard to the prevailing notion that

mechanical restriction of the stomach and weight loss are the sole mechanisms that mediate the therapeutic effects of bariatric surgery. The authors showed that both lowering of body mass index and improved glucose tolerance after vertical sleeve gastrectomy (VSG) surgery were mechanistically linked to an altered composition of circulating bile acids and their ability to modulate farnesoid-X receptor (FXR) mediated signaling mechanisms. Additionally, it was observed that the wild type and FXR knockout mice, after receiving VSG surgery, were significantly different with respect to the make up of their gut microbiomes. Finally, the experiments revealed that the composition of gut microbiota in wild type VSG and FXR^{-/-} VSG mice were highly correlated with their differential abilities to lose weight and acquire glucose tolerance.

Raghow R. Ménage-à-trois of bariatric surgery, bile acids and the gut microbiome. *World J Diabetes* 2015; 6(3): 367-370 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/367.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.367>

COMMENTARY ON HOT TOPICS

The provocative mechanism proposed by Ryan *et al*^[1], that mechanistically links bile acids, farnesoid-X receptor (FXR) nuclear receptor signaling and microbial ecology of the gut to therapeutic superiority of bariatric surgery over intensive drug therapies, opens up new avenues of clinical research that deserves serious consideration.

According to the World Health Organization (WHO), obesity associated type-2 diabetes mellitus (T2DM) and cardiovascular diseases represent a looming health-care crisis of the 21st century [WHO Global Infobase: data on overweight and obesity mean body mass index (BMI), healthy diets and physical inactivity; www.who.int/mediacentre/]. Traditionally, obesity, T2DM and their co-morbidities have been treated with anti-diabetic drugs combined with behavioral modification therapies (e.g., better nutrition and regular exercise). However, in recent years, a number of surgical interventions, that include Roux-en Y gastric bypass, vertical sleeve gastrectomy (VSG), laparoscopic adjustable gastric banding and bilio-pancreatic diversion, have emerged as highly effective treatments for obesity-associated diabetes^[2].

There is a growing body of evidence to indicate that patients undergoing bariatric surgery, achieve desirable clinical endpoints more rapidly and for a longer duration compared with therapeutic benefits obtained with anti-diabetic drug therapy alone^[2]. A recently completed, randomized clinical trial revealed that the superior post-surgical therapeutic benefits (e.g., improved glucose tolerance and lower BMI) of bariatric surgery over intensive drug treatment persisted for at least three years, when the study ended. Additionally, patients

receiving bariatric surgery not only achieved their main therapeutic goal of weight loss and alleviation of diabetes but also enjoyed a better quality of life, with fewer obesity-associated complications^[3]. Similar beneficial effects of bariatric surgery have also been observed in rodent models of obesity^[4,5]. The strikingly more effective therapeutic outcomes of surgical procedures over pharmacological and behavioral interventions in the treatment of obesity-associated diabetes represent an unsolved medical puzzle^[6,7].

The hormonal and metabolic underpinnings of surgical interventions and how they differ from conventional drug therapy in shaping the anabolic and catabolic pathways are being actively pursued^[6-8]. Obviously, much of this research is prompted by a desire to define the basic mechanisms involved in the clinical outcome of bariatric surgery. An additional motivation for such studies is the fact that bariatric surgery poses definite risks, and thus there is an urgent need for safer, less invasive therapies to assuage obesity associated diabetes and its complications. Investigations into the putative mechanisms that differentially regulate the therapeutic outcomes of bariatric surgery vs conventional drug therapies have led to somewhat conflicting findings^[6,9,10]. According to the prevailing view, a reduced intake and absorption of macronutrients by surgically downsized stomach is responsible for the post-surgical insulin sensitivity and weight loss after bariatric surgery^[2]. Although this scenario is generally supported by the data gathered from rodent models of obesity and in humans, this mechanism fails to explain the paradoxical finding that a substantial fraction of patients experienced remission of their diabetes long before they exhibited a significant weight loss^[6,7]. This has led some investigators to posit that in addition to causing weight loss bariatric surgery also leads to other physiological changes in the gastrointestinal (GI) tract. One of the key pieces of evidence in support of this view includes post-surgical changes in circulating bile acids seen in both rodents and humans after bariatric surgery^[11,12]. It has been suggested that simultaneous changes in the composition of bile acids and gut microbiota may be causally related to obesity and a loss of BMI^[13,14]. A highly revealing study, carried out with human twins discordant for obesity, showed that obese and lean individuals had unique gut microbial ecology; transplantation of the fecal microbiota from the obese or lean patients conferred analogous BMI and adiposity to the germ-free mice^[15]. Differences in body composition were correlated with differences in the metabolism of short chain fatty acids, branched chain amino acids, and altered bile acids and FXR signaling^[15]. These tantalizing correlations notwithstanding, the underlying mechanism by which gut microbiota regulates total body weight and glucose tolerance remain to be fully elucidated.

The experiments of Ryan *et al*^[1], reported in a recent issue of *Nature*, bring us a step closer to defining the molecular interactions that mediate the metabolic effects of VSG surgery in mice. Since bariatric surgery is known

to enhance enterohepatic circulation of bile acids^[16] that signal *via* nuclear FXR, Ryan *et al*^[1] hypothesized that altered bile acid homeostasis and FXR signaling were mechanistically involved in the weight loss and glucose tolerance. To test this hypothesis, the authors compared the gene expression profiles in the distal small intestines of wild type (WT) and FXR knockout mice after VSG surgery. These analyses led to the discovery of "glutathione-mediated detoxification", "nuclear receptors in lipid metabolism and toxicity", "meta-pathway bio-transformation" and "type II interferon signaling" pathways that were highly suggestive of a role of the gut microbiome in the metabolic changes elicited by VSG surgery.

The authors undertook an empirical investigation of this hypothesis. The WT and FXR^{-/-} mice, kept on high fat diet to induce obesity, showed similar rates of body weight loss in the first week after surgery. However, the FXR^{-/-} mice were compromised with respect to sustained (at 5 wk and after) losses of BMI and body fat. Interestingly, while the WT and FXR^{-/-} mice consumed lower calories in the first week after surgery only the former continued to maintain their hypophagic behavior. The cumulative caloric intake by sham-operated and VSG FXR^{-/-} mice were similar; both cohorts of animals consumed 15% higher than VSG WT mice. Thus, the authors concluded that the inability of FXR^{-/-} animals for sustained loss of body weight and total body fat were a result of their feeding behavior. Since FXR^{-/-} mice were also refractory to the metabolic benefits of VSG surgery, it became apparent that the metabolic outcomes of surgery were also influenced by the genotype of the mice. Nevertheless, VSG surgery had a more pronounced effect on the bacterial ecology of the gut than the absence of a functional FXR gene. Un-weighted UniFrac-based comparison of bacterial 16S rRNA data in sham-operated and VSG mice revealed that the population of *Bacterioides* was significantly reduced after VSG surgery in WT mice whose guts also showed greater abundance of *Porphyromonadaceae* and *Roseburia*. Genotype independent post-surgical changes in the populations of *Lactobacilli* and *Lactococci* in the guts were also observed. The abundance of *Roseburia* in the WT VSG correlated negatively with glucose intolerance. The abundance of *Roseburia* in the guts of sham operated and VSG FXR^{-/-} was similar and was significantly lower than in WT VSG guts. Thus, the authors posited that a functional FXR signaling was involved in the mechanisms of VSG-induced weight loss, feeding behavior and insulin sensitivity.

The current study did not directly address the molecular basis of how FXR contributes to the metabolic consequences of VSG surgery. The authors acknowledged however^[1], that in light of the inherent signaling complexity of bile acids that activate FXR as well as a G-protein coupled receptor, takeda G-protein-coupled receptor-5^[16], the explanation of these data is unlikely to be straightforward. This sentiment is supported by the contradictory phenotype of FXR^{-/-}

mice elicited in this study; thus, FXR knockout mice were resistant to some of the deleterious effects of high fat diet while remaining less responsive to the therapeutic benefits of VSG surgery. The apparently paradoxical phenotype of FXR^{-/-} mice is likely to be caused by (1) unique tissue-specific mechanisms involved in the activation of FXR; and (2) a possible induction of compensatory mechanisms that result from a global knockout of FXR. The data contained in this paper also did not directly address the key question of how post-surgical changes in bile acids modulate the gut microbial ecology, and vice versa. Finally, a role of the gut microbiota in differentially regulating the metabolism and energetics of WT and FXR^{-/-} mice could only be speculated upon in light of the limited information contained in this paper. It worth remembering however, that a number of earlier studies were driven by the hypothesis that obesity-associated microbiome was more efficient at extracting energy from lipids and carbohydrates^[13,14]. The observed differences in the abundance of common fatty acids and related metabolites among the WT and FXR^{-/-} mice following VSG surgery were not sufficiently clear to warrant an unequivocal explanation. Nevertheless, the mechanism involving more efficient extraction of energy from macronutrients by the microbiota appears to be too simplistic in light of some recent data showing that changes in gut microbial ecology impinged on the signaling mechanisms underlying satiety and motility of the GI tract^[17,18]. Despite these caveats, the experiments of Ryan *et al*^[1], have broken a new ground in elucidating a functional connection of FXR signaling and microbial ecology with the metabolic consequences of bariatric surgery. These exciting findings deserve to be systematically validated and extended in humans with an aim to discover less invasive therapies to treat obesity and its complications.

especially true in children and adolescents as they have unique psychosocial and diabetes needs. Despite the development of effective in-person interventions targeting improving self-management and ameliorating psychosocial difficulties there are still a number of barriers to implementing these interventions, namely time, cost, and access. Telehealth interventions allow for the dissemination of these interventions to a broader audience. Self-management and psychosocial telehealth interventions are reviewed with a special emphasis on mobile phone and internet based technology use. While efficacy has been demonstrated in a number of telehealth interventions with improved cost effectiveness over in-person interventions, many challenges remain including high participant attrition and difficulties with receiving reimbursement for services rendered. These and other challenges are discussed with recommendations for researchers and telehealth providers provided.

Core tip: Type 1 diabetes is a chronic illness with a high burden of care. Despite the development of effective in-person interventions, telehealth interventions are necessary to improve access to and engagement in interventions to improve diabetes management. Mobile phone and internet based interventions appear to have the most potential to enact change. Challenges and recommendations for these telehealth interventions are provided.

Abstract

Type 1 diabetes is a chronic illness with a high burden of care. While effective interventions and recommendations for diabetes care exist, the intensive nature of diabetes management makes compliance difficult. This is

Balkhi AM, Reid AM, Westen SC, Olsen B, Janicke DM, Geffken GR. Telehealth interventions to reduce management complications in type 1 diabetes: A review. *World J Diabetes* 2015; 6(3): 371-379 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/371.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.371>

INTRODUCTION

The prevalence of chronic diseases, such as diabetes, cancer, cardiometabolic and respiratory conditions continues to pose a challenge for often overtaxed health care systems, requiring fundamental changes in the delivery and maintenance of patient care^[1-4]. Telehealth (TH), defined as any medical activity involving an element of distance and use of a telecommunications strategy^[5], represents an approach which may enable patients with chronic medical conditions to seek disease specific information and support^[6-9], to be followed by clinicians more frequently and away from hospital settings^[10-12], reduce healthcare costs^[13], and to ultimately promote improved adherence to medical regimens resulting in improvement in health outcomes^[14].

BRIEF HISTORY OF TH

While TH interventions began more than 50 years ago with closed-circuit television, research into TH interventions did not truly begin to accelerate until the 1990s with a dramatic increase in TH publications through the 2000s^[15,16]. Initial TH interventions primarily emphasized providing the same care that would be provided in-person through an intermediary such as a closed circuit television or telephone. A majority of interventions that subsequently developed relied on direct telephone contact by nurses or skilled health care professionals or transmission of simple self-management data *via* a modem^[15]. The primary strength of these early TH interventions was in providing care coordination with more frequent feedback and without an in-person visit, which resulted in cost savings and improved patient health^[14]. As technology advanced, TH interventions did as well, moving to material presented through video phones, home computers, pre-programmed interactive problem solving programs, and mobile phone and internet based interventions^[17,18]. The flexibility and cost effectiveness of TH makes it well suited to be used in the treatment of chronic illnesses such as diabetes.

Previous interventions have shown efficacy implementing TH for a variety of chronic conditions, including cancer, transplant recipients, heart failure, and chronic pulmonary disease^[3,7-10,12]. These interventions have shown support for TH in providing condition specific education, social support, and self management assistance. In addition, this previous work has demonstrated the wide acceptability of TH and the ability for TH interventions to reach previously underserved populations.

NEED FOR TH IN TYPE 1 DIABETES

Type 1 diabetes (T1D) is one of the most common chronic diseases in pediatrics in the United States and affects

more than 151000 youth under 20 years of age^[19]. Poorly controlled diabetes poses many serious health complications thus optimal T1D management during childhood and adolescence is necessary to reduce negative health outcomes and improve life expectancy^[19,20]. The management of T1D is a complex and challenging task that involves integration of daily medical tasks and lifestyle modifications. While demanding, the successful intensive management of T1D is associated with improved health outcomes and protections against complications that maintain for as many as 6-10 years following intensive management^[21].

Children and adolescents with T1D have unique needs that dictate different standards of care than adults^[22]. Despite parental involvement in diabetes management being common, non-adherence is especially high in the transition to and within adolescence, increasing the risk of immediate and future microvascular complications^[23-28]. T1D management is further complicated by the social, emotional, and psychological demands of the disease^[23]. Poor psychosocial wellbeing (*e.g.*, depression, anxiety, stress) is related to poorer short and long term health outcomes due to suboptimal disease management^[29-34]. Family functioning, parent wellbeing, and family cohesion have also been identified as an important contributor to diabetes control^[35-44]. Therefore, when evaluating T1D management interventions, assessing and addressing the impact of patient and parent psychosocial wellbeing while being flexible and developmentally sensitive to the needs of the patient is essential to ensure that the intervention has a lasting impact.

TH IN T1D

While previous in-person diabetes interventions have successfully targeted increasing patient knowledge^[45-47], improving illness perception^[48,49], fostering family communication and relationships^[50,51], and advancing technological accuracy and ease of management devices^[52-54], there are several remaining challenges to in-person interventions. Primary limitations of in-person interventions include poor ease of access for rural or underserved families, increased healthcare utilization costs, and poor attendance^[55,56]. Additionally, individuals at greater risk for medical regimen nonadherence are likely to also be individuals who are at greater risk for not attending medical appointments^[57], making traditional clinic based recruitment and interventions potentially ineffective. TH addresses many of the limitations of previous T1D interventions by providing a unique avenue for improving the management of T1D that is engaging, cost effective, and accessible^[58].

SELF MONITORING AND EDUCATION INTERVENTIONS

A hallmark of many TH interventions are to focus on providing education, improving self-monitoring through

electronic check ins, and establishing more frequent communication with health care providers. While traditional phone interventions have demonstrated positive improvements in glycemic control and self-efficacy^[59,60], the increased availability of smartphones and the internet facilitated further innovation and development. Deploying interventions on a mobile device, especially those compatible with text messaging, also proved effective in improving glycemic control in both adults and children^[59,61-64]. These results suggest that text messaging and intervention through mobile phones are a substantial area for outreach and intervention. However, despite the increased ownership of mobile phones among adults (91%) and adolescents (78%), there is still a substantial portion of individuals without a mobile phone or texting ability, especially among younger adolescents^[65,66]. Additionally, some interventions using text messaging or smartphone applications in children or adolescents have not shown an ability to improve glycemic control, although secondary benefits such as increased adherence, communication or knowledge are generally noted^[41,67-69]. As such, while mobile based interventions are promising, continued research into maximizing desired outcomes and cost-effectiveness is necessary.

Internet based interventions have the potential to overcome this limitation of mobile phone based interventions, because of the wide spread availability of the internet for adults (85%) and teens (95%) in the United States^[66,70,71]. The internet may be especially appropriate for diabetes intervention, as one study suggests that 63.6% of parents of children with T1D use the internet to seek out diabetes information on their own^[72]. For a child or adolescent with T1D, diabetes psychoeducation^[73], problem solving vignettes^[74], and physician monitoring of HbA1c and intervention^[75-77], have all recently shown moderate to strong evidence of successfully improving glycemic control when implemented in an online environment. Similar results have been found with adults; however, most studies rely on adults with T2D^[78-80]. Despite their demonstrated efficacy and the wide spread availability of the internet, the primary challenge that continues to plague internet based interventions is the decreased engagement and participation of users over time, with participant attrition rates of 11.5%-37% reported^[74,78].

Notwithstanding the challenges in self-management interventions, these interventions have demonstrated effectiveness in multiple delivery modalities including voice calls, SMS/Text messaging, email, customized web portals, and video conferencing^[61,81,82]. A systematic review revealed that telemedicine solutions for diabetes care are also feasible and acceptable to patients and providers^[59]. Therefore, future research is necessary to integrate the previously proven delivery strategies with new technology that is engaging to users and cost-

effective.

PSYCHOSOCIAL AND SUPPORTIVE TH INTERVENTIONS

Other TH interventions have strived to improve adherence by providing psychosocial support and decreasing family conflict around T1D management. One such method of intervention developed by Grey *et al.*^[73] bundled effective psychoeducation intervention with Coping Skills Training which improved glycemic control, quality of life, social acceptance, and self-efficacy which maintained for a year after beginning the online program (which was only 5 wk in duration). Self-efficacy has also been targeted as a potential area of psychosocial intervention, with online interventions demonstrating a significant positive impact on self-care activities^[83]. Individual wellbeing has also been successfully addressed with web-based Cognitive Behavioral Therapy and peer mentoring^[84,85]. Taken together, the existing psychosocial interventions for patients with T1D have shown success in engaging patients and improving psychological wellbeing, but are mixed on their abilities to minimize attrition and improve objective measures of glycemic control (*i.e.*, HbA1c).

TH interventions have also been utilized to support the family and environment of patients with T1D. These interventions have successfully improved communication, improved HbA1c levels, and quality of life suggesting that targeting those supporting the individual with T1D (*i.e.*, nurses, physicians, and family) may also be an effective way to improve T1D health outcomes^[81]. There also appears to be awareness from family members and service providers of their need to find information and support regarding T1D care and a preference for online interventions^[86]. One way to reach supporting individuals and patients may be to extend interventions to build on pre-existing online networks and supports. Social networks and forums for T1D have been qualitatively examined; despite concerns regarding the quality of the information presented on these sources, it is clear that patients and family members actively use these online sources (such as Facebook and online message boards) for diabetes information and social support^[6,87-90]. Most notably, in one study 84.3% of caregivers that used online forums reported that their child's care was impacted by information they encountered online^[6]. Recent data also suggests that more than half of parents within a pediatric T1D clinic use the internet to seek out T1D information^[72]. This identifies pre-existing internet sources as a potentially strong source for information dissemination but also as a potential venue for the unintended spread of misinformation. While prospective studies are needed to understand the association between parents' use of online forums and their child's glycemic control, these may be an appropriate area for

future intervention.

ONGOING CHALLENGES IN TH

While research suggests that TH for patients with T1D can be a useful and effective method of improving glycemic control and overall adherence, there has been a significant delay in transitioning efficacious research interventions of T1D into community treatment settings. Chief among these issues are the financial feasibility and reimbursement for services delivered by skilled staff, creating and maintaining patient involvement in TH interventions while minimizing patient attrition, and ensuring patient safety, privacy, and legal accountability.

FINANCIAL CHALLENGES

A key challenge that permeates across the literature in TH is the difficulty in obtaining reimbursement for services. The literature suggests that providers' experience of receiving reimbursement varies significantly^[91-93]. As of this publication only 15 states in the United States mandate coverage for TH services with 39 states providing at least some reimbursement for TH, although dramatically less so for behavioral TH despite behavioral TH's appropriateness^[94,95]. Additionally, recent studies have suggested that private third party reimbursement is improving across the board, though the trajectory of these improvements continues to be slow^[93]. For example in 2005, 58% of TH programs received reimbursement for their services while in 2012, 45% of TH programs sought reimbursement and 81% of those reported receiving it^[92,93]. Obtaining grant funding to offset these costs increases the institution's ability to build a program^[92]; however, if program personnel lack information about how to obtain reimbursement for their services from third party payers, the program may be discontinued after the grant funding has remitted^[91,93]. This pattern of short term growth with long term discontinuation is concerning and hinders the growth of TH services.

The licensing and credentialing rules create another barrier to TH implementation. Similar to reimbursement regulations, there is a large discrepancy in state TH licensing laws. Current laws generally refer to the physical location of the patient as the place of service, regardless of the provider's location. Moreover, state laws generally require that providers be licensed and credentialed at the place of service, making state lines a finite barrier to service delivery^[91]. In 2011, Children's Medical Services (CMS) began to allow institutions to accept the credentialing of the provider's home institution instead of requiring the outside institution to put the provider through their credentialing process^[91]. The CMS regulations show promise for expanding the credentialing requirements and may facilitate providers' ability to reach patients who otherwise may not have been able to receive care. While efforts have been made to extend licensing adjustments by implementing

limited, federal, and reciprocal licenses, it is clear that the current system of licensure is hindering providers' ability to reach out to patients who live in other states and steps need to be made to resolve these concerns^[95].

PATIENT ENGAGEMENT AND ATTRITION

Attrition and noncompliance in TH interventions creates yet another barrier to successful establishment of TH interventions. As stated previously, attrition rates of 11.5%-37% among internet interventions have been reported^[74,78]. However, patients who complete TH interventions may also not adhere adequately to the intervention, given the lack of in-person oversight. In a study conducted by Wangberg^[83], participants were requested to repeatedly view and engage with online modules targeting self-efficacy and diabetes self-care, yet only 34% logged in more than twice to interact with the modules. Similarly, a review of TH adherence found a recurring theme in suboptimal frequency of uploading and submitting blood glucose values^[96]. Given these relatively high drop-out rates and problems with noncompliance, TH programs should incorporate measures to improve adherence and keep the patients engaged in treatment.

To this end, some studies have shown improved adherence when the TH interventions are tailored toward the patients unique needs by using customized messages, programs, or personalized functions within the program^[97]. For instance, a program may allow patients to use a data base of pictures of foods that have predetermined carbohydrate amounts instead of requiring the patient to estimate the carbohydrates for food they consume. Including features that communicated with patient's preexisting diabetes technology (*e.g.*, glucose monitors, insulin pumps) and automatically upload patients' blood glucose levels in order for parents or providers to review and provide feedback may also be helpful. Overall, these programs should be easy to access and provide immediate feedback^[98]. Programs should also take demographics into account. For instance, older individuals^[99], women^[100], and patients with higher self-efficacy^[101,102], are more likely to adhere to internet interventions. Thus, providers who are developing or implementing TH interventions should work to determine which patients are going to be appropriate for the TH intervention and how to address those groups with a history of poor adherence to TH interventions^[103].

PRIVACY AND SECURITY

Possibly the most common TH concern relates to the ability for TH interventions to maintain patient privacy and security in a mobile or online environment. Appropriately managing personal health information (PHI) is an important piece to maintaining patients' confidentiality. The federal laws provide regulations for protecting PHI under the Health Information Portability and Accountability Act^[104] (HIPAA). Each state also has

laws for managing PHI, which is not consistent from state to state and may be more or less stringent than HIPAA regulations^[95]. When state privacy laws conflict with HIPAA, the general rule is that the provider follows the more stringent law^[95]. TH providers who provide services across state lines must be aware of laws in both states and must work to resolve conflicts as they arise while being prepared for conflicting laws or regulations^[105]. While managing these challenges across providers, technology technicians, nurses, medical assistants, and billing personnel in two states may be manageable with practice, negotiating differences among state and federal privacy laws is likely to be increasingly more difficult with each additional state, thereby deterring providers from expanding their services and possibly hindering patients' access to specialized mental health care^[95]. In addition, though more recent technological advances and using secure or closed networks have improved security of online data transmission^[91,95] regulations are not clear regarding where or how the data should be stored (*e.g.*, online, at the providers' institution, or at the institution of the place of service). While providers should follow good safety procedures such as a personalized login, automatic time-out setting when not in use, encrypted data storage, and encrypted data transmission, they must also deliver informed consent and ensure a patient's understanding of the potential and ever-evolving risks of transmitting health information over the internet or mobile networks^[95,105,106]. These challenges require that a provider maintain understanding not only of the HIPAA and PHI laws but also of technological capabilities and challenges to technological safety, which is a daunting task for even the most informed provider.

CONCLUSION AND FUTURE DIRECTIONS IN TH

Taken together, research has shown the effectiveness and promise of TH in improving several primary (*i.e.*, glycemic control, adherence) and secondary (*i.e.*, social support, comorbidity, and knowledge) outcomes in T1D patients. Although a previous review suggested that phone interventions appear to have more promise than internet interventions in improving targeted T1D outcomes, the reviewed literature above suggests promise in both web based and mobile interventions. Broadly, TH interventions must strive to be theory driven, integrate multiple platforms, be secure, and be user-friendly^[87,107,108]. In doing so, TH interventions will expand to a broader audience and have an improved chance at reaching those most in need for TH, the underserved individuals who have difficulty accessing traditional services.

In order to improve current TH interventions, researchers and providers should invest in portability. As mobile computing and mobile phones reach a larger and larger share of the United States^[65] TH interventions must be optimized to provide an efficient, appealing, and

interactive environment on the smaller screen of mobile phones and tablets to reduce attrition and maintain participant engagement. This is especially true for adolescents and children, of whom a large portion (74%) access the internet from their phone and an increasing portion (25%) use their mobile phones as their primary device for navigating the web^[109]. Researchers who do not adjust their TH interventions to take advantage of the increased computing power and accessibility of portable technology will continue to struggle with participant engagement and attrition as fewer and fewer young individuals use a traditional desktop computer.

Researchers and clinicians should also seek to integrate their TH interventions into existing technological infrastructure both to increase participant familiarity and ease of use. By intentionally creating interventions that integrate with diabetes technology (*i.e.*, blood glucose monitors, insulin pumps), providers improve their ability to obtain objective health information and increase participant engagement through ease in integration. Integration, especially automated or hands free integration, with these technologies also has the benefit of providing a method for providers to easily view and provide feedback without relying on patients to physically produce their blood glucose meters at appointments. This improves the quality of information that providers have to deliver care, as well as decreases the burden of appointment preparation on the patient and potentially improving compliance.

In addition to technological integration, effective TH interventions should seek to involve family members, providers, and other supporting members of the patient's T1D management team. An effective way to do this may be by building on the preexisting support networks targeting these individuals and developing ways to improve how individuals find, interoperate, and communicate the information they find online. Recent research has demonstrated that parents of children with T1D are especially likely to use these online sources and actively incorporate them into how they care for their child's T1D^[6,72]. Providers may benefit from this predisposition of parents to search for information online by designing and implementing procedures to inform users of appropriate sources of information and increase awareness of effective TH interventions that may provide similar information. Building atop of pre-existing resources may also reduce the infrastructure cost that contributes to the short term growth and long term discontinuation of existing TH interventions.

Finally, clinical care providers are encouraged to advocate for improved legislation regarding TH. Notwithstanding substantial improvement over the last decade regarding TH reimbursement and rules, there continues to be a lack of guidelines regarding TH interventions delivered by the mental health profession and the associated technological, privacy, and security issues created by these interventions. In fact, many of the privacy and security concerns related to TH interventions may only be feasibly addressed by policy

makers and technology manufacturers. The development and national recognition of TH guidelines in conjunction with improved licensure recognition across state lines may provide increased support to mental health professionals who wish to pursue TH interventions. As a part of these guidelines, providers and researchers are encouraged to pair with technology consultants whom are informed and educated both on technological advances and advances in privacy and security laws. With proper support and the development of structured guidelines, TH interventions can grow to fit within the evolving scope of health care policy, reimbursement, and technological advancement while reducing the number of individuals who are underserved.

Abstract

Type 1 diabetes (T1D) is an autoimmune disease characterized by loss of insulin producing beta cells and reliance on exogenous insulin for survival. T1D is one of the most common chronic diseases in childhood and the incidence is increasing, especially in children less than 5 years of age. In individuals with a genetic predisposition, an unidentified trigger initiates an abnormal immune response and the development of islet autoantibodies

directed against proteins in insulin producing beta cells. There are currently four biochemical islet autoantibodies measured in the serum directed against insulin, glutamic decarboxylase, islet antigen 2, and zinc transporter 8. Development of islet autoantibodies occurs before clinical diagnosis of T1D, making T1D a predictable disease in an individual with 2 or more autoantibodies. Screening for islet autoantibodies is still predominantly done through research studies, but efforts are underway to screen the general population. The benefits of screening for islet autoantibodies include decreasing the incidence of diabetic ketoacidosis that can be life threatening, initiating insulin therapy sooner in the disease process, and evaluating safe and specific therapies in large randomized clinical intervention trials to delay or prevent progression to diabetes onset.

Key words: Autoimmunity; Autoantibodies; Diabetes prevention; Screening; Type 1 diabetes

Core tip: Type 1 diabetes (T1D), the immune mediated form of diabetes, is now a predictable disease with the measurement of islet autoantibodies. The presence of two or more antibodies defines preclinical disease as nearly everyone with multiple antibodies progresses to clinical diabetes. With improved platforms to measure islet autoantibodies, screening the general population is now a goal. Early identification of preclinical diabetes allows for less diabetic ketoacidosis, early initiation of insulin therapy, and the potential to delay or prevent diabetes onset. Clinical trials using safe and specific therapies to block disease specific immune cells are underway in T1D.

INTRODUCTION

Type 1 diabetes (T1D) is a chronic disease caused by immune-mediated destruction of insulin producing beta cells in the pancreas^[1]. The destruction of beta cells results in insulin insufficiency, and patients develop life-threatening hyperglycemia that clinically manifests with weight loss, polyuria, and polydipsia. The majority of patients who develop T1D have high-risk human leukocyte antigen (*HLA*) genes. Islet autoantibodies can be measured in the serum of these high-risk individuals years before the onset of any clinical symptoms, making T1D a predictable disease. Multiple prevention trials in patients with high-risk *HLA* genes or in patients who have measurable autoantibodies have been completed. To date, no trial has prevented the onset of T1D, but data indicates that the disease process may be delayed by administering oral insulin to induce insulin specific regulatory T-cells in the gut, resulting in decreased inflammation in the pancreas. This review summarizes the epidemiology, risk factors and pathogenesis of T1D. The review also examines the goal of screening the general population for T1D risk and preventing disease onset in individuals with preclinical disease.

EPIDEMIOLOGY

T1D is one of the most common chronic diseases in childhood and is diagnosed at an increasing rate in adults. The incidence rate varies significantly by geographical region. Sweden, Finland, Norway, United Kingdom, and Sardinia have the highest incidence of T1D at an age-adjusted rate of > 20/100000 patient years. For comparison, the United States has an incidence rate of 17.8/100000 patient years in a predominantly Caucasian population. China and South America have the lowest incidence of T1D, reported as < 1/100000 patient years^[2-5]. The rate of T1D diagnosis is increasing in most countries, with rates dramatically increasing in children less than 5 years of age^[6]. The annual incidence of T1D is increasing globally by 2.3% per year and is estimated to be increasing by 2.7%-2.8% in non-Hispanic white youth in the United States^[7]. Large registries in both Europe and the United States show that the incidence of T1D peaks between 5 to 7 years of age and again when children enter puberty^[8]. Unlike most autoimmune diseases, T1D is more common in males than females. The risk of T1D development in the general population is 1:300^[9]. In children who have a genetically related sibling, the risk is increased to 1:7 and is greatest in children under 5 years of age^[10,11]. Offspring of mothers with T1D carry approximately 3% risk and offspring of fathers with T1D carry approximately 5% risk^[12]. Genetics confer risk for development of T1D, as does seasonal variation and birth month suggesting an environmental influence on disease pathogenesis. Children born in the spring tend to be at a greater risk for developing T1D, while diagnosis is increased during climatically cold

seasons^[13-16]. This is an epidemiological association that requires further investigation.

RISK FACTORS

Genetic

T1D is a polygenic disorder with many genes contributing varying amounts of genetic risk for disease development. The genes conferring risk for diabetes are generally classified as *HLA* and *non-HLA* genes. Large genome wide association studies show that over 40 genes increase susceptibility to T1D^[17,18]. The major determinant of genetic susceptibility to T1D, contributing greater than 50% of the genetic risk, is conferred by genes in the *HLA* complex located on chromosome 6^[9]. The *HLA* complex is divided into 3 regions: classes I, II, and III. Alleles of the class II genes, DQ and DR (and to a lesser extent DP), are the most important determinants of T1D. These class II molecules are expressed on antigen-presenting cells (macrophages, dendritic cells, and B cells) and present antigens to CD4 T lymphocytes. DQ and DR genes are in close linkage disequilibrium on chromosome 6 with specific DQ and DR genes inherited together. The presence of the DR4/DQ8 haplotype increases the odds ratio for T1D development to approximately 11, indicating an individual with this haplotype is 11 times more likely to develop T1D than those without. Approximately 90% of all individuals with T1D have either or both the DR4/DQ8 or DR3/DQ2 haplotypes. Interestingly, *HLA* genes also confer protection from T1D development. Individuals who have the specific DQ6 allele (DQB1*06:02) are dominantly protected from T1D, with an odds ratio of 0.03 for disease development^[19].

Of the *non-HLA* genes, insulin and protein tyrosine phosphatase non-receptor type 22 (PTPN22) confer risk for T1D development but to lesser degrees than *HLA* genes^[20]. Similar to *HLA* class II genes, insulin gene polymorphisms can confer both susceptibility to and protection from T1D development. At the 5' end of the *insulin* gene, there are variable numbers of tandem repeats. Having more repeats correlates to more insulin message being expressed in the thymus. The thymus responds by developing central tolerance to insulin. In individuals with fewer repeats, autoreactive T-cells can persist, and the risk for T1D development is increased^[21]. PTPN22 helps regulate antigen receptor signaling and T cell activation, and a single nucleotide polymorphism (arginine to tryptophan at position 620) has been associated with a number of autoimmune disorders including T1D. A gain of function polymorphism decreases T cell receptor signaling which confers diabetes risk. It is unknown why decreased T cell activation leads to T1D risk, but it can be hypothesized that deficient negative selection of thymic cells may be involved^[22,23].

Environment

Genetics alone does not lead to T1D; the environment also plays a pivotal role. This is evidenced by the fact

that not all individuals with high-risk genes develop T1D. In fact, the majority of individuals with high-risk HLA class II genes (DR4/DQ8 and DR3/DQ2) do not develop T1D. There are likely one or more environmental factors that trigger and perpetuate the autoimmune disease process prior to hyperglycemia and a clinical diagnosis of hyperglycemia and T1D. Large natural history studies indicate that the development of islet autoantibodies (the first laboratory evidence of beta cell autoimmunity) in high-risk individuals often occurs between 9 mo and 2 years of age^[24]. This suggests that an environmental trigger is present early in life, possibly *in utero*.

One of the most extensively evaluated environmental triggers is viral infection. Many viruses are implicated in the development of T1D including enteroviruses such as coxsackie B virus, cytomegalovirus, congenital rubella syndrome, and rotavirus^[25-32]. Enterovirus is the leading candidate for contributing to T1D development. Epidemiologic studies in Finland show that the development of beta cell autoimmunity parallels the seasonal pattern of enterovirus infection and clinical symptoms of enteroviral infection^[33,34]. Enterovirus infection was strongly associated with the development of autoantibodies in the Diabetes Autoimmunity Study in the Young (DAISY) cohort^[35]. Laboratory evidence of enterovirus infection is reproducibly present in individuals with new onset T1D, pregnant women whose children develop T1D, and donor pancreata of individuals with T1D^[36,37]. The exact mechanism of how viruses induce autoimmunity is not clear. The molecular mimicry hypothesis proposes that because the P2-C protein sequence of enterovirus is similar to glutamic decarboxylase (GAD), which is expressed in islet cells, the immune system erroneously targets destruction of beta cells^[38]. The other leading hypothesis is that viral infection activates autoreactive T cells. As evidence, Cytomegalovirus B4 has tropism for pancreatic tissue and infection results in release of beta cell antigens that are phagocytized by macrophages and presented to autoreactive T cells^[39].

Another potential environmental influence relates to the north-south division of diabetes development in the world, with a higher incidence of T1D in northern climates compared to southern. The north-south hypothesis implicates that a lack of vitamin A and/or D exposure early in life predisposes individuals to the development of autoimmune diseases including T1D. Offspring of mothers supplemented with vitamin D during pregnancy and young children supplemented with vitamin D have shown a reduced risk of T1D development that may be dose responsive^[40,41]. However, an analysis from the DAISY Study found that vitamin D intake and 25(OH) vitamin D levels throughout childhood were not associated with the development of islet autoantibodies or T1D development^[42].

Early introduction of cow's milk and gluten have also been extensively studied. The introduction of gluten into an infant's diet prior to three months and after 7 mo has been associated with increased autoantibody development^[24,43]. Some studies also indicate

that breastfeeding or using elemental formula may be protective against T1D. Other environmental factors that continue to be explored include nitrosamine compounds, maternal age, pre-eclampsia, and childhood obesity. There is no evidence to suggest that vaccines increase the risk of T1D development^[44]. To date, there are no causal environmental factors that trigger the development of islet autoantibodies or increase the risk of progression to clinical T1D development. However, there is a large international prospective longitudinal study, The Environmental Determinants of Diabetes in the Young, currently underway to evaluate potential environmental factors in T1D^[45].

NATURAL HISTORY

Three decades ago, it was hypothesized that T1D is a chronic autoimmune disorder that develops in stages, and the model remains valid today (Figure 1). In genetically predisposed individuals (those with DR4/DQ8 and/or DR3/DQ2 haplotypes) there is an environmental trigger that leads to a break in immunologic tolerance and loss of beta cell mass. Over a period of time, usually years, there is autoimmune destruction of insulin producing beta cells that is marked by the presence of serum islet autoantibodies (Figure 2). As the process continues, very likely in a relapsing and remitting manner, there is a loss of glucose stimulated insulin release, and eventually insulin deficiency such that overt hyperglycemia results and clinical T1D is diagnosed^[4].

How an inciting event leads to an aberrant immune response is not completely understood. Most hypotheses focus on immunologic abnormalities in antigen presentation by HLA molecules to T cells in the thymus and peripheral lymph organs. T cells are educated in the thymus to self-antigens, such as insulin, and if there are dysregulated immune processes, self-reactive T cells can escape central tolerance and exist in the periphery^[46,47]. Once these cells encounter their target antigen or peptide in peripheral lymph organs, they become activated to target beta cells. Other hypotheses focus on environmental triggers leading to immune activation and targeting of beta cells. The molecular mimicry theory proposes that a viral or bacterial protein shares amino acid sequence homology with beta cells and induces immune system activation through targeting beta cell antigen that is molecularly similar to a foreign antigen^[38]. Finally an infectious triggering event may allow beta cells to become more sensitive to cytokine and free radical induced inflammation^[48].

Recently the network for pancreatic organ donors has been established to study the pancreata of deceased donors with islet autoantibodies (preclinical disease) or established T1D^[49]. The goal is to understand mechanisms of disease pathogenesis and interactions between beta cells and the immune system^[50]. What we have gleaned from the initial efforts is that islet infiltrates (insulinitis) are present in a lobular pattern in the pancreas, and there is a predominance of CD8 and CD4 T cells,

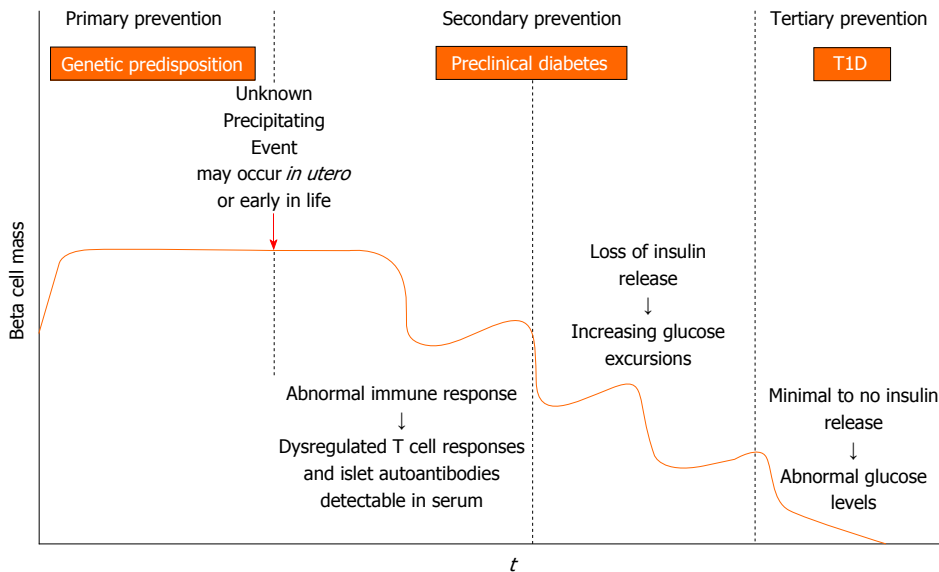

Figure 1 Stages in the development of type 1 diabetes adapted from the initial model proposed by George Eisenbarth. In genetically at risk individuals an unknown trigger, presumably environmental, initiates an autoimmune response that results in loss of beta cell mass. Before metabolic disturbances occur, islet autoantibodies (insulin, glutamic decarboxylase, islet antigen 2, zinc transporter 8) are measurable in serum. As beta cell mass decreases, potentially in a relapsing-remitting manner, there is loss of endogenous insulin release and ensuing hyperglycemia. Within this model, there are opportunities for type 1 diabetes (T1D) prevention in genotypically high risk individuals (primary prevention) and in autoantibody positive individuals (secondary prevention). Interventions to preserve remaining beta cell mass at diagnosis are also possible (tertiary prevention).

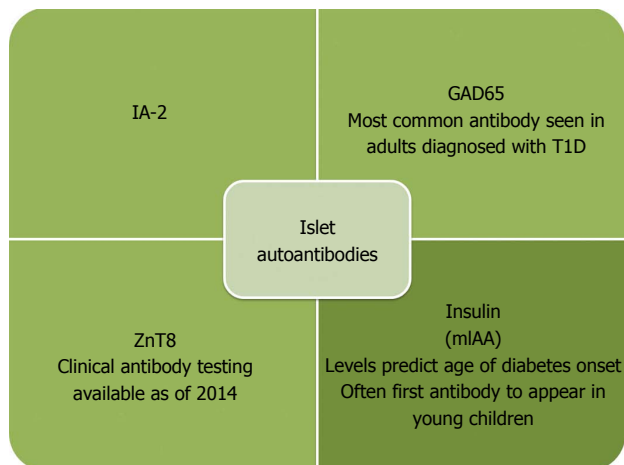

Figure 2 Insulin autoantibodies are often the first antibody to develop in young children. In contrast, adults most often are GAD65 and IA-2 autoantibody positive at diagnosis. The ZnT8 antibody is the most recently identified autoantibody with commercial testing now available. T1D: Type 1 diabetes; GAD65: Glutamic decarboxylase; IA-2: Islet antigen 2; ZnT8: Zinc transporter 8.

B-lymphocytes, and macrophages^[51,52]. Pancreata from established T1D patients also show an overall decrease in weight compared to age matched controls, potentially related to atrophy of the exocrine pancreas with the loss of beta cells^[52]. The first serological evidence of an autoimmune response to beta cells is the appearance of autoantibodies to insulin (IAA), GAD, islet antigen 2, and zinc transporter 8^[53]. Placental antibodies are no longer present after approximately 6 mo, so any antibodies in serum after that time reflect endogenous antibodies. If an individual develops two or more of these antibodies, they will eventually progress to clinical onset of T1D^[54].

Approximately 90% of individuals have two or more islet cell autoantibodies at diagnosis, and it is likely that the remaining 10% of individuals (islet autoantibody negative) have autoantibodies against antigens that have yet to be discovered. In children, IAA is usually the first antibody to develop, and the progression to T1D is 100% in children with a persistently high level of IAA^[55,56]. This is in contrast to adults who tend to have higher levels of GAD at diagnosis. Islet autoantibodies can be easily measured in the serum, with the gold standard method for detecting antibodies being fluid phase radioimmunoassays (RIA)^[57]. More recently, islet autoantibodies are now able to be measured from smaller volumes of serum and without the use of radioactivity using electrochemiluminescence as a detection method while maintaining similar sensitivity and specificity to RIA^[58,59]. The rate at which individuals with positive islet autoantibodies progress to clinical T1D is dependent upon the age of appearance, insulin autoantibody level, and the number of autoantibodies present^[55]. Hemoglobin A1c rises 1 to 1.5 years prior to diagnosis. Therefore, reduced insulin secretion and resultant hyperglycemia occur before T1D is clinically diagnosed^[60,61]. Once T1D is clinically diagnosed, individuals must commit to lifelong blood glucose monitoring and intensive insulin administration *via* multiple daily injections or an insulin pump to achieve good glycemic control. With improved diabetes management, the risk for long-term complications such as renal failure, myocardial infarctions, stroke, and lower extremity amputations has decreased over the last two decades^[62]. However despite the decreasing prevalence of complications in diabetes, the need still exists to understand the underlying pathogenesis of complications such as diabetic cardiomyopathy and

novel approaches for treating complications such as neovascularization in diabetic foot disease^[63,64].

SCREENING AND PREVENTION

The American Diabetes Association recently adapted their guidelines to recommend screening for islet autoantibodies in high-risk individuals^[65]. Highly sensitive serological assays are not widely available, and all screening is recommended to be done in the setting of a clinical research study. To date, general population screening has been done through large clinical trial networks such as the National Institutes of Health sponsored TrialNet, which enroll and screen first or second degree family members of individuals with T1D. By identifying individuals with positive islet autoantibodies, the rate of diabetic ketoacidosis (DKA) at diagnosis is reduced^[66]. Preventing DKA is important as altered mental status, coma, and even death can occur^[67]. In fact, DKA is the most common cause of death in children with T1D^[68]. Without screening, DKA at diagnosis is relatively common^[69]. In the EURODIAB study, 42% of children presented in DKA (pH < 7.3) at the time of diagnosis with T1D^[3]. By identifying individuals with positive autoantibodies, insulin therapy can be initiated early, and these children can enroll in studies aimed at preserving beta cell mass. In adults, maintaining endogenous insulin secretion reduces hemoglobin A1C, reduces the risk of severe hypoglycemia, decreases reliance on exogenous insulin, and decreases the rate of long-term complications^[70-77]. In children, there has been very little data collected regarding residual beta cell mass beyond the first year after diagnosis^[78-82]. A case-control study did show that children without severe hypoglycemia had increased residual beta cell mass compared to those children with severe hypoglycemia^[83]. An effective method of preserving beta cell mass is not yet available, and the benefit of increased residual beta cell mass in children remains to be confirmed.

According to the World Health Organization's principles of early disease detection, T1D is a condition that meets criteria for the establishment of a screening program. These principles include the condition is an important health problem, there is a recognizable latent stage of the disease, the natural history of the disease is understood, there is an adequate and accepted laboratory screening test, providers agree on who should receive treatment and there is a treatment available, there are adequate resources for diagnosis and treatment, and the cost of overall medical care would not increase^[84]. Islet autoantibodies can be reliably measured in serum, with each antibody assay having a specificity of 99% when measured by radioimmunoassay in tertiary referral centers such as the Barbara Davis Center for Diabetes. The sensitivity for each autoantibody assay ranges from 70%-80%. We view these radioimmunoassays as a confirmatory test for T1D. A desired screening test needs to be reliable with high sensitivity, cost effective, and technically feasible, likely as a multiplex assay in

which all four autoantibodies are measured in a single well of an assay plate. Currently, to measure islet autoantibodies a blood draw is required with subsequent shipping of venous or capillary blood samples to a reference laboratory. This is not feasible for population wide screening due to technical requirements of sample collection and high cost. Screening large populations of infants for metabolic diseases and other congenital disorders has been successfully done using dried blood spots^[85]. To establish an accepted screening program for T1D, the sensitivity and specificity of islet autoantibodies, specifically insulin autoantibody, needs to be established using a feasible collection method such as dried blood spots on filter paper, which would be a simplified collection method and more cost effective. Overall, T1D would not be over diagnosed with general population screening as diagnosis of the disorder requires both the presence of islet autoantibodies and metabolic abnormalities.

Ideally, individuals who screen positive for islet autoantibodies can be offered a treatment to prevent or delay the progression to T1D. Many secondary prevention trials have been completed with more currently underway^[86]. As population based screening may be feasible in the near future, it is important to continue secondary prevention trials with the goal of delaying or preventing progression to T1D in islet autoantibody positive individuals. Patients enrolled in clinical intervention trials benefit from close follow up by medical professionals, early diagnosis of T1D, decreased incidence of DKA, and early initiation of insulin therapy (Figure 3).

Secondary prevention trials

As T1D is a predictable disease with the measurement of islet autoantibodies, it logically follows that the disease should be preventable. To date, the majority of secondary prevention trials (enrolled individuals with preclinical disease) have administered different preparations of insulin to autoantibody positive individuals in an attempt to slow the progression to T1D onset^[87]. The first such trial was the diabetes prevention trial-type 1 in which at risk patients were either administered subcutaneous insulin or oral insulin in randomized, double-blinded, placebo controlled trials. Oral insulin has no metabolic effect; however, orally administered insulin does encounter mucosal gut-associated lymphoid tissue. The role of this lymphoid tissue is to provide protection from orally acquired pathogens and to keep individuals from developing reactions to ingested proteins. By administering low doses of oral insulin, insulin-specific T-regulatory cells are produced which may release cytokines that inhibit the inflammatory cascade that leads to β -cell destruction^[88-90]. Relatives of patients with T1D who were 3 to 45 years of age and had high-risk *HLA* genes and one or more positive autoantibodies were evaluated for abnormal glucose metabolism. Those individuals who had abnormal glucose tolerance ($n = 339$) were administered 0.25 units/kg per day of Ultralente insulin twice daily and received an intravenous insulin infusion for four

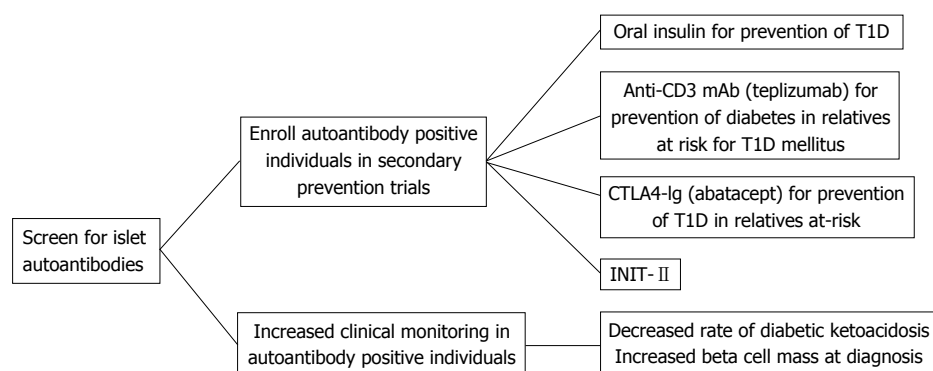

Figure 3 The measurement of serum islet autoantibodies has made type 1 diabetes a predictable disease. Early identification of islet autoantibody positive individuals leads to improved clinical outcomes by decreasing the risk for diabetic ketoacidosis and potentially preserving beta cell mass through clinical prevention trials. T1D: Type 1 diabetes; INIT- II : Intranasal Insulin Trial.

days at the beginning of the study and then annually. There was no effect of low-dose subcutaneous insulin on delaying the progression to T1D^[91]. Participants with normal glucose tolerance received 7.5 mg/kg per day of oral insulin ($n = 372$). An oral glucose tolerance test was completed every 6 mo during a 6-year follow up, and there was not a delay in progression to T1D. Of interest, a post-hoc analysis showed in participants with persistently high levels of IAA (≥ 80 nU/mL) there was a delay in disease onset of approximately five years^[92]. Also, the rate of progression to T1D onset after stopping insulin was more rapid^[93]. A follow-up oral insulin trial through TrialNet is currently enrolling participants in order to determine if oral insulin can delay the progression to T1D in individuals with high IAA levels (ClinicalTrials.gov Identifier: NCT00419562).

Another insulin intervention trial from the Belgian T1D Registry identified study participants who were insulin autoantibody positive and did not have a HLA haplotype conferring protection (DQB*0602). Study participants were given two subcutaneous injections of insulin daily for 3 years ($n = 25$) or observed and prospectively followed ($n = 25$). The participants who were treated with insulin and those who refused treatment or agreed to observation developed T1D at the same rate^[94].

Many preclinical studies have suggested that administration of intranasal insulin may delay T1D development through mucosal tolerance, in which mucosal antigens have been shown to impact regulatory T cell development^[95]. To translate these findings to humans, individuals with high-risk HLA haplotypes and one or more islet autoantibodies were enrolled in the Intranasal Insulin Trial (INIT- I) ($n = 38$). This randomized, double-blinded, crossover pilot study suggested that intranasal insulin protects against the development of T1D by increasing antibody formation and decreasing T cell responsiveness^[96]. The INIT- II, a randomized, double-blinded, placebo controlled trial, is now enrolling individuals to determine if intranasal insulin can delay or prevent the progression to T1D (ClinicalTrials.gov Identifier: NCT 00336674).

However, a large study in Finland, the T1D Prediction and Prevention Trial enrolled and followed siblings of children with T1D or infants of mothers with T1D who had high-risk *HLA* genes for islet autoantibody development. Once two or more autoantibodies were detected ($n = 264$), they were randomized to intranasal insulin ($n = 137$) or placebo ($n = 127$). Interim analyses showed no benefit of intranasal insulin in delaying the onset of T1D^[97]. This indicates that intranasal insulin may not be effective at delaying diabetes onset at the administered dose and timing in the disease process. Potentially insulin antigen specific therapies may need to be administered earlier in the disease course to have an impact on delaying progression to T1D.

Several trials using non-antigen specific therapies including bacille calmette-guerin injections, Ketotifen (histamine antagonist), oral cyclosporine, and nicotina-mide (B6) have been completed. No study has prevented or delayed T1D development^[98-104].

Clinical trials with drugs aimed at modulating the immune response and preserving endogenous insulin secretion in patients with new-onset T1D are termed tertiary prevention trials^[51]. Only recently have these drugs expanded to prevention trials in islet autoantibody positive individuals (Figure 3). The CTLA4-Ig antibody (Abatacept) for Prevention of Abnormal Glucose Tolerance and Diabetes in Relatives At-Risk (ClinicalTrials.gov Identifier: NCT 01773707) and Anti-CD3 monoclonal antibody (Teplizumab) for Prevention Of Diabetes In Relatives At Risk For T1D mellitus (ClinicalTrials.gov Identifier: NCT01030861) are both TrialNet studies currently enrolling participants. Abatacept is a fusion antibody that binds to antigen presenting cells and blocks co-stimulation to T cells. Anti-CD3 monoclonal antibodies bind the CD3 molecule which is present on CD8 and CD4 T cells, thereby inhibiting T cell activation^[105]. Both of these drugs have shown some degree of success when used in new-onset trials^[106-111]. DIAPREV-IT is an antigen-based treatment currently enrolling individuals who are positive for GAD and one or more additional autoantibodies (ClinicalTrials.gov Identifier: NCT 01122446). A GAD/alum vaccine

is given at enrollment and 1 mo later. Although GAD vaccination is safe and easily administered, new-onset intervention trials have not shown long-term preservation of endogenous insulin secretion^[108,112,113].

NOVEL APPROACHES TO PREVENT T1D

Currently, insulin is the only medication approved by the United States Food and Drug Administration for the treatment of T1D. Despite T1D being a predictable chronic autoimmune disorder, there are not any therapies to preserve endogenous insulin production. As mentioned above, many large clinical intervention trials have not slowed the progression or prevented disease onset. We believe T1D will be preventable and that safe and specific therapies targeting the immune system are needed. One such approach is to target the trimolecular complex, which consists of a self-reactive CD4 T cell, insulin, and HLA molecule^[114]. It is well established that specific HLA alleles, namely HLA DQ8 which is present in approximately 60% of all T1D patients, confer significant disease risk. DQ8 is a molecular target for diabetes intervention by using small “drug-like” molecules to block antigen presentation, thereby inhibiting specific T cell activation. Preclinical studies have shown this to be a potential pathway for diabetes intervention^[115]. This concept has been advanced from bench to bedside as a clinical trial in which methyldopa (Aldomet), a clinically well-established antihypertensive drug, is being investigated to block DQ8 antigen presentation. The phase 1b dose escalation trial is using personalized medicine as methyldopa is being administered to recent onset adult T1D patients with the presence of the DQ8 gene (ClinicalTrials.gov Identifier: NCT01883804). Methyldopa is orally administered, safe as it has been used clinically for the last 50 years, and currently indicated for the treatment of pregnancy induced hypertension. Furthermore, all individuals have three class II molecules (DQ, DR, and DP), and by blocking a single class II molecule, there are two others to permit normal immune system function.

Other approaches have targeted components of the insulin trimolecular complex including antibodies that specifically bind to an insulin peptide in the HLA molecule. Preclinical studies in an animal model of spontaneous autoimmune diabetes indicate that this approach can delay diabetes onset^[116]. Efforts are currently being made to make a human antibody, which again is a very specific immune therapy for diabetes intervention. Finally, insulin antigen specific therapy has the potential to evolve with recent advances in the field of immunology. A peptide from the insulin B chain amino acids 9-23 (B:9-23) has been extensively studied in animal models and human T1D^[117,118]. It is now appreciated that insulin B:9-23 is a key autoantigen in the disease process of both mice and humans, sharing an identical amino acid sequence in both species^[119,120]. A mutated insulin B:9-23 peptide, but not the native peptide sequence, induced protective immune responses (regulatory T cells) and prevented

diabetes onset in preclinical animal models^[121]. With a deeper understanding of how the insulin peptide binds to HLA molecules and activates T cells, an insulin vaccine again holds promise for diabetes prevention.

In conclusion, T1D is now a predictable disease with the measurement of islet autoantibodies and prevention will naturally follow. To prevent T1D, general population screening for islet autoantibodies is needed along with a safe and specific therapy for disease intervention. The genes that confer diabetes risk are now molecular targets, and tailoring therapies to specific HLA genes is personalized medicine. The future holds promise for delaying the progression and ultimately preventing diabetes.

Abstract

The diabetic foot is characterised by painless foot ulceration and/or arthropathy; it is a typical complication of painless diabetic neuropathy. Neuropathy depletes the foot skin of intraepidermal nerve fibre endings of the afferent A-delta and C-fibres, which are mostly nociceptors and excitable by noxious stimuli only. However, some of them are cold or warm receptors whose functions in diabetic neuropathy have frequently been reported. Hence, it is well established by quantitative sensory testing that thermal detection thresholds at the foot skin increase during the course of painless diabetic neuropathy. Pain perception (nociception), by contrast, has rarely been studied. Recent pilot studies of pinprick pain at plantar digital skinfolds showed that the perception threshold was always above the upper limit of measurement of 512 mN (equivalent to 51.2 g) at the diabetic foot. However,

deep pressure pain perception threshold at musculus abductor hallucis was beyond 1400 kPa (equivalent to 14 kg; limit of measurement) only in every fifth case. These discrepancies of pain perception between forefoot and hindfoot, and between skin and muscle, demand further study. Measuring nociception at the feet in diabetes opens promising clinical perspectives. A critical nociception threshold may be quantified (probably corresponding to a critical number of intraepidermal nerve fibre endings), beyond which the individual risk of a diabetic foot rises appreciably. Staging of diabetic neuropathy according to nociception thresholds at the feet is highly desirable as guidance to an individualised injury prevention strategy.

Core tip: The diabetic foot is characterised by painless ulcers and/or arthropathy. Although painless diabetic neuropathy is known as the underlying condition, little is known quantitatively about the pain evoked by noxious stimuli (nociception) at the diabetic foot. Preliminary evidence shows that pinprick pain perception threshold at plantar digital skinfolds is supranormal, beyond the upper limits of measurement. It is suggested that measuring nociception at the foot in diabetes could specify the individual risk of painless ulcers and/or arthropathy and, thereby, provide the basis of an individualised graded injury prevention strategy.

INTRODUCTION

The diabetic foot (also called diabetic foot syndrome,

or diabetic podopathy) is characterised by painless foot ulceration and/or arthropathy in diabetes. Foot injuries and inflammations do not hurt, as illustrated on Figure 1.

Painless diabetic neuropathy (PLDN) is the underlying condition. Skin ulcers extending to the subcutaneous tissues are completely anaesthetic, while arthropathy may display faint deep dull aching upon load bearing. Nociception, that is the perception of pain originating from neural processes of encoding and processing noxious stimuli, is failing at the diabetic foot. Although insensitivity to pain at the diabetic foot is common knowledge, details are largely unknown^[1,2].

Research into painlessness in diabetes is scarce. Early studies date back to Pamela Margaret Le Quesne^[3] and her group almost 30 years ago. They tried to measure the pain perception (nociception) at the diabetic foot by pinching the skin with a custom made "pinchometer". The results were inconclusive at best^[4]. Other authors designed calibrated tools for assessing hypersensitivity of so-called symptomatic, *i.e.*, painful, diabetic neuropathy (SDN, see below). To this end, pinprick pain perception, axon-reflex reaction and temperature detection of the skin were studied. These modalities represent the functions of the afferent A-delta and C-fibres (so-called small fibres; see below) whose contributions to SDN, however, remain controversial^[5,6]. SDN will not be discussed here.

To date, measuring pain perception (*i.e.*, nociception) at the diabetic foot was deemed futile with the excuse that "The threshold of sensation that protects normal feet from injury is difficult to define... it is extremely difficult to define a 'significant loss of sensation', or at what level sensory loss becomes 'critical'."^[7] However, there is some dissent on this issue, as expressed by Dyck *et al*^[8]: "Sadly, the clinical assessment of decreased sensation by physicians is generally inadequate because it is not performed or is performed badly." Undeniably, many a clinical physician or expert was biased against measuring diminished nociception in diabetic neuropathy, and for several possible reasons: (1) quantitative sensory testing (QST, see below) was considered inferior to nerve conduction velocity studies in the detection of symptomatic (painful) diabetic neuropathy; (2) Experts of QST not always knew enough of the diabetic foot, this typical complication of symmetrical diabetic neuropathy, to understand what they read. For example those reviewers, who commented on a paper: "In a group of 20 patients (...) the authors compared sensation in ulcerated vs nonulcerated feet and were unable to find any difference. Had a difference been found, one might interpret the sensory dysfunction as a pathophysiological factor in ulcer development"^[9]; (3) QST findings were assumed to be poorly reproducible, an argument which was often mixed up with the natural inter-individual variability (on average 5-fold^[10]). Intra-individual coefficients of variation are acceptable, for example those of pain perception thresholds are well

Pain makes a healthy man fall when he begins to twist his foot. The man who feels no pain walks on without realising the damage he is doing.

Figure 1 Sketch reproduced from Brand P^[2].

below 25%^[10-14]; and (4) A really important obstacle against routine QST of nociceptive functions was the lack of normative data. However, since 2005, extensive reference material using a particular QST protocol was published^[12,14-17], see below. Although this protocol had primarily been devised for examining hyperalgesia in non-nociceptive pain syndromes like fibromyalgia, or neuropathic pains, and not for assessing hypoalgesia^[18], the author (Chantelau EA) believes that parts of it may well be applied for studying the failing nociception at the foot in diabetes. Diabetic hyperglycaemia in general does not interfere with QST^[19-21]; however, subclinical or clinical hypoglycaemia makes QST virtually impossible.

PLDN: THE PRINCIPAL RISK FACTOR FOR THE DIABETIC FOOT

Peripheral diabetic (poly) neuropathy is the most frequent sequel of diabetes mellitus. The nature of diabetic neuropathy has been clearly established by Martin^[22,23] in 1953 and 1954, and by Catterall *et al*^[24] in 1956. While today many people still believe that the condition is always symptomatic with spontaneous pains and dysaesthesias in the legs and feet, these authors had already noted more than half a century ago: "non-myelinated nerve-fibre degeneration occurs in a high proportion of diabetic patients, who, on clinical examination, show no evidence of 'clinical' diabetic neuropathy...the presence in diabetics of such nerve-fibre disturbance explains the frequent finding of persistently cold feet and their proneness to traumatic lesions"^[24]. Indeed, the basic feature of diabetic neuropathy is small fibre degeneration^[25] with reduced or absent nociception at the feet as the key sign (PLDN). By contrast, SDN develops secondary to PLDN, superimposes on PLDN, and affects only a minority of 15%-30% of patients^[25,26]. The symptoms of SDN like spontaneous neuropathic pains and tingling in the feet may be alleviated by drug treatment; they resolve gradually while nerve degeneration^[27] and PLDN progress. However, diminished nociception in PLDN does

Figure 2 Intraepidermal nerve fibre ending density at the lower limb in relation to severity of diabetic neuropathy (adapted from Quattrini *et al*^[40,41]). HC: Healthy controls; DC: Diabetic controls; Dmi: Mild SDN; Dmo: Moderate SDN; Dsev: Severe SDN; SDN: Symptomatic diabetic neuropathy; INEF: Intraepidermal nerve fibre ending.

not resolve, nor does PLDN respond to drug treatment. Prevalence and incidence rates of PLDN are not known. However, the prevalence of the diabetic foot, indicative of severe, end-stage PLDN, in patients with SDN is about 10%, while the incidence is about 5%-7% per year^[28,29].

Most of the patients with PLDN never have complaints until they are facing a foot injury that -unexpectedly - does not hurt. To once more quote Catterall *et al*^[24]: "Cutaneous neuropathic changes commonly start as blisters about the tips of the toes or at the site of a corn or callosity in places constantly exposed to irritation by an ill-fitting shoe. Frequently the deceptive lack of normal sensation, and particular pain sensation, leads a patient to ignore the lesion and delay treatment until secondary infection with deep penetration of the tissues or severe inflammation is present." PLDN is associated to the duration of diabetes and to the cumulative effects of increased blood glucose (or deficient insulin function). It is symmetrical, age- and length-dependent (it starts in advanced age by affecting the endings of the longest axons in the body, in the skin of the toes^[30]). Thus, deficits in nociceptive function develop in the forefeet first, and subsequently ascend to the rearfeet, the ankles and the lower legs. The hands are affected only in most severe cases.

PLDN is a disease of the small primary afferent A-delta and C-fibres: they are thin and their conduction velocity is relatively slow. (A fraction of about 15% of small fibres extending to the skin are efferents; they belong to the sympathetic nervous system and are restricted to the dermis, innervating sweat glands, blood vessels, and the arrector pili muscles. Small fibre efferents will not be discussed here). Primary C-afferents (also named group IV fibres, axon diameter < 1.5 μm , conduction velocity 0.5-2 m/s) are unmyelinated nerve fibres. Primary A-delta afferents (also named group III fibres, axon diameter 1-6 μm , conduction velocity 5-30 m/s) consist of thinly myelinated axons whose intracutaneous endings, however, are unmyelinated^[31]. The endings of A-delta and C-afferents do not carry corpuscles but are "free"; they serve as receptors for noxious thermal,

mechanical and chemical stimuli (termed nociceptors), and as receptors for innocuous thermal stimuli. In the epidermis they are densely distributed, up to 1000 per 1 cm^2 , which is much more than in muscles, ligaments, joints and bones (periosteum). Most nociceptors are specific of one single modality, while some are polymodal. C-fibre afferents are estimated to account for 70% of all nociceptors in the skin (the remainder are A-delta nociceptors). Cutaneous A-delta nociceptor stimulation results in a short sharp, stinging "first" pain, whereas C-fibre nociceptor stimulation results in prolonged dull, burning "second" pain. In muscles, A-delta and C-fibre nociceptors evoke the same dull pain character^[32], see section 4.

In PLDN, the nociceptors degenerate progressively ("die back") by unknown molecular mechanisms. It is not clear, whether this insidious process of central-peripheral distal axonopathy^[33,34] begins already in a prediabetic stage^[25]. However, PLDN superimposes on the physiological age-related decline in sensory functions after the age of 50^[34-36], and is aggravated by other neuropathic conditions like vitamin B12 deficiency, alcohol toxicity, end-stage renal failure, or exposition to neurotoxic substances or conditions. Clinically, PLDN remains undetected until most nociceptors have died and painlessness of a foot trauma astounds the patient (and the doctor)^[24]. The vanishing of intraepidermal free nerve endings can be quantified by histomorphology^[31,37,38]; it correlates to increasing severity of diabetic neuropathy^[39-41] (Figure 2), and to rising thermal and pain perception thresholds^[34,38,40].

A-delta and C- fibre nociceptors and thermal receptors "die back" not only in the skin, but presumably also inside the adjacent subcutaneous tissues (equivalent to group III and IV fibre nociceptors in muscles, fascia, ligaments and joints) of the diabetic foot. However, this remains to be established by histopathology. A-delta (group III) fibres seem to be particularly susceptible to the neuropathic processes, as their functions deteriorate somewhat earlier than C- (group IV) fibre functions^[42].

Diabetes affects small fibres prior to large ones. When large myelinated A-beta afferents (axon diameter 6-12 μm , conduction velocity 30-70 m/s) become affected, the axon and the myelin sheet get damaged, and conduction velocity decreases. A-beta fibres mediate touch, deep pressure and vibration sensation by means of their corpuscular endings: Meissner's, Merkel's, and Pacinian corpuscles. A-beta fibres are not involved in nociception, but have a role in allodynia^[43] which, however, will not be discussed here.

Diabetic foot: End-stage complication of PLDN

The diabetic foot is characterised by painless ulceration and/or arthropathy. Since 60 years or so^[22,23,24,44] the condition is well known as an end-stage complication of diabetic neuropathy, of PLDN rather than SDN. The basic defect has frequently been termed "loss of protective sensation"^[44], which is, in fact, "loss of

nociception" (see below). Ulcers and arthropathy start from single injuries (mechanical, thermal or chemical skin wound, or skeletal trauma) which are subjected to persisting repetitive stress (load bearing by walking, because they do not hurt - Figure 1), whereby they enlarge enormously until they become apparent to the patient. The initial injury may also be caused by uninterrupted repetitive mechanical wear and tear (fatigue from overuse, remaining unperceived because of lack of nociception!) The ulcers become infected, and the infection spreads to the adjacent subcutaneous tissues. Bone and joint damage aggravates due to ongoing unprotected walking. When properly treated immediately (like any other acute foot injury in subjects with preserved nociception!), the initial injuries will heal uneventfully. Human experiments showed that wound healing is not impaired by PLDN^[45,46]. Perforating neuropathic foot ulcers heal if they are unloaded completely^[24], and if arterial blood flow is sufficient and infection is cured. The ulcers frequently break down again when repetitive stress from walking is resumed, "due to faulty and often excessive weight-bearing by the ulcerated area"^[23]. Hence, the overall amputation risk is increased: the diabetic foot is the most frequent cause of amputation in industrialised countries.

CURRENT CLINICAL PRACTICE OF DIAGNOSING DIABETIC NEUROPATHY

According to the common misconception that neuropathy in diabetes in general is SDN, current guidelines state that the condition be diagnosed and staged semi-quantitatively according to various symptom scores (e.g., Neuropathy Symptoms Score, Neuropathy Disability Score, Michigan Neuropathy Screening Instrument, Toronto Clinical Scoring System). However, testing sensory functions is also accepted: five simple nerve tests are considered diagnostic for symptomatic neuropathy, the 10-g monofilament plus 1 of the following 4: vibration using 128-Hz tuning fork, pinprick sensation, ankle reflexes, vibration perception threshold^[47]. All except vibration perception threshold are qualitative tests, all but pinprick sensation are unsuitable for diagnosing PLDN.

Vibration and touch represent A-beta fibre functions, not nociceptive functions. Nevertheless, vibration and touch sensation is used as surrogate markers of the risk of sustaining painless foot injuries (ulceration/arthropathy). To identify loss of protective sensation (LOPS) - without assessing nociception- "any of the five tests listed could be used (...). One or more abnormal tests would suggest LOPS, while at least two normal tests (and no abnormal test) would rule out LOPS"^[47].

Current guidelines claim that "estimating the severity of diabetic sensorimotor polyneuropathy has not received the attention it deserves. For a given patient with diabetes it is not sufficient to simply identify patients as having sensorimotor polyneuropathy - severity also

needs to be ascertained"^[48]. However, measuring loss of nociception (LON) as yet has no place in assessing neuropathy in diabetes^[47].

Current clinical practice of diagnosing a diabetic foot/ diabetic podopathy

Loss of touch or vibration sensation is not diagnostic of an active diabetic foot, while painlessness of a foot injury (soft tissue or skeletal lesion) or infection in a patient with diabetes mellitus is. Three different clinical pictures of active diabetic foot lesions may be discerned, according to the dominant clinical component: (1) septic; (2) ischaemic; and (3) arthropathic. After healing of such a lesion, the foot is an inactive diabetic foot (with scars, deformities, etc.) and remains a *locus minoris resistentiae* for the rest of the life. LON traditionally is not assessed systematically, but is taken as matter of fact when a patient with an injured foot does not limp. The patient history of traumatic events is often unproductive as far as normal symptomatology (pain!) is concerned. However, when concurrent symptoms of trauma onset other than pain are concerned, like swelling and erythema, patient history may be very well productive.

QST

The QST protocol, published by the German Research Network on Neuropathic Pain and supported by pharmaceutical companies, was designed for non-invasively diagnosing pain syndromes like spontaneous neuropathic pains, fibromyalgia or chronic lower back pain^[15,16,18]. It comprises 13 somatosensory sensory tests that measure the function of large (A-beta) and small (A-delta and C-) afferent nerve fibres, and the corresponding functions of the spinothalamic tract (cold detection threshold, warm detection threshold, thermal sensory limen, paradoxical heat sensation, cold pain threshold, heat pain threshold, mechanical detection threshold, mechanical pain threshold, mechanical pain sensitivity, dynamic mechanical allodynia, wind-up ratio, vibration detection threshold, and deep pressure pain threshold). Using this protocol in healthy subjects, a pool of normative reference data from face, hand and foot had been generated^[16,17].

QST of pain perception in diabetes

Of all sensory modalities that are impaired by diabetes mellitus, the nociceptive pain system is the most relevant. In the following sections, the focus will therefore be directed on pain perception thresholds: elevated thresholds indicate reduced perception of noxious stimuli, and *vice versa*. Pain tolerance or other sensory modalities (vibration, electrical current, chemicals, touch, thermal perception) will not be addressed. Some technical features of the threshold studies considered here are outlined below, concerning thermal (cutaneous heat and cold), and mechanical (cutaneous and deep pressure)

Figure 3 MSA Thermostest® (electronic device, expensive!).

Figure 5 MARSTOCKnervtest® PinPrick stimulator 512 mN (fibreglass, cheap!).

pain perception.

Cutaneous thermal pain perception: Thermal pain perception threshold is measured by applying warm or cold stimuli to the skin, generated by appropriate thermodes (Figure 3). The temperature of the thermode is gradually increased or decreased. The subject under study is asked to indicate whether a thermal sensation becomes painful. Heat pain represents C-fibre function, and cold pain represents A-delta fibre function. In healthy subjects, heat pain perception threshold may range from approximately 41 °C to approximately 47 °C (average approximately 44 °C), and cold pain perception threshold ranges from approximately 1 °C to approximately 30 °C (average approximately 12 °C).

Deep pressure pain perception: Deep pressure pain perception threshold (DPPPT) may be examined, for instance, by a hand held device (algometer, Figure 4) containing a mechanical or electronic force gauge, and a plunger with a flat blunt rubber tip. The diameter of the tip can be 11 mm (surface approximately 1 cm²), or larger, as appropriate. The plunger is pressed perpendicularly onto the skin and the underlying structures, with slowly increasing stimulus ramp (50 kPa/s, equivalent to 0.5 kg/s). The subject under study communicates when his pressure sensation turns to pain.

Figure 4 Algometer® (electronic device, expensive!).

The deep pressure pain sensation evoked by an algometer at muscle or joint is as yet not fully understood. For instance, the afferents involved (high and low threshold mechanosensitive units^[32]), the anatomical structures subjected to algometer pressure, and the role of spatial summation (pressure area 1 cm²)^[49,50], still have to be elucidated. The contribution of fascia, which is more pain-sensitive than muscle, and of periosteum, which is more pain-sensitive than bone marrow, remains to be determined. The pain quality at reaching DPPPT is dull and burning and probably more of a pressure discomfort than of a stinging or pricking^[49,50]. Inside deep tissues, stimulation of the few A-delta (group III) nociceptors simultaneously probably does not elicit a separate pricking pain sensation like a single punctuate stimulation at the skin does^[49,51]. DPPPT decreases at chronically ischaemic muscle^[52,53]. DPPPT at muscle (blunt stimulation) decreases with age, at variance to cutaneous pressure pain perception threshold (CPPPT, punctuate stimulation)^[42]. Using a pressure algometer with 1 cm² contact area to stimulate musculus abductor hallucis, DPPPT in healthy subjects may range from approximately 200 kPa to approximately 1000 kPa (average approximately 500 kPa, equivalent to 5 kg). Algometer stimulation of a joint evokes a DPPPT of the same range.

Cutaneous pressure pain perception: Cutaneous pressure pain perception threshold (CPPPT) is examined by the use of calibrated pinprick stimulators with a sharp edge, comparable to von Frey hairs. These punctuate stimulators are filaments of 50-350 µm diameter, with calibrated bending forces (or weight loads) over a range from 8 mN to 512 mN (equivalent to 0.8 g to 51.2 g) (Figure 5).

The investigator presses each single stimulator perpendicular to the skin (until bending of the filament) and the subject under study communicates, whether a painless touch is felt, or a painful (pricking or stinging) sensation, or nothing at all. The pain threshold is determined by the method of limits, or by the forced-choice-method. The stimulators excite single nociceptors representing A-delta (rather than C-fibre) functions; the

Percentages of supranormal results are shown. ¹Above upper limit of measurement. CPPPT: Cutaneous pressure pain perception threshold.

pain quality evoked is that of a stinging, pricking “first” pain. CPPPT increases with age (at variance to DPPPT, see above). At the non-callous plantar skin of healthy subjects, CPPPT may range from approximately 4 mN to approximately 450 mN (average approximately 100 mN, equivalent to 10 g).

Limitations of pain threshold measurements:

QST is a subjective psychophysical method, as it is based on the patient report. “A critical element in pain threshold determination is the particular sensory experience an individual considers painful. This factor will be influenced by, among other things, the subject’s pain experience history, and the instructions given by the experimenter. For instance, thresholds are likely to be different if a subject is instructed to indicate when he perceives ‘pain’ vs when he perceives ‘a sharp or burning sensation’ or ‘an uncomfortable situation’....”^[54]

In particular, pressure pain measurement is affected by the hardness of the skin at the site of measurement, and by the ramp rate of increasing the stimulus of hand-held algometers, amongst others.

QST of nociception at the diabetic foot

Early studies of pain perception thresholds:

Between 1988 and 2011, not a single study could be identified on cold pain perception threshold, or on DPPPT. However, there are at least 4 studies on CPPPT and/or heat pain perception threshold^[29,55-57], all of which found significantly elevated thresholds at the active (?) diabetic foot and the contralateral foot, as compared to neuropathic patients without diabetic foot (Table 1). In neuropathic patients with and without diabetic foot, pain perception thresholds were significantly higher than in non-neuropathic (healthy or diabetic) control subjects. Lang *et al*^[52] reported that perception thresholds for cold pain, heat pain and pinprick were elevated at legs with chronic severe foot ischaemia (rest pain with/without tissue loss); the 16 patients (8 of whom had diabetes mellitus) had polyneuropathy according to a vibration perception threshold < 4/8 (graduated tuning fork). DPPPT at ischaemic muscle, however, was lower than at healthy controls’ muscle (199 kPa vs 295 kPa^[52]). In another study of non-neuropathic patients with chronic leg ischaemia, CPPPT, and DPPPT at muscle, were lower

Figure 6 Pressure pain perception threshold measurements done in own studies^[58-61]. CPPPT: Cutaneous pressure pain perception threshold; DPPPT: Deep pressure pain perception threshold.

than in control subjects but cutaneous cold and heat pain perception thresholds were not^[53].

Recent pilot studies of pressure pain perception thresholds:

Between 2012 and 2014, we conducted four studies on the matter^[58-61] including explorative cross-sectional and follow-up studies. Our overall database comprised 123 subjects in whom pressure pain perception thresholds were measured: 43 control subjects, 23 of whom had an acute trauma of the foot skeleton (sprain, minor fracture), 59 diabetic patients with PLDN (46 of whom with a diabetic foot), and 21 diabetic patients without PLDN. Among the 46 patients with a diabetic foot, there were 33 with active painless foot ulcer, 13 with healed foot ulcer, 11 with healed Charcot foot (grade 1, inactive^[62]), and 13 with acute skeletal trauma (elective surgery). CPPPT and DPPPT were studied, as well as vibration perception threshold (not reported here). According to our study protocol, CPPPT was measured only at the forefoot (plantar digital skinfold), while DPPPT was measured at the hindfoot (m. abductor hallucis) and at the forefoot (metatarsophalangeal joint) (Figure 6).

By cross-sectional comparison, CPPPT at a plantar digital skinfold (glabrous skin) was above the safety limit of measurement of 512 mN (approximately 51.2 g) in 98% of cases with a past or present painless foot ulcer or healed arthropathy (Charcot foot). This is in line with the older reports cited above. Simultaneously, DPPPT at abductor hallucis muscle was above the safety limit of measurement (1400 kPa, equivalent to 14 kg) only in about 20% of cases. The DPPPT at metatarsophalangeal joint was above 1400 kPa in about 50% of cases (Table 2).

Serial pressure nociception studies to monitor pain thresholds after an acute foot trauma (ankle sprain, toe fracture) in otherwise healthy subjects revealed that CPPPT and DPPPT at the site of the trauma decreased slightly, indicating normal, inflammation-mediated posttraumatic hyperalgesia (Figure 7). This observation is consistent with previous reports (Martinez *et al*^[63]:

Table 2 Simultaneous measurements of pressure pain perception thresholds at the foot in subjects with and without painless diabetic neuropathy, with and without diabetic foot

Subject populations	Diabetic foot ¹	Healthy ²	PLDN ³	DM-controls ⁴
No. of subjects	46	43	13	21
% of subjects with CPPPT > 512 mN at toe skinfold	98%	4%	46%	5%
% of subjects with DPPPT > 1400 kPa at m. abductor hallucis	22%	0%	0%	0%
% of subjects with DPPPT > 1400 kPa at metatarsophalangeal joint	50%	2%	0%	5%

¹With previous or active ulcer/arthritis; ²Non-neuropathic, healthy; ³PLDN, no ulcer; ⁴Diabetes, no neuropathy, no ulcer. Percent subjects with thresholds above the safety limit of measurement are shown. Adapted from ref. [58-60]. CPPPT: Cutaneous pressure pain perception threshold (512 mN upper limit of measurement); DPPPT: Deep pressure pain perception threshold (1400 kPa upper limit of measurement).

Figure 7 Lowered pain perception thresholds (hyperalgesia) after acute skeletal trauma of the foot in 13 healthy control subjects (sprain, toe fracture) and in 12 diabetic foot patients (elective surgery) at the injured site. Data are combined from ref. [59,61]. A: Cutaneous pressure pain perception threshold (mN) (pinprick) at plantar digital skinfold (medians); B: Deep pressure pain perception threshold (kPa) over metatarsophalangeal joint (medians); C: Deep pressure pain perception threshold (kPa) over musculus abductor hallucis (medians).

decrements in CPPPT on day 1-4 at an operated knee; Lang *et al*^[53]: reduction in CPPPT and DPPPT in a chronic ischaemic leg up to 3 mo after successful endovascular revascularisation, Dominguez *et al*^[64]: reduced DPPPT at the foot immediately after a sprain). This physiologic, inflammation-mediated posttraumatic hyperalgesia is the essential trigger of avoidance behaviour to preserve the injured limb from further noxious and innocuous impacts.

By contrast, at the diabetic foot CPPPT was extremely elevated (above the safety limit of measurement) prior to an acute foot trauma (elective surgery), and also immediately thereafter (Figure 7A); there was no posttraumatic decrement of CPPPT at the site of the trauma^[61]. This suggests absence of A-delta "first" pain quality and inflammation-mediated hyperalgesia. DPPPT at the diabetic foot, being elevated prior to the surgery, showed a small posttraumatic decrement from this baseline level (Figure 7B and C) which, however, was not accompanied by clinical signs of hyperalgesia, or avoidance reaction, respectively.

These data, however, have to be interpreted with caution since our study groups were small (only 12 and 13 subjects, respectively) and heterogeneous. Furthermore, it cannot be ruled out that our study subjects may have behaved like those young healthy women, who reacted to consecutive daily measurements of DPPPT over 4 d by increased pain sensitivity^[65] - a reaction that may be an exception rather than the rule^[13].

CPPPT within the normal reference range may decrease slightly upon re-testing^[14] but remains consistently above the safety limit of measurement in patients with diabetic foot^[58-61].

Miscellaneous studies of A-delta and C-fibre sensory functions at the diabetic foot:

At least 7 studies^[66-72] could be ascertained, all of which reporting that the axon-reflex reaction is not much smaller in neuropathic patients with a diabetic foot than in those without. Axon-reflex reaction in the feet of neuropathic patients was consistently smaller than in the feet of non-neuropathic control subjects.

At least 11 studies^[57,67,73-81] could be ascertained, all of which reporting that neuropathic patients with a diabetic foot have higher thermal detection thresholds than neuropathic patients without. Thresholds were higher in the feet of neuropathic patients than of control subjects, and were particularly high in patients with more severe, relapsing diabetic podopathy and/or Charcot foot^[76-79]. One study^[79] showed a lower cooling detection threshold in the active or inactive Charcot foot vs the contralateral foot, while the warming detection threshold was similar on both feet.

CONCLUSION

At the diabetic foot, cutaneous thermal and mechanical (pinprick) nociception is reduced dramatically. CPPPT

Table 3 Percentages of subjects with active diabetic podopathy (ulcer, arthropathy) according to loss of nociception

Foot morbidity	Degree of loss of nociception			Ref.
	None (CPPPT ¹ approximately 100 mN) 0%	Mild/moderate (CPPPT ¹ < 512 mN) 0%	Severe (CPPPT ¹ > 512 mN) 100%	
Past/present painless ulcer				[59]
Foot ulcer, incidence per year	Approximately 0%-1%	Approximately 6%-15%	Approximately 20%-100% ²	[28,59,77,86-101]
Charcot-foot, prevalence	Approximately 0%	Approximately 0.05%	Approximately 2%	[102]

¹Cutaneous pressure pain perception threshold, pinprick stimulator, upper limit of measurement 512 mN, measured at a plantar digital skinfold;

²Depending on compliance with prophylactic podiatry and/or special footwear. CPPPT: Cutaneous pressure pain perception threshold.

was elevated beyond the safety limit of measurement in most of the small number of published studies. Patients with diabetic foot ulcers unanimously display a CPPPT at a digital plantar skinfold which is beyond the safety limit of 512 mN. However, details of the causal role of increased CPPPT (indicating lack of A-delta nociception) for the manifestation of diabetic podopathy remain to be established, as well as the anatomical distribution of PLDN at the foot. Concerning DPPPT at the diabetic foot, the data is less clear, as differences to control subjects often were surprisingly small. Compared to baseline DPPPT, inflammation-mediated posttraumatic DPPPT was reduced at the diabetic foot, albeit at a high level and far from indicating hyperalgesia. Pending confirmation, this may suggest that DPPPT probably does not need to be extremely elevated for a diabetic foot to develop.

There are many more open questions, for instance: what number of residual intraepidermal free nerve fibre endings corresponds to the elevation of CPPPT at the diabetic foot? What elevation of CPPPT is necessary to appreciably increase a patient's risk of sustaining painless foot ulceration and/or arthropathy? How much pain threshold elevation, *i.e.*, how much "LON", is clinically meaningful? Is the nociception at healthy tissues relevant, or is it the pain perception (hyperalgesia, allodynia), that is typically caused by stimulation of inflamed tissue? Is superficial and deep tissue nociception similarly impaired by PLDN? How much are "silent" nociceptors^[82] affected? Is the stinging "first" pain more reduced than the burning "second" pain? Is there a defect in posttraumatic ongoing (non-stimulated) pain? Is absolute or relative reduction of individual pain perception essential for the diabetic foot to develop? Is pain perception or pain tolerance more relevant? Do abnormalities of the central nervous system contribute to the painlessness of the diabetic foot? To what extent is sensitization, either peripheral or central, affected at the diabetic foot? Concerning the discrepancies between CPPPT (at the forefoot) and DPPPT (at muscle of hindfoot) in our own studies^[58-61] - does the distal-to-proximal gradient of PLDN provide an explanation?

Measuring nociception at the diabetics' feet-what is it good for?

LON is the principal pathogenic component of diabetic podopathy, as it is the principal functional component

of PLDN. Loss of pressure perception does not increase the risk of diabetic foot ulceration, whereas a history of foot ulceration (equivalent to cutaneous LON) does^[83]. Measuring nociception provides the opportunity for a clinically meaningful staging of the severity of PLDN. A critical LON needs to be elaborated (probably corresponding to a critical number of intraepidermal nerve fibre endings), "to be able to inform the patient adequately about the risk of ulcer formation and to prescribe preventative measures... otherwise, sensation loss and resultant ulcers may lead to amputation", as Assal *et al*^[84] advocated 25 years ago. Perhaps every patient may have his/her own individual critical LON to be taken into account. Small reductions in intraepidermal nerve fibre density may be mirrored by respective increases in CPPPT, as recent work by Selim *et al*^[85] shows. Hence, measuring CPPPT prospectively may be suitable for monitoring progression of PLDN.

Shifting the emphasis from amputation prevention by wound healing to amputation prevention by injury prevention:

Once an active diabetic foot/podopathy has become manifest, a multitude of cumbersome, laborious, tedious, expensive and costly therapeutic interventions is necessary to save the foot and prevent an amputation. Injury prevention in high-risk PLDN - to prevent the diabetic foot- is certainly much more efficient. Preventing the first or recurrent ulcers^[86] should be no question. Having had a first ulcer strongly predisposes to subsequent ones, most likely due to comorbidities from structural abnormalities that resulted from the (healed) first ulcer (scars, deformities, contractures, tissue loss). The same holds true for arthropathy. Hence, preventing the first ulcer/arthropathy must have absolute priority. To this end, intensive prophylactic measures are necessary in high-risk patients who should be identifiable by simple means. As a proposal, the following tentative risk-stratification is construed from various published data (assuming a "normal" average walking activity of 5000 strides per day^[87]); (Table 3).

Subjects with critical LON at their feet require signals other than foot pain to control foot usage and avoid over-usage. These signals can only come from technical devices, like step counters or load monitors incorporated into footwear, that send acoustic or optical alarms when a critical load (or an equivalent number of steps) has accumulated. Then, the feet have to be rested - for an

appropriate period of time as physiologically required to regenerate the stressed tissues - before their usage (walking) may be resumed. Moreover, feet with critical LON need special footwear to avoid rubbing of the skin while walking in order to prevent skin abrasion and blister formation.

Pain is a homeostatic emotion that drives behaviour, just as hunger and thirst are. Patients who cannot have it, either from acquired or inherited insensitivity to pain^[103,104], either in the feet or elsewhere in the body, need our special protection, and much more specific than we, their caregivers, may have been willing to concede in the past. Research into nociception at the foot in diabetes must continue and expand. Chances to improve injury prevention will be missed, if this uncharted territory remains unexplored.

a rise in the numbers of overweight and obese individuals. A number of diets have been shown to be effective for the management of T2DM: the Mediterranean diet, the vegetarian diet and the low-calorie diet. Results of studies clearly indicate, however, that the efficacy of these diets is not solely related to the biochemical structure of the individual nutrients they contain. This review discusses this point with reference to the potential role of the intestinal microbiota in diabetes. The macrobiotic Ma-Pi 2 diet is rich in carbohydrates, whole grains and vegetables, with no animal fat or protein or added sugar. In short- and medium-term trials conducted in patients with T2DM, the Ma-Pi 2 diet has been found to significantly improve indicators of metabolic control, including fasting blood glucose, glycosylated hemoglobin, the serum lipid profile, body mass index, body weight and blood pressure. The diet may also alter the gut microbiota composition, which could additionally affect glycemic control. As a result, the Ma-Pi 2 diet could be considered a valid additional short- to medium-term treatment for T2DM.

Key words: Ma-Pi 2 macrobiotic diet; Type 2 diabetes; Low-grade inflammation; Gut microbiota; Metabolic control

Core tip: Imbalances in the intestinal microbiota (dysbiosis) have been linked to diseases, including diabetes. In short- and medium-term trials conducted in patients with type 2 diabetes mellitus (T2DM), the Ma-Pi 2 diet, which is rich in carbohydrates, whole grains and vegetables, with no animal fat or protein or added sugar, has been found to significantly improve indicators of metabolic control, including fasting blood glucose, glycosylated hemoglobin, the serum lipid profile, body mass index, body weight and blood pressure. The diet may also alter the gut microbiota composition. Hence, the Ma-Pi 2 diet could be considered a valid additional short- to medium-term treatment for T2DM.

Abstract

In the past 10 years the prevalence of type 2 diabetes mellitus (T2DM) has increased hugely worldwide, driven by

Fallucca F, Fontana L, Fallucca S, Pianesi M. Gut microbiota and Ma-Pi 2 macrobiotic diet in the treatment of type 2 diabetes. *World J Diabetes* 2015; 6(3): 403-411 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/403.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.403>

INTRODUCTION

In the past 10 years, the prevalence of type 2 diabetes mellitus (T2DM) in Italy has increased greatly; currently, approximately 3.3 million people are diagnosed with T2DM (5.5% of the total population) and another million people are thought to be affected but as yet undiagnosed. These numbers are expected to increase in the near future, and it has been estimated that 9.0% of the population will have T2DM by 2030^[1]. Similar increases are anticipated in other European countries and, globally, the number of people with diabetes is predicted to reach 592 million by the year 2035 - an increase of 55% from 2013 data^[2].

This increase in the prevalence of T2DM, which accounts for approximately 90% of all diabetes cases, is clearly being driven by an increase in the numbers of individuals who are overweight or obese^[3]. Indeed, the risk of diabetes appears to literally soar as the weight piles on; a rise in body mass index (BMI) from 21 kg/m² (healthy) to 35 kg/m² (obese) can increase the likelihood of developing the disease by a factor of 80^[4]. In line with the increase in prevalence of diabetes, the number of obese adults, together with the rates of obesity-related diseases (e.g., coronary heart disease and stroke, hypertension and arthritis) and associated healthcare costs, are all expected to increase dramatically worldwide over the next 20 years^[4,5].

T2DM and obesity, and their associated complications and costs, are therefore among the most pressing healthcare problems that society is currently facing. Despite improvements in our understanding of T2DM and the development of new diagnostic and treatment methods, we are still failing to control this epidemic. There is a crucial need to find effective, simple, pragmatic, sustainable and cheap interventions (e.g., those aimed at changing lifestyle, such as exercise and diet).

Recent reviews highlight the benefits of physical exercise in T2DM^[6]. In Italy, the Italian Diabetes and Exercise Study^[7-10] has contributed to this evidence and has helped provide definitions and standards used by the American College of Sports and Medicine and the American Diabetes Association (ADA). Yet, despite the accepted benefits of physical exercise for patients with T2DM, the implementation of exercise recommendations has proved difficult. Reasons for this include a lack of patient compliance, insufficient knowledge/awareness of benefits among general practitioners, diabetologists or exercise professionals, and a lack of dedicated facilities^[11]. In addition, in order to be successful, exercise interventions in individuals

with T2DM tend to require intensive counseling and supervision from medical or exercise professionals.

As a result, recent attention has focused less on exercise and more on diet; dietary therapy (as a life-style intervention), with or without additional drug treatment, represents an efficacious and safe alternative for T2DM management^[12]. Various cohort studies have shown that selected healthy eating patterns, mainly characterized by a higher intake of fruit and vegetables, are associated with a lower risk of diabetes^[13]. In this review, we look at some of the various diets that have been shown to be effective for the management of T2DM, in particular the Ma-Pi 2 macrobiotic diet, and explore the potential role of the intestinal microbiota in T2DM.

MEDITERRANEAN DIET

A Mediterranean-type diet is one involving: a high consumption of cereals, grains, fruits, vegetables, legumes, nuts; olive oil as the principal source of fat; low-to-moderate consumption of fish and poultry; relatively low consumption of red meat; and moderate consumption of wine, normally with meals^[14].

Based on this definition, numerous epidemiological studies have indicated the favorable effects of this diet^[15-17]. Such diets have been reported in two prospective studies^[18,19] and one intervention study^[20] to be associated with a reduced risk of diabetes. However, the role of the Mediterranean diet in weight control remains controversial^[21], which suggests that the protective effect of this diet against diabetes are not based on weight control but through several of its dietary characteristics. Currently it is unclear which component of the Mediterranean diet contributes most to its favorable effects.

LOW CALORIE DIET

Weight loss following a reduction in energy intake (caloric restriction) and/or an increase in energy expenditure (through exercise) improves insulin sensitivity, hyperglycemia and other cardio-metabolic risk factors^[22]. Caloric restriction (CR) is defined as a reduction in caloric intake by around 20%-40%, with adequate intakes of protein and micronutrients to avoid malnutrition^[23,24]. Caloric intake can be reduced by eliminating the consumption of energy-dense foods (e.g., refined carbohydrates, potatoes, white bread, white rice, sweets and sweetened drinks) and by increasing the intake of a nutrient-dense foods (a wide variety of vegetables, fruits, nuts, low-fat dairy products, egg whites, wheat and soy proteins, fish and meat). The energy intake of such a diet is around 1100-2000 kcal/d, with approximately 26% of calories obtained from protein, 28% from fat and 46% from complex carbohydrates^[23]. CR may be administered as a short- (1 mo-1 year) or long-term diet. CR in healthy individuals as well as those who are obese or have T2DM has been reported to lower blood glucose

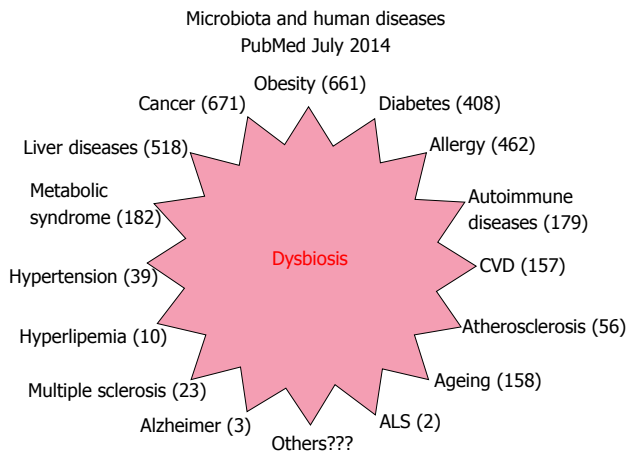

Figure 1 Articles indexed in PubMed concerning the microbiota and human diseases. Results of a research in PubMed looking for articles concerning gut microbiota that associated dysbiosis and human diseases. Number of articles for each kind of disease is indicated in brackets. CVD: Cardiovascular diseases; ALS: Amyotrophic lateral sclerosis.

levels, fasting insulin values and BMI^[25]. Weight loss induced by caloric restriction mediates a reduction in inflammatory markers and improves insulin resistance and sensitivity^[26]. With adequate nutrition, CR can improve cardio-metabolic health, prevent T2DM and may be a powerful tool against obesity and insulin resistance.

VEGETARIAN DIET

Vegetarian diets typically include large amount of fruits, vegetables and legumes, nuts and soya-protein and usually aim to eliminate all animal products. Studies have shown that, generally, vegetarians residing in Western countries have a lower BMI and a higher ratio of polyunsaturated to saturated fat intake than individuals consuming a non-vegetarian diet (people eating meat and/or fish)^[27,28]. Vegetarians have also been shown to have lower concentrations of low-density lipoprotein (LDL)-cholesterol^[29-31], lower blood pressure^[32,33] and a lower risk of diabetes^[34] than non-vegetarians. Factors associated with the higher fiber content in vegetarian diets promote increased insulin sensitivity^[35]. Vegetarian diets are also associated with other health benefits. According to the largest study ever conducted in the United Kingdom from the University of Oxford, the risk of hospitalization or death from heart disease was 32% lower in vegetarians than in people who ate meat and fish, with most of the difference in risk probably caused by effects on cholesterol and blood pressure^[36]. In addition to a lower risk of cardiovascular disease^[37,38], vegetarian diets have been reported to reduce the incidence of cancer in a low-risk population^[39,40].

MICROBIOTA

The results of some studies indicate that the efficacy of a diet is not solely related to the biochemical structure

of the individual nutrients it contains and the current standard definition of macronutrients fails to capture important information^[41]. This has become more obvious as knowledge of the gut microbiota^[42-46] has been gained and the "food as hormone" hypothesis^[47] has emerged.

The human gut microbiota weighs about 1500 g and the number of intestinal microbial cells it contains is tenfold greater than the total number of human body cells^[48]. The gut microbiome, which represents the collective genomes of all gut microbiota, is 150 times greater than the human gene complement^[46]. The gut microflora plays several metabolic active roles: it produces vitamins, synthesizes amino-acids, transforms bile acid, and is able to ferment non-digestible substrates and endogenous mucus, stimulating bacterial growth and producing short-chain fatty-acids (SCFA)^[49], which work in the gut and at distance after absorption^[49]. Moreover, the gut microbiota also causes pathogen displacement, by competing for attachment sites and nutrients, and by secreting antimicrobials^[50]. The microbiota plays a fundamental role in the development of the immune system^[51], as SCFA have a strong immunomodulatory activity, leading to the production and release of cytokines, chemokines and phagocytes^[52].

The gut microbiota is also involved in the development of cells and tissues^[53], and is responsible for the integrity of the gut barrier^[53] through its involvement in glucagon-like peptide (GLP)-2 production by enteroendocrine L-cells, and the circulation of endotoxins^[54]. In addition, the microbiota triggers the production of peptide YY, which regulates gut motility and the hungry sensation^[55].

Dysbiosis is a bacterial imbalance in the gut resulting in a modification of the normal local distribution of microbial communities that correlates with biochemical and clinical modifications in the host: hyperglycemia and T2DM have been observed in the presence of a low percentage of bacterial *Firmicutes* and *Clostridia* species^[56]. Diet and increase in bodyweight are linked to gut microbial imbalance, in both the presence and absence of obesity^[57].

Recent studies have shown a link between dysbiosis and several diseases, including diabetes (Figure 1).

Obesity and T2DM are associated with chronic low-grade inflammation and endotoxemia. Lipopolysaccharide (LPS) consumption and a diet rich in fat increase adiposity, impaired glucose tolerance, and insulin resistance those raises are reversible by the consumption of a pre-probiotic rich diet^[44,58,59], or a meal based on fiber and fruit, as recommended by the American Heart Association^[60]. Bacterial LPS derived from Gram-negative bacteria residing in the gastrointestinal microflora could act as a trigger for the development of diabetes and obesity; in a series of experiments in mice, it was observed that high-fat feeding favors an increase in the Gram-negative to Gram-positive colonizing bacteria ratio, which has been associated with an increased intestinal permeability that precedes the development of metabolic endotoxemia, inflammation, and associated disorders (obesity and diabetes)^[44]. Different nutrients have different enhancing-

effects on endotoxemia (LPS production by microflora or for higher gut permeability) and the consequent inflammatory response^[61]. Other factors may also influence our microbiota, such as age^[62-64], chemical products and antibiotics^[65], and prebiotics and probiotics^[58,66-68].

The internationally endorsed definition of probiotics is "live microorganisms which when administered in adequate amounts confer a health benefit on the host"^[69], whereas, definition for prebiotics is "a selectively fermented ingredient that allows specific changes, both in the composition and/or activity in the gastrointestinal microflora, that confer benefits upon host well-being and health"^[66]. Therefore, in order to be classified as a prebiotic, the ingredient should resist gastric acidity, hydrolysis and should be fermented by the intestinal microflora. The consumption of prebiotic foods enhances a reduction of triglyceride and postprandial glucose levels, gut permeability and inflammatory effect^[66,70]. It has been observed that administering prebiotics to obese mice induces a microbiota modulation, lowering both diet-induced LPS endotoxemia, and systemic inflammation and liver inflammation^[44]. The main positive effects of pro- and prebiotic administration are increases in GLP-1 and peptide YY secretion^[71-73], a reduction in the complications of pregnancy^[74], and improvements in metabolic diseases (obesity, T2DM, cardiovascular disease)^[75].

New findings in microbiota knowledge are opening new fields of study about human health and disease. However, the research regarding the interaction between bacteria and human health is at the beginning and many aspects are still not properly understood; well-defined clinical studies are needed in order to develop the potential of this new therapeutic area.

Until now, scientists have focused primarily on identifying human genetic markers, but research has shown that other factors, such as the intestinal flora, play a role in the development of T2DM^[45,46]. The results of metagenome-wide association studies in T2DM patients and non-diabetic controls^[45,46] clearly indicate that T2DM is a significant factor in the observed variation in gut microbial samples, and suggest that the gut microbiota in T2DM patients features dysbiosis. These studies^[45,46] indicate that a gut-microbiota-based index could be more effective and accurate in assessing and predicting the risk of T2DM than a human genome variation-based one.

Knowledge of the microbiota and the general concept of "food as hormone", as proposed by Ryan *et al.*^[47], suggest that diet has an enormous impact on our health. In fact, circulating substrates derived from food have both direct and indirect actions and, ultimately, food may be considered a cocktail of hormones that exert their effects on target tissues, activating cell-surface or nuclear receptors. Food components also interact with the gut flora to induce indirect signals. Therefore, if we consider this new role for food, we can make dietary recommendations to promote health or treat specific diseases, taking into account that until now macronutrients have been classified according to their energy-yielding biochemical properties and not by their

ability to work in a manner similar to that of hormones. Identifying these food- and food metabolite-receptor interactions will provide new opportunities for studying the relationship between the food we eat and diseases, including obesity.

MA-PI 2 MACROBIOTIC DIET

Macrobiotic diets are originally derived from an ancient Eastern philosophy of life based on two ancient Asian theories (Yin/Yang and the Five Transformations), formulated for Western culture by the Japanese philosopher Georges Ohsawa^[76] and further updated by Mario Pianesi who created the 5 Ma-Pi diets^[77]. The Ma-Pi 2 diet was specifically designed for patients with metabolic disorders, and consists of 50%-55% whole-grain (rice, millet and barley), 35%-40% vegetables (carrots, savoy cabbage, chicory, red radish, onions, parsley, cabbage) and 8%-10% legumes (adzuki beans, chickpeas, lentils and black beans), plus gomashio (roasted ground sesame seeds with unrefined sea salt), and fermented products [miso, wandadou jiangyou (soy sauce) and yanzimei (pickled ume plums)], which could have probiotic effect; seaweeds [Kunbu (*Laminaria japonica*, Aresch), Qundaicai (*Undaria pinnatifida*, Harv.), Haitai (*Porphyria tenera*, Kjell.) and Hiziki (*Sargassum fusiforme*, Harv.)] and Beicha tea (caffeine-free green tea). The daily average energy intake is in the range of 1700-2200 kcal (12% from proteins, 18% from fats and 70% from carbohydrates, mainly complex). The Ma-Pi 2 diet contains, on average, 18% saturated, 46% monounsaturated and 36% polyunsaturated fat, with no trans-fatty acids and an n-6:n-3 polyunsaturated fatty acid ratio of 5:1. It provides nutrients and phytochemicals with antioxidant, hypoglycemic and hypolipidemic effects, such as vitamin C, β carotene, magnesium (average 700 mg/d), manganese (average 16 mg/d), zinc (average 15 mg/d), chromium, phytosterols (average 326 mg/d), dietary fiber (average 50-60 g/d), inulin (average 9 g/d), polyphenols, tocotrienols, folates (more than 500 μ g/d), quercetin, and prebiotic and probiotic products. The Ma-Pi 2 diet excludes all animal products, (including egg and dairy), and has no added sugars^[77].

All of the ingredients used to prepare the Ma-Pi 2 diets are grown, stored and processed without the use of synthetic chemicals. The crops are from old seed varieties, which were produced using natural methods. All of the products used are labeled, providing detailed information on the origin and characteristics of the product and its supply chain (the Pianesian Transparent Label)^[78]. The nutritional content of one Ma-Pi 2 diet used in a clinical study in T2DM patients is presented in Table 1^[79].

Since 2001, various clinical studies have been carried out to assess the effect of the Ma-Pi 2 diet in T2DM patients.

Single-arm studies of the Ma-Pi 2 diet in patients with T2DM conducted in several countries and continents (e.g., America, Asia, Africa and Europe) have consistently

Table 1 Example of the average daily energy and nutrient intake for the Ma-Pi 2 diet during in one dietary intervention study^[79]

¹mg of amino acid per gram of protein.

shown that consumption of the diet for 3 or 6 mo resulted in statistically significant improvements from baseline in indicators of metabolic control, including fasting blood glucose (FBG), glycosylated hemoglobin (HbA1c), the serum lipid profile [including reductions in total cholesterol, LDL cholesterol and triglyceride values, and the LDL:high-density lipoprotein (HDL) cholesterol ratio], BMI, and insulin resistance, as well as body weight and blood pressure ($P < 0.001$) (Table 2)^[79,80-84]. These results were apparent even in patients with poor glycemic control (HbA1c $> 8.5\%$)^[85]. In patients being treated with insulin, use of this agent fell during the intervention^[79,85].

Similar results were obtained later in short-term (21-d) intervention studies^[86,87], thus demonstrating the ability of the diet to achieve rapid metabolic control.

The first randomized, controlled trial comparing the Ma-Pi 2 diet (in 25 participants) with Italian dietary recommendation for T2DM (in 26 participants)-the MADIAB trial-was carried out in 2013^[88]. After 21 d on the prescribed diet, which was administered under supervised conditions, the average daily energy intake was 1803 kcal (12% protein, 15% fat, and 73% complex carbohydrates, with 29 g/1000 kcal fiber) in the Ma-Pi 2 group and 1798 kcal (18% protein, 32% fat,

Table 2 Metabolic effects of the Ma-Pi 2 dietary intervention after variable periods of time

Metabolic parameters	Duration of Ma-Pi 2 intervention	Effect
Body mass index	3 wk-6 mo	↓
Body weight (kg)	3 wk-6 mo	↓

Interleukin 6 (pg/mL)	3 wk	↔
Insulin-like growth factor 1 (ng/mL)		↓

Taken from the results of studies investigating the Ma-Pi 2 diet in men and women with type 2 diabetes over variable periods. ↑: Increase; ↓: Decrease; ↔: No effect; HbA1c: Glycosylated hemoglobin; HDL: High-density lipoprotein; LDL: Low-density lipoprotein.

and 49% complex carbohydrates, with 20.5 g/1000 kcal fiber) in the control group ($P = 0.860$).

The multivariate analysis (adjusted for age, gender, BMI at baseline, and physical activity) showed that significantly higher percentage reductions in FBG, post-prandial blood glucose (PPBG), HbA1c, total cholesterol, LDL-cholesterol, LDL:HDL ratio, BMI, weight, waist and hip circumference, and insulin resistance were seen in the Ma-Pi 2 group than in the control group. Although the triglyceride levels were reduced in all subjects, the reduction detected in the controls was significantly higher than that in intervention subjects. Furthermore, all subjects in the Ma-Pi 2 group achieved FBG and PPBG target levels (< 110 mg/dL for FBG and < 140 mg/dL for PPBG) at the end of the 21-d dietary treatment^[88].

Further results from this trial, presented at the 2014 ADA 74th Scientific Sessions, have also demonstrated that the Ma-Pi 2 diet is a safe strategy by which to reduce markers of insulin resistance and inflammation. In addition, a significant reduction in insulin-like growth factor-1 was observed in the Ma-Pi 2 subjects vs the controls ($P < 0.001$)^[89].

The MADIAB trial is also currently assessing the hypothesis that the Ma-Pi 2 diet may affect the composition of the gut microbiota to a greater extent than the control diet. The results of this analysis will be published later this year.

These results strengthen the idea that the Ma-Pi 2 diet could play an important role in the treatment of T2DM,

as whole cereals, non-animal fats and protein, and the high fiber content (> 50 g/d) and probiotic presence could improve gut microbiota composition, favoring a reduction in inflammation and insulin resistance^[90].

Eliminating all animal products from the diet may increase the risk of certain nutritional deficiencies in some micronutrients such as vitamin D, calcium, iron, zinc and long-chain n-3 (omega-3) fatty acids^[40]. However, the Ma-Pi 2 diet content of those micronutrients seems to be adequate^[77,79]. Special concern should be given to possible deficiencies of vitamin B-12^[77], even though clinical evidences for deficiency in this vitamin are described only after several years of insufficient consumption^[91]. The MA-PI 2 diet was especially conceived for the treatment of T2DM and studies in adults with T2DM consistently showed that a 3 or 6-mo consumption of the Ma-Pi 2 diet was nutritionally safe, at least for the evaluated time^[79-83,85]. These evidences suggest that Ma-Pi 2 diet can be used as a short- and medium-term treatment, aimed to achieve a good metabolic control and that further research is needed to demonstrate the safety of this diet in the long-term.

However, currently available studies on the Ma-Pi 2 diet in patients with T2DM have a number of limitations, such as the use of relatively small sample sizes. This was due to the particular design of the studies, where subjects were required to dwell in isolated environment 24 h per day, in order to ensure a good compliance to the diets^[80-85,87-89]. However the MADIAB randomized trial was adequately powered and corroborative analyses were performed to ensure consistency and robustness of the clinical trial results^[88]. Other limitations in available studies on the Ma-Pi 2 diets include their short- or medium-term durations and the fact that, in some studies, participants (in both the intervention and control groups) were studied in a supervised environment^[84,85,87-89]. Subject compliance to dietary recommendations for T2DM are required to obtain clinically significant changes in outcomes, and improvements obtained with dietary interventions in clinical trials are not easy to reproduce in daily life. Future studies should aim to address all of these issues.

CONCLUSION

A variety of diets have been shown to be effective for the management of T2DM, including the Mediterranean-style, vegetarian and low-calorie diets. However, the Ma-Pi 2 diet, in both uncontrolled and controlled short- and medium-term trials conducted in patients with T2DM in several countries and continents, has been found to achieve a speed of metabolic control that has not been reported in studies of other diets.

This finding could be attributable to the composition of the Ma-Pi 2 diet, which is high in whole grains, vegetables and legumes, and fermented products, with no animal products and no added sugars. These characteristics allow to improve glycemic control, reduce insulin requirements, improve insulin sensitivity, lower blood cholesterol and

triglycerides, reduce body weight control, and lower systemic blood pressure. The dietary habits may also modify the gastrointestinal microflora composition, which could influence glucose control.

Hence, the Ma-Pi 2 diet could be considered a valid additional short- to medium-term treatment for T2DM, particularly when glycemic control needs to be rapidly improved. Further research is needed to demonstrate the efficacy of this diet in the long-term management of T2DM.

of hippocampus structure and function. Although, the exact mechanism by which maternal diabetes affects the developing hippocampus remains to be defined. Multiple biological alterations, including hyperglycemia, hyperinsulinemia, oxidative stress, hypoxia, and iron deficiency occur in pregnancies with diabetes and affect the development of central nervous system (CNS) of the fetus. The conclusion from several studies is that disturbance in glucose and insulin homeostasis in mothers and infants are major teratogenic factor in the development of CNS. Insulin and Insulin-like growth factor-1 (IGF-1) are two key regulators of CNS function and development. Insulin and IGF-1 receptors (IR and IGF1R, respectively) are distributed in a highly specific pattern with the high density in some brain regions such as hippocampus. Recent researches have clearly established that maternal diabetes disrupts the regulation of both IR and IGF1R in the hippocampus of rat newborn. Dissecting out the mechanisms responsible for maternal diabetes-related changes in the development of hippocampus is helping to prevent from impaired cognitive and memory functions in offspring.

Key words: Maternal diabetes; Cognition complications; Teratogenic factor; Hippocampus

Core tip: Diabetes mellitus is the most seriously metabolic condition in pregnancy that affects the hippocampal development and function of the offspring. Multiple biological alterations, including hyperglycemia and hyperinsulinemia are occurring in maternal diabetes and impair the neurodevelopment of the fetus. Insulin-like growth factor-1 (IGF-1) and insulin are important regulators of development of central nervous system. It has clearly showed that maternal diabetes disturb the regulation of both insulin receptors and IGF-1 receptors in the hippocampus of rat newborn. This article is a brief review of the literatures that suggests a probable

Abstract

Diabetes mellitus during pregnancy is associated with an increased risk of multiple congenital anomalies in progeny. There are sufficient evidence suggesting that the children of diabetic women exhibit intellectual and behavioral abnormalities accompanied by modification

mechanism of how diabetes during pregnancy affects the hippocampus development in the offspring.

INTRODUCTION

Diabetes mellitus (DM) is a chronic common metabolic illness characterized by hyperglycaemia associated with insulin deficiency or insulin resistance. There are two major types of DM: type 1 DM (T1DM) results from chronic and progressive destruction of the beta-cells of the islets of Langerhans in the pancreas. T2DM is primarily characterized by both insulin resistance and relative insulin deficiency^[1,2].

DM is one of the most common and most important metabolic condition affecting up to 7% of pregnancies. Several population studies show that the diabetes during pregnancy affects the health of both mothers and their infants^[3-6].

There are two main types of DM occurs in pregnancy period: pregestational DM (PGDM) and gestational DM (GDM)^[7]. GDM accounts for approximately 90% of all cases of diabetes in pregnancy. Of the remaining cases, 60% have preexisting T2DM before pregnancy, while 40% have a diagnosis of pre-conceptual T1DM^[8].

In a study in the United Kingdom, it was found that PGDM occurs in approximately 1 out of 250 pregnancies, with two-thirds of them having T1DM and the remaining one-third having T2DM^[9]. At present, type 2 diabetes is the most prevalent form of diabetes affecting women of reproductive age in the developed countries, with a mean prevalence of 27.6% in United Kingdom^[10]. Last data from Australia also showed that T2DM affected about 55% of pregnancies^[11]. Overall, GDM complicated from 2% to 12% of all pregnancies. So, however, the incidence of T1DM appears to be relatively constant and similar to the rate in young adults throughout the world; the incidence of T2DM is specially rising in developed world^[9,12]. Furthermore, the overall numbers of children born to mothers with diabetes will significantly rise in the next decades.

COMMON CONGENITAL MALFORMATIONS IN DIABETIC MOTHER INFANTS

An increasing number of evidence clearly showed that infants born to diabetic mothers are in increased risk of fetal and neonatal anomalies which results in increased infant mortality and morbidity rates. Although, the

wide spectrum of the effects of diabetes in pregnancy on the fetus development are determined by the time of onset and the severity of DM^[6,13,14].

Despite considerable progress in the clinical management of pregnant women who have diabetes, the prevalence of major congenital anomalies is approximately 3 times more in infants of diabetic women in comparison to the offspring of normal mothers^[12,15,16].

According to previous works, diabetes in pregnancy has been accompanied by increased risk of a wide range of fetal complications and malformations, including respiratory distress syndrome, macrosomia, organomegaly, obstetric, metabolic and hematological complications^[13,14,16,17].

The overall rate of major congenital anomalies in infants born to diabetic mothers is about 6% to 13%, which is approximately 2-3 times higher than that of the normal condition. However, the prevalence of major structural malformations in the children born to mothers with diabetes are to 10 times greater in comparison to the general population. The frequencies of perinatal mortality are also five-fold higher in women with diabetes compared with normal women^[12,14,16,18].

The prevalence of Minor congenital anomalies in infants born to 802 mothers with GDM, 117 mothers with PGDM, and 380 normal mothers were assessed by Hod *et al*^[19] (1992). They found a range between 19.4% and 20.5% in prevalence of minor congenital anomalies in their infant in all groups studied without any marked difference between groups. In their study, there was no correlation between the type and prevalence of minor congenital anomalies with the severity and the time of onset of the diabetes in mothers. Neither there was any relationship between the type or prevalence of minor congenital anomalies with the type or appearance of major congenital anomalies^[19].

Overall, the defects in central nervous system, heart, kidney, and skeletal system are among the commonest congenital malformations in the offspring of diabetic pregnancies^[3,14,16,18].

PATHOGENESIS OF COMMON COMPLICATIONS IN DIABETIC INFANTS

As yet, the exact mechanisms by which maternal diabetes alters the development of growing fetuses are not completely understood, and no distinct teratogenic mechanism has been identified to clearly explain a reason for this range of congenital anomalies observed in the infants born to diabetic mothers^[20,21].

Many of the developmental effects of diabetic pregnancies on the fetus can be attributed to maternal glucose (metabolic) control. In normal pregnancies, the blood glucose level in women remains within a tight range. Consequently, the blood glucose concentration in the fetus is fairly constant as the glucose in the mother's blood crosses the placenta freely. Nevertheless, in pregnancies complicated by DM, there are great

variations in the maternal blood glucose level^[12,14,22]. Pedersen *et al*^[23] (1954) emphasized the correlation between high blood glucose concentration in pregnant women with hyperglycemia during fetal period^[23], which stimulated the pancreas of the fetuses, leads to beta-cell hyperplasia and hypertrophy with increased insulin secretion and content^[23,24].

Several lines of studies also emphasized the direct correlation between high blood glucose concentration in mothers as revealed by increased level of glycosylated hemoglobin (HbA1c) with increased frequency of congenital malformations in offspring^[22,25]. Towner *et al*^[26] (1995) found a striking correlation between pregestational elevated HbA1c in early pregnancy with the increased risk of fetal congenital malformations^[26]. There is enough evidence accumulates to support this hypothesis that the tight glycaemic control in early and before pregnancy may reduce the frequency of anomalies in the infants born to diabetic mothers^[22]. Therefore, the prevalence of congenital abnormalities in children born to mothers with diabetes has decreased in the last three decades probably as a result of the overall progress in monitoring of blood glucose concentrations in diabetic pregnant women^[27-29].

In addition, fetal hyperinsulinemia also has been shown in the offspring of diabetic mothers. On separation of the newborn from the mother, the glucose former no longer is supported by placental glucose transfer, may develop neonatal hypoglycemia^[30,31].

In earlier works, chronic fetal hyperinsulinemia in the third trimester of pregnancy has been produced in monkeys. The researchers showed that *in utero* hyperinsulinemia results in an organomegaly and fetal macrosomia, except for kidney and brain^[32,33]. Increased plasma erythropoietin levels and body fat content was also evident in infants of diabetic mothers^[34].

Insulin is a hormone that primarily functions as an anabolic hormone of fetal development and growth resulting in macrosomia and visceromegaly^[14]. On the basis of *in vitro* and animal studies on the pancreas, the simplified hyperinsulinemia - hyperglycemia hypothesis has been expanded in earlier studies^[35,36].

Ketones in the mother's blood readily cross the placenta, but they cannot be cause fetal hyperinsulinemia; so, they might not influence fetal growth and development^[14].

In experimental diabetic rodents, fetal hyperglycemia, neonatal hypoglycemia, and disturbances in prostaglandin and arachidonic acid metabolism have been reported to result in congenital anomalies in their offspring^[14,37]. In diabetic pregnancies in rats, it is clearly established that the elevated intracellular free oxygen radicals concentrations have been accompanied by the increased risk of embryopathies^[38]. Nevertheless, hyperglycemia-induced fetal malformations in rodents have been demonstrated to associate with the number of genomic DNA mutations^[39]. Therefore, there are animal

studies showing that the free radical scavengers and antioxidants may decrease the risk of teratogenicity of maternal diabetes^[40,41].

DIABETIC PREGNANCY AND NEURODEVELOPMENTAL SEQUELAE IN HUMAN

Both PGDM and GDM can affect fetal neurodevelopment^[42-45]. Although the untoward effects of maternal diabetes on pregnancy outcomes with respect to congenital malformations have generally been appreciated, the effect of maternal diabetes on the development of central nervous system (CNS) in the fetuses and its behavioral sequelae remains to be completely defined. A limited number of long-term follow-up studies of neurodevelopmental outcomes in diabetic pregnancies have been reported^[46-50]. Nevertheless, it is demonstrated that children born to diabetic mothers are more likely to have neurodevelopmental abnormalities including impairments in learning ability, activity level, attention span, and motor functioning. Interestingly, some of these deficiencies are well-known as risk factors in children who develop schizophrenia later, but the degree of risk is variable and may be related to the severity of metabolic derangement in the mothers with diabetes^[42,46,50,51].

Examination of cognitive functioning and the behavior of the children born to diabetic mothers offers the opportunity to functionally assess the CNS development^[52]. Hence the assessment of the behavior and cognition in the offspring of diabetic mothers may clarify the maternal diabetes effects on the development of CNS.

The results of earlier studies clearly demonstrated that the diabetes during pregnancies may results in intellectual and behavioral functioning disturbances in the infants^[45,46,49,53]. These data suggest a teratogenic effect of diabetes in pregnancy on the function of CNS in fetuses and provides the earliest indicator of postnatal CNS deficiencies reflected in intellectual and behavioral problems observed in the children of mothers with diabetes^[54].

Earlier reports on the neurologic development in infants of diabetic mothers revealed serious CNS deficits, even in the absence of structural malformations. These alterations were significantly less severe when maternal diabetes was medically controlled and treated, but some alterations in cognitive function may persist throughout childhood^[6,42,45,48,51].

To elucidate the effects of diabetes during pregnancy period on cognitive functioning in the children, Yamashita *et al*^[45] (1996) studied 33 pregnant women (24 with T2DM, 6 with T1DM, and 3 with GDM). Their long term follow-up research showed that maternal diabetes significantly affects the development of intellectual functioning in infants. Although, they report no differences in IQ score among offspring of three groups^[45]. In another

study, Churchill *et al.*^[55] (1969), found that diabetic mothers had offspring with significantly lower mean IQs than control infants. In a cohort study of fifty infants at 1, 3, and 5 years of age born to diabetic mothers, Stehbens *et al.*^[56] (1977) reported an adverse effect of diabetes in pregnancy on CNS structure and function in their children. They also found that three infants born to diabetic mothers had major neurologic anomalies and six of them had IQs less than 80.

Rizzo *et al.*^[57] (1991) reported a strikingly correlation between diabetes in mothers during pregnancy and lower IQ in their children. In another study, the same researcher found significant correlations between second- and third-trimester regulation of glycemia and results on the Brazelton Neonatal Behavioral Assessment Scale; they reported an association between increases in maternal glucose levels with poorer infant responses^[58].

Other investigators have not found any differences in cognitive scores^[59-61]. Children born to diabetic mothers may sustain minor neurological damage which does not necessarily affect their scores in IQ tests^[49]. For example, Persson *et al.*^[60] reported more encouraging results in 73 infants born either to mothers with T1DM or to mothers with GDM; all subjects available for follow-up at 5 years of age had normal results on neurologic examinations, as well as normal IQs, and there was no relation between maternal diabetes and IQ^[60].

In a retrospective study at considerable variance with most other reported studies, Yssing *et al.*^[62] (1975) reported a 36% incidence of cerebral dysfunction or related conditions in 740 infants of diabetic pregnancies; 18% had a major cerebral disability. In a study by Haworth *et al.*^[63] (1976) on infants of diabetic pregnancies, noted an about 30% increase in the incidence of neurological and intellectual development impairments^[63]. No differences in behavioral adjustment and academic achievement between children born to T1DM mothers and children of normal mothers were reported in Hadden *et al.*^[64] study.

In addition, poorer habituation performance were also found in fetuses of diabetic pregnancies when compared to fetuses born to normal mothers^[65]. Since habituation reflects the fetal CNS performance, the observed habituation abilities differences between the diabetic and normal groups suggests differences in their CNS function or maturation^[65,66]. Recent investigations also have been demonstrated that there is a significant correlation between diabetes during pregnancy and increased risk of some psychologic disturbances including schizophrenia in their children^[67,68].

Together, these studies suggest a wide-range of teratogenic effects of maternal diabetes on the development and function of fetal CNS^[67]. However, no single molecular mechanism can fully explain the effects of maternal diabetes on fetal neurodevelopment because the CNS development is complex and regulated by a number of signaling molecules and transcription factors.

DIABETES IN PREGNANCY AND NEURODEVELOPMENTAL ABERRATION IN ANIMALS

Neurodevelopmental assessment of the offspring born to diabetic dams have been revealed a wide spectrum of behavioral, neurochemical, cellular, and molecular impairments^[69-72]. Experimental models subjected to streptozotocin - induced type 1 diabetic pregnancies developed significant deficits in cognitive behaviors^[68]. Kinney *et al.*^[73] (2003) found that the only female offspring born to diabetic dams showed deficits in long-term memory and learning. These results have suggested that the *in utero* diabetic condition has gender-specific effects on CNS development^[73].

In a study by Plagemann *et al.*^[74] (1998), alterations in catecholamines levels in the hypothalamic nuclei of newborns born to diabetic animals were evaluated. They reported an increased hypothalamic dopamine (DA) and norepinephrine (NE) concentrations in the offspring born to diabetic rats at birth. Twenty one-day-old pups born to diabetic mothers, NE levels were strikingly increased in the ventromedial hypothalamic nucleus and the lateral hypothalamic area (LHA), while DA levels were significantly elevated in the paraventricular hypothalamic nucleus and the LHA. The authors concluded that there are strikingly differences in hypothalamic catecholaminergic systems during early development in the rat newborns born to diabetic animals^[74].

It has been shown that PGDM is associated with an increases risk of neural tube defects (NTDs), also known as diabetic embryopathy. The prevalence of NTDs in the offspring of diabetic mothers is 3 to 10-fold higher than that of in general population^[75-77]. In earlier studies, the mitochondrial morphological changes has been shown in developing neural tubes subjected to a diabetic environment during the same time period when the NTDs are induced in diabetic pregnancies^[72,78]. Altered activity of cytochrome-c oxidase also has been manifested in the rat hippocampus that have iron deficiency in their brains due to fetal hyperglycemia^[79]. It has also been hypothesized that dysfunction in energy metabolism of developing brain leads to oxidative stress elevation and abnormal regulation of intracellular calcium^[80-82].

NEUROPATHOPHYSIOLOGY OF DIABETIC PREGNANCY

Several well-known biological alterations occur in mothers with diabetes that affect fetal neurodevelopment. These biological changes lead to alterations in neurotransmitter systems, synaptic membranes, neuronal integrity, and growth factors expression that have also been implicated in the development of neurodevelopmental and neurocognitive sequelae in offspring born to diabetic mothers^[14,42,69,72,74].

The hyperglycemia is the most distinct mechanism by which these predispositions might be mediated. The defining characteristics of diabetes during pregnancy, these are clearly showed to have effects on developing CNS and to induce fetal hyperinsulinemia, chronic tissue hypoxia, decreased in fetal iron levels and increased oxidative stress^[20,83-85].

Hyperinsulinemia, hypoxia, polycythemia and iron deficiency

It is revealed that fetal polycythemia induced by DM in pregnancy is likely triggered by the chronic *in utero* hyperglycemia and hyperinsulinemia and develops in response to higher concentration of blood glucose in mothers^[20,42]. A study by Mimouni *et al.*^[86] (1986) showed an incidence of 29.4% fetal polycythemia in infants born to diabetic mothers in comparison to 5.9% in normal conditions. One of the reasonable explanations is that *in utero* hyperglycemia and hyperinsulinemia produces a hypermetabolic state in the developing fetuses, which results in relative tissue hypoxia, leading to polycythemia *via* excess production of erythropoietin. Elevated fetal plasma erythropoietin concentrations in diabetic pregnancies suggests an increased prevalence of chronic fetal hypoxia during development. Although there are no distinct mechanisms for fetal hypoxia in diabetic pregnancies^[34].

Hypoxia affects the fetal CNS development including alterations in myelination, changes in cortical connectivity, excitotoxicity, and neuronal or glial cell death^[87-89].

In the hypoxia state, excess erythropoietin and hemoglobin are produced^[90]. So, the developing fetuses need for iron exceeds its supply that leads to Iron mobilization from vital tissues including the fetal brain^[91,92]. It is showed that human infants born to diabetic women possess brain iron content 40% less than that in normal pregnancies^[93].

Several authors have reviewed the role of iron on CNS development and function^[94-96]. Iron is one of the key component of the many enzymes involve in essential reduction or oxidation reactions, neuronal replication, synthesis and catabolism of neurotransmitters and myelin production^[97-101]. The uptake of Iron into the brain is maximal during the rapid brain development and growth, which coincides with the peak of myelinogenesis^[99-101]. In experimental animals, iron deficiency demonstrated to affect the development of neurotransmitter systems in the brain results in behavioral alteration^[98,102]. Moreover, iron deficiency in fetuses is also known to manifest as increased negative emotionality and higher levels of irritability in infants and is a predictive factor in the behavioral and developmental problems at 5 age old children^[103]. There are studies suggesting that iron deficiency during brain development leads to alterations in the hippocampal structure and function^[104].

Moreover, in animal models, hyperinsulinemia during *in utero* period reduced the fetal amino acid

concentrations, including levels of the nonprotein amino acid taurine, which is showed to be involved in the development of the brain^[105].

Diabetes during pregnancy as a proinflammatory milieu

Diabetes during pregnancy is associated with the disbalance of pro-inflammatory pathways supported by increased circulating concentrations of inflammatory molecules^[106,107]. It is demonstrated that inflammatory cytokines affect the neuronal development and metabolism of neurotransmitters^[108]. In experimental models, cytokines reduced the survival of dopaminergic and serotonergic cells^[109]. Earlier investigations demonstrated that cytokines, including tumor necrosis factor alpha and interleukin-6, are increased in infants exposed to diabetes *in utero* and have been implicated in neuronal damage^[110,111]. It is also clearly showed that imbalances in the regulation of cytokines have been increasingly associated by a number of prevalent and severe neurodevelopmental disorders^[112,113].

Currently, a limited number of human studies demonstrating the effects of inflammatory prenatal environment on neurobehavioural development in children^[114]. Evidence from a few studies suggests that immune alterations that occur in prenatal period may persist into postnatal life^[115,116]. Therefore, increased inflammatory cytokines in diabetic pregnancies may be relevant to neurodevelopment alterations exhibited by the infants born to diabetic women.

Diabetes in pregnancy and oxidative stress

Enhanced oxidative stress plays important roles in embryo development and implicated in the pathogenesis of some neurodevelopmental disorders observed in infants of diabetic mothers^[83-85]. Free radicals can inactivate the biological functions of proteins and lipids and potentially leading to cell death^[117,118]. It is showed that GDM is associated with an increased concentration of oxidative stress, due to both defect in the antioxidant defenses and/or overproduction of free radicals^[83-85]. Although, there are several studies demonstrating the presence of elevated oxidative stress in PGDM and GDM states. Some works also suggested that this milieu can be shared with the developing fetus^[83-85,119].

In experimental animals, it is emphasized that oxygen radicals play crucial roles in the progression and timing of the development and differentiation of neurons, and synaptic plasticity; so, imbalance in these signals can lead to changes in development of CNS^[120,121]. On the other hands, the developing CNS is particularly susceptible to increase in oxidative stress, owing to its poor antioxidant defenses and/or high oxygen consumption^[122].

Oxidative stress might contribute to the pathogenesis of some of neurodevelopmental disorders *via* an attenuation with gamma-aminobutyric acid receptor function in the brain, decreased synaptic efficiency in hippocampal cells, and inhibition of dopamine β -hydroxylase^[123-125]. On the other hand, there are evidence

indicating that maternal diabetes-induced NTDs are associated with some metabolic difficulties such as increase in superoxide dismutase activity and decreased in arachidonic acid level^[126]. There are evidence from human models indicating a potential role of elevated oxidative stress in neurodevelopmental diseases^[127-131]. Moreover, the incidence of congenital anomalies in infants of diabetic mothers has been reported to be significantly reduced by antioxidants supplements therapy including Ascorbic Acid and vitamin E. These data suggest that elevated oxidative stress is associated with the pathophysiology of fetal dysmorphogenesis^[132,133].

Role of insulin-like growth factor-1 and insulin in maternal diabetes - induced neuropathies

Insulin- like growth factor-1 (IGF-1) and insulin belong to the insulin superfamily and exert profound effects in the CNS development and function. Evidence of these peptides actions on CNS comes from a wide variety of *in vitro* and *in vivo* experimental data, the latter predominantly derived from rodent studies. In several studies, the authors demonstrated that the insulin and IGF-1 have a wide spectrum of biological actions in the developing CNS including neuronal/glia cell proliferation, differentiation, survival, synaptogenesis, longevity, and neuroregeneration. Most of these biological functions are mediated *via* two transmembrane receptors: the insulin receptor (IR) and the IGF-1 receptor (IGF1R)^[69,70,134-142].

The IR and IGF1R, which are homologous in structure, are composed of two α -subunits and two β -subunits linked by disulphide bonds. The extracellular α - subunit binds to their cognate ligand. The β -subunit comprises an extracellular domain and a cytoplasmic domain that contains intrinsic protein tyrosine kinase activity. The binding of either IGF-1 or insulin to α -subunit of their cognate receptors stimulates phosphorylation of the β subunit on serine and tyrosine residues. The autophosphorylation of the β subunit then results in the phosphorylation of cellular substrates and signal transfer cascade for IGF-1 and insulin^[141,143,144].

Using ligand binding autoradiography and *in situ* hybridization, several line of human and animal investigations have found that IR and IGF1R are irregularly distributed in developing and mature brain with the highest densities in the hippocampus, cerebral cortex, olfactory bulb, cerebellum, and hypothalamus. Interestingly, some of brain regions show a marked difference in the density of InsR and IGF1R between embryonic vs mature brain, implying a key role for these ligands in brain development^[145-147].

There are evidence from several researches implicating defects in IR and IGF1R signaling result in congenital developmental defects seen in offspring of diabetic mothers^[145,148-150]. Ramsay *et al*^[151] (1994) in their study was found that expression of IGF-1 in the brain were declined in swine newborns born to diabetic dams when compared to that of control animals.

The hippocampal formation subserves important physiological and behavioral functions including spatial

learning and memory and is a part of brain that particularly vulnerable to changes in blood glucose level^[152-154]. In an investigation by Tehranipour *et al*^[155] (2008) the effects of maternal T1DM on density of hippocampal pyramidal cells immediately after birth were examined. Those study results were clearly indicated that maternal diabetes can decreased the numerical density of pyramidal cells in the hippocampus of rat newborns, especially in CA3^[155].

Interestingly, the studies By Hami *et al*^[156] (2012) showed that there are prominent gender-and laterality-differences in expression and distribution pattern of InsR and IGF1R in the developing rat hippocampus. The authors concluded that these differences may be a probable mechanism for the control of sex and laterality differences in development and function of the rat hippocampus^[156].

In another study by Hami *et al*^[69] (2013), the effects of diabetes in pregnancy on gene expression and protein concentration of IGF1R and IR in the developing rat hippocampus at postnatal days 0, 7, and 14 were evaluated. In that study, the authors found a markedly upregulation of both IR and IGF1R expression in the hippocampus of diabetic group newborns at first postnatal day. At the same time point, they showed only slight changes in their hippocampal protein transcripts. In 7-d old rats, there was a significant decreased in IGF-1R gene expression and protein levels in the newborns born to diabetic dams. Moreover, they found a down regulation in hippocampal IGF1R transcripts in 14-d old diabetic group offspring. Two weeks after birth, the IR gene expression was significantly declined in the hippocampus of diabetic newborns. The authors claimed that maternal diabetes strongly altered the regulation of both IR and IGF1R during development of rat hippocampus^[67].

CONCLUSION

The Incidence of congenital anomalies in infants born to diabetic women is more common in comparison to children of normal population. There are multiple lines of evidence that suggest the disturbances in intellectual and behavioral functioning observed in the children of diabetic women are accompanied by modification of hippocampus structure and function. The etiology and pathogenesis of these impairments induced by diabetes during pregnancy have spurred considerable efforts for clinically and basically researches. The final goal at these investigations was to find the teratogenic factors, which may enable preventive or protective measures to be taken in pregnancies with diabetes. Nevertheless, the exact mechanism by which diabetes during pregnancy affects the CNS development remains to be defined. Until now, several biological changes are defined to occur in diabetic mothers and to affect development of CNS (*i.e.*, disturbance in glucose and insulin homeostasis, oxidative stress, hypoxia, and iron deficiency). Moreover, the new researches on genetic

predisposition involves in teratogenicity of diabetes in pregnancy starts to define new genes and their products involved in the etiology of CNS malfunctions and malformations observed in offspring born to diabetic mothers. Hyperglycaemia and hyperinsulinemia in the mothers and their fetuses are thought to be major factors in teratogenicity of maternal diabetes on the CNS development. There are sufficient evidences for this hypothesis as concise control of glycemia in mothers reduces the incidence of anomalies exhibited with the offspring born to diabetic mothers. Recent evidence clearly indicated that maternal diabetes markedly influences the regulation of both IR and IGF1R - as two important regulators of development and function of CNS - in the developing rat hippocampus. Dissecting out the mechanisms responsible for maternal diabetes-related changes in the development of hippocampus is helping to prevent from impaired cognitive and memory functions in offspring.

INTRODUCTION

Diabetes mellitus (DM) is an extremely common disorder which carries a risk of vascular impairment. In 1970s the attention has shifted towards haemostatic mechanisms with particular emphasis on the relationship between platelets and the vessel wall^[1].

The term "endothelial dysfunction" is usually defined as a disorder of the endothelial capacity to maintain vascular homeostasis^[2]. Endothelial dysfunction along with platelet hyperactivity are unquestionably involved in the hyperactivation of platelets and clotting factors in DM^[3]. It is an early sign of vascular damage in DM type 2 (DM2) but late in DM1. Endothelial dysfunction occurs even in normoalbuminuric (NAU) patients with DM2^[4]. Endothelial function can be assessed by the evaluation of endothelial "markers", circulating molecules synthesised in various amounts by the endothelium^[5]. In fact, markers precede the signs of evident microangiopathy^[4].

Microalbuminuria conventionally represents albumin excretion rate 30-300 mg in a 24 h urine collection. It is associated with endothelial dysfunction and serves as a predictor of DM at levels out of the characterized reference range^[4,6].

DM2 can be characterized by the dysfunction of haemostasis manifesting by stimulated coagulation process, disorder of platelet function and decreased fibrinolytic activity. These all are the reasons why DM2 is the most common acquired thrombophilia^[7].

Markers of activated haemostasis, for instance prothrombin activation fragment 1 + 2 (F1 + 2) and thrombin-anti-thrombin complexes, plasma levels of fibrinogen, factor VII, factor VIII, factor XI, factor XII, kallikrein, and von Willebrand factor (vWF) are elevated in DM^[3]. Impairment of fibrinolytic system because of imbalance between regulators of plasminogen represents the typical sign of thrombophilia present in diabetes^[7]. Increased amount of platelet aggregates in circulation, increased aggregation of platelets after addition of platelet agonists, increased platelet contractility, and the presence of elevated plasma levels of their contents, for example beta-thromboglobulin (β -TG), platelet factor 4 (PF4), and thromboxane B2 (TXB2), show platelet hyperactivity in DM^[3].

Eighty percent of individuals with DM are dying because of thrombosis^[3]. The most effective tool to preserve dysfunction of the endothelium and vascular

impairment in DM is the management of hyperglycaemia^[4].

This review will characterize mechanisms responsible for the development of endothelial and platelet functional abnormalities, endothelial and platelet markers of DM2 considered for implementation in clinical practice and possibilities of their detection.

MECHANISMS OF ENDOTHELIAL DYSFUNCTION IN DM2

The pathogenesis of endothelial dysfunction in both DM1 and DM2 is multifactorial^[4].

Altered cell signaling

The alteration of the insulin-mediated activation of nitric oxid synthase derived from endothelium is important factor of endothelial damage in the setting of DM and insulin resistance (IR). On the other hand, the activation of insulin-signalling cascade is associated with the expression of endothelin-1 (ET-1), a vasoconstrictor and mitogenic substance, and proinflammatory molecules as intercellular adhesion molecule 1 (ICAM-1)^[2].

Increased oxidative stress

Reactive oxygen species and circulating markers of oxidative stress are elevated in DM, IR and obesity^[2].

Pro-inflammatory activation of the endothelium

Systemic inflammation present in DM can impair the function of the endothelium and lead to atherosclerosis. Individuals with diabetes or obesity have elevated circulating levels of markers of inflammation, e.g., C-reactive protein, tumor necrosis factor α , interleukin 6 (IL-6), and ICAM-1. Moreover, elevated levels of pro-inflammatory substances predict vascular complications in diabetics^[2].

Activation of protein kinase C

Activation of protein kinase C beta can be the cause of the association between inflammation, endothelial damage, and IR in DM^[2].

Mitochondrial dysfunction

Recent works relationship between endothelial dysfunction and impaired mitochondrial biogenesis in subjects with DM^[2].

ENDOTHELIAL MARKERS OF DM2

vWF

vWF represents a marker of the activation of the endothelium^[8]. It is synthesised, stored and secreted both by megakaryocytes/platelets and by endothelial cells^[9]. vWF takes part in the processes of platelet adhesion, platelet aggregation and acts as a plasma carrier for factor VIII, thus enabling its stability in the circulation. Its role in platelet adhesion is particularly

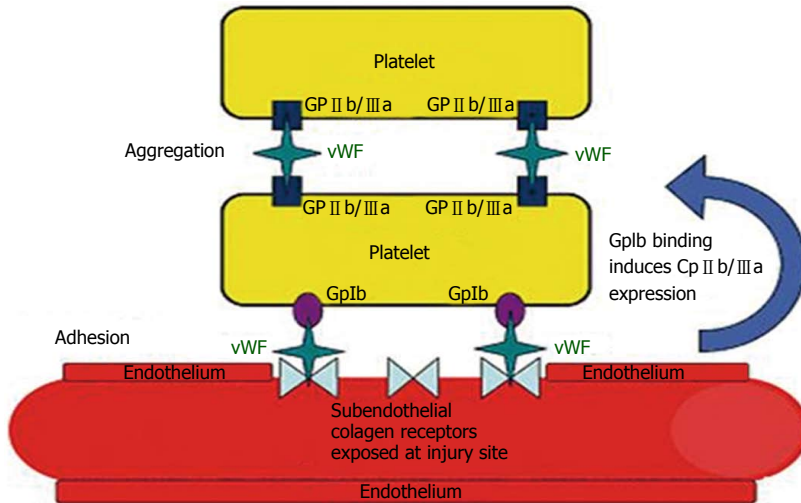

Figure 1 The role of von Willebrand factor in the platelet adhesion to the damaged vessel wall and the subsequent platelet aggregation. Adapted from: Trombose^[11]. vWF: Von Willebrand factor; GP: Glycoprotein.

important under conditions of high shear stress^[10] (Figure 1).

According to the results of the Framingham Offspring Study there was strong evidence that vWF is an independent risk factor for DM (relative risk = 1.37, 95%CI: 1.07-1.75; $P = 0.01$)^[12]. vWF level is already increased in NAU individuals, while in a few studies vWF level was increased firstly in microalbuminuric (MAU) individuals^[8]. For instance, Galajda *et al.*^[13] have found significant increase of vWF in DM2 subjects without vascular impairment comparing to healthy individuals (1.33 ± 0.39 IU/mL vs 1.01 ± 0.27 IU/mL, $P < 0.01$)^[13].

On the contrary, in the study of Kubisz *et al.*^[8] circulating vWF levels did not significantly increase in diabetic subgroups when comparing with the controls. Since then, many studies have confirmed no or no independent link between vWF and DM^[14,15]. This can be explained by the fact that the association between vWF and DM relates to the concentrations of the proinflammatory cytokine IL-6. Thus, vWF as a product of the acute phase response is associated with the risk of DM complications, but the relation between vWF and DM is probably indirect^[14,16].

Thrombomodulin

Plasma (soluble) thrombomodulin (TM) is a marker of endothelial damage^[8]. TM represents major substance of the protein C anticoagulant system^[17].

It was suggested that the elevation of plasma TM concentration in patients with DM2 could be the consequence of widespread vascular damage in diabetic patients with incipient nephropathy^[18]. Actually, vWF and TM levels are increased in group of subjects with DM2 and endothelial dysfunction^[19].

Widespread endothelial dysfunction is present in diabetic nephropathy. Hence, plasma vWF and TM represent valuable markers of endothelial dysfunction potentially useful in early confirmation of diabetic

microvascular complications^[20]. Surprisingly, our recent study found soluble TM more sensitive marker than vWF in individuals diagnosed DM2 with both, the normo- and microalbuminuria (TM $P < 0.0001$ in NAU, $P < 0.005$ in MAU)^[8]. Galajda *et al.*^[13] reported on the contrary to the previous studies, when comparing the DM2 patients without vasculopathy and control group, the concentrations of TM as calcium-independent marker of endothelial injury to be similar. This is the reason to assume that only elevated concentrations of intracellular calcium (Cai)-depending endothelial and platelet indicators can predict the dysfunction of the endothelium^[13].

Thrombin-activatable fibrinolysis inhibitor

Thrombin-activatable fibrinolysis inhibitor (TAFI) removes C-terminal lysine part from fibrin and inhibits plasminogen activation. Taking all the facts into the consideration, TAFI represents a substantial link between coagulation and fibrinolytic processes^[7]. Positive correlation between TAFI and F1 + 2 in MAU group ($r = 0.427$, $P = 0.001$) as well as TAFI and fibrinogen in the NAU group confirmed activation of TAFI in the course of stimulated coagulation^[6].

TAFI antigen levels and activity are significantly ($P < 0.05$) increased in diabetics when comparing with healthy subjects. Inverse and significant correlation of TAFI antigen and D-dimers was found in diabetic subjects supporting the function of TAFI in diabetes-induced inhibition of fibrinolytic activity^[6,7,21]. Elevated levels of TAFI may also be important in endothelial injury in MAU individuals^[6,8].

A significantly elevated plasma level of TAFI was present in diabetics with microalbuminuria when compared with diabetics with normoalbuminuria ($P \leq 0.001$)^[8]. Progression of DM2 therefore contributes to marked TAFI mediated downregulation of fibrinolytic activity. It is also suggested that fibrinolysis inhibition can be mediated by TAFI in early stages of diabetes

Table 1 The most important endothelial markers of diabetes mellitus type 2 with the method used for their detection

Endothelial markers	Method of detection	Normal values
PAI-1 antigen	ELISA	5-40 ng/mL
TAFI antigen	ELISA	5.8-10.0 µg/mL
t-TFPI antigen	EIA	70 (40-110) ng/mL
f-TFPI (men)	EIA	16 ± 4 ng/mL
f-TFPI (women)	EIA	16 ± 3 ng/mL
TM antigen	EIA	10-50 ng/mL
tPA antigen	ELISA	1-20 ng/mL
vWF antigen	EIA	Less than 1.4 IU/mL (140%)

EIA: Enzyme immunoassay; ELISA: Enzyme-linked immunosorbent assay; PAI-1: Plasminogen activator inhibitor 1; TAFI: Thrombin-activatable fibrinolysis inhibitor; f-TFPI: Free tissue factor pathway inhibitor; t-TFPI: Total tissue factor pathway inhibitor; TM: Thrombomodulin; tPA: Tissue plasminogen activator; vWF: Von Willebrand factor.

defined by microalbuminuria in DM2 subjects without macrovascular complications. It seems that discussed process is independent from the level of plasminogen activator inhibitor-1 (PAI-1)^[6,8].

Elevated circulating levels of TAFI were present not only in individuals diagnosed DM2, but also in patients with obesity, IR and arterial hypertension^[8]. On the contrary, increased total cholesterol level probably downregulates TAFI^[6].

PAI-1

PAI-1 represents one of the most significant and quick natural inhibitors of tissue plasminogen activator (tPA) and urokinase-type plasminogen activator^[7].

PAI-1 is produced in vascular and metabolic tissues^[7]. Therefore, up-regulation of PAI-1 occurs predominantly in obese patients and presence of endothelial dysfunction^[6].

PAI-1 is released to plasma predominantly from the endothelial cells^[7]. This is the cause of the elevation of PAI-1 concentrations in individuals with DM2 and hypertension with endothelial dysfunction^[6,22]. The inflammatory cytokines, as well as metabolic components are activators of PAI-1 production in the endothelial tissue^[7,23]. Insulin has inhibiting influence on the PAI-1 synthesis in endothelial cells. Significant decrease of PAI-1 level in DM2 individuals with endothelial impairment on long-term insulin therapy was confirmed^[7,24]. However, the mechanism of insulins action depend upon the metabolism in hepatic cells and endothelium^[7].

PAI-1 overproduction belongs to the most typical signs of thrombophilia in DM2 leading to the dysfunction of fibrinolytic system^[7]. Plasma levels of PAI-1 are significantly increased in both cohorts (MAU and NAU) compared with the controls ($P < 0.0001$ in both subgroups)^[8].

When comparing with other parameters, PAI-1 is the most complex one associated with IR. Level of PAI-1 highly correlates with parameters of the IR syndrome in healthy individuals, patients with IR, DM2, or subjects with coronary artery disease. Positive correlation was found between PAI-1 concentrations

and body mass index ($r = 0.43$, $P < 0.05$) in the MAU patients and between PAI-1 and triglycerides (TAG) ($r = 0.67$, $P = 0.01$) in NAU subjects, proving that obesity, dyslipidaemia and decreased fibrinolytic activity are related to each other^[6,7]. Subjects with DM2 and hyperinsulinaemia non-diabetics had significantly increased PAI-1 levels which correlated with the C-peptide ($r = 0.519$, $P < 0.001$), TAG ($r = 0.685$, $P < 0.001$), body mass index ($r = 0.607$, $P < 0.001$) and with levels vWF and soluble TM^[25].

Moreover, increased PAI-1 levels are an independent risk factor for DM2. It was proposed that a decrease of PAI-1 level may be linked with a decrease in transformation to DM2. On the other hand, the finding of elevation of PAI-1 preceding DM2 thus being, in the preexistence of IR, independent of glycaemia gives unquestionable evidence that abnormality of fibrinolytic system characterized with increased PAI-1 and tPA antigen occurs nearly at the beginning of the development of metabolic disorders and is considered a risk factor for future DM and metabolic complications^[7].

Tissue factor pathway inhibitor

Tissue factor pathway inhibitor (TFPI) acts as an inhibitor of tissue factor (TF)-initiated coagulation. TF binds to the activated factor X, subsequently TFPI-Xa complex binds to the TF/factor VIIa (FVIIa) complex and regulates its action^[26].

Enhanced TFPI activity was confirmed in individuals with DM and mainly in those with microalbuminuria. Increases in TFPI reflect endothelial dysfunction or impaired binding of TFPI to endothelial cells by glucosaminoglycans because TFPI is predominantly synthesized in endothelial cells^[26]. It may be the first consequence of increased glycosylation, and thus the deterioration of the antithrombotic potential of endothelial cells. Mentioned increase in TFPI activity does not compensate the procoagulant state associated with increased thrombinogenesis (excess of F1 + 2), and inversely correlates with the internal thrombin potential^[27,28]. Plasma levels of TF, TFPI and FVIIa are significantly increased in DM2^[26].

Total TFPI (t-TFPI) has a poor anticoagulant effect. On the contrary, free form of TFPI (f-TFPI) has an increased anticoagulant capacity. Moreover, the study of Morange *et al.*^[29] showed that f-TFPI has a strong correlation with endothelial markers and t-TFPI has increased relation to parameters indicating cardiovascular risk. Normal values of f-TFPI varying according to gender, as well as informative normal values of t-TFPI can be seen in Table 1.

tPA

tPA is a serine protease which converts plasminogen to plasmin, the form active in the process of fibrinolysis, thus being the most valuable initiator of fibrinolytic process. tPA is synthesised particularly in the endothelial cells, smooth muscle cells, monocytes and megakaryocytes^[6,7]. Quick tPA release to the circulation occurs

following the Cai - dependent stimulus. Minority of tPA is present in plasma in the form of complex binding PAI-1^[7].

tPA is present mainly on the endothelial surface and may be released to circulation following its injury^[7]. tPA levels are elevated in subjects with DM and metabolic syndrome. Increased tPA concentrations were proposed as a risk factor of DM in healthy subjects, because total tPA antigen levels were elevated in DM, but the level of free tPA and the tPA activity not. Therefore, the elevated total tPA is a facade masking the dysfunctional fibrinolysis in DM2^[6]. Moreover, an elevated tPA antigen concentration is a substantial feature of the IR syndrome and also relates to the inflammation. tPA antigen levels have strong correlations with IR, and can serve as helpful markers of diabetes^[14]. The increased tPA levels correlate with vWF and soluble TM in individuals with various locations of atherosclerotic lesions. This supports the position of tPA as an indicator of endothelial injury^[7].

The tPA levels were described to be increased in DM2 in an early phase of disease while tPA levels in DM1 are increased later in presence of vascular complications. Dependence between tPA levels and PAI-1 and IR is higher in the phase of complications than dependence between tPA and presence of complications in DM2. There is a correlation between tPA and PAI-1 found in patients with DM2 and the principle cause of the tPA increase is formation of the tPA/PAI-1 complexes^[7].

As it was mentioned earlier, insulin can inhibit the endothelial production of PAI-1 with the following decrease of tPA/PAI-1 complexes levels but it does not influence the tPA release from endothelium and tPA plasma levels. This can be explanation of the absent correlation between tPA and PAI-1 found in DM2 patients treated with insulin^[7,25].

E-selectin

E-selectin (CD62E), expressed by endothelium, is rapidly enhanced by proinflammatory molecules^[30].

At first the adhesion molecules were considered to be endothelial markers because of their general elevation in various vasculopathies^[25]. It was confirmed that individuals with increased E-selectin had a significantly higher probability of the development of DM2^[4]. Moreover, in the study of Thorand *et al.*^[15] soluble E-selectin and ICAM-1 significantly preceded DM2. In particular, soluble E-selectin remained an independent marker of diabetes after exclusion of inflammation, levels of insulin and hemoglobin A1c in both men and women^[15,30].

ICAM-1 and vascular cell adhesion molecule 1

ICAM-1 and vascular cell adhesion molecule 1 (VCAM-1) are synthesised in the endothelium and leukocytes. Increased concentrations of these cell adhesion molecules (CAMs) are early markers of endothelial dysfunction, cardiovascular disease and DM2^[30].

Increased concentrations of E-selectin, ICAM-1,

and VCAM-1 raise the relative risk of DM by 1.5- to 7.5-fold^[30]. Taking everything into account, elevated concentrations of CAMs representing an increased probability of the development of diabetes highlight the link between dysfunction of the endothelium and IR^[15].

Vascular endothelial growth factor

Vascular endothelial growth factor (VEGF) is a growth factor derived from endothelial cells, stimulating their proliferation, differentiation and survival, mediating endothelium-dependent vasodilatation, inducing increased permeability in the microcirculation and participating in other supporting functions. VEGF enhances the glomerular permeability to macromolecules and leads to profound proteinuria including albuminuria. Described action has probably a role in the development of endothelial dysfunction in diabetes^[8]. The beneficial effects of VEGF-A (principal member of VEGF family) inhibition in the early phases of diabetic glomerulopathy was also confirmed^[31].

Highly increased plasma VEGF levels were measured in individuals with retinopathy and nephropathy when compared with the control group. Widespread endothelial dysfunction occurs at the beginning of the development of diabetic nephropathy and precedes biochemical finding of the disorder of renal functions since the significantly increased VEGF level was present already in NAU diabetics without manifestations of microvascular impairment. Because VEGF levels were significantly elevated in the NAU cohort and had a tendency to be significant in the MAU patients, VEGF can be concluded as an indicator of diabetic endotheliopathy. VEGF ought to be evaluated only along with further markers representing the dysfunction of the endothelium, particularly soluble TM^[8]. It is assumed that VEGF may be a more sensitive indicator of renal changes than microalbuminuria^[8,32]. On the other hand, since there were no marked differences in VEGF concentrations in individuals with DM with physiological renal functions and at the beginning of the development of diabetic nephropathy, VEGF was not confirmed as a reliable marker of the progression in DM2 patients^[8].

ET-1

ET-1 is considered to be the most potent vasoconstrictor form of endothelin and is produced by the endothelial cells. During prolonged periods of stress caused by hyperglycaemia and IR in the course of DM2, there is a shift in the balance with more vasoconstrictors being produced compared to vasodilating agents. This leads to endothelial dysfunction and affects the permeability of the glomerular filtration barrier leading to microalbuminuria^[33].

Even experimental studies suggested that ET-1 drives development of glomerulosclerosis and podocyte loss^[34]. ET-1 is really significantly associated with early development of the endothelial dysfunction in the

Figure 2 The structure of the platelet and its most important functions, including the secretion of stored products, as well as the binding of specific surface glycoproteins to the endothelium (bottom), and other platelet (left side). Adapted from: Trombore^[11]. ADP: Adenosine diphosphate; ATP: Adenosine triphosphate; β -TG: Beta-thromboglobulin; GP: Glycoprotein; PDGF: Platelet-derived growth factor; PF4: Platelet factor 4; TSP: Thrombospondin; vWF: Von Willebrand factor.

glomerulus^[33].

MECHANISMS OF DIABETIC THROMBOCYTOPATHY

Primary dysfunction of megakaryocyte-platelet system

One of the manifestations of DM is the production of subpopulation of large and hyperreactive platelets in the bone marrow. Thrombocytopoiesis is increased^[35,36].

IR in platelets

In obesity and DM2 increased aggregability of platelets, as well as decreased sensitivity to antiplatelet effect of insulin was confirmed^[36].

Influence of endothelial dysfunction

Substances produced by the endothelium, represented by nitric oxide, prostacyclin and adenosine normally inhibit platelets. In diabetic patients due to the hyperglycaemia and oxidative stress the capacity of endothelium to produce prostacyclin and nitric oxide is decreased. In the cases of microangiopathy consumption of platelets in the sites of damaged endothelium causes paradoxically the decrease in the subpopulation of large activated platelets^[36].

Changes of the activity of membrane pumps and increase of Cai in platelets^[36]

Platelet markers of DM2: Platelets have an ethiopathogenic relation to the microangiopathy in DM. Their increased activity was confirmed in both types of

DM^[36,37]. The structure of the platelet with components involved in its physiological function and markers of platelet activity are illustrated in Figure 2.

Mean platelet volume

Mean platelet volume (MPV) is the parameter informing about the platelet size and activation. Bigger platelets indicate more activity^[38]. Patients with DM have significantly higher MPV due to the elevated alpha-granule content in cytoplasm as the sign of dysfunction of megakaryocyte-platelet system^[36,38]. Thus, platelets can be a useful tool to evaluate complications in DM^[38]. Further studies concluded that MPV is strongly and independently associated with the presence and severity of diabetes and higher MPV is the manifestation of early diabetic thrombocytopathy in both types of DM without vascular complications^[39,40].

Soluble P-selectin

P-selectin (CD62P) is a highly glycosylated membrane glycoprotein constitutively expressed in endothelial cells and megakaryocytes and present in the membrane of Weibel-Palade bodies of endothelium and in α granules of platelets^[36,41]. It is a marker of platelets' activation. Its increased levels in patients with arterial hypertension, lower extremity peripheral artery disease and coronary artery disease correlate with levels of β -TG, and they do not have a relation to vWF and TM^[42-44]. Increased levels of P-selectin occurred already in early stages of DM1 and DM2 without vascular complications. Elevated levels of P-selectin were also found in subjects diagnosed IR and impaired glucose tolerance^[45-47].

Elevated synthesis of P-selectin and ICAM-1 in diabetic human retina and choroid was confirmed. This is the reason why circulating levels of soluble adhesion molecules have been proposed as biomarkers playing a significant role in the pathogenesis of macrovascular and microvascular dysfunction and neuropathy of DM^[48]. Galajda *et al.*^[45] found in patients with DM2 significantly elevated P-selectin that paradoxically did not correlate with levels of PF4, but they correlated with vWF. This can propose also its function in the endothelial dysfunction in patients with DM2^[45].

P-selectin was significantly increased in patients with DM suffering myocardial infarction than in control group or those without myocardial infarction. It indicates contribution of elevated levels of P-selectin to the atherosclerosis leading to coronary heart disease in diabetics^[49]. Thus, detection of P-selectin level could be useful marker of possible cardiovascular event in individuals with DM^[50].

PF4

PF4 is a basic protein found exclusively in a granules of platelets. After release it is able to modulate haemostasis. PF4 has both procoagulant and anticoagulant properties. It has also angiostatic effect - it inhibits proliferation and migration of endothelial cells^[36].

Table 2 The most important platelet markers of diabetes mellitus type 2 with the method used for their detection

Platelet markers	Method of detection	Normal values
βTG	EIA/RIA	Less than 40 ng/mL
GPV	EIA	80 (40-160) ng/mL
MPV	Electric impedance or laser diffraction	6.5 (4.5-8.5) fl
PF4	EIA/RIA	Less than 10 ng/mL
TSP-1	EIA	40 (10-90) ng/mL, respectively 20-300 ng/mL

βTG: Beta-thromboglobulin; EIA: Enzyme immunoassay; GPV: Glycoprotein V; MPV: Mean platelet volume; PF4: Platelet factor 4; RIA: Radioimmunoassay; TSP-1: Thrombospondin 1.

In patients with both types of DM the increased levels of PF4 and β-TG as the manifestation of degranulation of activated platelets without influence on their lifespan were confirmed. In DM2 these levels are increased already in the early stage of the disease without the presence of vascular complications^[36].

In the study of Galajda *et al.*^[13] the correlation between vWF concentrations and calcium dependent substances as C-peptide ($r = 0.680$, $P < 0.001$) and PF4 ($r = 0.613$, $P < 0.01$) and no correlation with calcium-independent markers of endothelial damage, as TM ($r = 0.287$, $P = 0.196$) or TFPI ($r = 0.296$, $P = 0.181$) in diabetics was confirmed^[13]. In advanced cases of DM associated with retinopathy and nephropathy increased levels of PF4, β-TG, P-selectin, Cai in platelets, as well as their increased aggregability were confirmed^[36]. Moreover, patients with diabetes type 2 treated with sulphonylurea preparates and individuals treated 2-3 mo with insulin did not differ by endothelial and platelet parameters (vWF, TM and PF4)^[7].

β-TG

β-TG is a protein with 50% structural homology with PF4 acting as a leukocyte chemoattractant. Measurement of β-TG is considered to be a golden standard in the detection of activation of platelets in patients with normal renal function. Its levels are increased in renal insufficiency and correlate with levels of PF4^[39].

Glycoprotein V (CD42d)

Glycoprotein V (GPV) is exclusively expressed in platelets and megakaryocytes, where it is non-covalently bound to the complex GPIb/GPIX as the part of the receptor for vWF and thrombin^[51].

According to the fact that platelets are the only source of GPV it can be considered as a marker of specific activation of platelets by thrombin^[51].

TXB2

Metabolism of arachidonic acid with incorporation of its metabolites to membrane phospholipids of platelets in DM is upregulated. Production of TXA2 in platelets is increased. Plasma levels of its stable catabolite TXB2 produced in liver, kidneys, platelets and lungs are also

increased and correlate with raised levels of β-TG and PF4^[52].

Increased synthesis of TXA2 indicates that "resting" platelets of diabetics in general tend to be activated. TXA2 is a vasoconstrictor and prothrombotic factor with the risk of atherothrombogenesis present in DM^[53].

Moreover, synthesis of TXB2 has inverse correlation with the minimal level of arachidonic acid inevitable to 50% platelet aggregation. As the consequence, platelet aggregates in the circulation of patients with DM2 than in the healthy subjects. Platelets of diabetics therefore exhibit the signs of hyperactivity. This fact may also be very important for the arise of vascular disease in DM^[52].

Thrombospondin-1

This molecule represents a multifunctional glycoprotein synthesised in a wide range of cell types, to be more exact in platelets (increased expression), vascular smooth muscle cells and various kinds of renal cells^[53]. Unlike PF4 and β-TG, after release of thrombospondin (TSP) from activated platelets it binds to platelet surface, so levels of TSP-1, PF4 and β-TG usually do not correlate with each other. Last but not at least, its levels are influenced by hepatopathy. These are the reasons why analysis of TSP is not considered to be the golden standard in detection of platelet activity. Therefore, TSP is evaluated as the sign of activation of the whole vascular system^[36].

TSP-1 with antiangiogenic and proatherogenic properties is involved in diabetic vasculopathy. The endothelial dysfunction in DM was confirmed in many studies, and TSP-1 surely may contribute to this impaired function because it shows antiproliferative and apoptotic effect on the endothelium. It was confirmed that TSP-1 level has a relation with renal damage and vascular impairment^[53].

DETECTION OF MARKERS OF DM2

Informative normal values of the most important endothelial and platelet markers with the method used for their detection are documented in Tables 1^[36,54-56] and 2^[36].

Size of the platelet up to 7 μm and its volume more than 10 fl contribute to increased MPV^[36].

Levels of soluble P-selectin are measured using enzyme immunoassay method and their normal values vary between laboratories and are dependent on the commercial kit used for the detection^[36].

Values of β-TG 50 ng/mL and more are considered to be pathological^[36].

Plasma levels of VEGF, F1 + 2 and TXB2 can also be detected using enzyme-linked immunosorbent assay^[6,8,57].

CONCLUSION

Number of patients with DM2 is increasing incredibly and is expected to rise even in the future. Researchers

all over the world have made strong efforts to increase knowledge and improve understanding of mechanisms of abnormalities of endothelium and platelets unquestionably involved in the pathogenesis of this challenging health problem. As a natural consequence of continuous investigation, many markers of diabetic thrombocytopathy and endothelial dysfunction have been identified and are considered for implementation in clinical practice. These substances may improve the screening of high-risk individuals and lead to the early diagnosis, appropriate treatment, as well as to the effective prevention of the complications of DM2. However, these conclusions have to be confirmed by further research.

Abstract

Diabetic neuropathy is a common complication of both type 1 and type 2 diabetes, which affects over 90% of the diabetic patients. Although pain is one of the main symptoms of diabetic neuropathy, its pathophysiological mechanisms are not yet fully known. It is widely accepted that the toxic effects of hyperglycemia play an important role in the development of this complication, but several other hypotheses have been postulated. The management of diabetic neuropathic pain consists basically in excluding other causes of painful peripheral

neuropathy, improving glycemic control as a prophylactic therapy and using medications to alleviate pain. First line drugs for pain relief include anticonvulsants, such as pregabalin and gabapentin and antidepressants, especially those that act to inhibit the reuptake of serotonin and noradrenaline. In addition, there is experimental and clinical evidence that opioids can be helpful in pain control, mainly if associated with first line drugs. Other agents, including for topical application, such as capsaicin cream and lidocaine patches, have also been proposed to be useful as adjuvants in the control of diabetic neuropathic pain, but the clinical evidence is insufficient to support their use. In conclusion, a better understanding of the mechanisms underlying diabetic neuropathic pain will contribute to the search of new therapies, but also to the improvement of the guidelines to optimize pain control with the drugs currently available.

Core tip: Diabetic neuropathic pain is a common complication of diabetes and the most common form of neuropathic pain. In this review, we will discuss the various factors that may contribute to the pathogenesis of diabetic neuropathic pain, including metabolic, vascular, autoimmune and oxidative stress-related mechanisms. In addition, we will review the possibilities of pain treatment, taken into consideration the first line drugs clinically used, the antidepressants and anticonvulsants, but also other options such as opioids, tapentadol and drugs for topical use, such as lidocaine and capsaicin cream.

INTRODUCTION

According to the International Diabetes Federation, 382 million people worldwide are currently affected by diabetes^[1], one of the leading causes of neuropathy^[2]. The distal symmetrical polyneuropathy (DSPN) is the commonest clinical form of diabetic neuropathy, affecting more than 90% of the patients^[3]. Generally, DSPN affects the toes and distal foot, but slowly progresses proximally to involve the feet and legs in a stocking distribution. It is also characterized by a progressive loss of nerve fibers affecting both the autonomic and somatic divisions, thereby diabetic retinopathy and nephropathy can occur^[3]. Foot ulceration and painful neuropathy are the main clinical consequences of DSPN, linked with higher morbidity and mortality^[4]. Frequently, patients look for medical help only when pain appears^[5], a symptom that affects 10% to 26% of this population^[6,7].

Diabetic neuropathic pain (DNP) is characterized by tingling, burning, sharp, shooting, and lancinating or even as electric shock sensations^[3,8]. It is usually considered moderate to severe and often worse at night, causing sleeping disturbs. The pain can be constant and accompanied of cutaneous allodynia, which can substantially affect the quality of life of patients, impacting the ability to perform daily activities and having a negative influence on mood. The pain may also be a reason of withdrawal of recreational and social activities and may be associated with depression^[3,9,10].

The pathogenesis of DNP is not fully understood. Several theories have been proposed to explain the pain related to the diabetic neuropathy, such as changes in the blood vessels that supply the peripheral nerves; metabolic and autoimmune disorders accompanied by glial cell activation, changes in sodium and calcium channels expression and more recently, central pain mechanisms, such as increased thalamic vascularity and imbalance of the facilitatory/inhibitory descending pathways^[3]. Additionally, several risk factors are associated with DNP including worsening glucose tolerance, older age, longer diabetes duration, drinking alcohol and cigarette smoking^[10].

Currently, only three agents are approved in the United States for the treatment of DNP: duloxetine, a selective serotonin and norepinephrine reuptake inhibitor, pregabalin, an anticonvulsant, and the dual-effect drug tapentadol, an opioid receptor agonist and norepinephrine reuptake inhibitor^[11]. However, as pain relief is unsatisfactory for most patients, several pharmacological interventions have been used based on pre-clinical and/or clinical evidence, as well as an inference of mechanism of action.

PHYSIOPATHOLOGY OF NEUROPATHIC PAIN IN DIABETES

Although there is a great advance in understanding

the pathophysiological mechanisms leading to the development of diabetic complications, there is not yet a plausible hypothesis to explain why some patients develop the painful form of disease while others do not. In general, researchers seek to elucidate neuropathy underlying mechanisms as a bigger event, and include pain and other sensorial manifestations as direct consequences of neuropathy. However, interestingly, pain intensity normally is not associated with neuropathy severity, and can occur even in the absence of nerve injuries^[12,13]. In this review, it will be addressed the pathophysiological mechanisms currently believed to promote the DNP.

In this sense, the mechanisms that lead to DNP are not fully understood, although there is a consensus that toxic effects of hyperglycemia represent an important factor for the development of this complication^[14,15]. Nonetheless, other factors besides hyperglycemia should not be discarded^[16], and will be discussed as follows.

Polyol pathway hyperactivity

Metabolic disorders are the primary cause of diabetic neuropathy. Hyperglycemia, induced through decreased of insulin secretion or insulin resistance, is responsible for the enhanced of the polyol pathway activity. The rate-limiting first enzyme of this pathway aldose reductase catalyzes the formation of sorbitol from glucose, with the oxidation of nicotinamide adenine dinucleotide phosphate (NADPH) to NADP⁺. Sorbitol is further oxidized to fructose by sorbitol dehydrogenase, which is coupled with the reduction of nicotinamide adenine dinucleotide (NAD⁺) to NADH. It is described that during hyperglycemic states, the affinity of aldose reductase for glucose is higher, generating intracellular osmotic stress due to accumulation of sorbitol, since sorbitol does not cross cell membranes. Interesting, the nerve damage following the diabetic state seems not to be due to this osmotic stress since it has been reported insignificant sorbitol concentrations in the nerves of diabetic patients^[17-19]. However, the current accepted hypothesis states that polyol pathway hyperactivity is pathogenic primarily by increasing the turnover of cofactors such as NADPH and NAD⁺, which leads to a decrease in the reduction and regeneration of glutathione, as well as to an increase of advanced glycation end products (AGEs) production and activation of diacylglycerol and protein kinase C (PKC) isoforms. Depletion of glutathione could be the primary cause of oxidative stress and be related to the accumulation of toxic species^[19]. In fact, aldose reductase inhibitors are effective in preventing the development of diabetic neuropathy in animal models, but they have demonstrated disappointing results and dose-limiting toxicity in human trials^[20].

Oxidative and nitrosative stress

As already mentioned, the polyol pathway activation could be the primary cause of oxidative stress associated

with diabetes. However, oxidative stress could be also initiated by autooxidation of glucose and their metabolites, increased intracellular formation of AGEs, increased expression of the receptor for AGEs and its activating ligands, altered mitochondrial function, activation of PKC isoforms and overactivity of the hexosamine pathway^[21-23]. Moreover, there is mounting evidence that oxidative stress is caused by enhanced free radical formation due to glucose metabolism itself and/or deficits in antioxidant defense and it may play a major role among the putative pathogenic mechanisms of diabetic neuropathy. It seems that, in addition to oxidative stress, reactive nitrogen species, especially the peroxynitrite also play an important role in the development of diabetes and its complications^[24-26]. Although it has been clearly demonstrated significant changes in oxidative status in animal models of diabetes^[27], tissue concentrations of known carbonyl compounds are nearly negligible and plasma ET-1, nitric oxide, catalase and glutathione levels did not differ in neuropathic diabetic patients when compared to non-neuropathic diabetic ones^[28]. In line with this observation, clinical results have been contradictory for antioxidants as alpha lipoic acid, ranging from little benefit^[29,30] to interesting advantages^[31,32].

Microvascular changes

DNP is frequently associated with microvascular impairment^[33,34]. In clinical and preclinical studies, it was found that peripheral perfusion is reduced, not only in the nervous tissue^[35,36], but also in the skin^[37], being an important physiological evidence of microvasculature alteration. As a result, nerve ischemia occurs, caused by raise in wall thickness and hyalinization of the basal lamina of vessels that nurse peripheral nerves^[38,39], together with luminal reduction^[38]. These alterations are caused by plasma protein scape of capillary membrane to endoneurium, promoting swelling and augmented interstitial pressure in the nerves, accompanied by higher capillary pressure, deposition of fibrin and thrombus development^[40]. Hyperglycemia *per se* can evoke nerve hypoxia, especially in sensory nerves, altering their electrical stability^[41]. Apparently controversial data from clinical studies described that diabetic patients suffering from the DNP presented higher levels of intravascular oxygen and augmented blood flow in the lower limbs than painless patients. Nevertheless, authors still consider a hypoxic state inside the endoneurium^[42]. Alternatively, a potential sympathetic dysfunction can be the cause of higher blood flow^[43].

As a result of nerve ischemia, both diabetic patients and animals have shown a progressive nerve loss in proximal and distal segments^[44,45], resulting in reduction of intraepidermal nerve fiber density^[12]. Consequently, axonal degeneration and regeneration also occurs, but more frequently in patients that do not experience pain. Besides axonal retraction and regeneration, another structural modification related to hyperglycemia is myelin sheath alteration. The observed demyelination

can be related to Schwann cells altered capacity to support normal myelin sheath^[46].

It is also important to point out that endothelial function in patients with DNP is also altered. The vaso dilatation induced by acetylcholine (*i.e.*, the endothelium-dependent response) in dermal vessels of diabetic patients was reduced in comparison with healthy volunteers. In addition, vasoconstriction mediate by the sympathetic system (*i.e.*, endothelium-independent response) was also defective, what can also be implicated in the pathophysiology of diabetic neuropathy and then, in the DNP^[47].

It is believed that one potential cause of the microvascular changes described above may be the oxidative stress, since the treatment with antioxidant agents can maintain regular perfusion, restoring sensory transmission in type 1 diabetes model^[48].

Channels sprouting

Damaged nerve endings are believed to contribute to pain in DNP^[49,50]. The most accepted hypothesis states that disturbed action potentials can be produced by damaged nerve endings, being interpreted by central nervous system (CNS) as pain or dysesthesias^[51]. Changes in ion channel expression in peripheral fibers are direct consequences of nerve injury, leading to hyperexcitability^[52], that is far linked with neuropathic pain^[53].

In this regard, up-regulation of voltage-gated sodium channels (Nav) has been widely demonstrated in neuropathic pain models^[54,55]. These channels are involved in generation and transmission of action potential, and can be classified into sensitive (TTX-S) or resistant (TTX-R) to tetrodotoxin^[56]. There are several reports that the TTX-S channels Nav1.3, which primary function relays during the embryonic development^[57], and Nav1.7, that is constitutively expressed in peripheral sensory neurons^[58], are both up-regulated in the dorsal root ganglion (DRG) of diabetic animals^[59-61]. Nav1.3 expression was also found increased in small and large diameter DRG neurons of diabetic rats presenting allodynia^[62]. Considering TTX-R sodium channels, Nav1.8 and Nav1.9 are normally expressed in peripheral nociceptive neurons^[63], playing an important role in the generation of electrical activity in DRG^[64]. Intriguingly, DRGs of allodynic diabetic rats showed a reduction of Nav1.8 expression in the following days after diabetes induction^[62], and this reduction lasted 6 mo post diabetes induction^[61], indicating that other sodium channels may play an important role in DNP. The same reduction was detected for Nav1.6, another TTX-S channel, normally present at Ranvier nodes^[60,62].

In addition, an increase of Nav1.6, Nav1.7 and Nav1.8 phosphorylation is another feature observed in the diabetic state, which leads to augmentation in their activity. Thus, both abnormal expression and function of TTX-R and TTX-S sodium channels is linked to abnormal activity of nociceptive fibers^[60]. In this way, Sun *et al.*^[65] showed that TTX-S and TTX-R sodium

currents are increased in small neurons in the DRG of diabetic animals, being this related not only with sensory disturbances, but also with the rise of efficiency of conductance in polymodal C fibers, which in turn, facilitates nociceptive transmission.

In a recent *in vitro* study, it has been described that hyperglycemia evokes higher TTX-R Na^+ currents in a time and concentration-dependent manner, demonstrating a straight relationship between glucose levels and biophysical changes^[66]. In DNP patients, it was reported an increase in nodal Na^+ currents when compared to painless diabetic patients, what can also contribute to hyperexcitability in peripheral nerves^[67].

A new concept proposed by Hoeijmakers *et al.*^[68], links the beginning of pancreatic beta cells failure and DNP with genetic disruptions on Nav1.7 channels. Since both pancreatic beta cells and peripheral neurons express Nav1.7 channels, a susceptible genetic background could facilitate generation of Nav1.7 mutations, leading to gain-of-function that evokes beta cell lesions, and thereafter, diabetes and hyperexcitability in neurons^[69]. According to these authors, this theory could explain why some patients have neuropathy before diabetes onset^[68].

Another interesting finding related to sodium channels modulation is the increased levels of methylglyoxal in type 2 diabetes DNP patients, when compared with those painless^[70,71], and in complication-free type 1 diabetic patients^[72]. This glycolytic metabolite can activate nerve endings through transient receptor potential cation channel subfamily A member 1 activation in the DRG^[73], and also change the Nav1.7 and Nav1.8 function through posttranslational changes^[70]. In line with this clinical observation, in preclinical models methylglyoxal was found to reduce nerve conduction velocity, to elevate calcitonin gene-related peptide release from sensory nerves and to induce thermal and mechanical sensibility^[70]. In addition, in diabetic states methylglyoxal is also involved in the formation of AGEs^[74].

Calcium channels can also be misregulated in a diabetic condition, leading to an enhanced calcium influx in sensory neurons^[75], what can deflagrate both substance P and glutamate release^[76]. It was verified in two different animal models of insulin dependent diabetes that high voltage activated Ca^{2+} current amplitudes were increased in small diameter neurons^[75,77] and the activity of T-type channels (Cav3.2) is also augmented in small diameter fibers^[78], what could be normalized by molecular knockdown of this calcium channel^[79]. However, there was no translation of these results to patients in clinical trials^[80]. A possible future target for pharmacological intervention over calcium channels has been proposed by Orestes and colleagues (2013), which observed that glycosilation of Cav3.2 augments the current density, accelerates kinetics, and also increases the number of channels on neuron membrane, which can be directly involved in DNP. Interestingly, the deglycosylation treatment with neuraminidase inhibits native calcium currents in nociceptors and completely

and selectively reverses hyperalgesia in a pre-clinical model of type 2 diabetes^[80].

Resting membrane potential can also be altered by K^+ voltage dependent channels (Kv), also participating in the electrical properties of neurons^[81]. Regarding the currents generated by activation of these Kv channels in primary afferents there are two main types: rapidly inactivating A-type currents (I_A), and slowly inactivating currents (I_K)^[82,83]. It was verified that the total density of Kv currents as well as the mRNA of I_A subunits of Kv 1.4, 3.4, 4.2 and 4.3 were reduced in large and medium size DRG neurons of diabetic rats^[84]. So, this down regulation can increase neuronal excitability and peptide release^[83], which might also participate in hyperexcitability of peripheral nerves of diabetic subjects.

Microglial activation

It is becoming increasingly recognized that glial cells play an important role in the pathogenesis of many diseases of the nervous system, including chronic pain states^[85]. Glia comprises both macroglia (including astrocytes, radial cells and oligodendrocytes) and microglia cells, which are mainly responsible for maintain homeostasis, form myelin, and provide support and protection for neurons from both central and peripheral nervous system^[85]. Normally, microglial cells comprise less than 20% of spinal glial cells but in response to dorsal root ganglia and spinal cord after nerve injury there is a robust proliferation at spinal level^[86]. Activation of microglia occurs right after peripheral nerve injury, lasting for less than 3 mo, and is responsible for a production of several inflammatory mediators as cytokines, chemokines, and cytotoxic substances such as nitric oxide and free radicals, prompting to a pro inflammatory milieu^[83]. Diabetes has impact on all glial cells of the spinal cord since persistent microglial activation was observed in streptozotocin-induced diabetic rats lasting from 4 wk^[87,88] to 6 or 8 mo^[61,89]. This microglial activation has been associated with sensorial changes and up-regulation of Nav1.3 sodium channels in the DRG^[61], possible through p38 mitogen activated protein kinase dependent mechanism^[90,91]. Conversely, diabetes is associated with a reduction in glial fibrillary acidic protein (*i.e.*, glial fibrillary acidic protein) immunoreactive astrocytes in the spinal cord, which may affect the functional support and role of astrocytic cells in the nervous tissue, such as the clearance of neurotransmitters within the synaptic cleft^[92]. Considering the potential of microglial activation in driving spinal sensitization, in the near future, drugs that target these cells may become an important therapeutic alternative in chronic pain control.

Central sensitization

As already demonstrated in different neuropathic pain states, DNP may be a consequence of both peripheral and CNS changes^[93,94]. It was well described that during DNP, primary afferents are sensitized, inducing dorsal horn hyperactivity and neuroplastic changes in

central sensory neurons^[93]. The common occurrence of allodynia in DNP patients supports the idea that CNS pain processing is altered^[95].

Among the factors that can lead to the hyperactivity of spinal neurons in diabetic neuropathy is the increased glutamate release from primary afferents in the spinal cord^[96,97]. Moreover, spinal N-Methyl-D-aspartate (NMDA) receptor expression is augmented in this condition^[98], generating increased and more frequent excitatory post synaptic currents in the lamina II^[97]. Additionally, it has been described that cAMP response element-binding protein signaling, which directly regulates NMDA receptors activity^[99] is enhanced in DNP^[98,100]. Thus, it is plausible that augmented NMDA expression and glutamate release might contribute to spinal cord hyperactivity. On the other hand, GABA_B receptors seem to be downregulated in the spinal cord in diabetic neuropathy^[98]. Activation of GABA_B receptors results in inhibition of NMDA receptor activity through a direct inhibition of voltage-sensitive Ca²⁺ channels^[101] and opening of inwardly rectifying K⁺ channels^[102]. Furthermore, GABA_B receptor activation also causes downregulation of NMDA receptors at the spinal level in diabetic rats^[98]. Considering the importance of central sensitization in the hypersensitivity associated with DNP, strategies that aim to control spinal neurons hyperexcitability are very useful in pain control in this condition, as will be discussed below.

Brain plasticity

Functional changes in pain processing areas in the CNS, besides the spinal cord, have been ultimately linked with DNP^[103], in a tight relation to increased peripheral input^[93,104]. Among these areas, marked changes in the thalamus, cortex and rostroventromedial medulla (RVM) have been reported in DNP patients and or experimental models.

The ventral posterolateral nucleus (VPL) of the thalamus is the main receiving area of nociceptive stimuli that is processed in the spinal cord^[105]. Projection neurons reach the thalamus through the spinothalamic tract (STT), which represents a major ascending nociceptive pathway. It has been demonstrated that in diabetic rats, these neurons present increased spontaneous activity, enlargement of the receptive field and augmented responses to mechanical noxious and innocuous stimuli. The hyperexcitability of STT neurons probably accounts to hypersensitivity to external stimuli and spontaneous pain^[93], increased in primary afferents activity^[93,104] and to plastic changes in spinal neurons^[93].

In addition, in studies that assessed brain imaging in diabetic rats it was reported increased activity not only at VPL, but also in different thalamic nuclei that control sensory-motor aspects^[106]. In diabetic patients, a recent study showed increased activation of diverse brain areas, including medial thalamus after application of noxious thermal stimuli in feet^[107]. Moreover, it has been described that DNP patients has a marked reduction in the levels of N-acetyl-aspartate (NAA) levels in the

thalamus compared to painless diabetic individuals^[108]. It is important to point out that patients with brain disorders in which neuronal loss or dysfunction are involved have consistently decreases in brain NAA concentrations^[109]. Other clinical finding related to thalamus alterations in diabetic patients is that subjects with painful type 1 diabetic neuropathy presented increased thalamus blood flow, when compared with those without pain, which was considered to reflect higher neuronal activity^[110]. Taking account the thalamus relevance in the nociceptive pathway, it is plausible to suggest that the alterations reported in this area might contribute to the development and/or maintenance of DNP^[108,110].

Likewise, in a model of type 1 diabetes, increased glutamate transmission was reported in the anterior cingulate cortex a brain area involved in the processing of the affective-motivational dimension of pain^[111]. The consequence of higher stimulation of this area by glutamate is suggested to be a sustained negative perception of affective component of pain^[111].

Changes in the endogenous pain control system have also been described in pre-clinical and clinical studies of DNP. The RVM is a structure that receives direct influences of periaqueductal gray matter, which is, in turn, affected by other structures, such as amygdala and hypothalamus^[112]. Three different populations of cells have been describe within the RVM: activation of ON cells act in a pronociceptive way, while activation of OFF cells has the opposite effect^[113] and neural cells which activation is still contradictory and remains to be better clarified^[114,115]. In diabetic animals, there is evidence of a reduction on the OFF cells and increase on the ON cells population. In addition, basal activity is augmented in ON cells, and reduced in OFF cells, in a resultant misbalance between pain facilitatory and inhibitory descending modulation in diabetic animals^[103]. After noxious mechanical stimulation in the periphery, there was no difference between diabetic and control ON cells activity. Thus, the mechanical hyperalgesia detected in diabetic rats could be associated with OFF cells impairment and consequently reduction on descending inhibitory tone^[103].

Some studies have also addressed the levels of the main neurotransmitters of the endogenous pain control system in different areas of the CNS in diabetic rats, but they have shown discrepant results. While some researchers found reduced release of norepinephrine in the spinal cord in diabetic rats^[116], others have described opposite findings^[117]. There is also evidence of diminished norepinephrine levels in supra spinal areas, such as brainstem and thalamus, but higher concentration in the cortex of diabetic animals^[118]. Additionally, impaired spinal opioid-induced release of serotonin (5HT) has been demonstrated in diabetic rats, and this finding may be related to opioid hyporesponsiveness in experimental DNP^[119]. Increased norepinephrine and 5HT levels in the spinal cord, as well as, augmented expression of norepinephrine and 5HT in RVM neurons

was also demonstrated in diabetic rats^[117]. Considering the facilitatory role of serotonergic and noradrenergic descending modulation during chronic pain, these changes may probably account for enhanced pain during diabetic neuropathy^[117]. There is also clinical evidence for misbalance between excitatory and inhibitory neurotransmitters in the CNS of diabetic patients with positive symptoms of neuropathy. In this regard, it has been found reduced levels of GABA and higher levels of glutamate in the posterior insula of diabetic patients, as well as a higher glutamate/GABA ratio within the thalamus^[120]. These changes may contribute to pain development in DNP, but further studies are necessary to determine their clinical significance.

TREATMENT OF DNP

DNP continues to represent a therapeutic challenge as its pathophysiology is not yet fully understood and pain relief is still unsatisfactory. The pharmacological treatments, with exception to those targeted to the glycemic control, are symptomatic, not focused on the pathophysiological mechanisms, limited by side effects^[3,121] and by the development of tolerance^[121].

A wide variety of drugs, used alone or in combination, has been shown to significantly reduce neuropathic pain compared with placebo in randomized controlled trials, but pain relief remains inadequate for most patients^[122]. Generally, in clinical trials, treatment is considered successful if patients would obtain 50% of reduction in the pain level^[123-125] associated with some additional beneficial effects on sleep, fatigue, depression and quality of life^[125]. Thus, the management of this condition basically consists of excluding other causes of painful peripheral neuropathy, improving glycemic control as a prophylactic therapy and using medications to alleviate pain^[126].

Despite of multimodal and multidisciplinary approaches to the treatment, the primary pathway is pharmacologically based^[127]. Three different agents have regulatory approval in the United States for the treatment of DNP: pregabalin, duloxetine and tapentadol^[11,128]. However, as pain relief is still suboptimal and challenging for clinicians^[95], drugs from various pharmacological classes have been used and some of them are included in this review.

Anticonvulsants

Pregabalin was the first anticonvulsant to receive approval from the Food and Drug Administration (FDA) for the treatment of postherpetic neuralgia, DNP^[129,130] and neuropathic pain after spinal cord injury^[131]. Pregabalin is a GABA analogue that selectively binds to pre-synaptic voltage-gated calcium channels containing the $\alpha 2\delta$ subunit in the brain and spinal cord, causing inhibition of the release of excitatory neurotransmitters^[128,132]. Moreover, $\alpha 2\delta 1$ subunits are responsible for increasing the functional expression of these channels, as a consequence of increased trafficking. Thus, the analgesic

action of pregabalin is also proposed to be the result of impaired trafficking of $\alpha 2\delta 1$ subunit with a consequent diminished expression of functional calcium channels^[133].

Several clinical trials evaluating pregabalin in DNP showed efficacy in the management of this condition^[3,134,135] with a number needed to treat (NNT) of 6.3^[125]. In addition to its analgesic effects, pregabalin presents anxiolytic activity^[132,135] and it has a beneficial effect on sleep and quality of life^[132], contributing, therefore, to improve the general condition of the patients. The side effects include dizziness, somnolence, peripheral edema, headache and weight gain^[3].

Some guidelines have also recommended gabapentin to treat DNP^[136]. Besides pregabalin, gabapentin is the only other anticonvulsant drug that demonstrated efficacy in the treatment of this condition^[128] with an NNT of 5.8^[137]. Gabapentin and pregabalin have a similar mechanism of action and the first is licensed for neuropathic pain in the United Kingdom, but not in the United States^[128]. Some clinical trials have suggested that gabapentin and pregabalin present better analgesic efficacy than tricyclic antidepressants or opioids^[138] and other important aspects of these drugs include their tolerability and lack of serious toxicity^[139].

Antidepressants

Antidepressants represent the first line drugs in DNP management. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, is rated level A for efficacy and is approved in the United States for the treatment of this condition. Additionally, some clinical trials have pointed out the effectiveness of duloxetine in other chronic pain conditions, such as fibromyalgia and chronic musculoskeletal pain^[140,141].

Results from a meta-analysis that included randomized, double blind, placebo controlled studies in patients with DNP showed the superiority of duloxetine over placebo in reduction of pain severity and in Patient Global Impression of Improvement/Change, as well as efficacy similar to gabapentin and pregabalin^[142]. Moreover, in a 2-wk open-label randomized trial in diabetic patients poorly responsive to gabapentin, duloxetine was able to reduce the pain score to levels similar to those achieved with pregabalin^[143,144]. Furthermore, analgesic efficacy of duloxetine in the treatment of DNP is maintained over a 6-mo period^[145], reinforcing its importance as a treatment option for this condition. The NNT for duloxetine varies from 1.3 to 5.1 in DNP patients^[146,147], which experience more frequently nausea, somnolence and dizziness as side effects^[146].

Venlafaxine is also a selective serotonin and norepinephrine reuptake inhibitor, that predominantly inhibits serotonin reuptake at low doses and norepinephrine at higher doses^[148]. Venlafaxine was also shown to be effective in reducing pain intensity in diabetic neuropathic patients^[149], with an NNT between 2.2 and 5.1 and a number needed to harm (NNH) of 9.6, to minor adverse effects, and of 16.2, for major adverse effects^[150].

Tricyclic antidepressants can also be an alternative to

treat DNP^[151]. Amitriptyline was shown to be as effective as gabapentin in a direct meta-analysis study^[152] and as duloxetine in a randomized, double-blind, crossover trial^[153]. Likewise, nortriptyline was reported as being as effective as gabapentin in attenuating neuropathic pain in a double-blind crossover trial enrolling diabetic patients^[154].

Tricyclic antidepressants are estimated to have an NNT of 1.3^[151,155], and an NNH from 4.2 to 10.7^[151] in DNP. The most common side effects related to the use of these drugs are dry mouth, postural hypotension, arrhythmias, cognitive impairment, constipation and urinary retention, which are more frequently observed after amitriptyline than nortriptyline treatment^[155].

Opioids

Opioids are recommended to be used as second or third line treatment for DNP^[3,151]. One multicenter, randomized, placebo-controlled study reported the tramadol effectiveness to significantly improve scores on physical and social functioning ratings in patients with DNP, but beneath some side effects such as nausea, constipation, headache and somnolence^[156]. Morphine was also shown to be effective in reducing mean daily pain scores related to diabetic neuropathy and postherpetic neuralgia^[128,157]. Moreover, results of clinical trials indicated that diabetic neuropathic patients experienced a significant reduction in pain intensity and an improvement on quality of life during oxycodone treatment, compared to placebo-exposed group^[158,159]. Besides, oxycodone improved gabapentin but not the pregabalin effectiveness in promoting DNP relief^[160,161].

The clinical evidence for the effectiveness of opioids in the control of DNP is corroborated by some pre-clinical data, which have reported the effectiveness of morphine^[162,163] and buprenorphine^[164] in reducing thermal or mechanical hypersensitivity in DNP animal models.

There is also evidence that the anti-hyperalgesic effect of opioids is improved by the association with some drugs, such as the antidepressants amitriptyline, moclobemide and reboxetine^[165]. In line with this idea, new molecules that integrate additional mechanisms to the opioid receptor agonism have been shown efficacy in reducing nociceptive behavior in animal models of DNP, such as the cebranopadol, a nociceptin/orphanin FQ peptide and opioid receptor agonist^[166], and the mu-opioid receptor agonist and norepinephrine reuptake inhibitor, tapentadol^[162,167]. The latter was approved by FDA for DNP treatment since 2012^[111]. Tapentadol has been shown to be effective in the management of different types of chronic pain, including osteoarthritis knee pain, low back pain and DNP, with a tolerable safety profile^[168,169]. Specifically concerning DNP, a randomized-withdrawal, placebo-controlled trial reported reduction of at least 30% in pain intensity in about 50% of the patients that received tapentadol^[170]. Similar data were obtained in a recent clinical trial in diabetic

neuropathic patients with moderate to severe pain, which experienced nausea (21.1%) and vomiting (12.7%) as side effects^[171].

Others agents

The drugs discussed below are currently associated to the pharmacological treatments already described according to the patients' symptoms and needs in order to achieve a better relief of pain in DNP conditions. However, further studies are necessary, specially controlled clinical trials, to determine the more efficacious, safe and successful combinations to be applied in the management of DNP^[128].

Capsaicin topical cream: Topical agents may be associated with fewer and less clinically significant adverse events than systemic agents^[172]. In addition, the possibilities of drug interactions are markedly reduced with the use of local treatments, which represent good options for patients with multiple medical problems^[128]. The capsaicin cream has been shown to be effective in the treatment of neuropathic conditions^[150] and is approved for topical relief of neuropathic pain^[128]. Capsaicin is the pungent component of hot chilli peppers^[11] and an agonist of the transient receptor potential vanilloid 1. This receptor is a ligand-gated, nonselective cation channel, predominantly expressed on unmyelinated C nerve fibers^[173], which, after repeated exposure to topical capsaicin, are depleted of their content of substance P and other neurotransmitters^[173,174]. The C fibers depletion and desensitization reduce painful stimuli transmission from peripheral nerves to the central nervous system^[173]. Some clinical trials have demonstrated the effectiveness of low-concentration (from 0.025% to 0.075%) capsaicin cream in DNP^[11,174,175]. Higher concentrations are not indicated because of desensitization of nociceptive sensory nerve endings, which may increase the risk of skin injuries in DNP patients^[173,174]. Some adverse effects include itching, stinging, erythema, transient burning sensation and initial pain at the application site, that diminishes with repeated use^[132,175], leading many patients to withdraw from the treatment^[128,173].

Lidocaine patch: Lidocaine patches act as peripheral analgesics with minimal systemic absorption and are used in combination with other analgesic drugs^[132,172]. Lidocaine blocks sodium channels and counteracts the hyperexcitability of peripheral nociceptors that contributes to neuropathic pain^[132,176]. The blockade reduces ectopic discharges and raises the peripheral sensory neuron discharge threshold^[176]. The few DNP clinical trials that compared topical lidocaine with other relevant interventions suggested that the effects in pain reduction are comparable to other drugs, such as capsaicin, gabapentin, amitriptyline^[172] and pregabalin^[172,174]. Adverse events include local irritation^[172], contact dermatitis and itching^[132].

Alpha lipoic acid: The benefit provided by alpha

lipoic acid (ALA) in the treatment of DNP possibly is due to its direct effects on the neuropathy, by reducing the oxidative stress, which has been defined as an important factor in the physiopathology of the diabetic neuropathy^[122]. Its antioxidant and anti-inflammatory actions may contribute to an all-round improvement of diabetic neuropathy symptoms^[135]. In some clinical trials that evaluated ALA effect in diabetic patients, pain was not a primary end point. However, they have shown a moderate benefit in terms of pain reduction^[132]. In a randomized double-blinded trial, ALA-treated patients reported a greater reduction in neuropathic pain when compared to placebo-treated subjects^[122]. Compared to several drugs currently in use for DNP treatment, ALA has fewer side effects^[30], being nausea and vomiting the most common^[132].

Isosorbide dinitrate spray: Isosorbide dinitrate is a nitric oxide-dependent vasodilator with effects on both arteries and veins^[177]. The improvement of pain and burning sensation could be associated with the increased generation of nitric oxide, improving microvascular blood flow^[178]. In a clinical trial with diabetic patients, the isosorbide dinitrate spray reduced overall neuropathic pain and burning sensation in about 50% of the patients, which also reported improvement in their quality of life, with improvements in sleep, mobility and mood^[178,179].

Final considerations about DNP treatment:

Besides the fact of many diabetic complications can be reduced with improved blood glucose control and other lifestyle interventions^[132,150], such as quit smoking and reducing alcohol consumption^[150], the efficacy of these measures, as well as the pharmacological treatments on DNP are not predictable. The medications rated as level A based on their efficacy are able to reduce pain and improve some aspects of patients' quality of life, but are not able to fully eliminate pain or prevent/revert the neuropathy. Even their combination does not result in satisfactory pain control, being the best improvement in pain, restricted to 50% of relief for the majority of the patients. Considering the available pharmacological options, DNP treatment has to be based mainly on patients' symptoms, pain level and tolerance of side effects.

Abstract

A diagnosis of new-onset diabetes after transplantation (NODAT) carries with it a threat to the renal allograft, as well as the same short- and long-term implications of type 2 diabetes seen in the general population. NODAT usually occurs early after transplantation, and is usually diagnosed according to general population guidelines. Non-modifiable risk factors for NODAT include advancing age, African American, Hispanic, or South Asian ethnicity, genetic background, a positive

family history for diabetes mellitus, polycystic kidney disease, and previously diagnosed glucose intolerance. Modifiable risk factors for NODAT include obesity and the metabolic syndrome, hepatitis C virus and cytomegalovirus infection, corticosteroids, calcineurin inhibitor drugs (especially tacrolimus), and sirolimus. NODAT affects graft and patient survival, and increases the incidence of post-transplant cardiovascular disease. The incidence and impact of NODAT can be minimized through pre- and post-transplant screening to identify patients at higher risk, including by oral glucose tolerance tests, as well as multi-disciplinary care, lifestyle modification, and the use of modified immunosuppressive regimens coupled with glucose-lowering therapies including oral hypoglycemic agents and insulin. Since NODAT is a major cause of post-transplant morbidity and mortality, measures to reduce its incidence and impact have the potential to greatly improve overall transplant success.

Key words: Cyclosporine; Graft; Kidney; New-onset diabetes; Tacrolimus; Transplantation

Core tip: New-onset diabetes after kidney transplantation (NODAT) is detrimental to patient and graft survival. Early diagnosis through the identification of modifiable and non-modifiable risk factors for NODAT and appropriate screening, accompanied by good glycemic control that involves a multidisciplinary care approach will help result in good short- and long-term kidney transplant outcomes.

INTRODUCTION

Kidney transplantation is widely considered to be the therapy of choice for patients with end-stage renal disease (ESRD) because of its ability to provide the maximum amount of replacement of renal function and a consequent improvement in patient morbidity and mortality. Among the various complications experienced by kidney transplant recipients (KTR), new-onset diabetes after transplantation (NODAT) is a well-known condition by which an organ transplant recipient such as a KTR develops diabetes mellitus (DM) at some point after the transplant procedure. The purpose of this review is to discuss the epidemiology and management of this common and important post-transplant disorder. A special emphasis will be placed on studies performed during the past ten years, with the intent of providing management recommendations for both diabetes and transplant professionals.

A diagnosis of NODAT carries with it a threat to the renal allograft, as well as the same short- and long-term implications of type 2 DM, but these occur at an accelerated pace^[1]. DM can both cause and expedite the course of cardiovascular disease (CVD) as well as the failure of multiple organ systems^[2]. According to the World Health Organization (WHO), the number of patients worldwide with DM has doubled from 170 million to 340 million over the past ten years. In addition, the WHO predicts that DM will be the seventh leading cause of death by 2030. This increase in incidence of DM has extended across many population groups, including perhaps transplant recipients.

Over the past decade, concomitantly with DM, there has also been a corresponding increase in the number of patients seeking kidney transplants. According to the 2010 United States Renal Data System Annual Data Report, the annual number of kidney transplants in that country increased from 13425 to 17350 over the decade between 1998 and 2008^[3]. Thus, there is also a larger KTR population at increased risk for NODAT. Although type 2 DM is an important cause of ESRD and consequently an important contributor to clinical consequences in incident KTR cohorts, we focus here on NODAT, as an entity distinct from pre-existing DM in a patient receiving a kidney transplant.

INCIDENCE AND PREVALENCE OF NODAT

The prevalence of NODAT after kidney transplantation has increased^[4], and varies between 2% and 53% based on several estimates^[5]. One reason for the wide variation in reported prevalence may be due to the challenges faced in making the diagnosis. Until about a decade ago, there was no consensus definition for NODAT. Previously, it was defined by fasting or random blood glucose levels of varying thresholds, or perhaps quite naively, by the need for insulin or oral

hypoglycemic agents in the post-transplant period^[6]. This issue was addressed by the development of the 2003 Consensus Guidelines, developed by the American Diabetes Association (ADA) and the WHO^[7]. According to these guidelines, NODAT is present if the patient has symptoms of DM, casual plasma glucose ≥ 11.1 mmol/L, or 8-h fasting plasma glucose ≥ 7.0 mmol/L. In 2010, the definition for DM was revised by the ADA to include the 2-h oral glucose tolerance test (OGTT), with a 2-h value of ≥ 11.1 mmol/L being indicative of DM. The general principle behind standardized NODAT incidence reporting is that the diagnostic criteria should reflect what is used in the general population. Hopefully, these developments will allow for more consistent reporting of NODAT in the future, leading in turn to more precise estimates of incidence rates.

It is well established that NODAT usually occurs early after kidney transplantation. One long-term study^[8] conducted between 1976 and 2004 in 1580 Egyptian KTR demonstrated a diagnosis of NODAT in 18.2% patients overall, in whom 52.4% were diagnosed by 6 mo and 11.5% between 6 and 12 mo. A French study of 527 KTR indicated a median time-to-onset of 1.6 mo, with an incidence of 7% over 2 years^[9]. Incidence estimates in the United States are 9.1% at 3 mo, 16% at 12 mo, and 24% at 36 mo^[10]. The incidence may be increasing even in children^[11]. Most studies reporting NODAT prevalence do not include OGTT data, as a result of which significant underestimation of incidence may occur. Variation in studies with regards to length of follow-up, intensity of routine screening, and degree of use of standardized definitions will all have an impact on incidence estimates. Furthermore, glycemic control improves in some patients with increasing time post-transplant, as a result of immunosuppressive medication dose reduction and other interventions. This in turn affects prevalence estimates and interpretation of incidence rates. Addition of HbA1c testing may also modify reported incidence rates. However, HbA1c testing has not been routinely employed at most transplant centres.

RISK FACTORS FOR NODAT

The risk factors specific to NODAT have been well-delineated. These can be broadly classified into non-modifiable and modifiable risk factors. These are summarized in Table 1.

NON-MODIFIABLE RISK FACTORS FOR NODAT

Non-modifiable risk factors include advancing age, black race, genetic background, a positive family history for DM, and previously diagnosed glucose intolerance^[12]. Polycystic kidney disease is also believed to be a risk factor. All of these risk factors can usually be identified

Table 1 Risk factors for new-onset diabetes after transplantation

Non-modifiable	Modifiable
Advanced age	Obesity
African American, Hispanic, or South Asian descent	Sedentary lifestyle
Genetic, <i>e.g.</i> , HLA B27	Metabolic syndrome
Adult polycystic kidney disease	Viral infections, <i>e.g.</i> , HCV, cytomegalovirus
Previous glucose intolerance, <i>e.g.</i> , during pregnancy, steroid therapy for renal or non-renal disease	Corticosteroids
Male donor	Calcineurin-inhibitors (tacrolimus > cyclosporine)
Deceased donor	Sirolimus
	Acute rejection

HCV: Hepatitis C virus; HLA: Human leukocyte antigen.

before transplantation.

Since the ESRD population continues to age, it is possible that the incidence of NODAT will increase as a result of more elderly patients being transplanted for their ESRD. Age is considered to be the strongest risk factor for NODAT^[13]. It was long ago shown that patients above the age of 45 may be at higher risk for NODAT^[14]. A later study estimated that risk at about 2.9-fold^[15]. The incidence of NODAT may increase by as much as 50% for every 10-year increase in age^[16]. Age over 60 has been associated with a risk of 2.6-fold^[10]. However, age *per se* is not a precluding factor to kidney transplantation^[17] and the risk for NODAT does not typically dissuade transplant centres from performing transplants in older patients.

Besides African-American or Hispanic descent^[12], KTR of South Asian origin may also be at higher risk for NODAT^[18]. The relative risk for NODAT has been estimated at 1.68 for blacks and 1.35 for Hispanics compared to Caucasians^[10]. Using the 2003 consensus criteria, blacks are considered to be at a two-fold risk for NODAT^[19]. The increased risk for NODAT, at least in blacks, is believed to be at least partly due to variation in the pharmacokinetics of various immunosuppressive agents^[1]. Variability in dosing requirements based on ethnicity has been demonstrated recently for tacrolimus, with increased amounts of this diabetogenic agent needed in East Asians^[20]. It is unclear at this time, however, if the diabetogenic effects of immunosuppressive medication are influenced by ethnicity, although this has been speculated^[7].

Genetic predisposition to NODAT includes traditional associations with the alleles human leukocyte antigen A28, A30, B27, and Bw42. A number of genetic associations with NODAT have been identified in the last decade. For example, there has been a reported association with the R325W polymorphism in the SLC30A8 zinc transporter gene of pancreatic islets, with the R/r inheritance being associated with higher risk^[21]. Another study from the same group suggested the association of *TCF7L2* gene variants with NODAT^[22]. This

association with *TCF7L2* has also been demonstrated by another group^[23]. Other associations of specific gene variants with NODAT include *KCNQ1*^[24], *NFATc4*^[25], adiponectin 276G/T^[26], and mitochondrial haplotype H^[27]. While all of these associations are interesting, it remains to be seen if such findings can be replicated in different populations, and whether they can be demonstrated to be independent risk factors for NODAT in prospectively conducted studies. Furthermore, the expense and inconvenience of such assessments greatly limits the ability to study these and other gene candidates further.

In the past decade, NODAT has also been associated with autosomal dominant polycystic kidney disease (ADPKD)^[28,29], as well as autosomal recessive polycystic kidney disease^[30]. ADPKD in particular is a common disease and cause of ESRD, particularly in Caucasians, and so it remains to be definitively proven as a risk factor for NODAT since both ADPKD and NODAT are common in KTR. A plausible mechanism for the association also needs to be developed.

Finally, previously diagnosed glucose intolerance is a risk factor for NODAT^[13]. Glucose intolerance may have been diagnosed at the time of pregnancy, or when corticosteroids were used as part of the therapy for the primary renal disease or a related or unrelated systemic disease. In such cases, even though DM may have resolved with cessation of steroid therapy, the risk for DM may persist lifelong. To our knowledge, these risks have not been evaluated prospectively. Also, donor factors for NODAT considered "non-modifiable" include male gender and deceased, as opposed to living donor kidneys. However, these risk factors are unlikely to ever be evaluated prospectively, and so will not be discussed further.

MODIFIABLE RISK FACTORS FOR NODAT

There are many more risk factors for NODAT that may be considered modifiable, at least on a theoretical basis. The most significant risk factors are as follows.

Obesity has detrimental effects to transplantation for a variety of reasons. Obesity has been estimated to increase the risk for NODAT, with a relative risk of 1.73^[13]. The risk for NODAT increases linearly for every 1 kg above 45 kg^[13]. While obesity in the context of transplantation is traditionally understood as body mass index > 30 kg/m², body fat percentage may also be a useful marker^[31]. It remains undetermined, however, whether it is pre-transplant weight that increases the risk for NODAT, or whether it is the weight gain that occurs soon after transplantation that is the cause. At least one study indicates that is the former^[32]. Nonetheless, longer-term studies may be needed to demonstrate the association of weight gain with NODAT^[13]. Adiponectin is a hormone that is reduced with increasing adiposity. Increased adipose tissue is also associated with inflammation. NODAT has been associated with reduced

adiponectin and increased C-reactive protein levels^[33], indicating that these are also possible mechanisms for the association seen.

The metabolic syndrome is often associated with obesity. When a definition for metabolic syndrome such as the National Cholesterol Education Program Adult Treatment Panel III is used, which does not contain diabetes as a mandatory component, the presence of metabolic syndrome has been associated with an increased risk for NODAT. In the Patient Outcomes in Renal Transplantation study^[34], metabolic syndrome was independently associated with NODAT (HR = 3.46, 95%CI: 2.40-4.98, $P < 0.0001$).

Hepatitis C virus (HCV) infection has been associated with DM in the general population, particularly over the age of 40^[35]. Just like DM, HCV also causes ESRD by causing glomerular disease, and HCV can be acquired through blood contamination in hemodialysis units. As a result, it is not uncommon for HCV-infected patients to be considered for kidney transplantation when there is no evidence for hepatic dysfunction and viral titres are sufficiently low or undetectable. The one-year incidence of NODAT was found to be 25.6% in those who were HCV-positive, compared to 14.4% in those who were negative^[10]. Another study found an adjusted Odds ratio for NODAT approaching 4.0 in those with HCV^[36]. The risk for NODAT with HCV may be exacerbated by the use of tacrolimus^[37]. Cytomegalovirus (CMV) infection has also been considered as a risk factor for NODAT, with the mechanism being impaired insulin release^[38]. Unlike HCV however, CMV is much more easily treated in the post-transplant setting and so receives considerably less attention as a risk factor.

Corticosteroids remain a mainstay of post-transplant immunosuppression and are a part of most medication regimens. The risk for NODAT with steroids relates both to the dose used and the duration of therapy^[13]. Steroids induce gluconeogenesis and glycolysis, increasing both fasting and post-prandial glucose levels. Glycogenesis is decreased. Insulin resistance, to which KTR may be predisposed, is an important effect of steroid therapy. They also impair pancreatic beta-cell function^[39]. While a maintenance dose of 5 mg/d of prednisone is typically used for KTR, higher doses (such as 1 mg/kg per day) are used in the early post-transplant phase. Higher doses are also used as bolus therapy when acute rejection of the transplant occurs. There is a dose dependent relationship between steroid dose and glucose levels^[40].

Tacrolimus and cyclosporine are widely used calcineurin-inhibitor (CNI) drugs in KTR. Most patients receive one or the other drug as part of their immunosuppressive drug regimen. Between these two, tacrolimus is considered to be more diabetogenic by about 50%^[10,41]. Unlike in the case of steroids, this effect is not believed to be dose-dependent^[16,42], although this is controversial^[43]. Tacrolimus is being increasingly preferred as the CNI of choice at most transplant centres

due to its demonstrated superior efficacy and safety^[44], despite the risk for diabetes. However, it is possible to use much lower doses presently^[44]. Deficiency of calcineurin leads to decreased insulin production. CNI inhibit the uptake of glucose molecules by cells due to a reduction in the number of glucose transporter type 4 (GLUT-4) receptor molecules on the cell membrane surface of adipocytes^[45]. GLUT-4 is an insulin-regulated protein present primarily in adipose tissue and striated muscle, enabling the translocation of glucose into the cell cytoplasm^[46]. Thus, reduction in GLUT-4 leads to hyperglycemia. Tacrolimus also reduces glucokinase activity in pancreatic islets, thereby suppressing glucose-induced insulin release^[47]. Although both impaired insulin release and increased insulin resistance are both believed to be mechanisms for CNI-induced NODAT, the former may be more important. Islet cell damage in the form of cytoplasmic swelling, vacuolization, and altered insulin staining can be demonstrated as a result of CNI therapy^[48]. CNI also cause reduced insulin gene expression^[49].

Sirolimus is another immunosuppressive agent used in transplantation that has been contextualized to NODAT. The association of sirolimus with NODAT has been believed to be due to its combination with CNI, and so conversion from a CNI to sirolimus as the main immunosuppression has been perceived as beneficial^[50]. However, some studies seem to indicate that sirolimus is a risk factor for NODAT. These include both large database studies^[51] and smaller single-centre reviews^[52]. The effect may be mediated by hypertriglyceridemia^[53]. Sirolimus may also inhibit pancreatic beta cell proliferation. At best, sirolimus is neutral with respect to NODAT risk^[13].

The potential pathogenic mechanisms for drug-induced NODAT are summarized in Table 2.

CLINICAL SIGNIFICANCE OF NODAT

RTR who develop NODAT are most likely to be at the same risk for developing the short- and long-term complications of diabetes as people with type 2 diabetes. However, there have been few prospective, long-term, or interventional studies with adequate statistical power to support this statement. It is clear, however, from smaller studies that NODAT has an adverse effect on important transplant- and patient-related outcomes.

An older study has demonstrated that after 12 years of post-transplant follow-up, graft survival in patients with NODAT was only 48% compared to 70% in those who did not develop NODAT, with NODAT predicting a relative risk of graft loss of 3.72^[54]. In the shorter term, graft survival was shown to be reduced by 17% after 3 years and 34% after 4 years in those with DM compared to those without DM^[55]. In one prospective study, more than 1400 KTR underwent an OGTT at 10 wk post-transplant and were followed for a median of 6.7 years. Impaired glucose tolerance was found to be associated

Table 2 Potential pathogenic mechanisms for drug-induced new-onset diabetes mellitus after transplantation

Immunosuppressive drug	Mechanism for new-onset diabetes after transplantation
Corticosteroids	Increased gluconeogenesis
	Increased insulin resistance
	Reduced glycogenesis
	Decreased insulin release
	Impaired pancreatic beta cell function
Calcineurin-inhibitors (cyclosporine, tacrolimus)	Reduced glucose uptake
	Decreased insulin release
	Reduced insulin gene expression
	Direct pancreatic beta cell toxicity
Sirolimus	Hypertriglyceridemia
	? Decreased pancreatic beta cell proliferation

?: Requires further investigation.

with a 40% greater mortality risk^[56]. This increased risk was not seen with impaired fasting glucose (IFG). In a prospective, single-centre study of 201 consecutive KTR in Norway, the 8-year major adverse cardiac event rate was 7% in those without DM, 21% in those with DM before transplantation, and 20% in those with NODAT^[57]. Perhaps due to low statistical power, NODAT was not associated with mortality in this study. In another single centre cohort of over 1800 KTR, NODAT was associated with a hazard ratio of 1.80 for mortality^[58]. The main cause of mortality is CVD^[58].

An important distinction to be made is if NODAT leads to patient mortality independent of transplant graft function. In one study^[59], an association was detected between NODAT and death with a functioning graft, but there was no impact on graft survival when censored for death. It is easier to demonstrate associations when NODAT is combined with pre-existing DM^[60]. In order to identify the unique contribution of NODAT to mortality, independent of graft function, longer follow-up is required.

NODAT also imposes a significant cost to health care systems. In the United States, NODAT was estimated to cost more than \$12000 in the first post-transplant year, and over \$19000 in the year after this^[41]. This cost is most likely related to the treatment for, and morbidity associated with DM.

Regardless of the implications of NODAT for cardiovascular risk, graft function, or mortality, a diagnosis of NODAT carries great significance for the individual patient. Transplant patients typically require three immunosuppressive medications, to which prophylactic antibiotics, antihypertensive agents, and others are often added. Patients with NODAT are prescribed oral hypoglycemic agents and sometimes insulin in addition to all of these. They are also subject to new dietary restrictions, which will often be superimposed on those mandated by a chronic kidney disease state (such as potassium restriction). Hospitalization may occur for both hyperglycemia and hypoglycemia^[61]. All of these have an important impact on quality of life. Studies assessing this aspect of NODAT implications are few. NODAT has been associated in older studies with

peripheral neuropathy and diabetic nephropathy^[54], as well as more infections^[62], including severe infections^[63].

PREVENTION AND MANAGEMENT OF NODAT

Prevention of NODAT

Some common preventative strategies for NODAT are summarized in Table 3. Preventing NODAT has the potential to prevent many of the short- and long-term complications of NODAT. Screening is an important part of any preventative strategy. Screening for NODAT risk prior to transplantation, as well as the risk for cardiac events, will allow for better informed consent and also help to guide post-transplant management. One recommendation is to obtain a fasting glucose level in all transplant candidates, with a subsequent OGTT performed if IFG is detected^[64]. A pre-transplant OGTT may be justified if the fasting blood glucose (FBG) is as low as 5.1 mmol/L^[65]. Even if the OGTT is normal, a pre-transplant random BG > 6.0 mmol/L is associated with a NODAT risk of over 25%, and > 7.2 mmol/L with a risk exceeding 50%^[66]. Use of OGTT may be justifiable in all transplant candidates if the population is at particularly high risk, such as a multi-ethnic population. More sophisticated testing such as HOMA-IR assessment is not feasible routinely. HbA1c testing has not been evaluated as a pre-transplant screening strategy. If a transplant candidate is determined to be at high risk for NODAT, this should be discussed with the candidate before the transplant, and if appropriate, their proposed post-transplant immunosuppressive strategy discussed as well.

Screening for NODAT has also been employed in the post-transplant setting. Self-testing of blood glucose in the afternoon during the early post-transplant phase has been associated with an increased rate of detection of NODAT^[67]. An OGTT performed at 10 wk post-transplant may help to predict longer-term hyperglycemia^[68]. One difficulty with OGTT in large post-transplant clinics is that it may interfere with CNI blood level measurements, which are strictly timed. It is reasonable to measure fasting glucose at least monthly, and random blood glucose at least twice weekly for the first few months after transplantation. The HbA1c can also be checked. Since the published incidence and prevalence rates published in the literature are too variable to be helpful to individual transplant centres, it behooves every transplant centre to properly estimate its own incidence and prevalence rates, particularly in the early post-transplant period. Making an early diagnosis of NODAT is important because preventative measures can enhance the KTR's chances for a better quality of life and also prolong their graft survival^[12].

As with those at-risk for DM in other populations, lifestyle modification is likely to have a favorable impact on NODAT incidence. Recommendations for weight loss in obese patients prior to transplantation may be beneficial for preventing NODAT, but remains difficult

Table 3 Management strategies for new-onset diabetes after transplantation

Prevention strategies	Management strategies
Identification of risk factors (Table 1) with pre-transplant counseling	Regular blood glucose monitoring with appropriate follow-up
Pre- and post-transplant screening: random blood glucose, fasting blood glucose, 2-h oral glucose tolerance test with appropriate follow-up	Multi-disciplinary care
Lifestyle modification: weight control, diet, exercise (subject to dialysis-imposed restrictions)	Lifestyle modification: weight control, diet, exercise
Rapid corticosteroid reduction or avoidance	Rapid corticosteroid reduction
Selective calcineurin-inhibitor use (<i>e.g.</i> , cyclosporine instead of tacrolimus)	Conversion of cyclosporine to tacrolimus
? Newer immunosuppressive agents (<i>e.g.</i> , alemtuzumab, belatacept)	Oral hypoglycemic agents: metformin, sulfonylureas, meglitinides, dipeptidyl peptidase-4 antagonists (alone and/or in combination)
	Insulin
? Magnesium oxide	Monitoring for complications
? Statins	

?: Requires further investigation.

to enforce due to the predisposition for malnutrition in patients on dialysis. Nonetheless, safe and closely supervised dietary and exercise recommendations for dialysis patients should be encouraged, particularly in those identified to be at higher risk for NODAT. Prompt attention from allied health professionals such as nurse practitioners and dietitians may help prevent NODAT from being established when hyperglycemia is detected.

The role of pharmacotherapy in the prevention of NODAT has also been investigated. Since early post-transplant hypomagnesemia is common, magnesium oxide supplementation has been investigated and has been associated with a reduction in FBG^[69]. The use of statins in the post-transplant period has been associated with a reduced incidence of NODAT^[70]. However, rosuvastatin has not been associated with improved insulin sensitivity in non-diabetic KTR^[71], and so this pleiotropic effect of statins remains to be established^[72]. Although angiotensin-converting enzyme inhibitors have also been associated with reduced NODAT incidence^[70], their beneficial effect has not been demonstrated prospectively. Similarly, metformin has not been tested as a preventative strategy.

Since immunosuppressive medication remains the most readily available tool at the disposal of transplant clinicians to reduce the incidence of NODAT, much attention has been given to the reduction in exposure to existing immunosuppressive drugs such as corticosteroids and tacrolimus. Such reduction is often facilitated through the testing of newer pharmacological therapies. In a large, randomized controlled trial of corticosteroid withdrawal at 7 d post-transplant vs no withdrawal, a trend was noted towards better glycemic control in the withdrawal arm^[73]. However, there was no difference in NODAT rates^[73]. Despite this, fewer patients in the corticosteroid withdrawal arm required insulin for NODAT at 5 years^[73]. On the other hand, a large retrospective study involving more than 25000 KTR reported significant benefits of steroid avoidance at initial hospital discharge when compared to a steroid-containing regimen with respect to NODAT at three years^[74]. Corticosteroid withdrawal has also been shown to be beneficial when combined

with tacrolimus reduction^[75]. Other studies have shown that complete corticosteroid withdrawal has no additional benefit beyond only dose reduction^[40].

Although tacrolimus has a 50% greater association with NODAT than cyclosporine^[10], it is the preferred CNI in many transplant programs for other reasons such as graft function in large clinical trials^[44]. Reduced exposure to tacrolimus has also been associated with a similar incidence of NODAT to cyclosporine monitored using the 2-h instead of trough level^[76]. In the randomized DIRECT study^[77], which also used 2-h cyclosporine monitoring, a marginal increase in the composite safety endpoint of NODAT and IFG (33.6% vs 26.0%, $P = 0.046$) was noted with tacrolimus. Sometimes cyclosporine is switched to tacrolimus late after transplantation for reasons such as the development of other side effects, or rejection. In such instances, the risk of impaired glucose metabolism does not appear to be increased^[78]. In addition, either tacrolimus or cyclosporine may be switched to sirolimus in order to reduce the burden of CNI nephrotoxicity. However, conversion to sirolimus has been associated with worsening insulin sensitivity^[79]. The use of alemtuzumab, which is an anti-lymphocyte induction agent, has been associated with a reduced risk for NODAT^[80]. Belatacept, which is a recently introduced selective costimulation blocker in kidney transplantation, has been associated with a reduced incidence of NODAT compared to cyclosporine when studied as a prespecified endpoint in two Phase III studies^[81]. Both alemtuzumab and belatacept are induction therapies and so cannot be used for this purpose if a higher risk for NODAT is detected post-transplant.

Management of NODAT

Management strategies for NODAT are summarized in Table 3. Even if attempts to prevent NODAT are meticulous, it is likely that NODAT will occur in at least a proportion of KTR. The goals for management at this juncture include adequate glycemic control, perhaps with complete resolution of hyperglycemia without pharmacotherapy, and minimizing the short- and long-term complications of hyperglycemia. At our centre, non-fasting blood tests including glucose measurements

are obtained twice weekly for the first three months and weekly for the next three months. Fasting blood tests including glucose are obtained at least monthly. Our centre also employs an intensive multidisciplinary approach in the post-transplant clinic setting that includes a nurse practitioner with specialized expertise in diabetes prevention and management. This health care professional selectively reviews all clinic patients identified as having NODAT or being at high risk for NODAT. In addition, KTR have access to a dietician and pharmacist at all times in the clinic. Reading material about NODAT is also readily available. While such resource-intensive measures are probably helpful to individual patients, their overall effectiveness at a population level remains to be demonstrated. At other centres, adoption of a healthy diet and exercise program coupled with weight control strategies has demonstrated improvement in glycemic control over 6 mo^[82]. One challenge in this regard will be multi-ethnicity of KTR^[83] and possible language barriers. Collaboration between nephrologists and endocrinologists will help in the delivery of optimal care.

When antihypertensive medication is necessary for blood pressure control, it is reasonable to avoid or minimize the use of beta-blockers and thiazide diuretics in the absence of a compelling indication in those deemed at risk for NODAT. While clinical trials of antihypertensive agents in KTR are especially rare, there have also been no prospective studies of antihypertensive medications in KTR with NODAT as a pre-specified endpoint.

It is tempting for clinicians to alter transplant-related immunosuppression once NODAT has developed, with the view of optimizing glycemic control and perhaps avoiding the use of diabetes-specific medication. Reducing corticosteroid exposure carries an enhanced risk of transplant rejection^[84]. Switching from tacrolimus to cyclosporine once hyperglycemia or NODAT has developed is controversial. Cyclosporine possesses a side effect profile somewhat different from tacrolimus that includes hypertrichosis and gingival hyperplasia. Nonetheless, this conversion has been attempted as rescue therapy from NODAT in small studies, with demonstration that glycemic control can be improved^[85-87]. However, acute rejection remains a risk^[88]. Specific features related to NODAT in patients that can predict a successful conversion have not yet been identified.

If it is clear that lifestyle modification alone will be insufficient to control hyperglycemia, then pharmacotherapy targeting glucose metabolism should be initiated. In the very early post-transplant phase, when corticosteroids are being rapidly tapered, additional pharmacotherapy may not be required if the hyperglycemia is mild. The choice between insulin and oral hypoglycemic agents depends on the severity, timing, and expected duration of hyperglycemia^[49]. Insulin therapy is safe^[50] particularly when graft function is not yet established or is unstable. Since corticosteroids are typically administered in the morning in KTR, a combination of intermediate and short-acting insulin administered several

times during the day and corresponding to mealtimes may be required. In less urgent instances, oral hypoglycemic agents can be commenced without resorting to insulin firsthand.

The choice of oral hypoglycemic agent is dictated by the level of renal function. No agent is specifically contraindicated in KTR, and there are no significant drug interactions with CNIs or other immunosuppressive drugs. Pharmaceutical approaches generally mirror those utilized in the general population, with no studies specific to KTR available. In addition, the target HbA1c for KTR has not been defined^[49]. Metformin improves insulin sensitivity, which is often affected in NODAT. The safety of metformin in KTR with sufficient renal function has been formally demonstrated^[88]. Since the estimated GFR in KTR with well-functioning grafts often exceeds 50 mL/min per 1.73 m², metformin can be safely used for most patients. A theoretical disadvantage to using metformin in KTR would be gastrointestinal upset, to which KTR are already prone by virtue of immunosuppressive medications such as mycophenolate mofetil. However, metformin may counter the post-transplant weight gain associated with corticosteroid administration, but this has not been demonstrated. Keeping these in mind, metformin is often employed as a first-line agent in KTR with NODAT.

Sulfonylureas, which enhance insulin secretion, are also widely used in KTR. Their use is again dictated by level of renal function, and unlike metformin, they may exacerbate post-transplant weight gain. Newer sulfonylureas like glipizide and gliclazide may be used in KTR, with appropriate monitoring for hypoglycemia. Amongst the thiazolidinediones, which are selective agonists of the peroxisomal proliferator-activated receptor gamma, rosiglitazone has been shown to improve glucose tolerance, insulin sensitivity, and even endothelial function in a small group of KTR^[89]. Its short-term efficacy has also been shown by other groups^[90]. Thiazolidinediones should again be used with extreme caution if graft function is severely impaired. Congestive heart failure is a significant concern, and many KTR already have impaired cardiac function. Furthermore, cyclosporine may promote a sodium-retentive state. As a result, thiazolidinediones are usually not used.

Amongst the meglitinides, which are short-acting drugs that induce insulin secretion, repaglinide has been shown to be safe in KTR^[91]. Repaglinide can also be used in severe renal graft dysfunction. Dipeptidyl peptidase-4 (DPP-4) antagonists have been employed in KTR. These drugs inhibit DPP-4, which is responsible for the rapid degradation of numerous substrates including the glucagon-like peptide 1, whose role is to increase pancreatic insulin secretion. Among the DPP-4 antagonists, sitagliptin has been shown to be both safe and efficacious in KTR^[92,93]. A theoretical risk in KTR is an increased risk of infections, to which they may already be prone by virtue of being in an immunosuppressed state.

It is reasonable to employ rationally selected

combinations of two or three of the above drugs before proceeding to insulin therapy. However, the initiation of insulin should not be delayed unnecessarily, since prolonged hyperglycemia may result in hospitalization from intravascular volume depletion and serious comorbidities such as infections. Opportunistic infections of many kinds typically occur in the first 6 mo post-transplant, which corresponds to the phase when NODAT usually occurs.

FUTURE DIRECTIONS

Renal transplant survival has significantly improved over the last 50 years. Death with graft function, often as a result of CVD, has become a major cause of graft loss. As a result, increasing attention is being given to cardiovascular risk factors such as DM, within which NODAT is a significant component. Intensive screening for NODAT should be the norm in all transplant centres. Efforts to combat NODAT have to be balanced against the risks for graft rejection. Large clinical trials of newer immunosuppressive agents in kidney transplantation are few, but the inclusion of NODAT as a prespecified endpoint will help to better understand not only the most important contributing risks for NODAT, but also identify those interventions that are most likely to result in a lower NODAT incidence. Correspondingly, clinical trials that address treatment strategies for diabetes post-transplant have received very little attention. This is indeed unfortunate given the magnitude of NODAT prevalence and its financial implications for society, not to mention the profound impact of NODAT on transplant recipients. Until such trials are performed, multidisciplinary care focused on intensive glucose control in keeping with general population guidelines, along with management of other cardiovascular risk factors should remain the standard.

insulin resistance, dyslipidemia, β -cell dysfunction, impaired glucose tolerance and ultimately leading to T2DM. Chronic oxidative stress, hyperglycemia and dyslipidemia are particularly dangerous for β -cells from lowest levels of antioxidant, have high oxidative energy requirements, decrease the gene expression of key β -cell genes and induce cell death. If β -cell functioning is impaired, it results in an under production of insulin, impairs glucose stimulated insulin secretion, fasting hyperglycemia and eventually the development of T2DM.

Key words: Insulin resistance; Dyslipidemia; Type 2 diabetes mellitus; Oxidative stress

Core tip: Oxidative stress is underling in the development of cardiovascular disease, type 2 diabetes mellitus (T2DM) and diabetic complications. Increased oxidative stress appears to be a deleterious factor leading to insulin resistance, dyslipidemia, β -cell dysfunction, impaired glucose tolerance and ultimately leading to T2DM.

Tangvarasittichai S. Oxidative stress, insulin resistance, dyslipidemia and type 2 diabetes mellitus. *World J Diabetes* 2015; 6(3): 456-480 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/456.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.456>

Abstract

Oxidative stress is increased in metabolic syndrome and type 2 diabetes mellitus (T2DM) and this appears to underlie the development of cardiovascular disease, T2DM and diabetic complications. Increased oxidative stress appears to be a deleterious factor leading to

INTRODUCTION

Aerobic life uses oxygen to oxidize (metabolism) food substrates (carbon- and hydrogen-rich) to obtain the heat energy and chemical essential for life. When we oxidize molecules with oxygen, the oxygen molecule itself becomes reduced and forms intermediates.

In eukaryotic cells, reactive oxygen species (ROS) are always produced as the consequence of regular physiological metabolism^[1]. These ROS (pro-oxidants) productions are counter-balanced by cellular antioxidant defense mechanisms in the normal physiological conditions. ROS define as diverse chemical that have reactive properties are capable to accommodate or donate electrons (e-) to the broad range of biological molecules. Normally, the production and neutralization of ROS are balance with antioxidants in a living system and does not cause any oxidative damage, determines as physiological state^[2]. The imbalance between these prooxidants and antioxidants in the living organism system to determine as oxidative stress state, brings to cellular disruption and damage^[3]. The free-radical can attack polyunsaturated fatty acids oxidation in physiological systems known as lipid peroxidation. Lipid peroxidation is an autocatalytic free radical mediated destructive process whereby poly-unsaturated fatty acids in cell membranes undergo degradation to form lipid hydroperoxides^[4,5]. By-products of lipid peroxidation such as conjugated dienes and malondialdehyde (MDA) are increased in the patients with obesity, metabolic syndrome and type 2 diabetes mellitus (T2DM). Carbohydrates, lipids, proteins and DNA are the targets of oxidative stress modification biomolecules generally as the principal of ROS induced cellular damage. Therefore, these ROS modified biomolecules are used as oxidative stress markers both *in vivo* and *in vitro* measurement. Recent study suggests that ROS may act as the mechanical link of salt sensitive hypertension, over nutrition and high fat diet, metabolic syndrome and T2DM animal models^[6]. ROS levels are increased in obesity, especially in abdominal obesity which is the major component of metabolic syndrome and it can be reduced by weight loss^[7]. Many studies demonstrated that increased oxidative stress is associated with insulin resistance pathogenesis by insulin signals inhibition and adipokines dysregulation^[8,9]. In animal studies, oxidative stress enhances insulin resistance. The evidence suggested that angiotensin II (Ang II) infused rats required the increased glucose load to maintain normal glucose levels during hyperinsulinemic clamp to stimulate ROS production^[10]. Thus, ROS may also contribute and accelerate the insulin resistance development in insulin-targeted organs of the over nutrition and the excess salt individuals.

In the large general population studies demonstrated that insulin resistance is multifactorial^[11,12] and the genetic component^[11,13,14]. Insulin resistance most often precedes in many years before the onset of T2DM. Insulin resistance and the consequence of declined of insulin secretion are the principle of the T2DM pathogenesis^[11,12,15,16]. The late complications of diabetes have been associated and implicated in their etiology with oxidative stress^[17-19]. The influence of oxidative stress on insulin resistance, dyslipidemia, abnormal lipoprotein production and the pathophysiology of T2DM by using *in vivo*, *in vitro* and animal models data on these effects

were also included in this review.

ROS

Oxygen exists in air known as oxygen molecule (O₂) or dioxygen. Oxygen on the surface of earth appeared in significant amounts approximately 2.5 × 10⁹ years ago. It was created by the photosynthetic activity of plants and microorganisms (blue green algae). Increased atmospheric oxygen concentration was followed by the ozone layer formation in the stratosphere. Both oxygen and ozone layer were filters against the solar ultraviolet radiation reaching surface of the Earth. In eukaryotic cells, ROS is produced as the consequence of the normal aerobic physiological metabolism^[1]. These ROS levels are counter-balanced with the cellular antioxidants in the normal physiological conditions. ROS define as diverse chemical that have reactive properties are capable to accommodate or donate electrons (e-) to the broad range of biological molecules. These species include instability radicals arise from an unpaired e-. Existence of the presence of oxygen and the aerobic organisms on the earth is possible^[20].

However, these molecules are also played an adverse role in the biological systems as oxidative stress. At the steady state of the living systems, oxygen metabolism always produce oxygen-derived free radicals such as superoxide O₂^{•-}, hydroxyl OH[•], alkoxyl RO[•], peroxy RO₂[•], peroxyxynitrite ONOO[•] and oxygen-derived non-radicals such as hydrogen peroxide H₂O₂, hypochlorous acid HOCl and hypobromous acid HOBr. Both free radicals and non-radicals groups are the important factors of the oxidative stress mediated cellular damages^[21]. Normally, the neutralization of ROS productions by cellular antioxidant defense mechanisms are determine as the physiological state and do not cause any oxidative damage^[2]. The imbalance of the ROS production and antioxidants defense system in the living systems caused oxidative stress brings to cellular function disruption and damage^[3].

This imbalance occurs due to over production of ROS and reduction of the antioxidant defense mechanisms. The electron transport chain in mitochondrial, peroxisomes and cytochrome P450 system are the most important sources of ROS production (involves in O₂^{•-} production)^[22]. Moreover, various enzymes can be accelerated ROS production such as cyclooxygenases^[23,24], xanthine oxidase^[25], uncoupled nitric oxide synthases (NOS)^[26-28] and NADPH oxidases^[29]. Drugs such as doxorubicin^[30,31], cisplatin, acetaminophen^[32-34] and nimesulide^[35]. Heavy metals (Fe, Cd, Pb, Hg) as the toxic substances^[36-39], acrolein, chloroform, carbon tetrachloride^[40], tertiary butyl hydroperoxide^[41-44], environmental pollutants (oxides of

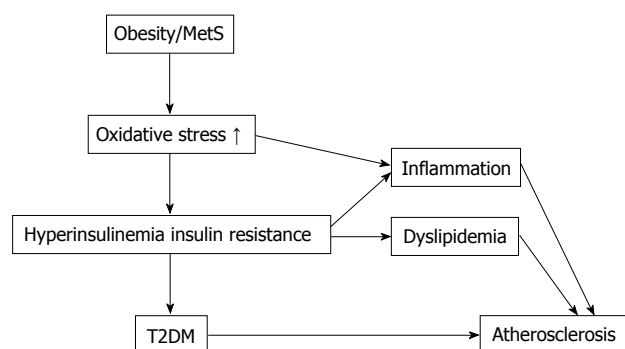

Figure 1 Summarized of obesity and metabolic syndrome elevate in oxidative stress. T2DM: Type 2 diabetes mellitus; MetS: Metabolic syndrome.

nitrogen, SO_2 , CO_2), xenobiotics, UV irradiation and the other factors induce ROS overproduction.

In metabolic disorders assist the increased ROS production in the physiological system such as obesity, insulin resistance and diabetes mellitus^[45-48]. In Figure 1 summarized of obesity and metabolic syndrome elevate in oxidative stress. Superoxide radical ($\text{O}_2^{\cdot-}$), hydroxyl radical (OH^{\cdot}) and hydrogen peroxide (H_2O_2) are the three major ROS in physiological organisms^[49]. Superoxide radical ($\text{O}_2^{\cdot-}$) acts as the parent ROS molecules caused from the one electron reduction of oxygen molecule by electron transport chain enzymes in mitochondrial such as enzymes in cytochrome P450, cyclooxygenase and NADPH oxidase. Various reactions of enzymes and non-enzymes system further convert these ROS molecules to hydroxyl radical (OH^{\cdot}), peroxyxynitrite ion (ONOO^{\cdot}) and hyperchlorous acid (HOCl). For example superoxide dismutase converts $\text{O}_2^{\cdot-}$ to H_2O_2 by the dismutase reaction^[50,51].

Elevated ROS molecules caused the cellular macromolecules damage such as lipids^[52], proteins^[53] and nucleic acids^[54]. In the anti-oxidants system of the living system, possess own antioxidant defense mechanisms^[55] includes enzymes and non-enzyme molecules such as SOD, catalase (CAT) and glutathione peroxidases (GPx). Enzyme SOD catalyzes $\text{O}_2^{\cdot-}$ conversion to H_2O_2 , while CAT converts H_2O_2 to H_2O and O_2 . For reduction of two peroxide molecules use non-enzymatic glutathione (GSH; reduced and oxidized forms), reduced glutathione (GSH) and GPx catalyze to produce oxidized glutathione (GSSG) and water^[56]. Various enzymes play the important combination roles in the series of antioxidant defense systems such as glutathione reductase, glutathione S-transferase, and glutathione disulfide (GSSG).

ROS production is identified as endogenous and exogenous source. UV exposure and xenobiotic agents has been shown to generate these ROS^[57]. In fact, dietary is the major source of these oxidant compounds, especially in animal fat as the source of high lipid peroxides^[58]. ROS may also be derived from the general biochemical reactions in living organism to generate ROS as by-products or end products. In the transition heavy metals such as iron (Fe^{2+}) and copper (Cu^+) are pose the oxidative stress production, especially in

Figure 2 Increased oxidative stress by xanthine oxidase. NADH: Nicotinamide adenine dinucleotide.

Fe^{2+} may cause autooxidation to cause $\text{O}_2^{\cdot-}$ generation and/or interaction with H_2O_2 can generate OH^{\cdot} via the Fenton and Harber Weiss reactions^[59]. Fenton chemical reaction may also causes lipid peroxides generation and propagation^[60].

Auto oxidation of Fe^{2+} :

Fenton reaction:

Harber-Weiss reaction:

The major cellular oxidative stress is come from mitochondrial respiration. Heart, brain, kidney, liver and skeletal muscle are the effective oxygen consumption organs is converted oxygen to $\text{O}_2^{\cdot-}$, approximate releasing 0.1%-0.2% while the liver is converted oxygen to $\text{O}_2^{\cdot-}$, approximately releasing 2%^[61]. Electron transport chain complex of the mitochondrial has been sourced to $\text{O}_2^{\cdot-}$ generation and have been estimated upto 107 ROS molecules per mitochondria per day^[62].

In the enzymatic systems of xanthine oxidase generated via xanthine dehydrogenase, which utilize oxygen molecule as e- acceptor during catabolism of xanthine. Xanthine oxidase is the generator of $\text{O}_2^{\cdot-}$, H_2O_2 ^[63] and OH^{\cdot} producer^[64], highly expressed in epithelial, injured and diseased tissues as shown in Figure 2. Xanthine oxidase has been involved to peroxyxynitrite (ONOO^{\cdot}) and nitric oxide (NO) productions through nitrite reduction^[65,66]. Intracellular nitric oxide synthases (NOS) catalyze L-arginine to form citrulline and NO. Endothelial NOS and neuronal NOS are activated by calcium-induced calmodulin binding to produce NO levels^[67]. Inducible NOS (iNOS) has also calmodulin bound molecule. It may rapid and chronic expression in many cell types such as smooth muscle cells, hepatocytes and macrophages. iNOS is induced by the many inflammatory cytokines

Figure 3 The chain reaction of lipid peroxidation.

[tumor necrosis factor- α (TNF- α), interleukin-6 and growth factors] regulation at the transcriptional level, results in micromolar NO production^[67]. INOS can produce O₂⁻ and OONO⁻ when lower in L-arginine substrate^[68].

LIPID PEROXIDATION

Fats and oils oxidized with characteristic changes in texture, color, taste and odor. This process, known as rancidity, was chemically defined in the 1940s as an autooxidative free-radical chain reaction^[69]. The most powerful oxidant formed in biological systems is hydroxyl radical. It can attack any biological molecule. The initiation step of lipid peroxidation occurred when hydroxyl radicals attack to polyunsaturated fatty acids, to cause the free-radical polyunsaturated fatty acids oxidation in biological systems. Lipid peroxidation is autocatalytic lipid hydroperoxides radical production mediated poly-unsaturated fatty acids in cell membranes destruction and degradation process^[4,5]. Conjugated dienes and MDA, by-products of lipid peroxidation are increased in the circulation of obesity, metabolic syndrome and T2DM patients.

First-peroxidation chain initiation, results from the attack by any species to reduce a hydrogen atom from methylene (-CH₂-) group of polyunsaturated fatty acid or membrane. Because one hydrogen atom contains one electron, reduction leaves an unpaired electron on the carbon of -CH-, double bond in the fatty acid weakens the C-H bonds on the carbon atom adjacent to the other double bond and facilitates its removal. Then, the polyunsaturated fatty acid chains in lipids membrane are sensitive to cause lipid peroxidation. The carbon-centered radical forms a conjugated diene by the molecular rearrangement (Figure 3), which combines with oxygen to form a peroxy radical that able to reduce a hydrogen atom from another fatty acid to start a chain reaction. Peroxidation continues to use up the polyunsaturated fatty acid substrate unless

the chain-breaking antioxidant (vitamin E) agent is added to terminate the chain reaction. The three stages of lipid peroxidation are initiation, propagation and termination. Hydroxyl radical (•OH), alkoxyl radical (RO•), peroxy radical (ROO•), and HO₂• species can abstract the first hydrogen atom of polyunsaturated fatty acid but not H₂O₂ or O₂⁻^[70]. Variety of lipid hydroperoxides and cyclic peroxides are the end products of the chain reaction. Lipid peroxides are stable molecules in the physiological temperatures. Lipid peroxides decomposition is catalyzed by transition heavy metals. For example, iron ion-active complexes present in circulating can participate in the Fenton reaction to promote lipid peroxide decomposition. Hemoglobin and the cytochromes molecules can also facilitate peroxide decomposition, although they do not directly catalyze Fenton chemistry. However, heme proteins can release chelatable iron that can participate in Fenton chemistry^[71]. Ferritin and hemosiderin are effective at stimulating lipid peroxidation and catalase is weakly effective, caused problems to use catalase as a probe for H₂O₂ in lipid peroxidation systems^[72].

Reduced heavy metal [Fe²⁺, Cu⁺] react with lipid peroxides (LOOH) to alkoxyl radical or Cu⁺ react with LOOH to alkoxyl radical.

In the reaction oxidized-heavy metals [Fe³⁺, Cu²⁺] slowly react with LOOH to produce alkoxyl and peroxy radicals. Both peroxy and alkoxyl radicals initiate the chain reaction by reducing hydrogen atoms (Figure 3). The fixed oxidation metals ions can affect the rate of lipid peroxidation (Ca²⁺, Pb²⁺ and Al³⁺ ions). Lipid peroxidation accelerates by the iron salts stimulation result in the membrane structure changes and important implications for environmental toxicology^[73].

Rawls *et al*^[74] demonstrated that singlet O₂^{*} is formed during the lipid peroxidation degradation and might contribute to cause more initiation in the chain

reaction. Initiation in the first-chain initiation should be used as lipid peroxide decomposition reactions to start the new chain reaction. Iron ions and ferrous ions are free radicals^[55], can act in electron transfer reactions with oxygen molecule. Then, the presence of iron ions can promote the hydroxyl radicals formation by Fenton reaction. Bielski *et al*^[75] demonstrated that the $\cdot\text{OH}$ radical production in any source can initiate lipid peroxidation reaction.

Superoxide-dependent Fenton reaction (superoxide resulting H_2O_2 and reducing Fe^{3+} to Fe^{2+}) did not demonstrate any substantial involvement of the hydroxyl radical in liposomal peroxidation systems as detected by the scavengers action^[76]. Hydroxyl radicals in the systems can be measured by spin trapping^[77] or deoxyribose degradation measurements^[76] but do not contribute to the lipid peroxidation rate^[76]. The addition of iron ion in any preparations can stimulate peroxidation reaction by lipid hydroperoxide degradation to generate peroxy (LO_2^\cdot) and alkoxy (LO^\cdot) radicals.

The rate constant of the reaction when ferrous ions are reacted as 1.5×10^3 /mol/L per second^[78], which is higher than the rate reaction constant of ferrous ions with H_2O_2 reaction (76 /mol/L per second)^[79]. The iron ions stimulate lipid peroxidation by the lipid degradation reactions from the present of abundant hydroperoxide.

Iron or copper in a biological system attach to biological molecules at the specific location of OH radicals formation to cause lipid, protein and DNA damage. On lipid membrane, the propagation step of lipid peroxidation reactions does not proceed further until the reaction reach the protein portion. Thus, lipid peroxidation *in vivo* causes proteins membrane damage^[80,81]. This damage has more biologically important than those lipids membrane damage. Cells also contain mechanisms for recognizing and removing oxidative modified proteins^[80,81].

OXIDATIVE STRESS

Oxidative stress occurs at the molecular level as the cellular event when increased ROS overwhelm the antioxidant defense capabilities systems. Oxidative stress was defines as the increasing ROS production, vary in intensities, the different cellular locations and may be occurred either acutely or chronically^[82]. Oxidative damage to macromolecules including carbohydrates, proteins, lipids and DNA typically viewed as increased ROS induced cellular damage to cause the irreversible macromolecules modifications. Therefore, the by-products of these oxidative modified biomolecules are used as oxidative stress biomarkers *in vivo* and *in vitro*. Many research studies demonstrated the association of oxidative stress and the pathogenesis

of insulin resistance *via* insulin signals inhibition and adipocytokines dysregulation^[8,9]. Oxidative stress biomarkers included MDA^[83], 4-hydroxy-2-nonenal and isoprostanes species^[84], protein carbonyls, 3-nitrotyrosine, hydroperoxides, protein oxidation products^[85], glycation end products, carbohydrate modifications^[86] and 8-hydroxy-2'-deoxyguanosine (8-OH-dG), an oxidized DNA product^[84].

Assaying lipid peroxidation

The lipid peroxidation contributes to the pathogenesis of atherosclerosis. It is occurred in the blood vessel walls and does not occur from low density lipoproteins (LDL) in circulation^[87,88]. LDL can enter to the blood vessel walls. The modified LDL (oxidized LDL) may escape from the scavenger recognition receptors and back to the circulation. Therefore, this circulating LDL peroxidation is a potentially useful biomarker of lipid peroxidation in circulation. Indeed, this assay is used for the demonstration of *in vivo* antioxidants inhibit the effects of lipid peroxidation^[89,90].

Thiobarbituric acid-reactive substance

MDA from the oxidative polyunsaturated fatty acids (PUFA) degradation is determined by the reaction of thiobarbituric acid (TBA) with MDA to generate the stable end product of MDA-TBA adduct^[91-95]. This MDA free radical has been demonstrated as a causative of the atherosclerosis pathogenesis^[96,97], aging^[98], cancer^[99] and Alzheimer's disease^[100,101]. Serum MDA levels have been used as the lipid peroxidation biomarker and indicator of free radical damage^[37,83,102]. MDA, the three-carbon dialdehyde, can exist in many forms in the aqueous circulation. This method was used the reaction of MDA with TBA and heated under acidic conditions but the TBA can react with many chemical species such as proteins, phospholipids, aldehydes, amino acid and nucleic acids^[103,104]. One MDA molecule reacts with TBA two molecules to form a stable pink to red chromophore that absorbs maximally at 532 nm^[105] or fluorescence detection. This chromophore is termed thiobarbituric acid reacting substances. Elevated MDA levels in T2DM patients are associated with cardiovascular disease risk^[83].

Isoprostanes

The most valuable of lipid peroxidation biomarker in the biological system is the isoprostanes, elevated from the PUFA peroxidation^[106-113]. Isoprostanes identified as free form and the most are esterified to lipids in circulation. Isoprostanes can be analyzed by mass spectrometry techniques, so that can easily be detected in human body fluids^[108,109,112,113]. Isoprostanes appear to turn over rapidly in metabolized and excreted^[108,109]. Isoprostanes and their metabolites detection in urine may be the useful biomarker for lipid peroxidation^[113]. Isoprostanes assay have focused on the F₂-isoprostanes measurement, which elevate from the arachidonic acid peroxidation^[109]. Elevation of F₂-isoprostanes levels have

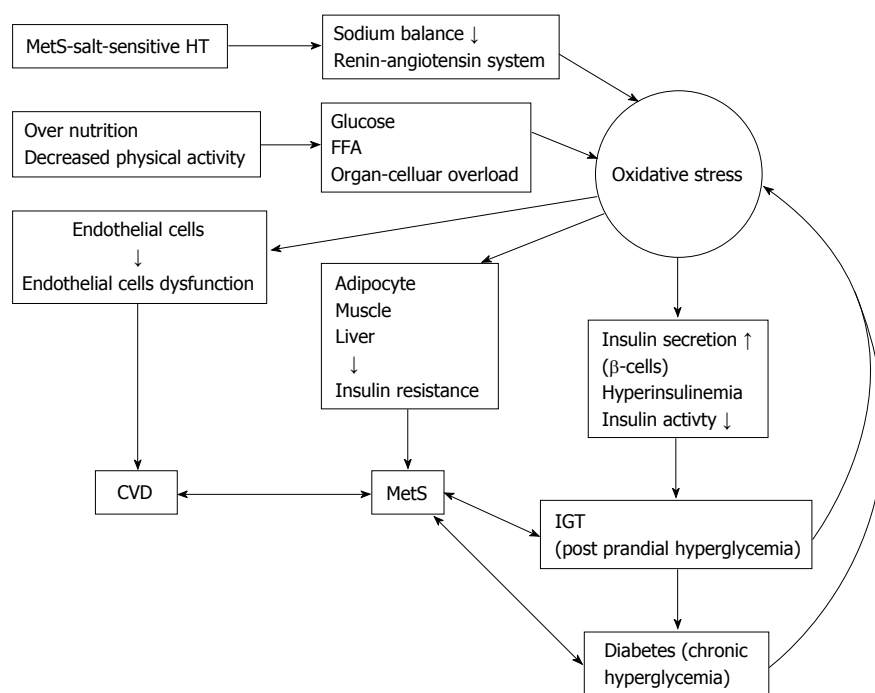

Figure 4 Summarized the increasing reactive oxygen species in obesity, metabolic syndrome and salt sensitive hypertension. FFA: Free fatty acid; MetS: Metabolic syndrome; HT: Hypertension; IGT: Impaired glucose tolerance.

been shown in conditions of the cardiovascular disease, diabetes development^[114,115], cigarette smoking^[111,116,117], hyperhomocysteinaemia^[118] and hypercholesterolaemia^[110,119]. F₂-isoprostane levels have also been shown to decrease by antioxidants supplementation both in animal models and humans subjects^[120-124].

Oxidative stress in metabolic syndrome

The components of metabolic syndrome consist with abdominal obesity, dyslipidemia, hypertension and diabetes^[125,126]. It is the major modern lifestyle complication cause from physical inactivity and overeating and associated with the increased risk of cardiovascular diseases, hypertension and T2DM that summarized in Figure 4.

Over nutrition and oxidative stress: In metabolism of glucose through glycolysis and tricarboxylic acid (TCA) cycle to generate nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FADH₂) as the electron donors. In over nutrition, the excessive glucose occur and a large amount of glucose is oxidized in the glycolysis and TCA cycle to increase NADH and FADH₂ generation in electron transport chain of mitochondrial and increased superoxide generation^[127]. The excessive of free fatty acids (FFAs) leads to increase FFA-oxidation and acetyl coenzyme A (CoA) oxidation in TCA cycle generate the NADH and FADH₂ electron donors as glucose oxidation results in mitochondrial ROS overproduction^[127]. Furthermore, NADPH oxidase in the plasma membrane can convert oxygen molecule to superoxide radical and involve in ROS nutrient-based generation. In adipocytes, ROS is generated by in fused

with FFAs, treatment with NADPH oxidase inhibitor can block this ROS generation. This indicates that NADPH oxidase involves in fatty acids ROS generation^[8]. Palmitate can activate diacylglycerol synthesis and protein kinase C (PKC) leading to activate NADPH oxidase^[128]. Thus, over accumulated fat result in the increased fatty acids oxidation and lead to activate NADPH oxidase (in local or remotely cells) to cause ROS over production in over nutrition or obesity (Figure 4). Conversely, calorie restriction may be associated with normal physiological system^[129] and may involve in normal cellular redox state^[130]. In aged animals models treated with antioxidant agents or hypocaloric diets led to ameliorate in oxidative stress status and tissue function^[131,132]. Treatment with resveratrol, a polyphenol reduced atherosclerosis and diabetes development^[133]. These studies demonstrate that nutrition is associated with increased or decreased redox status and over nutrition result to increase oxidative stress to contribute pathogenesis of atherosclerosis, cancer and other diseases.

Oxidative stress in adipose tissue: Increased fat accumulation in human has been associated with oxidative stress biomarkers^[134]. Similarly, obese mice were significantly higher oxidative stress levels in circulation^[8]. Moreover, lipid peroxidation and H₂O₂ levels were increased in adipose tissue^[8]. These mean that adipose tissue may the major source of ROS production and can be released to the circulation potentially affecting various distance organs functions and damage (Figure 4).

Increased NADPH oxidase expression in adipose

tissue associated with increased oxidative stress levels. Increased mRNA expression was found in adipose tissue of obese mice^[8]. Increased ROS generation in lipid accumulation and further elevating ROS generation with FFA treatment were found in 3T3-L1 adipocytes cultured^[8]. These ROS generation processes can be blocked by NADPH oxidase inhibitors, apocynin or diphenyleneiodonium. Many studies suggest that NADPH oxidase induces adipocytes ROS production^[8]. Moreover, obese mice ameliorated hyperinsulinemia, hypertriglyceridemia, hyperglycemia and hepatic steatosis by supplementation with apocynin^[8]. These data demonstrate that NADPH oxidase increase ROS production in obesity and metabolic syndrome may play the important roles in the atherosclerosis, T2DM and cancer pathogenesis. Adipose tissue tries to increase antioxidant enzymes levels to against ROS over production. However, these antioxidant enzymes activity and expression are decreased in adipose tissue^[8,135-137]. Then, increased ROS-production enzymes and decreased antioxidant enzymes may cause oxidative stress in obese and metabolic syndrome.

Oxidative stress and salt-sensitive hypertension:

As in mention above, ROS levels are increased in obesity and can be ameliorated by weight loss^[7]. Obese rats induced by refined sugar or high fat diet leading to ROS overproduction and increase oxidative stress^[6,138]. Many research evidences suggest that metabolic syndrome was associated with the salt-sensitive hypertension. ROS play the roles as mechanical link of metabolic syndrome and salt-sensitive hypertension^[125,126], which itself leads to ROS overproduction^[139-142]. Salt restriction in hypertensive obesity was more effective reduction in blood pressure than in hypertensive non-obesity patients, and weight loss in obesity and salt sensitive hypertensive patients caused the successful of blood pressure reduction^[143]. Salt-sensitive hypertensive patients were significantly more prevalent in metabolic syndrome patients than without metabolic syndrome^[144]. Oxidative stress in abdominal adipocytes due to increase adipocytokines secretion such as TNF- α , angiotensinogen, non-esterified fatty acids^[126]. Interestingly, infused Ang II -rats disturbed sodium balance to cause ROS overproduction in salt-sensitive rats^[139-141]. Moreover, in salt-sensitive hypertensive patients are also increased 8-isoprostane levels^[142]. Thus, ROS may the underling pathogenesis of diseases in metabolic syndrome, obese and non-obese intake excessive salt as the salt-sensitive hypertensive patients.

In high-renin patients (non-modulating salt sensitive hypertension) had elevated the homeostasis model assessment of insulin resistance (HOMA-IR) levels^[145]. In salt-sensitive hypertensive non-obesity patients had significantly lower insulin sensitivity than in non-salt-sensitive hypertensive patients^[146]. Insulin resistance caused salt-sensitive hypertensive obesity and/or metabolic syndrome patients^[125]. Increased renal ROS overproduction may increase the salt sensitive

hypertension^[147]. Then, increased renal oxidative stress may contribute to cause salt-sensitive hypertension development. Moreover, ROS overproduction in vascular endothelial cells suppresses the NO-dependent vasodilation^[148] and may play the role in the salt-sensitive hypertension development.

Oxidative stress in type 2 diabetes

Many research studies demonstrated that T2DM patients have increased ROS production-induced higher oxidative damage in the circulation and also have reduced antioxidant defenses mechanisms^[149-152]. Increased ROS production in T2DM patients is thought to activate many detrimental pathways including hexosamine pathways, advanced glycation end-products (AGEs) formation, and PKC β 1/2^[127]. Hyperglycemia condition can induce oxidative stress by several mechanisms such as glucose autooxidation, polyol pathway, AGE formation and PKC β 1/2 kinase. Elevated free fatty acids, leptin and other circulating factors in T2DM patients may also contribute to cause ROS overproduction. Figure 5 demonstrates the association of increased ROS production with atherosclerosis and sources of ROS generations in T2DM patients.

Glucose autooxidation

Hyperglycemia due to cause increased glucose metabolism leading to increase NADH and FADH₂ overproduction, which are used by the electron transport chain of mitochondria to generate ATP^[153]. NADH overproduction can cause the higher proton gradient production in mitochondria. These electrons are transferred to oxygen to produce higher superoxide^[154]. The NADH dehydrogenase of the complex I ubiquinone oxidoreductase and complex III cytochrome c reductase are the two main site of superoxide production *via* the electron transport chain^[155].

The polyol pathway

Oxidative stress increased in circulation of T2DM patients from the polyol pathway. ROS was generated by two enzymes: (1) Aldose reductase in the reaction use NADPH to change glucose to sorbitol. Sorbitol production is a minor reaction in normal physiological conditions. However, 30%-35% of glucose in T2DM conditions is metabolized by polyol pathway^[156]. In the condition of sorbitol overproduction, the availability of NADPH is reduced this reflect to reduce glutathione regeneration and NOS synthase activity to cause increased oxidative stress^[153]; and (2) Sorbitol dehydrogenase in the second step oxidizes sorbitol to fructose concomitant with NADH overproduction. Increased NADH may be used by NADH oxidases to increase superoxide production^[157] include in mitochondrial over superoxide production.

PKC β 1/2

Many structures and biochemical components changed in the circulation of T2DM patients were caused from PKC β 1/2 activation *via* diacylglycerol leading to cause dysfunction in endothelial contractility and permeability,

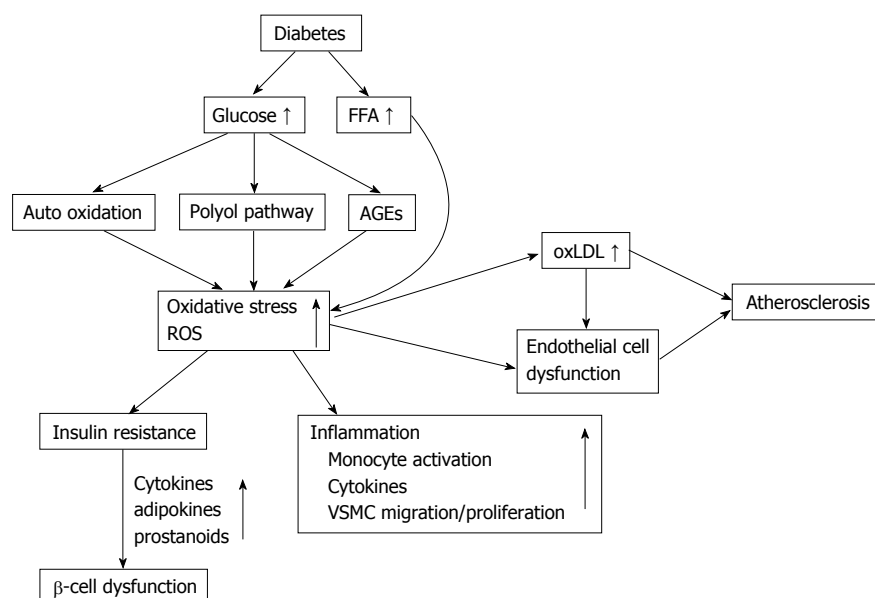

Figure 5 Summarizes the reactive oxygen species associations with atherosclerosis and sources of reactive oxygen species production in type 2 diabetes. oxLDL: Oxidized low density lipoprotein; FFA: Free fatty acids; AGEs: Advanced glycation end-products; VSMC: Vascular smooth muscle cells; ROS: Reactive oxygen species.

hemodynamics (retinal blood flow) changes, extra-cellular matrix protein synthesis, VEGF production and intracellular signaling in the vascular^[128,158,159].

Non-enzymatic glycation

Glycation end-product is the binding of ketone or aldehyde groups of glucose with the free amino groups of proteins leading Schiff bases formation without enzymes, then to form the Amadori product and rearrangements of the structure to the irreversible AGEs in the final^[160,161]. AGEs has been demonstrated in atherosclerotic lesions and their tissue of T2DM patients and increased AGEs levels associated with severity of the diseases^[162]. Moreover, binding of AGEs to specific cell surface receptor for AGE can activate intracellular redox signaling and subsequent to activate the expression of redox-sensitive transcription factors and inflammatory mediator^[163-165].

Inflammation

Oxidative stress is the major factor underlying in the CVD, insulin resistance and T2DM pathogenesis. These may explain by the presence of the inflammation conditions. Now, inflammation recognized as the one manifestation of oxidative stress^[166] and can be generate the inflammatory mediators including adhesion molecules and interleukins to induce oxidative stress^[166]. The concept of atherosclerosis is an inflammatory disease now well established. This chronic inflammation may be involved in the insulin resistance and T2DM pathogenesis^[167]. Recent clinical research indicates that sub-clinical inflammation may impact in the development and progression of diabetic complications^[165,168]. Moreover, excessive FFA and glucose induce inflammation effect through oxidative stress and reduced antioxidants^[169]. Interestingly, the subclinical pro-inflammatory state

observed in many pathogenesis conditions such as atherosclerosis, aging, T2DM and cancer, is caused from mitochondrial ROS overgeneration^[170].

Other sources of oxidative stress in diabetes

Non-esterified FFAs are elevated in T2DM patients^[171]. These excessive FFAs enter the citric acid cycle to generate acetyl-CoA to receive NADH overproduction to cause mitochondrial superoxide over production. In humans, infused FFA has been shown increased lipid peroxidation by elevated isoprostanes marker levels^[172,173]. Adipocytokine, leptin is secreted from the adipocytes to act on the central nervous system to decrease food intake. It reflects all effects on the vascular smooth muscle cells, endothelial cells, macrophages and monocytes^[174]. Leptin levels are increased and associated with cardiovascular disease in T2DM patients^[175-177]. In culture of endothelial cells incubated with leptin to cause ROS production^[178,179].

Antioxidants

Regulation of the cellular redox status is depends on the rate of ROS counterbalance and elimination from the enzymatic and/or non-enzymatic antioxidants. Superoxide is converted by SOD to H₂O₂ and O₂ molecule. There are 3 isoforms of SOD such as cytosolic Cu/Zn SOD (SOD1), mitochondrial Mn-SOD (SOD2) and extracellular SOD (SOD3). Catalase, the heme metalloenzyme is expressed in peroxisomes, mitochondria, cytoplasm and nucleus. H₂O₂ is catalyzed by catalase to oxygen and water^[180]. While glutathione peroxidase the selenoprotein, was found in both intracellular and extracellular. Glutathione peroxidase has a highly sensitive function for lipid peroxides degradation, converses H₂O₂ to water by using the thiol group of glutathione^[181]. Their H₂O₂

detoxification plays the important roles to prevent lipid peroxidation production and regulation of the cellular redox status^[182]. The glutathione system, thioredoxin peroxidase is key enzyme to regulate the cellular levels of thiol/disulfide while the production of antioxidant enzymes is regulated by the redox-cellular transcription factors^[183]. For example, the expressed transcription factor NF-E2 related factor in the cytosolic is interrupted binding with Keap-1 as the responsible to increase oxidative stress and translocate to the nucleus for initiation of the transcription of the various antioxidant enzymes^[184] as the strategy to develop many class of antioxidant, anti-inflammatory, and anticancer agents. Reduction in non-enzymatic antioxidants, thiol glutathione and thioredoxin are the major dysregulation of the cellular redox status^[185]. The cellular redox status is reflected by the reduction of glutathione (GSH), oxidized glutathione (GSSG) ratio (or GSH:GSSG ratio), ascorbic acid, tocopherols and methionine and cysteine amino acids. Exogenous herbal antioxidants compounds in dietary foods include flavanoids, anthocyanins and polyphenolics act as ROS scavenging^[186,187]. The direct interaction of ROS with non-enzymatic antioxidants is based on chemical structure properties. In free radicals participate in 1e- oxidation while non-radical species was 2e- oxidation. For example, $O_2^{\cdot-}$ and OH^{\cdot} radicals react with the ascorbic acid and thiols. While the OH^{\cdot} more activity and instability react with methionine and tocopherols. H_2O_2 and the non-radical may react with thiols and methionine, and the $OONO^{\cdot}$ discriminate to react with thiols, ascorbic acid, tocopherols and methionine^[188].

Oxidative stress induces insulin resistance

Oxidative stress plays the major role in the association with the insulin resistance pathogenesis by insulin signals disruption and adipocytokines dysregulation^[8,9]. In rat models, oxidative stress enhances insulin resistance. The evidence suggested that Ang II infused rats required the increased glucose infusion to maintain euglycemia during hyperinsulinemic clamp to stimulate ROS production^[10]. For this example, Ang II-infused rats were caused insulin resistance from the suppression on insulin-induced glucose uptake in skeletal muscle and increased in oxidative stress biomarkers in this animal experiment. In experimental model, superoxide dismutase and tempol can reduce the insulin resistance. Many evidences indicated that ROS overproduction may induce insulin resistance and confirmed by the supplementation of antioxidant tempol to cause insulin resistance amelioration in Ren-2 transgenic rats^[189]. Insulin-target organs of the obese and diabetic KKAY mice were stimulated and caused ROS over production (skeletal muscle, liver and adipose tissue)^[8] and to cause insulin resistance in these organs. High fat-fed mice found ROS overproduction in liver and adipose tissue of these obese mices to induce insulin resistance^[190]. Many research studies suggested that antioxidant agents decreased plasma insulin, glucose, triglycerides levels and ameliorate insulin resistance in KKAY mice

with no weight loss^[8]. Antioxidant coenzyme Q10 supplementation can ameliorate the increased insulin levels in circulation of SHR/cp rats^[191]. As mention above, in over nutrition, the excessive glucose occur and a large amount of glucose is metabolized in the glycolysis and TCA cycle leading to increased NADH and $FADH_2$ production in electron transport chain of mitochondrial and increased superoxide production^[127]. In aged animals models treated with antioxidant agents or hypocaloric diets led to ameliorate in oxidative stress status and tissue function^[131,132].

Insulin resistance

In general population, insulin resistance precede in many years before onset of T2DM and it is also multifactorial^[11,12] such as genetic component^[11,13]. Insulin resistance and reduction in insulin production are the major characteristics of the T2DM pathogenesis^[11,12,14-16]. Modern lifestyle, physical inactivity, abdominal obesity and excessive of adipokines can cause insulin resistance^[11,15]. In early stage, normal glucose tolerance is preserved by compensation hyperinsulinemia. About 25% of non-diabetic subject cause insulin resistance in the same ranges that found in T2DM patients^[12]. Insulin resistance continuous increases and/or decreases in insulin secretory compensation responses, the deterioration into impaired glucose tolerance occurred. Increased glucose, FFA and insulin levels lead to ROS overproduction, increased oxidative stress and activate stress transduction factor pathways. This can cause insulin activity inhibition and secretion to accelerate the onset of T2DM as shown in Figure 6.

Oxidative stress has been demonstrated the implication and association in the late complications of diabetes mellitus^[17,18] as in the schematic of Figure 5. Many studies have demonstrated ROS overproduction and increased oxidative stress to insulin resistance^[192-194]. Both *in vitro* studies and in animal models demonstrated that α -lipoic acid (LA), antioxidant agent increase insulin sensitivity^[194-196]. In clinical trials, supplementation with vitamin C, vitamin E, glutathione increases insulin sensitivity in both insulin-resistance and T2DM patients^[197,198]. LA act as insulin sensitizer agent, it increased insulin sensitivity about approximately 25% and approximately 20% higher than metformin and rosiglitazone, respectively^[199,200]. Oral supplementation with LA formulation for 6 wk decreased circulating fructosamine levels^[201] and increase insulin sensitivity^[202] in T2DM patients and the other studies have confirmed 2.5 mmol/L of LA to cause GLUT4 activation and translocation^[203-205].

Because insulin resistance occurred before chronic hyperglycemia development^[12], that difference from insulin resistance in the pre-diabetic state result from oxidative stress activation by increased glucose levels. However, obesity demonstrated the strong association with insulin resistance. In this regard, the mediator of oxidative stress-induced insulin resistance of the pre-diabetic state might be from the adipocyte-derived

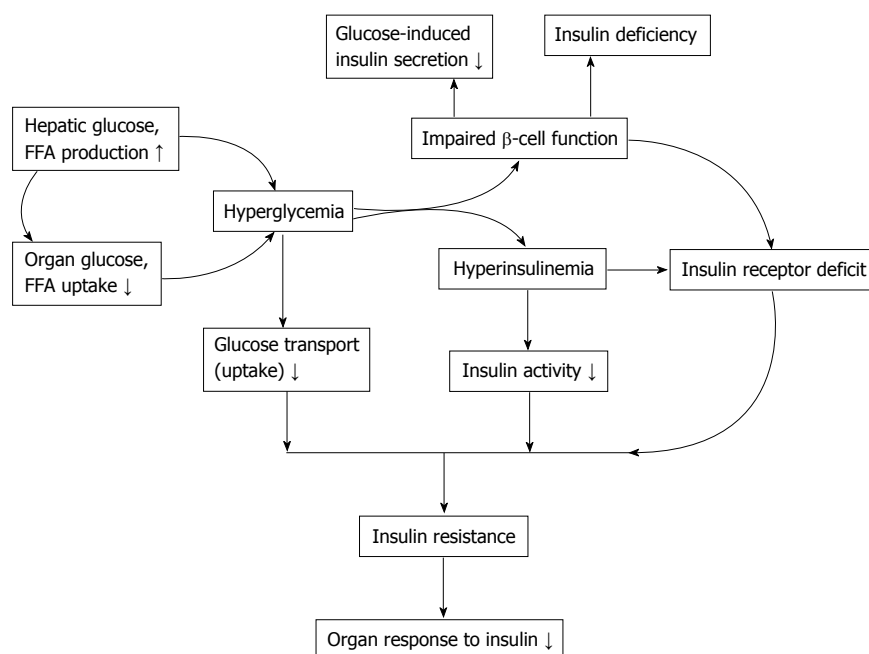

Figure 6 Insulin resistance development and consequence of β -cell dysfunction. FFA: Free fatty acid.

factor such as $\text{TNF-}\alpha$ ^[206], leptin^[207], FFAs^[208-210] and resistin^[211]. However, the FFAs elevations are associated with insulin resistance and obesity^[208,209,212]. Many studies found that increased FFA levels decrease insulin sensitivity, as in the Randle hypothesis^[210] and insulin-signaling inhibition^[212]. The increased fasting FFA levels are significantly correlated with decreased reduced/oxidized glutathione ratio in T2DM patients^[190]. Elevated FFA concentrations cause mitochondrial dysfunction such as uncouplers of oxidative phosphorylation in mitochondria^[213] and increased superoxide production^[214]. These caused the exacerbated situation from FFAs induce oxidative stress and reduce intracellular glutathione caused impaired endogenous antioxidant defenses^[190,215,216]. Supplementation with glutathione improves insulin sensitivity and β -cell function by the restoration of redox status in T2DM patients and healthy subjects^[217].

FFA mediated the nuclear factor- κB (NF- κB) activation, as the consequence of FFAs increased ROS overproduction and glutathione reduction^[216,218-220] and also linked to FFA-activated PKC- θ ^[221] to caused NF- κB activation^[222]. Vitamin E supplementation inhibits the FFA-induced NF- κB activation^[216] indicated that FFAs act as pro-inflammatory agent effects the alteration of the cellular redox status.

The HOMA-IR was proposed by Matthews *et al*^[223] that can be used to estimate insulin resistance and insulin sensitivity in individuals. HOMA-IR is easy to calculate and no more laborious technique. HOMA-IR method derives from the mathematic calculation from fasting plasma insulin and glucose concentrations.

Oxidative stress and β -cells dysfunction

Increased circulating glucose levels stimulate the β -Cells

function by sensing and secreting of insulin in appropriate amount^[224] and as the target of oxidative stress. The processes are complex and depend on many factors^[16]. The critical glucose metabolism in mitochondrial is the importance linking stimulus the insulin secretion^[224-226]. Therefore, mitochondria damage and markedly blunt insulin secretion is also occur by the ability of oxidative stress (H_2O_2)^[226]. Many studies in T2DM patients have suggested that chronic exposure to high glucose and/or high FFA levels impaired β -cells function and β -cells dysfunction^[16,227]. Because β -Cells are lower in antioxidant enzymes levels (superoxide dismutase, catalase and glutathione peroxidase) and higher sensitive to oxidative stress^[228]. Oxidative stress exposure to β -cells activated the increased p21 cyclin-dependent kinase inhibitor production, decreased insulin mRNA, ATP and calcium flux reductions in mitochondria and cytosol to cause apoptosis^[226]. Glucose or methyl succinate can stimulate insulin secretion and inhibit by response to K^+ within 30 min^[226]. The results indicate that mitochondria in β -cells involved in the processes of glucose induced insulin secretion are affected by increased oxidative stress. Lipid peroxidation, oxidative stress products exposed to islets, inhibited insulin secretion and also caused glucose oxidation^[229]. Conversely, antioxidants can protect β -cell against the toxicity of oxidative stress, AGEs production and inhibit NF- κB activation^[230-234]. These antioxidants are N-acetyl cysteine (NAC), α -phenyl-tert butylnitrone, aminoguanidine and zinc. Recent research study evaluated β -cells function after over expression of glutamine. Hexosamine over production resulted from the deterioration of insulin signaling of glucose-stimulated insulin secretion. Fructose-6-phosphate amidotransferase is the rate-limiting enzyme increase in hexosamine pathway^[235], coincident with increased

H₂O₂ production^[235] that can ameliorate by NAC supplementation.

β-cells glucose-induced toxicity

West^[19] demonstrated that insulin secretion in T2DM patients improved by the reduction of hyperglycemia with diet, insulin or sulfonylureas. On the other hand, in healthy normal, high glucose infused as a clamp reduces insulin secretion^[236]. In the study of long term culture of HIT-T15 and/or βTC-6 cells demonstrated that increased glucose levels cause decreased insulin secretion, insulin mRNA and decreased binding of transcription factors^[237,238]. Thus, glucose toxicity, the concept of the condition of hyperglycaemia itself can decrease insulin secretion which implies the irreversible damage to cellular components of β-cells^[239]. Generally in β-cells, excessive glucose oxidation and metabolism will always cause to ROS over production. Superoxide dismutase and catalase are normally as the detoxified antioxidant enzymes. β-Cells are low amount of these antioxidant enzymes and also low in glutathione peroxidase, a redox-regulating enzyme^[240]. Then, hyperglycaemia condition leads to increase ROS production and accumulation in β-cells and subsequent of cellular components damage. Pancreas duodenum homeobox-1 is an insulin promoter activity regulator was loss leading to β-cell dysfunction^[240]. Supplementation with NAC and/or aminoguanidine can ameliorate the glucotoxic effects on insulin gene activity^[230], reduced insulin levels and increased insulin mRNA and insulin sensitivity^[230].

β-cells lipid-induced toxicity

Lipotoxicity to β-cells concept, elevation of non-esterified fatty acids concentrations in diabetic and non-diabetic obese patients, result of the enhanced adipocyte lipolysis. In the presence of the excessive fatty acid oxidation in β-cells is caused increased long-chain acyl CoA accumulation leading to inhibit β-cells function^[241]. This process is as an integral part of the normal insulin secretory function. This long-chain acyl CoA can inhibit the insulin secretory function by opening β-cell K⁺-sensitive ATP channels. In the second mechanism, in long-term culture of β-cells formulas with FFAs can effect the potential reduction on mitochondrial membrane and uncoupler proteins-2 over expression to cause the K⁺-sensitive ATP channels opening which lead to decreased ATP production and insulin secretion^[242,243]. Third mechanism, β-cells apoptosis might possess from triglyceride or fatty acid induced ceramide synthesis and/or nitric oxide production. Thus, impaired insulin secretion and β-cell dysfunction strongly associated with the FFA-stimulated ROS overproduction^[244].

β-cells combined glucose/lipid toxicity

Elevation of glucose and FFA levels are the major characteristic of T2DM patients. This combination is the major β-cells toxicity and require the maximize protection. In culture cells of islets or HIT cells were

exposed to high concentrations of glucose and FFA levels. There was decrease in insulin-gene activity and insulin mRNA^[245]. In the study of islets co-culture with high glucose and palmitate levels caused impaired insulin signaling of the glucose-stimulated insulin secretion^[244]. Recent studies have confirmed that β-cells lipotoxicity is the concurrent status as the amplifying effect mediated by glucose toxicity in hyperglycemia condition^[246,247].

Dyslipidemia

Insulin resistance and T2DM are characterized by dyslipidemia one major risk factor for cardiovascular disease. Lipid triad is the complex metabolic milieu associated with dyslipidaemia^[248] comprise with hypertriglyceridemia, low levels of high-density lipoprotein cholesterol (HDL-C) and the appearance of small, dense, LDL (sdLDL) - and caused excessive post prandial lipemia^[249,250]. Diabetic dyslipidemia caused from the disturbance of lipid metabolism, an early event cardiovascular complications development and was preceded in T2DM patients by several years^[249-253]. Indeed, insulin resistance status in both with and without T2DM patients was display qualitatively similar lipid abnormalities^[250]. The different components of diabetic dyslipidemia are closely linked to each other metabolically^[249-253] and are initiated by the elevation of triglyceriderich very LDL (VLDL) from hepatic over production^[249,251]. It is the key importance mechanisms to elucidate the over production of VLDL involved in diabetic dyslipidemia^[249].

In insulin resistance state, decrease insulin function and lack of insulin inhibits lipolysis leads to increase FFAs generation of and lower lipoprotein lipase activity. This occurs after meal consumption, generates a chylomicron remnant rich in TG^[254], caused elevated hepatic FFAs and VLDL TG-rich particles secretion. These processes affects HDL-C metabolism through the interchange with TG-rich lipoproteins *via* cholesteryl ester transfer protein to produce HDL particles containing high TG concentrations. These HDL-TG particles were hydrolyzed with hepatic lipase to TG and HDL. This HDL becomes smaller and less antiatherogenic activity, easily to remove from the circulation by the kidneys. Moreover, insulin resistance in T2DM patients associated with endothelial dysfunction led to increase risk of CVD^[255]. The most atherogenic subfractions of sdLDL are elevated in circulation of obesity individuals, as a key feature in association with elevated triglyceride and low HDL cholesterol. Elevated sdLDL concentrations are also founded in abdominal obesity subjects and demonstrated greater myocardial risk. The mechanisms are related to excess accumulation of abdominal adipose tissues, elevated total cholesterol and LDL-C and related to high saturated-fat consumption, weight gain and obesity.

Dyslipidemia is commonly occurred in T2DM patients and might play the major role in accelerated

macrovascular atherosclerotic disease and increased CVD risk in T2DM patients^[256]. Dyslipidemia in T2DM patients as lipids triad is characterized by increased insulin levels, hypertriglyceridemia, low HDL-C levels and increased sdLDL-particles (independent of LDL-cholesterol) and increased TG-rich remnant lipoprotein (TGRs) concentrations^[257,258]. In this manner, low HDL-C levels associated with hyperinsulinemia or insulin resistance and insulin signaling for insulin-mediated glucose disposal^[259] characterized by higher fasting plasma glucose and insulin levels. Then, these major changes associated with the insulin resistance syndrome are increased TGRs and decreased HDL-C levels. Thus, in dyslipidemia, using the lipoprotein concentration ratios are associated with insulin resistance and increased CVD risk conditions. Lipoprotein ratios might be useful to identify insulin resistance individuals even different in fasting glucose or insulin levels. Obesity, metabolic syndrome, and T2DM may also show the same dyslipidemia characteristic^[12,257,259] and measuring TG, HDL-C, TC/HDL-C and TG/HDL-C ratio in circulation may also use as insulin resistance estimation. For example, these TG, HDL-C, TC/HDL-C and TG/HDL-C ratio are independently associated with insulin levels, insulin resistance and CVD risk^[258,260,261].

Lipoprotein ratios: In description above, the major change is increased TGRs and decreased HDL-C levels are associated with insulin resistance syndrome. Insulin plays the important role in TG metabolism, in normal condition TGRs particles reduces synthesis by the distinct pathways when compared with VLDL particles synthesis^[249,258]. Insulin fails to suppress VLDL particles synthesis^[262]. Insulin resistance is significantly associated with increased lipid synthesis in the liver, increased FFAs flow to the liver and decreased VLDL particles clearance resulting in increased VLDL levels in the circulation^[251]. Thus, dyslipidemia (as lipoprotein ratios) may associate with insulin resistance and increased CVD risk. On this basis, waist circumference, LDL-C, TG levels, insulin resistance and the CVD risk are estimated^[263]. The major features of dyslipidemia are determined by hypertriglyceridemia, low HDL-C levels and slightly high or normal LDL-C levels with altered composition. Hypertriglyceridemia is indicate as elevated atherogenic chylomicron and VLDL remnant and associated with increased CVD risk^[264,265]. These phenomenons demonstrated the problems of VLDL and HDL levels but not the LDL levels and concurrent with increased insulin levels. Low HDL-C level is associated with the hyperinsulinemia and/or insulin resistance and insulin signaling for insulin-mediated glucose disposal^[259]. All of these features are associated with coronary heart disease risk in obesity, metabolic syndrome and T2DM patients. The TC/HDL-C, TG/HDL-C ratios and non-HDL-C (as TC - HDL-C) were used as surrogate markers for insulin levels and insulin resistance estimation. In Tangvarasittichai *et al*^[258] study suggests that TC/HDL-C, TG/HDL-C ratios and non-

HDL-C can be used as markers of insulin levels, insulin resistance and CVD risk factor^[258,263]. The highest % sensitivity and % specificity cut-off points corresponding to the TC/HDL-C, TG/HDL-C ratios and non-HDL-C are 3.58, 2.48 and 130.4, respectively^[258]. Because of TC/HDL-C, TG/HDL-C ratios and non-HDL-C are easily calculated and ordered with every lipid profiles available to the clinician and no costs addition. The cut-off value of these ratios in Tangvarasittichai *et al*^[258] study was lower than the results from Western populations^[266-268]. Then, insulin resistance was significantly predicted by these markers. For atherosclerotic risk assessment in obesity, metabolic syndrome and T2DM patients requires more attention to lipid screening.

Development of T2DM from insulin resistance

Insulin resistance often occurs with T2DM but is insufficient for the T2DM development. β -cells dysfunction are important event for the T2DM development and progression. In early stage of insulin resistance, β -cells increase the secretory function try to compensate and control hyperglycemia. In Pima Indian population study caused acute insulin response dysfunction or decreased β -cell responses was found during the normal glucose tolerance state in individuals who eventually progressed from normal glucose tolerance to impaired glucose tolerance or T2DM when compared with individuals who persisted in the state of normal glucose tolerance^[269]. There was evidence of early defects in glucose disposal by decreased insulin sensitivity before the development of glucose intolerance state, although output of circulating glucose did not increase until the progression from impaired glucose tolerance to T2DM revealed. Interestingly, individuals who demonstrated transient glucose intolerance but were able to recover and to reach normal glucose tolerance and did not show the early secretory defect observed in progressed individuals^[269]. β -cells failure or dysfunction occurred as the results of the combination of increased oxidative stress, glucose and lipids accumulation to cause glucotoxicity and lipotoxicity to β -cells to progress increased apoptosis and loss of the insulin granule secretory components expression^[270].

T2DM

The World Health Organization updated the prevalence of T2DM estimated by the year 2025 those 30.3 million people in the United States and total of 380 million people worldwide will be diagnosed as DM^[271]. By the year 2050, those 45.6 million Americans will be diagnosed as DM^[272]. T2DM is associated with obesity, sedentary lifestyle and lack of exercise in the aging population. There are a number of gene abnormalities related to T2DM, that showed significant differences exist in the abnormalities gene associated with T2DM among the various ethnic populations, such as African Americans, Asians and Europeans^[273,274]. The contribution of any one of these genes to T2DM is small and total

Table 1 Type 2 diabetes mellitus and glucose levels for diagnostic criteria¹

Glucose management test	Range	Diagnosis
Fasting plasma glucose (mg/dL) (at least 8 h fast)	≥ 126	Diabetes mellitus
	100-125	Impaired fasting glucose
	≤ 99	Normal
2-h oral glucose tolerance test of 75 g glucose load (mg/dL) WITH	≥ 200	Diabetes
Random screening with common symptoms of diabetes (polyuria, polydipsia, weight loss, etc.)	140-199	Impaired glucose tolerance
	≤ 139	Normal
Hemoglobin A1c (%)	≥ 6.5	Diabetes
	5.7-6.4	Prediabetes/high risk
	≤ 5.7	Normal

¹All tests in diabetes range must be repeated after 24 h, to be confirmed diagnosis.

aggregate of all described genes accounts for < 15% of the predisposition^[273,275]. It is typically diagnosed in patients older than 30 years with overweight or obesity and positive in family history of T2DM. However, insulin resistance may occur and develop in many years before diagnosed as T2DM^[276]. Figure 7 summarized the etiology of the T2DM pathogenesis.

Patients are diagnosed as T2DM when plasma glucose levels reach at the diagnostic criteria (Table 1). These T2DM patients are at high risk for microvascular complications (e.g., nephropathy, retinopathy and neuropathy) and macrovascular complications (e.g., peripheral vascular disease, cerebrovascular disease and cardiovascular disease). T2DM patients with good controlled plasma glucose levels demonstrated to delay the progression of microvascular and macrovascular complications^[271,277].

MANAGEMENT OF DYSLIPIDEMIA AND HYPERGLYCEMIA IN T2DM PATIENTS

Fasting serum lipids profile should be determined annually in T2DM patients as in the recommendation by the American Diabetes Association (ADA)^[278]. ADA recommended for the satisfied lipids profile level as low-risk by LDL-C < 100 mg/dL (2.6 mmol/L), triglycerides < 150 mg/dL (1.7 mmol/L) and HDL-C > 50 mg/dL (1.3 mmol/L)^[276].

Treatment

Lifestyle interventions: The American Diabetes Association and the American Heart Association recommend that increased physical activity and lifestyle modifications should be advised for all T2DM patients^[278,279]. Combination with such interventions included nutrition therapy or supplementation, weight loss and non-smoking. These have been help T2DM patients to receive better controlled their lipid concentrations. Nutrition interventions and supplementations should be designed according to the condition of T2DM individuals such as diabetes status,

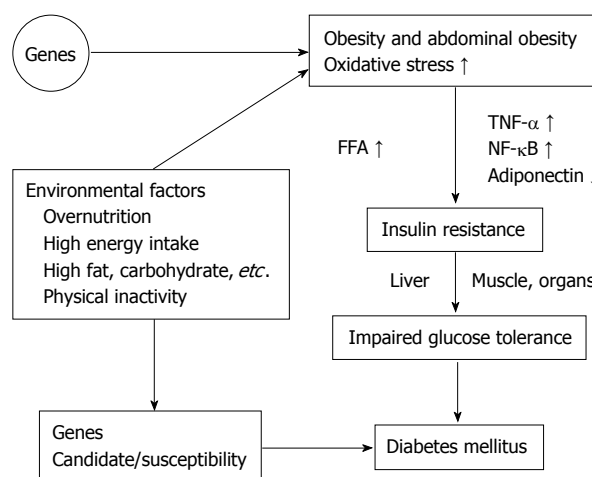

Figure 7 Summarized the etiology of the type 2 diabetes mellitus pathogenesis. FFA: Free fatty acid; NF-κB: Nuclear factor-κB; TNF-α: Tumor necrosis factor α.

age, other comorbidities and avoidance to intake transfat, saturated fat, cholesterol and should increase intake of fiber (fiber in oats, legumes, citrus), omega-3 fatty acids and plant stanols/sterols^[278]. Glycemic control can also modify circulating triglycerides levels, especially in T2DM patients with hypertriglyceridemia and poor glycemic control^[278].

Pharmacological interventions of dyslipidemia

There are many pharmacological classes available for dyslipidemia treatment.

Statins: Statins inhibit enzyme 3-hydroxy-3-methylglutaryl CoA reductase suppress cholesterol synthesis and increase number and activity of LDL-receptor. Statins are effective drug for lowering LDL-cholesterol, raising HDL-C and reducing TG levels. There are seven pharmaceutical forms of statins including lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, rosuvastatin and pitavastatin available in the market. Statins also have the other pharmacodynamic actions such as vascular inflammation reduction, immune suppression, improved endothelial function, platelet aggregability, enhanced fibrinolysis, antithrombotic action, increase neovascularization in ischemic tissue and stabilization of atherosclerotic plaques^[280].

Fibrates

Fibrates control the lipid metabolism by mediated through peroxisome proliferator-activated receptors-α activation, stimulation of β-oxidation of fatty acids in peroxisomes and mitochondria to cause lowering fatty acid and triglycerides levels in circulation. The first drug of this class is Clofibrate. Eventually, the revolution in lipid-lowering drugs research discover of many other fibrate drugs such as fenofibrate, bezafibrate, gemfibrozil and ciprofibrate. These drugs demonstrated the adverse effect to cause hepatomegaly and tumor formation in the liver of rodents. Then, they had restricted for the widely

use in humans. Gemfibrozil and fenofibrate are Food and Drug Administration (FDA)-approved for lipid lowering drugs due to milder effect on peroxisome proliferation.

Nicotinic acid

Long term study of the coronary drug project demonstrated that niacin is the effective drug to increase HDL-C levels and reduced CVD events^[281] in a non-diabetic subjects. Niacin cause adverse effects on the glycemic control levels in T2DM patients. In high doses treatment with niacin may increase blood glucose levels. The modest doses of 750-2000 mg/d of niacin are significantly increased HDL-C levels and decreased LDL-C, triglyceride levels and accompanied with modest changes in glucose levels for diabetes therapy^[282,283]. However, there is no evidence for the CVD outcomes reduction with niacin supplementation in T2DM patients.

Antihyperglycemic drugs: The standard care for T2DM patients is mainly in controlled blood glucose levels by using glycemic lowering drugs and concomitant with controlled diet and increased physical activity. With proper controlled and managed these contributors such as circulating glucose levels, hemoglobin A1c, lifestyle modifications, these can be effectively controlled and reduced the progression and complications disease. In general, only approximately 50% to 60% of T2DM patients have achieved their glycemic goals^[284]. There are many reasons for poor control of T2DM including medication efficacy, adverse effects, access to medications and health care education, poor adherence, lack of lifestyle changes and no physical activity. Now a day, more pharmacologicals for T2DM treatment have been approved for use. There are 12 classes of antihyperglycemic drugs FDA-approved in the United States^[285] such as sulfonylureas, meglitinides, thiazolidinediones, dipeptidyl peptidase-4 (DPP-4) inhibitors, biguanides, sodium glucose transporter 2 inhibitors, α -glucosidase inhibitors, amylin analogues and glucagon-like peptide-1 (GLP-1) receptor agonists. These are insulin analogues. Metformin is one of the most commonly prescribed medications for T2DM management. Metformin treatment ameliorate the insulin resistance especially in liver and skeletal muscle but less effect in adipose tissue^[286,287], decreased inflammatory response, improved glycemic control^[288,289] and enhance β -cell function in T2DM patients by increased insulin sensitivity and glucotoxicity reduction^[290]. Metformin reduces fatty acid oxidation in adipose tissue^[291], increased GLUT4 translocation in muscle and adipose tissues by activated enzyme adenosine monophosphate kinase and reduced gluconeogenesis in liver^[292-295]. There are many developed non-conventional drugs to improve glycemic control such as Cycloset is used together with diet and exercise to treat type 2 diabetes. Cycloset is not for treating type 1 diabetes. Welchol is a non-absorbed, polymeric form, lipid-lowering and glucose-lowering agent for oral administration. Welchol is a high-capacity bile acid-binding molecule. Afrezza Inhalation Powder is

the FDA approved the inhalation form of insulin. The new drug is not a substitute for long-acting insulin and use as the combination with conventional long-acting insulin drug for both types of diabetes and many drugs are in the late clinical trials state.

There are new medications and treatments were identified from the FDA, they are in the clinical trials or waiting for approval treatment in dyslipidemia, obesity and T2DM^[296]. Recent research study reports that metformin treatment cause metabolic effects to increase GLP-1 concentration in the circulation^[297,298]. GLP-1 is an incretin generated from the transcription product of the proglucagon gene. Incretin is a signaling polypeptide contained with 30-amino acid. GLP-1 secretion by ileal L-cells is not depend on the presence of nutrients in the small intestine and responsible for stimulated insulin secretion to limit glucose elevations with the higher efficacy at high glucose levels^[276,299]. Elevated GLP-1 secretion might possibly cause increased glucose absorption in the distal segments of small intestine.

Incretins are the gastrointestinal hormone secreted from the intestine and stomach responsible for oral food intake and stimulated the secretion of insulin during meals in healthy peoples^[276]. Two major incretin molecules are (1) GLP-1; and (2) Glucose-dependent insulinotropic peptide known as gastric inhibitory polypeptide (GIP) and to neutralize stomach acid to protect the small intestine and no therapeutic efficacy in T2DM. GLP-1 has lower glucose levels by stimulated insulin production and increased glucose metabolism in adipose tissue and muscle. GLP-1 promote the pancreatic β -cells proliferation, reduce apoptosis, increase cardiac chronotropic, inotropic activity, decreases glucagon secretion, reduces glucose production, increase appetite suppression for food intake reduction and slow gastric emptying^[271,276,299]. GLP-1 is degraded by enzyme DPP-4 and this enzyme does not inhibit by metformin^[298]. The prevention of GLP-1 degradation by DPP-4 is one method to increase the effects of GLP-1. DPP-4 inhibitor drugs inhibit the glucagon secretion which in turn increases secretion of insulin to decrease blood glucose levels and decreases gastric emptying. The FDA-approved the DPP-4 inhibitor drugs including sitagliptin (Januvia), alogliptin (Nesina), saxagliptin (Onglyza), linagliptin (Tajenta), anagliptin, vildagliptin, teneligliptin, gemigliptin and dutogliptin. The adverse effects are dose-dependent to cause headache, vomiting, nausea, nasopharyngitis, hypersensitivity and other conditions. Other side effects of exenatide (GLP-1 agonist) note for abdominal pain, acid stomach, diarrhea, altered renal function, weight loss, dysgeusia, belching and cause pruritus, urticaria and rash reactions at the injection site.

CONCLUSION

In this present review has described the detrimental effects from chemicals and biochemicals reaction, metals, medications, over nutrition, obesity and diseases in oxidative stress, insulin resistance development and

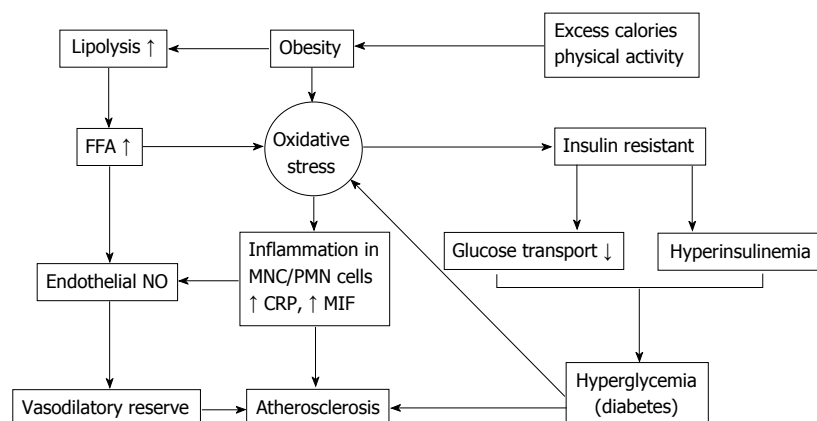

Figure 8 Connection between life style, oxidative stress, insulin resistance, inflammation and atherosclerosis. FFA: Free fatty acid; NO: Nitric oxide; MNC: Mononuclear cells; PMN: Polymorpho nuclear cells; CRP: C-reactive protein; MIF: Migration inhibitory factor.

the progression of T2DM and the progression of diabetic complications and organ dysfunctions. Oxidative stress played underlying associated with the pathogenesis of diseases, leading to increases risk of insulin resistance, dyslipidemia, elevated blood pressure, metabolic syndrome, inflammation and endothelial dysfunction. This reviewed support the oxidative stress contribution of the multifactorial etiology of oxidative stress and insulin resistance in the whole body. ROS act as the signal transduction factor and plays the important role in oxidative stress-mediated downstream signaling pathways and enhances the cell death. Furthermore, risk for several chronic diseases development associated with oxidative stress and metabolic syndrome including T2DM, hypertension, arthritis, congestive heart failure, chronic renal failure, cancer and Alzheimer's. These diseases may be substantially reduced by dietary modifications, increased physical activity and antioxidant drugs ameliorated oxidative stress. The therapeutic approaches target on oxidative stress may delay or prevent the progression and onset of diseases. Then, antioxidants supplementation may curtail the progression and onset of the metabolic disease complications. Antioxidant interventions, an importance goal of future clinical investigations should be implementation and to improve oral bioavailability targeted to the oxidant overproduction site. Lifestyle change remains the best prevention and therapeutic approach to oppose the increasing epidemic of cardiovascular diseases, obesity, hypertension, dyslipidemia and T2DM. Finally, the connection between oxidative stress, insulin resistance, dyslipidemia, inflammation, life style, atherosclerosis and diabetes as demonstrated in the schematic in Figure 8.

Abstract

Currently, 60 million women of reproductive age (18-44 years old) worldwide, and approximately 3 million American women have diabetes mellitus, and it has been estimated that this number will double by 2030. Pregestational diabetes mellitus (PGD) is a significant public health problem that increases the risk for structural birth defects affecting both maternal and neonatal pregnancy outcome. The most common types of human structural birth defects associated with PGD are congenital heart defects and central nervous system defects. However, diabetes can induce birth defects in any other fetal organ. In general, the rate of birth defects increases linearly with the degree of maternal hyperglycemia, which is the major factor that mediates teratogenicity of PGD. Stringent prenatal care and glycemic control are effective means to reduce birth defects in PGD pregnancies, but cannot reduce the incidence of birth defects to the rate of that is seen in the nondiabetic population. Studies in animal models have revealed that PGD induces oxidative stress, which activates cellular stress signalling leading to dysregulation of gene expression and excess apoptosis in the target organs, including the neural tube and embryonic heart. Activation of the apoptosis signal-regulating kinase 1 (ASK1)-forkhead transcription factor 3a (FoxO3a)-caspase 8 pathway causes apoptosis in the developing neural tube leading to neural tube defects (NTDs). ASK1 activates the c-Jun-N-Terminal kinase 1/2 (JNK1/2), which leads to activation of the unfolded protein response and endoplasmic reticulum (ER) stress. Deletion of the *ASK1* gene, the *JNK1* gene, or the *JNK2* gene, or inhibition of ER stress by 4-Phenylbutyric acid abrogates diabetes-induced apoptosis and reduces the formation of NTDs. Antioxidants, such as thioredoxin, which inhibits the ASK1-FoxO3a-caspase 8 pathway or ER stress inhibitors, may prevent PGD-induced birth defects.

Core tip: Pregestational diabetes is a rising problem with gravid impact on adverse pregnancy outcomes. This review concentrates on diabetes-induced birth defects and the underlying mechanism of diabetic embryopathy derived from animal studies. The main defects associated with pregestational diabetes are in the cardiovascular and central nervous systems, and are linearly related to maternal glycemic control. Animal studies reveal oxidative stress and stress kinase signalling-induced apoptosis as key factors in pathogenesis. However, many questions remain unanswered, and the rate of congenital defects in human diabetic pregnancies is still high. The cause of diabetic embryopathy warrants further investigations.

INTRODUCTION

Major structural or genetic birth defects affect approximately 3% of births^[1], and are the leading cause of infant mortality in the United States^[2]. The pathogenesis of most birth defects is unknown^[3,4]. Pregestational diabetes (PGD) is one of the leading known causes with up to a nine-fold increase in birth defects, compared with the rate seen in nondiabetic pregnancies^[5]. Although the risk for birth defects in PGD pregnancies can be significantly reduced by appropriate pregestational counselling and meticulous control of maternal glycemic levels^[6], it cannot be equalized to the background risk partially because at least 40% of diabetic pregnancies are usually unplanned^[6,7].

The pathophysiology of maternal diabetes induced birth defects is complex, however, clearly relates to maternal glucose levels. The mechanism is not entirely understood, but animal studies have shown it to be associated with decreased cell proliferation and increased cell apoptosis due to high oxidative stress. The second major change seen in animal models of PGD is altered gene expression causing deviation from the normal developmental process.

PGD can affect almost any organ. However, most congenital defects associated with diabetes occur in the cardiovascular, central nervous and musculoskeletal systems^[8-10].

In this review we will discuss how PGD increases the risk of birth defects, the range of defects seen in diabetic

pregnancies and the relationship of these defects to maternal glucose control. As the risk of birth defects is well established in type 1 and type 2 diabetes mellitus, while it is still controversial in gestational diabetes^[11], we will focus this review on PGD only.

RANGE OF DEFECTS

PGD is associated with a wide range of anomalies in almost any fetal organ. Based on available literature, women with PGD have 2- to 9-fold higher risk for having babies with birth defects, with a prevalence of birth defects of 2.7%-18.6%, compared with the healthy population^[5,12-17], having a prevalence of birth defects of 2%-3%.

Although any birth defect can be associated with PGD, more anomalies are seen in the cardiovascular, central nervous and skeletal systems^[9,10,18]. Rare abnormalities almost exclusively associated with diabetes include caudal regression syndrome with femoral shortening and sacral agenesis. Caudal regression syndrome consists of a spectrum of congenital anomalies of the lower spine and hips, is associated with genitourinary and lower limb defects, and is one of the few syndromes in which the presence of maternal diabetes has always to be considered as the cause, if not confirmed^[19]. Although very rare, some studies found this syndrome to be 200-600 times more prevalent in infants of diabetic mothers compared with nondiabetic mothers^[16]. Be that as it may, it can still be seen also in non-diabetic mothers as described in a case report by Versiani *et al*^[20] who reported 2 cases of caudal dysplasia sequence - one woman had PGD while the other had gestational diabetes.

Previous studies assessed the prevalence of congenital anomalies in the diabetic population. Eidem *et al*^[21] Studied the risk of congenital anomalies related to type 1 diabetes. They compared major congenital anomalies (excluding minor anomalies as defined by the EUROCAT system) between women with pregestational type 1 diabetes and controls. All women registered at the Norway national delivery registry from 1999 to 2004 were included. Anomalies were registered in 5.7% (91/1583) offspring of women with type 1 diabetes, compared with 2.9% in the background population. The risk for cardiovascular anomalies was 3 fold higher in the diabetic group (3.2% vs 0.94%, respectively) with ventricular septal defect (VSD) (12/1583) and patent ductus arteriosus (10/1583) being the most prevalent birth defects in the cardiovascular system and the most common compared with all other birth defects.

Game *et al*^[22] used the same EUROCAT classification to describe birth defects in 18 population-based EUROCAT registries of congenital anomalies, which included births between 1990 to 2005, and compared 669 diabetes cases with 92976 non-diabetes cases. The authors showed significantly increased odds ratios for neural tube defects (anencephaly and encephalocele, but not spina bifida) and several subgroups of congenital heart defects. Other birth defects found in increased odds ratios in

infants of pregnancies complicated by pregestational diabetes were anotia, omphalocele and bilateral renal agenesis. Multiple congenital anomalies were present in 13.6% of the diabetes cases and 6.1% of nondiabetes cases. The odds ratio for caudal regression sequence was very high (26.4, 95%CI: 8.98-77.64), but only 17% of all caudal regression cases occurred in pregnancies complicated by PGD.

Most recently, Correa *et al*^[23] reviewed the association of type 1 and type 2 PGD with 39 birth defects using the National Birth Defects Prevention Study. The authors examined databases from 10 birth defects surveillance systems in the United States looking for isolated (one or more major defects in same organ system or with known sequence) or multiple birth defects (2 or more major, unrelated defects) from births between 1997 to 2003. They found an association between PGD and 11 cardiac defects and 7 non cardiac defects.

Galindo *et al*^[12] prospectively followed 126 women with pregestational diabetes in a single tertiary centre in Spain. They reported 17 offspring with congenital anomalies (13.5%). Although chromosomal abnormalities are not generally associated with PGD, one fetus had trisomy 21 and atrioventricular septal defects. Eight fetuses were listed with major birth defects (6.3%), 35.3% of fetuses had cardiovascular defects, and genitourinary defects accounted for another 23.5%. They noted positive correlation between high levels of haemoglobin A1c (HbA1c) > 7% at early pregnancy and major congenital anomalies. Despite this study including only small number of women, the prospective nature of it allows strength in addressing its results.

Wender-Ozegowska *et al*^[16] studied a group of 198 diabetic women and found 17 pregnancies that resulted in infants with birth defects (8.6%). The most common defects were in the cardiovascular system (5.5%), with 7/198 (3.5%) of cases being atrioventricular septal defects (3 cases of VSD and 3 cases of atrial septal defect). Wren *et al*^[17] focused their research on cardiovascular birth defects. They followed 609 diabetic pregnancies and found that 3.6% of the women delivered infants with cardiovascular defects, the most common being transposition of great arteries, truncus arteriosus and tricuspid atresia. Janssen *et al*^[18] studied 1511 PGD cases, with congenital birth defects prevalence of 7.2%. The most common defects occurred in the cardiovascular system, NTDs, cleft lip/palate and skeletal defects.

Although many studies discuss diabetes associated congenital anomalies, the leading type of birth defects and the exact rate of diabetes associated birth defects are difficult to determine. The literature varies widely in what is considered the "leading" type of anomaly, as well as the rate of anomalies, because of suboptimal coding of the diabetic pregnancies according to White's classification, differences in anomaly coding and reporting bias. Moreover, the recognition of a birth defect may not always occur in the immediate neonatal period, thus, may not be entered into a registry. On the other

hand, over documentation of diabetes related birth defects, compared with birth defects in the nondiabetic population, may occur because of the known association of defects to diabetes, or the relatively high transfer of infants of diabetic pregnancies to neonatal intensive care units, both leading to a more thorough neonatal examination.

Based upon the available data, it seems that the major organ systems affected by PGD are the cardiovascular and the central nervous systems, which could be related to their embryonic origin in the neural crest. However, PGD can increase the rate of any other birth defects described above. Therefore, all pregnant women with PGD are advised to undergo a detailed anatomical scan and full fetal echocardiography to screen for possible birth defects, regardless of their having type 1 or type 2 diabetes mellitus or glycemic control at the time of pregnancy.

GLYCEMIC THRESHOLD FOR BIRTH DEFECTS

Periconceptional HbA1c is used as a surrogate marker for glycemic control, and is almost linearly related to PGD-induced birth defects. Previous studies have shown that stringent glucose control prior to or at early pregnancy, during organogenesis, can significantly reduce the incidence of birth defects^[12,24-29]. However, there are still questions to be answered. Hanson *et al*^[25] studied 532 type 1 PGD women and compared their malformation rate to 222 nondiabetic women. The rate of malformations did not differ significantly between the diabetic and the control groups (4.3% vs 2.4%) although significant difference was found in levels of first trimester HbA1c. The median value of HbA1c was 7.7% in the diabetic and 5.3% in the control group ($P < 0.001$). However, when higher levels of HbA1c were evaluated (HbA1c greater than 10.1% - equal to 8 SD above the normal mean control value), there was statistically significant higher occurrence rate of congenital malformation ($P < 0.01$).

Wender-Ozegowska *et al*^[16] tried to determine the cut-off for first trimester glycemic levels for prediction of congenital anomalies. They used whole day glycemic profile as well as HbA1c to assess glycemic control. Their cohort included 198 diabetic pregnancies and 4700 nondiabetic pregnancies. The rates of malformation were 8.6% and 3.6%, respectively. They determined the cut-off of value of HbA1c that could predict congenital malformations as 9.3% (measured up to 16 wk).

Other studies demonstrated the connection between poor glycemic control before or early at pregnancy: Ylinen *et al*^[29] found that the mean HbA1c for women whose infants had congenital malformations was higher than that measured for women with healthy infants prior to 15 gestational weeks (9.5% vs 8.0%, respectively). Mironiuk *et al*^[27] compared an occurrence rate of congenital malformations in newborn to mothers with

type 1 diabetes ($n = 170$), newborns of healthy mothers ($n = 26368$) and mothers with GDM ($n = 56$). They demonstrated that type 1 diabetes was associated with congenital malformations (11.2%, 1.8% and 2.2%, respectively) and that the risk of major birth defects was directly proportional to the level of maternal blood glucose control during the first trimester. These studies all support the idea that lack of glycemic control leads to congenital malformations, but do not indicate what HgA1c value should be maintained to reduce the risk for infant anomalies. Moreover, Shields *et al.*^[30] tried to find cut-off value associated with congenital anomalies but failed to do so, and Lucas *et al.*^[31] proved the association of PGD with congenital anomalies only when HgA1c was combined with other factors such as diabetic classification (White's classification) and maternal vascular complications. The Atlantic-Diabetes in Pregnancy (DIP) trial compared PGD pregnancy outcomes in the same population after a change in pre-pregnancy care policy and improved glycemic control throughout pregnancy. In the Atlantic DIP study, the first trial conducted from 2005-2007, included 104 diabetic pregnancies (87% type 1 PGD). The authors reported two pregnancies with birth defects that had HgA1c values of 6.6% and 5.4% at early pregnancy. The second trial, conducted from 2008-2010, included 168 pregnancies, with more women affected by type 2 PGD (81/168, 48%) and lower HgA1c values (7.3% compared to 6.9%); however, despite of presumed better prenatal care and the lower HgA1c - rate of malformation reported was not changed between the trials. The authors did not report the type of birth defects seen in either of the two studies^[32,33].

Other studies have demonstrated a linear relationship between HgA1c and major congenital defects. Greene *et al.*^[34] showed an increase in PGD-induced birth defects correlating to the level HgA1c. Their risk for major malformation was 3.0% when HgA1c taken at first trimester was less than or equal to 9.3% and 40% with HgA1c was greater than 14.4% (RR = 13.2; 95%CI: 4.3-40.4). Todorova *et al.*^[35] studied 124 pregnancies complicated by pregestational diabetes. The mean values of HgA1c were significantly higher in pregnancies complicated by fetal malformations ($n = 19/15.3\%$) than those values measured in pregnancies without fetal malformations [9.01% (SD ± 1.53) vs 8.06% (SD ± 1.64) $P = 0.022$, respectively].

In conclusion, it is clear that glycemic control is associated with a reduced risk of congenital anomalies. However, the recommended threshold of HgA1c for pregestational diabetic women planning pregnancy is still not known. Reaching a consensus as to what HgA1c level a diabetic pregnant woman should strive for has remained elusive for many reasons. First, differing definitions for major and minor anomalies, and taking into account the various forms of diabetes, limit the ability to derive conclusions from the published data. Second, PGD pregnancies can have the same spectrum of anomalies as nondiabetic pregnancies which makes

it difficult to differentiate PGD-induced anomalies from others encountered in nondiabetic pregnancies. Third, most studies use HgA1c to reflect the level of glycemic control, but HgA1c only measures a woman's average glycemic control over a 3-mo period. Therefore, it does not necessarily reflect a woman's level of glycemic control during organogenesis and embryogenesis. Moreover, because it is an average measurement, the same level of HgA1c may reflect completely different glycemic patterns, one being constant around the average, and the other with larger fluctuations lower and above from the mean HgA1c value^[35]. The effects of such fluctuations (*i.e.*, episodes of acute hyperglycemia and hypoglycemia with "normal" HgA1c) are yet to be determined. Fourth, given the complicated metabolic nature of diabetes, coupled with metabolic changes that are normal during pregnancy, other factors may influence the developing embryo. Finally, lower prenatal detection rates of fetal anomalies (due to obesity, lack of prenatal care, *etc.*) in diabetic women may lead to statistic skewing when studying infants with congenital anomalies born to PGD mothers^[36,37].

DOES DIABETES TYPE AFFECT THE RATES OF CONGENITAL ANOMALIES?

Diabetes can be classified by the mechanism (type 1, type 2 or gestational diabetes) or alternatively, by White's classification^[38]. Rates of diabetes, both type 1 and types 2 are increasing all over the world^[39,40] causing an increase in the incidence of maternal diabetes in pregnancy^[41]. Although hyperglycemia is a common mechanism for teratogenicity, differences in disease characteristics, such as age of onset, ethnicity, obesity and duration of disease, may affect the disease impact on the perinatal outcome and the rate of congenital anomalies. Current literature does not specify the risk for anomalies for any type of diabetes separately, as some studies include only type 1 diabetes^[25,42], others only type 2 diabetes^[32] and only a few compare the outcomes between them^[43,44].

Gonzalez-Gonzalez *et al.*^[44] retrospectively compared the outcomes of type 1 diabetes ($n = 904$), type 2 diabetes ($n = 516$), gestational diabetes ($n = 3188$) and control ($n = 115996$) deliveries in Ontario, Canada. Congenital anomalies were most frequently observed in women with type 1 diabetes and gestational diabetes, with risk approaching 1.5- to 2-times that of controls. They found a total of 44 anomalies (6.1%) among all women with diabetes, most commonly in the cardiovascular system. Adjusted OR for anomalies was 3.5, 1.7, 2.5 and 1.9 for type 1, type 2, gestational diabetes and control deliveries, respectively. Peticca *et al.*^[45] found similar results in a multicentre study in Italy. They prospectively compared 504 type 1 PGD to 164 type 2 PGD pregnancies. The rate of birth defects was significantly higher in women with type 1 diabetes (5.9%), compared with in women with type 2 diabetes

(2.0%). Difficulties in glycemic control, increased disease severity and frequent episodes of ketoacidosis and hypoglycaemia were postulated as explanations for this difference. Other studies have found the opposite results^[46,47]. Clausen *et al.*^[47] compared 389 type 1 and 146 type 2 diabetics delivering in the United Kingdom. Pregnancies affected by type 2 diabetes had worse perinatal outcomes with congenital abnormalities (12.3% in type 2 vs 4.4% in type 1; $P = 0.002$) accounting for most of this difference. In 2005, Clausen *et al.*^[47] showed similar results with almost doubled number of congenital anomalies among pregnant women with type 2 diabetes (6.6%) compared to type 1 diabetes (2.9%)^[46]. Both studies cited a delay in antenatal care, suboptimal glycemic control prior to conception, inadequate folate supplementation and maternal obesity, as possible reasons to explain the worse outcomes in pregnancies complicated by type 2 diabetes. Another explanation could be the tendency toward oral glycemic agents in type 2 diabetes, which may lead to less than optimal glycemic control compared to the use of insulin only in type 1 diabetes. Conversely, Roland *et al.*^[48], showed a high rate of congenital anomalies in women with type 1 diabetes and type 2 diabetes, compared with the nondiabetic population, with no significant difference between them. Jensen *et al.*^[43] found similar results.

Over the past years, there has been a great improvement in perinatal outcomes for women with type 1 diabetes. However, with rising incidence of obesity and type 2 diabetes, it seems that type 2 diabetes has become a more prominent concern. Women with type 2 diabetes tend to be under less stringent control of their glucose values, either because they use oral glycemic agents, have lower compliance with management strategies or have a lower prevalence of pre-pregnancy counselling, as sometimes type 2 diabetes is regarded as a "lesser" problem compared with type 1 diabetes. Moreover, lack of folate supplementation, obesity with lower ultrasound detection rates and other demographic differences between the women with type 1 or type 2 diabetes may account for the differences showed by different studies comparing the types of diabetes. There is no doubt that pre-pregnancy care and good glycemic control is equally important in type 2 and type 1 diabetes.

PATHOGENESIS OF DIABETES INDUCED BIRTH DEFECTS

Most data regarding the pathophysiology of diabetes associated birth defects originates from animal studies. Our research group, as well as others, have shown that maternal diabetes triggers multiple cellular stress responses and subsequent aberrant signal transduction pathways^[49-51]. All these may contribute to gene dysregulation and apoptosis in the affected organs of the developing embryo leading to structural birth defects. Studies from animal models have shown that maternal

diabetes increases the production of cellular reactive oxygen species and simultaneously impairs endogenous cellular antioxidant capacity, leading to an overall oxidative stress in the embryo^[50,52-55]. Maternal diabetes also appears to increase the expression of inducible nitric oxide synthase (iNOS)^[56], whose enzymatic activity catalyzes the reaction of superoxide with nitric oxide to produce reactive nitrogen species. Work in animal models indicates that reactive nitrogen species create a severe form of oxidative stress, nitrosative stress, which is responsible for the activation of cellular stress signalling. Our laboratory has shown that over expression of an antioxidant enzyme, superoxide dismutase 1 (SOD1), in SOD1 transgenic mice, mitigates maternal diabetes-induced oxidative stress and reduces embryonic malformations in diabetic pregnancies^[57-59]. Likewise, studies indicate that eliminating the *iNOS* gene in *iNOS* knockout mice reduces the incidence of embryonic malformations caused by maternal diabetes^[60]. Therefore, our work and that of others has shown that oxidative and nitrosative stress mediates the teratogenicity of maternal diabetes in the developing embryo.

In our studies, maternal diabetes-induced oxidative stress activates the c-Jun-N-terminal kinase 1/2 (JNK1/2)^[49,50,61-63]. Deletion of either *JNK1* or *JNK2* gene ameliorates maternal diabetes-induced NTDs formation^[49,50], supporting the hypothesis that activation of the cellular stress kinases, JNK1/2, mediates the adverse effect of maternal diabetes on neural tube closure. In the absence of JNK1 or JNK2, maternal diabetes-induced apoptosis in the neuroepithelial cells are blunted^[49,50]. Thus, JNK1/2 activation induced by maternal diabetes transmits the pro-apoptotic signal emanating from oxidative stress under diabetic conditions^[49,50].

JNK1/2 belongs to the mitogen-activated protein (MAP) kinase family, whose activation follows a three-tier cascade: MAP three kinases activate MAP kinase kinases, which in turn trigger JNK1/2 phosphorylation. Subsequent studies have revealed the upstream kinases in diabetic embryopathy, including apoptosis signal-regulating kinase 1 (ASK1)^[64]. ASK1 is a three kinase that leads to JNK1/2 activation. We have observed that *ASK1* gene deletion abolishes maternal diabetes-induced JNK1/2 activation, as well as activation of four major transcription factors downstream of JNK1/2. Similar to our findings in the *JNK1* and *JNK2* gene deletion studies, *ASK1* gene deletion blocks maternal diabetes-induced apoptosis in the developing neural tube, and consequently reduces the number of embryos with NTDs^[64]. Thus, the ASK1-JNK1/2 pathway, which is activated by oxidative stress, appears to play a causal role in the induction of diabetic embryopathy.

Recently, we have worked to understand how cellular ASK1-JNK1/2 kinase signalling relays its pro-apoptotic signals to the nucleus^[64]. We have observed that ASK1 activation increases the activity of Forkhead transcription factor 3a (FoxO3a), and that FoxO3a

induces TNFR1 associated death domain (TRADD)^[64]. TRADD up-regulation triggers caspase 8 activation, which, in turn, activates the caspase cascade and leads to apoptosis^[64]. Both germline deletion and conditional deletion of the *FoxO3a* gene significantly reduce maternal diabetes-induced apoptosis and NTDs formation, underscoring the potential importance of FoxO3a in the induction of diabetic embryopathy^[64]. We have successfully inhibited the whole stress pathway, ASK1-JNK1/2-FoxO3a-TRADD-caspase 8, using an endogenous ASK1 inhibitor, thioredoxin. Thioredoxin treatment ameliorates NTDs formation in embryos of diabetic dams and cultured embryos^[64]. These studies reveal the ASK1 initiated stress signalling with the activity of a transcription factor and pro-apoptotic gene expression.

We and others have shown that JNK1/2 activation leads to endoplasmic reticulum (ER) stress^[50]. Under ER stress, the unfolded protein response (UPR) is activated, and prolonged UPR activation induces apoptosis^[65,66]. Maternal diabetes *in vivo* and high glucose *in vitro* induce ER stress and activate the UPR pathway^[50]. Treatment with an ER chemical inhibitor, 4-Phenylbutyric acid, reduces high glucose-induced JNK1/2 activation, neuroepithelial cell apoptosis and NTD formation^[50]. Deletion of either the *JNK1* or the *JNK2* gene abrogates maternal diabetes-induced UPR and ER stress^[50]. These findings support a reciprocal causation between JNK1/2 and ER stress in diabetic embryopathy. Other studies have found that activation of the inositol-requiring enzyme 1 alpha, one of the major UPR arms, activates ASK1 and subsequently leads to JNK1/2 activation and apoptosis^[67,68], which support our hypothesis that ASK1 plays a major role in diabetic embryopathy.

CONCLUSION

While the risk for major congenital defects has been well established in women with pregestational diabetes, many questions remained unanswered. For example, it is still unknown why some organs display vulnerability to glucose teratological effects more than others, or why meticulous control of maternal blood glucose does not reduce the rate of birth defects to the background risk of non-diabetic population, or why some women with pregestational diabetes will have normal pregnancies even when their levels of HgA1c are way above the accepted threshold for birth defects.

The key to understanding the true relationship between PGD and birth defects lies in a basic understanding of the pathogenesis of congenital defects. Based on our research, the oxidative stress-triggered ASK1 pathway mediates the pro-apoptotic effect of maternal diabetes and high glucose *in vitro* by inducing pro-apoptotic gene expression and causing UPR and ER stress. The endogenous ASK1 inhibitor, thioredoxin, and the ER stress inhibitor, a Food and Drug Administration approved drug, may be potential therapeutics against maternal diabetes-induced structural birth defects.

We believe further research to evaluate glucose teratological effects on different embryonic organs, *via* animal models that can encompass the diversity seen in human diabetes, is needed. Research should utilize type 1 and type 2 models, as well as models of chronic and acute glycemia and how these two conditions may affect organogenesis. Our hope is that, by combining all known clinical data with current and future basic and translational science studies, we will be able to establish better ways to care for the diabetic mother and prevent the mal-effects of maternal diabetes on the developing embryo.

Abstract

In industrialized nations diabetic retinopathy is the most frequent microvascular complication of diabetes mellitus and the most common cause of blindness in the working-age population. In the next 15 years, the number of patients suffering from diabetes mellitus is expected to increase significantly. By the year 2030, about 440 million people in the age-group 20-79 years are estimated to be suffering from diabetes mellitus worldwide (prevalence 7.7%), while in 2010 there were 285 million people with diabetes mellitus (prevalence 6.4%). This accounts for an increase in patients with diabetes in industrialized

nations by 20% and in developing countries by 69% until the year 2030. Due to the expected rise in diabetic patients, the need for ophthalmic care of patients (*i.e.*, exams and treatments) will also increase and represents a challenge for eye-care providers. Development of optimized screening programs, which respect available resources of the ophthalmic infrastructure, will become even more important. Main reasons for loss of vision in patients with diabetes mellitus are diabetic macular edema and proliferative diabetic retinopathy. Incidence or progression of these potentially blinding complications can be greatly reduced by adequate control of blood glucose and blood pressure levels. Additionally, regular ophthalmic exams are mandatory for detecting ocular complications and initiating treatments such as laser photocoagulation in case of clinical significant diabetic macular edema or early proliferative diabetic retinopathy. In this way, the risk of blindness can considerably be reduced. In advanced stages of diabetic retinopathy, pars-plana vitrectomy is performed to treat vitreous hemorrhage and tractional retinal detachment. In recent years, the advent of intravitreal medication has improved therapeutic options for patients with advanced diabetic macular edema.

Core tip: Diabetic retinopathy is a potentially blinding complication of diabetes mellitus. In patients with diabetes, regular retinal exams are essential. While laser photocoagulation is effective, if performed in time, advanced stages of diabetic retinopathy need to be treated by vitreo-retinal surgery and have limited visual prognosis. Even though new therapeutic options such as intravitreal medical therapy and sutureless pars-plana vitrectomy have improved ophthalmic care of patients

with diabetes, interdisciplinary care of these patients is essential. Good metabolic and blood pressure control is indispensable for reducing the risk of ophthalmic complications.

INTRODUCTION

Diabetic retinopathy is a potentially blinding complication of diabetes mellitus. Reasons for loss of vision are diabetic maculopathy and complications of proliferative diabetic retinopathy (PDR) such as vitreous hemorrhage, tractional retinal detachment, and neovascular glaucoma. By 2030 developing countries will face an increase by 69% and industrialized countries by 20% of the number of patients with diabetes compared to 2010^[1]. For Africa more than 18 million, according to some estimations even 24 million, diabetic patients are predicted for the year 2030^[1,2].

Probability of retinal complications increases with increasing duration of disease. In up to 50% of patients with type 1 diabetes and 30% of those with type 2 diabetes potentially vision-threatening retinal changes develop over time, while early retinal changes are not noticed by the patients^[3].

Diabetic retinopathy is the most common micro-vascular complication of diabetes mellitus and affects between 3%-4% of people in Europe, while the relative risk for developing diabetic retinopathy is higher in type 1 diabetes compared to type 2^[4-6]. Diabetes mellitus is responsible for about 15% of all cases of legal blindness (best corrected visual acuity less than 0.02) in Germany^[7]. It is the main cause of blindness within the working-age population in industrialized nations^[4].

While retinal changes are rarely seen in patients with type 1 diabetes before adolescence, about one third of patients have signs of diabetic retinopathy at time of initial diagnosis of diabetes mellitus. The risk of PDR is higher in type 1 diabetes than in type 2, while diabetic macular edema is more commonly found in type 2 diabetes (prevalence after 15 years of disease: type 1 vs type 2 = 15% vs 25%)^[8].

Kramer *et al*^[9] reported in a recent study, that in patients with type 1 diabetes progression of diabetic retinopathy and development of nephropathy each increase the risk for incidence of the other. This association was independent of established risk factors for micro-vascular complications and the authors suggested a shared etiologic basis of these two complications of diabetes mellitus^[9]. Another group also found proliferative diabetic retinopathy to be an independent marker of long-term nephropathy in patients with type 1 diabetes^[10].

Other studies indicated association of the presence of diabetic retinopathy and increased overall-mortality and cardiovascular events both in type 1 and type 2 diabetes^[11].

Therefore an interdisciplinary approach of physicians, endocrinologists, and ophthalmologists is needed for optimal care.

PATHOGENESIS OF DIABETIC RETINOPATHY

Micro-angiopathy due to hyperglycemia in patients with diabetes mellitus results in vascular leakage, which causes diabetic macular edema on one hand, and capillary occlusion on the other hand. Capillary occlusion then again causes retinal ischemia and increased levels of vascular endothelial growth factor (VEGF) which are responsible for the development of neovascularization and the proliferative stage of diabetic retinopathy.

More recently new pathways which may be involved in the pathogenesis of diabetic retinopathy have been identified, such as inflammation, nerve growth factor autophagy and epigenetics. A detailed discussion of all these pathways would go beyond the scope of this mini-review about clinical aspects of diabetic retinopathy, however some aspects should be addressed.

Biochemical alterations such as oxidative stress, activation of protein kinase C and formation of advanced glycation end products have been detected as a response of the retina to hyperglycemia^[12]. Also kinin B1 and B2 are thought to increase vascular permeability, infiltration of leukocytes and inflammation. Especially kinin B1, which is almost non-existent in normal tissue, is upregulated in the retina of diabetic patients. These findings may be important for developing new therapeutic strategies aiming at antagonizing kinin receptors or at inhibiting kallikreins^[13].

Recent investigations showed that the whole retinal neurovascular system is impaired by diabetes mellitus resulting in loss of neurovascular coupling, neurodegeneration and neuroinflammation, which can be detected even before the advent of vascular damage^[14]. Clinically, reduced dark adaption, impaired colour and/or contrast vision and visual field defects are found during functional examinations of diabetic patients^[15].

Diabetic retinopathy tends to deteriorate during hormonal changes such as adolescence and pregnancy^[16].

CLASSIFICATION AND PATHOPHYSIOLOGY OF DIABETIC RETINOPATHY

During fundoscopy, which should be performed after dilation of the pupil (mydriasis) to allow visualization of the entire retina, presence and grade of diabetic retinopathy can be assessed clinically. Typical changes seen in early diabetic retinopathy (non-PDR) are micro-

Figure 1 Non-proliferative diabetic retinopathy. Wide-field fundus photo of a 65-year-old female patient (right eye) showing several retinal hemorrhages.

Figure 2 Non-proliferative diabetic retinopathy. Color fundus photo of a 51-year-old male patient with micro-aneurysms and lipid exudates.

Figure 5 Advanced proliferative diabetic retinopathy with tractional retinal detachment.

aneurysms, retinal hemorrhages, and exudates (Figure 1). In the beginning, these alterations are often found slightly temporal to the central area of the macula (Figure 2). These are caused by deranged vascular integrity and loss of pericytes. In the later course of disease, intra-retinal micro-vascular anomalies may develop, which represent dilated and therefore during fundoscopy visible retinal capillaries, and indicate possible risk of neovascularization and proliferative diabetic retinopathy.

Proliferative diabetic retinopathy is caused by increased intraocular VEGF-levels due to retinal ischemia because of capillary occlusion of retinal vessels. Proliferation may

grow at the optic disc (neovascularization at the disk) or elsewhere in the retina (neovascularization elsewhere) into the vitreous (Figure 3). These newly formed vessels leak on fluorescein angiography and may cause vitreous hemorrhage and finally tractional retinal detachment (Figures 4 and 5). Tractional retinal detachment results in separation of the neurosensory retina from the retinal pigment epithelium. Detached sections of the retina cause relative visual-field defects (scotoma) and loss of visual acuity in cases with macular involvement.

Further, neovascularization on the iris in the anterior segment of the eye may evolve as anterior segment sequel of ischemia (Figure 6). These new blood vessels grow towards the anterior chamber angle and may obstruct the trabecular meshwork, thus increasing outflow resistance of aqueous humor. This results in increased intraocular pressure followed by optic atrophy (neovascular glaucoma).

CLASSIFICATION AND PATHOPHYSIOLOGY OF DIABETIC MACULOPATHY

Diabetic maculopathy may develop in the non-proliferative and in the proliferative stage of diabetic retinopathy. While complications of untreated proliferative diabetic

Table 1 Types of diabetic maculopathy^[19]

Focal	Localized edema Lipid exudates Intraretinal hemorrhages Focal hyperfluorescence in late fluorescein angiography
Clinically significant without foveal thickening (non-center-involving) (sight-threatening)	Edema within 500 µm around the foveola Exudates within 500 µm around the foveola accompanied by edema
Clinically significant with foveal thickening (center-involving)	Edema ≥ 1 optic-disk diameter within one optic-disk diameter around the foveola Ill-defined edema, which may be cystoid Exudates Intraretinal hemorrhages Origin of leakage often not clearly identifiable by fluorescein angiography
Tractional	Due to vitreous traction to the fovea Thickened posterior hyaloid membrane OCT visualizes vitreal traction
Ischemic maculopathy (occlusion of the perifoveal capillaries)	Loss of vision without any clearly visible cause on fundoscopy Fluorescein angiography needed for diagnosis Difficult to diagnose by fundoscopy only Edema may be present or absent

OCT: Optical coherence tomography.

retinopathy, such as vitreous hemorrhage and tractional retinal detachment involving the macula may cause the most severe loss of vision in diabetic retinopathy, diabetic maculopathy is the main cause of visual impairment in patients with type 2 diabetes^[17].

Diabetic macular edema is caused by a disruption of the inner blood-retinal barrier, formed by the retinal vascular endothelium, due to hyperglycemia, increased levels of growth-factors, inflammation and cytokines. This also causes impairment of pericytes and leads to consecutive exudation of fluid, proteins and lipids by para cellular and trans cellular transport mechanisms^[18]. Clinically, areas of thickened retina are often demarcated by surrounding yellowish lipid exudates (Figure 7). Diabetic macular edema may be limited or affect a large retinal area and it may also involve the macula (center-involving) or spare the central area (non-center-involving) (Figure 8).

Traction caused by vitreous attachment to the fovea may result in macular thickening, as well. Vitreous traction can excellently be documented by high-resolution optical coherence tomography (OCT, spectral-

domain OCT). Vitrectomy is needed in patients with symptomatic tractional macular edema in order to release traction by surgical removal of the vitreous.

Apart from edema, diabetic maculopathy may also present as occlusion of perifoveal capillaries resulting in distinct visual impairment in the absence of edema on fundoscopy. In these cases, fluorescein angiography is needed to confirm the diagnosis by visualizing capillary occlusion in around the fovea.

Table 1 summarizes the different types of diabetic maculopathy (adapted from Nentwich *et al.*^[19]).

CLINICAL DIAGNOSIS

Dilated funduscopy is the most important clinical investigation in patients with diabetes during screening examinations by an ophthalmologist. Dilation of the pupil is necessary in order to enable a proper stereoscopic view, which is needed for evaluation of macular edema, and to allow visualization of the peripheral retina.

Fluorescein angiography was introduced by Novotny *et al.*^[20] in the 1960s into the clinical ophthalmic practice and allows evaluation of the retinal vascular status. Fluorescein, a fluorescent dye, is injected intravenously and distributes throughout the body. In the eye, fluorescence is activated by blue light of 490 nm. During fluorescein angiography vascular leakage, capillary occlusion, ischemic areas of the retina and neovascularization can be seen (Figure 9A and C). It provides information on the area of leakage as well as of the location of non-perfused parts of the retina. In patients with suspected diabetic maculopathy, fluorescein angiography is mandatory for excluding ischemic maculopathy and guiding possible focal laser photocoagulation.

Wide-field fundus photography (2-laser wavelength nonmydriatic 200° ultra-wide-field scanning laser ophthalmoscopy) has been introduced recently. Wide-field images and traditional color fundus photography

Figure 7 Clinically significant diabetic macular edema without involvement of the fovea. A: Fundus photo; B: Fluorescein angiogram depicting leakage of perifoveal retinal blood vessels.

Figure 8 Center-involving diabetic macular edema with subfoveal edema and numerous lipid exudates.

in mydriasis seem to correlate with regard to the classification of diabetic retinopathy and visualization of diabetic macular edema according to recent studies (Figure 10A)^[21-23]. This wide-field imaging technique can be combined with fluorescein angiography and provides information about peripheral retinal ischemia or peripheral neovascularization (Figure 10B)^[24].

Probably the most important new imaging technique, which was introduced in ophthalmologic practice, is OCT. Recently, resolution and recording speed have been greatly improved by spectral-domain OCT technique (SD-OCT). OCT provides data on retinal volume and configuration of the macular region. In diabetic macular edema SD-OCT is a very valuable examination technique comparing follow-up visits with baseline data, as modern OCT-devices use eye-tracking for finding the same imaging position during follow-up examinations (Figure 11)^[25].

IMPORTANCE OF PREVENTION

In early diabetic retinopathy, laser photocoagulation can be used effectively for preventing loss of vision^[26]. However, early diabetic retinopathy is not noticed by patients because of the absence of visual loss in early diabetic retinopathy. Thus, regular retinal exams with dilation of the pupil are necessary in patients with

diabetes mellitus in order to detect sight-threatening changes timely and enable ophthalmologists to perform treatment.

Patients with type 1 diabetes should undergo retinal exams starting at the age 11 and/or after 5 years of diagnosis on a yearly basis. In case of retinal changes, shorter follow-up intervals are recommended.

In type 2 diabetes, the first retinal exam should be performed immediately after first diagnosis of diabetes, because the previous duration of the disease is unknown. Annual follow-up examinations are recommended in the absence of retinal changes, otherwise shorter intervals are recommended.

Pregnancy bears an increased risk of worsening of diabetic retinopathy due to hormonal changes. During pregnancy diabetic retinopathy may start in about 10% of cases and may worsen in an even higher percentage in case of preexisting diabetic retinopathy at time of conception^[27]. In case of proliferative diabetic retinopathy before or shortly after conception, pan-retinal laser photocoagulation should be performed as retinal changes may worsen in one out of two women in this population. This risk can be reduced by half by thorough retinal laser photocoagulation. Therefore all females with diabetes, who are planning to get pregnant, should undergo fundoscopy prior to conception and then every three months during pregnancy to enable early intervention, if needed. Additionally good metabolic control should be achieved before conception^[28].

On the other hand, the presence of diabetic retinopathy is no indication for cesarean section per se, as no study has indicated so far, that Valsalva-maneuvers during vaginal delivery bear an increased risk of vitreous hemorrhages^[29].

The German Diabetes Society recommends scheduling of follow-up examinations depending on the grade of diabetic retinopathy as summarized in Table 2 (Adapted from^[30]).

These recommended examination intervals will result in an increased work-load for ophthalmologists due to the rising number of diabetic patients. Studies examined the effect of an extension of follow-up intervals and found no increased risk of progression to sight-

Figure 9 Fluorescein angiogram of a 49-year-old female patient. A: Fluorescein angiogram of the right eye 50 s after intravenous injection of fluorescein dye. Here, leaking micro-aneurysms in the macula can be seen; B: Fluorescein angiogram of the left eye 25 s after intravenous injection of fluorescein dye. Leakage from neovascular blood vessels causes spots of increased fluorescence at the optic disk and temporal to the fovea; C: Fluorescein angiogram of the temporal part of the left eye 30 s after intravenous injection of fluorescein dye. Areas of retinal non-perfusion can be seen as reason for neovascularization.

Figure 10 Wide-field picture of the right eye of a 65-year-old female patient. A: On scanning-laser-ophthalmoscope-Imaging some micro-aneurysms and lipid exudates can be seen; B: Fluorescein angiogram shows leakage from micro-aneurysms and extensive areas of retinal non-perfusion.

Figure 11 Spectral-domain optical coherence tomography of a female patient with center-involving diabetic macular edema. On the left side of the picture, an infra-red image shows the exact location of the OCT-scan on the right. The OCT-scan visualizes intraretinal edema with thickening of the fovea. OCT: Optical coherence tomography.

threatening diabetic retinopathy in patients with good metabolic control (HbA1c < 8%) and no known diabetic retinopathy^[31-35]. By adequate selection of patients, the number of necessary screening examinations could be reduced by 40% according to one study and even by 59% in case a special mathematical algorithm is used^[31,33]. However, feasibility of these strategies remains to be proven in routine clinical practice and until then

ophthalmic screening intervals as indicated above are recommended.

GENERAL MEDICAL THERAPY AND INTERVENTIONS

Blood glucose and blood pressure control

Good metabolic and blood-pressure control are essential for successful ophthalmic care of patients with diabetes.

In type 2 diabetes, a reduction of HbA1c from 7.9% to 7.0% resulted in a decline in the frequency of laser treatments needed^[36]. In type 1 patients, improved blood glucose control with a reduction of HbA1c values from 9.1% to 7.1% reduced the risk of developing diabetic retinopathy within 6.5 years by 76%, the risk of progression of diabetic retinopathy by 54%, and the risk of developing proliferative diabetic retinopathy by 47%^[37]. Therefore an HbA1c level of about 7% should be aimed for from the ophthalmologist's point of view^[19], for the individual patient a bespoke treatment regime may be needed.

Rapid improvement of metabolic control may result in temporary worsening of diabetic retinopathy ("early-worsening") in patients with long-lasting disease and

Table 2 Recommended timing of retinal examinations in patients with type 2 diabetes^[41]

Patient characteristics	Timing of retinal examination
Initial diagnosis of type 2 diabetes	Soon
No diabetic retinopathy	Once a year
Presence of symptoms such as	During the next few days
Loss of vision	
New difficulties during reading	
Altered color perception	
New, moving dark spots in the eye	
Presence of diabetic retinopathy	Depending on the severity of retinopathy, e.g., every 3-6 mo

high HbA1c levels. Thus, retinal exams should be performed every three months during the first year after initiation of an improved anti-diabetic treatment^[5,38]. However, in the long-term, positive effects of good metabolic control outweigh these initial problems^[37,39]. Also a slow decrease of blood sugar levels, which would be a therapeutic challenge, does not have any advantages in the long term and is not recommended from the ophthalmologist's point of view^[19].

Additionally, optimizing blood pressure helps to reduce the necessity of laser photocoagulation and the risk of loss of vision^[40]. While some studies suggested a protective effect of ACE inhibitors, according to the results of studies available to date, reduction of blood pressure itself seems to be more important than the type of blood pressure lowering medication^[41-43]. Levels of about 140/80 mmHg should be aimed for.

Acetylsalicylic acid and smoking

Acetylsalicylic acid has neither been shown to have any positive effect on diabetic retinopathy or diabetic macular edema, nor to be harmful for patients with diabetic retinopathy. Therefore acetylsalicylic acid should be recommended for cardiovascular reasons in patients with early non-proliferative diabetic retinopathy, in case there are no contraindications^[44].

Data on the effect of smoking on diabetic retinopathy is heterogeneous. While some studies did not find an association of smoking with diabetic retinal changes, others identified smoking in a multiple regression analysis as risk factor for any grade of diabetic retinopathy^[45-47]. However, results of a recent experimental study suggest that nicotine expedites diabetes-induced retinal changes^[48]. Additionally, patient characteristics such as selective mortality among smokers and patients with proliferative diabetic retinopathy at baseline may provide some explanation for the apparently absent association, reported in some studies^[47]. Cessation of smoking should therefore be recommended from the ophthalmologist's point of view.

OPHTHALMIC THERAPEUTIC OPTIONS

Diabetic macular edema

Until the advent of anti-VEGF medication, focal and grid laser photocoagulation was the standard of care

Figure 12 Color fundus photo of a 53-year-old male patient several months after focal laser photocoagulation because of clinical significant diabetic macular edema. While the laser scars and some remaining dot-hemorrhages are visible, lipid exudates and retinal edema have disappeared.

for clinical significant diabetic macular edema (CSME) as well as for diffuse diabetic macular edema.

In patients with focal CSME without involvement of the fovea, focal laser photocoagulation of microaneurysms and localized areas of leakage reduces the relative risk of moderate loss of vision by 50% (from 24% to 12%) as demonstrated by the ETDRS Group (Figure 12)^[49]. In case of persisting areas of leakage two to three months after initial focal laser photocoagulation, repeated laser treatment should be considered^[26].

Apart from the direct effect by coagulating microaneurysms, focal laser photocoagulation is thought to increase oxygenation of the retina by improving diffusion of oxygen from choroidal vessels and to reestablish the blood-retinal barrier by thermal stimulation of the retinal pigment epithelium and of endothelial cells of retinal capillaries^[50].

Grid laser photocoagulation of diffuse diabetic macular edema with involvement of the fovea ("center-involving") has a limited functional prognosis^[49]. Therefore, grid laser photocoagulation has been replaced by intravitreal anti-VEGF therapy, which provides superior functional results^[51].

VEGF is associated with a breakdown of blood-retinal barrier causing leakage and retinal edema^[52]. Intravitreal application of anti-VEGF medication enables high local concentrations in the vitreous and a low systemic exposure. However, repeated intravitreal injections of anti-VEGF medications are necessary in patients with center-involving diabetic macular edema. The average number of injections is around 7 in the first year of treatment and 4 in the second year as indicated by recent studies^[53,54]. Intravitreal anti-VEGF therapy is generally safe with regard to side-effects of medication, although the incidence of systemic thromboembolic events varies among trials^[55]. As the intravitreal application of medication is a surgical procedure, it is associated with the possible risk of postoperative infection, which is called endophthalmitis in case of severe infection of the inner eye and its internal structures. For this reason several recommendations of ophthalmologic societies

Figure 13 Wide-field picture of the right eye of a 48-year-old male patient after pan-retinal laser photocoagulation because of proliferative diabetic retinopathy. The peripheral laser scars can be seen in the picture, while neovascularization have regressed.

Figure 14 Proliferative diabetic retinopathy with extensive fibro-vascular membranes.

have been published concerning prevention of post-injection endophthalmitis. Recent studies reported very low rates of post-injection endophthalmitis of less than 1 in 8000 injections performed in an operating theater setting after diligent disinfection of the conjunctiva with povidone-iodine, using sterile gloves and wearing face-masks^[56,57]. Other studies report somewhat higher rates of infectious endophthalmitis after intravitreal injection, both after procedures performed in an office-setting and in a theater-setting^[58]. The effect of meticulous povidone-iodine prophylaxis on the conjunctival bacterial load and contamination of needles used for injection prophylaxis has been shown in several studies^[59-62].

Apart from anti-VEGF medication intravitreal steroids have been evaluated for the treatment of diabetic macular edema. Compared to anti-VEGF medication, steroids have additional anti-inflammatory effects and sustained-release devices can lengthen the intervals between re-treatments^[63]. In Europe, a non-absorbable implant containing 190 µg fluocinolone acetonide has been approved as second-line treatment of chronic diabetic macular edema not responding to other therapeutic options. Also approval of an absorbable dexamethasone implant for the treatment of diabetic macular edema is expected by the end of 2014. While

intravitreal steroids are effective in reducing diabetic macular edema, patients need to be informed about possible progression of cataract and increased intraocular pressure^[64-67].

Proliferative diabetic retinopathy

In early proliferative diabetic retinopathy, pan-retinal laser photocoagulation is effective in reducing the risk of visual loss, while surgery needs to be performed in very advanced proliferative diabetic retinopathy^[68]. The suggested screening intervals of patients with diabetes are intended to enable the treating ophthalmologist to detect proliferation amenable for laser treatment early. Pan-retinal laser photocoagulation should be performed when retinal neovascularization is detected during fundoscopy or *via* fluorescein angiography in order to prevent complications of proliferative diabetic retinopathy such as vitreous hemorrhage or tractional retinal detachment (Figure 13)^[68]. Pan-retinal laser photocoagulation aims at eliminating non-perfused parts of the retina, thus reducing ischemia, intravitreal VEGF-levels, and the stimulus for proliferation. The efficacy of pan-retinal laser photocoagulation in reducing the risk of loss of vision has already been shown more than 30 years ago^[68]. However, patients need to be informed about side-effects of pan-retinal laser treatments such as constriction of visual fields and reduced dark-adaptation due to loss of rod function. These side-effects may also interfere with the patients' driving ability.

Pars-plana vitrectomy is performed in advanced cases of proliferative diabetic retinopathy, the presence of extensive tractional membranes, vitreous hemorrhage, and tractional retinal detachment (Figure 14). About ten years ago trans conjunctival sutureless 23 gauge vitrectomy started to replace conventional 20 gauge technique and offers comparable safety and efficacy as well as reduced surgery-times and faster rehabilitation of patients^[69].

Combination of diabetic macular edema and proliferative diabetic retinopathy

In patients with diabetic macular edema and proliferation, treatment of macular edema should be performed before pan-retinal laser photocoagulation in order to prevent worsening of macular edema due to peripheral pan-retinal laser photocoagulation.

CONCLUSION

In patients with diabetes, regular retinal exams are essential. While laser photocoagulation is effective, if performed in time, advanced stages of diabetic retinopathy need to be treated by vitreo-retinal surgery and have limited visual prognosis. Even though new therapeutic options such as intravitreal medical therapy and sutureless pars-plana vitrectomy have improved ophthalmic care of patients with diabetes, interdisciplinary care remains essential. Good metabolic and blood pressure control is indispensable for reducing the risk of

ophthalmic complications.

can attack macromolecules, such as lipids, nucleic acids or amino acids. Phenylalanine (Phe) can be enzymatically converted to the physiological para-tyrosine (p-Tyr); however, a hydroxyl free radical attack on Phe may yield meta- and ortho-tyrosine (m- and o-Tyr, respectively) in addition to p-Tyr. Hence, m- and o-Tyr may be regarded as markers of hydroxyl free radical-induced damage. Their accumulation has been described; *e.g.*, this accumulation has been found in the urine of patients with diabetes mellitus (DM) and/or chronic kidney disease, in cataract lenses, in vessel walls, in irradiated food and in amniotic fluid, and it may serve as an indicator of oxidative stress. The use of resveratrol to treat patients with type 2 DM led to a decrease in the urinary excretion of o-Tyr and concomitantly led to an improvement in insulin signaling and insulin sensitivity. Literature data also suggest that m- and o-Tyr may interfere with intracellular signaling. Our group has shown that erythropoietin (EPO) has insulin-like metabolic effects on fat cells in addition to its ability to promote the proliferation of erythroid precursor cells. We have shown that the supplementation of cell culture medium with m- and o-Tyr inhibits erythroblast cell proliferation, which could be ameliorated by p-Tyr. Additionally, *in vivo*, the o-Tyr/p-Tyr ratio is higher in patients with renal replacement therapy and a greater need for EPO. However, the o-Tyr/p-Tyr ratio was an independent determinant of EPO-resistance indices in our human study. The o-Tyr content of blood vessel walls inversely correlates with insulin- and acetylcholine-induced vasodilation, which could be further impaired by artificial oxidative stress and improved by the use of antioxidants. In rats that receive o-Tyr supplements, decreased vasorelaxation is detected in response to insulin. Additionally, o-Tyr supplementation led to the incorporation of the unnatural amino acid into cellular proteins and caused a decrease in the insulin-induced phosphorylation of endothelial nitric oxide synthase. Our data suggest that m- and o-Tyr may not only be markers of oxidative stress; instead, they may also be incorporated into cellular proteins, leading to resistance to insulin, EPO and acetylcholine.

Abstract

Oxidative stress processes play a major role in the development of the complications associated with diabetes and other diseases *via* non-enzymatic glycation, the hexosamine pathway, the polyol pathway and diacylglycerol-protein kinase C. Oxidative stress may lead to the production of hydroxyl free radicals, which

Core tip: Hydroxyl-free radical-derived amino acids, such as meta- and ortho-tyrosine (m- and o-Tyr, respectively) are regarded as free radical markers, but they may also be taken up and incorporated into blood vessel walls, erythroid precursors and endothelial cells. These pathological amino acids can induce vascular insulin and acetylcholine, as well as cellular erythropoietin resistance.

Molnár GA, Mikolás EZ, Szijártó IA, Kun S, Sélley E, Wittmann I. Tyrosine isomers and hormonal signaling: A possible role for the hydroxyl free radical in insulin resistance. *World J Diabetes* 2015; 6(3): 500-507 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/500.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.500>

OXIDATIVE STRESS IN THE OLD PERSPECTIVES

Oxidative stress plays a role in the pathogenesis of many diseases, such as diabetes mellitus (DM), chronic kidney disease (CKD) and inflammatory diseases, as well as in the development of the complications associated with these diseases. Oxidative stress, free radicals and reactive oxygen species (ROS) are tightly connected to DM in several ways. Hyperglycemia may lead to a shift in cellular metabolism toward the polyol pathway, which leads to an oxidative shift in the NADPH/NADP ratio. NADPH is in turn required for antioxidant defense, *e.g.*, for the reduction of oxidized glutathione by glutathione reductase. Furthermore, hyperglycemia activates the diacylglycerol-protein kinase C intracellular signaling pathway, which can activate NADPH oxidases; this oxidation leads to the translocation of nuclear factor κ B into the nucleus and then to the transcription of proinflammatory cytokines, which results in increased oxidative stress. Additionally, hyperglycemia increases the rate of non-enzymatic glycation, which produces advanced glycation end-products (AGEs) that can bind to their receptors of AGE (RAGE), and the AGE-RAGE interaction also leads to inflammation and oxidative stress. DM involves the enhancement of not only non-enzymatic glycation but also enzymatic glycation *via* the hexosamine pathway; this enhanced glycation may also result in a proinflammatory response and oxidative stress. However, this interplay is complex; the ROS arising from oxidative stress may also contribute to the activation of the abovementioned pathways and reactions and can thus generate a vicious circle^[1,2].

DETECTION OF OXIDATIVE STRESS

The study of oxidative stress processes is therefore important, albeit somewhat cumbersome. Per their definition, free radicals are highly reactive molecules with a very short lifetime; therefore, detecting these molecules requires spin traps and an electron spin resonance device^[3,4], but the sensitivity of this method is usually too low for many diseases. Because of the high reactivity of free radicals, they can react with macromolecules and yield oxidation products, some of which are more chemically stable molecules. These products may include lipid peroxidation products (such as malonyldialdehyde derivatives), nucleobase products (such as 8-hydroxydeoxyguanosine), so-called advanced oxidation products or amino acid derivatives^[5,6].

DETECTION OF HYDROXYL FREE RADICALS BY STABLE L-PHENYLALANINE DERIVATIVES

L-Phenylalanine (Phe) is a highly abundant essential amino acid in proteins of the human body, and Phe plays a role in forming peptides and proteins; Phe also gives rise to the semi-essential amino acid L-para-tyrosine (p-Tyr) and its derivatives, such as 3,4 dihydroxy-phenylalanine (DOPA), and derivatives thereof^[7]. p-Tyr is mainly produced *via* the enzymatic reactions catalyzed by the Phe hydroxylase enzyme, especially in the kidney and liver^[8]. p-Tyr synthesis becomes impaired in patients with renal failure (*e.g.*, CKD); therefore, the serum levels of p-Tyr in these patients are lower than those in patients/controls with normal renal function [CKD: 28 (26-34), DM + CKD: 32 (29-39) μ mol/L vs controls: 56 (36-57) μ mol/L]^[9]. However, other isomers of tyrosine, namely meta- and ortho-tyrosine (m-Tyr and o-Tyr, respectively) also exist in humans. These amino acids cannot be formed enzymatically in humans; instead, they are stable products of the reaction between the hydroxyl free radical and Phe. Additionally, p-Tyr may be formed non-enzymatically, *via* the hydroxyl radical, but the enzymatically produced p-Tyr is much more abundant than the free radical-derived p-Tyr. Therefore, p-Tyr is regarded as the physiologic isoform, whereas m- and o-Tyr are considered to be free radical markers^[10-14].

All four aromatic amino acids (p-Tyr, m-Tyr, o-Tyr and Phe) can be readily detected in the nanomolar range *via* their autofluorescence and reverse-phase high performance liquid chromatography^[9,15-22], as well as by gas chromatography combined with mass spectrometric detection^[23] or by ultra-performance liquid chromatography combined with mass spectrometry^[24].

ABUNDANCE OF THE HYDROXYL FREE RADICAL MARKERS M- AND O-TYR

In vitro measurements^[25] and *in silico* calculations^[26] have shown that in free radical reactions, the three isoforms (p-,

Figure 1 Changes in urinary ortho-tyrosine:creatinine excretion after resveratrol treatment. For each participant, the value measured at baseline was subtracted from that measured at week 4 (*i.e.*, Δ o-Tyr:creatinine ratio), and then the resulting values were averaged within the respective groups. The values are the means, with the standard deviations represented by vertical bars. ^aMean values were significantly different ($P = 0.043$). Comparisons were performed using ANOVA and Bonferroni post hoc tests; $P < 0.05$ was regarded as statistically significant. m- and o-Tyr) are not produced stoichiometrically (*i.e.*, 1:1:1), and their concentrations and ratios may vary from tissue to tissue *in vivo*. These isoforms, along with others, have been detected in cataractous lenses by our group and others^[16,27], in the brain after acute oxidative stress^[28], in the serum/plasma of diabetic patients with/without CKD by our group^[9], after the administration of thyroid hormone^[29], after ischemia-reperfusion injury^[14], in the hair of the *Homo tirolensis* and mummies^[30], in irradiated food^[31], in urine specimens^[9,24] and in amniotic fluid^[32]. In earlier publications, we have shown that m-Tyr, o-Tyr and DOPA accumulate in the non-water soluble proteins of cataractous lenses during aging and in patients with DM^[16], and we also showed that the urinary excretion of o-Tyr increases in patients with type 2 DM and/or CKD [CKD: 122 (94-183), DM: 641 (272-499), DM+CKD: 403 (258-651) nmol/d vs controls: 24 (0-35) nmol/d]^[9]. Using the so-called fractional excretion values,

Figure 2 Increase in protein kinase B phosphorylation in platelets upon resveratrol treatment. Values are the means, with the standard deviations represented by vertical bars. ^aMean values were significantly different for baseline vs week 4 within the resveratrol group ($P = 0.032$). Comparisons were performed using ANOVA and post-hoc tests; $P < 0.05$ was regarded as statistically significant. which show the renal handling of o-Tyr, we have found active urinary secretion or *in loco* renal synthesis of o-Tyr in the kidney of diabetic patients [DM: 125 (69-140), DM + CKD: 112 (69-187)% vs controls: 8 (4-12)%]^[9].

In patients with stroke, the urinary excretion of o-Tyr is associated with the total urinary albumin excretion; immunoreactive albumin excretion; and most significantly, urinary non-immunoreactive albumin excretion^[17].

DECREASED URINARY EXCRETION OF O-TYR IS ASSOCIATED WITH AN IMPROVEMENT IN INSULIN RESISTANCE IN TYPE 2 DIABETES

In a human study, we demonstrated the protective effect of the polyphenolic compound resveratrol in patients with type 2 DM; a short-term administration of resveratrol led to a decrease in urinary o-Tyr excretion (Figure 1), an increase in the phosphorylation of the insulin signaling molecule protein kinase B (or Akt), (Figure 2) and an amelioration of the calculated marker of insulin resistance (homeostasis model assessment-insulin resistance) (Figure 3)^[18].

ARE M- AND O-TYR JUST MARKERS OR ALSO MAKERS?

All of the abovementioned papers focused on m- and o-Tyr as markers of hydroxyl free radical damage. However, the last of our abovementioned studies (on the *in vivo* effects of resveratrol) raised the possibility that these molecules may not only be markers; instead, they may also play a role in the development of pathological states^[18]. Independent of our results, Ruggiero *et al.*^[33,34] showed that m- and o-Tyr can inhibit tumor cell growth *via* influencing the mitogen-activated protein kinase/extracellular signal regulated kinase (ERK) and

Figure 4 Effects of treatment with r-mo-erythropoietin on the rate of [3H]-deoxy-D-glucose uptake in 3T3-L1 adipocytes cultured in either normal (5 mmol/L) or high (25 mmol/L) glucose medium (insulin: $n = 8$ and $n = 6$; r-mo-erythropoietin: $n = 6$ and $n = 5$, respectively). ^a $P < 0.05$ vs control in the same medium; ^c $P < 0.05$ between the two media; Comparisons with control were performed using a one-sample *t*-test; pairwise comparisons between 5 and 25 mmol/L glucose-cultured cells were performed using a paired samples *t*-test. Republished with permission of Georg Thieme Verlag KG Stuttgart, New York from Mikolás *et al.*^[37]. EPO: Erythropoietin.

the signal transducer and activator of transcription (STAT) pathway. In plants, m-Tyr inhibits cell growth and plant root growth and may be considered a natural herbicide^[35,36]. This finding raises the possibility that the unnatural isoforms, m- and o-Tyr, might affect cellular function in mammals and plants and may interfere with hormonal signaling.

INSULIN-LIKE EFFECT OF ERYTHROPOIETIN ON GLUCOSE METABOLISM

In a subsequent study, we have shown that under hyperglycemic circumstances, erythropoietin (EPO) exerts insulin-like effects on the uptake of isotope-labeled glucose by 3T3-L1-type fat cells (Figure 4) and can lead to the translocation of glucose transporters (GLUTs) from their intracellular pools to the membrane (Figure 5). EPO also improves glucose metabolism in streptozotocin-induced diabetic rats^[37].

M- AND O-TYR ARE INCORPORATED INTO CELLULAR PROTEINS AND LEAD TO ERYTHROPOIETIN RESISTANCE

In further studies, we showed that the administration of m- and o-Tyr to erythroblasts inhibited erythroblast proliferation in a time- and concentration-dependent manner. Increasing doses of p-Tyr could overcome the inhibition by m- and o-Tyr, suggesting potential competition among the structural isoforms (Figure 6).

Erythroblasts grown in cell culture medium supplemented with m- or o-Tyr incorporated the Tyr isoforms into their cellular proteins (Figure 7).

Supplementing erythroblast cells with o- or m-Tyr inhibited the EPO-dependent increase in the rate of

phosphorylation of STAT5 and ERK1/2 (Figure 8). This finding indicates that the unnatural isoforms, o- and m-Tyr, can be incorporated into cellular proteins and interfere with the hormonal signaling of EPO^[21].

This finding is consistent with a clinical observation of our group that the ratio of the pathological o-Tyr to the physiological p-Tyr (o-Tyr/p-Tyr ratio) is higher in patients who receive renal replacement therapy compared with controls. Additionally, the o-Tyr/p-Tyr ratio in the blood was higher in the individuals receiving hemodialysis and EPO replacement than in those patients receiving hemodialysis who did not require EPO replacement or in patients receiving peritoneal dialysis and requiring markedly lower EPO doses. Furthermore, the plasma o-Tyr/p-Tyr ratio was an independent predictor of the EPO dose and EPO-resistance indices in these patients. This finding is another indirect demonstration that o-Tyr may interfere with EPO signaling and lead to EPO resistance^[22].

VASCULAR INSULIN RESISTANCE ACCORDING TO THE O-TYR CONTENT OF THE VESSEL WALL

In a further set of experiments, we analyzed the o-Tyr levels in the blood vessel walls of rodents and found that the o-Tyr content of blood vessels decreases toward the peripheral vasculature (*i.e.*, thoracic aorta > abdominal aorta > femoral artery) (Figure 9A). The o-Tyr content could be increased by treatment with hydrogen peroxide and aminotriazole or by aortic banding, and it could be inhibited using superoxide dismutase and catalase (Figure 9B).

We have shown that vascular segments with higher o-Tyr content show lower vasorelaxation in response to insulin; *i.e.*, the insulin-induced vasorelaxation is lowest in the thoracic aorta, higher in the abdominal aorta and the highest in the femoral artery (Figure 10).

Furthermore, the insulin-induced relaxation could be increased by an antioxidant (superoxide dismutase and catalase) treatment in the thoracic aorta. By contrast, pro-oxidant therapy further diminished the vasorelaxation in an ERK1/2-dependent manner^[19].

VASCULAR ACETYLCHOLINE RESISTANCE ACCORDING TO THE O-TYR CONTENT OF THE VESSEL WALL

In the same set of experiments, the vasorelaxation in response to acetylcholine was also tested, and we also found an inverse relationship between the vessel wall o-Tyr content and the vasorelaxation in response to acetylcholine; *i.e.*, the blood vessels with high o-Tyr content (see Figure 9A) show less vasorelaxation in response to Ach (Figure 11, previously unpublished data).

Based on these experiments, we subjected rats

Figure 5 GLUT4 translocation (red fluorescence) after a 30 min treatment with insulin (400 nmol/L) or r-mo-erythropoietin (40 ng/mL) in 3T3-L1 adipocytes cultured in high glucose (25 mmol/L) or normal glucose (5 mmol/L) medium compared with that in untreated cells (Control). Nuclei are shown with blue fluorescence. The GLUT4 translocation was apparent after both the erythropoietin (EPO) and insulin treatments, whereas it was not present in untreated cells. Representative images are shown from $n = 3$ independent experiments. Republished with permission of Georg Thieme Verlag KG Stuttgart, New York from Mikolás *et al.*^[37].

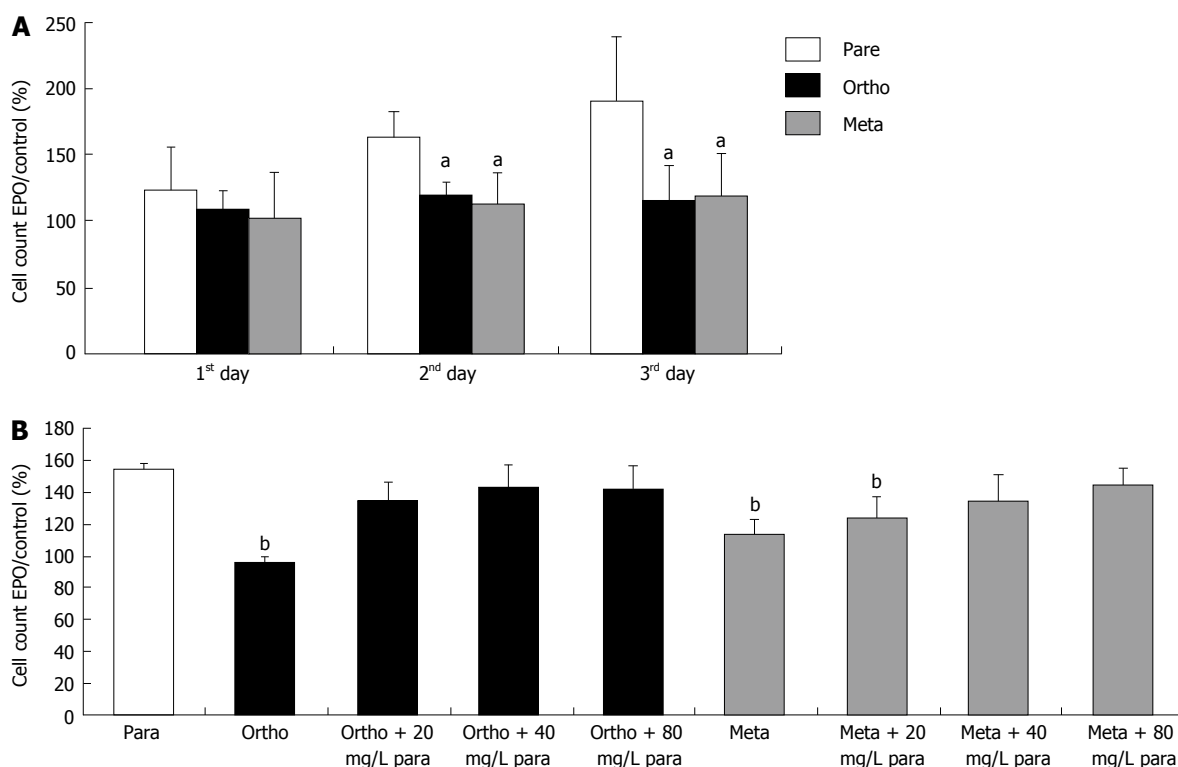

Figure 6 Effect of para-, ortho-, or meta-tyrosine supplementation on the proliferation of cells cultured in medium with or without erythropoietin. A: The time-dependent increase in cell count in medium supplemented with p-Tyr (open bars), o-Tyr (black bars) or m-Tyr (grey bars) ($^aP < 0.05$ vs p-Tyr cultured cells on the same day; $n = 10$); B: The alterations in the cell counts after incubation for 3 d in medium containing o- or m-Tyr and the indicated additional amount of para-tyrosine ($^bP < 0.001$ vs p-Tyr-containing medium; $n = 5$). The results are expressed as the ratio of the protein content of erythropoietin (EPO) and non-EPO (control) cells ($^aP < 0.05$ vs p-Tyr cultured cells; $n = 10$). Comparisons were performed using ANOVA and Bonferroni's post-hoc test. Republished with permission of S Karger AG, Basel from Mikolás *et al.*^[21]. p-Tyr: Para-tyrosine; o-Tyr: Ortho-tyrosine; m-Tyr: Meta-tyrosine.

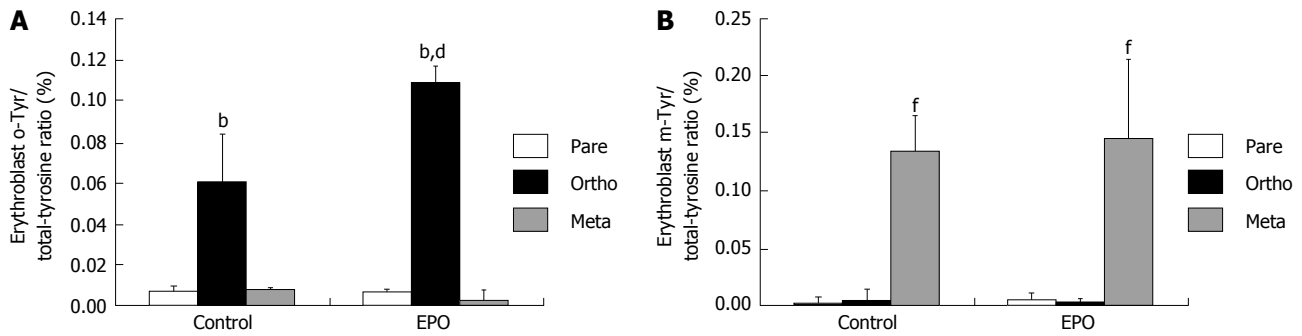

Figure 7 Relative meta- and ortho-tyrosine content (*i.e.*, ratios of meta- and ortho-tyrosine/total tyrosine) of the cellular proteins of TF-1 cells (**A** and **B**, respectively). ^b $P < 0.001$ vs p- and m-Tyr cultured cells; ^{b,d} $P < 0.001$ vs o-Tyr cultured control cells; ^f $P < 0.001$ vs p- and o-Tyr cultured erythroblasts; $n = 10$. Comparisons were performed using ANOVA and Bonferroni's post-hoc test. Republished with permission of S Karger AG, Basel from Mikolás *et al*^[21]. p-Tyr: Para-tyrosine; o-Tyr: Ortho-tyrosine; m-Tyr: Meta-tyrosine.

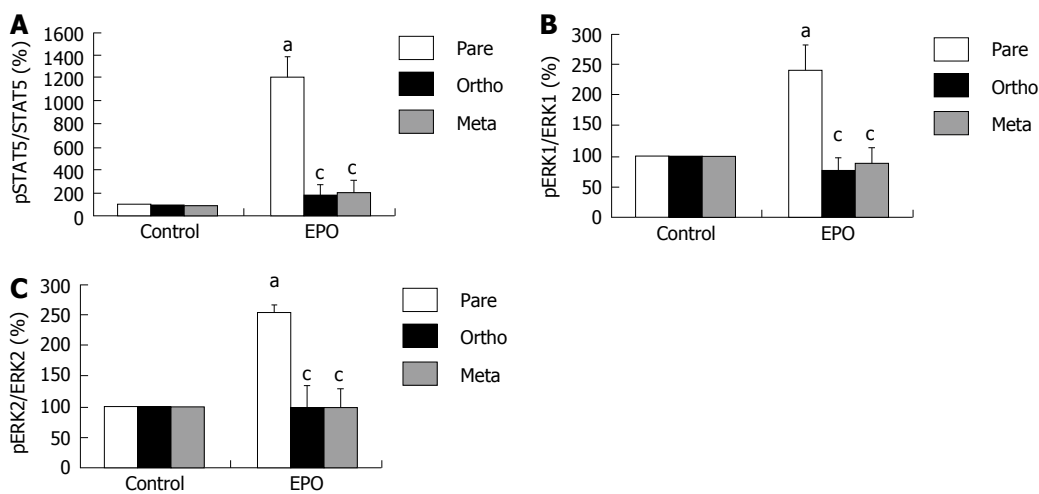

Figure 8 Densitometric analyses of the phosphorylation of signal transducer and activator of transcription 5 (**A**; $n = 3$); densitometric analysis of extracellular signal regulated kinase 1 (**B**; $n = 4$) and extracellular signal regulated kinase 2 (**C**; $n = 4$). The data are expressed as the percent of untreated (control) cells. ^a $P < 0.05$; erythropoietin (EPO) vs control (one-sample *t*-test); ^c $P < 0.05$ vs para EPO (one-way ANOVA). Republished with permission of S Karger AG, Basel from Mikolás *et al*^[21].

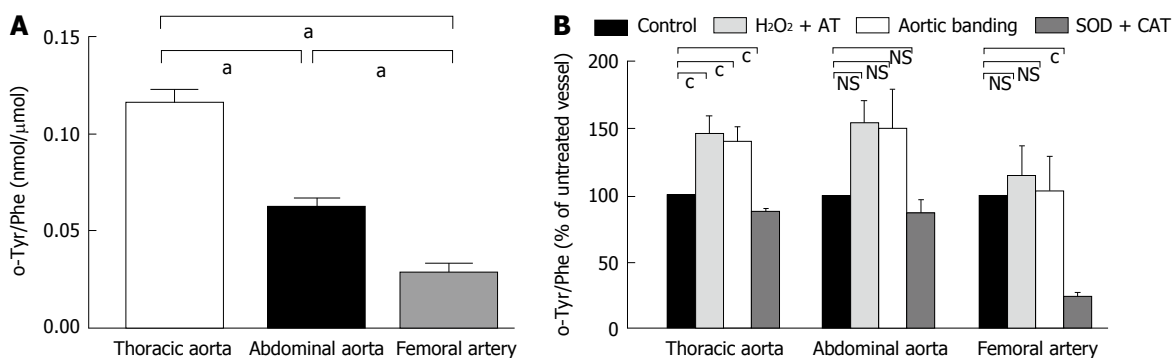

Figure 9 The ortho-tyrosine levels of consecutive arterial segments isolated from rats (**A**). There were significant differences (^a $P < 0.05$) in the o-Tyr levels among the thoracic aorta ($n = 7$), abdominal aorta ($n = 7$), and the femoral artery ($n = 9$) of rats. The changes in the o-Tyr levels in the consecutive arterial segments of rats after H₂O₂ + AT treatment (*i.e.*, high oxidative state), SOD + CAT treatment (*i.e.*, low oxidative state), and aortic banding were compared with those of the control vessels (**B**). Control: untreated, control vessels (thoracic: $n = 7$; abdominal: $n = 7$; femoral: $n = 9$); H₂O₂ + AT: hydrogen peroxide- and aminotriazole-incubated vessels (aminotriazole is an inhibitor of catalase) (thoracic: $n = 5$; abdominal: $n = 5$; femoral: $n = 4$); SOD + CAT: superoxide dismutase- and catalase-incubated vessels (thoracic: $n = 5$; abdominal: $n = 5$; femoral: $n = 5$); aortic banding (thoracic: $n = 5$; abdominal: $n = 4$; femoral: $n = 4$). Data are the mean \pm SEM. The o-Tyr levels are relative to the phenylalanine (Phe) levels (Panels A and B) and are expressed as the percentage of the control vessels (Panel B). ^c $P < 0.05$; NS, $P > 0.05$ (ANOVA). Republished with permission of Informa Healthcare from Szijártó *et al*^[19]. o-Tyr: Ortho-tyrosine; NS: Non-significant; SEM: Standard error of the mean.

to vehicle or o-Tyr supplementation for 4 wk. By the end of the 4 wk, we showed decreased vasorelaxation in response to insulin in the o-Tyr-supplemented rats

compared with the controls. Additionally, the endothelial cells that received o-Tyr supplementation incorporated o-Tyr into their cellular proteins. In these cells, the

Figure 10 The dose-response curve of the insulin-induced relaxation of consecutive arterial segments isolated from rats. The relaxation in response to insulin was the greatest in the femoral artery ($n = 7$) and was less pronounced in the abdominal aorta ($n = 7$) and even less in the thoracic aorta ($n = 7$). The relaxation is depicted as a function of the logarithm of the insulin dose. Data are the mean \pm SEM. $^aP < 0.05$; NS, $P > 0.05$ (Extra sum-of-squares F test). Republished with permission of Informa Healthcare from Szijártó *et al.*^[19]. NS: Non-significant; SEM: Standard error of the mean.

Figure 11 Acetylcholine-induced vasorelaxation in the abdominal aorta and femoral artery. Data are the means \pm SEM. $^aP < 0.05$; NS, $P > 0.05$ (Extra sum-of-squares F test). NS: Non-significant.

insulin-induced increase in endothelial nitric oxide synthase phosphorylation was diminished compared with that in the control cells^[20] (data not shown).

CONCLUSION

Our results, which are consistent with previous findings, indicate that m- and o-Tyr are valuable markers of oxidative stress and other types of stress in patients or experimental animals with DM. Furthermore, the results suggest that these unnatural amino acids may also perform a pathogenic role, *i.e.*, interfere with the signaling of three distinct hormones: insulin (vascular and perhaps metabolic signaling), acetylcholine and erythropoietin (also has metabolic effects). This inhibition may be even more pronounced in patients who have high levels of the pathological amino acids m- or o-Tyr (*e.g.*, in DM) and simultaneously have lower levels of physiological p-Tyr (*e.g.*, patients with impaired kidney function). This finding, together with the effect in which p-Tyr overcomes the inhibitory effect of m- and o-Tyr, raises the possibility that the physiological amino acid p-Tyr could be a therapeutic tool in hormone resistance in states with increased oxidative stress (*e.g.*,

in DM).

Abstract

The small GTPase Rab27a is a member of the Rab family that is involved in membrane trafficking in various kinds of cells. Rab27a has GTP- and GDP-bound forms, and their interconversion regulates intracellular signaling pathways. Typically, only a GTP-bound GTPase binds its specific effectors with the resulting downstream signals controlling specific cellular functions. We previously

identified novel Rab27a-interacting proteins. Surprisingly, some of these proteins interacted with GDP-bound Rab27a. The present study reviews recent progress in our understanding of the roles of Rab27a and its effectors in the secretory process. In pancreatic β -cells, GTP-bound Rab27a regulates insulin secretion at the pre-exocytotic stages *via* its GTP-specific effectors such as Exophilin8/Slac2-c/MyRIP and Slp4/Granuphilin. Glucose stimulation causes insulin exocytosis. Glucose stimulation also converts Rab27a from its GTP- to its GDP-bound form. GDP-bound Rab27a interacts with GDP-specific effectors and controls endocytosis of the secretory membrane. Thus, Rab27a cycling between GTP- and GDP-bound forms synchronizes with the recycling of secretory membrane to re-use the membrane and keep the β -cell volume constant.

INTRODUCTION

Diabetes mellitus is defined as chronic hyperglycemia due to relative insulin deficiency. Impairment of secretory activity in pancreatic β -cells plays an important role in the pathogenesis of this disease. In particular, decreased output in the early phase of glucose-induced insulin release precedes the onset of type 2 diabetes mellitus^[1,2]. Insulin secretion from pancreatic β -cells is finely tuned for glucose homeostasis by multiple physiological factors such as nutrients, hormones and neurotransmitters. Some of these factors induce or enhance insulin release whereas others decrease it, thereby enabling sophisticated glucose regulation. One characteristic of this regulation in pancreatic β -cells is the control of secretion by several nutrients. Glucose, the most important insulin secretagogue, stimulates insulin secretion mainly by the generation of ATP *via* glucose metabolism, although there appear to be other signaling pathways involved that have not been fully identified.

The insulin secretory process comprises insulin synthesis and its packaging into secretory granules, granule transport in the cytoplasm, interaction with the cell membrane, exocytosis as a result of an increase in cytoplasmic Ca^{2+} , endocytosis and retrograde transport. The present study reviews recent progress in our understanding of the roles of the small GTPase Rab27a and its effectors in the secretory process.

SMALL GTPASE CYCLE

Small GTPases are GTP-binding proteins with molecular masses ranging from 20 to 30 kDa. These proteins, comprising Ras, Rho, Rab, Ran and Sar/Arf, are expressed in almost all eukaryotic cells and participate in a wide variety of cellular functions including proliferation, cytoskeletal rearrangement and intracellular transport^[3]. Small GTPases have GTP- and GDP-bound forms, and their interconversion regulates intracellular signaling pathways (Figure 1). Typically, only the GTP-bound small GTPase binds its specific effectors and the resulting downstream signals control specific cellular functions^[4]. Therefore, GTP- and GDP-bound small GTPases are considered as active and inactive forms, respectively. The activation of small GTPases is modulated by guanine nucleotide exchange factors (GEFs), GTPase-activating proteins (GAPs), and GDP-dissociation inhibitors (GDIs). Small GTPases localize in the cytosol as a GDP-bound form under unstimulated conditions. Cell stimulation recruits GDP-bound small GTPases to the vicinity of the plasma membrane and converts them to the GTP-bound form through the action of GEFs^[4,5]. These GTP-bound forms interact with their specific effectors and transduce signals. GAPs promote the intrinsic GTPase activity of small GTPases and induce the conversion of the GTP- to the GDP-bound form^[4,6]. GDIs form a complex with GDP-bound small GTPases and induce their intracellular redistribution from the

plasma membrane to the cytosol^[7-9].

RAB27A

The Rab family, which consists of more than 60 members, regulates membrane trafficking^[10-12]. Rab27 is a Rab-family member that controls vesicle transport in various kinds of cells^[13]. There are two isoforms of Rab27; Rab27a and Rab27b. Mutations in Rab27a have been reported to cause Griscelli syndrome^[14]. This disorder results in pigment dilution in the skin and the hair. The same symptoms are observed in ashen mice with a natural mutation in Rab27a^[15]. To date, three forms of Griscelli syndrome have been reported. Mutations in Myosin Va^[14,16-18], Rab27a^[14,15], and its effector Slac2-a/melanophilin^[19,20] cause type 1 (GS1), type 2 (GS2), and type 3 (GS3) Griscelli syndrome, respectively. These proteins play an important role in melanosome transport in melanocytes. Peripheral melanosome distribution is regulated by the molecular motor protein myosin Va. GTP-bound Rab27a localizes on the surface of melanosomes where it interacts with Slac2-a/melanophilin. Since Slac2-a/melanophilin binds myosin Va, this complex functions as a linker protein between the melanosome and the motor protein^[10,21,22]. GTP-bound Rab27 also interacts with another effector protein Slp2-a, thereby regulating docking of the melanosome to the plasma membrane^[23].

Griscelli syndrome also results in immunodeficiency^[14,17]. Exocytosis of granzyme-A-containing granules is decreased in ashen mice cytotoxic T lymphocytes^[24,25]. Although both Rab7 and Rab11 are also present on the surface of these granzyme-A-containing granules, Rab27a is the main regulator of granule exocytosis^[26]. Indeed, GTP-bound Rab27a interacts with phosphatidylinositol 4,5-bisphosphate (PIP₂) *via* its effector protein Munc13-4 and regulates the docking of the granules to the synapse. These results suggest that Rab27a regulates the secretion of lytic granules in cytotoxic T lymphocytes.

Rab27b, a closely related isoform of Rab27a, also participates in intracellular transport and secretion. Rab27b and its effector proteins including Slac2-c and Slp4-a are expressed in parotid acinar cells^[27]. In these cells, GTP-bound Rab27a interacts with both Slac2-c and Slp4-a. Amylase release was inhibited when streptolysin O-permeabilized cells were treated with anti-Slac2-c antibody^[28]. Amylase release was also inhibited when the Rab27b/Slp4-a complex was dissociated with a GST-Slp4-a-linker^[29]. Isoproterenol (IPR) stimulation promoted intracellular redistribution of Slac2-c from the cytosol to a luminal site^[30]. Since Slac2-c potentially interacts with Myosin Va, it is possible that the Rab27b/Slac2-c complex regulates F-actin-dependent intracellular transport of secretory vesicles. In contrast, the intracellular distribution of Slp4-a was not changed in the presence or absence of IPR stimulation^[30]. The Rab27b/Slp4-a complex may regulate docking of the secretory vesicles to the membrane^[31].

Amylase is also released from pancreatic acinar

Figure 1 Small GTPase GTP/GDP cycle. Small GTPases localize in the cytosol as a GDP-bound form under unstimulated conditions. Cell stimulation recruits GDP-bound small GTPases to the vicinity of the plasma membrane and converts these proteins to the GTP-bound form through GEF activity. The GTP-bound form interacts with its specific effectors and thereby transduces signals. GAPs promote the intrinsic GTPase activity of small GTPases and induce conversion of the GTP- to the GDP-bound form. GDIs form a complex with GDP-bound small GTPases and induce their intracellular redistribution from the plasma membrane to the cytosol. GEFs: Guanine nucleotide exchange factors; GAPs: GTPase-activating proteins; GDIs: GDP-dissociation inhibitors.

cells in which Rab27b is localized on the surface of zymogen granules^[32]. Rab27b-Q78L, a constitutively active Rab27b mutant, enhances amylase release. In contrast, Rab27b-N133I, a dominant negative mutant, inhibits amylase release. These results suggest that Rab27b regulates amylase release in pancreatic acinar cells. Exophilin7/Slp1/JFC1 is a GTP-bound Rab27a interacting protein. The number of zymogen granules was increased in the pancreatic acinar cells of fasted Exophilin7/Slp1/JFC1-KO mice^[33]. Moreover, amylase release was promoted in pancreatic acinar cells from Exophilin7/Slp1/JFC1-KO mice that were treated with carbamylcholine chloride or cholecystokinin-8, which mimic fed conditions. Thus, Rab27b may be involved in amylase release *via* Exophilin7/Slp1/JFC1 in pancreatic acinar cells.

Rab3a, which has the highest homology to Rab27, is highly expressed in synaptic vesicles^[27]. In PC12 cells, Rab27a and Rab3a are co-localized on the surface of dense-core granules^[34]. Silencing of both Rabs caused a significantly greater decrease in the number of these granules docked to the plasma membrane compared to silencing of either Rab alone. Since, Rab27a and Rab3a interact with the same effector proteins, these Rabs must cooperatively regulate the docking step of dense-core granules. In contrast, each of these Rabs has a specific function in pancreatic β -cells^[35]. Rab3a-GAP inhibited the dot-like distribution of Rab3a in the insulin-secreting β -cell line MIN6. In contrast, the distribution of Rab27a was not changed in Rab27a-GAP expressing

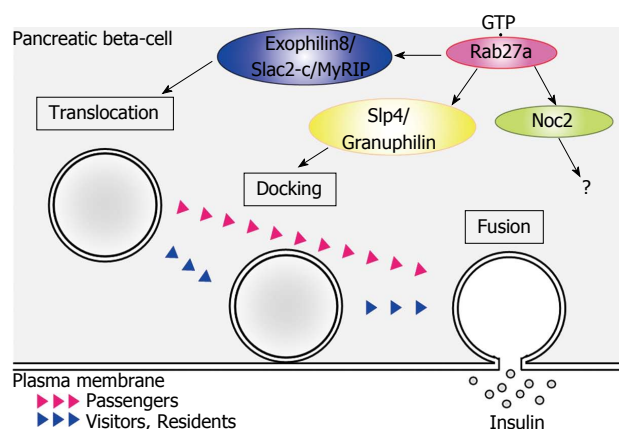

Figure 2 Schematic model of GTP-bound Rab27a function in pancreatic β -cells. Insulin-containing granules transported in the cytoplasm attach to the inner surface of the cell membrane (docking). The contents of both docked and undocked granules are eventually released following elevation of intracellular Ca^{2+} levels. GTP-bound Rab27a regulates insulin secretion by modulating the granule transport and docking steps *via* its effector proteins. Residents are granules that are pre-docked to the plasma membrane before fusion. Passengers are granules that fused without stably docking. Visitors are granules that remain near the plasma membrane for some time before fusion.

cells. Furthermore, whereas Rab3a is localized on insulin granules as a GTP-bound form, the Rab27a on these granules is present as both GTP- and GDP-bound forms. Moreover, these Rabs direct unique kinetic and functional properties of the exocytic pathway.

RAB27A IN PANCREATIC β -CELLS

Rab27a is highly expressed in pancreatic β -cells and is involved in insulin secretion^[36]. In ashen mice, blood glucose levels after a glucose load were higher, and insulin secretion in response to high glucose was lower than that in control mice. Interestingly, the decrease in insulin secretion was specific to glucose stimulation. These data suggest that Rab27a signaling in pancreatic β -cells is glucose-specific.

Insulin granules that are synthesized in pancreatic β -cells are eventually released by exocytosis *via* a series of stages (Figure 2). Granules that are transported in the cytoplasm attach to the inner surface of the cell membrane (docking). The contents of both docked and undocked granules are eventually released following elevation of intracellular Ca^{2+} levels. The granules are categorized into three types^[37,38]. Residents are granules that are pre-docked to the plasma membrane before fusion. Passengers are granules that fused without stably docking. Visitors are granules that remain near the plasma membrane for some time before fusion. GTP-bound Rab27a regulates insulin secretion by modulating the transport and docking steps of insulin granules *via* its effector proteins (Table 1)^[39-41]. To date, Exophilin8/Slac2-c/MyRIP, Slp4/Granuphilin, Exophilin7/Slp1/JFC1 and Exophilin1/Rabphilin3A are known to act as GTP-dependent Rab27a effectors in pancreatic β -cells. Exophilin8/Slac2-c/MyRIP possesses a potential

Table 1 GTP-bound Rab27a effectors in pancreatic β -cells

GTP-bound Rab27a effectors	Interacting proteins	Function
Exophilin8/Slac2-c/MyRIP	Myosin Va, Actin, PKA	Translocation
Slp4/Granuphilin	Munc18-1, Syntaxin1a, Myosin Va	Docking
Noc2	Munc13-1	-
Exophilin7/Slp1/JFC1	-	Docking
Exophilin1/Rabphilin3A	Myosin Va	Translocation

Table 2 GDP-bound Rab27a effectors in pancreatic β -cells

GDP-bound Rab27a effectors	Interacting proteins	Function

IQGAP1	GTP-bound Cdc42 GTP-bound Rac1	Scaffold

myosin binding site. Although Exophilin8/Slac2-c/MyRIP functions as a linker protein between GTP-bound Rab27a and Myosin Va in melanocytes^[42,43], this effector may form a different complex in pancreatic β -cells. Indeed, some reports suggest that there are several conditions under which Exophilin8/Slac2-c/MyRIP does not interact with Myosin Va^[44]. Slp4/Granuphilin and Exophilin1/Rabphilin3A interact with Myosin Va in pancreatic β -cells^[45]. Moreover, they are linked to a different subset of insulin granules. Further studies are required to investigate the regulation of the transport of insulin granules to the plasma membrane.

Slp4/Granuphilin was identified as a molecule that associates with insulin granules in pancreatic β -cells^[46]. This molecule forms a complex with Syntaxin1a and Munc18-1 and regulates the docking step of insulin granules in the insulin secretion pathway^[47]. The number of insulin granules docked to the plasma membrane was decreased in pancreatic β -cells from Slp4/Granuphilin-KO mice^[48]. Interestingly, insulin secretion was promoted in these mice. These results suggest that Slp4/Granuphilin regulates the docking state and inhibits the fusion of the insulin granule membrane and the plasma membrane in unstimulated pancreatic β -cells (Figure 2). Exophilin7/Slp1/JFC1 also tethers insulin granules to the plasma membrane^[49]. There seem to be multiple docking states of insulin granules in pancreatic β -cells.

Noc2 is a potential Rab27a effector. Noc2 displays 78% similarity to the N-terminus of Exophilin1/Rabphilin3A^[50]. Ca^{2+} triggered insulin secretion from pancreatic islets of Noc2-KO mice was impaired, but was restored by treatment with the G-protein inhibitor pertussis toxin^[51]. Although Noc2 is involved in insulin secretion through G-protein Gi/o signaling, its role in pancreatic β cells has not been identified. A yeast two-hybrid experiment identified zyxin as a Noc2-interacting protein. Because zyxin has been reported to bind the actin-binding protein α -actinin in fibroblasts^[50], the interaction between Noc2 and zyxin may regulate insulin secretion by modulating actin dynamics in

pancreatic β -cells.

GDP-DEPENDENT EFFECTORS OF RAB27A

We have identified novel Rab27a-interacting proteins. Surprisingly, some of these proteins interacted with GDP-bound Rab27a (Table 2)^[52,53]. Since GDP-bound GTPases have been considered to be an inactive form, these proteins might be suspected to be regulators of Rab27a GTP/GDP cycles. Indeed, protrudin, which was identified as a GDP-bound small GTPase interacting protein, forms a complex with GDP-bound Rab11 *via* its GDI consensus sequence and regulates neurite formation^[54]. Therefore, protrudin is thought to be a GDI that regulates GTPase cycles. In contrast, the GDP-bound Rab27a interacting proteins that we identified do not contain any GDI consensus sequences. Moreover, these proteins interact with GDP-bound Rab27a and transduce downstream signals in a similar manner to classical GTP-dependent effectors of small GTPases. We consider that these proteins are GDP-dependent effectors of Rab27a^[40,41].

Coronin 3

We identified coronin 3 as a GDP-bound Rab27a interacting protein^[52]. Coronins have been purified from precipitated actin of *Dictyostelium discoideum* cells^[55]. To date, more than ten coronin subfamilies have been reported. Coronin 3 is a ubiquitously expressed coronin that shares a central domain with other coronin family members that contains five WD40 repeats, which are known to form β -propeller structures and to mediate protein-protein interactions (Figure 3). Initially, these repeats were thought to form a five-bladed β -propeller structure. However, recent studies of coronin structure demonstrated that the N-terminal region of coronin forms two additional blades (not identified from the sequence). Therefore, coronin 3 is now considered to possess a seven-bladed β -propeller structure^[56,57]. It was noted that this propeller structure of coronin 3 is a GDP-bound Rab27a binding site^[52]. Oligomerization of coronins and their interaction with F-actin are mediated by the C-terminal 30-40 amino acids, which form a coiled-coil structure. These interactions modulate actin assembly and participate in various cellular functions. Human coronin 3 also modulates F-actin through binding to Arp2/3^[57], a key protein in the formation of a branched actin filament network^[57-59]. These direct and indirect modulations of F-actin must play a crucial role in the cellular function of coronins, because they are conserved in eukaryote cells^[60]. Both F-actin-binding and -bundling activities of coronin 3 were promoted by its interaction with GDP-bound Rab27a^[61]. In contrast, GDP-bound Rab27a did not affect the interaction between coronin 3 and Arp2/3. GDP-bound Rab27a regulates F-actin bundling by modulating a direct effect of coronin 3 on F-actin (Figure 3).

Figure 3 Interplay between Rab27a, coronin 3 and IQGAP1. GDP-bound Rab27a simultaneously binds coronin 3 and IQGAP1, resulting in the formation of a trimeric complex. WD: Five WD40 repeats; CHD: Calponin homology domain; NTR: N-terminal repeats; IQR: IQ repeats; GRD: RasGAP related domain; CT: Carboxy terminus of IQGAP1.

Coronins regulate membrane internalization in some types of cells through F-actin remodeling. In pancreatic β -cells, silencing of coronin 3 inhibited the internalization of both FM4-64 and phogrin^[52]. Internalization of these molecules was also inhibited when Rab27a-coronin 3 binding was inhibited by a dominant negative mutant of coronin 3. Moreover, the inhibition of F-actin binding to coronin 3 had the same effect^[61]. Thus, coronin 3 regulates the endocytosis of secretory membranes *via* the modulation of actin assembly in pancreatic β -cells.

Endocytosis is a complex process that involves cargo sorting, membrane invagination, vesicle scission and vesicle targeting (Figure 4). The uptake of an antibody against the extracellular domain of phogrin was inhibited and phogrin was located near the plasma membrane in MIN6 cells expressing a dominant negative mutant of coronin 3^[62]. Interestingly, phogrin staining near the plasma membrane remained when the cells were treated with acid wash, suggesting that the anti-phogrin antibody near the plasma membrane is separated from the plasma membrane. Thus the formation of GDP-bound Rab27a-coronin 3 complexes regulates the retrograde transport of internalized secretory membrane, at a stage after scission from the plasma membrane.

Insulin secretagogue glucose stimulation induced the intracellular redistribution of both Rab27a and coronin 3 from the cytosol to the plasma membrane^[62]. These redistributions were inhibited in Rab27a-silenced and Rab27a-Q78L-expressing MIN6 cells. Glucose-induced translocation of coronin 3 is due to its interaction with GDP-bound Rab27a. It has been reported that coronin 3 forms a closed conformation through an intramolecular interaction between its C- and N-termini^[59]. Therefore, the glucose-dependent binding of its N-terminus to GDP-Rab27a may shift coronin 3 to the open conformation, which enables this molecule to interact with F-actin^[41].

Figure 4 Schematic model of GDP-bound Rab27a function in pancreatic β -cells. Endocytosis is a complex process that involves cargo sorting, membrane invagination, vesicle scission and vesicle targeting. GDP-bound Rab27a modulates F-actin assembly and regulates the retrograde transport of the internalized secretory membrane, at the stage after scission from the plasma membrane. Scission is indicated by the dynamin step.

IQGAP1

We identified IQGAP1 as another GDP-bound Rab27a interacting protein^[53]. IQGAP1, an effector for Cdc42 and Rac1, is a member of the IQGAP family^[63]. IQGAP1 regulates cell-cell contacts and cell migration^[64-70]. In pancreatic β -cells, IQGAP1 interacts with vesicle-tethering exocysts under basal conditions. Moreover, this IQGAP-exocyst complex is dissociated by GTP-bound Cdc42^[71]. GTP-bound Cdc42 regulates insulin secretion by modulating F-actin bundling^[72,73]. Active Cdc42 also interacts with SNARE proteins such as VAMP2 and Syntaxin1a, and promotes the fusion step in insulin secretion^[74]. Since glucose converts Cdc42 from the GDP- to the GTP-bound form^[75], the IQGAP1-vesicle tethering exocyst complex is dissociated by glucose. It has been reported that vesicle-tethering to the plasma membrane is not a prerequisite for, but instead temporarily inhibits glucose-induced membrane fusion^[37]. This finding raises the possibility that the IQGAP1-exocyst complex may inhibit subsequent fusion events. IQGAP1 also binds A kinase anchoring protein 79 and functions as a scaffold protein^[76].

IQGAP1 binds GDP-bound Rab27a through its RasGAP related domain (Figure 3)^[53]. This domain lacks GAP activity and forms part of the GTP-bound Cdc42 and Rac1 interacting site^[63,70,77]. Moreover, IQGAP1 interacts with GDP-bound Rab27a when it forms a complex with GTP-bound Cdc42^[53]. IQGAP1 is distributed in the vicinity of the plasma membrane in both glucose-stimulated and -unstimulated cells. In contrast, glucose-induced redistribution of Rab27a and its binding protein coronin 3 was inhibited in both IQGAP1-silenced cells and in cells expressing the dominant negative mutant Cdc42-T17N. Since endocytosis of secretory membrane was also inhibited in these cells, these data indicate that activated Cdc42-bound IQGAP1, to which GDP-bound Rab27a binds,

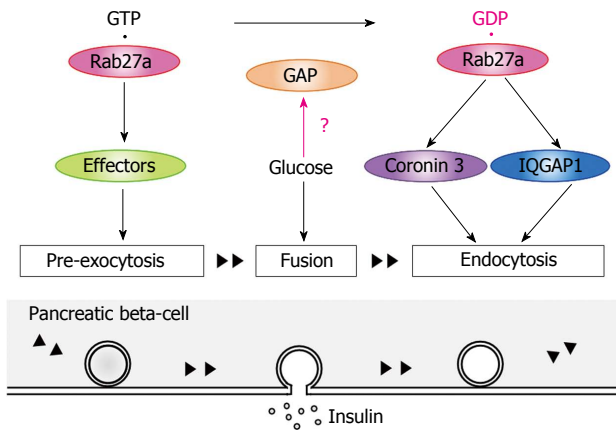

Figure 5 Rab27a GTP/GDP cycling synchronizes with the recycling of secretory membrane. In the basal state, GTP-bound Rab27a controls insulin secretion at pre-exocytotic stages *via* its GTP-specific effectors. Glucose stimulation causes insulin exocytosis. Glucose stimulation also converts Rab27a from its GTP- to its GDP-bound form. GDP-bound Rab27a interacts with IQGAP1, recruits coronin 3, and controls endocytosis of the secretory granule membrane. GAPs: GTPase-activating proteins.

recruits endocytic machinery including coronin 3 and regulates endocytosis of secretory membrane.

In summary, IQGAP1 functions at pre-exocytotic stages *via* interaction with the exocyst complex^[71] and this complex is dissociated by GTP-bound Cdc42. Our results indicate that IQGAP1 also plays a crucial role in the control of endocytosis *via* interaction with GTP-bound Cdc42 and GDP-bound Rab27a^[53]. Based on the combined data, we propose a model where IQGAP1 functions as a scaffold protein and is a key molecule for membrane recycling.

IQGAP1 also interacts with GTP-bound Rac1^[63,77]. Interestingly, IQGAP1 interacts with GDP-bound Rab27a when it forms a complex with GTP-bound Rac1^[53]. Moreover, endocytosis of secretory membrane was inhibited in MIN6 cells expressing the dominant negative Rac1-T17N mutant. These results suggest that Rac1 also recruits endocytic machinery and regulates endocytosis of secretory membrane. Cdc42 and Rac1 display some different characteristics in pancreatic β -cells. The most important difference is the timing of the glucose-induced conversion from the GDP- to the GTP-bound form. Glucose stimulation causes a shift from GDP-bound Cdc42 to GTP-bound Cdc42 within 3 min. In contrast, the glucose induced conversion of GDP- to GTP-bound Rac1 requires 20 min^[73,75]. These findings raises the possibility that Cdc42 regulates rapid endocytosis whereas Rac1 regulates subsequent, prolonged endocytosis, a pattern that may be associated with the biphasic release of insulin in response to glucose.

CONCLUSION

In the basal state, GTP-bound Rab27a controls insulin secretion at pre-exocytotic stages *via* its GTP-specific effectors (Figure 5). Glucose stimulation causes insulin exocytosis. Glucose stimulation also converts Rab27a

from its GTP- to its GDP-bound form, which interacts with IQGAP1, recruits coronin 3, and controls endocytosis of the secretory granule membrane. A long-term overexpression of a dominant negative coronin 3 mutant caused β -cell death (unpublished data), suggesting that the membrane recycling system controlled by Rab27a may be necessary for β -cell survival. Thus, we consider that Rab27a GTP/GDP cycling synchronizes with the recycling of secretory membrane to re-use the membrane and to keep the β -cell volume constant. It raises the possibility that a pharmacological agent that modulates the recycling system may become a new therapeutic option for the treatment of β -cell dysfunction in diabetes. Further studies are required to investigate whether Rab27a is involved in the pathogenesis of diabetes mellitus.

Typically, small GTPases are predominantly present in the GDP-bound form under unstimulated conditions and are converted to the GTP-bound form by stimulation. In contrast, glucose stimulation causes a shift of Rab27a in pancreatic β -cells from its GTP- to its GDP-bound form^[52]. The same conversion also occurs in thrombin stimulated platelets^[78]. These findings suggest that specific Rab27a-GAPs are activated by these stimulations. Two candidate Rab27a-GAPs, EPI64A and EPI64B, have been reported^[79]. In melanocytes, EPI64A has the higher GAP activity and functions as the main Rab27a-GAP. In pancreatic acinar cells, EPI64B regulates amylase secretion by modulating Rab27a GTP/GDP cycles^[80]. Further studies are needed to identify and characterize Rab27a-GAPs in pancreatic β -cells.

Abstract

Eating disorders (ED) are characterized by a persistent disturbance of eating that impairs health or psychosocial functioning. They are associated with increased rates of medical complications and mortality. Insulin omission is a unique purging behavior available to individuals with type 1 diabetes mellitus (T1DM). The standard treatment regimen for T1DM requires a major focus on food and

eating patterns. Moreover, intensive insulin therapy is associated with increasing body weight. These factors, combined with the psychological burden of chronic disease management and depression, may contribute to ED. The comorbidity of ED in T1DM patients is associated with poorer glycemic control and consequently higher rates of diabetes complications. Early recognition and adequate treatment of ED in T1DM is essential.

Key words: Type 1 diabetes; Eating disorders; Insulin omission

Core tip: Intentional insulin omission for the purpose of preventing weight gain is a unique behavior available to individuals with type 1 diabetes mellitus (T1DM). It is classified as either an inappropriate compensatory feature of bulimia nervosa or as a purging disorder component of other specified feeding or eating disorder (ED). Its prevalence increases with age, affecting up to 40% of young adult females with T1DM. The comorbid of ED in T1DM patients is associated with higher rates of short and long-term diabetes complications. A high index of suspicion is needed since ED behaviors are often well hidden and denied. Treatment involves a complex interplay of psychosocial, dietary and medical aspects and requires a multidisciplinary team.

Pinhas-Hamiel O, Hamiel U, Levy-Shraga Y. Eating disorders in adolescents with type 1 diabetes: Challenges in diagnosis and treatment. *World J Diabetes* 2015; 6(3): 517-526 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/517.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.517>

DEFINITIONS OF EATING DISORDERS

Eating disorders (ED) are characterized by a persistent

disturbance of eating that impairs health or psychosocial functioning^[1,2]. Based upon the fifth edition of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-V), which was released in May 2013, ED are divided into eight mutually exclusive categories^[3]. These categories are based upon observed symptoms and include anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder, avoidant/restrictive food intake disorder, pica, rumination disorder, other specified feeding or eating disorder (OSFED) and unspecified feeding or eating disorder. Some diagnoses include a dimensional component that enables clinicians to specify the severity of illness^[4-6].

In patients with type 1 diabetes mellitus (T1DM), intentional insulin omission or reduction for the purpose of preventing weight gain is recognized as either an inappropriate compensatory feature of bulimia nervosa or as a purging disorder, a component of OSFED. The latter is relevant when the recurrent purging behavior to influence weight or shape (*e.g.*, insulin omission) occurs in the absence of binge eating.

The two categories: "eating disorders not otherwise specified (EDNOS)" and "disturbed eating behavior (DEB)", compromised a wide spectrum of eating disorder pathologies, at a frequency or severity that does not merit a formal ED diagnosis. Though these categories are not included in DSM-V, they appear in the current review, due to their use by several studies involving individuals with diabetes.

ARE ADOLESCENTS WITH T1DM AT INCREASED RISK TO DEVELOP ED?

This question should be answered for the specific ED studied, according to the tools used for assessment and the prevalence rates in the general population.

Diagnostic tools of ED in persons with T1DM

The diagnosis of ED in individuals with T1DM is difficult, since eating behaviors are often well hidden and denied. The use of different questionnaires for assessing prevalence rates of ED makes comparisons across studies difficult. Furthermore, as Markowitz *et al.*^[7] pointed out, that general diagnostic questionnaires for detecting ED are not appropriate for individuals with T1DM for two main reasons. Firstly, these questionnaires do not identify eating disorder behaviors that are unique to T1DM, such as insulin omission^[7]. Secondly, such questionnaires may inflate the prevalence of eating problems in those with T1DM, because behaviors that are considered disturbed, such as particular concern about diet, reduced intake of certain food groups, and eating when not hungry, are integral to diabetes care^[8].

Prevalence rates of ED among persons with T1DM

Prevalence rates of ED among persons with T1DM vary according to the different ED categories and the populations studied. Some studies examined prevalence

rates of AN and BN only, while others examined the prevalence of insulin omission only, and some reported the prevalence of a combination of all ED together. Some studies reported the prevalence of full-threshold diagnoses of ED, whereas others also included subclinical ED. Reported prevalence rates differ also according to characteristics of the study populations, such as age range, and whether males were included or only females.

Prevalence of AN: A meta-analysis of controlled studies that defined ED in females according to DSM III-R or DSM IV criteria reported the prevalence of AN in T1DM subjects was not significantly different from that of controls^[9].

Prevalence of BN: This same meta-analysis showed a significantly higher prevalence of BN among the females with T1DM than those without diabetes^[9].

Overall prevalence of AN, BN and EDNOS: In a recently published meta-analysis^[10] of six studies of adolescents^[11-16], 7.0% of the 825 individuals with T1DM had ED, compared with 2.8% of the 2282 individuals without T1DM.

Prevalence of DEB: In a meta-analysis^[10] of five studies^[11,15-18], a higher proportion of adolescents with T1DM than without T1DM were classified as having DEB (39.3% vs 32.5%). The prevalence rate of DEB increased significantly with weight and age, from 7.2% in the underweight group to 32.7% in the obese group, and from 8.1% in the youngest age-group (11-13 years) to 38.1% in the oldest age-group (17-19 years)^[19].

Prevalence of insulin omission in T1DM: Insulin omission is a unique purging behavior available to individuals with T1DM. As presented in Table 1, insulin omission for weight loss is identified mainly in females; its prevalence increases with age, affecting up to 40% of young adult females with T1DM.

PREDISPOSING FACTORS FOR DEVELOPING ED

We suggest a three level model to describe the development of disturbed eating in adolescents with T1DM. This model comprises a hierarchically arranged continuum of potential effects on health problems (Figure 1). The first circle in the model, the premorbid status, includes a tendency to overweight, and factors relating to personality and family characteristics and dynamics. The second circle comprises factors arising at diagnosis of diabetes, such as the age of diabetes onset and satisfaction from weight loss. The third circle comprises factors associated with the chronic management of diabetes, such as recurrent hypoglycemic episodes,

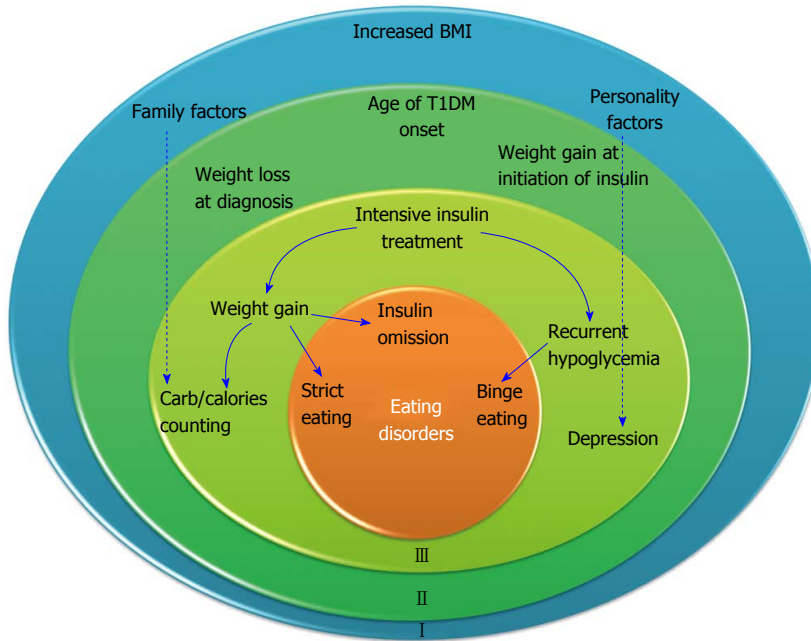

Figure 1 Three level models describing the development of eating disorders in adolescents with type 1 diabetes mellitus. The outer circle delineates the premorbid status. The middle circle delineates weight changes at diagnosis and with initiation of treatment. The inner circle includes factors associated with the management of T1DM that predispose to eating disorders. Dashed arrows imply that the specific factor extends on all levels. T1DM: Type 1 diabetes mellitus; BMI: Body mass index.

Table 1 Prevalence rates of insulin omission according to age range and gender

Prevalence of insulin omission (%)	Age range (yr)	Number and sex	Ref.
2	9-13	101 females	Colton <i>et al</i> ^[12]
26.2	11-19	390 females	Wisting <i>et al</i> ^[19]
4.5		380 males	
11	12-19	361 females	Jones <i>et al</i> ^[11]
14	12-19	356 females	Rodin <i>et al</i> ^[61]

11	12-56	141 females	Philippi <i>et al</i> ^[75]
0		58 males	

strict insulin treatment and carbohydrate counting.

FIRST CIRCLE - PREMORBID FACTORS

Increased body weight and a tendency to gain weight

It has been suggested that the single question "Have you ever been overweight?" may be sufficient to screen for those with T1DM who are at a high risk for disordered eating attitudes/behaviors^[20]. Indeed, adolescent girls with T1DM who reported ever being overweight endorsed more disordered eating attitudes and behaviors^[21]. In addition, a higher body mass index percentile among teenagers and adults with T1DM, particularly among females, one to two years prior to the onset of ED, was found to be associated with disordered eating^[22]. Furthermore, youth at risk for disordered eating have been shown to have poorer

diet quality, including a higher intake of total fat and saturated fat^[23].

Low self-esteem and body dissatisfaction

Higher levels of weight dissatisfaction tended to be associated with unhealthy weight control/disordered eating among adolescent females^[24]. Low self-esteem predicts eating disturbances in the general population. Lower self-esteem was associated with disturbed eating behavior in girls with T1DM^[25]. Of note, low self-esteem and body dissatisfaction could also arise along the course of the disease. In a longitudinal study the development of DEB in girls with T1DM, was predicted by lower self-esteem related to physical appearance, and lower global self-esteem^[26].

Personality characteristics

Perfectionism has been associated with attitudinal aspects of eating disorders such as weight preoccupation. Borderline personality characteristics were related to insulin omission^[27]. Adolescent girls with T1DM and an ED showed deficits in self-regulation and narcissistic gain from illness^[28], and tended to blame themselves for the situation^[29].

Comparing adolescents with ED and adolescents with T1DM and ED, those with T1DM were less pathologically compromised, scored lower on several affective areas and had a lower prevalence of depression and anxiety^[30].

Family characteristics and dynamics

Several factors involving family characteristics and dynamics are associated with an increased risk for ED. Firstly, in many families of adolescent girls with T1DM,

interactions within the family center around food and weight. The prevalence of ED was found to be higher in families in which parents tended to make negative comments about eating or weight^[31]. Secondly, mothers who engaged in dieting and binge-eating themselves were more likely to have daughters with disturbed eating behavior. Maternal weight and shape concerns and impaired mother-daughter relationships significantly predicted eating disturbances in girls with T1DM, accounting for 57% of the variance^[32]. Finally, family dysfunctioning has been identified as an important risk factor for eating disorders among the general population. Specifically, among girls with T1DM, less support from, poorer communication with, and less trust in their relationships with their parents, were reported among those with eating disturbances than among those without^[33]. Families of girls with ED more often reported having infrequent family meals than did families without ED^[34].

SECOND CIRCLE - FACTORS ASSOCIATED WITH DISEASE ONSET

Age of diabetes onset

The age of onset of T1DM that is most closely related to the subsequent development of a severe eating disorder such as AN and BN was studied in 53 women with ED compared with 49 with T1DM who had no eating disorder - related problem^[35]. It was demonstrated that for diabetes onset age between 7 to 18 years, the density of the "eating disorder" group was higher, but for the younger and older onset ages the densities were lower. Thus the development of T1DM in preadolescence or adolescence seems to place girls at risk for the subsequent development of AN or BN. Similarly, frequent insulin reduction or omission was reported in type 1 diabetic patients with later disease onset (mean age at onset between 8 and about 17 years)^[36]. It was suggested that later age at diabetes onset, in particular during pubertal age with hormonal changes and gain in weight and fat mass may be associated with a greater risk for ED especially in female patients.

Weight issues

The cycle of weight loss at disease onset and subsequent weight gain with the initiation of insulin treatment is a risk factor for the development of ED in susceptible patients^[11].

THIRD CIRCLE - FACTORS ASSOCIATED WITH THE CHRONIC MANAGEMENT OF DIABETES

Intensive insulin treatment

Intensive insulin treatment conveys an increased risk of weight gain^[37]. A model of disordered eating and T1DM

proposed by Goebel-Fabbri *et al.*^[38,39] suggests that the increased weight gain causes negative feelings. Fear of further weight gain can lead to insulin restriction for caloric purging or weight regulation^[40].

Dietary restraint

Diabetes management imposes dietary restraint. This may lead to the yearning and craving of "forbidden foods", and result in bingeing, without administration of the appropriate insulin dose^[41].

Hypoglycemic episodes

The delicate balance between dietary regimen, insulin and exercise that is integral to T1DM management can result in recurrent hypoglycemic episodes. Hypoglycemia is accompanied by intense hunger and by eating sweetened foods and drinks that are normally forbidden. Patients may subsequently feel guilty about consuming these foods and restrict eating, which may result in yet another hypoglycemic episode. This vicious cycle of dietary restriction, over-eating and guilt is similar to that experienced by individuals with bulimia^[42].

Chronic disease and depression

The risk of significant depressive symptoms in individuals with T1DM has been assessed as about double that of the general population^[43]. Depression may increase the susceptibility for developing disturbed eating behavior. Indeed, among girls with T1DM, those diagnosed with depression scored higher on the Eating Disorder Examination than did those without depression; 75% and 45%, respectively^[44]. Furthermore, anxiety disorders and eating disorders co-occur in the general population, and 21% of children and adolescents with T1DM were reported to screen positively for anxiety^[45].

CLINICAL SIGNS OF ED AMONG INDIVIDUALS WITH T1DM

The diagnosis of subclinical or clinical eating disorders in individuals with T1DM is not easily established. Due to the frequent concealment and denial of eating disorder behaviors, a high index of suspicion is needed. In addition to the predisposing characteristics described above, a number of clinical signs should alert health care providers to the possibility of ED.

Poor glycemic control

Among females with T1DM, mean HbA1c levels were shown to be significantly higher in those with disturbed eating than among those with non-disturbed eating^[46]. HbA1c level of patients who confessed intentional under-dosing of insulin was $9.0\% \pm 1.6\%$ compared with $7.8\% \pm 1.2\%$ of compliant patients^[47]. Similarly, in a nationwide population-based study, conducted in Norway, a significantly higher HbA1c was documented in patients reporting insulin restriction ($9.0\% \pm 1.7\%$) than in nonrestrictors ($8.3\% \pm 1.2\%$)^[19]. In a meta-

Figure 2 Typical example of the course of HbA1c levels in a patient, with intentional insulin omission for weight loss, plotted on the HbA1c percentile reference curves. HbA1c levels were around the 10th percentile from age 10 to 14 years. From age 18 the pattern changed and was characterized by sharp increases to levels above the 90th percentile, sharp decreases and multiple measurements above the 90th percentile.

analysis, eating problems, including both DEB and ED, were found to be associated with poorer glycemic control^[10]. Using a computer model of data mining, we recently showed that adolescent females with intentional insulin omission were discriminated by HbA1c > 9.2% and by more than 20% of HbA1c measurements above the 90th percentile^[48].

Recurrent episodes of diabetic ketoacidosis

Intentional insulin omission has long been recognized as a cause of recurrent episodes of recurrent episodes of diabetic ketoacidosis (DKA) in adolescents with T1DM^[49]. Thus, any recurrent episode of DKA in established diabetes should arouse suspicion^[50].

Recurrent hypoglycemic episodes

Recurrent hypoglycemic episodes may occur among individuals with T1DM and ED, mainly among those participating in binge eating and self-induced vomiting. Deliberately inducing hypoglycemia to justify eating sweets and high carbohydrate meals were described in individuals with T1DM. Eighteen percent of a cohort of males and females with T1DM, aged 10–22 years, reported intentional overdosing of insulin^[47]. The most common reason (49%) stated was the desire for uncontrolled binge eating, followed by self-destructive behavior in stressful situations.

Other characteristics and signs of ED

Other characteristic and clinical signs of ED are: frequently missed medical appointments, refusal to be weighed, preoccupation with appearance, a tendency to vegetarianism, and the calculating of caloric values and weighing of foods. Apparently, due to the availability of insulin omission as a weight loss strategy, females with diabetes are less likely to use other unhealthy weight control behaviors like vomiting, laxatives or diuretics,

and skipping meals or fasting, compared to their peers without diabetes^[51].

DIAGNOSIS

Several questionnaires were developed specifically for adolescents with T1DM. The revised Diabetes Eating Problem Survey (DEPS-R) is a 16-item diabetes-specific self-report measure of disordered eating that was designed specifically to identify patients with T1DM who are at risk for early intervention for disordered eating behaviors^[7]. The mSCOFF is a simple 5 item screening tool, with demonstrated reliability and validity, which can easily be used during a follow-up visit^[52]. Using data mining methods, a clinical prediction model that provides a decision support system for the detection of intentional insulin omission for weight loss in adolescent females with T1DM was developed^[48]. The model is based on identifying a pattern of HbA1c levels indicative of intentional insulin omission. After a period of apparently stable HbA1c levels, the onset of insulin omission is characterized by both high HbA1c levels and wide fluctuations between clinical visits. A typical example of the course of HbA1c levels in a patient who developed ED is depicted in Figure 2.

MORBIDITY AND MORTALITY

ED result in poor metabolic control and cause short and long-term complications.

Short term complications

Insulin omission is associated with recurrent events of DKA, and disturbed eating behavior is associated with recurrent episodes of severe hypoglycemia^[53]. Data from the diabetes patienten verlaufsdokumentation study, including 52215 T1DM males and females aged 8 to 30 years, revealed significantly higher rates of severe hypoglycemic episodes in adolescents with AN, BN or EDNOS, than with no ED: 12.1, 18.0, 12.9 and 5.7, respectively^[54]. Moreover, rates of hypoglycemia with coma, and DKA with hospitalization were higher, and the duration of hospital stay longer, among those with eating disorders^[54].

Long term complications

Long-term complications have been shown to be markedly increased among individuals with both T1DM and ED^[54]. Data from the DPV study revealed that both hypertension and dyslipidemia were more common in persons with T1DM and either EDNOS or BN than in those with T1DM without ED^[54].

Of T1DM patients who developed serious micro-vascular complications, 21% had a probable clinical ED, 47% had a history of DEB, and 48% had a history of insulin omission. The development of two or more serious complications was associated with the presence of a probable clinical eating disorder^[55].

Different ED are associated with varying prevalence

Table 2 Prevalence rates of retinopathy and nephropathy among type 1 diabetes mellitus patients with eating disorders

Complication	Average T1DM duration (yr)	T1DM patients with severe ED (%)	T1DM patients with moderate ED (%)	T1DM patients without ED (%)
Retinopathy ^[46]	11 ± 4	86	42	24
Nephropathy ^[46]	11 ± 4	43	20	18
Nephropathy ^[57]	28	25		10
Foot problems ^[57]	28	25		12

ED: Eating disorders; T1DM: Type 1 diabetes mellitus.

rates of morbidities. For example, data from the DPV study revealed a 2.5-fold higher risk for retinopathy in T1DM patients with BN than in those without ED. Patients with EDNOS also had a higher risk but without statistical significance, whereas those with AN had no increased risk for retinopathy^[54].

The duration of ED may also affect diabetes complications. The duration of severe insulin omission was the factor most closely associated with the development of retinopathy and nephropathy in T1DM females^[56].

As seen in Table 2, higher rates of retinopathy^[46] and nephropathy^[57] were documented in young T1DM patients with ED than in those without ED.

Mortality

Several studies documented increased relative risk of death among patients with ED. Mortality rates per 1000 person years were reported as 2.2 in girls with T1DM, 7.3 in girls with ED and 34.6 in girls with both T1DM and an ED^[58]. During an 11-year period, self-reported insulin restriction at baseline increased the relative risk of death by 3.2 times in women, mean age 45 years, mean diabetes duration 28 years; those with ED were younger when they died (aged 44 vs 58 years, $P < 0.01$)^[57]. In a 12-year follow-up of a cohort of 14 women with T1DM and ED (12 with AN), 5 died (36%)^[59]. The median age of the cohort was 37 years (range 25-46), with a median duration of diabetes of 26 years (14-33). The age of death of the 5 patients was 30 years (25-42).

PREVENTION

Promoting the understanding and awareness among healthcare providers of factors involved in the development of ED in young vulnerable individuals with T1DM may help prevent these disorders^[60]. These factors include the weight gain with the initiation of insulin treatment^[11], the dietary restraint necessitated by diabetes management, and recurrent hypoglycemic episodes. Diabetes treatment should therefore afford flexibility where possible, and non-depriving approaches to eating^[61]. As current clinical practice includes a focus on measuring body weight, health care professionals should be sensitive to preoccupation with body weight. Interventions aimed at increasing self-esteem and body acceptance, as well as family-based interventions aimed

to improve family management of obesity and diabetes, may also help to diminish the risk of developing ED in individuals with diabetes^[62].

Girls aged between 10 and 12 with a diagnosis of T1DM for at least 1 year, attended two group sessions, each of 4-h duration^[63]. The content of the sessions targeted perfectionism, media literacy, self-esteem. The program was found to have impact on self-efficacy relating to diabetes management. As lower T1DM regimen adherence is associated with lower self-efficacy in adolescents, it was concluded that a brief interactive program had a favorable impact on protective factors for disordered eating.

Among college-age women at highest risk for an eating disorder an internet-based intervention, has successfully reduced weight/shape concerns and prevented eating disorders^[64]. Specifically guided discussion group resulted in reduction in weight/shape concern. We did not find similar reports among adolescent girls with T1DM, however it is possible that online interventions may be successfully used to reduce eating disorder risk factors and preventing eating disorders in this group.

TREATMENT

Treatment of ED in patients with T1DM is challenging, especially since the clinical improvement achieved with insulin treatment is associated with weight gain. Compliance to the therapeutic regimen may therefore be poor.

Treatment should mirror the three circle model presented above, and address the factors predisposing to the development of ED (Figure 3).

Treating the first circle - premorbid variables

Increased body weight and a tendency to gain weight should be addressed by prudent dietary management: Since a tendency to gain weight was found to be associated with ED^[22], particular attention should be given to the constellation of excess weight and preoccupation with food.

Low self-esteem, body dissatisfaction and personality variables should be addressed by individual psychological treatment or group therapy: The concurrence of eating behavior disorder and mood disorder in patients with T1DM supports the importance of treating depression as a means of

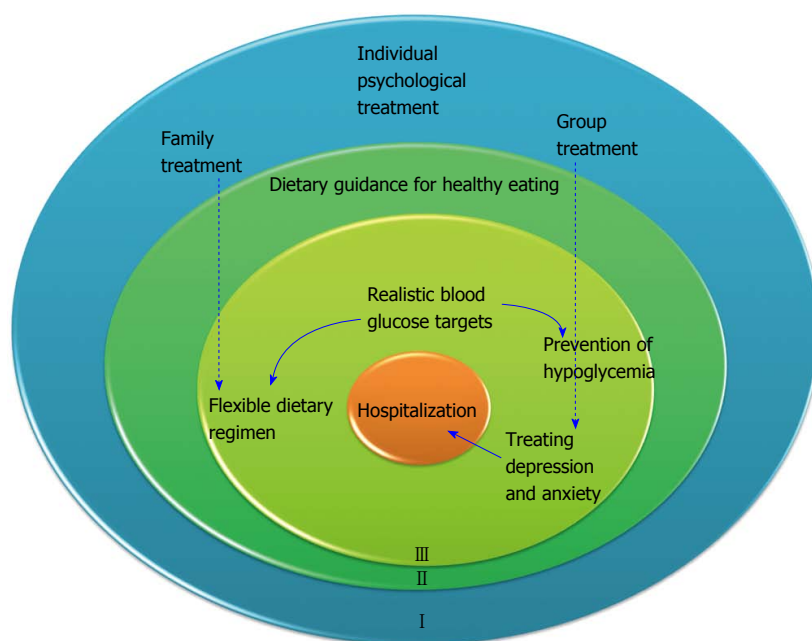

Figure 3 Three level models describing treatment modalities of eating disorders in adolescents with type 1 diabetes mellitus. The outer circle addresses treatment for premorbid variables. The middle circle delineates. The inner circle includes factors associated with the management of T1DM that predispose to eating disorders. T1DM: Type 1 diabetes mellitus.

treating ED. If depression and anxiety are suspected, a psychiatric consultation is needed. Psychiatrists have a distinct role in the diabetes care of children under their care, specifically in working through issues associated with the burden of the disease^[65]. The impact of antidepressant and anti-anxiety medications on recovery from eating disorders in adolescents with T1DM has not been studied systematically.

The effect of psychoeducation on adolescents with T1DM and ED is controversial. A psychoeducation approach with six weekly group sessions was associated with reductions in dieting, in body dissatisfaction and with preoccupation with thinness and eating; the reduction in disturbed eating behaviour was maintained for at least 6 mo^[66]. In another study, a six week intervention was as effective as a wait list control group^[67].

Group cognitive-behavioral therapy intervention has been shown to improve glycemic control, well-being and diabetes related stress among poorly controlled adult T1DM patients^[68], and among patients with T1DM and depression^[69]; however, it was not studied in patients with insulin omission.

As family dynamics may influence the development of ED^[34], family education is an important component of the treatment. However, we could not find data on the impact of family intervention as a treatment modality for adolescents with T1DM and ED.

Treating the second circle - factors associated with disease onset

Current T1DM management involves carbohydrate counting, which may lead to excessive preoccupation with food and diets. The cycle of weight loss at disease

onset, and subsequent weight gain with the initiation of insulin treatment, is a risk factor for the development of ED in susceptible patients^[11]. Dietary treatment should focus on healthy choices and low calorie alternatives with a high satiety index.

Treating the third circle - factors associated with the chronic management of diabetes

Intensive insulin treatment, dietary restraint, and hypoglycemic episodes should be addressed by the diabetes management team: As good metabolic control is associated with weight gain, changes in target blood glucose levels should be gradual. Setting higher than standard target blood glucose ranges (preprandial 120 to 150 mg/dL and postprandial < 200 mg/dL) may yield more benefit in the long run. In contrast, achieving excellent control may result in marked weight gain. Moreover, since low glucose target levels are associated with an increased risk of recurrent hypoglycemic episodes, which may result in additional increased calorie intake, setting higher target levels may be a better initial objective. In girls who were skipping insulin dosing at almost every meal, starting with adequate insulin injection at a single meal is sometimes helpful as a first step. Caregivers should be aware that patients often switch from one disturbed behavior to another, ie from insulin omission to restrictive eating or binge eating; thus, a prescribed diet should be flexible.

Treatment with an insulin pump was postulated as a means of enabling better physiological insulin delivery to adolescents with T1DM than achieved with multiple daily injections. Patients with insulin pumps require less insulin and thus gain less weight. Furthermore, the occurrence of hypoglycemic episodes is decreased, and

thus the need to consume extra calories. A recently published multicenter study demonstrated a decrease in disturbed eating behaviors, as assessed by the DEPS-R, in youth with T1DM, 6 mo after pump initiation^[70]. Moreover, among adolescent girls with T1DM and ED, the mean HbA1c level was significantly lower in those who were treated by insulin pumps than in those who were treated with multiple daily injections ($9.07\% \pm 1.33\%$ vs $10.40\% \pm 2.01\%$; $P = 0.04$)^[71].

Failure of outpatient treatment, the presence of a severe psychopathological state and poor glycemic control are key elements in the decision for hospitalization. Information is limited regarding the long-term outcomes of hospitalized adolescents with ED. Significantly lower levels of HbA1c and lower psychological test scores related to eating disorder psychopathology, depressiveness and anxiety were reported for 9 patients who were hospitalized, compared to 10 who were not^[72]. At 3-year follow-up, 78% of the hospitalized patients in that study no longer fulfilled any criteria for clinical or subclinical ED.

Thus, treatment of ED in individuals with T1DM involves a complex interplay of psychosocial, dietary and medical aspects and requires a multidisciplinary team. It is important to realize that adolescents with T1DM and ED tend to have lower motivation to change their eating habits^[73]. Furthermore, they are characterized by giving up easily when confronted with frustration and with low levels of accomplishment. These personality characteristics may explain the high dropout rate from therapy (79%) among patients with T1DM and ED^[73].

CONCLUSION

Deliberate insulin omission as a weight loss strategy is recognized as either an inappropriate compensatory feature of bulimia nervosa or as a purging disorder, a component of OSFED. About one-third of individuals with T1DM intentionally omit insulin. Diagnosis of eating disorders in individuals with T1DM is difficult, since eating disorder behaviors are often well hidden. Weight loss that is related to deteriorated glycemic control and recurrent DKA should raise suspicion. Early diagnosis is essential, as the combination of eating disorders and diabetes is associated with increased morbidity and mortality.

Abstract

AIM: To investigate whether perceptions of task difficulty on neuropsychological tests predicted academic achievement after controlling for glucose levels and depression.

METHODS: Participants were type 1 diabetic adolescents, with a mean age = 12.5 years (23 females and 16 males), seen at a northwest suburban Chicago hospital. The sample population was free of comorbid clinical health conditions. Subjects completed a three-part neuropsychological battery including the Digit Symbol Task, Trail Making Test, and Controlled Oral Word Association test. Following each task, individuals rated task difficulty and then completed a depression inventory. Performance on these three tests is reflective of neuropsychological status in relation to glucose control. Blood glucose levels were measured immediately prior to and after completing the neuropsychological battery using a glucose meter. HbA1c levels were obtained from medical records. Academic performance was based on self-reported grades in Math, Science, and English. Data was analyzed using multiple regression models to evaluate the associations between academic performance, perception of task difficulty, and glucose control.

RESULTS: Perceptions of difficulty on a neuropsychological battery significantly predicted academic performance after accounting for glucose control and depression. Perceptions of difficulty on the neuropsychological tests were inversely correlated with academic performance ($r = -0.48$), while acute (blood glucose) and long-term glucose levels increased along with perceptions of task difficulty ($r = 0.47$). Additionally, higher depression scores were associated

with poorer academic performance ($r = -0.43$). With the first regression analysis, perception of difficulty on the neuropsychological tasks contributed to 8% of the variance in academic performance after controlling for peripheral blood glucose and depression. In the second regression analysis, perception of difficulty accounted for 11% of the variance after accounting for academic performance and depression. The final regression analysis indicated that perception of difficulty increased with peripheral blood glucose, contributing to 22% of the variance. Most importantly, after controlling for perceptions of task difficulty, academic performance no longer predicted glucose levels. Finally, subjects who found the cognitive battery difficult were likely to have poor academic grades.

CONCLUSION: Perceptions of difficulty on neurological tests exhibited a significant association with academic achievement, indicating that deficits in this skill may lead to academic disadvantage in diabetic patients.

Core tip: The objective of the current study was to investigate the association between perceptions of difficulty and academic performance in adolescents with type 1 diabetes. Perceptions of difficulty are reflected in executing cognitive activities as well as in the task of glucose regulation. Glucose control needs to be understood, not so much from a biological perspective but as an effortful process that is also reflected in academic challenges. The problem of anergia observed generally in patients with diabetes seems to broadly affect a variety of tasks and challenges. Thus, the novelty of the study is in showing that the regulation of glucose in diabetic patients is another example of the broad challenges confronted in the life of patients with diabetes.

INTRODUCTION

Type 1 diabetes is one of the most common chronic diseases of childhood. In the United States, type 1 diabetes affects approximately 1 in 300 children and is usually diagnosed between the ages of 5 and 11 years^[1,2]. The course of this autoimmune version of diabetes is characterized by ongoing beta cell destruction

and the need for exogenous insulin^[3]. Since the central nervous system (CNS) is dependent on a supply of glucose for normal neural functioning, reduced glucose concentrations may result in temporary and/or enduring impairments in CNS function^[4]. Dysregulation of the CNS may have negative effects on neuropsychological functioning, such as impaired memory, attention, motor skills, and executive functioning^[5].

Adolescents with type 1 diabetes face many challenges that can impact metabolic control along with physiological and psychological complications. The need for adherence to metabolic control and compliance with regimen is effortful. Beyond the demands for medical compliance, adolescents are often burdened by depression^[6] as well as anergia^[7] and thus may be at academic disadvantage^[8].

Along with academic adversity, individuals with type 1 diabetes may be challenged by self-evaluative factors such as the perception of control, which affects behavioral and social functioning^[9,10]. The literature has described three prominent types of control: perceived control, perceived confidence (self efficacy), and perceived difficulty^[11]. Perceived difficulty, a subjective experience, can be defined as the extent to which individuals believe that performance on a task or behavior would range from easy to difficult^[11]. If adolescents believe they are substandard at a task because of its difficulty, they are likely to devalue the activity and decrease effort expenditure^[12].

Perceived difficulty has also been shown to relate to an individual's beliefs regarding how much effort is needed to succeed at a task and whether success is possible^[13]. The effort expended in performing a task is predicted to increase proportionally with the level of perceived task difficulty^[14]. Indeed, effort has been associated with academic performance. Studies^[15] have found that self-reported grades are positively correlated with effort. Moreover, adherence to regimen^[16] and metabolic control^[17] also reflect the expenditure of effort. Therefore, poor glucose control may be positively correlated with perceptions of task difficulty and inversely associated with academic performance^[18]. Indeed, self-control and willpower are both functions of available glucose levels^[19]. Thus, glucose control and effort are two highly related processes that need to be differentiated.

Perceptions of difficulty rely on executive functioning skills, such as problem solving and decision-making. These skills require an individual to make a decision regarding the degree of difficulty associated with the task and whether he or she will be successful in carrying out the task. Since problem solving and decision-making skills contribute to academic performance, these executive functioning skills may be impaired in diabetic individuals^[20]. A meta-analytic finding indicated that children with type 1 diabetes performed slightly, yet significantly, lower on attention/executive functioning tasks than non-diabetic individuals^[21]. This finding, in turn, was associated with poor glucose control and

hypoglycemic episodes as well^[21].

To open the question of effort, three brief but well validated neuropsychological tests were administered^[22] and participants rated the difficulty of each test. Secondly, academic performance and depression levels were evaluated and analyzed. Since long-term glucose control (HbA1c) is associated with cognition^[18], HbA1c levels from within the past three months were collected from medical records. Acute glucose levels immediately prior to and following neuropsychological testing were also collected and evaluated. These procedures enabled the distinction between the assessment of effort-associated processes supporting academic and neuropsychological processes vs those putatively supporting glucose control.

MATERIALS AND METHODS

Participants

This study was designed as a cross-sectional, prospective study. Participants were type 1 diabetic patients who attended a diabetes clinic in a northwest suburban Chicago hospital. Adolescents were approached to participate in the study during their regularly scheduled doctor's appointment. Adolescents were excluded from participation if they had co-morbid clinical health conditions, such as asthma, anemia, vascular disease, kidney disease, chronic tiredness, depression, psychiatric history, or obesity. Parents of the patients filled out consent forms that outlined the procedure and risks of participation. The subjects also signed an assent form. The study measures were carried out in a quiet, separate room for each participant individually. Pre-doctoral psychology students administered the assessments. Participants were provided modest monetary compensation for participation in the study. There were a total of 39 participants, consisting of 23 females and 16 males. The population was comprised of 71.8% Caucasian, 20.5% Hispanic, 5.1% Asian, and 2.6% African American. The mean age of the participants was 12.5 years (SD = 2.73). This study was approved by the Institutional Review Board at Rosalind Franklin University as well as the hospital's review board. There is no conflict of interest related to this study.

Materials

Glucose control: Blood glucose measurements were performed immediately prior to administering and again after completing the neuropsychological battery with glucose meters (One Touch, Blood Glucose Monitoring System). This procedure was used to obtain an average peripheral blood glucose measurement. A single HbA1c level was recorded from the medical records retrieved from the previous three months, prior to testing.

Neuropsychological battery: The neuropsychological battery included the Digit Symbol task (Wechsler Intelligence Scale for Children-Forth Edition), Trail Making test Parts A and B, and Controlled Oral Word

Association (COWA) in that order. This three-part neuropsychological battery was selected because the tests are brief, well researched, psychometrically sound, and are commonly used^[23]. Performance on these tests is reflective of neuropsychological status in diabetic patients in relation to glucose control^[22].

The Digit Symbol task of the Wechsler Intelligence Scale for Children-Fourth Edition (DS; WISC-IV)^[24] was used to assess psychomotor performance, attention, memory, and perceptual organization. It consists of Coding and Incidental Learning. In Coding, the individual was presented with several rows of a series of numbers (1 through 9). Each number was paired with a corresponding unique symbol. The individual was asked to fill in as many symbols as possible in boxes directly under the corresponding number and was allowed 120 s to complete this task. In Incidental Learning, individuals were asked to carry out two tasks: to recall as many digit-symbol pairs as possible (Pairing) and to recall as many symbols as possible without the corresponding numbers (Free Recall). Internal consistency of the Digit Symbol Coding task is 0.85.

The Trail Making Test^[23] was used to assess attention, visual-motor tracking, and speed of information processing. It consists of two parts: in Part A, individuals were asked to draw a line that accurately connected the correct sequence of numbers as quickly as possible. In Part B, individuals were asked to draw a line that accurately connects the correct sequence of numbers and letters in an alternating pattern as quickly as possible. Reliability for Part A is 0.78 and for Part B 0.67.

The COWA test^[25] assessed verbal functions. Individuals were asked to generate as many words as possible that began with the letter S in 60 s and then the letter F in 60 s as the examiner recorded these. Test-retest reliability is 0.88 and inter-scorer reliability was almost perfect.

Rating of task difficulty: After completing three tasks (the Digit Symbol task of the Wechsler Intelligence Scale for Children-Fourth Edition, Trail Making test Part A and B, and Controlled Oral Word Association test), participants were asked to rate the level of perceived difficulty of each task on a scale from 1-5, where 1 = very easy and 5 = very difficult. These evaluations were summed and averaged to develop a task difficulty measure.

Academic performance: Participants self reported academic grades in several courses during the current school year: Math, Science, and English. For the purposes of tabulation, grades were converted into a scale score from 1-5, where 1 = F, 2 = D, 3 = C, 4 = B, and 5 = A. Grades were then averaged for each participant.

Depression: To avoid possible reactive effects^[26], participants were lastly administered the Children's Depression Inventory (CDI)^[27] which is a 27 item self report inventory used to measure depressive symp-

Table 1 Characteristics of participants

	Mean	SD
Disease duration (mo)	48.05	41.08
BMI (kg/m ²)	21.18	3.85
Peripheral blood glucose (mm/dL)	190.99	89.27
HbA1c (%)	8.39	1.63
Digit symbol coding	55.38	14.7
Digit symbol paring	11.44	5.16
Digit symbol free recall	7.38	1.41
Trails A (s)	39.67	19.02
Trails B (s)	92.74	64.84
COWA	20.26	6.62
CDI	7.23	5.54
Perception of difficulty ¹	10.15	2.95
Grades ²	4.1	0.77

tomatology in youth aged 7-17. Respondents indicated which of three options best represented their mood in the context of everyday life: absence of symptom = 0; mild symptom = 1; and definite symptom = 2. The CDI provides a total score on five domains of depression. The reliability coefficient for the total inventory was 0.86^[27].

Data was collected and entered into Statistic Package for Social Science (SPSS) Version 13. Zero order correlation tables were examined to assess the degree of relationship between the variables. *P*-values of less than 0.05 were considered statistically significant. Multiple regression analyses were used to assess outcome variables.

RESULTS

Basic description of the sample population is presented in Table 1. The primary results (Table 2) indicated that perceptions of difficulty on the neuropsychological tests were inversely correlated with academic performance ($r = -0.48$), while acute (blood glucose) and long-term glucose levels (HbA1c) increased along with perceptions of task difficulty ($r = 0.47$). Finally, higher depression scores were associated with poorer academic performance ($r = -0.43$).

To evaluate the relationship of difficulty on neuropsychological tests and academic performance after controlling for peripheral glucose levels and depression, a multiple regression analysis was conducted (Table 3). The predictors in the regression analysis were entered in the following order: (1) peripheral blood glucose; (2) CDI; and (3) perception of difficulty with academic performance as the dependent variable. Results from the first predictor indicated that as peripheral blood glucose increased, academic performance decreased. The second predictor (CDI) indicated that increasing depression was associated with poorer academic performance after controlling for peripheral blood glucose. Lastly, the third predictor (perception of difficulty) showed

that higher levels of difficulty perceived on the neuropsychological test was inversely associated with academic performance after taking into account peripheral blood glucose and depression. The result of this analysis indicated that the perception of difficulty on the neuropsychological tasks contributed to 8% of the variance in academic performance after controlling for peripheral blood glucose and depression. Thus, stronger ratings of laboratory task difficulty were associated with poorer academic performance.

After controlling for academic performance and depression, a regression analysis was conducted with peripheral blood glucose as the dependent variable to test if perceptions of task difficulty were associated with glucose levels (Table 4). The predictors in the regression analysis were entered in the following order: (1) academic performance; (2) CDI; and (3) perceptions of difficulty on the neurological tests with peripheral blood glucose as the dependent variable. Results indicated that the first predictor (higher academic performance) was inversely related to peripheral blood glucose, contributing to 14% of the variance. The second predictor (CDI) showed that the levels of depression had insignificant effects on peripheral blood glucose. The third predictor (perception of difficulty) showed that the higher level of difficulty perceived on the test accounted for the higher peripheral blood glucose level. Perception of difficulty accounted for 11% of the variance after accounting for academic performance and depression. This indicated that higher perceptions of task difficulty were associated with higher blood glucose levels while depression seemed to play no significant role in this model. Individuals, who perceived the neuropsychological battery as challenging, may also experience difficulty controlling glucose levels.

The purpose of the final analysis (Table 5) was to determine whether academic performance would predict glucose levels after controlling for perceptions of task difficulty. The order of predictors was: (1) perception of difficulty; (2) academic performance; and (3) CDI with peripheral glucose levels as the dependent variable. The first predictor (perception of difficulty) showed that perception of difficulty increased with peripheral blood glucose, contributing to 22% of the variance. Most importantly, after controlling for perceptions of task difficulty, academic performance no longer predicted glucose levels. Additionally, it was found that the level of depression was not associated with peripheral glucose levels. Results from Table 5 indicated that peripheral blood glucose was positively correlated with the perception of task difficulty.

DISCUSSION

The general purpose underlying this research was to critically evaluate the various explanations for the problems that diabetic adolescents experience in the performance of cognitive tasks. In addition to elevations

Table 2 Correlations among the variables

in blood glucose, there are two alternatives, namely anergia^[7] and depression^[6]. Since these processes each exacerbate or contribute to the diminution of effort, it is possible that the actual mediator of compromised cognition can be found in reduced effort. Thus, the primary purpose of this introductory study was to assess the contribution of effort^[14] to both metabolic control and reduced cognition in these patients.

Through a series of multiple regression analyses, the results showed that after controlling for levels of effort, the role of metabolic control was compromised with respect to cognition. A key assumption in this process is that metabolic control is per se an effortful process. If effort is viewed as the primary process, metabolic control remains as an adjunctive player in cognition.

To examine this model, we turn to the results of the multiple regression analyses presented earlier. That is, adolescents who perceived the neuropsychological battery as more difficult were more likely to have lower grades in Math, Science, and English. Thus, perceiving the battery as difficult may indicate a broad weakness in executive functioning skills, such as problem solving and decision-making. Furthermore, increased levels of depression also negatively contributed to academic performance. As a result, academic performance was

Table 4 Linear multiple regression analysis for variables predicting peripheral blood glucose¹

¹Low score-lower glucose levels; ²Low scores indicate poor grades; ³Higher scores more depression. ^b $P < 0.01$. β : Standardized coefficient beta.

poorer in adolescents with elevated peripheral blood glucose, which in itself may be a reflection of the difficulty or effort necessary for exercising metabolic control.

This study provided insight into how academic performance may be associated with self-ratings of difficulty on neuropsychological tasks after controlling for blood glucose levels and depression. Further, the study showed how peripheral blood glucose levels can be derived from perceptions of difficulty based on neuropsychological testing after controlling for academic performance and depression. Each of these observations will be discussed serially.

Previous findings^[28,29] have suggested a relationship between glucose control and academic performance. Greater difficulty in maintaining strong glucose control was associated with poorer academic performance. The list of predictors of academic performance included a neuropsychological battery that assessed psychomotor performance, attention, memory, speed of information processing, and verbal functioning.

Participants who perceived the neuropsychological battery as difficult were also more likely to exhibit poor grades (Table 4). However, this finding may not be surprising, since performance on the neuropsychological battery and academic performance share some conceptual space. Thus, a basic question in this study is whether the commonly observed relationship between glucose levels and cognitive functioning represents a basic physiological relationship between glucose and neuropsychological functioning? Alternatively, is the index of glucose control merely a reflection of the basic challenge between compliance with regimen, an effort-demanding task, and the challenge intrinsic to the cognitive task?

After controlling for appraisals of task difficulty, blood glucose levels seem to no longer account for cognitive

performance once task difficulty is factored into the equation (Table 5). Finally, by eliminating the influence of perceptions of difficulty in maintaining blood glucose control and complying with medical regimen, peripheral blood glucose and academic performance were no longer significantly related.

This may be the first study to illustrate how perceptions of task difficulty on neuropsychological tests are associated with poor academic performance in diabetic patients. While several studies have reported that individuals with diabetes exhibit relatively poor academic performance, the present study identifies how perceptual evaluative factors diminish academic performance.

Thus, careful disease management is needed to prevent or effectively treat potentially life-threatening complications such as hypoglycemia, diabetic ketoacidosis, and hyperglycemia as well as effort.

Limitations to the study include a relatively small sample size as well as the use of a single item to assess perceptions of task difficulty. However, this method of assessing perceptions of difficulty with one item was also utilized in a previous study^[11]. In their study, Rogers and colleagues assessed self-efficacy, perceived control and perceived difficulty with the use of a single item Likert scale question for each construct^[11]. Therefore, single item indicators may be regarded as similarly robust as multiple item indicators^[30,31]. Lastly, academic performance was assessed by participant self-report. Systematic biases may influence the validity of self-reported grades, but self-reported grades generally predict outcomes as effectively as actual or objectively culled grades^[32].

In conclusion, this study demonstrated that perceptions of task difficulty can predict academic difficulty in a sample of diabetic adolescents. Task difficulty was also associated with the relationship between glucose levels and academic performance. Hence, perceptions of difficulty can be viewed as a generalized executive function. When individuals perceive a task as more difficult, this may promote academic disadvantage along with increased challenges in controlling glucose. Overall, such information may be useful in training and counseling students in enhancing academic success and performance as well as in assistance with disease control.

COMMENTS

Background

Type 1 diabetes is one of the most common chronic diseases of childhood. In the United States, type 1 diabetes affects approximately 1 in 300 children and is usually diagnosed between the ages of 5 and 11 years.

Research frontiers

Adolescents with type 1 diabetes face many challenges that can impact metabolic control along with physiological and psychological complications. Cognitive functioning is an important aspect of life and can be impaired in individuals with diabetes. Academic performance in diabetic adolescents may also be compromised due to fluctuations in glucose.

Innovations and breakthroughs

Along with academic adversity, individuals with type 1 diabetes may be

challenged by self-evaluative factors such as the perception of control, which affects behavioral and social functioning. Perceived difficulty has also been shown to relate to an individual's beliefs regarding how much effort is needed to succeed at a task and whether success is possible. Perceptions of difficulty rely on executive functioning skills, such as problem solving and decision-making. Since problem solving and decision-making skills contribute to academic performance, these executive functioning skills may be impaired in diabetic individuals. The current study sought to examine the role of effort on glucose and academic performance.

Applications

This may be the first study to illustrate how perceptions of task difficulty on neuropsychological tests are associated with poor academic performance in diabetic patients. While several studies have reported that individuals with diabetes exhibit relatively poor academic performance, the present study identifies how perceptual evaluative factors diminish academic performance.

Terminology

Diabetes mellitus is a major health problem in the United States affecting approximately 29.1 million people. There are two major classifications of diabetes: insulin dependent diabetes (type 1) and non-insulin dependent diabetes (type 2). Diabetes is a group of metabolic diseases that either cause defects in insulin action, insulin secretion, or a combination of both, resulting in hyperglycemia. Perceived difficulty, a subjective experience, can be defined as the extent to which individuals believe that performance on a task or behavior would range from easy to difficult.

Peer-review

The study addresses a relevant scientific question and is well-conducted. The results are significant indicating that deficits in perception of difficulty may lead to academic disadvantage in diabetic patients. The manuscript is interesting and may provide important information for the reader of the journal.

Abstract

AIM: To evaluate the long-term effect of aerobic and/or anaerobic exercise on glycemic control in youths with type 1 diabetes.

METHODS: Literature review was performed in spring and summer 2014 using PubMed/MEDLINE, Google Scholar, Scopus, and ScienceDirect with the following terms: aerobic, anaerobic, high-intensity, resistance, exercise/training, combined with glycemic/metabolic control, glycated haemoglobin A1c (HbA1c) and type 1

diabetes. Only peer-reviewed articles in English were included published in the last 15 years. It was selected from 1999 to 2014. Glycemic control was measured with HbA1c. Studies with an intervention lasting at least 12 wk were included if the HbA1c was measured before and after the intervention.

RESULTS: A total of nine articles were found, and they were published between the years of 2002-2011. The sample size was 401 diabetic youths (166 males and 235 females) with an age range of 10-19 years except one study, in which the age range was 13-30 years. Study participants were from Australia, Tunisia, Lithuania, Taiwan, Turkey, Brazilia, Belgium, Egypt and France. Four studies were aerobic-based, four were combined aerobic and anaerobic programs, and one compared aerobic exercise to anaerobic one. Available studies had insufficient evidence that any type of exercise or combined training would clearly improve the glycemic control in type 1 diabetic youth. Only three (two aerobic-based and one combined) studies could provide a significant positive change in glycemic control.

CONCLUSION: The regular physical exercise has several other valuable physiological and health benefits that justify the inclusion of exercise in pediatric diabetes treatment and care.

Key words: Type 1 diabetes mellitus; Glycemic control; Exercise; Aerobic; Anaerobic

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Diabetic patients should be aware that exercise interferes with the glucose homeostasis. Anaerobic exercise can increase glycemia, whereas the aerobic exercise may cause a decrease during the exercise and post-exercise. By evaluating the long-term effect of exercise on glycemic control in type 1 diabetic youths

according to the major metabolic pathway involved in energy utilization (aerobic or anaerobic), we found insufficient evidence in the latest literature that any type of exercise or combined aerobic and anaerobic training would clearly improve the glycemic control. The regular physical exercise has several other valuable benefits that justify the inclusion of exercise in pediatric diabetes treatment and care.

Lukács A, Barkai L. Effect of aerobic and anaerobic exercises on glycemic control in type 1 diabetic youths. *World J Diabetes* 2015; 6(3): 534-542 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i3/534.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i3.534>

INTRODUCTION

Physiological, social and emotional benefits of regular exercise and physically active lifestyle are well documented mostly in a healthy population^[1-4], but they are also important for diabetic patients regardless of the type of diabetes^[5-8]. For type 1, successful diabetes management is based on individualized insulin therapy, adjusted diet and regular exercise^[9].

Exercise used as prevention and therapy in diabetes is not a new concept in the literature. Even the ancient Ayurvedic physician, Susruta Shamita (born around 600 B.C.), noted the reduction in the sweetness of urine from diabetic patients with exercise, and included moderate exercise within his treatment regimens^[10]. In 1919, Allen proved that exercise reduced blood glucose level and improved acutely the tolerance to a carbohydrate load^[11]. After the discovery of insulin in 1921^[12], Lawrence demonstrated that exercise has an effect on insulin requirements and glucose uptake^[13]. Joslin believed in "troika" (group of three) in the treatment of diabetes, symbolizing insulin, diet and exercise correlation^[14]. Regular exercise helps to improve overall health and fitness, and reduces risk factors for vascular complications. Diabetic youths with regular exercise have improved blood lipid profile, and increased insulin sensitivity, primarily in the skeletal muscles, which leads to a reduced need for insulin^[15-17]. The American Diabetes Association recommends all levels of physical exercise including leisure activities, recreational sport and competitive sport for youths with type 1 diabetes mellitus (T1DM) if they are in good blood glucose control and have no long-term complications^[18]. Until the sympathetic nervous and endocrine systems control the blood glucose level at the physiological levels during and after physical exercise in healthy subjects^[19], the regulation is external in diabetic patients considering many internal influences. Youths with T1DM should be aware that exercise interferes with the glucose homeostasis, although there are individual differences in blood glucose response due to type, duration and intensity of the exercise, the pre-exercise level of counterregulatory hormones, and blood glucose

concentrations^[20,21]. Several studies examined the role of physical activity and exercise in the treatment of T1DM and considered it an important component. The evidence for improvement in glycemic control is equivocal. Some studies suggest a positive effect^[22-27], whereas others fail to show this effect^[28-34]. Scientific questions remain concerning what is the exact effect of different types of exercise on glycemic control in youths with T1DM.

In this systematic literature review, we evaluated the latest studies examining the long-term effect of aerobic and/or anaerobic exercise on glycemic control in youths with T1DM. We also made distinguishing between concepts of physical activity, physical fitness, and aerobic-anaerobic exercise. Finally, we considered clinical applications and future directions.

Conceptualisation

Physical activity: Physical activity encompasses body movement produced by skeletal muscles which requires energy consumption^[35]. Physical activity can range from sports to any other lifestyle activities including school and out-of-school activities, weekend activities where youths play, are active and expend energy. There is evidence that behavioural patterns of physical activity in childhood are maintained throughout adulthood^[36,37]. This term is often used interchangeably with regular exercise and physical fitness in studies, although they are different concepts^[38].

Exercise: Exercise has been defined as any form of body movement that results in an increase in metabolic demand with the intention of developing one or more components of physical fitness. It is generally planned, structured and systematic^[35]. Regular exercise improves physical fitness. Exercise is characterised by five components: type [dynamic (isotonic) or static (isometric), and both of them can be performed aerobically or anaerobically on the basis of energy utilization]^[39], intensity (degree of effort that individual puts into exercise), duration (the length of each training session), repetition (number of times individual performs a complete movement of a given exercise) and frequency (number of exercise sessions per week)^[40].

Fitness: Fitness refers to the "possession of adequate levels of strength, endurance, and mobility to provide for successful participation in occupational effort, recreational pursuits, familial obligation, and that is consistent with a functional phenotypic expression of the human genotype"^[41]. Physical fitness determines cardiovascular, respiratory, and musculoskeletal systems in order to perform physically demanding activities such as exercise, sport, or work. Fit youth has normal body fat, good immune system and, in general, is in a physiologic state of well-being.

Aerobic-anaerobic exercise: Whether an activity is aerobic or anaerobic depends primarily on its intensity and duration. Most physical exercises are characterised

by both static and dynamic contractions as well as aerobic and anaerobic metabolism. Thus, exercise is classified by their dominant features.

Aerobic exercise includes any type of exercise, typically those performed at moderate levels of intensity for extended periods of time that maintains an increased heart rate. Activities such as cycling, swimming, jogging, rowing, cross-country skiing, and aerobic dancing require oxygen to produce ATP. Regular aerobic exercise improves maximal oxygen consumption and overall endurance performances. Anaerobic exercise is used to promote strength, power, and speed. Generally, anaerobic exercise has a short duration and high intensity activity. Unlike aerobic exercise, it does not depend on exogenous oxygen. Activities such as heavy weightlifting, all types of sprint (running, cycling, or swimming) or any hard exercises require anaerobic metabolism. During exercise various forms of energy sources are utilized markedly depending on the intensity and duration of exercise, but the activity is classified typically based on the predominantly used system. The anaerobic energy system is used for resistance training and increasing speed^[42]. During high intensity (anaerobic) exercise almost the entire metabolic fuel source is glucose, whereas during low intensity (aerobic) exercise fat utilization increases and glucose oxidation decrease^[43]. Both types of exercise increase the mechanical efficiency of the heart (cardiac adaptation), changes in morphology and functionality of the left ventricle^[44].

Measuring the intensity of exercise using maximal heart rate:

Maximal heart rate (HR_{max}) is one of the most commonly used values in clinical settings and physiology. HR increases nearly linearly with the increase in the intensity of exercise; and this is the simplest physiological response to measure. As maximal exercise intensity is approached, HR begins to plateau even as the exercise workload continues to increase. This HR_{max} is a reliable value and it remains constant for a longer period^[45]. To estimate HR_{max} for children, formula $208 - 0.7 \times \text{age in years}$ is applied^[46,47]. There are several more and less accurate types of estimation existing for determining the exercise intensity^[48]. Aerobic training zone is around between 60%-70% of the HR_{max} . Between 70%-85% of HR_{max} , the youths are in the mixed zone, and above 85% of HR_{max} the anaerobic metabolism will come to the fore.

Effects of different types of exercise on blood glucose level in type 1 diabetes patients

Different types of exercise produce different effects on blood glucose level. If the carbohydrate intake and the insulin dosage are not in line with the exercise the patient does, it will result in metabolic disturbances^[49]. The most common problems are the evaluation of pre-exercise level of blood glucose, evaluation of the intensity and duration of the expected exercise, and to

take into consideration the time of day when the patient exercises, because of the body's different physiological insulin need^[49]. Exercise functions like insulin, so the balance between the insulin therapy and diet could be facilitated if the daily schedule for exercise and the exercise parameters are consistent^[50], although this goal is almost impossible to obtain in the real life for youths. Findings from exercise training studies support the concept that moderate intensity aerobic workload increases the risk of hypoglycemia during the exercise and several hours after the exercise. High-intensity training with anaerobic utilization may increase the blood glucose level due to the release of adrenaline and noradrenalin in the blood, which then stimulates the liver to release glucose faster than normal. The exercise-induced rise in glucose level is followed by hypoglycemia after hours of finishing the exercise as counterregulatory hormone levels decrease^[21,51-53]. Both aerobic and anaerobic exercise training regimens improve glucose uptake and insulin sensitivity^[21,54]. School-aged children engage a combination of moderate- and high-intensity sessions in their everyday sport activities. Their exercise is often spontaneous and unplanned. Thus, a different plan is needed for each type of exercise to optimize blood glucose level, but problems with the management are well recognised. Patients differ in tolerance to exercise and insulin requirements and it is impossible to give precise guidelines suitable for everyone with T1DM, therefore experiences with regular blood glucose testing are inevitable. Continuous glucose monitoring may assist the active diabetic participants to follow the changes in blood glucose level and give information about the individual response to the exercise^[21,54]. There are several guidelines to discuss safe sport participation in children and adolescents with T1DM^[5,55-59]. These guidelines can be adjusted to own measurements and awareness of the usual responses to a particular type of exercise.

MATERIALS AND METHODS

Study eligibility

A systematic review was performed in spring and summer 2014 using PubMed/Medline, Google Scholar, Scopus, and ScienceDirect with the following terms: aerobic, anaerobic, high-intensity, resistance, exercise/training, combined with glycemic/metabolic control and type 1 diabetes. Only peer-reviewed articles in English were included published in the last 15 years with at least five subjects per group. Studies were selected from 1999 to 2014 that measured the long-term effect of aerobic and/or anaerobic exercise on glycemic control in type 1 diabetic children, adolescents and young adults without diabetes complications. Glycemic control was measured with glycated haemoglobin A1c (HbA1c). As the HbA1c provides an average of blood glucose control over a 12-wk period, we included studies with an intervention lasting at least 12 wk if the HbA1c was

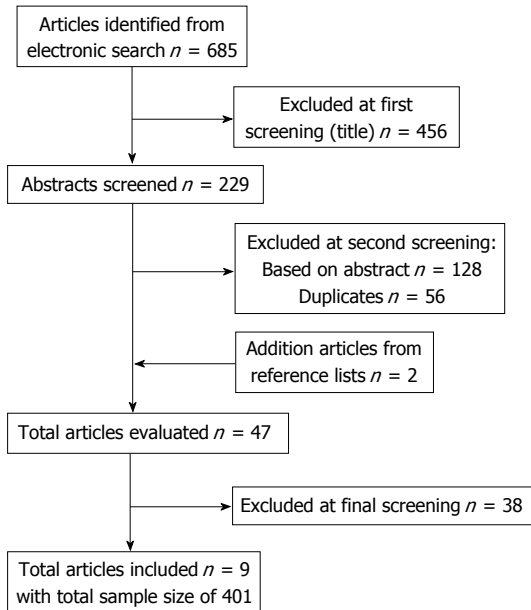

Figure 1 Flow diagram illustrating selection of the included studies.

measured before and after the intervention. The flow diagram of study selection is shown in Figure 1.

Statistical analysis

This manuscript does not describe basic or clinical research using biostatistics for raw data, therefore biostatistics statement is not relevant.

RESULTS

A total of nine articles was evaluated from nine different countries including Australia^[30], Tunisia^[60], Lithuania^[61], Taiwan^[62], Turkey^[63], Brazilia^[64], Belgium^[65], Egypt^[66] and France^[67], and they were published between the years of 2002-2011. The list of articles is presented in Table 1. Across included studies the total sample size was 401 (166 males and 235 females) with an age range of 10-19 years except one study, in which the age range was 13-30 years^[64]. Four studies were aerobic-based^[60-63], four were combined aerobic and anaerobic programs^[30,65-67], and one compared aerobic exercise to anaerobic one^[64]. The Turkish study^[63] conducted a Pilates program that is considered low-impact aerobic workout^[68]. All studies had diabetic control group except one^[61].

Effects of different types of exercise on glycemic control in youths with T1DM

Studies investigating aerobic exercise: Studies measuring the effect of aerobic exercise on glycemic control presented variable results^[60-63]. Only one study recognised a significant improvement in HbA1c after 12-wk exercise (girls swimming twice a week for 45 min a week)^[61]. In a study investigating the impact of the frequency of the supervised aerobic training on

glycemic control, exercise three times a week (one hour) for three months had no significant impact on glycemic control, but exercise four times a week (one hour) for 6 mo resulted in a significant improvement^[60]. Neither guided or self-directed home-based aerobic exercise program nor supervised Pilates exercise had a significant effect on glycosylated haemoglobin after a 12-wk session^[62,63].

Study investigating anaerobic exercise: We found only one study that measured the efficacy of resistance (anaerobic) and aerobic exercise in parallel. Both groups were trained three times a week (40 min) for 12 wk under supervision by a physical trainer and an endocrinologist. Interestingly, the HbA1c increased in the aerobic group significantly after 12 wk, whereas a non-significant reduction was observed in the resistance training group^[64].

Studies investigating combined exercise program:

Four randomised controlled trials examined the effect of combined (aerobic and anaerobic) exercise on glycemic control^[30,65-67]. Supervised combined aerobic and resistance training twice a week (70 min) for 20 wk resulted in no significant change in glycemic control^[65]. In a 12-wk supervised training followed by a 12-wk unsupervised training, HbA1c level remained unchanged regardless of the baseline HbA1c level^[30]. There were two trials that explored the effect of supervised combined exercise on glycemic control for a longer duration (6 mo)^[66,67]. The Egyptian study found significant improvements in HbA1c level in both training groups exercising three times a week and once a week. However, patients exercising three times a week produced significantly greater improvements^[66]. In the Heyman's study, the participants completed a two-hour supervised training and a one-hour unsupervised training a week including aerobic and strength exercises. The author could not prove a significant effect on glycated hemoglobin after a 6-mo session^[67].

DISCUSSION

The primary aim of diabetes treatment and care is to achieve as stable glycemic control as possible in order to prevent or delay the long-term complications^[69]. Regular exercise is recommended for diabetic youths for several psychological and health benefits^[7,70]. It is evidence-based that regular exercise has a preventive and curative role in type 2 diabetes, but its physiological role in type 1 diabetes is not fully explored. Exercise physiology in diabetes is described thoroughly by Robertson *et al*^[7] and Riddell *et al*^[53,59]. Another issue that remains unresolved is related to the type of exercise: aerobic or anaerobic workout is most beneficial for glycemic control. We evaluated the studies from the previous 15 years that investigated the long-term effect of exercise on glycemic control in youths with T1DM according

Table 1 Study characteristics, objective and result regarding glycemic control

Source	RCT	Objective	Sample size/gender	Age (y/o) gender	Intervention	Duration, frequency	Significant positive change in GC

to the major metabolic pathway involved in energy utilization (predominantly aerobic or predominantly anaerobic). Results of investigated studies are open to debate. Most studies found no significant improvement in glycemic control regarding the aerobic^[62,63] and combined exercise intervention^[30,65,67]. The only study investigating the anaerobic effect on glycemic control presented a positive tendency, although there was no statistically significant effect^[64]. One of the possible reasons for these varied results could be the small sample sizes. The glucose profile varies greatly in patients with T1DM before, during and after exercise, and can be very different in patients with similar HbA1c. All except one study^[66] had less than 20 participants in a group in our studies. The other reason could be the short period. It seems that at least 6 mo of exercise intervention might lead to significant results^[60,66]. Kennedy *et al*^[71] also noticed in their systematic review and meta-analysis that longer duration of intervention shows a trend for HbA1c reduction. We had a total of 401 samples in our studies and the Egyptian study^[66] alone offered 187 participants. Weighting its results, it might be supposed that combined long-term exercise intervention is more beneficial for the glycemic control, than aerobic or anaerobic alone. Irvine *et al*^[72] in their systematic review with 372 patients with T2DM have reported that (anaerobic) progressive resistance exercise is not significantly better than aerobic exercise in improving glycosylated haemoglobin. There was a lack of evidence to suggest that one type of exercise was better than another^[72]. Yang *et al*^[73] in their systematic review with 595 patients with

T2DM also enunciated that either form of exercise appears to have comparable effects on glycemic control. A meta-analysis by Tonoli *et al.*^[74] with type 1 diabetic participants explored a tendency for improvement in glycaemic control due to aerobic or combined training, but they could not confirm this statistically. Individual studies on aerobic training had no significant evidence, but “in total” demonstrated a reduction in HbA1c, although they carefully interpret their results because of insufficient data on these topics^[74]. Neither Kennedy’s meta-analysis in children and adults^[71] nor Kavookjian’s systematic review in the adult population^[75] revealed evidence for statistically significant glycemic benefits of exercise. Kennedy *et al.*^[71] suggest that HbA1c may not be a sensitive indicator of glycaemic control, and that improvement in glycaemic variability may not be reflected in this measure. Tight metabolic control is very important for diabetic individuals, and the regular physical exercise is part of the diabetes management. Available studies provide insufficient evidence that any type of exercise or combined training would clearly improve the glycemic control in type 1 diabetic young patients. Long-term exercise-induced glycemic benefits are based on the continuous effect of each successive bout of exercise. Glycemic variability can be detected by continuous glucose monitoring that could help individuals to learn their own response to different type of physical exercise; and it might be a more appropriate marker to explore the exercise-induced beneficial effect than HbA1c^[71]. Youths with T1DM are recommended to be engaged in a sport they like, and do it regularly as much as possible at the same period of the day. Having the appropriate exercise physiology knowledge, they can accumulate own experiences regarding exercise in addition to insulin requirement and dietary program that may result in stable glucose levels. The insulin-diet-exercise adjustment must be personalized and discussed with the patient’s endocrinologist. The regular exercise is associated with numerous health benefits and chronically ill youths enjoy the same benefits as the healthy counterparts^[1,70].

There are miscellaneous results regarding the long-term effect of various forms of exercise on glycemic control. Meta-analyses also suffered from the insufficient randomised controlled trials with greater sample sizes to examine the short- and long-term effect of glycemic control on different exercise modalities in youths with T1DM. Patients and health professionals may want more information they currently received, but there are concerns that the results would be overestimated. Different forms of exercise generate different skills in youths. They need a comprehensive form of exercise to help their healthy many-sided physical development. Diabetic patients should be aware that glycemic control is influenced by multiple factors (initial blood glucose level, insulin absorption, time of the day), and shows individual responses to exercise. It is advisable that young patients choose some kind of sports or physical exercise they like and be engaged with it for a longer

time. Clinical treatment and management should be adjusted to the exercise form and the diabetic patients should acquire how to change nutrition and insulin dose according to their daily physical exercise. Patients who can monitor themselves intensively around periods of activity can learn how to keep glucose levels in an acceptable range.

Although current studies have insufficient evidence of the beneficial effect of any type of exercise on glycemic control, any type of regular physical exercise has several other valuable physiological and health benefits that justify the inclusion of exercise in pediatric diabetes treatment and care.

ACKNOWLEDGMENTS

This research was partially carried out with the contribution of the Workgroup for Health Sciences, Center of Excellence of Applied Materials Science and Nano-Technology at the University of Miskolc.

COMMENTS

Background

Regular exercise is recommended for diabetic youth for several psychological and health benefits, but its physiological role in type 1 diabetes is not fully explored. So far, there are only few studies evaluating the long-term effect of different types of exercise on glycemic control.

Research frontiers

In this systematic literature review, the authors evaluated the latest studies examining the long-term effect of aerobic and/or anaerobic exercise on glycemic control in youths with type 1 diabetes. They also made distinguishing between concepts of physical activity, physical fitness, and aerobic-anaerobic exercise.

Innovations and breakthroughs

Most studies found no significant improvement in glycemic control regarding the aerobic and combined exercise intervention. The only one study evaluating anaerobic exercise observed a non-significant reduction in glycemic control. It might be supposed that longer duration (at least 6 mo) and more frequent (more than twice a week) exercise has a positive effect on glycemic control, but it is not proved yet.

Applications

Although current studies have insufficient evidence of the beneficial effect of any type of exercise on glycemic control, any type of regular physical exercise has several other valuable physiological and health benefits that justify the inclusion of exercise in pediatric diabetes treatment and care.

Terminology

Aerobic exercise includes any type of exercise, typically those performed at moderate levels of intensity for extended periods of time that maintains an increased heart rate. Anaerobic exercise is used to promote strength, power, and speed. Generally, it has a short duration and high intensity activity. Unlike aerobic exercise, it does not depend on exogenous oxygen.

Peer-review

The manuscript covers an important topic in type 1 diabetes management. The contribution that the manuscript provides is an overview of the dearth of scientific evidence to support exercise intervention in this population.

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Peter J Little, PhD, Professor, Head, Diabetes and Cell Biology Laboratory, BakerIDI Heart and Diabetes Institute, St. Kilda Rd Central, PO Box 6492, Melbourne, VIC 8008, Australia

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Asian American ethnic groups; with Filipino, Pacific Islander, Japanese, and South Asian groups consistently described as having the highest prevalence of T2DM. Disentangling and strengthening prevalence data is vital for on-going prevention efforts. The strongest evidence currently available to guide the prevention of T2DM in the United States comes from a large multicenter randomized clinical control trial called the Diabetes Prevention Program, which targets individual lifestyle behavior changes. It has been translated and adopted for some Asian American groups, and shows promise. However stronger study designs and attention to several key methodological considerations will improve the science. Increased attention has also been directed toward population level downstream prevention efforts. Building an infrastructure that includes both individual and population approaches is needed to prevent T2DM among Asian American populations, and is essential for reducing health disparities.

Key words: Type 2 diabetes mellitus; Asian American; Prevalence; Prevention; Health disparity

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Current estimates suggest that type 2 diabetes affects approximately 9% of Asian Americans overall. However, when examining disaggregated data across different ethnic groups Filipino, Pacific Islander, Japanese, and South Asian groups consistently have the highest prevalence of type 2 diabetes mellitus. This highlights how aggregating Asian Americans into one category can potentially mask the disease burden in high risk groups, while inflating the burden in low risk groups. Prevention efforts therefore need be culturally tailored to meet the unique needs of the various Asian American ethnic groups. In addition, prevention efforts should address both individual and population level strategies.

Abstract

Type 2 diabetes mellitus (T2DM) is a growing problem among Asian Americans. Based on the Centers for Disease Control, the age-adjusted prevalence of T2DM for Asian Americans is 9%, placing them at "moderate risk". However differential patterns of disease burden emerge when examining disaggregated data across

Nguyen TH, Nguyen TN, Fischer T, Ha W, Tran TV. Type 2 diabetes among Asian Americans: Prevalence and prevention. *World J Diabetes* 2015; 6(4): 543-547 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/543.htm> DOI: <http://dx.doi.org/10.4239/wjcd.v6.i4.543>

INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a growing epidemic in the United States. In 2012, over 21 million people were diagnosed with the disease as compared to 1.6 million in 1958^[1,2]. Moreover, the current cost associated with DM care in the United States is estimated at \$113 billion, and is expected to escalate to \$336 billion by 2034^[3]. The high prevalence of T2DM has been well documented for Native Americans, non-Hispanic Blacks, and Hispanic Americans^[4]. However, increasing attention has been drawn to the problem of T2DM among Asian Americans^[5,6], one of the fastest growing racial/ethnic minority groups in the United States^[7]. Disentangling and strengthening prevalence data will provide more support for activities and resources to address this important health problem among Asian Americans. In addition, understanding best practices and building an infrastructure to prevent T2DM among Asian American populations is essential for reducing health disparities, and more broadly for curbing the growing epidemic of T2DM in the United States.

PREVALENCE OF T2DM

For many years, health services for Asian American populations have been hampered by the model minority myth; the notion that Asian Americans are self-sufficient, well-educated, and have lower burdens of disease^[8,9]. In large part, the myth was perpetuated by the lack of reliable data that often lumped Asian Americans into one large category, when in fact they represent a heterogeneous group. This issue is particularly relevant when examining the prevalence of T2DM among Asian Americans. For example, the 2014 Centers for Disease Control (CDC) report estimated that the age-adjusted prevalence of T2DM for Asian Americans as a whole was 9%. This rate is lower than that of Native Americans (15.9%), non-Hispanic Blacks (13.2%), and Hispanic Americans (12.8%), but higher than that of non-Hispanic Whites (7.6%); placing Asian Americans at "moderate risk" for T2DM^[2]. When examining disaggregated data across various Asian American ethnic groups though, differential patterns of disease burden emerge.

For example, a study by Choi *et al.*^[10] using population based data from the 2009 California Health Information Survey (CHIS) found that Native Americans, non-Hispanic Blacks, and Hispanic Americans had higher overall age-adjusted prevalence of T2DM than

Asian Americans (as a whole); supporting findings from the CDC report. However, a more complex story is revealed when the data for Asian Americans are disaggregated across six different ethnic groups. Based on disaggregated data, Filipinos had the highest age-adjusted prevalence (15.8% men, 9.4% women), followed by Japanese (11.8% men, 7.6% women), Korean (6.7% men, 5.1% women), South Asian (6.3% men, 2.7% women), Chinese (5.0% men, 3.6% women), and Vietnamese (2.5% men, 2.1% women). These results demonstrated that among some Asian American groups the age-adjusted prevalence of T2DM was even higher than in non-Hispanic Black (8.8% men, 13.3% women), and Hispanics American (6.7% men, 10.7% women) groups. In particular, Filipino (15.8%) and Japanese (11.8%) American men were found to have among the highest rates of T2DM. Other population based prevalence studies have reported similar findings, with Filipino, Pacific Islander, Japanese, and South Asian groups consistently described as having the highest prevalence of T2DM across all Asian American ethnic subgroups^[11-14]. These examples highlight how aggregating Asian Americans into one category can potentially mask the disease burden in high risk groups, while inflating the burden in low risk groups.

While disaggregated data has clear advantages, much of the data available on the prevalence of T2DM among Asian Americans is at the aggregate level. When exploring aggregate data, there are some important patterns that can be used to underscore the urgency of addressing T2DM in Asian American populations. Specifically, when examining trends over time, several methodologically rigorous studies suggest that the prevalence of T2DM is increasing faster among Asian Americans than non-Hispanic Whites, non-Hispanic Blacks, and Hispanic Americans^[15-17]. Moreover, in a study that used fasting plasma glucose test to estimate the prevalence of T2DM, Asian Americans had higher levels of "pre-diabetes" than non-Hispanic Whites, non-Hispanic Blacks, and Hispanic Americans^[18]; foreshadowing further potential increases in the burden of T2DM among Asian Americans over the next few decades. Additionally, across DM prevalence studies that measure Body Mass Index (BMI), the relationship between T2DM and BMI appears to be different among Asians Americans than non-Hispanic Whites, with Asian Americans reporting T2DM at significantly lower BMI levels^[12,13,16,19]. These data provide strong evidence of disparities in T2DM among and across various Asian American ethnic groups, and underscores the urgency of addressing T2DM in Asian American populations.

To strengthen future prevalence data, providing disaggregated rates across ethnic subgroups is important. In addition, to simulate demographic data collected at the state and national level, it is helpful to report prevalence rates based on aggregated categories of "Asian" and "Asian Pacific Islander"

groups. When the goal of measuring prevalence is to compare rates across groups and time, it is also important to make sure that: (1) data are collected using a random population-base sampling strategy rather than with convenient samples; (2) adjustments are made to account for age given that T2DM significantly increases with age; and (3) rates are reported with their associated 95% confidence interval, which highlight the fact that prevalence rates are estimates of the population burden and allow readers to assess the precision of the estimate. These strategies will ensure that high quality data are collected and reflective of the realities and needs of the diverse Asian American population. Continued work in this area is essential to garnering ongoing support and resources to address the growing problem of T2DM among Asian Americans.

PREVENTION OF T2DM

The strongest evidence currently available to guide the prevention of T2DM in the United States comes from a large multicenter randomized clinical control trial ($n = 3234$) called the Diabetes Prevention Program^[20]. The program targets individuals with "pre-diabetes," and includes a 16-session "lifestyle" curriculum covering diet, exercise, and behavior change. Each session is taught on a one-to-one basis by a case manager trained in motivational interviewing techniques. In addition, six follow-up sessions are provided on a monthly basis to reinforce behavior changes. The main goals of this intervention include a 5%-7% weight reduction and ≥ 150 min of moderate physical activity per week. Study results demonstrated that this intervention reduced the development of diabetes by 58%^[20], and that the protective benefits persisted over 10 years^[21].

While the aims of the Diabetes Prevention Program are straight forward, the resource burden and lack of cultural relevance associated with the program have resulted in calls to test new models of program delivery, as well as to translate the program for use in minority populations^[22]. Several studies have demonstrated success in adopting the program in a variety of different minority populations; however they have largely been done with non-Hispanic Black and Hispanic American groups^[23,24]. Efforts to translate these findings with Asian American populations are limited, with most published studies designed at the pilot or quasi-experimental level, and focused on select Asian American ethnic subgroups including Chinese, Korean, Filipino, Pacific Islanders, and South Asians^[14,25-28]. Continued work in this area is critical because the diets and cultural norms among Asian Americans are vastly different from the general population, and vastly differ across Asian American ethnic groups^[29].

This heterogeneity likely explains most of the variance in prevalence rates described earlier, and

highlights the importance of culturally tailoring prevention interventions for a given ethnic subgroup. In 2008, the National Institutes of Health held a workshop to discuss strategic options to further investigate cardio-metabolic diseases among Asian American populations in the United States^[30]. Among their recommendations, the need to further understand dietary and physical fitness habits of Asian American subgroups was highlighted as a critical component to successfully tailoring interventions. Specifically, they suggests that more research is needed to understand the social context of eating, shopping, cooking, household dynamics on food choices (particularly related to influences on traditionally high carbohydrate diets and unhealthy eating patterns), as well as feasibility, perceptions, barriers (*i.e.*, social role strain), outliers, and motivators to exercising (perhaps by contrasting Asians who exercise and those who do not). To examine these topics, in-depth qualitative and mixed-methods studies will be vital. Of special note- given that the Asian American population represents individuals from over 60 countries with varying languages, cultures, and immigration status, a working group associated with the National Heart Lung and Blood Institute suggests clustering Asians into manageable groups that have similar risk profiles as a way to save cost and ensure broad generalization^[31]. These groups include: East Asians, South Asians, Southeast Asians, and Hawaiian/Pacific Islanders.

In addition to exploring these topics, future work aimed at adopting and/or translating the Diabetes Prevention Program should also consider some of the following opportunities and challenges. First, given that Asian Americans tend to have T2DM at lower BMI levels, expanding the inclusion criteria to include individual with BMI values between 23-25 kg/m² may be warranted. Related to this, it is advisable to also measure waist circumference, a potentially stronger predictor of DM risk given that Asian Americans tend to gain weight around the abdomen (*i.e.*, central adiposity). Second, many of the existing studies highlighted earlier use community health workers (CHWs) as the "interventionist". Future studies should describe in more detail how standardized training was provided for CHWs; this will enhance intervention fidelity, and provide stronger evidence for the value and use of CHWs. Other "burning" questions that will help move the field forward include evaluating whether or not outcomes differ when the interventionist is a "Certified Diabetes Educator", a designation that requires advanced training and increased cost. Addressing these questions will further promote the benefits of interventions like the Diabetes Prevention Program, and make them more generalizable to Asian American populations.

While there are clear benefits to interventions that target individual lifestyle changes, our current efforts underestimate how hard it is to change behavior not just once or twice, but every day of our

lives. As such, efforts directed toward population level downstream prevention efforts have gained increased attention. Primordial prevention refers to activities (*i.e.*, interventions and policies) that are put in place to prevent the development of risk factors (*i.e.*, obesity, inactivity, poor diet, and chronic stress) in the first place^[32]. Creating optimal defaults is the prevailing strategies for addressing primordial prevention. This involves creating environments that enables healthy choices and behaviors for all people across all age groups. This approach necessarily requires a population perspective that engages members of the community not traditionally involved with healthcare (*e.g.*, Boards of Education, Parks and Recreation, Department of Housing, Transportation, and Social Services). Engaging with communities and working with various stakeholders to change the environment (*i.e.*, improve social determinants of health) is especially essential in Asian American communities where coordinated advocacy work may not be as strong.

Whether prevention approaches are targeted at the individual or population level, some final thoughts that are important to consider include upfront planning to (1) estimate the cost and quality of these interventions, and (2) build in continuous longitudinal evaluation. This information will become increasingly relevant as the United States healthcare system enters an era of accountability. Together with improved reporting of prevalence data, these cumulative efforts will ensure that a strong infrastructure is built to prevent T2DM among and across Asian American populations.

hypoxia contribute to immune cell immigration and activation which further aggravates adipose tissue fibrosis. There is substantial evidence that adipose tissue fibrosis is linked to metabolic dysfunction, both in rodent models and in the clinical setting. Peroxisome proliferator activated receptor gamma agonists and adiponectin both reduce adipose tissue fibrosis, inflammation and insulin resistance. Current knowledge suggests that antifibrotic drugs, increasing adipose tissue oxygen supply or HIF-1 antagonists will improve adipose tissue function and thereby ameliorate metabolic diseases.

Core tip: The close association of adipose tissue fibrosis and metabolic complications in obesity has been corroborated in rodent and human studies. Adipose tissue hypoxia initiates fibrosis which is further aggravated by inflammation. In adipose tissue preadipocytes, adipocytes and resident macrophages produce collagen showing that the fibrotic process differs from the extensively studied scar formation in the liver. Strategies to resolve fibrosis in fat tissues thereby promoting healthy adipose tissue growth are suggested to improve metabolic situation in obese patients.

Abstract

The increasing prevalence of obesity causes a major interest in white adipose tissue biology. Adipose tissue cells are surrounded by extracellular matrix proteins whose composition and remodeling is of crucial importance for cell function. The expansion of adipose tissue in obesity is linked to an inappropriate supply with oxygen and hypoxia development. Subsequent activation of hypoxia inducible factor 1 (HIF-1) inhibits preadipocyte differentiation and initiates adipose tissue fibrosis. Thereby adipose tissue growth is limited and excess triglycerides are stored in ectopic tissues. Stressed adipocytes and

INTRODUCTION

Obesity related diseases including type 2 diabetes and non-alcoholic fatty liver disease have become a major health problem. Inappropriate insulin production, insulin

Figure 1 In obese adipose tissue hypoxia, lipopolysaccharide, lysophosphatidic acid, M1-type macrophages and matured mast cells contribute to adipose tissue fibrogenesis. Hypoxia and LPA mediated effects involve activation of HIF-1 and LPS activates TLR4. Fibrosis impairs adipogenesis and healthy adipocyte growth. Lipids are therefore stored in peripheral tissues like the liver. This is associated with impaired insulin sensitivity and inflammation. Adipose tissue fibrosis negatively affects surgery-induced weight loss. LPS: Lipopolysaccharide; LPA: Lysophosphatidic acid; HIF-1: Hypoxia inducible factor 1.

resistance and dyslipidemia are commonly associated with obesity. It is widely accepted that adipose tissue dysfunction is the major underlying reason for metabolic diseases in obesity^[1-3].

White adipose tissue is a highly dynamic organ which rapidly responds to nutrient excess and shortage. In obesity adipose tissue expands by hypertrophy and hyperplasia^[2,4]. In epididymal fat of rodents fed a high fat diet adipogenesis is detected after four weeks feeding while subcutaneous fat expands by hypertrophy for up to twelve weeks^[5]. Distinct adipose tissue depots also differ in gene expression, adipokine release and function^[4,6]. Accumulation of visceral adipose tissue is an independent risk factor for metabolic diseases while gain of subcutaneous fat may even be protective^[2,4]. The mechanisms regulating fat pad weight and distribution of body fat are, however, not well understood.

Macrophages are localized in adipose tissues and their number is strongly increased in obesity^[2,4]. Macrophages are classified as M1 and M2 types which is a very simplified approach in view of the high diversity of these cells^[7]. M1 cells express proinflammatory factors and M2 cells anti-inflammatory proteins. Adipose tissue resident macrophages in the lean state

are polarized to the M2 type and in the obese state to the M1 type (Figure 1). Various studies demonstrate a close association between adipose tissue resident macrophages and insulin resistance^[8].

Adipocyte inflammatory pathways are, however, essential for adipose tissue growth. Fat tissue expression of: (1) a dominant-negative tumor necrosis factor (TNF); (2) RID α/β , an adenoviral protein complex that inhibits proinflammatory signaling pathways like toll-like receptor 4 (TLR4)-, TNF- and IL-1 beta-mediated signaling; and (3) a mutated human I κ B α which inhibits NF κ B pathway, impairs adipogenesis and intestinal barrier function and favors ectopic lipid storage, systemic inflammation and insulin resistance. Therefore, adipocyte inflammation may be an adaption to an increased fat storage demand^[9].

Not all of the obese suffer from metabolic diseases. Obese people protected from metabolic complications display reduced adipocyte stress, lower inflammation and less accumulation of central fat than obese insulin-resistant individuals. Serum adiponectin is similar to levels in normal-weight controls. Adipose tissue growth of these individuals does not provoke adipocyte dysfunction, inflammation and fibrosis^[10]. Evaluation of the mechanisms underlying healthy and unhealthy obesity will help to identify the pathways associated with metabolic disturbances.

Research during the last 20 years revealed that rapid adipose tissue expansion is linked to adipocyte dysfunction^[2,3,11]. Adipose tissue inflammation, adipocyte death, low adiponectin, systemic inflammation, increased lipolysis and more recently adipose tissue fibrosis have been identified in obesity and are clearly associated with metabolic disturbances^[2,3,11].

ADIPOSE TISSUE EXTRACELLULAR MATRIX

Extracellular matrix proteins in adipose tissues regulate mechanical properties, adipogenesis and lipid droplet growth^[12,13]. Disruption of collagens impairs triglyceride storage during adipocyte differentiation and collagen 5 (COL5) and COL6 are essential for proper adipogenesis^[13]. High flexibility of the extracellular matrix guarantees healthy adipose tissue expansion. Inappropriately increased and rigid extracellular matrix hinders adipose tissue growth and promotes local and systemic pathologies associated with obesity^[3,14].

Fibrosis has been extensively studied in the liver. Liver injury activates "quiescent" hepatic stellate cells and these cells start to proliferate, synthesize connective tissue growth factor (CTGF) and extracellular matrix proteins. Transforming growth factor beta (TGF- β) is the main profibrotic factor in liver fibrosis and upregulates CTGF. CTGF stimulates binding of TGF- β to its receptor and thereby enhances TGF- β activity. CTGF is induced by TGF- β indicating an autocrine or paracrine loop that mutually enhances synthesis of both proteins^[1]. TGF- β also upregulates

Figure 2 Mice with leptin deficiency (*ob/ob* mice) have large adipocytes and their size further increases when collagen 6 (*COL6KOob/ob*) is knocked-out in these animals. Weakening of the extracellular matrix is associated with improved adipose tissue insulin response, reduced inflammation and TGF- β signaling, and diminished adipocyte necrosis. Subsequently metabolic situation is improved.

CTGF in adipocytes which has been shown to inhibit adipogenesis^[15]. TGF- β correlates with adiposity in humans and rodents. Blockage of TGF- β signaling protects from obesity, insulin resistance and fatty liver. Beneficial effects are partly explained by browning of white adipose tissue^[16]. In fat tissue, preadipocytes, adipocytes and macrophages produce collagens demonstrating differences in adipose tissue and liver fibrosis where alpha-smooth muscle actin and collagens are mainly synthesized by activated hepatic stellate cells^[1,2,17,18].

HYPOXIA IN ADIPOSE TISSUE FIBROSIS

Adipose tissue grows by hyperplasia and hypertrophy which leads to a hypoxic state. Oxygen levels are markedly reduced in white fat of obese rodents and are also lower in white adipose tissues of humans. In obese adipose tissue capillary density is reduced and more large vessels are detected^[19].

Hypoxia-inducible factor 1 (HIF-1) is activated

when oxygen is low. Hypoxia is supposed to induce tissue fibrosis, and collagen, type I, alpha 1 (COL1A1), COL3A1 and the enzyme lysyl oxidase with a central role in collagen cross-linking are increased when mice are exposed to low oxygen. The HIF-1 α inhibitor PX-478 and expression of dominant negative HIF-1 α block high fat diet induced HIF-1 α activation, lower body weight gain and antagonize the development of metabolic diseases. Adipose tissue fibrosis and inflammation are improved^[20]. Therefore, hypoxia mediated activation of HIF-1 seems to be critically involved in limiting healthy adipose tissue growth (Figure 1).

Hypoxia and HIF-1 activation is also believed to significantly contribute to fibrogenic progression of chronic liver diseases and HIF-mediated processes independent of hypoxia have also been described to be involved herein^[21].

Hypoxia stimulates cytokine and chemokine release from adipose tissue resident macrophages and inhibits preadipocyte differentiation by lowering peroxisome proliferator-activated receptor gamma (PPAR γ) in these cells. Therefore, hypoxia is suggested to link adipose tissue growth, inflammation and adipose tissue fibrosis. Improving adipose tissue angiogenesis lowers hypoxia, HIF-1 α , TGF- β pathway and fibrogenesis^[22].

COL6 IN ADIPOSE TISSUE FIBROSIS

Inflammation and adipocyte death are reduced by the absence of COL6 which is a highly abundant extracellular matrix component of rodent fat tissues. The increased flexibility of the extracellular matrix enables healthy adipocyte growth, lowers local and systemic inflammation and improves metabolic disease (Figure 2). PPAR γ agonist and adiponectin reduce adipose tissue collagens in mice demonstrating that improvement of adipose tissue extracellular matrix composition is one of their beneficial features^[23].

The carboxy-terminal domain cleaved from COL-6A3 promotes adipose tissue fibrosis, angiogenesis and inflammation. Increased production of this so called endotrophin in obesity contributes to metabolic disturbances. Blockage of endotrophin by a neutralizing antibody protects from adverse metabolic effects of high fat feeding^[24]. Higher BMI is a risk factor for cancer and cancer-related deaths. Endotrophin enhances tumor growth and metastasis and thus may be one of the factors connecting obesity and malignant diseases^[25,26].

IMMUNE CELLS IN ADIPOSE TISSUE FIBROSIS

Increased cell death of adipocytes in obesity may be partly caused by the rigid extracellular matrix. Crown-like structures representing macrophages surrounding dead adipocytes are characteristic for obese adipose tissue and correlate with the extent of interstitial

fibrosis. Macrophage-inducible C-type lectin is expressed in these macrophages and enhances the formation of crown-like structures, activates myofibroblasts and expression of profibrotic genes^[27]. Macrophage depletion and blockage of TLR4 signaling improve while infusion of lipopolysaccharide aggravates adipose tissue fibrosis further confirming a central role of immune cells in fat tissue dysfunction^[28].

Mast cells are well known mediators of allergic reactions and it is known for a long time that their number is increased in obese adipose tissue^[29]. Mast cells release inflammatory mediators and promote immune cell recruitment. Obese animals lose body weight after mast cell inactivation^[30]. Progression of obesity is associated with mast cell maturation which induces COL5 shown to inhibit adipogenesis^[31] (Figure 1). COL5 has also been found to be important for adipocyte maturation demonstrating that different experimental designs reveal discordant results^[13]. Mast cells in human fat are activated and are mainly localized in fibrotic regions. Mast cell number is positively associated with fibrosis and macrophage accumulation^[32].

LYSOPHOSPHATIDIC ACID AND FIBROSIS

Autotaxin is a secreted lysophospholipase D and hydrolyzes lysophosphatidylcholine to produce lysophosphatidic acid. Autotaxin is increased in obesity and liver fibrosis^[33]. Lysophosphatidic acid inhibits adipogenesis and mice with an adipocyte-specific knockout of the lysophosphatidic acid receptor 1 (LPAR1) or treated with the receptor antagonist Ki16425 gain more weight and accumulate more adipose tissue. Despite being more obese animals show improved glucose tolerance^[34]. Treatment of db/db mice with the LPAR antagonist Ki16425 reduces COL1 and COL4 mRNAs and collagen protein in inguinal and perigonadal adipose tissues. Human adipose tissue explants release autotaxin spontaneously and its levels increase over time. Lysophosphatidic acid in supernatants increases in parallel along with elevated expression of COL1 and COL3, TGF- β and α smooth muscle actin and higher level of collagen protein. *In vitro* fibrosis is blocked by the LPAR antagonist and interestingly by the HIF-1 α inhibitor YC-1 while it is further increased by oleoyl-lysophosphatidic acid^[35] (Figure 1). Upregulation of HIF-1 α by lysophosphatidic acid has been shown in colon cancer cells^[36]. Current data suggest that HIF-1 is involved in fibrotic processes even in the absence of hypoxia.

COLLAGEN EXPRESSION IN HUMAN OBESITY

In humans COL6A3 is mainly expressed by stromal vascular cells and is higher in subcutaneous than omental fat depot. In both adipose tissues its expression

is reduced in obesity and increases upon weight loss in subcutaneous fat. Leptin dose dependently decreases COL6A3 demonstrating a role of this adipokine in adipose tissue extracellular matrix organization^[37]. Animal studies have proven that leptin directly promotes liver fibrogenesis. Leptin induces COL1, TGF- β and CTGF in hepatic stellate cells and this effect is mediated via enhancing TGF- β release from Kupffer cells^[38]. Whether leptin exerts opposing effects in the liver and adipose tissue or whether its activity may be affected by adipose tissue macrophages needs further studies.

In humans with a BMI between 35 and 55 expression of COL3A1, COL5A2 and COL6A3 is lower in omental and subcutaneous adipose tissue of those suffering from the metabolic syndrome compared to the healthy obese^[39].

In contrast, positive correlations of COL6A3 expression in abdominal subcutaneous fat with body mass index (BMI) and fat mass have been described in a further study while an association with type 2 diabetes has not been identified. Elevated COL6A3 mRNA levels are found in patients with greater visceral fat mass and higher inflammation. Eight weeks overfeeding increases and pioglitazone reduces COL6A3 expression. Further, in abdominal subcutaneous adipose tissue COL5 is higher expressed in the obese than the lean^[40].

In subcutaneous abdominal adipose tissue of patients with a wide range of BMI (19-40 kg/m²) there is a strong positive correlation of COL6 and CD68 mRNA expression. COL6 and CD68 expression are associated with BMI and inversely with insulin sensitivity. Fibrotic areas are increased in the obese fat tissue and are associated with macrophage number and negatively correlate with insulin sensitivity. Alternatively activated macrophages localize to fibrotic regions and express TGF- β ^[18]. COL5 is increased and elastin is reduced in obesity^[19]. Collagens quantified by picrosirius red staining are found increased in subcutaneous and visceral adipose tissues of obese vs lean patients^[32].

Picrosirius red has also been used to quantify subcutaneous and omental fat fibrosis in a further investigation. Positive associations with liver fibrosis and systemic IL-6 but not lipid and glucose parameters of the patients have been identified. The subcutaneous white adipose tissue stiffness measured by shear-wave velocity using a prototype vibration-controlled transient elastography method positively correlates with fasting glycemia and insulin, HbA1C and fat-free mass, and negatively with body fat and HDL cholesterol. Diabetes status is also significantly associated with increased shear-wave velocity. These data suggest that subcutaneous white adipose tissue stiffness is not solely defined by collagen content. Cross-linking of collagens and other extracellular matrix proteins such as elastin, laminin, and fibronectin most likely contribute to tissue rigidity^[41].

In summary most data in humans find increased adipose tissue fibrosis in obesity. There is, however, no simple explanation for the discrepant results on

the expression of single collagen species which are found reduced and induced in human obesity. Whether this is somehow related to differential composition of the extracellular matrix of the patients analyzed or to regional variations in adipose tissues needs further analysis. Techniques to directly measure adipose tissue stiffness may be more appropriate than determining mRNA expression of individual genes for the analysis of adipose tissue fibrosis.

ADIPOSE TISSUE FIBROSIS AND WEIGHT LOSS

Mild to modest liver fibrosis is reversible^[42] and previous studies have shown that adipose tissue collagen levels are reduced by adiponectin and treatment with PPARgamma agonists in mice^[23]. In patients, transcriptional and histological analysis of subcutaneous adipose tissue revealed persistence of fibrosis two years after bariatric surgery. As expected, adipocyte hypertrophy and inflammatory infiltration are improved^[43]. Adipose tissue fibrosis is even found negatively associated with surgery-induced weight loss^[44]. These findings have been confirmed in a second cohort and the association between collagen expression in white adipose tissue and gastric bypass induced weight loss persists even when age, diabetes and IL-6 have been considered^[41]. It has also been shown that diet and surgery-induced weight loss increase COL6A3 expression in subcutaneous adipose tissue in accordance with low COL6A3 expression in the fat tissues of obese patients described in this study^[37].

CONCLUSION

Adipose tissue fibrosis limits healthy growth of adipose tissue and is associated with metabolic complications in obesity. Hypoxia and subsequent activation of HIF-1 initiate profibrotic mechanisms in fat tissues. Fibrosis in obese fat tissues is not resolved upon weight loss and is even negatively associated with surgical-induced body weight reduction. More detailed analysis of the composition of extracellular matrix, biologic function of the individual constituents and non-invasive techniques to determine adipose tissue fibrosis will give further insights into the complex association of extracellular matrix proteins and metabolic health.

Abstract

Diabetes affects at least 382 million people worldwide and the incidence is expected to reach 592 million by 2035. The incidence of diabetes in youth is skyrocketing as evidenced by a 21% increase in type 1 diabetes and a 30.5% increase in type 2 diabetes in the United States between 2001 and 2009. The effects of toxic stress, the culmination of biological and environmental interactions, on the development of diabetes complications is gaining attention. Stress impacts the hypothalamus-pituitary-adrenal axis and contributes to inflammation, a key

biological contributor to the pathogenesis of diabetes and its associated complications. This review provides an overview of common diabetic complications such as neuropathy, cognitive decline, depression, nephropathy and cardiovascular disease. The review also provides a discussion of the role of inflammation and stress in the development and progression of chronic complications of diabetes, associated symptomatology and importance of early identification of symptoms of depression, fatigue, exercise intolerance and pain.

Key words: Toxic stress; Type 1 diabetes; Inflammation; Type 2 diabetes; Chronic complications; Symptomatology

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The incidence of diabetes and associated complications are increasing. Toxic stress and inflammation may be contributors to the development and progression of diabetes complications. Current evidence supports early identification of symptoms of toxic stress for preventative strategies of associated risks for diabetes complications as well as assessment of the exacerbation of symptoms related to neuropathy, cardiovascular disease and nephropathy.

INTRODUCTION

The notion that exposure to chronic stressors predisposes individuals to developing diabetes or succumbing to worsening diabetes complications has gained

attention in recent years^[1-4]. The global epidemic of both type 1 and type 2 diabetes^[5-7] is occurring in an era of worldwide threats to personal, organizational and societal security due to psychosocial and economic burdens. According to the International Diabetes Federation, diabetes affects at least 382 million people worldwide, and that number is expected to reach 592 million by the year 2035^[8]. Although it is well-known that type 2 diabetes comprises the largest proportion of affected individuals, the number of individuals with type 1 diabetes around the world is increasing as well. Worldwide estimates for type 1 diabetes are unknown, but are estimated to be up to 3 million in the United States^[9]. A recent report on the prevalence of type 1 diabetes in youth in the United States indicated a 21 percent increase between 2001 and 2009. At the same time, rates of type 2 diabetes in youth rose 30.5%^[10].

In the midst of this public health crisis, there is tremendous need to embrace the impact of "toxic stress" from biological and environmental interactions on the development of chronic complications in persons living with diabetes. Toxic stress can result from strong, frequent, or prolonged activation of the body's stress response systems, particularly in the absence of protective mechanisms through daily coping strategies and healthy interpersonal relationships^[11]. The impact of toxic stress is apparent in current society and is garnering a paradigm shift regarding a more comprehensive understanding of health and disease across the lifespan^[11,12]. Toxic stress can be viewed as the catalyst of a physiological memory that confers lifelong risk for disease, especially due to inflammatory processes, well beyond its time of origin^[13]. How individuals, institutions, and governments respond to these stressors can have an enormous effect on the collective health of a nation. Health care clinicians serve on the front line of care delivery for identifying the most vulnerable individuals for the ravages of diabetes complications through an understanding of underlying etiologies associated with toxic stress and recognition of resultant symptomatology.

With the growing numbers of individuals diagnosed with diabetes, particularly in younger cohorts, the disease burden is ever apparent, as is the importance of minimizing the role of toxic stress on associated diabetes complications. According to Shonkoff^[14], the future consequences of significant adversity and chronic stress in early childhood extend beyond socioemotional and cognitive development. They also have significant implications for the pathogenesis of adult disease^[15], including biological manifestations of alterations in immune function^[16] and measurable increases in inflammatory markers^[17,18] that are known to be associated with poor health outcomes such as cardiovascular disease^[19-21], liver cancer^[22], asthma^[23], chronic obstructive pulmonary disease^[24], autoimmune diseases^[25], poor dental health^[26], and depression^[27-29]. Although there is no absolute evidence that chronic stress has a direct effect on the development of

diabetes in adults or children, stress can influence the onset of type 2 diabetes secondary to obesity and metabolic syndrome^[2].

With regard to the effects of stress on the neuroendocrine system, the hypothalamus-pituitary-adrenal (HPA) axis exerts considerable importance^[30]. Upon experiencing a stressor, the hypothalamus secretes corticotropin-releasing factor, which causes the release of adrenocorticotropin (*i.e.*, ACTH). This in turn stimulates the adrenal cortex, which leads to the secretion of glucocorticoid hormones, in particular cortisol. Under normal circumstances, cortisol is secreted according to a circadian rhythm, with cortisol levels highest in the morning and lowest in the evening. However, exposures to stress stimulate the HPA axis to release additional amounts of cortisol to maintain homeostasis and reduce the effects of stress. Cortisol influences a wide range of processes, including the breakdown of carbohydrates, lipids, and proteins to provide the body with energy. Cortisol has an immunosuppressive effect and therefore plays a role in the regulation of immune and inflammatory processes.

The relationship between inflammation and the HPA axis is a complex one since pro-inflammatory cytokines also stimulate the HPA axis and contribute to stress-induced elevation in cortisol^[31]. Cortisol in turn, normally plays a fundamental role in limiting the further production of pro-inflammatory cytokines *via* the important cytokine-glucocorticoid feedback cycle. This occurs through cortisol binding to glucocorticoid receptors in the white blood cells (WBCs), which once activated, leads the activated receptor [*e.g.*, Nuclear factor- κ B (NF- κ B)], to block intracellular cytokine signaling pathways, ultimately stopping the further production of pro-inflammatory cytokines^[32] and promotion of anti-inflammatory cytokines^[33]. NF- κ B consists of a family of transcription factors that play critical roles in inflammatory processes, immune regulation, cell proliferation, differentiation, and survival^[34].

With toxic stress, chronic exposure of the WBCs to high cortisol leads to down regulation of the glucocorticoid receptors, resulting in their resistance to cortisol. This stops the cytokine-glucocorticoid feedback cycle, leading to dysregulated cytokine production and chronically elevated cortisol; two states known to worsen disease outcomes. Thus, toxic stress has been associated with inflammation due to glucocorticoid receptor resistance, a mechanism of dysfunctional inflammation regulation that allows proinflammatory mediators to be uncontrolled, adding to stress-related morbidity^[35].

ROLE OF INFLAMMATION IN THE PHYSIOLOGY OF DIABETIC COMPLICATIONS

Chronic inflammation contributes to diabetes and its

complications. Features of chronic inflammation include an up-regulation of proinflammatory cytokines, such as TNF- α , interleukin (IL)-1, IL-6, IL-8, monocyte chemo attractant protein-1, and C-reactive protein that are produced by activated immune cells, resident macrophages and adipocytes^[36]. Production of these proinflammatory cytokines functions to amplify the immune response. It is recognized that a chronic, low-grade inflammatory response that occurs with an activated immune system is involved in the pathogenesis of obesity-related insulin resistance and type 2 diabetes^[37].

Markers of systemic inflammation correlate with risk for the development of diabetes related macrovascular complications^[38]. For example, in obesity-related type 2 diabetes, adipose tissue, liver, muscle and pancreatic tissues are sites of inflammation. There is an infiltration of macrophages and other immune cells coupled with a shift in cell population from anti-inflammatory to a pro-inflammatory profile. The shift in the inflammatory profile promotes insulin dysfunction leading to hyperglycemia^[39].

One complication of hyperglycemia is the formation and accumulation of advanced glycation endproducts (AGEs), ubiquitous irreversible end products of protein glycation which are formed from Amadori protein products^[40]. AGEs crosslink proteins to form stable complexes that are resistant to enzymatic degradation. In addition to hyperglycemia, oxidative stress appears to increase AGE formation. AGEs ligate with their receptor, RAGE, to amplify and perpetuate the inflammatory response through nuclear factor $\kappa\beta$ (NF- $\kappa\beta$), cAMP regulated element binding protein (CREB), and activator protein-1 (AP-1) signaling pathways. RAGE is a promiscuous receptor and has multiple ligands including lipopolysaccharide, S100/calcium binding proteins, High Mobility Group Box Protein 1 (HMGB1) and Amyloid- β peptide (A β), as well as many others^[40,41]. Data from multiple studies demonstrate that AGEs and their receptor, RAGE, are important contributors to the development of diabetes related complications^[40,42].

Oxidative stress, an alteration in redox regulation and control, occurs in response to excessive reactive species production that overwhelms antioxidant defenses^[43]. Reactive species may modify glucose, free fatty acids, oxysterols or lipids through oxidation-reduction reactions. For example, oxidize glucose is involved in the formation of AGEs. AGEs ligate with their receptor RAGE to promote an inflammatory response; modification of lipids has been shown to affect mitochondrial metabolic pathways leading to mitochondrial damage^[44,45]. Inflammation and mitochondrial damage result in oxidative stress thereby producing an autocrine feedback pathway to perpetuate inflammation and oxidative stress^[46]. This pathway has been described in the macrovasculature as well as in peripheral neurons and is recognized as a contributor to the complications of diabetes^[47,48].

Vascular dysfunction characterized by an activated

endothelium that is primed to facilitate immune cell migration into tissue also occurs in diabetes. Indeed vascular dysfunction is a key contributor of neuropathy, impaired cognition, nephropathy and cardiovascular diseases (e.g., atherosclerosis, cardiomyopathy, etc.) that underlie complications of diabetes.

DIABETIC NEUROPATHY

Peripheral neuropathy (PN) affects up to 50% of people with diabetes and the diffuse peripheral neuropathies (distal sensori-motor polyneuropathy and autonomic neuropathy) are major risk factors for foot ulceration and amputation^[49]. The etiology of PN is complex; however, studies show that altered blood flow, hyperglycemia and alterations in metabolites (oxidative/nitrative stress, advanced glycation end products and a pro-inflammatory response) are involved.

In animal models of diabetes, evidence of reduced blood flow to the nerve is seen within the first few days of the induction of diabetes with a chemical agent such as streptozosin (STZ). These changes often precede changes in nerve conduction velocity^[50-52]. However, the loss of blood flow results in neuronal hypoxia sufficient to compromise nerve function and initiate neurodegeneration^[53]. This effect has also been described in autonomic ganglia, dorsal root ganglia and in the hippocampus^[54-56].

Hypoxia also induces the expression of numerous pro-angiogenic and pro-inflammatory genes in macrophages^[57]. Alterations in the microvasculature effect associated peripheral nerves^[58]. Indeed capillary occlusion induces ischemia to the nerve producing ischemic nerve fiber damage and perineural capillary luminal occlusion (due to endothelial cell hypertrophy and hyperplasia)^[59]. In rats, hypoxic conditions reduced nerve velocity conduction, and within the context of hyperglycemic hypoxia, blockade of potassium channels leads to intra-axonal acidification by anaerobic glycolysis. This suggests that hypoxia induced neuronal changes may play a role in the development of neuropathy^[60,61]. However, reversal of hypoxia in the ischemic limbs of individuals with diabetes does not improve nerve function^[62].

Hyperglycemia appears to contribute to the pathogenesis of diabetic neuropathy. Within the first month of inducing diabetes in rats, hyperglycemia resulted in slowing of sensory^[63-65] and motor^[66,67] nerve conduction velocity coupled with hyperalgesia^[68,69] and allodynia^[70]. Over time prolonged hyperglycemia produces axonopathy, demyelination and nerve degeneration in diabetic animals^[71,72].

Metabolic alterations are thought to play a central role in the development of neuropathy in diabetes. Elevation in polyol pathway activity, oxidative stress, the formation of advanced glycation end products and a persistent pro-inflammatory response through activation of the NF- $\kappa\beta$ and p38 mitogen activated protein kinase signaling have been consistently shown

to contribute to diabetic neuropathy^[73-75].

There is considerable evidence that pro-inflammatory cytokines such as TNF- α , IL-1 β and IL-6 are involved in the pathogenesis of diabetic neuropathy. TNF- α is a potent proinflammatory cytokine that appears to play a role in the pathogenesis of diabetic neuropathy and have a central role in central and peripheral sensitization of neuropathic pain^[76]. Pharmacologically inhibiting TNF- α in mice ameliorates the electrophysiological and biochemical effects of the cytokine^[77].

IL-1 β is an important cytokine that induces the production of a wide variety of cytokines through NF- κ B activation. Studies show an increase in the mRNA expression of TNF- α and IL-1 β in the spinal cords of STZ-diabetic rats^[78]. Activated astrocytes in the spine increase IL-1 β expression, which may induce *N*-methyl-*D*-aspartic acid receptor phosphorylation in spinal dorsal horn neurons to enhance pain transmission^[79]. Hyperglycemia induces the production of IL-1 β through the NOD-leucine-rich repeats-and pyrin domain containing inflammasome^[80]. In the spinal dorsal horns of db/db mice, increased IL-1 β , TNF- α and IL-6 levels are inhibited by anti-high-mobility group box protein-1, a known RAGE ligand^[81].

IL-6 is a member of the neurotrophic cytokine family that participates in neuronal development and has neurotrophic activity. IL-6 is a sensitive marker of diabetic neuropathy and predicts progression and severity of type 1 diabetes^[82]. Increased levels of IL-6, IL-1 and TNF- α correlated with the progression of nerve degeneration in diabetic neuropathy^[83]. It is believed that these proinflammatory cytokines affect glial cells and neurons to set the pathological process of diabetic neuropathy in motion. However, the role of these cytokines in diabetic peripheral neuropathic pain is unclear^[84]. It is clear that inflammation is a complex scenario. To that end other signaling molecules such as interferon- γ , IL-10, C-reactive protein, adhesion molecules, chemokines and adipokines may also play a role in the inflammatory process associated with diabetic neuropathy and neuropathic pain.

NEUROPATHIC PAIN

Pain is the body's perception of actual or potential damage to the nerve or tissue by noxious stimuli. Large A-delta myelinated fibers and small C unmyelinated fibers are sensory afferent nerves that are mainly responsible for carrying nociceptive sensation from the skin, joints, and viscera. Tissue damage results in the release of inflammatory mediators such as prostaglandins, bradykinins, and histamines at the site of injury, which triggers the depolarization of nociceptors, thereby generating an action potential. The action potential transmits the nociceptive sensation, *via* the dorsal root ganglion (DRG) to the dorsal horn of the spinal cord. The release of glutamate and substance *P* results in the relay of nociceptive sensations to the

spinothalamic tract, thalamus, and subsequently, the cortex where pain is interpreted and perceived.

Nociceptive pain is the normal response to noxious stimuli and nociceptive pain usually subsides upon removal of the stimulus (e.g., healing of injured tissue). Neuropathic pain occurs in the absence of noxious stimuli and represents a pathological change affecting the somatosensory system. Neuropathic pain is characterized by the activation of abnormal pathways of pain at the peripheral nerve and posterior nerve roots. Neuropathic pain is a critical feature in diabetic neuropathy.

The development of painful diabetic neuropathy is complex and not completely understood. However, evidence suggests that glycemic shifts, inflammation and oxidative stress are important contributors. Hyperglycemia affects glial cells leading to demyelination and impaired neurotrophism that culminates in impaired regeneration and decreases nerve conduction velocity; ultimately this results in pain. Hyperglycemia also activated the microvascular endothelium causing endothelial hypertrophy affecting downstream endoneurial circulation to promote hypoxia and ischemia of the nerve. Hyperglycemia and hypoxia affects neurons by promoting axonopathy and neuronal degeneration. Hyperglycemia may also contribute to painful diabetic neuropathy through the polyol pathway^[85], advanced glycation end-products^[86], hexosamin flux^[87], mitogen-activate protein kinases^[73], altered activity of the Na⁺/K⁺-ATPase^[88], poly-ADP ribose polymerase (PARP) over activation^[89], and cyclooxygenase-2 activation^[90]. Nerve cells are prone to hyperglycemic injury as the neuronal glucose uptake is based on glucose concentration.

The expression of voltage-gated sodium and calcium channels and voltage-independent potassium channels in the DRG has a significant role in the generation of nociceptive sensation and peripheral sensitization. Indeed voltage gated sodium channels are active following nerve injury and demonstrate continued generation of ectopic impulses; similar findings have been observed from some voltage-gated calcium channels suggesting that voltage-gated calcium channels play a role in neuropathic pain. Calcium entry through voltage-gated calcium channels causes the release of substance *P* and glutamate, which results in the modulation of pain at the dorsal horn. The transient receptor potential vanilloid 1 (TRPV1) channel has been found to be associated with neuropathic pain as well. Methylglyoxal, a reactive intracellular by-product of glycolysis and hyperglycemia, depolarizes the sensory neuron by activating the TRPV1 channel^[91] in the DRG and also induces posttranslational modification of the voltage-gated sodium channel Nav1.8^[92]. In addition, these changes increase electrical excitability and facilitate firing of nociceptive neurons.

Neuroplasticity is the brain's response to changes within the body or the external environment. In response to chronic neuropathic pain, neuroplasticity

is associated with somatosensory cortex remodeling, reorganization, and hyperexcitability in the absence of external stimuli. Provoked pain and spontaneous stimuli may reverse the remodeling and reorganization at the somatosensory cortex^[93]. In a study of patients with chronic neuropathic pain and nonneuropathic pain Gustin *et al*^[93] found using functional and anatomical resonance imaging cortical reorganization and changes in somatosensory activity in patients with neuropathic pain.

IMPAIRED COGNITION AND DEPRESSION

Diabetes can lead to a number of secondary complications, and the most common brain complications include cognitive decline and depression. The incidence of cognitive decline, measured by behavioral testing may be as high as 40% in people with diabetes^[94]. Subjective feelings of cognitive decline have also been reported from persons with diabetes^[95], which illustrates the impact of diabetes on the individuals perception of how well their brain functions. Indeed multiple studies have reported that diabetic patients have a 2-5 fold increased risk for Alzheimer's Disease compared to non-diabetic subjects^[96,97]. Furthermore, alterations in cognitive functioning in type 1 diabetic children (less than 5 years old) has been reported^[98,99], as well as evidence of changes in white matter structure^[100].

The mechanisms responsible for the development of high rates of cognitive decline in diabetics are not well understood, although evidence suggests that neuroplasticity may play an important role. The dentate gyrus of the hippocampus and the subventricular zone are two important areas in neurogenesis^[101], the process of proliferation of progenitor cells or their differentiation into astrocytes, oligodendrocytes or neurons and survival and incorporation of the newborn cells into target regions. Hippocampal neurogenesis is diminished by exposure to environmental stress, HPA axis hyperactivity and increased inflammation^[102,103]. Changes in neurogenesis alter a number of key functions of the hippocampus, such as learning and memory, affective expression and regulation of the HPA axis^[104,105].

Wide variations in glucose levels and oxidative stress may also play an important role in the development of cognitive decline in diabetics. In animal models, studies show that repeated bouts of hypoglycemia inhibits hippocampal neurogenesis, presumably through oxidative injury to hippocampal CA1 dendrites^[106]. Hyperglycemia also promotes oxidative stress and neurodegeneration^[107]. Prolonged hyperglycemia promotes the development of AGEs which bind to their receptor, RAGE, to promote and sustain an inflammatory response through NF- κ B, AP-1 and CREB signaling pathways. RAGE ligation also promotes increases expression through an autocrine feedback mechanism^[108]. RAGE is also responsible

for the transport of amyloid- β (A β) across the blood-brain barrier. A β contributes to the development of Alzheimer's Disease^[109,110] by participating in the formation and accumulation of amyloid plaques and fibrils that facilitate neurodegeneration and impair cognition^[107]. Also, A β and hyperglycemia have been shown to activate microglia to induce oxidative injury^[111].

The relationship between diabetes and depression is reciprocal as either is known to be a risk factor for the other^[112]. The importance of depression in diabetes is highlighted by studies consistently report a higher prevalence rate for depression among type 1 and type 2 diabetics compared to the general population^[113]. Comorbid depression and diabetes is associated with poor self-care, lack of exercise, and nonadherence to dietary or medication routines, leading to inadequate glycemic control.

The mechanisms responsible for the development of depression in diabetics is unclear, although there is likely overlap between physiological and non-physiological factors to account for the pathogenesis of their comorbidity. Non-physiological factors such as sedentary life style, lack of self-care, and diet, as well as the emotion burden of managing diabetes, contribute to the development and progression of diabetes. Insulin resistance is gaining attention as a potential link between diabetes and depression and cognitive decline^[114,115]. Neuroendocrine signaling, through hyperactivity of the HPA axis, is thought to cause or exacerbate depression in diabetics^[116]. Indeed antidepressant treatment has been shown to abrogate abnormal HPA responses while facilitating recovery from depression^[117].

Stress has been shown to decrease brain derived neurotrophic factor (BDNF) in the hippocampus. Stress also appears to decrease the expression of other types of neurotrophic and growth factors such as nerve growth factor and neurotrophin-3^[118], which could lead to the alteration in the structure and function of hippocampal neurons. Stress also decreases the expression of vascular endothelial cell growth factor, a growth factor that influences vascular permeability and the proliferation of endothelial cells, in the hippocampus^[119]. The significance is that antidepressant treatment increases expression of BDNF and other growth factors in individuals recovering from depression^[120-122].

There is also considerable evidence that inflammation plays an important role in the pathogenesis of depression and diabetes^[123]. Many studies describe an increase in peripheral cytokine of individuals with depression that is often comorbid with other chronic diseases such as coronary artery disease and chronic obstructive pulmonary disease^[124]. Interestingly, cytokines have been shown to be associated with suicidality and depression^[125]. Diabetes and inflammation have been associated with alterations of dopamine, serotonin, brain derived neurotrophic factor and insulin growth factor-1 which have been implicated

in depression^[126].

CARDIOVASCULAR DISEASE, NEPHROPATHY AND ASSOCIATED SYMPTOMS

Given the worldwide increase in the incidence of diabetes, the dual complications associated with cardiovascular disease and nephropathy heighten the importance of preventive therapies through early identification of biomarkers of inflammation and causative etiologies for stress responses regardless of age or type of diabetes^[127]. In 2010, high blood pressure was the leading risk factor for deaths due to cardiovascular diseases, chronic kidney disease, and diabetes in every region of the world, causing more than 40% of worldwide deaths from these diseases^[128]. The National Diabetes Statistics Report: Estimates of Diabetes and Its Burden in the United States, 2014^[129], indicated that from 2003-2006 after adjusting for population age differences, cardiovascular disease (CVD) death rates were approximately 1.7 times higher among adults (≥ 18 years) with diabetes than among adults without diabetes. Regardless of the type of diabetes, the risk of CVD is evident and likely begins at an earlier age for those diagnosed with type 1 diabetes. Endothelial dysfunction is an integral part of the pathogenesis underlying the increased cardiovascular complications seen in individuals with T1D but it is unclear how early it appears^[130].

Results from the Epidemiology of Diabetes Interventions and Complications study, a long term follow up study of the Diabetes Control and Complications Trial (DCCT), showed that adults with T1D had increased carotid intima medial thickness (CIMT) compared to a healthy non-diabetic population 6 years into the study. Individuals receiving intensive insulin treatment during the DCCT had much less progression in their CIMT compared to those who had received conventional treatment. However there was not a significant difference in their percent HbA_{1c} at that time, suggesting the effect of "metabolic memory"^[131]. These data suggest that glycemic control may have long lasting effects on cardiovascular morphology and function^[130]. Hence, there exists a caveat to minimize exposure to toxic stressors in early life and at the onset of T1D that may aggravate optimal glycemic targets.

Cardiovascular morbidity related to diabetes is associated with vascular changes due to inflammation, resulting in both macrovascular (*i.e.*, atherosclerosis)^[132] and microvascular (*i.e.*, cardiovascular autonomic neuropathy)^[133] alterations. In type 1 diabetes, several causative factors are implicated in these inflammatory vascular changes^[134]. The oxidative modification of LDL and associated immune responses^[135] may be one of these key factors, resulting in damage to the endothelium^[136], activation of macrophages, adherence

of monocytes^[137] and impairment of nitric oxide action with resulting vascular cell cytotoxicity^[138]. Although markers of inflammation have not been extensively studied in the development of CAD in T1D, the Eurodiab study group, using a standard score based on combined levels of C-reactive protein, IL-6, and TNF- α , reported a significant difference between those with and without CAD ($P < 0.001$) after adjusting for age, gender, HbA_{1c}, diabetes duration, and systolic blood pressure^[139]. Research has also indicated that in subjects with known coronary atherosclerosis, low-degree inflammatory activity (*i.e.*, C-reactive protein, fibrinogen, erythrocyte sedimentation rate and white blood cell count) is not only increased in patients with T1D and T2D diabetes, but also increased with increasing HbA_{1c} in non-diabetic individuals. This later finding indicates an early association between degree of glycaemia, inflammation and atherosclerosis prior to the development of diabetes^[140].

Cardiovascular autonomic neuropathy is a common form of autonomic neuropathy and one of the most overlooked of all serious complications of diabetes, resulting from microvascular damage to parasympathetic and sympathetic fibers and increased risks for cardiovascular arrhythmias, sudden death, and myocardial infarction in adults with diabetes^[141]. There are multiple etiologies of diabetic neuropathy, including hyperglycemic activation of the polyol pathway leading to accumulation of sorbitol causing direct neuronal damage and/or decreased nerve blood flow^[142], oxidative stress with increased free radical production leading to vascular endothelium damage and reduced nitric oxide bioavailability^[143,144], and the formation of advanced glycosylated end products with reduced blood flow, activation of inflammatory cytokines (*e.g.*, IL-6, TNF- α), nerve hypoxia and altered nerve function^[141].

Cardiovascular autonomic neuropathy has been linked to postural hypotension, exercise intolerance, enhanced intraoperative cardiovascular lability, increased incidence of asymptomatic (*i.e.*, painless) ischemia, myocardial infarction, and decreased likelihood of survival after myocardial infarction^[145]. The presence of palpitations and tachycardia at rest due to loss of parasympathetic modulation can be present early in the development of this complication prior the onset of other associated symptoms. Cardiovascular autonomic neuropathy occurs in approximately 17% of patients with T1D and 22% of those with T2D. An additional 9% of T1D and 12% of T2D have borderline dysfunction^[133]. Since the 1970s, the seminal work by Ewing *et al.*^[146] unveiled the predictive relationship between cardiovascular autonomic neuropathy and mortality in adults with T1D. The Hoorn Study also found increased mortality in adults with T2D who had decreased cardiovascular autonomic function^[147]. Within the pediatric literature, heart rate variability (a measure of cardiovascular autonomic function) was lower in adolescents with T1D compared with healthy control

subjects^[148,149] and lower in youth with T2D vs T1D^[150].

New pathways in the development of diabetic nephropathy also implicate inflammatory processes due to hyperglycemia, renin-angiotensin system and oxidative stress, involving infiltration of the kidneys with monocytes and lymphocytes that increase pro-inflammatory cytokine production, reactive oxygen species and tissue damage^[151,152]. This leukocyte activity amplifies the inflammatory response and promotes cell injury and organ tissue fibrosis. Improved future understanding of the inflammatory response in diabetic kidneys is expected to identify novel anti-inflammatory strategies for the potential treatment of diabetic nephropathy. Familial predisposition to disease, including risks for toxic stress, race and other environmental factors interact with hemodynamic changes producing advanced glycation end products, glucose reduction and sorbitol accumulation into the cell, and overproduction of reactive oxygen species^[151]. For individuals exposed to toxic stress that may further exacerbate dysglycemia, glycemic control is of upmost importance for preventing the onset and progression of nephropathy by influencing both hyperglycemia itself and hyperglycemia induced metabolic abnormalities. Evidence for this premise is supported by randomized controlled clinical trials in both type 1 and type 2 diabetes^[153,154].

CLINICAL IMPLICATIONS FOR SYMPTOM RECOGNITION

The complications of diabetes related to neuropathy, nephropathy and cardiovascular disease are the major contributors to morbidity and mortality in this population. Given the projected increase in the worldwide numbers of individuals to develop diabetes in the coming years, the potential additional burden of toxic stress on the development of disease related complications is of tremendous concern. Key symptoms that warrant clinician recognition during routine assessment in persons with diabetes include signs of cognitive decline, depression, fatigue (including disturbed sleep patterns), exercise intolerance and pain associated with peripheral neuropathy. Although the emphasis in diabetes management is achievement of glycemic targets, weight, lipid and blood pressure control, the environmental and physiological effects of daily stress may be "ticking away" at the emergence of subtle inflammatory changes leading to devastating complications. Therefore, diabetes care management should emphasize symptom palliation as well as cardiometabolic control^[155].

Chronic low-grade inflammation in metabolic disorders such as diabetes contributes to behavioral symptoms, including depression, cognitive impairment, fatigue, sleep disturbance and pain^[156]. The quality and quantity of sleep may play a key role in the inflammatory processes associated with diabetes and

related cardiovascular disease^[157]. Additionally, several biomarkers of inflammation, specifically IL-6 and CRP, have been found to be associated with fatigue, poor concentration and sleep quality in a healthy adult cohort^[158], which has implication for the stress-induced inflammatory effect on individuals prior to the development of diabetes. There is increasing evidence that hypercytokinemia and activated innate immunity affect the pathogenesis of T2D and related symptoms of fatigue, sleep disturbance and depression^[159].

CONCLUSION

Toxic stress exposes individuals at all ages to chronic, low-grade inflammation that is a risk for the development of diabetes and may increase the physiological alterations leading to neuropathy, nephropathy and cardiovascular disease that are so prevalent in diabetes. Evidence supports the importance of minimizing toxic stress to promote glycemic control and lessening immune and inflammatory responses in an attempt to prevent the emergence or worsening of diabetes complications. At a time when the evaluation of immune and inflammatory biomarkers is not standard clinical practice, routine examination strategies are essential for the assessment of stressful life experiences and the effects of these experiences that contribute to the symptoms related to neuropathy, nephropathy and cardiovascular disease and overall quality of life.

grassroots level, involving the leaders and members of the community, the patients, the local health system and the healthcare providers. A second analysis making use of certain organizational theories was done to explore on improving feasibility and acceptability of organizing care for chronic conditions. The analyses indicated that care for chronic conditions may be introduced, considering the needs of people with diabetes in particular and the community in general as recipients of care, and the issues and factors that may affect the healthcare workers and the health system as providers of this care. The context-adapted chronic care model-based service delivery model was constructed accordingly. Key features are: incorporation of chronic care in the health system's services; assimilation of chronic care delivery with the other responsibilities of the healthcare workers but with redistribution of certain tasks; and ensuring that the recipients of care experience the whole spectrum of basic chronic care that includes education and promotion in the general population, risk identification, screening, counseling including self-care development, and clinical management of the chronic condition and any co-morbidities, regardless of level of control of the condition. This way, low-to-middle income countries can introduce and improve care for chronic conditions without entailing much additional demand on their limited resources.

Key words: Chronic care models; Context adaptation; Diabetes mellitus type 2; Low-to-middle income countries; Service delivery model

Abstract

A contextual review of models for chronic care was done to develop a context-adapted chronic care model-based service delivery model for chronic conditions including diabetes. The Philippines was used as the setting of a low-to-middle-income country. A context-based narrative review of existing models for chronic care was conducted. A situational analysis was done at the

Core tip: This paper introduces strategies that low-to-middle-income countries can employ to introduce feasible care and prevention for diabetes amidst problems of the double burden of disease and scarcity of resources, and presents a context-adapted service delivery model that integrates care for diabetes and similar chronic conditions in the current health services

and assimilates the delivery of diabetes care with other responsibilities of the health system so that people under the care of health services and the health system can experience the whole spectrum of diabetes prevention and care.

Ku GMV, Kegels G. Adapting chronic care models for diabetes care delivery in low-and-middle-income countries: A review. *World J Diabetes* 2015; 6(4): 566-575 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/566.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i4.566>

INTRODUCTION

Chronic conditions are said to be a global crisis that threatens human development, especially in low-to-middle income countries (LMIC)^[1,2]. A large number of people from LMICs live with chronic conditions. This includes around 291 million with diabetes^[3].

The macroeconomic effects of chronic conditions including diabetes in LMICs are substantial. These disproportionately affect the poor^[4] and the care for these conditions leads to continued and, as the condition worsens and complications develop, escalating expenditures while decreasing productivity. The costs of care and the disability or death of a household income earner may cause (further) poverty^[5]. For every 10% rise in mortality from chronic conditions, the yearly economic growth of a country is estimated to be reduced by 0.5 percentage points^[6]. Abegunde *et al*^[7] computed projections of foregone national income due to heart disease, stroke and diabetes in 23 LMICs and showed that these countries combined are at risk of losing US\$ 84 billion in economic output over the ten-year period 2006-2015.

Thus, LMICs should move towards strategies to deal with chronic conditions including the provision of good quality chronic care in order to address the evolution that is threatening their people. However, the acute disease-oriented health systems of LMICs may face a number of difficulties in adjusting health care delivery to accommodate the growing burden of chronic conditions in general and diabetes in particular. This could be attributed to various reasons including resource constraints, absence of programs directed towards chronic conditions, and difficulties in introducing and/or integrating care for chronic conditions.

An adequate approach to care for chronic conditions such as diabetes is very different from the acute disease-oriented approach practiced in most LMICs: in addition to the disease prevention and drug prescription activities usually done in acute disease care, chronic care also needs to focus on disability limitation and rehabilitation^[8]; should give attention to the psychosocial aspects of the patient^[9]; and should involve and enable the patient in caring for the

condition^[10]. Other features that make chronic care different from acute disease care include: (1) case finding for assessment of risk factors, detection of early disease, and identification of high risk status; and (2) long term follow-up with regular monitoring and promotion of adherence to pharmacological and psychological interventions^[11].

Analyses have demonstrated that in spite of increased funding in LMICs, progress towards agreed Millennium Development Goals, including the health-related ones, remains slow^[11]. This could be attributed to weak health systems, human resource constraints, and over-concentration of resources to specific programs. Introducing chronic disease care *in toto* as practiced in high income countries (HIC) or separately structured and resourced vertical programs to address specific chronic disease problems to LMIC health systems may prove detrimental if not fatal. A better approach could be to strengthen the first line and progressively integrate care for chronic conditions into primary care activities, taking into consideration the capabilities of the health system.

LMICs can take the initiative to undertake the first steps towards the provision of good quality chronic care. Adapting models for chronic care to fit the context of a country and selecting specific elements for implementation is likely to stand a better chance of improving chronic care. This way, specific problems such as resource constraints may be addressed; certain characteristics of the people, the health system and the country that could be capitalized on may be identified; and particular context-adapted strategies may be employed.

For this research, the investigators reviewed existing models for chronic care considering the results of a situational analysis of a low middle-income country, the Philippines, to come up with a model for diabetes care delivery that could be adapted in low-to-middle-income countries with similar characteristics.

BACKGROUND ON THE PHILIPPINES: HEALTH SYSTEMS, CHRONIC CONDITIONS AND DM TYPE 2

Public health care in the Philippines was devolved in 1992 and the responsibility of providing basic health care services for the people was handed down to the local government units, specifically municipalities and cities, through their respective local government health units (LGHU)^[12]. A decade before this health care devolution, the country implemented a primary health care policy which led to the creation of a large cadre of community-based health care workers locally called barangay health workers (BHW)^[13]. The barangay (village) is the smallest unit of government; a city or a municipality would be composed of a number of barangays. Organizationally, the BHW fall under the governance of the barangay and are selected to work

in their respective areas of residence; functionally, they are under the LGHU. A BHW is assigned approximately 10-20 families and is responsible for dissemination of health information and health promotion activities, and conducts other health-related undertakings to any member of the families being attended to.

The Philippines is among the 23 low-and-middle-income countries where 80% of the LMIC mortality due to chronic conditions is accounted for^[7]. It is likewise predicted to be among the 10 countries worldwide with the highest numbers of people with DM type 2 by 2030^[14]. For the past decade, eight of the 10 leading causes of mortality in the Philippines are chronic conditions and DM type 2 has been consistently among these^[15]. Furthermore, the complications and consequences of DM type 2 in the Philippines are on the rise and have become alarming. For renal complications alone, it is seen that 55% of Filipino diabetics will eventually develop kidney disease; in 2007 there was an increase of more than 2800 diabetic nephropathy patients requiring dialysis^[16]. Aside from these, the International Diabetes Federation estimated undetected type 2 diabetes (UDD) in the Philippines at 58.8% in 2011^[3]. It seems that the current screening strategies in routine conditions cannot adequately identify previously undetected cases of DM type 2 in the Philippines. The high rate of UDD, the rapidly increasing prevalence of DM type 2, and the poor control of disease progression and emergence of complications only show that current case management of diabetes mellitus in the Philippines is below optimum, and the burden will only escalate if no measures are employed to address these problems. On the macroeconomic level, the Philippines lost US\$60 million in 2006 from coronary heart disease, stroke, and diabetes alone^[7].

METHODS OF REVIEW AND CONTEXTUAL ANALYSIS

Narratives on models for chronic care and their elements, records of implementation and outcomes of implementation, if any, were analyzed and adapted to the context of the Philippines, an LMIC where the health system is still acute disease-oriented, there is limited organized care for chronic conditions, if at all, and healthcare expenditures are mostly out-of-pocket. The investigators focused on the two main models for chronic care, which have been used by HIC health systems as bases for the organization of chronic care. For the situational analyses, they considered a number of organizational theories: on how an organization may respond to pressure to change and what factors could influence an organization's response; and the factors that may facilitate or hinder adoption of innovations introduced to an organization. Key factors affecting the adaptation of chronic care models and the development of a context-adapted chronic care model-derived service delivery model were explored

making use of theories presented by Oliver^[17] in her analysis of organizational responses to pressures towards conformity and Greenhalgh *et al.*^[18]'s theories on diffusion of innovation, taking into consideration the background of the country and its health system and the profiles of the healthcare workers, the people with chronic conditions, and the community. The Philippine context was used and informal interviews with representatives of the community (the government and the people), the healthcare system/service and people with diabetes were conducted.

MODELS FOR CHRONIC CARE

In HICs, models and frameworks for chronic care and its delivery have been implemented, most of which were derived from Wagner's Chronic Care Model (CCM)^[19]. The CCM was conceptualized from a primary care perspective and advocates improvements in six essential elements: self-management support, clinical information systems, delivery system redesign, decision support, health care organization, and community resources^[20]. The basic idea of the CCM is quite sound: to optimize "productive interactions" between "informed, activated patients" on one hand, and "prepared, pro-active practice teams" on the other, resulting in "functional and clinical outcomes" (Figure 1). However, the CCM appears to be grounded in a preponderantly clinic-based perspective with a background of abundant resources and a highly technological environment such as can be found in HICs. Its focus seems to be on optimizing clinical interaction for more effect in dealing with chronic conditions.

To adapt the basic principles and elements of the CCM to something actionable in developing countries, the World Health Organization^[21] introduced the Innovative Care for Chronic Conditions framework (ICCCF) (Figure 2). The same essential chronic care elements specified in Wagner's model were retained. The guiding principles of the ICCCF are evidence-based decision making, population focus, prevention focus, quality focus, integration, and adaptability. It has the following essential elements for taking action: supporting a paradigm shift, managing the political environment, building integrated health care, aligning sectoral policies for health, using health care personnel more effectively, centering care on the patient and family, supporting patients in their communities, and emphasizing prevention. The ICCCF seeks to improve health care at the macro, meso, and micro levels. However, essential components for the policy environment (macro level) are needed (leadership and advocacy, integrated policies that span different disease types and prevention strategies, consistent financing, developing human resources, legislative frameworks and partnership working), requirements that many low-to-middle-income countries, especially those encountering scarcity in human resources for health,

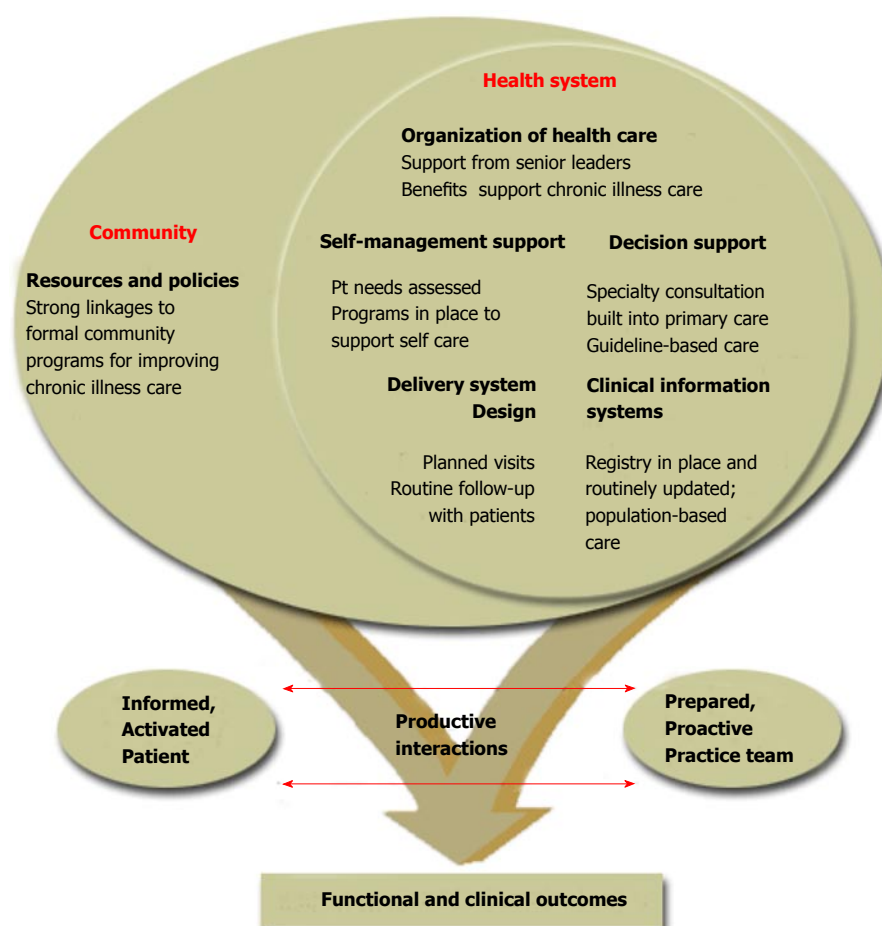

Figure 1 The chronic care model.

economic crisis, and instabilities in leadership, may be unable to fulfill.

In Canada, the Province of British Columbia formulated the Expanded Chronic Care Model (Figure 3) integrating population health promotion and prevention with the existing elements of the CCM to address the social, environmental and cultural factors that affect health^[22]. This way, the role of the community has become well delineated and added to the clinically focused initial CCM.

Some countries chose to implement selected elements of these models. In Scotland, key principles in chronic care have been established, namely: pathways of care focused on individuals with chronic conditions; partnership between health care professionals and people with chronic conditions; partnership between primary care, social care, and other agencies; integrated solutions that respond to the needs of people with chronic conditions; focus on providing care in primary care and community settings; and focus on self-care^[23].

Certain LMICs have made use of the CCM or the ICCCF to design systems of care for chronic conditions. The CCM-based Vera-Cruz Initiative for Diabetes Awareness in Mexico reports improved glycemia among its study participants 18 mo after implementation^[24] while Rwanda made use of ICCCF elements to strengthen its health system and design a system of care for

HIV/AIDS, with impressive results^[25,26]. However, such implementations of elements of the CCM/ICCCF in LMICs are exceptions rather than the rule. The health systems response in many LMICs is still characterized by a public health system focused on prevention programs; little consideration for the organization, coordination and regulation of health care services; routine medical practice without attention to the opportunities and resources for the specific aspects of chronic care; and large out-of-pocket expenses for patients^[27].

Studies conducted on the implementation of the CCM in HICs demonstrated significant correlations between specific elements of the CCM and better health outcomes^[28,29]. The number of elements of the CCM and the type and intensity of implementation may vary, depending on many contextual and organizational factors^[30].

THE ORGANIZATIONAL THEORIES USED

Oliver's typology of strategic responses to institutional processes^[17] lists five behaviors that organizations may enact in response to pressures toward conformity with the institutional environment: acquiescence and its alternative forms of habit, imitation, and compliance; compromise including pacifying tactics and bargaining; avoidance, concealment, buffering and

Figure 2 The innovative care for chronic conditions framework.

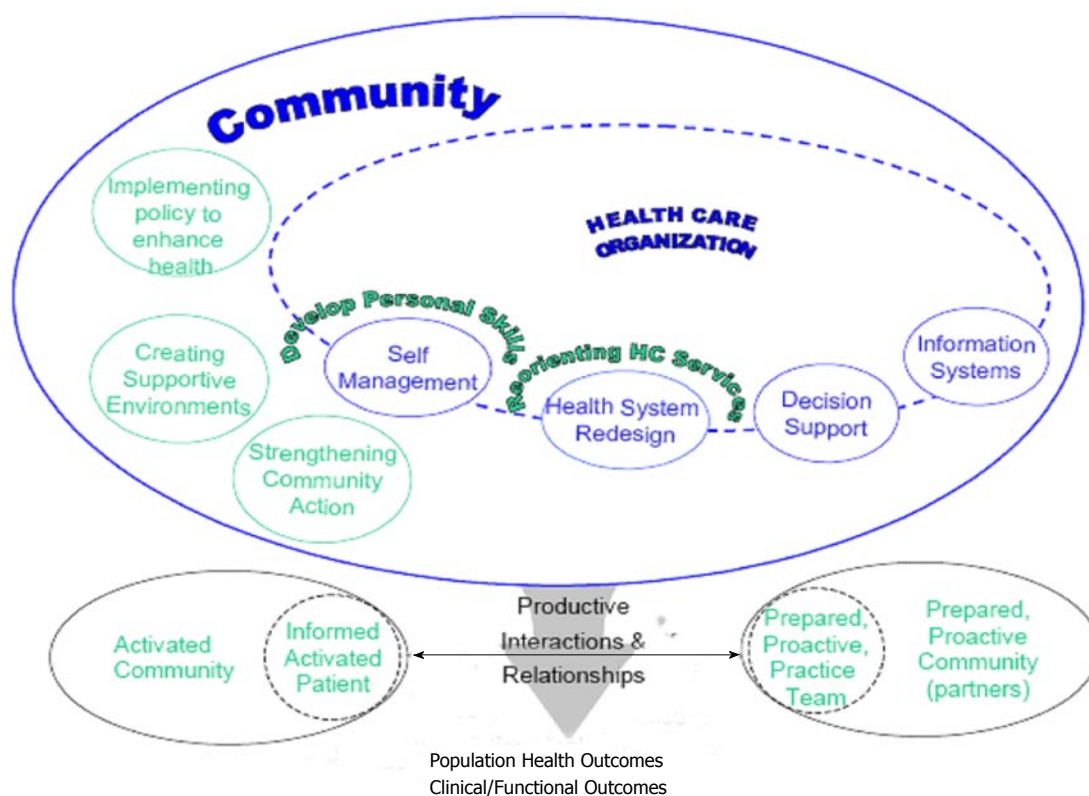

Figure 3 The expanded chronic care model.

escape; defiance, dismissal, challenge and attack; and manipulation including use of co-opting, influencing and controlling tactics. Oliver further states the following antecedents of strategic response: (1) the cause - why the organization is being pressured to conform to institutional norms or expectations; (2) the constituents - who are exerting institutional pressures on the organization; (3) the content - to what norms or requirements is the organization being pressured to conform; (4) the means of control - how or by what means are the institutional pressures being exerted; and (5) the context - what is the environmental context within which institutional pressures are being exerted. Ten predictive dimensions on which the response of the organization will depend are theorized from these antecedents. The investigators considered seven of these theoretical dimensions: social legitimacy; economic efficiency; external dependence on institutional constituents; consistency with organizational goals; constraints on decision-making imposed on the organization; voluntary diffusion of norms; and environmental interconnectedness. The other three dimensions namely multiplicity of constituents demands, legal coercion and environmental uncertainty, although necessary for implementation of top-down policies, were deemed to be less relevant for the present purpose, the perspective of which is rather how institutions would react to bottom-up innovations.

Greenhalgh *et al.*^[18] theorized that adoption of any intervention by an organization is variable - some interventions may be fully adopted, partially or not at all, while some may be eventually abandoned in time - and presented a unifying conceptual model for considering the different aspects of a complex situation and their many interactions. Certain attributes influence the (non)adoption of interventions based on the characteristics of the innovation, the individuals who will adopt the intervention and the system where the innovation will be assimilated. For this research, the investigators considered the following characteristics of an innovation in designing the context-adapted chronic care model-based service delivery model: relative advantage; compatibility; simplicity; trialability; observability; reinvention; risk; consideration of task issues; knowledge required; and augmentation/support. In constructing the model, the investigators envisioned a care model that could be applied in the context of an LMIC such as the Philippines, and that would engage the two main groups of stakeholders: those who are involved in the provision of care and prevention activities (the care providers, the health service/health system, and the policy makers); and the intended recipients of these activities (the person with the condition and the community members).

A 2-step situational analysis was conducted to help determine what specific interventions for chronic care could be feasibly applied to successfully organize care for chronic conditions, particularly type 2 diabetes mellitus (DM type 2), in the Philippines.

RESULTS OF THE CONTEXTUAL ANALYSIS

Results of analysis of key factors on the proposed organization of care for chronic conditions considering the current situation including awareness and level of knowledge on chronic conditions in general and on DM type 2 in particular, and skills for its care among the leaders and members of the community, the patients, the health system and the healthcare providers are listed in Table 1.

The community, the patients, the health system and the healthcare providers were taken into consideration as these would be the key potential players in implementing any of Wagner's six essential chronic care elements (self-management support, clinical information systems, delivery system redesign, decision support, health care organization, and community resources). The patient is central to all of these chronic care elements; the community, separately as an organized group and as a unit of government, would be responsible for the community resources; and the healthcare provider and the health service would be involved in at least five if not all of the elements.

This first analysis would indicate that there are no insurmountable barriers to the introduction of at least basic interventions for the care of chronic conditions.

The analysis of these factors was taken a step further by applying Oliver's typology and the theories of Greenhalgh *et al.*^[18] (Table 2), which explored aspects that could affect adaptation of chronic care models towards the development of a chronic care service delivery model.

Based on these, a feasible service delivery model for DM type 2 and similar chronic conditions was constructed, taking into consideration the existing healthcare organization and design, the current duties and responsibilities of individual cadres of healthcare workers, and the chronic care activities that need to be and can be provided.

THE CONTEXT-ADAPTED SERVICE DELIVERY MODEL FOR DM TYPE 2 AND SIMILAR CHRONIC CONDITIONS

Health care reorganization to concentrate primarily on chronic care is neither feasible nor desirable for developing countries still dealing with the problems of acute diseases concurrently with the rising prevalence of chronic conditions. Gradual accommodation of care to include chronic conditions is a better choice as LMICs continue their battle against malaria, pneumonia, diarrheal diseases and other acute illnesses. With this double burden of disease, the health care system should address the care for both chronic and acute conditions in terms of a more inclusive priority setting.

As mentioned previously, creating more vertical programs with specialized structures, dedicated

Table 1 Key contextual factors that is expected to affect chronic care model adaptations for the development of a service delivery model for chronic conditions including type 2 diabetes mellitus

Key factors	Analysis based on context
Community-related	
Policy	No specific policies on chronic care delivery exist at both national and local levels
Politics	Informal interviews with government officials suggested some awareness of chronic conditions such as DM type 2 and the needs that must be addressed for the care of chronic conditions in general and DM type 2 in particular in the political environment
Support	National support is limited mostly to prevention and one-day health promotion campaigns on specific chronic conditions Support from private organizations and civil societies is currently untapped
Awareness	Informal interviews with local government officials and community members suggested a low level of awareness of DM type 2, the care for DM type 2 and other associated factors, and the prevalence and burden of DM type 2 in the locality
Patient-related	
Support	Informal interview with healthcare staff and people with diabetes gave an impression of low level of support given to people with diabetes by the community and health services
Awareness	Informal interview with healthcare staff and people with diabetes gave an impression of low level of knowledge on the condition and care for the condition
Perceived need	Informal interview with people with diabetes revealed a moderate level of perceived need to improve care delivery for their condition
Perceived benefits	Informal interview with people with diabetes revealed a moderate level of perceived benefits of improving care delivery for their condition
Self-efficacy	Informal interview with healthcare staff and people with diabetes suggested a low level of self-efficacy in managing the condition
Provider-related	
Perceived need	Informal interview with healthcare staff revealed a high level of perceived need to improve primary care for chronic conditions
Perceived benefits	Informal interview with healthcare staff revealed a high level of perceived benefits of delivering good quality chronic care
Self-efficacy	Informal interview with healthcare staff suggested an impression of low level of self-efficacy in the provision of good quality chronic/diabetes care
Skill proficiency	Informal interview with healthcare staff suggested an impression of a need for skills and knowledge development regarding delivery of good quality chronic/diabetes care
Health service-related	
Leadership	The (local) government leaders and health officers are supportive of project implementation
Shared vision	The health system has a shared vision in improving the quality of care for chronic conditions
Organizational norms regarding change	The healthcare workers may be open to small, incremental changes as long as these do not lead to a drastic increase in demands on resources and workload
Administrative support	Administrative support for the project is limited

DM: Diabetes mellitus.

personnel and earmarked budget may prove more detrimental to an already-weak health system, and may inadvertently lead to inattention and cause neglect to other health issues that also need to be addressed. Primary care strengthening and capacity building of an existing health service may pave the way towards health care delivery to the people rather than prevention and care of a specific disease, moving health care towards a person-centered, comprehensive approach and veering away from being disease-centered.

LMICs can deliver prevention and care for chronic conditions such as DM type 2 by applying carefully thought-through implementation principles.

Although the care for acute and chronic diseases may seem contrasting, the people involved in health care delivery are basically not. The usual personnel complement of a health service can also be used for chronic care. Chronic care activities may range from simple, standardizable procedures that require low expertise to complex ones that require more expertise and more extensive training and education. These activities may be distributed to different types of health care personnel. A model for the delivery of chronic care services where the activities were stratified according

to the level of expertise of health care personnel in LMIC was conceptualized (Figure 4). In this model, healthcare personnel may range from volunteers/community-based health workers and expert patients, constituting the health care personnel with lesser formal expertise, to paramedical personnel (midwives, nurses) to physicians (general practitioners, specialists) constituting health care personnel with more formal expertise, although the highest tier may only involve up to the nurses in certain settings. Chronic care activities may involve health promotion and prevention in the general population, among a population at risk, and a subpopulation with high risk of developing certain chronic conditions; clinical management, counseling and health education of those with good control of their chronic conditions and with stable co-morbidities; and clinical management, counseling and health education of those with poor control of their chronic conditions and/or with unstable co-morbidities.

For DM type 2 (and similar chronic conditions, *i.e.*, hypertension, coronary artery disease, cerebrovascular accidents, some cancers, chronic obstructive pulmonary disease), health care workers with the least formal expertise may perform population-based health promotion and prevention activities, carry out pre-screening activities

Table 2 Contextual analysis of key factors affecting adaptation of chronic care models and subsequent selection of CACCM elements for implementation making use of Oliver's typology and characteristics enumerated by Greenhalgh *et al.*^[18]

CACCM- and project-related	
Oliver's dimensions	
Social legitimacy	Improving care for chronic conditions and protection and promotion of the health and wellbeing of the LGU population enhances the social fitness of the LGHU and the local government
Economic efficiency	The introduction of additional activities in any organization entails additional expenses. Cost-effective or cost-saving innovations would be preferred
External dependence on institutional constituents	The LGHU are dependent on the LGU for funding; the LGU officials who decide on the allocation of these resources are dependent on the populace for their seats in office
Consistency with organizational goals	The primary goal of the LGHU is to provide good quality healthcare to the people
Discretionary constraints imposed on the organization	The LGHU expects full autonomy especially in substantive decision-making such as resource-allocation, resource acquisition, organizational administration, <i>etc.</i>
Voluntary diffusion of norms	A moderate to high degree of voluntary diffusion with some degree of pressure from the LGU officials to diffuse said norms may be most effective in promoting adoption of the intervention
Environmental interconnectedness	A certain degree of predictability of the environment is seen: the general population, especially the people with diabetes and their families will most likely appreciate the intervention. Such appreciation may be reflected on goodwill towards the LGU officials and consequently to the LGHU (for example additional budget allocated to health)
Greenhalgh's characteristics	
Relative advantage	Implementing a diabetes-care project gives the advantage of improving the care for this condition and a number of its comorbidities, but without reduction of other health benefits
Compatibility	Compatibility of the intervention with current/pre-existing activities in the LGHU and with the current duties, responsibilities and workload of the LGHU staff is sought
Simplicity	Simplicity and ease of use of the intervention favors adoption of the intervention
Trialability	Flexibility in accomplishing a number of tasks, <i>i.e.</i> , giving leeway to the healthcare staff regarding performance of activities related to the intervention will increase acceptability of the intervention
Observability	Providing information to the intended adopters of the benefits of the intervention, <i>e.g.</i> , improvements of glycemia, favors adoption of the intervention
Reinvention	Flexibility of the intervention allowing adaptation and refinement to suit the context, the needs of the individual person with diabetes and the capabilities of the healthcare provider favors its adoption
Risk	Based on outcomes of previous studies conducted on implementation of chronic care models and provision of self-management education, it is certain that the benefits far outweigh the risks
Task issues	Workable and easy to use interventions favor adoption Relevance of the intervention to the work of the staff and tasks that may contribute to the relevance of the work of the individual health care worker is preferred However, the intervention may also be interpreted as an added workload to the LGHU staff
Knowledge required	Knowledge and skills required for full implementation of the intervention need to be supplied/supplemented
Augmentation/support	Provision of a training workshop prior to implementation increases the probability of adoption of the intervention

LGHU: Local government health units; LGU: Local government units.

to identify a subpopulation at risk for developing DM type 2, and may follow-up on people noted to be at high risk or already identified to have prediabetes. These activities are standardizable; operating procedures and work flow diagrams/decision trees may be constructed to instruct the health care worker, and checklists may be prepared to serve as guides. On the next tier of health care workers, activities that may be assigned include specific screening or confirmatory testing for dysglycemia (DM type 2 and prediabetes), identification of co-morbidities, and counseling, health education and clinical management of patients in good glycemic control and with stable co-morbidities. Although certain guidelines and diagrams still make these activities standardizable, a higher level of expertise is expected to clinically manage optimally controlled DM type 2 and co-morbidities and to recognize and know when to refer impending instabilities; special skills also need to be developed to initiate effective communication and counseling/health education. At the higher end of the spectrum, activities are focused on those with poor glycemic control and/or unstable co-morbidities and

complications, which would require clinical expertise and judgment for appropriate clinical management and counseling.

CONCLUSION

The context-adapted service delivery model for DM type 2 and similar chronic conditions may be far-removed from that in HICs, but it is designed to deliver prevention and care that encompasses the spectrum of diabetes from those at risk to those with poor glycemic control and/or unstable co-morbidities and includes counseling for self-management education and support. It is likewise designed for the general population to experience this service through general health (diabetes) education and healthy lifestyle promotion. The model incorporates care for diabetes into a current package health care activities making use of pre-existing human resources for health. It taps the potential of a workforce that may assume simple and standardizable diabetes prevention and care activities. In so doing, the additional burden on

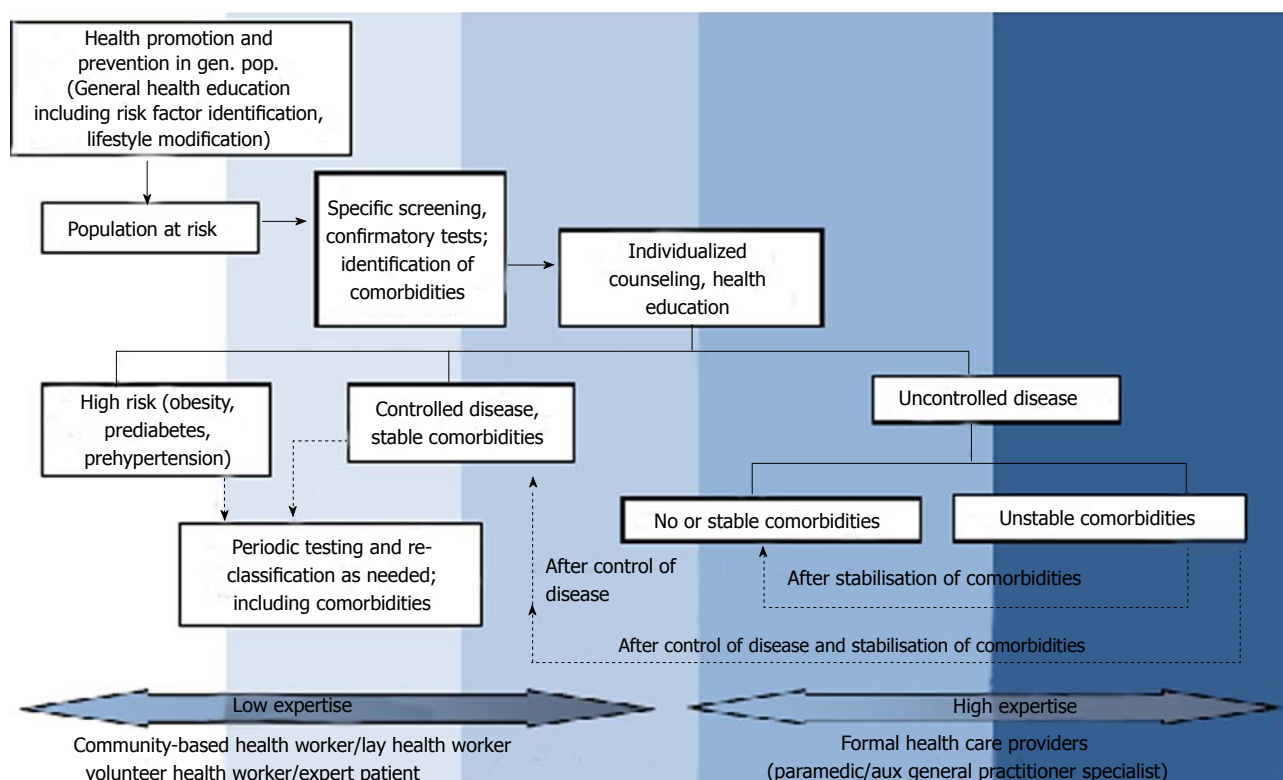

Figure 4 The context-adapted service delivery model for type 2 diabetes mellitus and similar chronic conditions.

professional healthcare workers who are now required to focus attention on both acute and chronic conditions is decreased. This service delivery model, adapted to the Philippine context, may be applicable to other LMICs having a similar situation as the Philippines. The model, however, requires additional support in terms of preparing all cadres for the delivery of diabetes care. These include sustained decision support, and materials such as the flowcharts, decision trees and checklists.

Taking inspiration from models of chronic care and carefully selecting essential elements according to effectiveness potential and local feasibility can result in basic but efficient care strategies^[31].

A low resource healthcare system with no specific attention at all for chronicity can be induced to include chronic/lifelong conditions among its priorities, even with minimal means. Well applied, however, such minimal means can make a lot of difference for increasing numbers of people.

Abstract

In this review, we focused on two molecules, connexin and sodium-glucose cotransporter, which can link to diabetic hyperfiltration. In diabetic kidney, the activation of renin-angiotensin system occurs simultaneously with glomerular hyperfiltration. The latter largely depends

on pathophysiological afferent arteriolar dilation in the presence of high angiotensin II. As a mechanistic basis for the above, tubular hypothesis has been proposed for type 1 diabetic patients as well as experimental models. Although tubular hypothesis has not been well evaluated in type 2 diabetes, clinical observations support that tubular hypothesis is true also in type 2 diabetes. Recent results on tubular hypothesis along with connexin abnormality in type 2 diabetes were revisited. In addition, the importance of sodium-glucose cotransporter in diabetic hyperfiltration is discussed. The link between salt paradox and the activation of renin-angiotensin system will be also reviewed.

Key words: Tubuloglomerular feedback; Salt paradox; Connexin; Glomerular hyperfiltration; Sodium-glucose co-transporter

Core tip: A diminished tubuloglomerular feedback (TGF) in diabetes can explain both glomerular hyperfiltration and the activation of renin-angiotensin system. An enhanced absorption through sodium-glucose co-transporter in proximal tubule decreases the delivery to macula densa, reducing TGF signal generation in diabetes. Connexin phosphorylation and subsequent ubiquitination by oxidative stress in type 2 diabetes reduces its expression in juxtaglomerular apparatus, disabling TGF signal transduction. Clinical as well as experimental evidences support that this tubular hypothesis is working, and suggest that drugs targeting the above to normalize TGF, an intrinsic physiological system, would be effective to ameliorate diabetic nephropathy.

OPENING REMARKS

As reported recently^[1], many clinical trials have demonstrated that the inhibitors of renin-angiotensin system (RAS) are effective to prevent the development and progression of diabetic nephropathy (DMN). There is an emerging agreement that the activation of RAS give deleterious influences on DMN. Why is RAS activated even in the early course of diabetes? Many experimental hypotheses for an overproduction of angiotensinogen by hyperglycemia and pathological activation of pro-renin in diabetes have been proposed experimentally^[2,3]. They appear very true at least in some aspects of DMN. From the renal hemodynamic point of view, DMN is characterized as glomerular hypertension and hyperfiltration from its early stage. In non-diabetic chronic kidney disease, single nephron glomerular hypertension and hyperfiltration occur in remnant nephrons to suffice the function of lost glomeruli due to its underlying renal disease. Thus, glomerular hyperfiltration starts when renal injury has progressed to some extent. However, all nephrons in diabetes show glomerular hypertension and hyperfiltration before microalbuminuria is developed^[4]. The main character of DMN is abnormal afferent arteriolar dilation^[5]. Tubular hypothesis is proposed more than 2 decades ago, which explain both glomerular hyperfiltration and RAS activation^[6]. Is tubular hypothesis true for type 2 diabetes, which now provides medical as well as socio-economical problems over the world? This has not been well examined. Let us start from basic experiments.

TYPE 1 DIABETES

Tubular hypothesis

Tubular hypothesis is based on physiological responses to hyperglycemia and its mechanisms are following^[6]. In type 1 diabetes, insulin deficiency causes marked hyperglycemia, resulting in the ultrafiltrate with high glucose concentration in Bowman capsule. Although proximal tubules reuptake most amounts of filtered glucose, glucose exceeding the capacity of tubular reuptake excretes into urine (glycosuria). Since proximal tubule possesses sodium glucose co-transporter 1 (SGLT1) and SGLT2, glucose is up-taken together with sodium. Then, the reuptake of sodium chloride through SGLT is increased in hyperglycemic condition, which is considered as a cause of salt-sensitive hypertension in diabetes. Furthermore, the delivery of sodium and chloride to macula densa is decreased by the enhanced reuptake through SGLT by proximal tubules (Figure 1). A reduced delivery to macula densa dilates the afferent arteriole by removing constrictor signals from tubuloglomerular feedback (TGF), to induce glomerular hypertension and

hyperfiltration. Moreover, TGF signal from macula densa inhibits renin release. Again, a reduced delivery to macula densa during hyperglycemia (due to increased proximal tubular absorption through SGLT) removes TGF signals, to activate RAS which constricts efferent arterioles, worsening glomerular hypertension^[7].

TGF mechanisms (adenosine triphosphate + adenosine) and salt paradox

There are still debates how macula densa cell transduces TGF signal to afferent arterioles. Although two hypotheses have been raised for "second messenger" for TGF, our data support the notion that both ATP and adenosine are required for full expression of TGF responses^[8]. Macula densa cell releases adenosine triphosphate (ATP) into the interstitium when it reabsorbs sodium chloride delivered by tubular flow (Figure 2). On the one hand, ATP released from macula densa binds to ATP receptor located on extraglomerular mesangial cells to induce membrane depolarization and/or an increase in cytosolic calcium^[9]. These signals travel to neighboring mesangial cells through gap junctions, and finally the signals are transduced to afferent arteriolar myocytes through gap junction^[10]. Gap junction constitutes an important intercellular communication tool. Indeed, the inhibiting the function of connexin (Cx37 or Cx40), which compose of gap junction, elicits both suppression of TGF-dependent autoregulation and RAS activation. There is a possibility that ATP secreted from macula densa diffuses to afferent arteriolar myocytes and directly interacts with ATP receptors to induce afferent arteriolar constriction. On the other hand, ATP is degraded to adenosine by nucleotidase on extraglomerular mesangial cells, and subsequently adenosine binds to its specific receptor on afferent arteriolar myocytes to induce constriction^[11].

Many paracrine factors modulate TGF. Angiotensin and endothelin enhance TGF responsiveness, whereas nitric oxide and prostaglandin diminish it^[9]. Under physiological condition, salt load that enhances the renal production of nitric oxide and prostaglandin weakens TGF. However, experimental data indicate that salt intake enhances TGF in type 1 diabetes. Salt load reduces proximal tubular reabsorption, which is enhanced in diabetes. As a result, the delivery to macula densa is increased, thereby restoring TGF that constrict afferent arteriole, thereby ameliorating glomerular hypertension, hyperfiltration and albuminuria in type 1 diabetic model^[12]. This is called salt paradox. An inverse relationship between salt intake and glomerular filtration rate is seen in type 1 diabetic patients as well as the animal models. Collectively, both tubular hypothesis and salt paradox are truly working in human^[13].

Insulin deficiency and resistance

In contrast to type 1 diabetes, which is characterized by absolute insulin deficiency due to beta-cell damage, type 2 diabetes shows normal or excessive insulin

Figure 1 Working hypothesis for glomerular hyperfiltration in diabetes. On the one hand, hyperglycemia enhances sodium reabsorption in type 1 and type 2 diabetes, thereby decreasing the delivery to macula densa with resultant weakening of tubuloglomerular feedback (TGF). The latter impairs renal autoregulation that dilates afferent arterioles, and activates renin-angiotensin system (RAS). On the other hand, TGF signal by adenosine triphosphate (P2) is damaged in type 2 diabetes due to connexin phosphorylation and gap junction malfunction, worsening glomerular hyperfiltration. High salt intake inhibits proximal tubular reabsorption, thereby increasing the delivery of sodium chloride to macula densa. This ameliorates pathological afferent arteriolar dilation by the restoration of TGF through adenosine (A1) signal^[18].

Figure 2 Sodium chloride is delivered to macula densa, macula densa releases adenosine triphosphate. Adenosine triphosphate (ATP) binds to P2 receptor on extraglomerular mesangial cell (EGM), and induces membrane depolarization and/or elevations of cytosolic calcium. These signals are transduced to juxtaglomerular cells (JGC) by intercellular communication through gap junctions consisted of connexins (Cx). In addition, ATP is degraded to adenosine by ecto-nucleotidase (eNT) on EGM. Adenosine binds to A1 receptor on JGC, increasing cytosolic calcium. Calcium waves generated in JGC transduce through gap junctions between afferent arteriolar myocytes to its upstream, eliciting ascending vasoconstriction (refs 8 and 10). MD: Macula densa; Cl: Chloride.

secretion, especially during its early clinical course. The patients with type 2 diabetes are usually obese and manifest insulin resistance, underlying hyperglycemia in type 2 diabetes. The mechanisms mediating insulin resistance are out of focus of this review, but involve oxidative stress that inhibit insulin signaling by facilitating serine phosphorylation of insulin receptor

substrate^[14].

HOW ABOUT TYPE 2 DIABETES?

Connexin

As mentioned above, gap junctions are required for the transmission of TGF signal. Juxtaglomerular apparatus

Figure 3 Expression of connexins (Cx37, 40, 43) in juxtaglomerular apparatus of type 2 diabetic (Zucker diabetic fatty) and control (Zucker lean) rats. A, B, D, E: Renin secreting cells (RSC, blue) and endothelial cells (EC) express Cx37 (A: Lean; D: Fat) and Cx40 (B: Lean; E: Fat). Cx40 is expressed on glomerular and extraglomerular mesangial cells (EGM) in control (B) and diabetes (E). Cx43 is expressed in cytosol of RSC in both groups (C, F). Quantification reveals that the expression of Cx37 in RSC is reduced in diabetic model^[15].

shows the expression of Cx37, Cx40 and Cx43. Type 2 diabetic model animals exhibit Cx abnormality^[15]. Six Cxs form one hemichannel on cell membrane^[16]. The binding of a hemichannel in a cell with the other one in an adjunct cell forms a gap junction. Gap junctions pass through small molecules such as inositol triphosphate and/or calcium, and transduce membrane depolarization, enabling intercellular communication. Post-transcriptional alterations of Cx induce conformational changes and prevent hemichannels to bind each other, especially when their extracellular loops are modified. Serine residue of Cx can be phosphorylated by protein kinase C and/or MAP. In type 2 diabetes, insulin resistance and associated oxidative stress activate these kinase activities. Phosphorylated Cx diminishes its ability to form gap junction, impairing intercellular signal transduction. Abnormal function

of gap junction/connexin is considered to be one of the causes of arrhythmia in diabetes. Indeed, the abundance of phosphorylated Cx43 is elevated in type 2 diabetic animal model. Furthermore, functional analyses demonstrated abnormal gap junction function in juxtaglomerular apparatus that inhibiting Cx37 or Cx40 failed to stimulate renin release. Phosphorylated Cx is prone to be ubiquitinated and broken down. Expression of Cx37 on renin-secreting cells is reduced in type 2 diabetic animals (Figure 3). In type 2 diabetes, functional derangements of Cx induce the removal of TGF signal, which dilates afferent arterioles and activates RAS (Figure 1). As discussed, functional impairments of Cx in DMN cause glomerular hyperfiltration through reductions of TGF signal transmission. The latter may allow direct transmission of systemic blood pressure to glomeruli, facilitating glomerular sclerosis together with

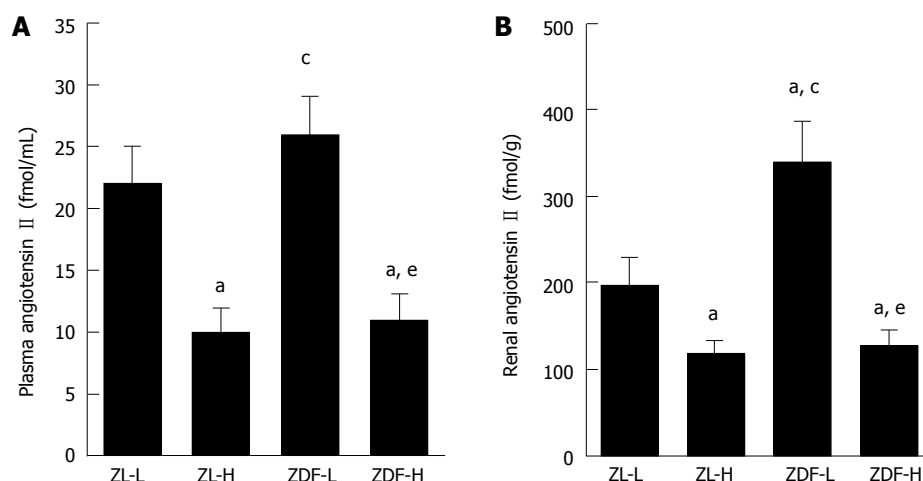

Figure 4 Plasma and kidney concentration of angiotensin II in type 2 diabetic model (Zucker diabetic fatty rat) and control rat (Zucker lean rat). ZL-L and ZL-H indicate ZL fed normal and high salt diet, respectively. Alike, ZDF-L, ZDF-H describe ZDF fed normal and high salt diet, respectively. ^a*P* < 0.05 vs ZL-L, ^c*P* < 0.05 vs ZL-H, ^e*P* < 0.05 vs ZDF-L^[18]. ZDF: Zucker diabetic fatty rat; ZL: Zucker lean rat.

Figure 5 Compared to normal condition (left), ultrafiltrate in Bowman capsule contains significant amount of glucose in diabetes (middle). Because proximal tubules reabsorb more sodium with glucose through SGLT in diabetes (1), the delivery to macula densa is decreased (2). This weakens TGF signals to increase glomerular filtration rate (3), accounting for hyperfiltration in early stage of diabetes. Either GLP or SGLT inhibition (right) inhibits proximal tubular reabsorption (1), restoring sodium chloride delivery to macula densa even under hyperglycemic condition (2). This would have TGF work and normalize glomerular filtration rate (3), ameliorating glomerular hyperfiltration. SGLT: Sodium glucose co-transporter; GLP: Glucagon-like peptide; TGF: Tubuloglomerular feedback.

systemic hypertension induced by RAS activation^[4]. Of interest, there is a report that abnormal Cx is related to the prognosis of DMN in type 2 diabetic patients^[17].

Hyperglycemia and salt

Is tubular hypothesis true for type 2 diabetes? The answer appears to be YES. Our recent data indicate that enhanced proximal tubular reabsorption and glomerular hyperfiltration exist in type 2 diabetic animal model^[18]. In addition, renal RAS is activated in this model, as evident that renal angiotensin concentration is elevated. Furthermore, in this model, acute salt load induces the

suppression of proximal tubular reabsorption and the amelioration of glomerular hyperfiltration, together with the decrease in renal angiotensin concentration (Figure 4). The observations that salt load reduces albuminuria in this diabetic model suggest that glomerular hypertension is also controlled by high salt intake. These findings provide compelling evidence that salt paradox exists in type 2 diabetes. It is proved that adenosine is a mediator of salt paradox in type 1 diabetes. When salt consumption is increased in type 1 diabetes, the delivery of sodium chloride is increased, restoring TGF signals to produce adenosine that constricts afferent

arterioles and ameliorates glomerular hyperfiltration. Our experimental results demonstrated that under adenosine receptor blockade, the amelioration of glomerular hyperfiltration by salt load was not happened. Because TGF signal transmission pathway for ATP has been already diminished due to Cx abnormality in type 2 diabetes, residing adenosine pathway works for salt paradox in type 2 diabetes. Is salt paradox truly functioning in type 2 diabetic patients? No answer was given for this question until recently. However, there is a report that proximal tubular reabsorption positively relates to glomerular hyperfiltration in type 2 diabetic black patients^[19]. Furthermore, an inverse relation between salt intake and albuminuria is demonstrated in type 2 diabetic Japanese patients^[20]. Taken together, salt paradox is working in type 2 diabetic patients regardless of difference in race.

HOPE FOR NEW ANTI-DIABETIC DRUGS

We would not recommend for diabetes to take high salt diet to prevent the development and progression of DMN. Salt load could induce hypertension and facilitate the development of cardiovascular diseases. How can we prevent DMN? Although it should be important to strongly inhibit RAS, new anti-diabetic drugs have some hope. The inhibition of DDP-4 elevates GLP1, which binds to its specific receptor on proximal tubules to induce natriuresis through suppressing proximal reabsorption of sodium chloride (Figure 5). Emerging evidences indicate that DDP-4 inhibitors show blood pressure lowering effects^[21]. Thus, according to tubular hypothesis, GLP1 ameliorates RAS activation, glomerular hypertension and hyperfiltration in DMN independently of its blood glucose lowering actions (Figure 1). Indeed, it was recently reported that DDP-4 inhibitors exhibit antiproteinuric effects in DMN. Many SGLT inhibitors are becoming available for clinical use. SGLT inhibitors may share similar renal actions with DDP-4 inhibitors. According to tubular hypothesis, SGLT inhibitors suppress proximal tubular reabsorption, which is enhanced in diabetes, suggesting that SGLT inhibitors possess blood pressure lowering and renal protective actions beyond its blood glucose lowering effects^[22]. Indeed, experimentally SGLT inhibitor showed protective effects on diabetic nephropathy. However, the influences on RAS of SGLT and DDP-4 inhibitors have not been examined. Further studies are required to clarify this issue.

CONCLUDING REMARKS

Recently, the number of patients with DMN is progressively increased, showing medical-economic problem. Research on DMN is promising from many aspects, and numerous new findings have been obtained. This is a good news, and we hope that new results could be applied for clinical care as soon as possible. However, we are sorry that they do not intend

to integrate the findings, so that they are isolated to each other. We have tried to sum up several findings in this review, although it might be inadequate. Discussion was focused on the mechanisms underlying DMN common in diabetic patients as well as animal model. The treatment with RAS inhibitors on DMN is effective, but we have to admit that they are not enough. In near future, we wish that new therapy that eventually halts DMN will be developed along with complete understanding of underlying mechanisms for DMN.

using experimental animals are a suitable option to overcome this drawback, and animal studies have improved continuously according to the needs of the experimenters. Since brain health is the most significant factor in human life, it is very important to assess brain functions according to the different exercise conditions using experimental animal models. Generally, there are two types of DM; insulin-dependent type 1 DM and an insulin-independent type 2 DM (T2DM); however, the author will mostly discuss brain functions in T2DM animal models in this review. Additionally, many physiopathologic alterations are caused in the brain by DM such as increased adiposity, inflammation, hormonal dysregulation, uncontrolled hyperphagia, insulin and leptin resistance, and dysregulation of neurotransmitters and declined neurogenesis in the hippocampus and we describe how exercise corrects these alterations in animal models. The results of changes in the brain environment differ according to voluntary, involuntary running exercises and resistance exercise, and gender in the animal studies. These factors have been mentioned in this review, and this review will be a good reference for studying how exercise can be used with therapy for treating DM.

Abstract

Human life span has dramatically increased over several decades, and the quality of life has been considered to be equally important. However, diabetes mellitus (DM) characterized by problems related to insulin secretion and recognition has become a serious health problem in recent years that threatens human health by causing decline in brain functions and finally leading to neurodegenerative diseases. Exercise is recognized as an effective therapy for DM without medication administration. Exercise studies

Core tip: Brain is a highly sensitive and vulnerable tissue easily influenced by diabetes mellitus (DM). Physical exercise has been known to be one of the best non-pharmacologic ways to prevent and treat DM. Animal exercise experiments are very useful for research on DM because experiments cannot be performed in humans. Exercise has various benefits that help to improve brain function by reducing chronic inflammatory responses, accumulation of adipose tissue, appetite, insulin resistance, and dysfunction of the negative

feedback mechanism. In this review, the author reports a battery of animal models of exercise, and presents the beneficial effects of exercise on the brain.

Yi SS. Effects of exercise on brain functions in diabetic animal models. *World J Diabetes* 2015; 6(4): 583-597 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/583.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i4.583>

INTRODUCTION

Diabetes mellitus (DM) is one of the most common endocrine disorders and is mainly divided into two types according to the activity of β -cells in the pancreas: type 1 DM (T1DM) is characterized by degeneration of β -cells, while the main cause of type 2 DM (T2DM) is a progressive decline in insulin sensitivity resulting in sustained hyperglycemia^[1-3]. Particularly, DM is known as the main factor that can cause various pathologic brain complications and can promote cognitive impairment and vascular dementia in humans^[4-8]. A number of studies have reported that DM can cause hormonal dysregulation, systemic vascular changes, dysregulation of the plasma glucose level, changes in blood chemistry, and other organ dysfunctions such as kidney and heart failure^[9-19]. Various medical treatments are available to regulate glucose dysregulation, correct hormonal changes and vascular conditions in DM patients; however, these medical treatments cannot always cure the metabolic disorder completely, and physicians also cannot predict the progression of the complications with uncontrolled patient's life styles^[20-24].

Particularly T2DM is significantly related to the incidence of obesity and its associated disorders^[25-27]. Obesity is defined as a surplus of body fat accumulation, with the excess of adipose tissue really being a well-established metabolic risk factor for the development of obesity-related comorbidities such as insulin resistance, T2DM, cardiovascular diseases, and some common cancers^[2,28-32]. The mechanisms linking excess adiposity and cancer are unclear, but the obesity-related low-grade chronic inflammation is widely accepted as a critical factor in the pathogenesis of various diseases such as T2DM, cardiovascular disorders, dementia, cancers, dietary control failure^[26,28,33-42]. Currently, particular attention has been placed on the pro-inflammatory microenvironment in the body associated with obesity, specifically underlining the involvement of obesity-associated hormones/growth factors in the cross-talk between macrophages, lymphocytes, adipocytes, and epithelial cells involved in the development of T2DM^[28,43]. In addition, accumulated peripheral white adipose tissue (WAT) is an endocrine tissue that secretes hundreds of cell-signaling molecules known as cytokines, chemokines, and adipokines^[29,32,33,44,45]. The endocrine

function of adipose tissue might be a key factor in the mechanisms linking adipose tissue to insulin resistance, leptin resistance, dietary control failure, T2DM-associated dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis, neurodegenerative diseases, vascular diseases related to aging, cognitive impairment, and dementia^[27,35,45-50]. Hence, uncontrolled chronic obese condition can be a critical factor in the development of T2DM, and it also acts as an agent that affects normal brain functions.

Recently many studies have shown the positive effects of regular physical activity on improving complications caused by DM, and hence regular physical activity intervention is regarded as a promising adjuvant therapy^[7,37,51-62]. Exercise can affect various physical environments and has decisive effects on improving brain functions for a better quality of life^[7,59-61,63-72]. However, the precise mechanisms responsible for the positive effects of exercise on brain functions under obesity and T2DM conditions have not yet been well understood, and many studies have been performed using animal models of different diabetic stages regardless of the DM type and under various kinematic conditions to assess the related mechanisms for changing the microenvironment of the brain. Thus, experiments with animal exercise models mimicking the etiology and progression of human DM have been actively performed and developed to assess the preventive and therapeutic effects of exercise on brain functions^[1,73-81].

Therefore, we review recent evidences on the role of exercise in promoting brain functions mainly under T2DM conditions in animal models and provide practical applications for the management of T2DM.

PHYSIOPATHOLOGICAL CHANGES CAUSED BY DM

Most of the DM conditions gradually impair normal brain functions by causing excessive production of pro-inflammatory cytokines, insulin resistance, and reactive oxygen species due to certain causes such as prolonged obese condition or hormonal dysfunction^[15,27,28,31,32,35,82-88]. Excessive and/or compulsive overeating disturbs the normal blood composition, deteriorates cardiovascular circulation, induces insulin resistance, and increases the visceral fat^[29,45,82,89-91]. Particularly, the infiltrated inflammatory immune cells such as macrophages and lymphocytes in adipose tissues secrete a variety of cytokines into the blood stream, and negatively influence the systemic cardiovascular system and the brain^[32,44,82,92-94]. A number of studies have shown that elevations in levels of systemic inflammatory mediators such as adipokines, tumor necrosis factor- α , resistin, interleukin-6, plasminogen activator inhibitor-1, C-reactive protein, monocyte chemoattractant protein (MCP)-1 play a pivotal role in changing the physiology of the brain^[3,45,56,82,95-98]. Particularly, results of animal

and human studies have showed that insulin passes *via* the systemic circulation to the brain and it may have some physiologic actions which are different than its peripheral metabolic effects. Insulin resistance in peripheral tissues leads to the elevation of pro-inflammatory cytokines, neurotoxic ceramides, obesity-induced NADPH oxidase-associated oxidative stress in the brain, and insulin action on the brain is thought to be a regulator of peripheral glucose homeostasis in rodent studies *via* melatonin related mechanisms, increased unfolded protein response activation, mitochondrial and ER stress related overeating, leptin and insulin resistance, corticotropin-releasing factor-related islet cell control^[47,67,99-102]. Recent studies of the mouse brain have demonstrated that degenerative plaque formation observed in AD (AD is the most prevalent form of dementia) is associated with insulin resistance^[47,103]. Insulin regulates food intake and cognitive functions in the brain; however, deranged insulin signaling in the brain has also been implicated in neurodegenerative disorders^[104-107].

Insulin action in the brain is regarded as the main factor for maintaining DM patients in a healthy condition due to the interrelationship between peripheral and central insulin resistance.

ANIMAL MODELS IN DM RESEARCH

DM is a chronic disease that is characterized by a relative or absolute lack of insulin release, resulting in hyperglycemia. Since T1DM and T2DM, as endocrine disorders, represent quite complex diseases in which different organ systems are involved, animal models should be chosen carefully depending on what aspect of the disease is being investigated. On the other hand, for developing specific models of T1DM and T2DM, investigators should be aware of the different pathogenic mechanisms of DM that involve different inducible factors.

T1DM animal models

The main characteristic of T1DM is autoimmune destruction of the pancreatic β cells, leading to lack of insulin release. In animal models, investigators can induce this deficiency by chemical ablation of the beta cells in breeding animals that spontaneously develop the autoimmune diabetic condition. The representative chemicals that induce T1DM are streptozotocin synthesized by *Streptomyces achromogenes*^[108-110], and alloxan^[1,73,111,112] which causes poor β cell defense mechanisms against free radicals. Thus, these chemicals can be used for developing new insulin, transplantation models for testing treatments that may prevent beta cell death. However, the researchers should be aware that a number of studies using STZ did not consider the time period between chemical injection in animals and sacrifice. Thus, it is true that many researches on T1DM using STZ injection have ignored this factor. Shin *et al*^[110] and Yi *et al*^[113]

demonstrated chronological hippocampal changes in the brain at different time points of animal sacrifice after STZ injection. Therefore, researchers should remember that the results of T1DM *via* the chemical might be different based on how many days or weeks have passed following chemical administration in animals.

The non-obese diabetic mice, Biobreeding rats, and LEW. 1AR1/-iddm rats are the most commonly used animal models of spontaneous autoimmune diabetes showing beta cell destruction due to an autoimmune process^[1,73,75]. Akita mice, a genetically induced insulin dependent T1DM diabetic animal model, are characterized by beta cell destruction *via* ER stress. Lastly, T1DM can be induced by viruses such as Coxsackie B virus^[114], Encephalomyocarditis virus^[115,116], and Kilham rat virus^[116,117]. The virus-induced model can be complicated as the outcome is dependent on replication of the virus as well as timing of the infection^[118].

Several other large animal models except for rodent animals have been developed to study T1DM extensively. Since it is relatively difficult to expect the development of spontaneous diabetes in large animal models, induced models of T1DM are required. The most commonly used method of inducing T1DM in large animal models is by performing pancreatectomy and chemical ablation of beta cells (STZ)^[119-122]. The T1DM rodent models are summarized in Table 1.

T2DM animal models

The main characteristics of T2DM are insulin resistance and β cell dysfunction, and defective insulin secretion from β cells. Therefore, animal models of T2DM tend to include models of insulin resistance and/or β cell dysfunction. Most of the T2DM animal models are characterized by the obese phenotype, which reflects the human condition where obesity is closely related to T2DM development^[1]. The T2DM animal models are categorized according to the type of induction mechanism as follows: spontaneously obese models^[1], diet/nutrition induced obesity models^[123,124], non-obese models^[125], genetically induced models of β cell dysfunction^[126], and surgically induced diabetic animal models^[127]. The T2DM rodent models are summarized in Table 2.

DM AND THE NEURAL SYSTEM

DM and central nervous system

Diabetes is significantly related with brain microenvironments and functions. Diabetes is known to largely affect the intensely vascular organs such as kidneys, liver, and brain^[16,18-20,49,50,87,88,95,98,99,128-130]. Brain is the key organ that is involved in hormonal, sensory, and motor regulations so that living organisms can maintain homeostasis *via* the negative feedback system^[46,131]. However, diabetic condition can be a serious chronic stress factor, and its secondary negative effects can exert a bad influence on the

body^[10,46,113]. What is more important is that, since the brain is a very vulnerable and sensitive organ, the duration and severity of DM might result in serious neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease^[10,70,102]. The HPA axis regulates responses to various stress factors, digestion, immune response, mood and emotions, sexuality and energy expenditure/storage^[11,59,104,132-134]. In addition, since the HPA axis is also connected with the autonomic nervous system^[135,136], it is very important when the

brain orders right responses to diverse physiological conditions. If DM persists and/or is increased without any modification, the brain cannot maintain the normal HPA axis regulation, and the HPA axis based on the negative feedback system tends to be highly activated due to uncontrolled DM. However, sometimes exercise-induced stress might influence the beneficial effects of exercise are not observed in certain behavioral test. It is recognized that the amount of psychological stress that an animal encounters determines the degree of

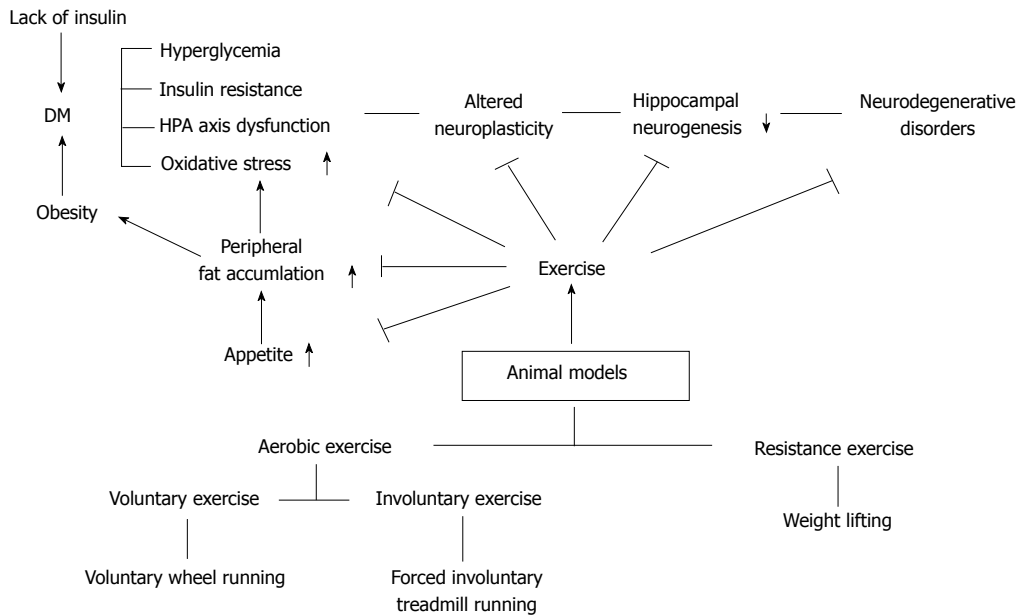

Figure 1 Exercise animal models can separate aerobic voluntary/involuntary exercises and non-aerobic resistance exercise. The exercise can attenuated many neuro-related disease followed DM and obesity. DM can develop many kinds of dysregulation such as hyperglycemia, increasing insulin resistance and HPA axis dysfunction and oxidative stress. Exercise reduces peripheral fat accumulation and appetite in animal models, and it has preventive and therapeutic effects for the many risks to develop obesity and DM. A number of studies about diabetes have been revealed the related mechanisms through exercise animal models. Non-aerobic resistance exercise described in Table 3. DM: Diabetes mellitus; HPA: Hypothalamo-pituitary-adrenal.

response of the HPA axis regulation^[137]. Moreover, it has been reported that animals performing an exercise at the stress-induced physiological and environmental factors can be strongly affected^[59,137-139]. Therefore, there would be enough possibilities to show different behavioral effects under various kinds of stress factors in exercise animal models such as metabolic DM and psychological depression/anxiety disorders. Cayado *et al.*^[137] reported that different training showed different exercise effects at the horse exercise training. Martínez-Mota *et al.*^[138] indicated that the HPA axis response can be different according to sex and age at the exercise animal model. Furthermore, since DM is defined as a chronic systemic inflammatory condition, the disease can contribute to the development of different metabolic disorders. The most significantly affected organs by the chronic inflammatory condition are the vascular converged areas, and thus cardiovascular system is mostly vulnerable and its vascular microenvironment is changed leading to profound damage. Particularly, the occurrence of T2DM is generally characterized by the development of chronic obese condition *via* overnutrition and/or increased hyperphagia^[123,124,133,140,141]. In addition, neuroinflammation and neurodegeneration have been known to be closely related with overnutrition-induced disease and diabetic animal models^[2,4,9,99] (Figure 1).

T2DM is commonly known to be the consequence of chronic obesity and it is usually accompanied by uncontrollable hyperphagia^[142-144]. Many factors contribute to pathologic overeating and mediate feeding behavior in humans and animals, and the most important factor is leptin^[104,145,146]. Leptin, which

is a cytokine originating mainly from white adipose tissue, plays an important role in regulating energy expenditure, food intake, and obesity^[45,71,91,98,104,145,146]. The mechanism by which leptin modulates these hypothalamic neurons involves the binding of leptin to the long form of leptin receptor (Ob-Rb) and subsequent intracellular signaling, initiated by autophosphorylation of Janus kinase 2 (JAK2) and activation of signal transducer and activator of transcription (STAT3). Following the translocation of STAT3 to the nucleus, suppressor of cytokine signaling-3 is activated, exerting feedback inhibition on JAK2. Leptin activation of insulin receptor substrates and the protein kinase B pathway inhibits food intake and modulation of extracellular regulated kinases has been demonstrated to play a role in the control of energy homeostasis^[147]. Obese patients and animals cannot regulate their hedonic appetite except for acceptable daily intake of calories. They have excessive WAT in the body and it secretes leptin in the blood; however, the appetite center does not recognize leptin and shows resistance to leptin. Therefore, leptin administration to obese rats and humans has elicited small effects on fat mass and appetite due to leptin resistance^[2,53,148]. Likewise, many neuropeptides located in hypothalamic nuclei transmit related anorexigenic or orexigenic signals^[104,146]. Furthermore, many kinds of neurotransmitters such as serotonin, dopamine, and norepinephrine participate in regulation of mood, emotions, and appetite^[149]. Particularly, specific serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have been introduced and used as medical treatments to reduce food intake of overweight patients^[150-153]. These

drugs have been modified continuously to overcome their side effects or toxicities^[154]; however, chronic administration of SSRIs or SNRIs causes rebound body weight gain in the patients. The phenomenon has been observed for a while; however, the cause was not the patients' psychological drug dependence, and same results have been obtained in many studies performing animal experiments^[155,156]. Since these agents not only influence the appetite center but also the other areas in the brain, the environment of the brain gets affected^[157-159]. Therefore, more specific target regions in the brain and promising regulatory drugs are required. Finally, failure of appetite control can easily lead to T2DM, and then the continuous progression of this metabolic disorder harms the neuroenvironment of the brain and affects learning/memory and cognitive functions^[47,49,85,87,160]. According to the severity of DM, hippocampal neurogenesis in the dentate gyrus is significantly reduced and neuronal plasticity is also negatively influenced through reduction in neurotrophic factors^[31,130,160]. Uncontrolled DM with hyperglycemia can cause serious brain damage; therefore, appropriate therapies that can slow the progression of this disease are needed.

DM and peripheral nervous system

Diabetic neuropathy affecting the peripheral nervous and autonomic nervous systems is the most frequent complication of diabetes. The most common neuropathies are chronic sensorimotor distal polyneuropathy (DPN) and autonomic neuropathies^[161]. Morphologically, DPN is characterized by alterations in peripheral nerve fibers as well as degeneration and regeneration of both myelinated and unmyelinated fibers in humans, decreased axonal diameter of the sciatic nerve and myelin sheath thickness of the sural nerve, and alteration of the cytoskeletal component in dorsal root ganglia of rats^[162-164].

Currently, human life span has dramatically increased due to advances in medical science, and moreover, improving the quality of life has also received attention. Therefore, people are feeling the need to maintain their brain health throughout their life. However, DM poses a threat to the health of people and therefore it has become a problem that needs to be conquered.

EFFECTS OF EXERCISE ON THE BRAIN OF DIABETIC ANIMALS

It is already well known that regular physical activity has a tremendous impact on health and has protective effects against chronic diseases, including heart disease, stroke, hypertension, and DM. Over several decades, many evidences have demonstrated that exercise in human and animal models helps to maintain brain health such as cognitive performance, and it can even protect the central nervous system and improve

learning/memory functions following chronic exercise, both in animal models and humans^[59,61,104,165-171]. In recent years, many exercise and cognition studies have been carried out in adult rodents. These researches have provided insights into the underlying cellular mechanisms^[169,172]. Both voluntary and forced exercise enhanced spatial memory in Morris water maze, Y-maze, T-maze, and radial arm maze test^[65,169]. Particularly, running exercise improved performance in hippocampus-dependent tasks that require limited movement, and there were non-hippocampal dependent benefits from voluntary and forced exercise. Chronic involuntary treadmill exercise in an T2DM animal model (ZDF rats) reduced blood glucose levels, caused cell proliferation and an increase in neuroblasts in the hippocampal dentate gyrus; however, the onset of treadmill exercise in the severe chronic diabetic condition has a limitation in increasing neuroblast differentiation although it increases neural plasticity^[77,80]. Therefore, for achieving effectiveness of treadmill exercise in increasing neuronal differentiation in the hippocampus and for counteracting the negative effect of DM in the brain, the initiation time of exercise during the early stage of DM may be a very critical point to achieve the positive effects of exercise^[77]. Furthermore, Hwang *et al*^[77,173] reported that Cox-2 is very important factor for hippocampal neurogenesis in the T2DM animal exercise models. Griffin *et al*^[167] reported that voluntary exercise also increased volume of the hippocampus resulting in improved search strategies and decreased perseveration once the platform had been moved to a new location. Voluntary exercise results in elevation of levels of factors such as brain-derived neurotrophic factor (BDNF), whose levels increases with aerobic exercise, and enhances hippocampal function^[167].

Interestingly, Burghardt *et al*^[174] studied the behavioral effects of voluntary and involuntary running exercise with a battery of behavioral tests; they investigated the effects of 8 wk of forced treadmill running and voluntary wheel running on behavior measures in the elevated plus maze, open field, social interaction and conditioned freezing paradigms. They found that chronic voluntary running produces behavioral changes in the elevated plus maze and open field; however, chronic treadmill running failed to produce behavioral changes with their running protocol. Changes in opioidergic^[175], serotonergic^[176], GABAergic^[177], and catecholaminergic^[178] systems have also been observed after wheel running. Regular running exercise is closely associated with food preference and appetite depending on the volitional wheel running and involuntary treadmill exercise. Recently, attention has been paid to various causes of food preference and consumption according to a wide range of conditions for overcoming the obese and DM conditions^[179]. Diet composition may lead to changes in neuropeptides within brain nuclei regulating energy metabolism. Dietary manipulation has been thought to influence energy expenditure *via* changes in

central neuropeptide activity. Many studies report that medicines such as morphine, fenfluramine influence the neuro-regulatory systems and exercise can modify palatability in animals^[175]. Blundell *et al*^[37] asserted that changes in dietary preferences could be due to alterations in the hedonic properties of the food as a result of exercise in rodent models. Shin *et al*^[144] also indicated a possibility that treadmill exercise in animals inhibits diabetes-induced increment of the desire for food. Hormonal (leptin and insulin) and nutrient signals from the periphery are mainly integrated in the hypothalamus, and multiple factors regulate food intake. AMP-activated protein kinase (AMPK) is the downstream component of a kinase cascade that acts as a sensor of cellular energy charge, being activated by rising AMP coupled with falling ATP^[180]. Although the effects of AMPK on desire for food are still controversial, exercise may contribute to appetite suppressive actions in the hypothalamus due to the effects of leptin and in different causes in the rodent model^[147,179-182]. As mentioned above, alterations in opioid or inhibitory neurotransmission systems in both limbic and brainstem areas could be implicated, including the nucleus accumbens^[183]. Multiple mechanisms of action in the brain could be responsible for this behavioral difference and lack of gross metabolic difference^[171]. In humans, texture, temperature, color, and appearance all play a role in food acceptance^[184,185]; however, animals exhibit a wide range of food preferences and animal studies can eliminate the points of dispute in human studies. In addition, an important element in the study of effects of exercise on food preference is sex differences^[171,175,179]. Sex differences exist such that female rats tend to prefer carbohydrates over other macronutrients following exercise^[134,175]. Unfortunately, there is still no clear evidence on the effect of exercise on macronutrient or carbohydrate selection in different sexes in animal or human studies. Therefore, further research for assessing the sex differences in food preference after exercise is needed.

Chronic inflammation and increased oxidative stress are observed in the animals showing insulin resistance following diet-induced obesity^[36,44,45,62,131,186,187]. Indeed, since the brain tissue is highly sensitive to chronic inflammation and oxidative stress due to its high oxygen consumption, iron and lipid contents, and low activity of antioxidant defenses^[102,188], energy metabolism impairment and oxidative stress are important events that have been related to the pathogenesis of diseases affecting the central nervous system^[47,180]. Exercise has been known to decrease chronic systemic inflammatory response, show antioxidant effects and positive effects on synaptic plasticity in the obese and/or diabetic rodents^[55,60]. In the T1DM animal model, significant inflammatory responses are found and they showed different action in a time-dependent manner^[113]. These responses induced by DM lead to mitochondrial dysfunction, which can progress to various pathologies such as neurodegenerative diseases (dementia,

Alzheimer's disease, Parkinson's disease)^[33,34,47,61]. Both T2DM and neurodegenerative diseases are associated with impaired glucose tolerance and cognitive decline in the human and animal studies, and insulin resistance and subsequent hyperinsulinaemia have been found to increase the risk of Alzheimer's disease and promote decline in memory and cognitive dysfunction^[3,34,61,133,189]. Regular exercise and dietary restriction can attenuate the progression of metabolic and neurodegenerative disorders^[4,5,67,190]. Exercise (particularly vigorous aerobic exercise)^[111,167,191-193] and energy restriction (caloric restriction and intermittent fasting)^[143,194,195] can result in striking improvements in glucose and lipid metabolism, and can eliminate the need for medications. Exercise and dietary energy restriction activate a wide range of adaptive cellular responses in the peripheral organs (muscle, liver) and the brain, resulting in improved bioenergetics and brain function, and resistance to neurodegenerative disorders.

As mentioned previously, the causes of DM belong to different metabolic conditions and can show diverse pathologic phenotypes in a time-dependent manner^[113]. This review mainly focused on the changes in the brain caused by DM and exercise; however, changes in peripheral neuropeptides and organs are also significant. Adiposity, chronic inflammatory response, activation of oxidative stress, dysfunction of pancreatic islets, insulin and leptin resistance, dysfunction of the negative feedback mechanisms, and appetite disturbance constantly affect brain homeostasis. Indeed, exercise has been thought to attenuate brain damage caused by these risk factors; however, exercise during the early stage of diabetes is considered to be a critical factor for preserving brain function^[10,80]. The risk factors listed above can be therapeutic targets to treat and ameliorate DM; thus, refinements using various animal exercise models can give new insights into the treatment of DM.

It is well accepted that physical activity by contracting skeletal muscles (resistance exercise) secretes enhanced levels of myokines which have a beneficial endocrine effect on other organs, presenting novel targets for the treatment of metabolic diseases and T2DM^[70-72,94]. Pedersen hypothesized that physical inactivity leads to T2DM, depression, dementia, cancers, cardiovascular diseases, and asserted that skeletal muscle should be considered as an endocrine organ^[70]. Cytokines and other peptides that are produced, expressed, and released by muscle fibers and exert paracrine or endocrine effects should be classified as myokines. Actually, since skeletal muscle is the largest organ in the human body, skeletal muscle should receive attention for identifying its new multiple functions in metabolic disorders and T2DM. Skeletal muscle has the capacity to express several myokines including IL-6, IL-8, IL-15, BDNF, FGF21, MCP-1, vascular endothelial growth factor, leukemia inhibitory factor, Irisin, and ANGPTL4^[71]. IL-6 was discovered as a myokine because of the observation that it increases

up to 100-fold in the circulation during exercise. In particular, the identification of IL-6 production by skeletal muscle during physical exercise generated renewed interest in the metabolic role of IL-6 since it created a paradox^[70]. IL-6 can also alter brain function after peripheral administration, moreover, some myokines might be able to cross the blood-brain barrier^[196,197]. IL-6 is significantly produced and released in the post exercise period when insulin action is increased; on the other hand, IL-6 has also been associated with obesity and reduced insulin action. However, many researches during the past decade have reported that in response to muscle contraction, both type 1 and type 2 muscle fibers express the myokine IL-6, which subsequently exerts its effects locally and systemically in several organs^[70-72]. Within skeletal muscle, IL-6 acts to signal *via* AMPK and/or PI3-kinase to enhance glucose uptake and fat oxidation. In addition, muscular derived IL-6 mediates anti-inflammatory responses^[70].

A few researches on the relationship between myokines and the brain in animal models have just been published, and the effects of skeletal muscle derived myokines on brain function must be plausible enough directly and/or indirectly. Recently, Dun *et al*^[198] reported that myokine Irisin was detected in three types of cells; skeletal muscle cells, cardiomyocytes, and Purkinje cells of the cerebellum. Moreover, they reported that Irisin not only mediates the animal's movements but also regulates adipose tissue thermogenesis by neurons in the caudal ventrolateral medulla and rostral ventrolateral medulla that are an integral component of the medullary sympathetic circuitry and these neurons project their axons to spinal sympathetic premotor neurons^[198]. Similarly, it is known that resistance exercise improves body and brain bioenergetics for PD

risk reduction^[4], insulin and leptin signaling in obese rats^[2,45,82,104,199], and exerts antidepressant-like effects *via* improving the impaired neuroplasticity^[101,200]. Aerobic exercise and non-aerobic resistance exercise described in the Table 3.

Evidences of positive effects of resistance exercise on brain health in T2DM for therapeutic purposes with other aerobic exercises and pharmacologic treatments have been reported recently, and further studies on the mechanisms of treatment according to the severity of DM are needed.

CONCLUSION

It is confirmed that exercise is an incredible therapeutic option for treating DM patients. Animal exercise models are significant methods to study the network between central and peripheral organs. Brain is an extremely sensitive and soft tissue that can be damaged due to chronic insulin resistance, hyperglycemia, and chronic inflammation; however, various kinds of exercise can attenuate the brain damage and delay neurodegeneration caused by the risk factors. Many diabetic experimental animals with a genetic background and nutrition induced diabetic animals can be used in various DM studies; however, many physiopathologic conditions should be considered, and researchers should choose the animal models after giving careful consideration. Many aerobic running exercises and resistance skeletal muscle exercises have been performed recently in various animal models to study their therapeutic effect on brain function; however, more careful considerations reflecting the clinical conditions should be added in the animal models. Furthermore, it is important to study the therapeutic effects of exercise on brain health during

the stages of DM in animal models; however, dramatic effects of more prospective methods for maintaining brain health during DM seem to be achieved through development of various combinations of animal models in the pre-diabetic condition. A number of target signals from the exercise studies can also be the candidates for development of pharmacologic medicines.

target tissues and a relative deficiency of insulin secretion from pancreatic β -cells are the major features of type 2 diabetes (T2D). Chronic low-grade inflammation in T2D has given an impetus to the field of immuno-metabolism linking inflammation to insulin resistance and β -cell dysfunction. Many factors advocate a causal link between metabolic stress and inflammation. Numerous cellular factors trigger inflammatory signalling cascades, and as a result T2D is at the moment considered an inflammatory disorder triggered by disordered metabolism. Cellular mechanisms like activation of Toll-like receptors, Endoplasmic Reticulum stress, and inflammasome activation are related to the nutrient excess linking pathogenesis and progression of T2D with inflammation. This paper aims to systematically review the metabolic profile and role of various inflammatory pathways in T2D by capturing relevant evidence from various sources. The perspectives include suggestions for the development of therapies involving the shift from metabolic stress to homeostasis that would favour insulin sensitivity and survival of pancreatic β -cells in T2D.

Key words: Diabetes mellitus; Inflammation; Insulin resistance; β -cell dysfunction; Adipose tissue

Core tip: Immuno-metabolism, the confluence of metabolism and immune system has emerged as a chief breakthrough especially in the field of diabetes mellitus; a metabolic disorder of great magnitude. Activation of immune system by metabolic stress has opened new insights in the pathogenesis and progression of type 2 diabetes (T2D). The link between metabolic overload and activation of the immune system form the core tip of this review. Metabolic stress can cause pathologic activation of the immune system, thus metabolic disorders like T2D manifest and progress as an inflammatory disorder with severe consequences thereof.

Type 2 diabetes mellitus: From a metabolic disorder to an inflammatory condition. *World J Diabetes* 2015; 6(4): 598-612 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/598.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i4.598>

INTRODUCTION

Diabetes mellitus, a life style disease affecting 8.3% of the adult population of the world and increasing at an alarming rate, is one of the most common non-communicable diseases of current era^[1]. The burden of this disease is immense owing to transition in lifestyle and dietary habits, ageing of the population and urbanization in the setting of a genetically predisposed environment^[2]. The fact that the number of subjects with diabetes mellitus has doubled over the past three decades has made this disease a global challenge^[3]. The number of diabetes mellitus patients is projected to increase from 382 million in 2013 to 592 million by 2035, denoting a net increase of 55%^[1]. The predominant form is type 2 diabetes (T2D) which accounts for nearly 90% of all diabetes cases.

Diabetes mellitus-not so sweet

T2D is a metabolic disorder characterized by insulin resistance and pancreatic β -cell dysfunction as a consequence of unsettled hyperglycemia^[4,5]. In response to nutrient spill over in the setting of insulin resistance and eventual β -cell dysfunction, the general fuel homeostasis of body is altered^[2]. Insulin resistance in target tissues and a relative deficiency of insulin secretion from pancreatic β -cells are the major features of T2D. β -cell hyperplasia and hyperinsulinaemia in response to insulin resistance occur in the preclinical period of disease. Relative insulin deficiency as a consequence of failure of β -cells to compensate for insulin resistance, progresses into overt T2D^[6].

Metabolic alterations associated with T2D are well characterised by epidemiological and research based studies. The pathogenesis and progression of T2D is ascribed to four mechanisms; increased advanced glycation end product (AGE) formation, increased polyol pathway flux, activation of protein kinase C (PKC) isoforms, and increased hexosamine pathway flux^[7]. Till recently no common linking element was apparent for these mechanisms: however, recently production of superoxide emerged as a unifying mechanism for these four pathways. Downstream to oxidative stress, activation of inflammatory pathways has emerged as an imperative link between T2D and inflammation. Since, abundant data have elucidated the role of oxidative stress in T2D pathogenesis. In this review, we will evaluate the inflammatory component of T2D and underscore the link between metabolic alterations in T2D and inflammation.

T2D AS AN INFLAMMATORY CONDITION

Studies investigating the relation between inflammation and T2D have coalesced sufficient data implicating the role of inflammation towards the development of insulin resistance and pathogenesis of T2D^[8,9]. Metabolism and immune system were conventionally regarded as two distinctive mechanisms governing nutrient disposal and body defense, respectively. Typically, little was known about the coordination and interplay between these two systems. However, present research has led to combining these distinct entities as studies perceive pathological activation of the immune system as a regulatory mechanism associated with multiple disorders underlying the metabolic syndrome^[10]. Potency of steroid hormones as immune suppressors and hyperglycemic inductors, metabolic alterations associated with pyrexia, wasting syndrome initiated by chronic infections and of late, markers of acute-phase response have been associated with insulin resistance, insulin secretion defects, T2D and vascular complications of T2D^[8,11-15].

T2D encompasses colossal cellular factors characteristic of triggering inflammatory signalling cascades. A detailed analysis of these molecules cannot be underscored in this review, however their particular roles in T2D has been outlined in Table 1. Consequently, T2D at the moment is considered an inflammatory disorder triggered by disordered metabolism^[16]. The probable history of diabetes involves a more or less latent prodromal period followed by progressive deterioration of glucose tolerance culminating into explicit disease. Progression of islet β -cell failure results in hypertrophy of pancreatic islets and proliferation of β -cells. This phase is associated with an inflammatory response precipitating into reduction of cells by apoptosis and fibrosis of islets. In fact, an analogy of sequence of events involving an incipient inflammatory phase is associated with other T2D complications also^[17]. Hyperglycemia is regarded as the major upstream mechanism, and micro-inflammation is regarded as the subsequent downstream driving force of diabetes related complications^[17]. Epidemiological data advocate that markers of inflammation are predictive of T2D^[18]. The role of inflammation in insulin resistance is traced by the integration of metabolism and innate immunity *via* nutrient-sensing pathways mutual to pathogen-sensing pathways. Components of nutrition (free fatty acids, glucose, and amino acids) signal through collective receptors and pathways in a similar way as pathogens and/or cytokines. Cells of the immune system (macrophages) and metabolism (adipocytes) also share many functions like secretion of cytokines, and trans-differentiation into macrophages. Nutrients can activate macrophages and adipocytes through common receptors, such as toll-like receptors (TLRs) that sense broad classes of molecular structures common to pathogen groups, and are central to innate

Table 1 Role of various inflammatory molecules in type 2 diabetes

Category	Molecule	Role
Pro-inflammatory cytokines and signaling molecules	TNF- α	Increased levels related to IR and T2D
		Reduces insulin sensitivity by influencing the phosphorylation state of the insulin receptor
	IL-6	Major pro-inflammatory cytokine that induces inflammation and IR leading to T2D
	CRP	Elevated serum CRP associated with the incidence of T2D
	IL-1	Associated with obesity and IR
Transcription factors		Affects insulin signaling directly through the induction of SOCS-3
	IL-8	Leads to IR <i>via</i> the inhibition of insulin-induced Akt phosphorylation in adipocytes
	IL-1 β	Mediates auto-inflammatory process resulting in β -cell death
	NF- κ B	Increase the expression of genes encoding cytokines, chemokines, transcription factors and various receptors involved in IR and pathogenesis of T2D
	JNK	Promotes IR through phosphorylation of serine residues in IRS-1
Adipokines	IKK β	Leads to IR through transcriptional activation of NF- κ B
	Leptin	High leptin levels, reflecting leptin resistance predict increased risk of T2D
	Adiponectin	Low levels of this protective adipokine correlate with T2D. Adiponectin is downregulated by TNF- α
	Resistin	Promotes IR and decreases insulin-stimulated glucose transporters in adipose tissue
	Adipsin	Role in maintaining β cell function
Chemokines		Lower levels of adipsin found in T2D patient
	Visfatin	Visfatin binds to the insulin receptor at a site distinct from that of insulin and causes hypoglycaemia by reducing glucose release from liver cells and stimulating glucose utilization in adipocytes and myocytes
	MCP-1	MCP-1 expression in adipose tissue contributes to the macrophage infiltration into this tissue, IR and T2D
	IP-10/CXCL10	Downstream effector of pro-inflammatory cytokines involved in T2D-related complications
	CCR2	Imitates tissue inflammation and IR
Toll like receptor	TLR2 and TLR4	TLR2 and TLR4 play a critical role in the pathogenesis of IR and T2D
Adhesion molecules	E-selectin/P-selectin	Lead to leukocyte recruitment in local tissue and contributes to inflammation, IR and T2D
	ICAM-1/VCAM-1	Alters endothelial and sub-endothelial structure leading to reduced vascular permeability, reduced insulin delivery to peripheral insulin sensitive tissues and ultimately T2D
Nuclear receptors	PPAR α , PPAR γ , and PPAR β/δ	Mutations in PPAR genes associated with IR and T2D
	VDR	Regulates expression of insulin receptor preferentially by binding as a heterodimer with the RXR to VDREs in the promoter regions of insulin receptor gene

immunity and inflammation.

ADIPOSE TISSUE AS A SITE OF INFLAMMATION

Clinical and experimental studies show that adipose tissue acts as a site of inflammation. The first insight came from the study on adipose tissue of obese mice exhibiting elevated production of TNF- α ^[11]. Consequently, increase in adiposity is associated with upregulation of genes encoding pro-inflammatory molecules and associated with accumulation of immune cells^[19-21]. Adipocytes hoard excessive nutrient load and become hypertrophic gradually. Events initiating a pro-inflammatory response involve synergistic contributions of various mechanisms like an increase in nuclear factor κ B (NF- κ B) and c-Jun NH2-terminal kinase (JNK) activity by hypertrophied adipocytes, endoplasmic reticulum (ER) stress causing altered unfolded protein response (UPR), hypoxic stress in adipose tissue, activation of TLR by excess free fatty acids (FFAs), or increased chylomicron-mediated transport from the gut lumen into the circulation in a lipid-rich diet^[16,22,23].

Stressed adipocytes produce various cytokines and chemokines promoting immune-cell activation and accumulation in adipose tissue^[24]. A pro-inflammatory loop is formed by several macrophages by clustering around adipocytes, particularly with dead adipocytes forming crown-like structures^[19,21,25]. Sustained accumulation of lipids in adipose tissues results in switching of macrophages from an anti-inflammatory "M2" (alternatively activated) to a pro-inflammatory "M1" (classically activated) phenotype^[19,21,26,27]. The skew in balance results in an increased secretion of inflammatory molecules that subsequently stimulate the hypertrophied adipocytes resulting into a pro-inflammatory response^[28]. The inflammatory response in macrophages is induced by adipocyte-derived FFAs *via* TLR or NOD-like receptor family, the pyrin domain containing 3 (NLRP3) dependent pathways^[29,30]. Local hypoxia as a result of vasculature insufficiency in hypertrophied adipocytes has been proposed to stimulate expression of inflammatory genes in adipocytes as well as immune cells^[31]. However, the hypothesis lacks confirmation in the situation of human obesity^[32]. Instead, mechanisms like ER stress and

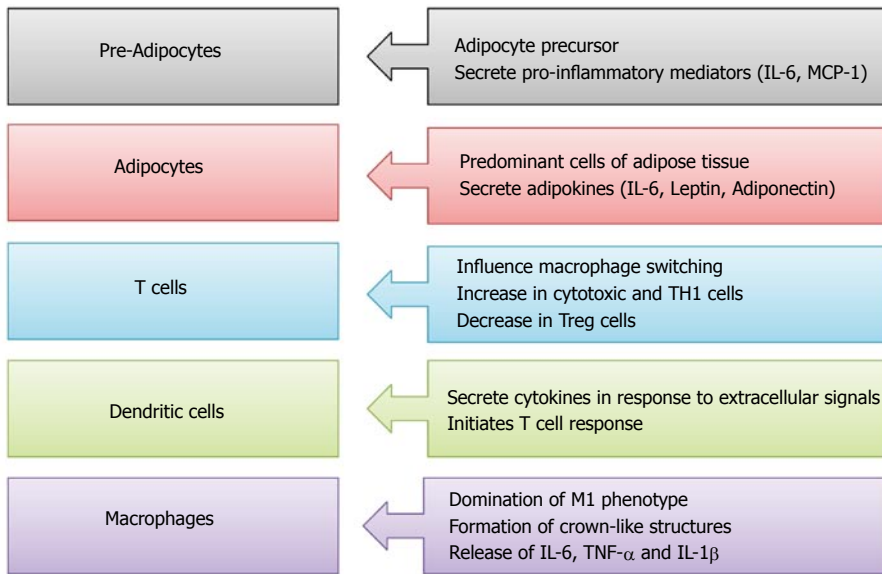

Figure 1 Functions of various immune cell types in pathogenesis of type 2 diabetes. IL: Interleukin; MCP-1: Monocyte chemoattractant protein-1; TNF- α : Tumor necrosis factor α .

autophagocytosis have been proposed as origin of local inflammatory signalling pathways in adipose tissue^[22,33]. Recently, the role of the incretin hormone glucose-dependent insulintropic peptide has also been implicated^[34,35]. In addition to adipose tissue, a pro-inflammatory state in liver and skeletal muscle result in disruption of systemic insulin sensitivity and glucose homeostasis that are characteristic of T2D^[36-38].

Metabolic inflammation is regulated by critical orchestration of innate and adaptive immune cell interactions^[39,40]. Studies investigating immuno-metabolism have recognised that the inflammatory status of immune cells is dictated by their metabolic programming, mitigating the progression of T2D. T2D is preceded by an extensive period of disease development, and inflammation has been shown to be a precipitating factor underpinning insulin resistance, preceding T2D^[41,42]. The progression of T2D involves an intricate interplay between metabolism and immunity. The progression of T2D has been causally linked to various types of immune cells but the primary sources of inflammatory effectors contributing to insulin resistance are macrophages^[43-45]. Among various cell types, pre-adipocytes, adipocytes, T cells, dendritic cells and macrophages are major cell types involved in obesity-induced inflammation and insulin resistance^[46]. Their prime functions are shown in Figure 1. The key inducers of cytokine release in metabolic organs leading to impaired insulin action are tissue-resident macrophages^[47].

Nutrient overload corresponds to increased infiltration of macrophages in metabolic tissues promoting a pro-inflammatory environment characterised by augmented TNF- α , IL-1 β and inducible nitric oxide synthase (iNOS) levels. The accrual of these pro-inflammatory macrophages in metabolic organs like liver, adipose tissue and muscle directly suppresses

insulin action, thereby promoting hyperglycemia^[48].

ROLE OF INFLAMMATION IN INSULIN RESISTANCE

Insulin is a key endocrine hormone produced by β -cells of pancreatic islets. Insulin is regarded as "hormone of abundance" owing to the array of functions it performs, the effects of which extend from metabolic to mitogenic activity (Figure 2). It is likely that disruption of insulin-mediated pathways will have pleiotropic effects that are not confined to carbohydrate metabolism only. Various mechanism working separately or in synergy have been linked to the development of insulin resistance among which chronic inflammation represents as a triggering point^[8].

Inflammation is an important component linking insulin resistance with nutrient overload and increased visceral adipocyte mass^[42]. During an insulin-sensitive state, the signalling cascade of insulin upon binding to its receptor results in phosphorylation of tyrosine residues of the insulin receptor substrate 1 (IRS-1) ensuing in downstream insulin signalling^[49]. However, in an insulin-resistance state, pro-inflammatory molecules activate various other serine kinases like JNK, inhibitor of NF κ B kinase subunit β (IKK- β), extracellular-signal regulated kinase (ERK), ribosomal protein S6 kinase (S6K), mammalian target of rapamycin (mTOR), PKC and glycogen synthase kinase 3 β ^[50]. The activation of these kinases inhibits insulin action by phosphorylating serine residues instead of tyrosine residues in the insulin signalling pathway^[49].

The development of insulin resistance is linked to two prime transcription factor-signalling pathways: JNK and IKK β /NF- κ B^[51]. Activation of these two pathways involves a series of proinflammatory stimuli, many of which comprise of both activators and upregulators of

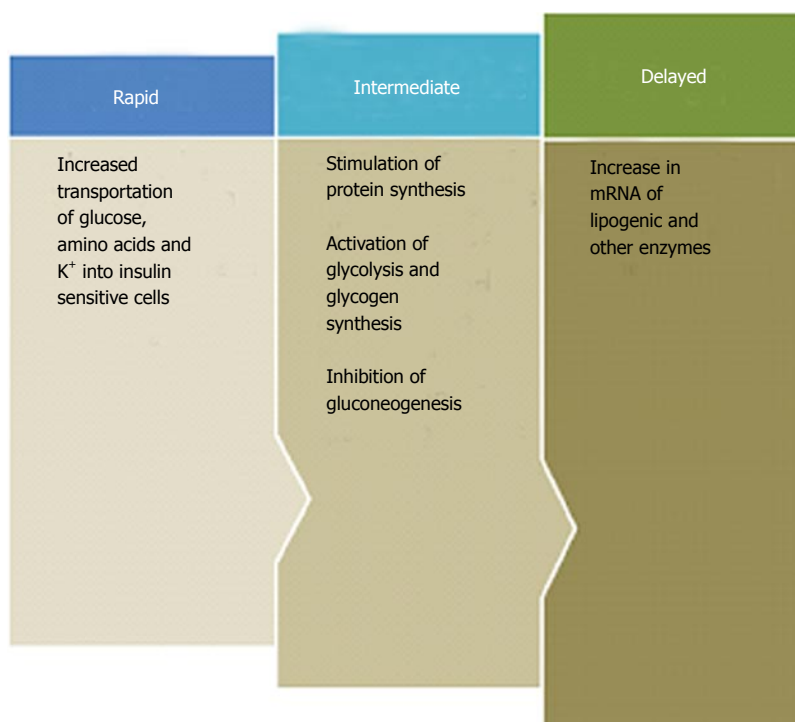

Figure 2 Various hormone functions of insulin.

NF- κ B. In addition, these pathways are also activated by pattern recognition receptors like TLRs and receptors for advanced glycation end products (RAGE). Elevated levels of FFAs result in an increase in diacylglycerol (DAG) that activates PKC isoforms leading to concomitant activation of JNK and NF- κ B pathways^[52]. Further stimuli involve production of reactive oxygen species (ROS), ER stress and changes in adiposity^[53-55].

The mechanisms in development of inflammation-induced insulin resistance are different for JNK and IKK β . Unlike JNK that phosphorylates the serine residues of IRS-1, IKK β induces insulin resistance by transcriptional activation of NF- κ B^[56-59]. The physiological substrates of IKK β are I κ B protein inhibitors of NF- κ B. IKK β phosphorylation promotes proteosomal degradation of I κ B α liberating NF- κ B for nuclear translocation where it stimulates the expression of several target genes (Figure 3)^[9]. The products of these target genes of NF- κ B induce insulin resistance. The production of inflammatory molecules further activates JNK and NF- κ B pathways promoting a vicious loop of insulin resistance by feed-forward mechanism.

PANCREATIC ISLET INFLAMMATION IN T2D

Increasing evidence suggests the presence of an inflammatory milieu in pancreatic islets in T2D, such as increased cytokine levels, chemokine levels and immune cell infiltration. Evidence of islet inflammation was initially observed in hyperglycemia induced β -cell apoptosis^[60]. Recent studies on human islets

and monocytes have shown that the combination of hyperglycemia and elevated FFAs induces a more efficient pro-inflammatory phenotype^[61,62]. Various T2D experimental animal models like db/db mice and Goto-Kakasaki rats showed increased infiltration by immune cells in the pancreatic islets^[63]. Studies on experimental animal models elucidated islet inflammation and macrophage infiltration as an event occurring as early as eight weeks before the onset of frank diabetes^[63]. Recruitment of macrophages is a consequence of phagocytic clearance owing to the death of islet β -cells^[64]. Alternately, in a diabetic milieu endocrine cell-derived inflammatory molecules like IL-6 and IL-8 produced in islets are also attributed to increased macrophage infiltration^[63]. Production of pro-inflammatory cytokines and secretion of chemokines by β -cells results in a vicious cycle speeding up islet inflammation. In humans, IL-1 β secreted by infiltrating immune cells is related to the pathogenic process of T2D, as blockade of IL-1 has been associated with reduced hyperglycemia, improved β -cell function and reduced expression of inflammatory markers^[65]. However, recent studies involving human islets have shown that induction of IL-1 β plays a role in precipitating the clinical features of diabetes and is unlikely involved in initial pathogenesis^[66-68]. The first study demonstrating the hyperglycemia-induced IL-1 β secretion documented a pro-inflammatory response induced by a non-autoimmune mechanism in β -cells^[12]. *Ex vivo* experiments on isolated human islets exposed to high glucose levels showed increased IL-1 β production preceding activation of NF- κ B, upregulation of Fas, fragmentation of DNA, and reduction

of insulin secretion^[69]. Upregulation of IL-1 β plays a predominant role as a major cytokine regulating other chemokines and cytokines in islets of T2D patients^[12,66,70,71]. This master cytokine elicits a broader response by recruitment of various immune cells and also by induction of IL-1 β in β -cells, provoking a vicious inflammatory cycle^[66]. The critical role of IL-1 β in islet inflammation was recently confirmed by analysing global gene expression in pancreatic islets of humans that showed an association of a group of co-expressed modules enriched for IL-1 related genes with T2D and insulin resistance^[72]. *SFRP4* gene encoding the secreted frizzled-related protein 4 was one of the interesting genes that were overexpressed, likely mediating the effect of IL-1 β on islets^[72]. In islets of both T2D subjects as well as in animal models, an eminent number of immune cells along with cytokines and chemokines has been observed^[63,66,73]. In fact, T2D animal models invariably exhibit islet immune cell infiltration^[63,71].

ISLET INFLAMMATION AND β -CELL DEATH

Islet tissue sections of T2D subjects show well-defined fibrosis which is a hallmark of the late stage of a chronic inflammatory process. In clinically overt T2D subjects

a decreased β -cell mass has been reported indicating a probable role in its pathogenesis^[4,74]. Decreased β -cell mass in T2D has been attributed to pancreatic β -cell apoptosis and to β -cell dedifferentiation^[75]. In slowly progressing T2D, the probability of detecting β -cell damage in pancreatic sections is low, thus very few studies on this aspect have been reported^[4,76]. Several mechanisms like amyloid deposition in islets, presence of long-chain FFAs^[77], and chronic hyperglycemia^[60] has been implicated in β -cell apoptosis. Sustained gluco-lipotoxic conditions amplifies the β -cell stress responses by potentiating effects of elevated levels of FFAs, glucose causing ER stress and mTORC1 activation^[78,79,54]. The underlying mechanism for hyperglycemia-induced β -cell apoptosis is attributed to the glucose-induced IL-1 β production that upregulates the Fas receptor^[80,81,12]. FFAs act as important effector molecules causing β -cell dysfunction by lipoapoptosis (a metabolic cause of programmed cell death). The most abundant saturated FFA in blood is palmitate that has direct lipotoxic effects on β -cells by inducing ER stress and ROS^[82-85]. Ceramide, an effector molecule responsible for inducing lipoapoptosis of β -cells, is a metabolic product of FFAs that activates JNK^[86-88]. Likewise, incomplete β -cell oxidation of fatty acids resulting in metabolites like DAG and triglycerides (TGs) also elicits final effector molecules contributing to FFA-

induced lipotoxicity as well as insulin resistance^[89-91]. In addition to this, FFA-induced activation of JNK by Src has also been reported in a recent study^[92]. These studies show that islet inflammation contributes to β -cell dysfunction.

TRIGGERING OF THE INNATE IMMUNE SYSTEM IN T2D

Nutrient excess in metabolic tissues resulting in metabolic inflammation, *i.e.*, a low-level pro-inflammatory milieu, has emerged as an important factor underlying the development of T2D^[11-15,93,94]. Activation of innate immunity in T2D is linked to the activation of TLRs. These receptors have been implicated in diabetes-induced inflammation and vascular complications^[95]. TLRs comprise the pattern-recognition receptors characteristic of the innate immune system. Various pathogen-associated molecular patterns (PAMPs) encompassing carbohydrates, proteins, nucleic acids and lipids, are recognised by TLRs followed by initiation of an immune response. TLR2, a receptor for pathogen lipoproteins and TLR4, a receptor of lipopolysaccharides, are activated by FFAs^[96,97]. Binding of FFAs to TLRs has been postulated to directly induce a pro-inflammatory response^[97,98]. Also, various indirect ways of TLR activation by FFAs has been postulated recently^[99]. *In vitro* studies have demonstrated that, unlike the short chain FFAs, the long chain palmitate and oleate that comprise 80% of circulating FFAs are pro-inflammatory in various cell types^[29,96,98,100,101]. Contemporary studies report the activation of TLR signalling by FFA-induced formation of lipid rafts that favour TLR dimerization in cell membranes^[92,102]. Recently, fatty acid transporter CD36 binding to TLR2 and liver-derived glycoprotein fetuin-A binding to TLR4 were identified as endogenous ligands linking FFAs to TLRs, eliciting inflammation and prompting insulin resistance^[103,104]. In addition, damage-associated molecular patterns (DAMPs) like high-mobility group box 1 (HMGB1) and AGEs also act as endogenous ligands which are recognised by TLRs, thereby activating pro-inflammatory pathways^[105]. TLR2 is responsible for upregulation of inflammatory molecules like NF- κ B, myeloid differentiating factor 88 (MyD88) and chemokine (C-C motif) ligand 2 (CCL2)^[106]. TLR4 knockout mice have been shown to be protected from insulin resistance as well as from fat-induced inflammation^[106]. TLR4 silencing by siRNA technology has been shown to attenuate the hyperglycemia-induced activation of I κ B/NF- κ B^[107]. TLR5 is a receptor for bacterial flagellin that controls metabolic pathways through sensing gut microbiota. TLR5 knockout mice have been reported to exhibit increased adiposity along with hyperphagia, hypertension, hyperlipidemia and insulin resistance^[108]. Activation of inflammatory pathways in a TLR-independent mechanism by metabolic stress involves generation of ROS that induce stress kinases and NLRP3 inflammasome (multiprotein complexes responsible for production of bioactive IL-

1 β) formation^[109].

Both TLR-dependent and TLR-independent mechanisms function in concert. This finding is demonstrated by animal models of diabetes in which there is partly protection of pro-inflammatory cytokine production in case of deficiency of TLR2 or TLR4, whereas deficiency of a universal intracellular docking protein MyD88 required for TLR signalling, exerted total protection^[61]. Apart from FFAs, systemic inflammatory responses are also elicited by elevated glucose levels^[110]. Sustained hyperglycemia results in non-enzymatic glycation of lipids and proteins resulting in the formation of AGEs. AGEs stimulate the pattern recognition receptor RAGE. Numerous cell types, like macrophages, T cells, smooth muscle cells, neuronal cells, podocytes and cardiomyocytes, express RAGE^[111]. RAGE activates the pleiotropic pro-inflammatory transcription factor NF- κ B along with stress kinases ERK1 and ERK2^[112]. Excessive glucose metabolized by oxidative phosphorylation to ATP results in ROS generation that tends to activate the NLRP3 inflammasome concomitantly with FFAs^[67]. This results in release of active IL-1 β along with IL-1-dependent cytokine and chemokine production^[61].

FROM INNATE TO ADAPTIVE IMMUNITY IN T2DM

The role of specific or adaptive immunity comes from the recent clinical overlap between type 1 diabetes (T1D) and T2D such as younger age of onset in T2D and increasing body mass index (BMI) coinciding with increased incidence in T1D. Moreover, progressive decrease in β -cell mass observed in T2D and evidence of insulin resistance in T1D has blurred the etiology^[113]. The argument supporting the involvement of autoimmunity in islets of T2D patients is evident from the presence of β -cell specific antibodies in nearly 10% of T2D patients and presence T cells reactive to β cell antigens in some patients^[114]. The number of autoantigen-responsive T lymphocytes in islets from T2D patients has been reported to correlate with disease progression^[114], however the exact role of islet autoimmunity in T2D requires further studies. A monogenic form of diabetes characterised by typical features of T1D like lean body mass, young age of onset, autoantibodies to β -cells, rapid disappearance of C-peptide and insulin requirement concomitantly with T2D-associated insulin resistance provides genetic support for the overlap between T1D and T2D^[115]. The genetic alteration is attributed to an autosomal-dominant mutation in the *SIRT1* gene, and the pathogenesis involves β -cell impairment and death, paralleling a state of activation of immune system^[115]. As a consequence of insulin resistance, stress induced β -cell death results in the release of autoantigens along with alarmins (endogenous molecules released by necrotic cells causing activation of immune system). Alarmins have potentiating effects of promoting pathologic self-antigen presentation, resulting in enhanced adaptive

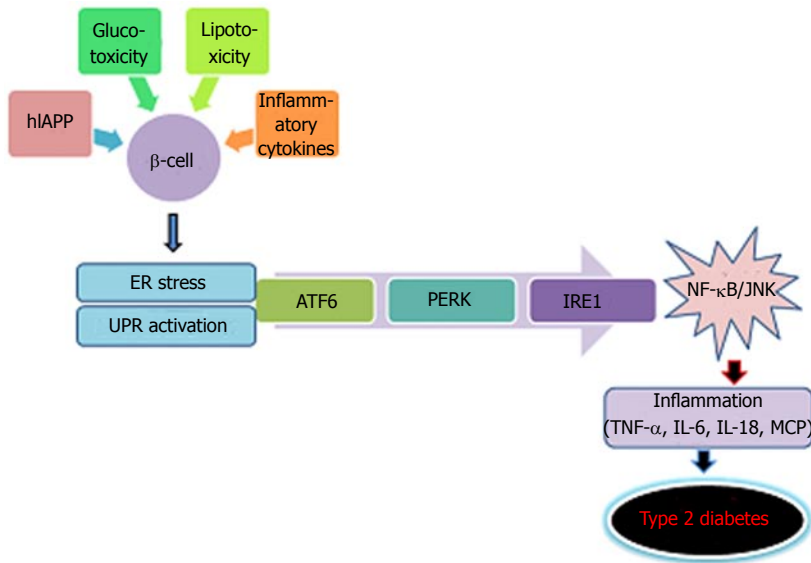

Figure 4 Mechanism of endoplasmic reticulum stress. immune response^[116]. In light of these observations, sirtuins are recognised as novel regulators of immuno-metabolism in humans. Apart from SIRT1, SIRT2 has been recently linked to cytoskeleton remodeling and activation of NLRP3 in intracellular pathways^[117]. Apart from the activation of innate immunity, the contribution of adaptive immune cells in inducing inflammation is now established in T2D at the cellular level.

Experimental animal models of insulin resistance have demonstrated a Th2/Th1 shift in favour of Th1, shifting the T_{reg}/Th17 shift towards Th17 and shifting the CD8/CD4 ratio in favour of CD8 and finally reduction of T-cell receptor (TCR) diversity^[118-121]. These studies have recently been extrapolated to human subjects^[122] and confirm the observation that an increase pro-inflammatory stimuli (IFN- γ) causing M1 phenotype switching of adipose tissue macrophages result in the activation of a Th1 type response^[121]. IFN- γ and IL-17 produced by these T cell populations interact directly with adipocytes in addition to contributing to a pro-inflammatory loop in cells of innate immunity. IFN- γ inhibits the JAK-STAT pathway, and IL-17 induces the secretion of IL-6 from adipocytes^[123]. β -cells isolated from T2D patients exhibit increased IL-8 and decreased IL-10 secretion^[124]. Recent studies regard the contribution of B-cell humoral immunity in adipose tissue inflammation. A study on experimental mice models involving B-cell knockout mice and anti-CD20 therapy showed a significantly improved metabolic phenotype and adipose tissue inflammation^[120].

LINK BETWEEN ER STRESS AND INFLAMMATION IN T2D

Activation of ER stress and the UPR forms a convincing hypothesis for the induction of inflammatory pathways

in T2D. ER stress in T2D occurs by virtue of nutrient overload, hypoxia and accumulation of unfolded proteins in metabolic organs^[22]. Under normal conditions, the flux of proteins through ER is high, and in the setting of insulin resistance or glucotoxicity, a prolonged state of insulin need generates ER stress^[125].

Three ER localized sensors control the activation of ER stress and UPR (Figure 4): (1) the double-stranded RNA-activated protein kinase (PKR)-like ER kinase (PERK); (2) inositol-requiring kinase 1 (IRE1); and (3) activating transcription factor 6 (ATF6). ER stress by protein overload or accumulation of unfolded proteins causes dissociation of GRP78, and the subsequent binding to unfolded proteins in ER prevents their transport to cis Golgi.

Prominently, UPR activation stimulates inflammatory stress kinases like JNK and IKK and their critical downstream transcriptional targets; activator protein 1 (AP-1) and NF- κ B, respectively^[126,127].

These transcription factors control the induction of inflammatory cytokines and chemoattractants that are known to have a direct link with the development of insulin resistance^[128,129]. ER stress can also impair insulin signalling by activation of stress kinases (JNK, IKK) that can inhibit insulin receptor substrates by direct phosphorylation. Recently, death protein 5 (DP5) and p53-upregulated modulator of apoptosis (PUMA) have been reported as inducers of β -cell apoptosis by mediating ER stress^[130]. ER stress can also cause induction of lipogenic genes that promote lipid accumulation and thereby contributes to the development of lipid-induced insulin resistance^[131].

ER stress and UPR pathways

Triggering of inflammatory signals by three pathways of UPR is initiated by activation of JNKs and NF- κ B in B

Figure 5 Activation of inflammasomes in type 2 diabetes (metabolic stress activates multiprotein complex, inflammasome in β -cells that induce caspase-1 to cleave pro-interleukin-1 β (pro-IL-1 β) into active IL-1 β . β -cell-derived IL-1 β promote the release of chemokines and recruitment of macrophages that are activated by human islet amyloid polypeptide, leading to deleterious concentrations of IL-1 β . FFA: Free fatty acid; IL: Interleukin.

cells. This activation acts as the linkage point between metabolic and immune pathways since the activation of these very kinases is analogous to that elicited by an immune response^[94,132]. JNKs play an important role in T2D, as increased activity has been shown to promote insulin resistance^[56,133].

The first responses for opposing ER stress involve decreasing the translation of proteins. This involves phosphorylation of α subunit of eIF2 by PERK. In humans and mice, loss of PERK expression is linked to dysregulation of the UPR response which is fundamental to ER stress, resulting in increased cell death and T2D^[134]. A permanent form of neonatal diabetes in humans is related to elevated ER stress markers as a result of a mutation in PERK, confirming the pivotal role of PERK in regulating ER stress during fetal development^[135-137].

A factor in the second pathway of UPR, IRE1, is a prime regulator of ER stress and is highly expressed in the pancreas. An *in vitro* knockdown study on IRE1 signalling showed a decreased synthesis of insulin^[138,139]. Upon activation, IRE1 initiates activation of X-box binding protein 1 (XBP1) that leads to upregulation of ER expansion and biogenesis^[140]. The critical role of XBP1 in achieving an optimal insulin secretion and glucose control was demonstrated in β -cell-specific XBP1-deficient mice that exhibited impaired pro-insulin processing and secretion, reduced β -cell proliferation and hyperactivation of IRE1^[141].

The third pathway of UPR involves the activation of ATF6, the basic leucine zipper domain protein, that upregulates PERK1 and IRE1 pathways by suppressing the apoptotic UPR signalling cascade under chronic ER stress. The role of ATF6 activation in β -cell dysfunction has been concluded in studies that showed decreased expression of insulin gene by ER stress-induced ATF6

activation and a decrease in ER chaperones along with induction of apoptosis in ATF6 knockdown insulinoma cells^[142,143].

ACTIVATION OF INFLAMMASOME IN T2D

Inflammasomes are multiprotein complexes in the intracellular machinery responsible for production of bioactive IL-1 β in response to multiple stimuli^[144]. NLRP is a subfamily of Nod-like receptors containing a central nucleotide binding and oligomerization (NACHT) domain with flanking C-terminal leucine-rich repeats (LRRs) and N-terminal caspase recruitment (CARD) or pyrin (PYD) domains^[145]. The NOD-like receptor family, the pyrin domain containing 3 (NLRP3) inflammasome is in a pathway that controls the production of IL-1 β and IL-18^[146-148]. Unlike TLR, a potential role of NLR in metabolic abnormalities has not been extensively investigated. NLRP forms a constituent of the inflammasomes responsible for maturation and release of IL-1 β , and thus is a relevant candidate for metabolic disorders and T2D^[149]. NLRP3-dependent activation of inflammasomes in diabetes was proposed by studies implicating the release of IL-1 β as a consequence of elevated levels of glucose, FFAs and human islet amylopolypeptide (hIAPP)^[16,150,151]. However, the effective metabolites involved in activation of inflammasomes are not clearly elucidated yet (Figure 5).

The NLRP3 inflammasome is a general metabolic alarmin stimulated by different endogenous and exogenous stimuli^[152]. NLRP3 inflammasome activation is augmented in T2D patients^[153]. Dysregulation of lipid metabolism, paving the way to aberrant lipid accumulation, as well as formation of oxidized LDL and cholesterol, triggers NLRP3 activation^[30,153,154] similar

to ER stress that acts as one of the important factors triggering NLRP3 activation^[155,156]. In T2D subjects, increased oxidative stress also contributes to NLRP3 inflammasome activation^[157,158].

Studies on obesity-induced inflammation and insulin resistance are also indicative of the role of NLRP3. In experimental models of calorie-restricted mice, a positive correlation has been observed between IL-1 β /NLRP3 mRNA and body weight^[30] whereas disruption of *NLRP3* gene in obese mice has revealed changes in metabolic profiles. Insulin resistance as a consequence of inflammasome activation is directly related to FFAs and LPS^[109]. Apart from Insulin resistance, activation of inflammasomes is related to β -cell dysfunction, as NLRP3-knockout mice exhibit improved glycemic profiles after consumption of a high-fat diet, likely due to attenuation of IL-1 β ^[67]. In response to hyperglycemia-induced increased production of ROS, NLRP3 activation occurs as a result of dissociation of thioredoxin interacting protein (TXNIP) from thioredoxin and its subsequent binding to NLRP3^[67]. Nevertheless, shortage of TXNIP has shown effects on glucose metabolism in addition to the NLRP3 activation^[159]. A substantial role of inflammasome activation in β -cell dysfunction was recently reported by ablation of NLRP3 that conferred protection to β -cell function and structure from injury inflicted by metabolic stress^[160].

Secretion of IL-1 β requires two induction stimuli; the first stimulus induces pro-IL-1 β expression and the second inflammasome activation. Inflammasome activation triggers caspase-1 resulting in cleavage of pro-IL-1 β and release of mature IL-1 β . In T2D, the first stimulus comes from minimally-modified LDL in islets which prime the macrophages for processing of IL-1 β by activation of TLR4 signalling. Recently, the second stimulus was recognized to regard islet hIAPP, secreted by β -cells in response to high glucose levels^[151]. hIAPP was shown to direct NLRP3 activation by inducing β -cell injury. In islets, interaction of macrophages and β -cells is essential for the activation of inflammasomes. hIAPP, a soluble oligomer induces activation of NLRP3 and subsequent release of IL-1 β from macrophages and dendritic cells which are primed with TLR4 agonists like LPS or modified LDL molecules^[151]. The macrophages are attracted to islets by hIAPP-induced synthesis of chemokines (CCL2 and CXCL1). It has been reported that overexpression of hIAPP in islet grafts increases the recruitment of macrophages by 50%^[161]. Recently the activation of inflammasomes in myeloid cells in T2D patients was elucidated. A study on untreated T2D subjects showed upregulation of IL-1 β production and maturation in macrophages^[153]. Treatment of macrophages with various alarmins like FFA, hIAPP, HMGB1 and ATP resulted in release of inflammasome products. Studies have shown that T2D subjects exhibit elevated levels of circulating alarmin molecules thereby advocating a possible role of these molecules in NLRP3 inflammasome activation in myeloid cells^[162].

PERSPECTIVES

The concept of chronic low-level inflammation in T2D has given an impetus to the field of immune-metabolism. Elucidation of various cellular mechanisms linking inflammation to insulin resistance and β -cell dysfunction has revolutionized insights in the molecular pathogenesis of diabetes. Insights into intricate pathways provide a platform to tackle the distinct pathway without compromising immuno-surveillance. Nutritional and therapeutic interventions aimed at controlling/inhibiting the escalating pro-inflammatory response can help in attenuating the pathogenesis and progression of T2D. Well-designed studies should offer the development of novel targeted therapeutics to deal with the disease burden of T2D and its associated complications.

Abstract

Much has been published on the characteristics of type 2 diabetes mellitus and its association with the epidemic of obesity. But relatively little is known about the incidence of lean diabetes, progression of disease and fate of the patients with low-normal body mass index (< 25). Studies in developing countries have shown that the clinical characteristics of these patients include history of childhood malnutrition, poor socioeconomic status, relatively early age of onset and absence of ketosis on withdrawal of insulin. In the United States, recent studies showed that the lean,

normal weight diabetes is not rare especially among minority populations. They showed that these patients are mainly males, have higher prevalence of insulin use indicating rapid beta cell failure. They might have increased total, cardiovascular and non cardiovascular mortality when compared to obese diabetic patients. In this review, the epidemiologic and clinical features of lean diabetes are presented. The potential causal mechanisms of this emerging diabetes type that may include genetic, autoimmune, acquired and behavioral factors are discussed. The need for studies to further elucidate the causation as well as specific prevention and treatment of lean diabetes is emphasized.

Key words: Lean diabetes; Beta cell failure; Ketosis resistant diabetes of young; Obesity paradox; Sarcopenic obesity

INTRODUCTION

The prevalence of diabetes mellitus (DM) has increased exponentially over the past decade globally. In the United States, nearly 26 million adults have diabetes with over 9 million being prediabetic. The numbers are expected to double by 2050. Nearly 35% of American adults are obese putting them at an increased risk for the development of Diabetes. Healthy people 2020 initiative has stressed the importance of reduction in obesity to lower the incidence of this morbid condition among the United States population^[1].

Since early times obesity has been a well known risk factor for diabetes. However, beyond the classical obesity related type 2 diabetes and other well defined types of diabetes like type 1, Maturity onset Diabetes of the Young, Gestational diabetes, *etc.*, there is a renewed interest in the underweight or normal weight lean diabetes that is emerging also in the developed countries like United States. This review will focus on the low-normal weight diabetes that is so far not well characterized and defined. More importantly, this review will highlight the differences in the clinical features of diabetes mellitus in normal body weight patients in the United States in comparison to the classical obese diabetes. The evidence related to the profile, peculiarities, morbidity, mortality and pathogenesis associated with lean type diabetes will be described.

DIABETES IN LOW BODY WEIGHT GROUP (BODY MASS INDEX < 18 KG/M²)

Though recognized as a distinct entity early on, very little attention has been paid to the qualitative changes associated with it. Any "atypical diabetes" syndrome which did not meet the classical American Diabetes Association or World Health Organization Classification suffered from imprecise definitions which led to a group of complex phenotypes^[2]. Further studies have been undertaken only recently shedding much insight into their disease burden, progression and natural history. Adult onset diabetes with body mass index (BMI) < 25 was initially placed under the category of "malnutrition related diabetes mellitus" in a subcategory termed "protein deficient pancreatic diabetes"^[3]. Later this syndrome was noted to be similar to that originally described as "Jamaica type Diabetes", a term used to represent around 5% of Caribbean diabetics^[4]. Similar clinical syndromes were subsequently described in regions of south Asia and Africa and has acquired various names; "Tropical Diabetes, Mixed onset type Diabetes, Phasic insulin dependent Diabetes, J type Diabetes, Z type Diabetes, M type or type 3 Diabetes, Ketosis resistant growth onset type Diabetes"^[5].

Many of the overlapping categories described above could be lumped together under the term

coined by Ahuja^[6] as "Ketosis Resistant Diabetes of the Young (KR DY)". This category includes a broad subset of patients mostly of Asian and African ethnicity. The following criteria were suggested for the diagnosis of KR DY^[6]: (1) blood glucose > 200; (2) onset < 30 years of age; (3) BMI < 18 kg/m²; (4) absence of ketosis on insulin withdrawal; (5) poor socio-economic status or history of childhood malnutrition; and (6) insulin requirement > 60 units/d or 1.5 units/kg.

Although early age of onset and low BMI may raise suspicion for type 1 diabetes, the presence of islet cell specific antibodies has consistently been lower than those with type 1 diabetes across multiple population groups. It can be argued that the wasting or leanness noted in around 25%-50% of patients could represent the effects of long standing glycosuria^[7]. Though BMI mostly improved with weight gain following optimal glycemic control, the mean value remained within the definition of low body weight among both genders^[8]. Phenotypic similarities have been described from various other regions of the world with nearly all of them demonstrating a male preponderance with the most extensive data being described from Ethiopia^[9,10].

A study from India on around 10000 type 2 diabetics revealed that around 3.5% patients were lean with a BMI < 18.5, with the larger share of around 63% patients having ideal body weight at diagnosis. Age of diagnosis (45 ± 13) and smoking patterns were not significantly different among the lean, ideal body weight and obese groups, although a male preponderance was noted only in the former two. This study also highlighted the fact that HbA1c, fasting and postprandial blood glucose levels were higher among those in the lean group. Micro-vascular complications of Diabetes such as retinopathy, nephropathy and neuropathy were more common among the lean male patients presumed to be related to the higher plasma glucose and HbA1c levels^[11]. Other studies have also highlighted the higher incidence of peripheral neuropathy among lean diabetic males^[12], whereas hypertension and coronary artery disease tend to be more common in the obese group^[13]. A limitation of these studies were that auto antibodies were measured only in a very small number, thereby leaving a chance that the lean diabetics could represent type 1 diabetics^[14], although patients who had an abrupt onset, ketosis or ketoacidosis at any time or required insulin at time of diagnosis were excluded from the study to avoid bias. In whom C-peptide levels were measured, they were found to be significantly higher compared to the type 1 diabetics being followed at the respective centers. Moreover the results of islet cell antibodies and antibodies against Glutamic acid decarboxylase were not significantly different between the 3 groups^[15]. Nearly 48% of the lean NIDDM patients responded to diet or oral hypoglycemic agents after a mean duration of 9.2 ± 8.1 years, which is a clear distinction from type 1 diabetics. Symptomatic ketoacidosis was absent in this group^[11].

The pathophysiology and its distinction from classic

type 2 diabetes is still unclear and a subject of much debate. The key feature appears to be a defect in insulin secretory capacity as opposed to peripheral insulin resistance as noted in classical diabetes. Multiple studies have shown an association between lean diabetes, malnutrition in early years of life and poor socioeconomic status. Although prospective human studies are lacking, experiments done on rats and primates have shown that low protein diet in early life leads to decreased beta cell mass and insulinopenia. Insulin mediated glucose disposal appears to be similar in KRDY and type 1 Diabetic patients^[16]. These patients have fasting C-peptide levels intermediate between type 1 and type 2 diabetics^[17,18]. Despite the "decent" C-peptide levels suggesting a good beta cell reserve, the circulating insulin levels at baseline and post stimulation with insulin secretagogues (glucose, tolbutamide and amino acids) have been consistently lower in lean diabetics when compared to their obese counterparts^[8,19-24]. The 2 mechanisms that have been postulated to cause this are excessive extraction of insulin in the porto-hepatic circulation from raised glucokinase activity and hyperactive futile cycles of carbohydrate metabolism^[8]. Resistance to ketosis noted in these cases is due to a small but sufficient insulin secretory reserve which is absent in type 1 diabetics^[2]. They have also been noted to have lower fasting plasma free fatty acid and ketone levels and a blunted response to catecholamines further delaying the development of ketoacidosis^[19-21]. The occurrence of fat malabsorption in a small subset of patients contributes evidence to an exocrine defect in KRDY patients^[25].

Auto-antibodies can be present in anywhere between 2%-25% of KRDY patients. Glutamic acid decarboxylase (GAD), tyrosine phosphatase like protein (IA-2) or high mobility group box transcription factor SOX-13 (ICA-12) antibodies are commonly found, though co-occurrence of GAD and IA-2 was observed in only 4.7% of lean patients compared to 22% type 1 diabetics^[26]. Any single antibody by itself is neither sensitive nor specific to distinguish between the phenotypes of type 1 or type 2 diabetes as GAD or ICA positivity has been reported even in 4%-13% of obese type 2 diabetics^[8]. In summary the primary etiology appears to be depressed beta cell function most likely due to malnutrition in utero and early infancy in addition to autoimmune modulations. However more studies are needed on this front to unearth the metabolic, hormonal and immunological characteristics of lean type 2 diabetics.

DIABETES IN NORMAL BODY WEIGHT GROUP (BMI 18-24.9)

The term "lean" has been described variously in different studies. The major distinction seems to originate from the geographic region where the study was conducted. Those from developing countries use a BMI < 18 to describe leanness whereas studies

performed in the United States describe lean patients to have a BMI ranging from 18-24.9.

A study cohort of 18000 patients with type 2 diabetes in Chicago, United States showed that around 13% belonged to this group, with ideal body weight defined as a BMI ranging from 17-25. The study failed to demonstrate a significant difference between the age of diagnosis (43 ± 13) between the lean and obese diabetics, and corroborated the previous finding of male preponderance among the lean group (62%). Asians were shown to have a five-fold higher prevalence in the lean group (17% vs 4%). Environmental insults such as use of alcohol and cigarette smoking were more common among lean diabetics. As confirmed by various other studies, glycemic control was worse among lean diabetics and coronary complications more prevalent among the obese with no significant difference noted among micro-vascular complications^[27].

The major pathophysiology in this group appears to be rapid beta cell failure as opposed to insulin resistance. This was highlighted by the fact that lean individuals had both a higher prevalence and early initiation of insulin use^[27]. They were also noted to have lower TG/HDL ratios, which is an indirect marker of lower insulin resistance^[28-30]. In diabetics, central obesity (waist circumference > 102 cm in males and 88 cm in females by NCEP) correlates with the degree of insulin resistance^[31]. In the above cohort, 96.9% of the lean males did not have central obesity which points away from insulin resistance causing hyperglycemia^[27].

The key defect responsible for hyperglycemia in the lean diabetics is impaired pancreatic insulin secretion^[32-34] which is partly due to a reduced beta cell mass as demonstrated *via* autopsies^[35,36]. The more severe beta cell dysfunction in these patients may be functional rather than structural as beta cell mass was noted to be equally reduced in both lean and obese patients^[34]. Lean healthy Caucasian subjects born with a low birth weight have been demonstrated to develop several physiological defects of type 2 diabetes such as decline of insulin secretion, reduced muscle glucose uptake, reduced insulin stimulated glycolysis, lower fasting plasma glycerol levels and increased fat accumulation more prematurely than expected^[37-40]. Dutch Famine Study has also proven that a brief period of malnutrition during postnatal period or early childhood increases the risk of diabetes^[41]. These findings have been further validated in Asian populations too.

In addition, there was a higher prevalence of smoking, alcoholism and pancreatitis in the lean group in the Chicago study^[27]. Chronic alcohol consumption induces pancreatic beta cell dysfunction and apoptosis^[42]. Exposure to passive and active smoking are positively and independently associated with the risk of diabetes^[43]. Whether the pronounced male prevalence among the lean is due to inherent genetic differences or unhealthy life style that can promote beta cell failure in comparison to females is still a matter of debate.

Genetic modulators might also predispose to reduced beta cell function in the lean body weight group. Polymorphisms of transcription factor FL2 gene (TCF7L2) and a genetic defect of ATP sensitive potassium channel Kir6.2 (or KCN JII) are associated with defective insulin secretion. Carriers of TCF7L2 gene polymorphism were also shown to be leaner and more insulin sensitive as compared with other type 2 diabetics^[44]. Genetic scores for insulin resistance have shown association of lower subcutaneous fat mass and ectopic fat deposition highlighting the role of impaired adipose expandability and body fat distribution even among lean type 2 diabetic individuals^[45].

Higher prevalence of Asians in the lean group could be from greater intrauterine insults and under-representation of overweight and obesity amongst them based on standard Body Mass Index definitions available. GAD antibodies though less frequently noted^[46,47] may play a role in the autoimmune destruction of beta cells. It remains to be proven whether occurrence of these antibodies is merely secondary to the loss of beta cell function as compared to an etiological agent in itself^[48]. The role of genetics and autoimmunity in lean diabetics needs to be further elucidated prior to drawing more concrete conclusions in this group.

THE OBESITY PARADOX AND SARCOPENIC OBESITY

Another interesting aspect is the occurrence of complications and increased rate of mortality in certain normal weight diabetes patients in comparison to their obese counterparts. This phenomenon is called the "obesity paradox". A pooled analysis done on 2625 participants from 5 longitudinal cohorts showed that normal weight adults at the time of incident diabetes had higher mortality than adults who were overweight or obese^[49]. This "obesity paradox" has also been previously noted in other studies on diabetics and in various other chronic conditions such as hypertension, end stage renal disease and heart failure. It is likely that lower body weight in the presence of obesity related metabolic disorders may just be a reflection of preexisting illness that may predispose to mortality^[49]. It is also known that despite having a leaner body mass, cigarette smokers are more insulin resistant, more likely to develop diabetes, and have a higher mortality from chronic lung disease and malignancies as compared with non-smokers. Carnethon *et al.*^[49] concluded that the elevated mortality in normal weight participants could not be entirely attributed to smoking, though a subgroup analysis demonstrated that there is no statistically significant difference between mortality in non-smoker adults of either cohort. A main limitation of this analysis was inability to assess the smoking burden and relatively low statistical power that limited the body mass index classification to 2 broad and

heterogeneous groups (BMI 18.5-24.9 and BMI \geq 25).

Further research into this obesity paradox by Tobias *et al.*^[50] in over 11000 participants, showed a J-shaped association between body mass index among all participants and in current or previous smokers. A direct linear relationship was observed in those who had never smoked. The lower mortality was observed among participants with a BMI of 22.4-24.9. The obesity paradox was therefore not observed in this study^[50]. The increased mortality among lean diabetic smokers has been observed in the general population as well^[51-54] and further studies are needed to address whether they represent an effect modification or is secondary to bias^[55]. In participants 65 years or older, a null or weaker linear association was observed, which was probably due to increased prevalence of co-existing chronic diseases and decreased validity of BMI as a measure of adiposity due to age related decline in muscle mass and wasting^[50,56].

A possible explanation for the observed obesity paradox could be sarcopenic obesity, defined as the presence of high body fat with reduced or normal lean body mass^[1]. The localization of adipose tissue particularly abdominal obesity, independent of total obesity is associated with increased risk of cardiovascular disease. Sarcopenic obesity reduces the cardio-pulmonary fitness and physical functioning possibly leading to premature death and could account for the higher mortality eventually seen in individuals who are normal weight at the time of diabetes onset^[23]. The sarcopenic obesity may also indicate a catabolic underlying illness that leads to increased mortality. This was further supported by a systematic review, which showed that all cause mortality was lower among those with a high body mass index and good aerobic fitness as compared with individuals of a normal body mass index and poor fitness^[57]. A study on veterans has also supported this view^[58]. Hence questions can be raised regarding the sufficiency of such a simplistic classification of diabetes into obese or non-obese groups solely based on BMI.

IS FURTHER WEIGHT LOSS RECOMMENDED IN LEAN DIABETICS?

Weight loss is recommended for all overweight or obese diabetics. Studies such as the diabetes prevention program outcome study (DPP) and Look AHEAD^[59] have primarily focused on weight management in overweight and obese individuals^[1]. Could such recommendation be also effective in lean diabetics? Some concerns may be raised that additional weight loss could worsen both bone loss and decrease further the lean body mass contributing further to sarcopenic obesity. In the Chicago study, it appeared that leaner individuals had worse beta cell failure. One can then postulate that lean diabetics is a special variant of type II diabetes whereby the failing beta cell cannot even

Table 1 Clinical differences between type 1, type 2, ketosis resistant diabetes of the young and lean type 2 variant diabetes

Clinical features	Type 1 diabetes	Type 2 diabetes	KRDY	Lean type 2 variant
Age of diagnosis	Can occur at any age, usually < 25	Usually > 25 yr, but increasing prevalence in adolescents	< 30 yr	Average age around 40 with male preponderance
Weight	Usually lean	Overweight and obesity	BMI < 18	BMI 18-25
Autoantibodies	Present	Absent	Variable	Absent
Family history of diabetes	5% to 10%	75% to 90%	Unknown	Around 50%
Insulin sensitivity	Normal	Decreased	Normal	Normal, in females might be decreased
Insulin dependent at diagnosis	Yes	No	40% at diagnosis	35% at diagnosis
Risk of ketoacidosis	High	Low	Low	Low

KRDY: Ketosis resistant diabetes of the young; BMI: Body mass index.

Figure 1 Pathogenetic model of development of lean type 2 diabetes. In the obese individuals the diabetes develops once the beta cell cannot cope with the insulin resistance conferred by the growing obesity. In the lean diabetes the early failure of the beta cells results in development of diabetes at much lower insulin resistance. It might be speculated that in individual with similar beta cell dysfunction but lower insulin resistance (lower weight) diabetes might not develop. NGT: Normal glucose tolerance; IGT: Impaired glucose tolerance; T2DM: Type 2 diabetes; Modified from Weyer *et al. J Clin Invest* 1999; 104: 787–794.

cope with the small amount of insulin resistance that lean body weight confers. Could then achievement of a lower body weight or lower adiposity in these patients prevent diabetes? Currently there is no answer to this intriguing hypothesis (Figure 1).

CONCLUSION

The patients with lean diabetes in comparison to classical obese type 2 diabetes (Table 1) are characterized by younger age at onset, earlier and more prevalent use of insulin, higher prevalence in males and higher rates of cigarette smoking and alcohol abuse. It was initially shown that patients with diabetes who are leaner have higher mortality rate in comparison to the obese (the obesity paradox). This was explained by the concept of sarcopenic obesity whereby these patients are metabolically obese with excess of adiposity but have decreased muscle mass (sarcopenia) which is the predisposing factor for the increased mortality. The obesity paradox however could not be confirmed in a most recent study in a larger cohort.

The underlying pathogenetic mechanism of lean diabetes has not yet been clarified and more studies are needed for its elucidation. It could be a completely new pathogenic entity, however there is a possibility that it may just be a variant of type 2 diabetes. In type 2 diabetes, the beta cells that are genetically destined to fail gradually over the years cannot cope with the increasing insulin resistance that is conferred by obesity. Lean diabetes might be a variant of these main operating pathogenic mechanisms. The difference is the much more pronounced beta cell failure that occurs earlier and results in more rapid exhaustion. Several potential mechanisms could be involved in the beta cell failure. The initial predisposing factors may be an adverse intrauterine or early postnatal environment with insufficient nutrients that result in a smaller beta cell mass. Then genetic predisposition of a more fragile beta cell mass may cause early destruction and apoptosis. Studies have showed that genetic markers of such fragility are more common in the lean than in obese diabetics. In addition, in developed countries like the United States, acquired insults like cigarette

smoking and alcoholism might be newly defined and significant pathogenetic contributors that could further weaken the beta cells. In these circumstances, even the little insulin resistance associated with lean body weight could precipitate diabetes (Figure 1). Recent study has also shown that genetically determined insulin resistance may also play a role in the pathogenesis of lean diabetes.

Considering the inadequacy of BMI in distinguishing leanness, future studies should investigate the complex interaction between body composition, amount and distribution of adipose tissue and physical functioning in determining the development of lean diabetes. In the meantime emphasis on modifiable risk factors like smoking and alcohol abuse that may further accelerate beta cell failure in lean patients may prevent further progression of the disease.

Abstract

It has long been accepted that psychological factors adversely influence efforts to optimise glycaemic control. These are often unrecognised in terms of clinical assessment and therefore under reported. This essay presents an introduction to psychological issues that interact with psychiatric co-morbidities and diabetes-specific distress, and a case scenario illustrating the interconnectedness of presenting problems and themes. In the way that we cannot separate carbohydrate counting, blood glucose monitoring and insulin dose

adjustment in the understanding of a presenting problem such as poor control, so we cannot separate the concurrent thoughts, feelings, and behaviours. Each of these emotional aspects are self-managed either through avoidance, or by delayed disclosure and are frequently associated with poor health outcomes. There is a requirement for the healthcare team to be sensitised to these issues and to develop styles of communication that are empathic, reflective and non judgemental. A brief outline of evidence-based psychotherapy treatments is given.

Key words: Psychological factors; Glycaemic control; Anxiety; Depression; Eating disorder; Diabetes distress; Maladaptive coping; Psychotherapy

Core tip: Psychological factors adversely influence efforts to optimise glycemic control. The focus on psychiatric diagnosis has done a disservice to people with diabetes who experience significant levels of sub-clinical distress and it is essential to develop an understanding of the psychological issues that underpin poor self-management of type 1 diabetes. The diabetes healthcare team needs to be sensitive to the underlying issues and to be confident in the use of consultation styles that facilitate recognition and appropriate signposting for specialised support and treatment.

INTRODUCTION

It has long been accepted that psychological factors

adversely influence efforts to optimise glycemic control and for many years these have been addressed in the context of psychiatric diagnoses anxiety^[1], depression^[2,3] and eating disorders^[4,5]. Until recently the Quality Outcomes Framework^[6] has been used to remunerate United Kingdom General Practitioners for recording assessments of anxiety and depression in those living with long-term conditions. This focus on diagnosis has been to the detriment of people with diabetes who experience significant levels of distress, visible in terms of poor control but unrecognised in terms of clinical assessment and therefore under reported. More recently attention has been given to the need to differentiate between clinical diagnoses and diabetes-emotional distress^[7-9]. This article, informed by literature and the clinical experience of the author, presents an introduction to psychological issues that interact with psychiatric co-morbidities and diabetes-specific distress, and a case scenario illustrating the interconnectedness of presenting problems and themes. A brief outline of psychotherapeutic models available to treat these difficulties is given.

Management of type 1 diabetes requires optimising a sequence of actions or behaviours that include blood glucose monitoring, carbohydrate counting, insulin administration and physical activity, in the context of cognitions and emotions (thoughts and feelings). On the face of it the most straightforward approach to management is to advise people what to do, and expect it will be done. Living with and managing diabetes in the context of education, employment, recreation, ill health and relationships to name a few aspects of daily living, can be challenging. Diabetes is not an exact science and day to day life, early learning, emotions and motivation can, and do emerge as barriers to the consistent application of the "straight-forward" approach.

EMOTIONS AND COGNITIONS ASSOCIATED WITH DIABETES

Diabetes is the ultimate gatecrasher. There is no satisfactory explanation to answer the question "why me?" and at best glycaemic control can be managed, but unlike the party gatecrasher, diabetes cannot be sent away. Clinicians are familiar with the lexicon offered by people living with diabetes in response to the question "How does diabetes make you feel?" that includes words like anxious, worried, afraid, mood swings, depressed, euphoric, shame, guilty, angry and frustrated. Similarly when asked about thoughts triggered by living with diabetes the responses reflect what it means to live with the condition and its impact on quality of life, and the difficulties of management. This thinking interacts with beliefs about the self, the reaction of others and unconscious motives derived from early experience.

TOWARDS AN UNDERSTANDING OF THE MISMANAGEMENT OF DIABETES

In the way that we cannot separate carbohydrate counting, blood glucose monitoring and insulin dose adjustment in the understanding of a presenting problem such as poor control, so we cannot separate the co-existing thoughts, feelings, and behaviours.

Psychiatric diagnoses of anxiety, depression and eating disorders are frequently listed as psychological aspects of diabetes, and improvements in glycaemic control (HbA1c) reported as the primary outcome measure of treatment. As stated in the introduction, in recent years there has been increasing attention given to the need to differentiate psychiatric comorbidities and diabetes-related emotional distress. Identifying the factors that influence the decisions for particular actions that contribute to poor control is the crux of psychological formulation. Assessment of the presenting problem and the context in which it occurs offers a pathway to a personalised understanding that informs the treatment of choice. This might include further diabetes education, pharmacological treatment, appropriate psychological therapy, or indeed any combination of these.

Assessment of an individual presenting with poor control may reveal distress associated with, for example, a fear of hypoglycaemia. Thoughts might reflect a fear of loss of control, or of drawing unsolicited attention giving rise to emotions such as anxiety, frustration or guilt. Actions to elevate blood glucose such as reducing insulin or eating to maintain a "safe" blood glucose level result in both a reduction of risk of hypoglycaemia and a reduction in anxiety. Alternatively, high blood glucose readings frequently trigger guilt and fears about long term health. Evidence of high blood glucose is denied by avoidance of blood monitoring, and the emotional equilibrium thereby maintained. These are examples of the mismanagement of diabetes being used to manage emotional distress.

Managing diabetes requires multifactorial consideration of food choice and quantity, activity, blood glucose, ill health, ambient temperature, alcohol consumption, and menstrual cycle to name a few of the factors. The psychological responses are equally complex and influence actions with consequences on a continuum ranging from subtle to extreme outcomes on glycaemic control and psychological well-being.

PRESENTING PROBLEM AND UNDERLYING PSYCHOLOGICAL ISSUES

The following case history is used to illustrate psychological issues underlying poor control evidenced by elevated HbA1c and frequent episodes of hypoglycaemia. It invites consideration as to whether the presenting problem requires direct treatment or

is a symptom of underlying difficulties that need to be addressed.

CASE STUDY (REPORTED WITH PERMISSION)

Sam is a 60-year old post menopausal woman approaching retirement. She has been married for 38 years and although she experienced difficulty with conception she has one adult child. Her family of origin practised strict religious beliefs and she was brought up to be sensitive to the needs of others before her own. She had little preparation for independent living and intimate relationships: indeed such topics were taboo and usually associated with duty, guilt, shame and blame. There was an expectation that she would be self-sufficient and undemanding which contributed to considerable reluctance to seek help and resulted in her needs not being met. She suffered a sexual assault in her late teens not disclosed at the time, for which she did not receive emotional support and which subsequently influenced intimate relationships and generated a sense of shame. Her predominant employment has involved looking after others in a variety of roles, consistently prioritising the needs of others above her own. Sam has had type 1 diabetes for 20 years with significant fluctuations in control over that time and frequent hypoglycaemia, severe episodes occurring most frequently during sleep. Weight and body-image concerns are relevant in terms of her self-perception as unloveable and unattractive. She engages in regular exercise and has the not uncommon challenge of balancing energy needs, insulin dose and extremes of blood glucose levels. Whilst there is no indication that Sam uses insulin omission to influence her weight she tends to maintain elevated blood glucose to protect against hypoglycaemia. Pervading themes reflect guilt, shame, blame, a sense of being undeserving and either not good enough or a failure.

On the face of it a diabetes-specific intervention might focus on insulin adjustment, reducing episodes of hypoglycaemia, optimising exercise and blood glucose control or, less likely, weight management. The brief history offers insight into interconnecting psychological factors that contribute to poor glycemic control (Figure 1).

We can map the interlinking of the psychological factors, many of which are derived from early experience, others of which are accentuated by the role of diabetes and its impact on daily living. The experience of hypoglycaemia potentially predisposes fear of further episodes interconnecting with blame from others for "getting it wrong", shame and personal failure for "getting it wrong" and embarrassment and a fear of being out of control. Maladaptive coping behaviours include overeating and/or the reduction of insulin to elevate blood glucose, avoiding any physical exertion that may result in hypoglycaemia and avoiding social

situations. The awareness that the coping mechanism results in short term relief with adverse consequences on long-term health perpetuates the cycle with resulting feelings of guilt, shame, and body-image concerns.

The spider's web gives some indication of why managing diabetes can be so challenging. Advice to adjust insulin:carbohydrate ratios, conservative treatment of hypoglycaemia, dietary advice and information about women's sexual function and diabetes may all be appropriate but do not address the psychological themes underpinning the maladaptive behaviours contributing to poor control.

PSYCHOLOGICAL ISSUES AND MALADAPTIVE COPING

The earlier paragraphs describe circumstances and events with psychological consequences, in the context of diabetes, that lead to maladaptive coping and mismanagement of diabetes. The following is a brief account of some of these with reference to the literature for more detailed exploration. Evidence has been provided for different components of type 1 diabetes distress: emotional burden, interpersonal and social distress, regimen related, and health care related^[9-12]. The psychological issues are inextricably interconnected and related to specific aspects of diabetes-distress and presenting problems such as hypoglycaemia, fear of complications and body-image concerns.

Fear and anxiety

Fear and anxiety are the cognitive and emotional responses to threat. In order to reduce emotional discomfort individuals either "overdo" in an attempt to prevent the feared event or "under do" (avoid) the action in the misapprehension that by not addressing it, it will go away. The lack of exposure to the feared event (*e.g.*, hypoglycaemia) means that the individual reinforces the avoidance behaviour and does not learn how to cope were the threat to occur.

Blame and shame

Blame and shame indicate perceived negative judgement. Both emotions result from and give rise to the instigation of thoughts of not being good enough, having done wrong, or having failed, and are consistent with the experience of distress. "Shame plays a major role in the eventual consequences of diabetes self-management"^[13]. Embarrassment and shame are also associated with specific diabetes symptoms which are both embarrassing to experience and for which to seek help^[14].

Stigma

"Health related stigma is a negative social judgement based on a feature of a condition or its management that may lead to perceived or experienced exclusion, rejection, blame, stereotyping and/or status loss"^[15].

Figure 1 The spider's web: Visual representation of interconnecting psychological issues associated with the presenting problems of a female with type 1 diabetes.

Consequences of stigma span emotional, behavioural and social domains with specific implications of an unwillingness to disclose the condition which may compromise care, and fear of being judged or blamed for suboptimal diabetes management. A model is proposed to understand diabetes-related stigma^[15].

Guilt

Guilt is a personal emotion experienced when there is recognition that something has not been done as believed it should have been, or something has been done that should not have been. It is similar to shame in its negative impact on self esteem but tends to relate to a specific action whereas shame is more to do with the perception of self. It evokes efforts to correct or make reparation, however this can result in perpetuating the negative feelings as a consequence of negative thoughts about self worth.

Each of these emotional aspects are self managed either through avoidance, striving to maintain invisibility, with poor outcomes or by delayed disclosure which can intensify the distress, at least in the short term, and frequently are also associated with poor outcomes.

There is a requirement for the healthcare team to be sensitised to these issues and to develop styles of communication that are empathic, reflective and non judgemental.

Models of therapy

Assessment and formulation guide treatment plans and until there is a robust evidence base specific to

people with diabetes that suggests otherwise there is a choice of psychological therapies available for accredited practitioners to use. Behaviour therapy^[16] focuses on modification of observable behaviours without taking into account "invisible" emotions and cognitions and is rarely an appropriate model to use with people with type 1 diabetes.

Cognitive behavioural therapy

Traditional cognitive behavioural therapy is a goal oriented, problem focussed therapy that combines behavioural and cognitive models. It is a collaborative approach that focuses on current problems rather than past issues. It has evolved as a specific treatment for symptoms associated with specific diagnoses, and is used to challenge cognitive distortions thereby promoting behaviour change^[17].

Acceptance and commitment therapy

Acceptance and Commitment Therapy is an example of "Third Wave Therapies". It is particularly relevant in the context of fluctuating and frequently negative thoughts and feelings associated with diabetes. Rather than focus on the influence of emotions and cognitions as drivers for behaviour, the emphasis is on promoting value driven behaviour. The treatment facilitates a willingness to step back, notice and accept thoughts as they occur without becoming ensnared by the emotional response. Individuals commit to value driven actions whilst noticing the thoughts and feelings that invite self-sabotaging behaviour. For a detailed review of the full range of Third Wave therapies the reader is

invited to a recent review article by Kahl *et al*^[18].

Cognitive analytic therapy

Cognitive analytic therapy is a time limited therapy which integrates concepts from cognitive and psychodynamic models^[19]. The treatment involves the identification of sequences of thoughts and emotions that explain how a problem is established and maintained. The recognition of unhelpful self-sabotaging patterns of interaction derived from early experience, replayed in later life are interpreted in the context of diabetes management.

CONCLUSION

Non-psychiatric psychological aspects of living with type 1 diabetes interconnect with the day to day self-management tasks and related diabetes distress. There is a need for the diabetes healthcare team to be sensitive to the underlying issues and to be confident in the use of consultation styles that facilitate recognition, assessment, and appropriate signposting for specialised support and treatment. There is an unequivocal need for the multi-disciplinary team to include experienced psychological-therapists with considerable knowledge of diabetes management so that difficulties can be addressed as an integral part of the diabetes care available.

Abstract

Under normal metabolic conditions insulin stimulates microvascular perfusion (capillary recruitment) of skeletal muscle and subcutaneous adipose tissue and thus increases blood flow mainly after meal ingestion or physical exercise. This helps the delivery of insulin

itself but also that of substrates and of other signalling molecules to multiple tissues beds and facilitates glucose disposal and lipid kinetics. This effect is impaired in insulin resistance and type 2 diabetes early in the development of metabolic dysregulation and reflects early-onset endothelial dysfunction. Failure of insulin to increase muscle and adipose tissue blood flow results in decreased glucose handling. In fat depots, a blunted postprandial blood flow response will result in an insufficient suppression of lipolysis and an increased spill over of fatty acids in the circulation, leading to a more pronounced insulin resistant state in skeletal muscle. This defect in blood flow response is apparent even in the prediabetic state, implying that it is a facet of insulin resistance and exists long before overt hyperglycaemia develops. The following review intends to summarize the contribution of blood flow impairment to the development of the atherogenic dysglycemia and dyslipidaemia.

Core tip: Insulin resistance and type 2 diabetes present with diminished glucose transport and disposal in muscles and fat and inadequate inhibition of lipolysis after meal ingestion or during physical exercise. This defect lies mainly in the cellular and subcellular level of insulin action. However, the resistance in the haemodynamic properties of insulin is another facet of type 2 diabetes and the metabolic syndrome. In this review, we intend to summarize the contribution of this impairment to the development of the atherogenic dysglycemia and dyslipidaemia.

INTRODUCTION

The role of insulin in regulating glucose disposal in peripheral tissues, such as skeletal muscle and adipose tissue is well established. In the 50s, when it was discovered that insulin stimulated glucose uptake and disposal into the muscles, this effect was thought to be the most important way by which insulin regulated glycaemia *in vivo*. When the glucose/fatty acid regulatory cycle was discovered in the 60s a new insight of the way that insulin regulates glucose metabolism was introduced^[1]. However, apart from its direct action on cells, insulin is also a vasoactive hormone, and it is now recognized that its vascular and metabolic actions are closely linked. Baron *et al*^[2-4] originally introduced the concept that insulin might control its own access and that of other substrates - like glucose, lipids and several signalling molecules- to peripheral tissues, by increasing blood flow, and that this effect is compromised in states of insulin resistance.

In states of metabolic dysregulation, as in diabetes and obesity, there is deterioration in the cellular effects of insulin in peripheral tissues, which leads to a reduced ability of the latter to stimulate glucose uptake from the skeletal muscle and adipose tissue, as well as to inhibit lipolysis in fat depots^[5]. Apart from the defects at the cellular level, the metabolic derangement could also be a result of the inability of insulin to cause vasodilatation and delivery of substrates to peripheral tissues especially in the postprandial period. This could contribute to the progression to type 2 diabetes as well as to the development of atherosclerosis, which is often evident even before overt hyperglycaemia develops^[6].

In this review we summarize the current understanding of insulin action on peripheral blood flow and its implications on metabolic impairment both under fasting and postprandial conditions in type 2 diabetes.

INSULIN AND THE VASCULATURE IN NORMAL METABOLIC PHYSIOLOGY

Skeletal muscle

In skeletal muscle, insulin promotes the rate of glucose transport and the activities of hexokinase and 6-phosphofructokinase and subsequently the rate of glycolysis. In terms of protein metabolism, insulin increases synthesis and decreases degradation of proteins, in favour of an anabolic process^[1]. Insulin also enhances vasodilatation and capillary recruitment, consequently increasing the flow of nutrients in peripheral tissues and especially in skeletal muscle^[7]. It acts through traditional insulin receptors on the vascular endothelium to stimulate production of nitric

oxide and induce vasodilatation^[8]. The endothelial insulin response is mediated through a PI3-kinase pathway, which after several intermediate steps ends up activating endothelial nitric oxide synthase (eNOS)^[6].

Blood flow is highly important for the metabolic function of skeletal muscle and under normal conditions increases after meal ingestion and during exercise and a correlation between the rate of insulin stimulated glucose uptake and the extent of vasodilatation seems to exist^[9].

Insulin stimulates skeletal muscle glucose disposal and total muscle blood flow in a time- and dose-dependent fashion. *In vivo*, it enhances nitric oxide synthase-dependent vascular actions, in order to increase total skeletal muscle blood flow and to recruit muscle capillaries (by relaxing resistance and terminal arterioles, respectively). It is speculated that enhancing blood flow in this way on resistance vessels may induce the delivery of glucose and insulin to peripheral tissues and thus contribute to overall glucose disposal.

Capillary blood volume increases when precapillary arterioles dilate, thus increasing the flow to previously unperfused or underperfused areas, and total blood flow to skeletal muscle increases when larger resistance vessels relax^[10].

Insulin increases tissue perfusion by augmenting microvasculature and, at normal concentrations, the rise in total muscle blood flow follows 60-90 min later^[11,12].

Both haemodynamic effects of insulin, muscle blood flow increase and capillary recruitment seem to be independent of each other. Capillary recruitment occurs earlier *in vivo*, and at lower doses of insulin^[13].

Insulin resistance may correlate to endothelial dysfunction in many ways, including dysregulation of sub-cellular signalling pathways that influence both insulin action and nitric oxide production^[14,15].

Adipose tissue

Subcutaneous adipose tissue represents about 85% of whole body fat stores in subjects with various degrees of adiposity. Its main metabolic role is the storage of triglycerides which derive from energy overflow, and the release of stored lipids when other tissues are in need. Adipose tissue metabolism is under distinct control: usually, when a person consumes a meal, within the first hour postprandially, fat catabolism converts to fat storage, while the opposite happens in the case of physical activity. Adipose tissue interacts with the circulation by providing or drawing triglycerides and non-esterified fatty acids depending on metabolic needs. There are two kinds of triglyceride-rich lipoproteins: (1) chylomicrons, the largest particles, that carry the fat from absorbed nutrients within the intestine; and (2) very-low-density lipoproteins, that carry "endogenous" triglycerides and are released by the liver. Chylomicron- triglycerides are preferably stored within adipose tissue, and the fatty acid composition of adipose tissue (*i.e.*, the kind of fatty acids that form its triglycerides) usually represents the

composition of a person's dietary fat intake, suggesting that adipose tissue triglycerides derive mainly from the ingested fat through diet. However, a proportion of plasma triglycerides are endogenously produced from non-lipid substrates (*de novo* lipogenesis) in adipose tissue^[16-22].

In terms of metabolic regulation, adipose tissue can be divided into central (abdominal) and peripheral (lower body) depots. An unfavourable metabolic profile has been related to central fat accumulation (visceral and subcutaneous, each with distinct metabolic, endocrine and paracrine characteristics and blood flow rates)^[23,24].

Adipose tissue regulates its metabolism, at least in part, by increasing its blood flow rate mainly in the early postprandial period^[16]. Capillary perfusion is essential for that function. In the case of increased energy demands, as in physical activity, blood flow increases to facilitate the delivery of lipolytic products to peripheral tissues. Furthermore, after meal consumption, it helps the delivery of ingested substrates to fat depots for storage^[16]. Adipose tissue blood flow responses are subject to adrenergic stimulation or inhibition. Adrenaline administration stimulates postprandial increases whereas beta-blockers inhibit the latter. Genetic studies in subcutaneous adipose tissue biopsies have identified expression of the type A receptor of A natriuretic peptide and of the synthase of nitric oxide, and have found an association of those with post-challenge blood flow responses^[16,25-28].

Lipid kinetics and subcutaneous adipose tissue blood flow alterations are closely linked. More specifically, blood flow rises in response to an increased demand for lipolytic products as energy, or that for cleavage of free fatty acids from the circulation. In euglycaemic subjects with normal weight blood flow peaks within the first hour after a glucose load or a mixed meal. This facilitates the postprandial delivery of energy substrates and insulin to the fat depot, leading to adipose tissue lipoprotein lipase stimulation which stores circulating triglycerides and the suppression of hormone-sensitive lipase, which results in the inhibition of endogenous lipolysis^[16,29-31].

On the other hand, visceral adiposity exerts even more unfavourable metabolic actions. Increased visceral fat has been associated with atherogenic dyslipidaemia and the development of atherosclerosis, even in non-diabetic individuals^[32]. Although increased abdominal fat is in general positively associated with markers of inflammation and atherosclerosis, visceral fat is more strongly correlated with C-reactive protein, monocyte chemoattractant protein-1, interleukin-6 and isoprostanes independently of total adiposity, indicating a major role in systemic inflammation^[33]. Furthermore, visceral fat has been more strongly related to hypertension both in men and women, and provides information towards the latter above BMI and waist circumference. However, subcutaneous adipose tissue is also contributing to vascular dysfunction,

possibly through the actions of leptin apart from the presence of insulin resistance^[34]. Both adipose tissue beds' size has been found correlated to adipose tissue blood flow, independently of BMI, leptin or adiponectin concentrations^[35].

INSULIN AND BLOOD FLOW IN TYPE 2 DIABETES

Skeletal muscle

Insulin provokes microvascular recruitment in skeletal muscle^[10]. Impaired muscle blood flow as a facet of insulin resistance in subjects with either dysglycaemia or diabetes is well recognized in the literature. In the early 90s Steinberg *et al.*^[36] have shown that obese insulin resistant subjects present with an endothelial dysfunction and during a euglycaemic hyperinsulinaemic clamp they fail to increase endothelium-dependent vasodilation. In these trials, catheterizations of the femoral artery was used to measure the response to an intra-arterial vasodilator stimulus, comparing control to euglycemic-hyperinsulinemic clamp conditions^[36].

Thereafter, it was suggested that since insulin exerts its vasodilatory effects through endothelial nitric oxide release, *in vivo* stopping nitric oxide production could inhibit insulin's vasoactive actions in skeletal muscle and consequently reduce glucose uptake^[37]. Moreover in obese insulin resistant subjects, insulin resistance in skeletal muscle was promoted by the increased endogenous endothelin action^[38].

A rat model of insulin resistance has shown that endothelial-dependent vasodilation is blunted, in part due to an unresponsive nitric oxide synthase to insulin, leading to decreased nitric oxide levels in the endothelial cells^[39,40].

In type 2 diabetes and other insulin-resistant states, impaired suppression of adipose tissue lipolysis and postprandial hyperglycemia favour non-esterified fatty acid utilization and oxidation and increase glucose uptake from insulin independent tissues (like liver). Dyslipidaemia, usually related to lack of insulin sensitivity, enhances atherosclerosis and triggers inflammation in endothelial cells^[41].

In insulin-resistant patients basal blood flow is generally not altered^[42-44]. Laakso *et al.*^[45] demonstrated that insulin cannot effectively increase muscle blood flow in type 2 diabetic patients, using the combined euglycemic clamp and leg balance techniques during different insulin infusions. They also concluded that impaired insulin-dependent rise in skeletal muscle blood flow can be attributed to the diabetic milieu and not to obesity, in a study of obese diabetic patients^[45].

Lambadiari *et al.*^[46] studied simultaneously lean subjects with insulin sensitivity varying from normoglycaemic insulin-resistant first-degree relatives of diabetic subjects to prediabetic and diabetic patients with either isolated postprandial hyperglycaemia or overt diabetes^[46]. They demonstrated that using a

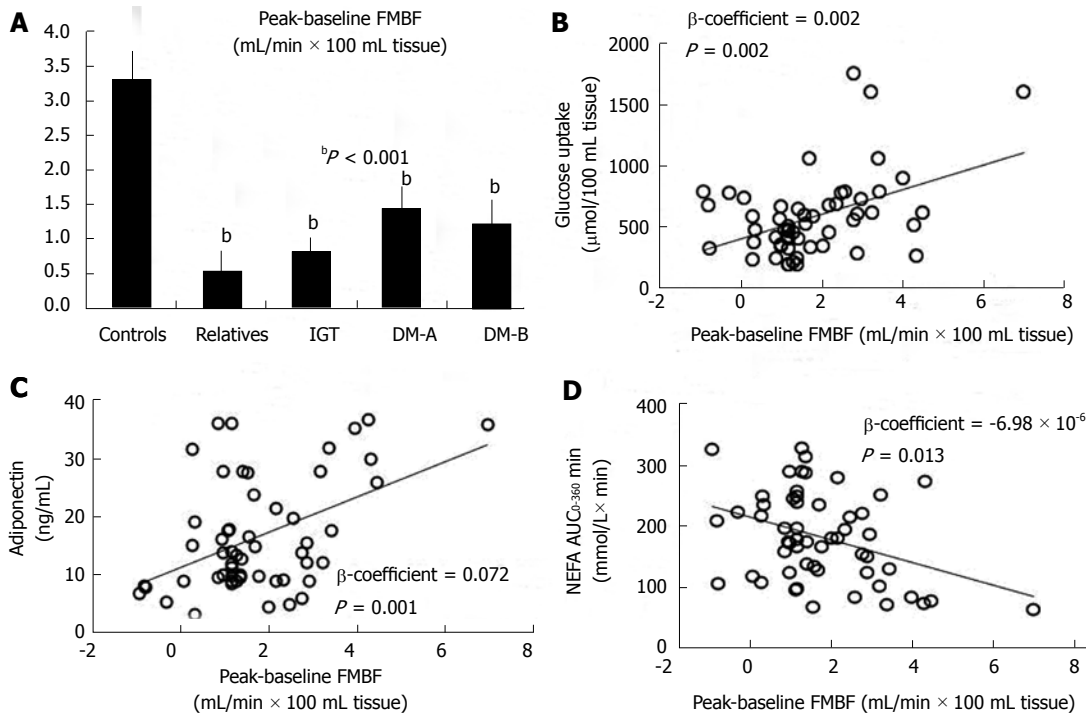

Figure 1 Forearm muscle blood flow peak-baseline values in all groups (A), and associations between peak-baseline forearm muscle blood flow and forearm muscle glucose uptake (B), plasma adiponectin (C) and postprandial non-esterified fatty acids (D), in subjects at all stages of type 2 diabetes. A: bP overall < 0.001; B: Forearm muscle glucose uptake = $427.9 + 101.4$ peak-baseline FMBF, $P = 0.001$; C: Adiponectin = $12.17 + 3.05$ peak-baseline FMBF, $P < 0.001$; D: Postprandial NEFA (AUC₀₋₃₆₀) = $209.5 - 18.52$ peak-baseline FMBF, $P = 0.005$. FMBF: Forearm muscle blood flow; NEFAs: Non-esterified fatty acids. IGT: Impaired glucose tolerance; DM: Diabetes mellitus. Adapted from Lambadiari *et al.*^[46].

physiological mixed meal as a stimulus, the postprandial augmentation in forearm muscle blood flow is blunted throughout all stages of metabolic impairment compared to controls; this occurs even before overt hyperglycaemia develops. The latter affected glucose disposal in muscle, which was also unresponsive after meal delivery and was also positively correlated to the post-load muscle blood flow differences. Lipid substrates affected blood flow peak as well. Triglyceride levels had a negative impact on blood flow responsiveness in the fed as well as in the fasting period. Post-challenge non-esterified fatty acids levels exhibited a negative effect on blood flow responsiveness, suggesting a possible mechanism for the decrease in muscle glucose clearance after the meal. A lower serum adiponectin level was also seen in the diabetic and the prediabetic insulin-resistant subjects, with the latter being positively related to the decreased postload blood flow rise^[46] (Figure 1).

In subjects with morbid obesity postprandial muscle blood flow was also blunted in a study by the same group and this contributed to the decrease in muscle glucose uptake postprandially^[47]. The same was observed by the same group in another insulin resistant state, such as hypothyroidism, in which a decreased postprandial blood flow response was coupled with an impairment in muscle glucose uptake^[48]. In a study by Magalhães *et al.*^[49] administration of metformin to non-obese type 2 diabetic patients increased post-load forearm muscle blood flow and lowered free fatty acids,

thus improving glucose oxidation and insulin sensitivity in the muscle bed.

However, there is not universal agreement with the above mentioned results, since numerous studies have failed to reveal a defect in insulin-mediated blood flow in type 2 diabetic patients^[42,50]. There is a certain discrepancy since the literature either confirms or not a substantial^[45,51], or an unimportant correlation between insulin kinetics, muscle blood flow and glucose disposal^[52,53].

Some of these discrepancies may at least partially explained by the different studies populations and by the experimental protocol used. The commonly used clamp technique is not physiological, because these exceptionally high insulin concentrations are not normally present for long after meal consumption. Hence, one could question the physiological significance of such an increase in blood flow rates. A normal stimulus, such as a mixed meal, can provide evidence of a real life metabolic state^[46,54]. However, not only the type of meal but the method for the detection of blood flow is important in this evaluation.

Adipose tissue

In lean insulin-sensitive subjects, abdominal adipose tissue blood flow increases by two- to four-times in response to feeding. The same seems to be true for blood flow in lower body fat depots (thigh) and forearm tissues. Physiologically, adipose tissue blood flow peaks within half to one hour after nutrient ingestion. This rise

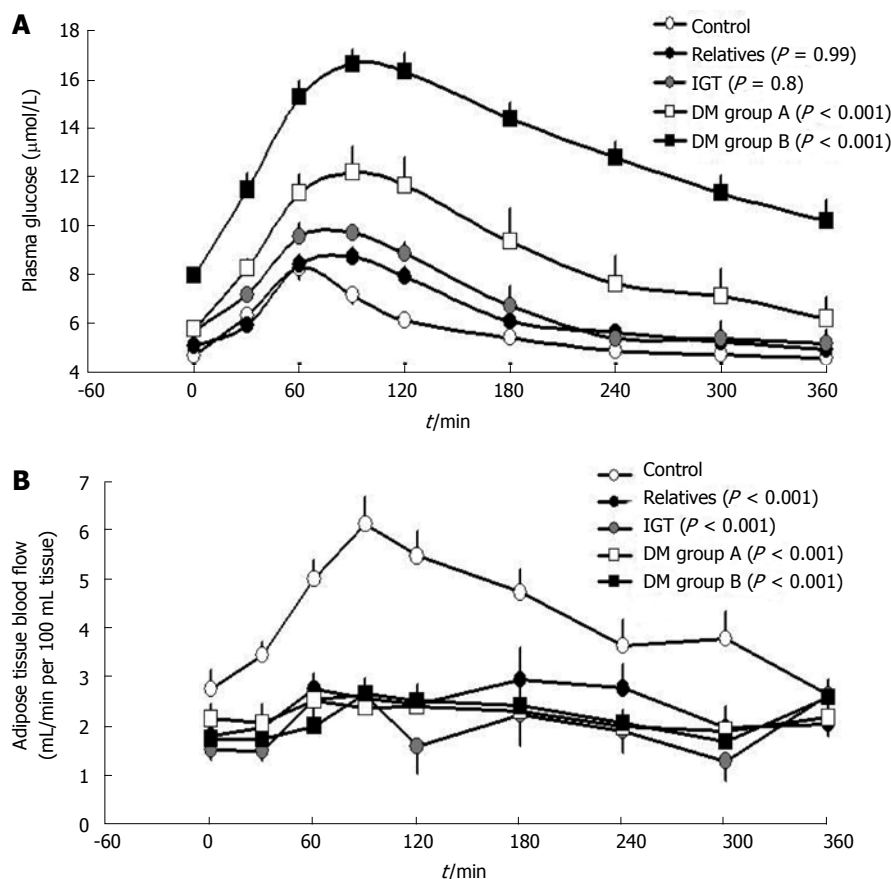

Figure 2 Plasma glucose, and adipose tissue blood flow in healthy subjects (control), first degree relatives of subjects with type 2 diabetes (relatives), subjects with impaired glucose tolerance, subjects with type 2 diabetes with postprandial hyperglycemia and normal fasting plasma glucose levels (diabetes mellitus group A) and subjects with type 2 diabetes with both postprandial and fasting hyperglycemia (diabetes mellitus group B). " P " stands for overall comparison (repeated measures ANOVA) between control and patient groups. IGT: Impaired glucose tolerance. Adapted from Dimitriadis *et al*^[62].

coincides with plasma insulin peak and the inhibition of lipolysis^[23].

By studying obese or diabetic individuals in the 90s, Jansson *et al*^[55,56] detected impairment in adipose tissue blood flow response as a facet of insulin resistance coupled with hypertension and elevated lipolysis products.

Since then, numerous studies have shown that in states of decreased insulin sensitivity, as in "diabesity", the postprandial increase in adipose tissue blood flow is reduced^[57-60]. Karpe *et al*^[61] showed that the postprandial blood flow rise is associated with insulin sensitivity independently of weight. Moreover, they showed that hyperinsulinaemia affects adipose tissue blood flow indirectly by stimulation of sympathetic activity^[61].

Previous reports in healthy subjects by the same research group have demonstrated that nitric oxide determines the actual rate of adipose tissue blood flow, whereas postprandial augmentation of it is mainly under adrenergic regulation *in vivo*, and that blood flow regulation and lipolysis are co-regulated^[25].

Dimitriadis *et al*^[62] showed an altered fasting and postprandial adipose tissue blood flow in all stages of metabolic regulation, from the prediabetic state to clinical diabetes, even in lean first-degree relatives of

diabetic patients. This study, using a mixed meal as a stimulus, showed significant association of postprandial adipose tissue blood flow with insulin sensitivity. Basal and post-challenge triglycerides were negatively correlated to the responsiveness of adipose tissue blood flow; the same was true for postprandial non-esterified fatty acids but not for fasting values^[62] (Figure 2).

Fatty acid overflow (mainly palmitic acid), a well recognized factor to interfere with insulin sensitivity, causes both cellular and vascular insulin dysfunction^[63]. The increased rate of lipolysis in diabetes may result in increased lipid oxidation and a decreased glucose oxidation rate^[61,64].

Impairment in blood flow response of adipose tissue has been found in other insulin resistance states. Mitrou *et al*^[47] study in morbidly obese subjects, shows a drop in postprandial adipose tissue blood flow response and in glucose disposal per 100 mL fat tissue. However, glucose fractional extraction from subcutaneous fat depot was unaltered and glucose uptake per total fat mass was increased. Thus, it seems that although an expanded adipose tissue causes insulin resistance, total fat mass provides a buffer for glucose overflow and compensates for insulin resistance.

Diabetic subjects fail to increase adipose tissue blood flow during prolonged exercise of moderate

intensity, in combination to the inability to regulate non-esterified fatty acid mobilization and adipose tissue glucose clearance^[65]. Exercise augments adipose tissue lipolysis in diabetic patients, but due to an impaired blood flow response, a high proportion of free fatty acids that come from lipolysis cannot be released into the circulation. Visceral glucose release is lower than whole-body glucose utilisation during exercise and post-exercise recovery^[66].

The cause of the impairment in postprandial adipose tissue blood flow reactivity in insulin resistance is still obscure. One potential explanation is the downregulation of the adrenergic receptor during chronic sympathetic stimulation in a milieu of long-standing hyperinsulinaemia. Sympathetic nervous system overactivity induces oxidative stress. Increased levels of circulating free oxygen radicals consumes nitric oxide, and inhibits physiological insulin-dependent vasodilatation^[23]. Interestingly, the transcription of eNOS and natriuretic peptide receptor-A, which are expressed in adipose tissue and interfere with vasoactive actions, was associated with adipose tissue blood flow responsiveness to feeding. This finding suggests that part of blood flow regulation is at a transcriptional level and it is independent of adiposity^[28].

At the bottom line, adipose tissue is an important buffer against the postprandial spill-over of nonesterified fatty acids in the circulation, thus protecting other peripheral tissues. This buffering effect is dysregulated in states of an over-expanded inflammatory, hypoxic adipose tissue, where the postprandial blood flow response is minimized, potentially leading to atherogenic dyslipidaemia^[67].

CONCLUSION

Resistance in the haemodynamic actions of insulin is essential for the development of type 2 diabetes and insulin resistant states as well as their complications, namely cardiovascular disease, the development of which often precedes overt hyperglycaemia and which is the primary cause of mortality within the diabetic population.

Insulin normally stimulates microvascular perfusion (capillary recruitment) of skeletal muscle and subcutaneous adipose tissue and thus increases blood flow mainly after meal ingestion or physical exercise. This effect is impaired in insulin resistance and type 2 diabetes early during metabolic dysregulation development and reflects early-onset vascular dysfunction. Failure of insulin to increase muscle blood flow results in the inability to regulate its own delivery and that of other substrates and hormones and consequently to a decrease in glucose disposal. In fat depots blood flow is closely related to triglyceride clearance and non-esterified fatty acid kinetics. Therefore, we may speculate that dysregulation of post-challenge blood flow responsiveness in skeletal muscle and adipose tissue may together underlie some of the detrimental

aspects of insulin resistance.

morbidity and mortality among patients with diabetes mellitus, who have a risk of cardiovascular mortality two to four times that of people without diabetes. An individualised approach to cardiovascular risk estimation and management is needed. Over the past decades, many risk scores have been developed to predict CVD. However, few have been externally validated in a diabetic population and limited studies have examined the impact of applying a prediction model in clinical practice. Currently, guidelines are focused on testing for CVD in symptomatic patients. Atypical symptoms or silent ischemia are more common in the diabetic population, and with additional markers of vascular disease such as erectile dysfunction and autonomic neuropathy, these guidelines can be difficult to interpret. We propose an algorithm incorporating cardiovascular risk scores in combination with typical and atypical signs and symptoms to alert clinicians to consider further investigation with provocative testing. The modalities for investigation of CVD are discussed.

Key words: Diabetes; Cardiovascular risk; Risk scores; Provocative testing; Silent ischaemia; Atypical symptoms

Core tip: Current guidelines focus on testing for cardiovascular disease in symptomatic patients. However, patients with diabetes often present with atypical features of underlying vascular disease. An individualised approach to cardiovascular risk estimation and management is needed in patients with diabetes. We propose an algorithm incorporating cardiovascular risk scores in combination with typical and atypical signs and symptoms to alert clinicians to consider further investigation with provocative testing. The modalities for investigation of cardiovascular disease are discussed.

Abstract

Cardiovascular disease (CVD) is the leading cause of

Lam T, Burns K, Dennis M, Cheung NW, Gunton JE. Assessment

of cardiovascular risk in diabetes: Risk scores and provocative testing. *World J Diabetes* 2015; 6(4): 634-641 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/634.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i4.634>

INTRODUCTION

The incidence of diabetes mellitus is increasing globally. The World Health Organisation estimated there were 30 million people who had diabetes worldwide in 1985. This number increased to 217 million in 2005, and by the year 2030, it is predicted this number will increase to at least 366 million^[1].

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality among people with diabetes mellitus, who have a risk of cardiovascular mortality two to four times greater than that of people without diabetes^[2]. Diabetes is commonly associated with other cardiovascular risk factors, interacting with these to accelerate atherogenesis^[3-6]. Multifactorial interventions, such as those targeting hyperglycaemia, hypertension and hypercholesterolaemia, significantly reduce the risk of both fatal and non-fatal CVD^[7]. The National Cholesterol Education Programme Adult Treatment Panel III (NCEP-ATPIII) has listed diabetes as a coronary heart disease (CHD) equivalent, which would obviate the need for risk stratification. However, clearly not all patients with diabetes have the same cardiovascular risk. An individualised approach to cardiovascular risk estimation and management is needed^[8]. Furthermore there is a high prevalence of asymptomatic coronary artery disease (CAD), and higher incidences of silent ischaemia and of atypical symptoms^[9].

Over the past two decades, there has been a significant reduction in the incidence of diabetes-related complications. The greatest absolute decline was in the number of cases of acute myocardial infarction, likely reflecting a combination of enhanced awareness, detection and early management of risk factors^[10]. The development of statistical models, such as the Framingham equations, has allowed the probability of future cardiovascular events to be calculated based on multiple risk factors^[11]. This allows targeted preventative therapy for those with highest absolute risk^[12]. However, the majority of these risk equations have not been validated enough in the diabetic population, and either overestimate or underestimate cardiovascular risk.

USE OF CARDIOVASCULAR RISK SCORES IN DIABETES MELLITUS: PREDICTORS, VALIDATION AND IMPACT ON CLINICAL OUTCOME

There have been a multitude of risk scores developed

over the past decades, but only a few have been specifically developed for use in the diabetic population. In a systematic review of prediction models for CVD risk in type 2 diabetes^[13], 12 of 45 prediction models were specifically developed for patients with type 2 diabetes. The majority of these predicted 5-year risk of CHD or total CVD, with the most commonly used predictors being age, sex, duration of diagnosed diabetes, HbA1c (glycosylated haemoglobin A1c) and smoking. Non-traditional risk factors, such as novel biomarkers and low birthweight, have generally not been incorporated into these models, and are of questionable clinical significance^[14,15]. Prediction models derived from the general population, in which diabetes was used as a predictor, included other risk factors such as age, sex, systolic blood pressure, smoking and cholesterol. Of the risk scores, only a third had been externally validated in a diabetic population^[13].

The International Diabetes Federation recommends calculating cardiovascular risk in patients with type 2 diabetes with prediction models that can be applied to the diabetes population, including the United Kingdom Prospective Diabetes Study (UKPDS) risk engine^[16]. This risk engine provides a comprehensive model for predicting CHD risk in patients with type 2 diabetes. The Australian National Vascular Disease Prevention Alliance^[17] recommends using both the Framingham prediction model and UKPDS risk engine. However, certain subgroups (Table 1) are at high risk of cardiovascular events because of their comorbidities, and a calculation of absolute CVD is not considered necessary^[17].

Kengne *et al.*^[11] evaluated the performance of the Framingham and UKPDS models in a cohort of patients with established type 2 diabetes, and found both models to overestimate the 4-year risk of CHD; by 146% and 198% respectively. The Action in Diabetes and Vascular Disease: Preterax and Diamicon MR Controlled Evaluation model^[18] was developed from a contemporary multinational cohort of diabetic patients, and includes both retinopathy and microalbuminuria as risk predictors. They are both significantly associated with CVD. It has largely outperformed the Framingham models in validation studies, with only a modest risk underestimation^[19]. Similarly, the Fremantle prediction model^[20], developed from a type 2 diabetic cohort, had good positive and negative predictive values, but requires further validation^[13].

Very few studies have examined the impact of applying a prediction model in clinical practice. In a cohort of patients with type 2 diabetes at high risk of CVD, clear documentation of a cardiovascular risk prediction score on patient medical records was associated with more intensive intervention through prescription of lipid-modifying or antihypertensive medications^[21]. Furthermore, use of risk scores has resulted in improvements in lipid profiles and significant reductions in risk of CHD^[22].

The use of cardiovascular risk scores has been

Table 1 Clinical features suggesting diabetes patients at high risk

Diabetes and age > 60 yr
Diabetes and microalbuminuria (> 20 mcg/min or urine albumin to creatinine ratio > 2.5 mg/mmol for males, > 3.5 mg/mmol for females)
Diabetes and moderate or severe chronic kidney disease (persistent proteinuria or eGFR < 45 mL/min per 1.73 m ²)
Diabetes and a previous diagnosis of familial hypercholesterolaemia in the individual
Diabetes and systolic blood pressure ≥ 180 mmHg or diastolic blood pressure ≥ 110 mmHg
Diabetes and serum total cholesterol > 7.5 mmol/L

Albumin to creatinine ratio - confirmed on second test and not due to another cause (*e.g.*, urinary tract infection).

Table 2 American Diabetes Association guidelines on stress testing in diabetic patients^[23]

Typical or atypical cardiac symptoms
Resting electrocardiogram suggestive of ischaemia or infarction
Peripheral or carotid occlusive arterial disease

Table 3 Signs and symptoms of concern in an otherwise asymptomatic patient

Symptoms suggestive of cardiovascular autonomic neuropathy
Resting tachycardia
Postural hypotension
Signs/symptoms suggestive of coexisting vascular disease
Erectile dysfunction
Claudication symptoms
Carotid bruit
Diminished/absent peripheral pulses
Inappropriate exercise tolerance
Shortness of breath without clear pathology

incorporated into multiple guidelines, and may be a useful initial step towards CVS risk stratification. However, given the modest performance of most prediction models, and need for more extensive validation studies, further decision-making may be useful before proceeding to provocative testing.

PROVOCATIVE TESTING: FACTORS INFLUENCING DECISION MAKING

The onset of microvascular and macrovascular complications in diabetic patients is frequently insidious, with the absence of typical symptoms often delaying diagnosis. Studies have demonstrated that a significant percentage of patients with diabetes who have no symptoms of CAD have abnormal stress tests, either by stress electrocardiogram (ECG), stress echocardiogram or stress nuclear perfusion imaging^[23]. CAD in patients is often silent, more advanced and associated with less favourable prognosis than those in the non-diabetic population^[23]. Diabetic cardiovascular autonomic neuropathy (CAN) resulting in damage to the neural fibres responsible for innervation of the heart and cardiac vessels can lead to atypical clinical manifestations, hence the concept of screening an asymptomatic patient is complex^[24]. However, the American Heart Association recommends against routine screening in diabetic patients who are asymptomatic, as there is currently no outcome data to support stress

testing in this group of patients^[25]. In contrast, the American Diabetes Association (ADA) recommends exercise stress testing in both symptomatic and asymptomatic patients with specific criteria (Table 2).

There are further specific guidelines for screening for CVD before beginning moderate to vigorous exercise training program which expand to include the length of disease; 15 years for type 1 diabetes and 10 years for type 2 diabetes, and age ≥ 35 for type 2 diabetes. Given we encourage all our patients to exercise as part of a general care plan for diabetes, it may be argued that all patients should be screened prior to this recommendation.

Furthermore, given symptoms may be atypical in the diabetic patient, there may be some clues to the presence of CVD to alert the treating clinician to investigate (Table 3). Symptoms of exercise intolerance and erectile dysfunction may suggest underlying coronary artery disease and may prompt further investigation. Peripheral arterial disease and the presence of Q waves and or ST/T wave abnormalities on ECG have also been shown to predict presence of coronary artery disease^[26].

Erectile dysfunction

Erectile dysfunction may be the manifestation of endothelial dysfunction in many cases and is recognised to represent the coexistence of vascular disease in other areas^[27]. It has been documented that men with

Table 4 Sensitivity and specificity of provocative tests in patients with diabetes

Diagnostic test	Sensitivity (%)	Specificity (%)
Exercise stress test ^[33]	47	81
Stress echo ^[35]	82	54
Stress nuclear perfusion study ^[36]	86	56
CT coronary angiogram ^[40]	76	90
Coronary calcium score ^[39]	64-75	75-83

CT: Computed tomography.

no cardiac symptoms and erectile dysfunction have increased risk of cardiac events over the following 3-5 years^[28]. Furthermore a large meta-analysis found patients with erectile dysfunction have an increased risk of CVD, cerebrovascular disease, stroke and all-cause mortality independent of traditional risk factors^[29]. The suggestion that patients with erectile dysfunction are likely to be vasculopathic validates the investigation of cardiovascular and peripheral vascular disease, even in the absence of typical symptoms. We therefore propose that patients with a history of erectile dysfunction be investigated further for underlying vascular disease.

Exercise tolerance and CAN

Autonomic dysfunction in diabetes leads to exercise intolerance. Suboptimal cardiac output in times of exertion can be a result of CAN as well as vascular disease and silent ischaemia^[30]. Signs and symptoms of CAN may include resting tachycardia due to impaired vagal tone or orthostatic hypotension^[30]. CAN significantly increases the risk of fatal or non-fatal cardiovascular event^[24]. The suspicion of CAN may therefore justify further investigation for coronary vascular disease.

Claudication symptoms

Symptoms of claudication in the diabetic patient justify consideration of investigating other vascular disease including coronary artery disease, even in the absence of symptoms. Patients with peripheral vascular disease have increased mortality from cardiovascular causes^[31]. Assessment of peripheral pulses should be performed in all patients, given this is a simple method of screening. If abnormal, further investigation with ankle brachial indices and provocative testing for cardiac ischaemia may be warranted^[31].

CHOICE OF INVESTIGATION FOR RISK STRATIFICATION IN DIABETIC PATIENTS WITH SUSPECTED CVD

The choice of investigation will depend on a number of factors including mobility, exercise tolerance, plans for future increases in exercise and potentially gender. As a baseline investigation, the American Heart Association recommends that a resting electro-

Table 5 Sensitivity and specificity of provocative testing in women^[44]

Diagnostic test	Sensitivity (%)	Specificity (%)
Exercise electrocardiogram	31-71	66-78
Exercise echocardiogram	80-88	79-86
Pharmacological echocardiogram	76-90	85-94
Nuclear perfusion study	78-88	64-91
Computed tomography coronary angiogram	97	79

cardiogram (ECG) is a reasonable tool for risk assessment in asymptomatic adults with diabetes^[32]. Beyond this, the factors influencing selection of a particular modality for provocative testing are similar between diabetic and non-diabetic patients and include availability, sensitivity and specificity and risk. Each modality has varying performance accuracy in terms of sensitivity and specificity with some specific differences in patients with diabetes (Table 4).

Exercise ECG

Exercise ECG (stress testing) is widely regarded as the first line test in mobile patients with a normal baseline electrocardiogram and it has been found to have similar predictive value between diabetic and non-diabetic populations^[33]. However sensitivity is variable, and in some studies is less than 50%^[33]. A positive test will identify the majority of patients with left main or significant multi-vessel coronary artery disease^[33]. One study found a positive predictive value of 94% in a cohort of asymptomatic older males with poorly controlled diabetes^[34].

Stress ECG is less sensitive and specific in asymptomatic populations, *i.e.*, where there is a lower pre-test probability. The test is highly dependent on the patient's capacity to exercise long enough to provide a valid test. Whilst a patient reaching above expected exercise capacity provides useful prognostic and clinical information, many diabetic patients with obesity, peripheral neuropathy, decreased physical conditioning or other co-morbidities are unable to exercise long enough to determine low cardiovascular risk. It can therefore be argued that this form of investigation is suboptimal for patients with diabetes who are unlikely to be able to reach an appropriate workload owing to co-morbidities. In women, the test may also be less useful, with quoted sensitivities of 31%-71% (Table 5).

Stress echocardiography

In the general population addition of imaging modalities such as echocardiography to stress testing provides greater diagnostic accuracy. Addition of echocardiography gives additional information about regional wall motion abnormalities (suggesting prior infarcts) and ventricular dysfunction, both of which are more common in people with diabetes. However data regarding diagnostic accuracy of stress echocardiography specifically in diabetic populations is relatively limited. Hennessy *et al.*^[35] evaluated

dobutamine stress echo in 52 patients with diabetes, finding a sensitivity of 82% but a specificity of only 54%. The positive predictive value was 84% with a poor negative predictive value of 50%^[35]. Availability may be limited by cost and operator expertise.

Nuclear perfusion scans

Stress nuclear imaging has been the most widely investigated modality for the detection of CAD in people with diabetes. The sensitivity of this tool has been quoted as 86% with a specificity of 56% in patients with diabetes^[36]. Wackers *et al.*^[37] examined asymptomatic patients with diabetes using adenosine Single Photon Emission Computed Tomography (SPECT) imaging and found positive test results for CAD in 22%. Interestingly, 41% of these patients with abnormal imaging findings would not have met usual criteria for further investigation of coronary disease according to previous ADA guidelines. Thus, use of stress imaging in selected people with diabetes who have high absolute cardiovascular risk is reasonable even if they are asymptomatic. Nuclear imaging studies can be performed with exercise, or in subjects with limited exercise capacity with other modalities to increase coronary flow such as adenosine. This modality provides information about coronary flow at rest, with exercise or stimulated stress, as well as regional wall motion, although the last is much less precise than the information obtained with echocardiography.

Computed tomography coronary angiogram and coronary calcium score

Computed tomography (CT) coronary angiogram (CTCA) may provide information on the vascular lumen and the arterial wall^[38]. In people without diabetes it has been reported to have high sensitivity^[39]. However, a study comparing the use of CTCA in diabetic vs non-diabetic patients found reduced sensitivity and specificity in people with diabetes, due to differences in artefacts and calcification^[40]. While coronary calcium score may be able to predict coronary disease beyond standard risk factors, significant stenosis can occur in the absence of calcification, so this tool should not be used in isolation^[31,41,42].

A study by Maffei *et al.*^[42] showed that coronary plaque burden and coronary calcium scores were higher in diabetic vs non diabetic patients. Furthermore it has been shown that asymptomatic patients with diabetes with high coronary artery calcium scores have a high prevalence of inducible ischaemia on stress imaging^[43]. The American Heart Association acknowledges that measurement of coronary artery calcium score is reasonable for cardiovascular risk assessment in patients with diabetes who are asymptomatic and age over 40^[32]. The efficacy of this test in women with diabetes is less clear, see below.

Gender effects

Both symptoms and pathophysiology of coronary

artery disease can differ between males and females. Women, whether diabetic or not, are more likely to have atypical symptoms and are often older at the time of onset of disease or events. Prognosis is poorer in women than men with higher mortality rates from acute myocardial infarction^[44]. Detection of disease in women is more difficult given the lower likelihood of obstructive coronary disease and apparently lower levels of clinical suspicion^[45].

As well as these issues, currently available provocative tests are both less sensitive and less specific in women^[44]. Information regarding the characteristics of coronary artery disease in diabetic women vs the general female population is surprisingly sparse. To date, guidelines suggest the use of exercise ECG testing as first line investigation in women with symptoms of coronary disease with a normal baseline ECG^[46]. If either the baseline ECG or exercise ECG is abnormal, the addition of stress testing with imaging is recommended^[46]. However, these investigations are well known to have limitations in the female population due to interference from breast soft tissue and differences in coronary anatomy in women^[45].

Stress SPECT and stress echo are considered superior to exercise ECG in women for both sensitivity and specificity. Adenosine stress nuclear imaging has similar prognostic ability in men and women, though it has been shown that women have worse clinical profiles for the same degree of imaging abnormality^[47]. However, the ultimate decision may be limited by cost and local expertise. Table 5 summaries the sensitivity and specificity of the different provocative investigations in women.

Risks associated with different testing modalities

There are risks associated with each of the tests discussed. For non-invasive stress testing such as exercise stress tests and exercise stress echo, 5% of patients may experience mild angina, shortness of breath or musculoskeletal pain. Less commonly (< 5%) chest pain, hypotension or syncope may occur and rarely (< 1%) there is a risk of acute myocardial infarction, stroke or arrhythmia^[45]. Investigations requiring contrast such as CTCA carry risks of associated renal toxicity or allergic reaction, and exposure to significant radiation with resultant cancer risk. Nuclear perfusion scans may employ the use of agents such as adenosine, which are known to induce asthma in some individuals and also involve some radiation exposure. Each of these factors must to be considered in the decision to utilise a certain modality. In women who are considering pregnancy, stress ECG or stress echocardiography are radiation-free, which is an important consideration.

SUGGESTED ALGORITHM

The decision to proceed with provocative testing should be based on a combination of cardiovascular risk

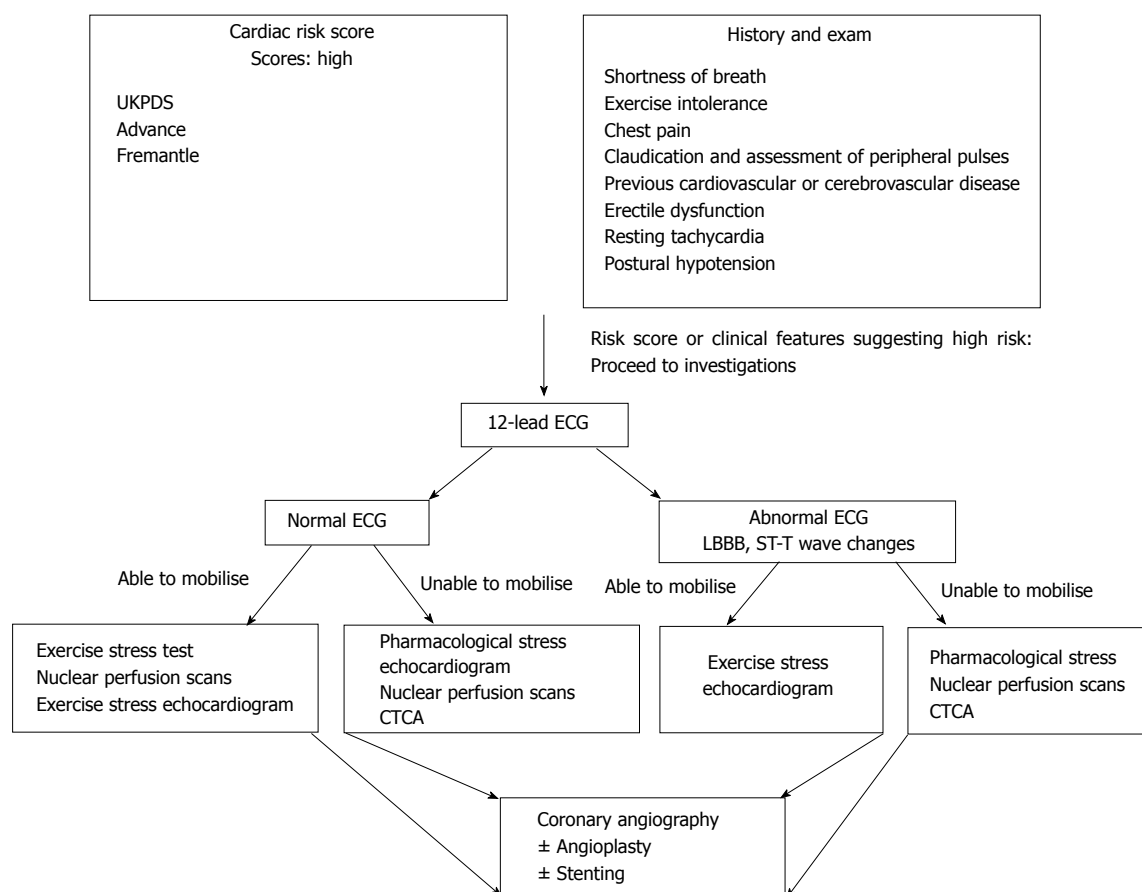

Figure 1 Suggested algorithm for investigation of cardiovascular disease in patients with diabetes. Since a 12-lead ECG is a safe and cheap test, it should be performed in people with diabetes with a low threshold. At each layer of testing, if the test is normal or unchanged from previous testing, consider whether the next level of testing is needed. ECG: Echocardiogram; LBBB: Left bundle branch block; CTCA: CT coronary angiogram; UKPDS: United Kingdom prospective diabetes study.

score and suspicious features on clinical history and or examination. As discussed above, risk calculators do not consider specific features such as erectile dysfunction or cardiac autonomic neuropathy. Therefore, risk calculators may fail to identify potential high risk features when used in isolation.

Firstly, a baseline 12-lead ECG should be performed in all patients considered at risk. Following this, the choice of modality for provocative testing will depend on factors such as abnormal resting ECG (left bundle branch block or ST-T wave changes at baseline), mobility including ability to perform exercise testing, gender, cost and access to local expertise. There is a need to highlight and alert the treating clinician to recognise novel markers of disease that have been previously under-recognised by traditional risk scores. Considering these risk factors, we propose the algorithm in Figure 1.

CONCLUSION

Patients with diabetes are at high risk of mortality from CVD. Given this group of patients often present with atypical symptoms and silent ischaemia, traditional recommendations for screening in symptomatic individuals may not be applicable. National guidelines

recommend incorporation of a cardiovascular risk score in risk stratification. Risk scores have arguably suboptimal performance when used in isolation and have not been extensively validated. Additionally, to date such clinical signs as erectile dysfunction or autonomic neuropathy have not been incorporated into cardiovascular risk prediction models, though it is well recognised that these pathologies represent underlying cardiac disease. We propose the use of a combination of a risk score and relevant clinical findings in the overall assessment of cardiovascular risk. The algorithm (Figure 1) presented may provide treating clinicians with various clues to prompt further investigation with provocative testing. There is an ongoing need for re-evaluation of guidelines for screening in this high risk patient group.

Abstract

Inflammation plays a significant role in the etiology of type 2 diabetes mellitus (T2DM). The rise in the pro-inflammatory cytokines is the essential step in glucotoxicity and lipotoxicity induced mitochondrial injury, oxidative stress and beta cell apoptosis in T2DM. Among the recognized markers are interleukin (IL)-6, IL-1, IL-10, IL-18, tissue necrosis factor- α (TNF- α), C-reactive protein, resistin, adiponectin, tissue plasminogen activator, fibrinogen and heptoglobins. Diabetes mellitus has firm genetic and very strong environmental influence; exhibiting a polygenic mode of inheritance. Many single nucleotide polymorphisms (SNPs) in various genes including those of pro and anti-inflammatory cytokines have been reported as a risk for T2DM. Not all the SNPs have been confirmed by unifying results in different studies and wide variations have been reported in various ethnic groups. The inter-ethnic variations can be explained by the fact that gene expression may be regulated by gene-gene, gene-environment and gene-nutrient interactions. This review highlights the impact of these interactions on determining the role of single nucleotide polymorphism of IL-6, TNF- α , resistin and adiponectin in pathogenesis of T2DM.

Core tip: Single nucleotide polymorphisms (SNPs) in inflammatory cytokines play role in insulin resistance and type 2 diabetes mellitus (T2DM). These SNPs are found to be correlated with cytokine serum levels, body mass index, insulin resistance and dyslipidemia although these findings are challenged by other studies. Gene-gene, gene-environment and gene-nutrient interactions alter the impact of these SNPs in pathogenesis of T2DM. These interactions may explain the inter-ethnic variations in role of inflammatory cytokines in T2DM reported in international studies. This mini-review highlights these gene-genes, gene-environment and gene-nutrient interactions and their impact on inflammatory cytokine SNPs.

INTRODUCTION

The prevalence of diabetes mellitus (DM) has increased globally over decades and is projected to continue increasing^[1]. The etiology of DM is multi-factorial and inflammation plays a role in its pathogenesis. DM is considered as chronic low grade inflammatory state and markers of sub clinical inflammation increase in type 2 diabetes mellitus (T2DM) years before diagnosis of the disease^[2]. They have a role in pathogenesis of the disease, obesity, insulin resistance and apoptosis of beta cells of endocrine pancreas by various mechanisms. Among the recognized markers are interleukin (IL)-6, IL-1, IL-18, tumor necrosis factor- α (TNF- α), C-reactive protein (CRP), tissue plasminogen activator (tPA), heptoglobulins, fibrinogen, resistin and adiponectin. The single nucleotide polymorphisms (SNPs) of pro- and anti-inflammatory cytokines have been found to influence the cytokines at translational level and modify serum levels. Inter-ethnic variations have been reported regarding association of SNPs of cytokines with T2DM and serum levels (Table 1). Pro-inflammatory cytokines induce glucotoxicity and lipotoxicity which in turns leads to mitochondrial damage, oxidative stress and beta cell apoptosis^[2].

Although the relationship between single nucleotide polymorphisms of cytokines/adipokines and risk of T2DM has been robustly proven, inter-ethnic and intra-ethnic variations in this relationship cannot be explained in generalized terms. A number of factors including demographic features, sample size, gene-gene, gene-environment and gene-nutrients interaction, average age of onset, duration of disease, life style, degree of obesity, glucose tolerance and pathogenesis of disease can confound association studies.

GENE-GENE INTERACTION

Variable results regarding association of cytokines SNPs with T2DM in different ethnic groups have been reported in international studies^[1-7]. Even different studies in the same ethnic group have also reported varying results^[8,9]. This variation is also found in association of cytokines SNPs with serum levels of respective cytokines, insulin resistance, serum insulin, lipid profile and body mass index (BMI). Gene-gene interaction is an established fact and a few studies have reported this factor as a contributing one in inter-ethnic variations in various parameters. There might be another unidentified functional gene polymorphism in close linkage disequilibrium with cytokine SNPs.

It has been found that presence or absence of a minor allele of inflammatory cytokine genotype may influence the binding of transcription factors to promoter region altering the promoter activity from almost non-existent to augmented by many folds^[4]. Similarly gene-gene interactions may also influence either the binding of transcription factors or translational activity. Polymorphism of a stress protein gene; P2/P2 genotype of heat shock protein 70-2 is found to be close to and in linkage disequilibrium with TNF- α promoter area and is statistically associated with obesity in Tunisian subjects and may influence the impact of TNF- α polymorphism^[3].

IL-6 -174 G/C SNP is in the promoter region (-173 to -145) that contains multiple response elements. These functional sites respond to many factors including IL-1, TNF- α , NF- κ B and glucocorticoids^[6]. Presence or absence of a minor allele may influence the binding of transcription factors to DNA response elements. Moreover, *IL-6* gene promoter function is also effected by a variable run of A and T bases (-257 to -276)^[4]. *IL-6* promoter variants; G and C are also affected by the *IL-6* haplotype, age and sex of the individual and presence of sex steroids^[5]. Estrogen regulates protein synthesis at transcriptional levels, particularly those proteins which are involved in glucose and lipid metabolism.

In overweight IGT Finnish subjects, simultaneous polymorphism *C-174G* in *IL-6* and the *G-308A* polymorphism in TNF- α showed a 2.2 fold increased risk of T2DM than any other SNP^[6] neither of SNP, although risk was not higher in simultaneous SNPs as compared to the *G-308A* SNP alone showing a gene-gene interaction^[6].

Individually, *IL-6-597 G/A*, *TNF- α -308G/A* and *IL-10 -592C/A* do not show any association between SNP and risk of T2DM in Indian population but combined genotypes of *IL-6 -597 GA* and *TNF- α -308 GG* increased the risk of T2DM up to 21 times, while triple combination of *IL-6 -597 AA*, *TNF- α -308 GG* and *IL-10 -592 CA* increased the risk to 314 times. Presence of minor allele A in all 3 genes increased the risk up to 1.41 times in Indian population, showing strong gene-gene interaction^[7].

Table 1 Frequencies of single nucleotide polymorphisms of cytokines in various ethnic groups

S no	Ethnic group	n	IL6 -174G/C genotype frequency			Ref.

17	Diabetics White	503	79	21		Chiodini <i>et al</i> ^[42]
18	Diabetic Han Chinese	212	68.6	31.4		Yang <i>et al</i> ^[43]
19	Diabetic Germans	365	71	29		Schwarz <i>et al</i> ^[44]

Impact of SNPs in the resistin promoter region is also found to be influenced by gene-gene interaction. Presence of Pro/Pro genotype of PPAR gamma acts synergistically with *RETN* -420 G allele in augmenting serum resistin levels in Japanese population^[8]. SNPs in regions outside the coding region may influence transcription or mRNA stability and thus affect the expression of the gene. Nuclear proteins are specifically recognized with a single base difference at SNP-358 in *RETN* gene but not at SNP *RETN* -638. Therefore, A at *RETN* -358 is required for G at *RETN* -420 to confer the highest plasma resistin in the general Japanese population^[9]. In Caucasians, the association between SNP *RETN* C -420G and plasma resistin is not strong, and A at *RETN* -358 may not exist, suggesting that SNP *RETN* -358 could explain this ethnic difference^[9].

Similarly, in Filipino population, common SNPs in *ADIPOQ* gene were found to be in linkage disequilibrium with a rare coding variant in *R221S* at *ADIPOQ* locus. This variant was unique to Filipino population and was not found in 12514 European individuals^[10].

PPAR-γ agonists are identified transcription factor for *ADIPOQ* expression. In differentiated 3T3L1 mice adipocytes cell line, the haplotype AC or AG both at -11426 and -11377 position results in 2-3 fold increase in rosiglitazone induced promoter activity whereas

GG haplotype result in almost non-existent promoter activity. The result indicates that inducibility of *ADIPOQ* promoter activity by rosiglitazone (PPAR-γ agonist) depend on SNP variant combination rather than a particular allele^[11].

Genome-wide association studies (GWAS) on large sample size and various ethnic groups are required to reach a definitive conclusion about gene-gene interaction.

GENE-ENVIRONMENT INTERACTION

T2DM is a disease in which environmental factors play a very significant role. Physical activity, BMI, physical and mental stress, dietary habits, smoking and life-style not only influence the pathogenesis of the disease but also the age of onset of disease, response to treatment, and onset of complications of the disease. These environmental factors are not functioning alone and there is strong gene-environmental interaction.

Adipose tissue is the source of 30% of IL-6. Some studies suggested the role of adiposity in modulating the association between IL-6 genetic variability and T2DM risk^[12,13]. Association of IL-6 SNP with S. IL-6 levels has also been found highly variable in different ethnic groups. IL-6 C-174G SNP is suggested to

enhance IL-6 expression, IL-6 mRNA levels and thus serum levels but these effects are cell-type specific^[12]. Various IL-6 producing cell types may respond differently to various risk factors like inflammation, obesity, insulin resistance or yet unidentified parameters and thus altering the impact of SNP. This hypothesis is supported by the finding that TNF- α -308A allele was associated with significant elevation of TNF- α expression but when catering for genotypes, A allele association with insulin resistance in presence of obesity but not in absence of it, has been reported in diabetic Canadians^[14]. Interestingly not many studies were found in literature indicating positive association of A allele presence with higher insulin resistance even in absence of obesity. In one study, insulin resistance was found greater in both obese and lean Romans^[15] in either allele carriers. It may indicate the possibility that insulin resistance may be secondary to raised BMI, in all obese irrespective of genotype; a fact supported by studies on obese Australian^[16], obese Americans^[17], overweight IGT Finnish subjects^[6] and obese female Polish Caucasians^[18], where insulin resistance was present in obese subjects carrying either allele. TNF- α polymorphism may act as a genetic factor enhancing the insulin resistance in presence of obesity, irrespective of serum TNF- α levels as found in many studies. Why in some studies, this association between polymorphism and insulin resistance is not found even in presence of obesity is not known.

Smoking is a known factor inducing oxidative stress and increased levels of inflammatory cytokines are found in smokers. Genotype-smoking interaction has been found statistically significant in Korean healthy subjects. IL-6 -174C allele was associated with significant elevation of IL-6 expression after coronary artery bypass surgery, although IL-6 levels were same in either C or G allele carriers before surgery. It indicates that probably stress led to an altered impact of the IL-6 G-174C SNP on IL-6 expression^[19]. Similarly, C allele was found to be associated with reduced levels of IL-6 after long term exercise although no difference was reported between genotypes before exercise training program^[4,20]. Although, the low level of physical activity may increase the risk of T2DM in the absence of the risk allele, presence of the risk allele may not always assure the protection from the disease with exercise.

Association of TNF- α -308 G/A polymorphism with T2DM is explained by increased insulin resistance caused by raised serum levels of TNF- α . Despite quite a large number of studies on association of T2DM with this SNP, insulin resistance and BMI; very few studies correlated the TNF- α SNPs with serum levels of TNF, insulin resistance, BMI. Association of A allele with higher serum levels of TNF has been reported various ethnic groups such as in overweight Finnish subjects^[6], Danish Caucasians^[21] and in Chinese^[22]. Negative association has been reported in healthy controls, impaired glucose tolerant and diabetic Czech

Caucasians^[23] and in healthy Chinese^[24].

Homozygous IL6 -572GG genotype results in higher serum IL-6 in smokers as compared to GC and CC genotype (P value = 0.04)^[25]. Evidences indicate that environmental factors not only alone through metabolic derangement but also through gene-environmental interaction influence the impact of cytokine SNPs on pathogenesis of T2DM.

GENE-NUTRIENT INTERACTION

Single nucleotide polymorphisms in cytokines also interact with dietary factors influencing the cytokine expression induced by diet. IL-6 -174G allele has been found to be associated with higher energy expenditure as compared to C allele which could be one of the possible causes of lower BMI in G allele carriers in this cohort^[26]. A recent study indicate the higher BMI in IL-6 -174 CC genotype in Koreans but greater reduction in weight in CC genotype as compared to GG genotype by low fat diet/virgin olive oil diet for 3 years. The effect of gene variant on obesity indices was reversed by low fat diet^[27].

TNF- α -238 A allele alter the post-prandial suppression of FFA and levels remain high in obese, but not in non-obese A carriers. High TNF-expression in obese due to presence of A allele but also due to larger adipocytes may explain the absence of this effect in non-obese despite having A allele in Canadians^[14].

A recent study highlighted the strong gene-nutrient interaction affecting the serum levels of adiponectin. Marine fish oil contains unsaturated fatty acids which are ligands for transcription factor; PPAR γ which enhances the adiponectin expression thus increasing its serum level. The presence of SNPs in ADIPOQ fosters the effect of dietary marine fish oil on adiponectin expression^[28].

Another example of gene-nutrient interaction is dependence of insulin sensitivity on plasma saturated fatty acid (SFA) levels in the presence of homozygous minor alleles ADIPOQ -11377 GG. Insulin resistance was higher in GG carriers with high SFA levels. In the presence of homozygous major alleles; ADIPOQ -11377 CC and heterozygous CG genotypes, the insulin sensitivity was not altered by plasma concentrations of SFA^[29]. ADIPOQ -11377 SNP also influences the extent to which energy is derived from dietary fat in obese women^[30]. ADIPOQ CC homozygotes men have less insulin resistance after consumption of a monounsaturated fatty acid and carbohydrate diet as compared to saturated fatty acid diet; an effect not seen in females^[31]. On the other hand, serum adiponectin was reduced after α -linolenic acid supplementation in obese individuals irrespective of C or G allele at -11377 ADIPOQ^[29].

Heterogeneity in serum levels of cytokines in response to lipid lowering drugs in various patients may be due, in part to genotypes of inflammatory cytokines. IL-6 -572 GG is associated with higher S.

IL-6 levels as compared to GC and CC genotypes in those who are not taking lipid-lowering drugs while levels are comparable in GG, GC and CC genotypes who were taking those drugs. It is possible that statins might reduce the augmented effect of GG genotype on inflammation^[32].

CONCLUSION

Pathogenesis of T2DM is multi-factorial. Genetic background has a profound effect especially in T2DM. The genetic makeup itself is governed by many factors; some of which are still unidentified. Contribution of T2DM susceptibility genes in insulin resistance and beta cell failure and their interaction with cytokine genes, environment and nutrients need to be explored. There could be additional, still unidentified risk factors which obscure the impact of SNP with specific genetic/environmental/nutrient background in various ethnic groups in population. Single nucleotide polymorphism may be considered as a susceptibility factor in certain population segments based on other risk factors; both genetic and environmental. GWAS with large number of sample sizes may indeed be required to statistically manifest SNP-related risk factors. Most of the studies are done in relatively small population groups in a particular ethnic group. Sampling might include patient selection inherent biases and do not reflect the general risk of population for the disease.

Gene-gene, gene-environment and gene-nutrient interactions strongly influence the impact of cytokine polymorphisms on not only serum levels of cytokines but also on the insulin sensitivity, susceptibility to disease, response to weight reduction and lipid lowering drugs, energy expenditure and energy derivation from dietary fats. Such multi-dimensional regulatory factors can explain the wide variations in the role of single nucleotide polymorphisms in cytokines in pathogenesis of T2DM and MS reported in various ethnic groups.

Abstract

Women with a history of gestational diabetes should be screened during and after the postpartum period because of a high risk for developing type 2 diabetes mellitus. Although differences exist between guidelines practiced throughout various parts of the world, all recommend the use of cutoffs for fasting and/or post-load plasma glucose to diagnose diabetes or pre-diabetes. The use of these glycemic parameters could be optimized when a trend is observed, rather than considering them as isolated values at various time points. As the presence of insulin resistance and beta-cell dysfunction start before glycemic changes are

evident, the estimation of insulin sensitivity and beta-cell function by Homeostatic Model Assessment is suggested for women who have additional risk factors for diabetes, such as obesity. Disease-modifying lifestyle intervention should be the first-line strategy to prevent or delay the onset of diabetes in women with a history of gestational diabetes mellitus. Intensive lifestyle interventions are designed to decrease caloric intake and increase physical activity in order to reduce body weight and fat, which will in turn reduce insulin resistance. This article also reviews unique problems of postpartum women, which should be considered when designing and implementing an intervention. Innovative "out of the box" thinking is appreciated, as continued adherence to a program is a challenge to both the women and the health care personnel who deal with them.

Key words: Gestational diabetes mellitus; Glycemic parameters; Lifestyle intervention; Screening; Type 2 diabetes mellitus

Core tip: This article reviews and highlights important areas concerning diabetic risk during and after the postpartum period in women with gestational diabetes mellitus. Optimizing the use of glycemic parameters and assessing beta-cell function, particularly in high-risk women, will facilitate early recognition of those on the path to pre-diabetes and diabetes. Lifestyle interventions designed to attenuate the progression should be carefully planned, taking into consideration the unique set of problems in these women. "Out of the box" thinking is necessary to design lifestyle intervention protocols that will have high acceptance by these women.

DIABETIC RISK FOR WOMEN WITH GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM), which occurs and is diagnosed during pregnancy^[1], is a condition that increases the risk of developing type 2 diabetes mellitus (T2DM)^[2,3]. In a large meta-analysis of 20 cohort studies in 2009, Bellamy *et al*^[4] showed that women with GDM have a more than seven-fold increased risk of developing T2DM when compared to women with normoglycemic pregnancies. However, the incidence of diabetes in these women varies, with relative risks ranging from 6^[5] to 12^[6], possibly due to differences in screening and diagnostic criteria, associated risk factors^[7], and inclusion of subjects with overt diabetes uncovered by pregnancy^[8]. Feig *et al*^[6] further demonstrated an increase in the probability of developing diabetes from 3.7% at 9 mo to 18.9% at 9 years after delivery, suggesting the need for long-term follow-up and monitoring of women with a history of GDM.

The development of peripheral insulin resistance during pregnancy is facilitated by the increased maternal adiposity and release of insulin-desensitizing hormones from the placenta^[9]. The secretion of insulin is increased to compensate, and women with a deficit in this secretion can develop GDM. The effects of pregnancy on glucose homeostasis are alleviated following delivery of the offspring and removal of the placenta, such that the glycemic profile should return to normal within 6-12 wk postpartum.

POSTPARTUM SCREENING OF PATIENTS WITH A HISTORY OF GDM

Despite the lack of a consensus concerning precise recommendations for postpartum screening of women with a history of GDM^[10], the importance of optimal screening is universally accepted. The American Diabetes Association recommends using the oral glucose tolerance test (OGTT) to screen these women for persistent diabetes at 6-12 wk postpartum, and lifelong screening for development of diabetes or pre-diabetes at least every three years^[1]. However, the Mexico City Diabetes Study demonstrated that the progression from normoglycemia to diabetes ranges over three years with a probable phase of impaired glucose tolerance^[11], which suggests that three years between screens is insufficient for high-risk individuals. In the United Kingdom, the National Institute for Health and Clinical Excellence guidelines recommend glucose estimation prior to discharge, at 6 wk postpartum, and annually thereafter using fasting plasma glucose (FPG)^[12]. In

2010, however, Kakad *et al*^[13] used retrospective data of 470 women to show that diabetes was missed in 26% of women when only the FPG was used for screening. Furthermore, unlike OGTT, FPG does not allow for detection of impaired glucose tolerance. Hemoglobin A1c, an additional parameter introduced to the diagnostic criteria of pre-diabetes and diabetes in 2009^[14], is also considered unsuitable for use in postpartum women due to its low sensitivity on its own^[15] or in combination with FPG^[16]. Thus, OGTT with 75 g fasting glucose challenge and two-hour glucose measurements is the preferred screening method for women with previous GDM^[17]. The interpretations should be based on diagnostic cutoffs for pre-diabetes and diabetes for non-pregnant adults^[1].

Tabák *et al*^[18] used serial measurements of yearly glucose levels over 13 years to evaluate glycemic parameters in normoglycemics and diabetics. They found that during the transformation from normoglycemia to diabetes, FPG and post-load glucose gradually increased, followed by an abrupt increase approximately two years before a diagnosis of DM. This indicates that continual glycemic measurements during screening can be even more informative and predictive, despite being within the normal range. Therefore, it is suggested that rather than looking solely at isolated values at any given time, changes in glycemic measures should be observed.

With the global increase in the prevalence of DM^[19], the current recommendations for screening women with GDM for the development of T2DM should be revised. The present guidelines detect problems only when they reach the end point (diabetes), or a landmark very close to the end point (pre-diabetes). Can we use knowledge of the underlying pathophysiology to identify these cases earlier, before they reach the end point? The transition from normoglycemia to diabetes is a continuous process^[11,18,20]. Although the glycemic profile assessed by FPG or post-load glucose should return to normal after delivery in a woman with a diagnosis of GDM, these parameters are not indicators of the ongoing pathophysiologic process. An analysis of the British Whitehall II study showed a steep decline in insulin sensitivity, along with a marked increase followed by a steep decrease in insulin secretion, approximately 3-5 years before the onset of diabetes^[18]. These parameters can be estimated by the Homeostatic Model Assessment^[21]. However, this assessment by itself is inappropriate for evaluation of beta-cell function, and serial measurements are required in order to observe the longitudinal changes in insulin secretion^[22]. Repetitive monitoring of insulin sensitivity and secretion may be confined to the initial postpartum years due to increased cost, as Kim *et al*^[3] showed that T2DM appears rapidly within the first five years and plateaus after ten years. Furthermore, these measurements can be limited to women with a higher predictive risk of developing diabetes, such

as those who are overweight^[23], have a higher pre-pregnancy body mass index^[24,25], were diagnosed with GDM before the 24th week of gestation^[25], and who needed insulin for glycemic control during pregnancy^[23]. Finally, the recent call for developing standardized screening protocols for Indian women with GDM^[26] is worth considering for all Asian women, as they show a greater risk than Caucasian women^[23].

Nonetheless, the risk of developing T2DM can persist for more than 25 years in women with a history of GDM^[8,18,27]. Therefore, continued life-long follow-up of these women is justified, particularly with recognition of the fact that ageing is an independent risk factor for T2DM. In addition, women who are not diagnosed with GDM but have mild glucose abnormalities^[28] or a single abnormal value in the OGTT^[29] should be screened because of the increased risk for developing T2DM. However, as revised recommendations stipulate that only one abnormal value, not two, is sufficient to for a diagnosis of GDM^[1], more women may be recommended for T2DM screening.

LIFESTYLE INTERVENTIONS

Lifestyle interventions are the most appropriate initial approach to mitigate the development of diabetes in high risk individuals, such as those with a history of GDM^[30], and can reduce the incidence of DM by at least 50%^[27,31]. Such interventions may slow down or arrest the pathophysiologic processes, such as the beta-cell exhaustion that occurs in response to chronic insulin resistance^[32,33].

Lifestyle intervention programs designed for high-risk individuals generally propose a low-calorie, low-fat diet with moderate intensity physical activity (e.g., brisk walking) for 150-180 min per week to achieve a weight reduction of 5%-7% of the initial body weight^[31,34-36]. The recommended calorie limit varies between 1000-1200 kcal/d^[35] and 1200-1800 kcal/d^[34]. Although it is advised that no more than 30% of energy should come from fats^[36], a recent study found adequate glycemic control with a very low-carbohydrate, high-fat, non-calorie-restricted diet^[37]. Other simple measures include increasing the amount of fiber in the diet^[36], decreasing the amount of energy-dense foods, such as fast foods, increasing the amount of fruit and vegetable intake^[38], and controlling portion size^[35]. Although it is important to combine physical activity with dietary support to enhance the efficacy of an intervention program^[39], results of a small study showed that women perceived diet as more important for the prevention of T2DM than physical activity^[40], emphasizing the importance of effective counseling to reinforce the value of both aspects for weight reduction and maintenance^[35].

Although almost all published protocols are based on similar principles of intervention, a thorough investigation of these illustrates minor but important differences between them, especially when it comes

to the stage of implementation. To augment dietary and exercise interventions, Gabbe *et al*^[35] suggested incorporation of behavioral therapy, which includes stress management, stimulus control, problem solving, and goal setting. The Mothers After Gestational Diabetes in Australia Diabetes Prevention Program offers an intervention program handbook, six face-to-face sessions, and two follow-up telephone calls within the 12-mo follow-up period to ensure that participants achieve the program goals^[36]. Substantial decreases in glycemic and anthropometric parameters after one year of intervention^[41] is strong evidence for implementation of an effective lifestyle intervention program by community health workers^[34]. A randomized control study for high-risk Hispanic women initiated interventions during late pregnancy, and continued for 12 mo postpartum^[38]. Further support for prenatal implementation was provided by greater weight loss and improved health behaviors in the postpartum period in mothers who underwent a low glycemic index dietary intervention during pregnancy^[42]. It is the responsibility of the researchers and health care personnel planning the interventions to utilize such reported evidence when designing implementation strategies for a particular population.

Although almost all programs aimed at preventing T2DM promote increased physical activity, healthy eating, and weight loss, "out of the box" thinking is necessary in order to increase participant acceptance of, and thus adherence to, a given intervention. A high level of acceptance was reported in a novel intervention in England that used group leisure activities for adults at risk for DM^[43], though the recruitment procedure may have contributed to these results. Another interesting study protocol published in 2013 used motivational interviews to influence lifestyle changes in individuals with impaired fasting glucose^[44], a method based on the transtheoretical model of health behavior change^[45].

Although pharmacologic interventions are also beneficial in attenuating the onset of T2DM in women with a history of GDM^[27,46], a discussion of these is beyond the scope of this review.

Barriers to effective screening and lifestyle interventions and strategies to overcome them

Despite the importance of clear understandings of the nature of the disease, the risk for developing DM, and measures to prevent or delay its onset, the knowledge itself may not be enough. A recent qualitative study exploring factors that influence postnatal health behaviors in women with GDM showed that, although nearly all participants were aware of the increased risk for diabetes, this knowledge did not motivate them for action^[47]. However, a low level of awareness remains, even among college-educated affluent women^[48], which justifies the need for intensive awareness programs to counsel these women.

The health care team has an enormous respon-

sibility to educate these patients about the diabetes risk and the importance of regular screening, to motivate them to adapt to healthy lifestyles, and to support them to adhere to these changes. Although an OGTT is mandatory for women with prior GDM, a population-based cohort study in Canada found that women who chose an obstetrician for follow-up as opposed to a family physician were more likely to undergo a postpartum OGTT^[49], which highlights the importance of educating all levels of health personnel on current recommendations. However, there are conflicting results concerning the efficiency of obstetricians for enforcing postpartum T2DM screening of GDM women^[50,51]. It is the responsibility of the health care personnel to maintain records of these women and routinely remind them^[52], preferably through some form of written information^[53], as postal reminders^[54] or laboratory slips^[48] greatly increase the screening rates. Text message-reminder systems for screening^[55] and internet-based programs for lifestyle intervention^[56] are novel approaches worth trying in this era of technological dependence.

Postpartum women are a special group with a unique set of problems. The most common barriers to lifestyle interventions reported by these women were insufficient time^[40,57,58], lack of support for child care^[40,47,57], and other family commitments^[40,47]. As the amount of available social support is associated with adherence to lifestyle interventions^[57], educational and counseling sessions should be extended to the spouse and the immediate family of these women.

CONCLUSION

This review highlights important aspects concerning the screening of women with GDM, during the prenatal and postpartum periods, and thereafter. Women with GDM are a unique group for whom diabetes prevention strategies can be applied. In addition to being familiar with the general recommendations for screening and managing these patients, health care personnel should be able to appropriately support their patients to ensure greater acceptance of these valuable screening tests and interventional programs. The real challenge is not the planning of a lifestyle intervention, but implementing it effectively within the target population.

MetS patients have about five-fold greater risk of the T2DM development compared with people without the syndrome. Peroxisome proliferator-activated receptors are a subgroup of the nuclear hormone receptor superfamily of ligand-activated transcription factors which play an important role in the pathogenesis of MetS and T2DM. All three members of the peroxisome proliferator-activated receptor (PPAR) nuclear receptor subfamily, PPAR α , PPAR β/δ and PPAR γ are critical in regulating insulin sensitivity, adipogenesis, lipid metabolism, and blood pressure. Recently, more and more studies indicated that the gene polymorphism of PPARs, such as Leu¹⁶²Val and Val²²⁷Ala of PPAR α , +294T > C of PPAR β/δ , Pro¹²Ala and C1431T of PPAR γ , are significantly associated with the onset and progressing of MetS and T2DM in different population worldwide. Furthermore, a large body of evidence demonstrated that the glucose metabolism and lipid metabolism were influenced by gene-gene interaction among PPARs genes. However, given the complexity pathogenesis of metabolic disease, it is unlikely that genetic variation of a single locus would provide an adequate explanation of inter-individual differences which results in diverse clinical syndromes. Thus, gene-gene interactions and gene-environment interactions associated with T2DM and MetS need future comprehensive studies.

Key words: Polymorphisms; Metabolic syndrome; Type 2 diabetes mellitus; Peroxisome proliferator-activated receptors

Core tip: Recently, more and more studies indicated that the gene polymorphism influence of peroxisome proliferator-activated receptors (PPARs), including PPAR α , PPAR β/δ and PPAR γ , acted as a pivotal role in the onset and progressing of metabolic syndrome (MetS) and type 2 diabetes mellitus (T2DM). We reviewed the recent advances in the relationships between PPARs polymorphisms and MetS and T2DM. Also, we discussed

Abstract

Metabolic syndrome (MetS) and type 2 diabetes mellitus (T2DM) are the serious public health problems worldwide. Moreover, it is estimated that

the effects of gene-gene interaction among *PPARs* genes on the MetS and T2DM herein.

Dong C, Zhou H, Shen C, Yu LG, Ding Y, Zhang YH, Guo ZR. Role of peroxisome proliferator-activated receptors gene polymorphisms in type 2 diabetes and metabolic syndrome. *World J Diabetes* 2015; 6(4): 654-661 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i4/654.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i4.654>

INTRODUCTION

Globally, about 25% and 5.4% of adult population have been estimated to have metabolic syndrome (MetS) and type 2 diabetes mellitus (T2DM), respectively^[1]. MetS is defined as a constellation of metabolic disorders including insulin resistance, central obesity, dyslipidemia and hypertension. The underlying cause of the MetS has been linked to the disorders of glucose metabolism including insulin resistance and glucose intolerance^[2,3]. One study in Nigeria reported that the prevalence of the MetS in T2DM patients is up to 86%^[4]. The study in Cameroon indicated that 71.7% T2DM patients diagnosed with the MetS^[5]. Thus, it is estimated that MetS patients have about five-fold greater risk of the T2DM development compared with people without the syndrome^[6].

Peroxisome proliferator-activated receptors (PPARs) are ligand-activated transcription factors that are part of the superfamily includes receptors for steroid hormones, thyroid hormones, retinoic acid and fat-soluble vitamin A and D. The primary role of PPARs is to regulate glucose, fatty acid and lipoprotein metabolism, energy balance, cell proliferation and differentiation, inflammation and atherosclerosis^[7]. PPAR α , the first member of the PPAR family identified in 1990, is mainly expressed in tissues in which fatty acid catabolism is important^[8,9]. Since that time, two additional members of the family, PPAR β/δ and PPAR γ , have been identified^[10,11]. Recently, more and more studies on the associations of PPARs polymorphisms and disorders of glucose metabolism and abnormal lipid metabolism have been published, indicating that the gene polymorphism influence of PPARs acted as a pivotal role in the development of MetS and T2DM^[12-15]. This review is aimed to summarize the recent advances in the relationships between PPARs polymorphisms and the metabolic disorders that related with MetS and T2DM. Moreover, the effects of gene-gene interaction among *PPARs* genes on the MetS and T2DM also will be discussed.

PPAR α

PPAR α gene is located on chromosome 22q12.2-13.1, and it is the first member of the *PPAR* isotypes to be cloned and was named based on its ability to be

activated by peroxisome proliferator chemicals. PPAR α is robustly expressed in tissues with elevated fatty acid catabolism and regulates transcription of multiple genes involved in glucose metabolism, such as the liver, heart and skeletal muscle, where it functions as a major regulator of fatty acid homeostasis^[8,9]. Along with regulation of lipid and glucose metabolism, PPAR α is as an attractive candidate gene for the risk of MetS and T2DM^[7].

Role of *PPAR α* gene polymorphisms in T2DM

Until now, more than 20 different base substitutions have been identified in the *PPAR α* gene. Among of them, Leu¹⁶²Val (rs1800206) has been shown to be significantly related with the risk of T2DM in different population^[16-20]. Flavell *et al.*^[17] reported that the variant of Leu¹⁶²Val variant was associated with increased plasma levels of total-cholesterol, HDL-cholesterol, and apoA-I, indicating that PPAR α gene variation influences the onset and progression of T2DM. Furthermore, the PPAR α haplotype significantly influenced age at diagnosis, with the C-L-C and C-V-C haplotypes [rs135539 (intron 1)-Leu¹⁶²Val (rs1800206)-rs4253778 (intron 7)] accelerating onset of diabetes by 5.9 and 10 years, respectively, as compared with the common A-L-G haplotype, and was associated with an odds ratio for early-onset diabetes (age at diagnosis \leq 45 years) of 3.75. Intron 1 C-allele (rs135539) carriers also progressed more rapidly to insulin monotherapy (AA 9.4 ± 1.5 and AC + CC 5.3 ± 1.1 years). In another study, Andrulionyte *et al.*^[19] reported that the presence of the G (162V) allele of rs1800206 in *PPAR α* gene increased the risk of developing diabetes. Moreover, haplotypes C-G-C and A-G-C, based on SNPs rs135539, rs1800206, and rs4253778, increased the risk of developing diabetes by 4.58-fold and 3.18-fold, respectively, compared with the C-C-C haplotype. Additionally, it should be noted that the Leu¹⁶²Val polymorphism has different effects on gene transcription. Evans *et al.*^[20] demonstrated that the Leu¹⁶²Val polymorphism was associated with a lower body mass index (BMI) in two independently recruited groups of patients with T2DM, suggesting that Leu¹⁶²Val polymorphism in PPAR α protects T2DM patients from the overweight which is frequently associated with their condition.

Role of *PPAR α* gene polymorphisms in MetS

Leu¹⁶²Val polymorphism not only plays a pivotal role in the T2DM development, but also significantly associated with the risk of MetS. In young Caucasians males, Uthurralt *et al.*^[21] found Leu¹⁶²Val polymorphism of PPAR α to be a strong determinant of serum triglyceride levels, where carriers of the V allele showed 78% increase in triglycerides relative to L homozygotes. Moreover, men with the V allele showed lower HDL, but women did not. Recently, Smalinskiene *et al.*^[22] reported that males with the G (162V) allele of rs1800206 in *PPAR α* gene had higher OR of elevated

triglyceride levels vs carriers of *PPARα* genotype CC, indicating that *PPARα* Leu¹⁶²Val polymorphism gene influences the onset and development of MetS.

Val²²⁷Ala, a non-synonymous variant at the *PPARα* locus encoding a substitution of valine for alanine at amino acid residue 227, is another important *PPARα* polymorphism reported that associated with MetS development^[23-28]. In Japanese population, significant interactions between *PPARα* Val²²⁷Ala polymorphism and triglyceride levels and AST/ALT ratios were found in drinkers^[23,24]. Chan *et al*^[26] reported that the level of weight, BMI, hip circumference, waist circumference, waist-hip ratio, percentage of body fat, abdominal wall fat thickness in Chinese subjects with Val²²⁷Ala variant were significantly lower than that in Val²²⁷Val type. Additionally, in Chinese females, the presence of the A227 allele was significantly associated with lower serum concentrations of total cholesterol and triglycerides^[26,27]. Moreover, Chan's results also showed that the Val²²⁷Ala polymorphism modulates the association between dietary polyunsaturated fatty acid intake and serum high density lipoprotein concentration^[26].

In addition, the other variants of *PPARα* gene associated with MetS were also demonstrated in previous studies^[29-33]. A Rotterdam study observed that the minor alleles of the *PPARα* rs4253728 and rs4823613 polymorphisms are associated with a better total and LDL-cholesterol-lowering response to simvastatin, possibly through influence on CYP3A4^[33]. Therefore, better understanding the associations between *PPARα* polymorphisms and lipo-protein metabolism would be helpful for the prevention and treatment of MetS.

PPARα

PPARδ, also known as *PPARβ*, has 441 amino acid residues. Its coding gene is located in 6p 21.1-21.2, which includes 11 exons. *PPARδ* is widely expressed in the liver, kidneys, cardiac and skeletal muscle, adipose tissue, brain, colon and vasculature^[34,35]. Animal studies found that *PPARδ* knockout mice showed glucose intolerance on normal chow, and were prone to obesity on high-fat diet^[36,37]. *PPARδ* activation in the liver also appears to decrease hepatic glucose output, thereby contributing to improved glucose tolerance and insulin sensitivity^[36,37]. Meanwhile, treatment with *PPARδ*-specific agonist enhanced β-oxidation, decreased free fatty acid, and improved insulin sensitivity in mice and moderately obese men^[38,39]. Hence, *PPARδ* has emerged as a key role for the development of MetS and T2DM in recent years.

Role of *PPARδ* gene polymorphisms in T2DM

PPARδ is an important candidate gene for T2DM. About ten years ago, Vanttinen *et al*^[40] reported that a statistically significant increase in insulin-stimulated whole-body and skeletal muscle glucose uptake

in carriers of the alleles of three variants in *PPARδ* (rs6902123, rs2076167 and rs1053049), and the association was strongest for the rs6902123 variant. After that, the results from "The STOP-NIDDM Trial" demonstrated an increased risk of conversion to overt T2DM in carriers of the rs6902123 variant^[41]. Similar to these findings, Lu *et al*^[42] observed that rs6902123 was significantly associated with risk of T2DM and impaired fasting glucose in Chinese Han population. The minor C allele of rs6902123 was associated with increased levels of fasting glucose and HbA1c. In addition, a previous study revealed that the haplotype, composed of -13454G>T, -87T>C, 2022+12G>A, 2629T>C, and 2806C>G, is closely related to fasting plasma glucose and BMI of normal people in Korea^[43]. Also, Hu *et al*^[44] and Yu *et al*^[45] reported that gene polymorphism of *PPARδ*, -87T>C, is significantly associated with higher fasting plasma glucose concentrations in both normal glucose tolerant and diabetic subjects.

However, with 886 middle age Chinese female T2DM patients, Villegas *et al*^[46] did not find a main gene effect of *PPARδ* on T2DM or an interaction between the genes with BMI or exercise participation and the risk of T2DM. The similar result was also observed in another study of 7495 middle age white people that sequenced the *PPARδ* gene and found no association between variants and T2DM^[47]. The reason for this disparity is not clear. It should be considered that both genetic and environmental heterogeneity, including differences in their interaction, could give rise to population-specific discrepancies in the association of allelic variants and insulin resistance and thereby account for the inconsistent findings.

Role of *PPARδ* gene polymorphisms in MetS

Based on the analysis of a *PPARδ* null mouse model, it was demonstrated that *PPARδ* gene-deficient mice who bypassed the lethal placental defect displayed a lean phenotype, with a significantly smaller amount of fat mass. In addition, the muscle-specific *PPARδ* transgenic mice displayed increased mitochondrial-rich, oxidative type-1 myofibers with enhanced oxidative enzymatic activities^[36,37,48,49]. Skogsberg *et al*^[50] screened the 5'-untranslated region of the human *PPARδ* gene and found that a +294T > C (also named -87T > C, rs2016520) polymorphism in nucleotide 15 of exon 4 (located 87 nucleotides upstream of the start codon), was significantly associated with plasma levels of LDL and cholesterol in two cohorts of healthy men. In a Canada study, Robitaille *et al*^[51] reported that *PPARδ* +294T > C polymorphism may be associated with a lower risk to exhibit the MetS and this association is influenced by dietary fat intake. Also, Aberle *et al*^[52] showed that a highly significant association between the +294T > C and lower HDL-cholesterol levels in dyslipidemic female subjects. Moreover, MetS patients with CC genotype had significantly higher total and LDL-cholesterol

levels than those with TT and TC genotypes. The risk variant of *PPARδ* +294T >C marker was associated with higher LDL-cholesterol and increased serum total cholesterol^[53]. Additionally, several other studies demonstrated that the *PPARδ* +294T >C polymorphism was associated with modifications of serum lipid concentrations in healthy subjects and the risk of CAD in dyslipidemic women and hypercholesterolemic men and cholesterol metabolites in Alzheimer's disease patients^[54,55].

However, previous studies of *PPARδ* +294T >C polymorphism provided conflicting results regarding association with MetS. In another study in Scottish males, Skogsberg *et al.*^[56] reported that the +294C allele did not influence LDL-cholesterol concentrations. Gouni-Berthold *et al.*^[57] demonstrated that the presence of the C allele had no effect on triglyceride, HDL-cholesterol, and LDL-cholesterol levels, both in diabetic and non-diabetic German controls, or both in men and in women. In a Chinese study, Wei *et al.*^[58] showed that serum total cholesterol, HDL-cholesterol, LDL-cholesterol, ApoA1, and ApoB levels were not correlated with +294T >C polymorphism in nondrinkers. In addition, Grarup *et al.*^[47] also did not replicate the associations of +294T >C polymorphism with metabolic traits in 7495 middle-aged white people. Therefore, more studies focused on the impact of *PPARδ* gene polymorphism on the MetS development should be performed in different populations in future.

PPAR γ

The gene of *PPAR γ* (isoforms *PPAR γ 1*, *PPAR γ 2* and *PPAR γ 3*) is located on chromosome 3p25 encodes a nuclear transcription factor involved in the expression of hundreds of genes. *PPAR γ* gene contains 9 exons, spans more than 100 kb. Since 1997, more and more evidences indicated that both common and rare polymorphisms of the genes of *PPAR γ* acted as key roles in the regulation of lipid and glucose metabolism^[59-62]. Rare mutations of *PPAR γ* (loss-of-function mutations) exhibit a limited impact due to their low frequency but are associated with severe phenotypes such as hypertension, T2DM and MetS^[63]. Conversely, common polymorphisms of *PPAR γ* significantly associated with the risk of T2DM development, obesity and cardiovascular diseases in the general population due to their relatively high frequency^[64].

Role of *PPAR γ* gene polymorphisms in T2DM

PPAR γ was the first gene reproducibly associated with T2DM. The association between the substitution of alanine by proline at codon 12 of *PPAR γ 2* (Ala12 allele) and the risk for T2DM has been widely studied since Yen *et al.*^[65], first reported this polymorphism. In a recent study on the association between Pro¹²Ala polymorphism with both T2DM and the development of diabetic nephropathy, the results demonstrated

that the Pro/Pro genotype was the most common in diabetic patients as well as in controls followed by Pro/Ala genotype and Ala/Ala genotypes was the least common one. The allelic frequency of Pro was significantly higher in diabetic patients than controls and also significantly higher in diabetics with nephropathy than without nephropathy^[66]. In South Africa population, Vergotine *et al.*^[67] reported that the Pro¹²Ala of *PPAR γ 2* is significantly associated with insulin resistance and this polymorphism interacts with IRS1 Gly⁹⁷²Arg, to increase the risk of T2DM. In addition, Wang *et al.*^[68] demonstrated that the presence of the Ala allele may contribute to improved insulin secretory capacity and may confer protection from T2DM and obesity in the Chinese population. Moreover, a meta-analysis confirmed the association between the *PPAR γ 2* Pro12 allele and T2DM, and suggested that patients who carry the Pro12 allele have a 1.27-fold higher risk for developing T2DM than Ala12 carriers. This seemingly modest effect translates into a staggering 25% population-attributable risk because of the higher frequency of the Pro12 allele, especially in Japanese and European populations^[69].

Compared to the effects of the common Pro¹²Ala variant, rare mutations of *PPAR γ* gene affecting the ligand-binding domain of *PPAR γ* , such as 185Stop, Arg⁴²⁵Cys, and Pro⁴⁶⁷Leu, also associated with decreased transcriptional activity, improves glucose homeostasis and insulin sensitivity^[70-72]. Additionally, the other *PPAR γ* polymorphisms such as Cys¹¹⁴Arg, Cys¹³¹Tyr and Cys¹⁶²Trp could restrict wild-type *PPAR γ* action *via* a non-DNA binding, transcriptional interference mechanism. Heterozygous carriers of these new mutations are severely insulin resistant also been reported in the previous studies^[73,74].

Role of *PPAR γ* gene polymorphisms in MetS

The functional mutation Pro¹²Ala has also been reported to be associated with MetS in several populations^[75,76]. Tellechea *et al.*^[75] reported that individuals carrying the Ala12 allele of *PPAR γ* have a high risk for MetS and IR, especially among nonsmokers from Buenos Aires, Argentina. Also, The Québec Family Study observed that Ala12 carriers had a higher BMI, WC, fat mass than Pro/Pro homozygotes, suggesting that this polymorphism can modulate the association between dietary fat intake and components of the MetS^[76]. However, studies investigating the association between Pro¹²Ala polymorphisms and the risk of MetS in different populations have been inconsistent. In a large French population-based study, Meirhaeghe *et al.*^[77] found no association between Pro¹²Ala polymorphism of *PPAR γ* and MetS. Based on the analysis of 423 subjects with MetS and families without MetS, Yang *et al.*^[78] reported that Pro¹²Ala polymorphism was not associated directly with MetS, although MetS patients with Ala allele have higher fasting blood sugar (FBS) and higher left ventricular voltage. Similar to these findings, Ala carriers of middle-aged Swedish individuals did

not show statistically significantly different levels of fasting blood glucose, triglycerides, HDL-cholesterol, waist circumference or BP when compared with Pro¹²Pro homozygotes, suggesting that Pro¹²Ala polymorphism in *PPAR γ* gene does not have a major role in determining MetS prevalence^[79]. More recently, a meta-analysis included 4456 cases and 10343 controls from 10 case-control studies, indicated that no significant statistical difference was observed between the variant and metabolic syndrome, even if stratified by ethnicity, definition of metabolic syndrome, source of control groups, and quality score of selected studies^[80].

Another polymorphism, the C1431T silent substitution (rs3856806) in the 6th exon of *PPAR γ* , has also been shown to be associated with MetS in the different populations^[78,81]. In Iranian population, a significant difference in the frequencies of the C1431T genotypes was observed between MetS and control subjects. The T allele carriers had a significantly increased risk of MetS compared to the CC genotype even after correction for multiple-testing and adjustment for age, sex and genotype^[81]. In Chinese population, the association of C1431T polymorphism with MetS has also been observed. There were significant differences in terms of gender, FBS, LDL-cholesterol levels, triglyceride between CC genotype and CT +TT genotype groups in patients with MetS^[78]. However, not all studies had similar results. In Meirhaeghe's French population study, polymorphisms of C1431T were not individually associated with MetS. However connected with the other three polymorphisms, -681C>G, P2-689C>T, Pro¹²Ala, haplotypes are significantly associated with the risk for MetS^[82].

GENE-GENE INTERACTION AMONG *PPAR α* , *PPAR δ* AND *PPAR γ*

Until now, increasing evidences suggested that gene-gene interaction among *PPAR α* , *PPAR δ* and *PPAR γ* influenced the onset and progressing of T2DM and MetS^[41,83-88]. Andrulionyte *et al.*^[41] reported that SNP rs6902123 of *PPAR δ* alone and in combination with the Pro¹²Ala polymorphism of *PPAR γ* 2 predicted the conversion from impaired glucose tolerance (IGT) to T2DM. More recently, our results indicated that there was a significant association between plasma Lp(a) level and gene-gene interaction among the polymorphisms rs1800206, rs135539 in *PPAR α* and rs10865710, rs1805192, and rs4684847 in *PPAR γ* , suggesting that *PPAR α / γ* gene may influence the risk of T2DM and MetS by regulating Lp(a) level^[83,84]. In addition, the results from our another study demonstrated that gene-gene interaction among *PPAR α / δ / γ* polymorphisms contribute to the risk of hypertriglyceridemia independently or in an interactive manner^[86,87]. Thus, gene-gene interactions among SNPs in *PPAR α* , *PPAR δ* and *PPAR γ* should be further investigated in future in order to better understand the small single gene effects that

cannot be detected by single-locus studies.

CONCLUSION

Although the molecular mechanisms are still uncovered, more and more studies indicated that the gene polymorphism influence of PPARs acted as a pivotal role in the development of MetS and T2DM. Therefore, identification of polymorphic variants of PPARs in different populations and the genotypic associations between SNPs and gene-gene interactions would be helpful for the prevention and treatment of T2DM and MetS. However, given the complexity pathogenesis of metabolic disease, it is unlikely that genetic variation of a single locus would provide an adequate explanation of inter-individual differences which results in diverse clinical syndromes. To this end, gene-gene interactions and gene-environment interactions associated with T2DM and MetS needs future comprehensive studies.

Basic Study

Advanced glycation end-product expression is upregulated in the gastrointestinal tract of type 2 diabetic rats

Peng-Min Chen, Hans Gregersen, Jing-Bo Zhao

Peng-Min Chen, Department of Molecular Biology, Institute of Clinical Medicine, China-Japan Friendship Hospital, Beijing 100029, China

Hans Gregersen, GIOME Center, College of Bioengineering, Chongqing University, Chongqing 400045, China

Jing-Bo Zhao, Institute of Clinical Medicine, Aarhus University, Aarhus N 8200, Denmark

Author contributions: Gregersen H and Zhao JB designed the research; Chen PM and Zhao JB performed the research and analyzed the data; Chen PM and Zhao JB wrote the paper; Gregersen H revised the paper.

Supported by Karen Elise Jensens Foundation.

Ethics approval: Ethics of the study was approved by the Danish Committee for Animal Experimentation. The license number is 2008/561-1530.

Institutional animal care and use committee: All procedures involving animals were reviewed and approved by the Danish Committee for Animal Experimentation. The license number is 2008/561-1530. Animals in poor clinical condition were euthanized and excluded from the study. The rats were euthanized with CO₂ inspiration during the anesthesia. The animals were acclimatized to laboratory conditions (22 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water) for 2 wk prior to experimentation. The animal protocol was designed to minimize pain or discomfort to the animals.

Conflict-of-interest: We declare that we have no proprietary, financial, professional or other personal interest of any product, service and/or company that could be construed as influencing the position presented in, or the review of, the manuscript entitled "Advanced Glycation End-Product expression is upregulated in the Gastrointestinal Tract of Type 2 Diabetic Rats".

Data sharing: No additional data are available.

Open-Access: This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

AIM: To investigate changes in advanced glycation end products (AGEs) and their receptor (RAGE) expression in the gastrointestinal (GI) tract in type 2 diabetic rats.

METHODS: Eight inherited type 2 diabetic rats Goto-Kakizaki (GK) and ten age-matched normal rats were used in the study. From 18 wk of age, the body weight and blood glucose were measured every week and 2 wk respectively. When the rats reached 32 wk, two-centimeter segments of esophagus, duodenum, jejunum, ileum, and colon were excised and the wet weight was measured. The segments were fixed in 10% formalin, embedded in paraffin and five micron sections were cut. The layer thickness was measured in Hematoxylin and Eosin-stained slides. AGE [N epsilon-(carboxymethyl) lysine and N epsilon-(carboxyethyl)lysine] and RAGE were detected by immunohistochemistry staining and image analysis was done using Sigmascan Pro 4.0 image analysis software.

RESULTS: The blood glucose concentration (mmol/L) at 18 wk age was highest in the GK group (8.88 ± 1.87 vs 6.90 ± 0.43 , $P < 0.001$), a difference that continued to exist until the end of the experiment. The wet weight per unit length (mg/cm) increased in esophagus, jejunum and colon from the normal to the GK group (60.64 ± 9.96 vs 68.56 ± 11.69 , $P < 0.05$ for esophagus; 87.01 ± 9.35 vs 105.29 ± 15.45 , $P < 0.01$ for jejunum; 91.37 ± 7.25 vs 97.28 ± 10.90 , $P < 0.05$ for colon). Histologically, the layer thickness of the GI

tract was higher for esophagus, jejunum and colon in the GK group [full thickness (μm): 575.37 ± 69.22 vs 753.20 ± 150.41 , $P < 0.01$ for esophagus; 813.51 ± 44.44 vs 884.81 ± 45.31 , $P < 0.05$ for jejunum; 467.12 ± 65.92 vs 572.26 ± 93.60 , $P < 0.05$ for colon]. In esophagus, the AGE and RAGE mainly distributed in striated muscle cells and squamous epithelial cells. The AGE distribution was much stronger in the GK group compared to the normal group both in the striated muscle layer and mucosa layer (immuno-positive area/total measuring area %: 4.52 ± 0.89 vs 10.96 ± 1.34 , $P < 0.01$ for muscle; 8.90 ± 2.62 vs 22.45 ± 1.26 , $P < 0.01$ for mucosa). No visible difference was found for RAGE distribution between the two groups. In the intestine AGE and RAGE distributed in epithelial cells of villi and crypt. RAGE was also found in neurons in the myenteric and submucosal plexus. The intensity of AGE staining in mucosa of all segments and RAGE staining in neurons in all segments were strongest in the diabetes group. Significant difference for AGE was found in the epithelial cells of villi and crypt in duodenum (immuno-positive area/total measuring area %: 13.37 ± 3.51 vs 37.48 ± 8.43 , $P < 0.05$ for villi; 0.38 ± 0.12 vs 1.87 ± 0.53 , $P < 0.05$ for crypt) and for RAGE in neurons of all segments (*e.g.*, for jejunum: no staining neurons% 0 vs 0 , mild 36.0 ± 5.2 vs 28.7 ± 3.5 , moderate 53.2 ± 4.8 vs 55.8 ± 5.4 , strong 10.7 ± 1.1 vs 15.4 ± 2.0 , $P < 0.05$). In the colon, RAGE was primarily found in neurons in the myenteric and submucosal plexus. It was stronger in the diabetes group than in the normal group (no staining neurons% 6.2 ± 0.2 vs 0.3 ± 0.04 , mild 14.9 ± 2.1 vs 17.6 ± 1.5 , moderate 53.1 ± 4.6 vs 44.7 ± 4.4 , strong 25.6 ± 18 vs 43.6 ± 4.0 , $P < 0.05$). In the rectum, RAGE was primarily found in the mucosa epithelial cells.

CONCLUSION: The AGE and RAGE expression was up-regulated in the GI tract of GK diabetic rats and may contribute to GI dysfunction in type 2 diabetic patients.

Key words: Diabetes mellitus; Gastrointestinal complications; Advanced glycation end products; Receptor of advanced glycation end products

Core tip: Changes in advanced glycation end products (AGEs) and their receptor (RAGE) expression in the gastrointestinal (GI) tract in type 2 diabetic rats were studied. The AGE and RAGE were widely distributed in epithelial cells of all segments as well as in striated muscle cells in the esophagus. RAGE also distributed in neurons in all segments. Up-regulated AGE and RAGE expression was found in the GI tract of GK diabetic rats. The altered AGE and RAGE may be a contributing factor for GI dysfunction in type 2 diabetic patients.

INTRODUCTION

Sensory-motor abnormalities are common in the gastrointestinal (GI) tract in diabetes mellitus patients. Symptoms may arise from the entire GI tract. Common complaints are dysphagia, heartburn, abdominal pain, early satiety, nausea, vomiting, constipation, and diarrhea^[1-3]. The pathogenesis of such symptoms in diabetes mellitus is complex, multi-factorial with motor dysfunction, glycemic control, autonomic neuropathy, and psychological factors, and is not well understood^[4].

Previous studies demonstrated changes in the morphological and biomechanical properties of the GI tract during diabetes, *e.g.*, the wall thickness and stiffness of GI tract increased^[5-7]. The structure or deformation changes may alter the relative positions of the mechanosensitive afferents (zero setting of the mechanosensitive afferents). The changes in stress distribution and wall stiffness likely alter the stress in the vicinity of the mechanosensitive afferents. Consequently, the perception and motility of the intestinal tract will change as well. Therefore, the morphological changes and biomechanical remodeling are likely to affect the function of mechanosensitive afferents in the GI wall and further affect the motor and sensory function. Only sparse information, however, is available about the mechanisms for these changes.

Advanced glycation end products (AGEs) are formed in physiological states and gradually increases with age but AGEs formation is accelerated in diabetes^[8]. AGEs can lead to changes in structure and function directly in the target protein. They also can bind to their receptor (RAGE), leading to activation of signaling pathways resulting in serial changes^[9-11]. AGEs and RAGE play important roles for diabetic complications in the cardiovascular system^[12-14] and for retinopathy^[15] and nephropathy^[16,17]. It was also demonstrated that AGEs and RAGE were associated with diabetic-induced arterial wall stiffening^[18-20]. Therefore, they may also play an important role in the diabetic GI tract. In our previous study we demonstrated that AGE [N epsilon-(carboxymethyl)lysine, CML and N epsilon-(carboxyethyl)lysine, CEL] and RAGE were up-regulated in the small intestine and colon of streptozotocin (STZ)-induced diabetic rats^[21]. However, to the best of our knowledge, data on the distribution of AGE and RAGE in the GI tract of type-2 diabetes have never been described.

The aims of this study were to investigate the AGE and RAGE distribution in the GI tract in type-2 diabetic rats and to compare those with normal rats. The data obtained may serve as the basis for further studying AGE and RAGE effects on type 2 GI diabetic dysfunctions.

MATERIALS AND METHODS

Reagents

Anti-AGEs mouse monoclonal antibody (6D12), against N(epsilon)-(carboxymethyl)lysine (CML, a major immunological epitope in AGEs) and N epsilon-(carboxyethyl)lysine (CEL) was purchased from COSMO BIO CO.,LTD. Japan. Other substances were rabbit polyclonal antibody against the N-terminal of human RAGE from Cell Applications, INC, United States; LSAB2 System-HRP for rat specimens, proteinase K, citrate buffer (pH = 6.0, 10xconcentrated), bovine serum albumin (BSA) and Mayer haematoxylin from Dako A/S, Denmark; soluble RAGE from Shanghai Yanji Bio; STZ, ethanol, methanol and xylene from Sigma-Aldrich Denmark A/S, Vallensbæk Strand, Denmark. Blood glucose analyzer and test strips were supplied by Hemocue Corporation, Sweden. The slides and cover glasses we used for immunohistochemical staining were Menzel-Glaser products, Germany.

Animal

Approval of the protocol was obtained from the Danish Committee for Animal Experimentation. Eight inherited type 2 diabetic Goto-Kakizak rats (GK group), 12 wk old and weighting about 330 g, were purchased from Taconic Europe DK-8680 Ry, Denmark. Ten age-matched normal rats (same strain as GK rats) served as controls (Normal group). During the breeding, the rats freely drank tap water and ate food except fasting over night before measuring body weight and blood glucose, which were done every week for body weight and every 2 wk for blood glucose from week 18. The rats survived until 32 wk of age.

Sampling

At the termination of the experiments, the rats were anaesthetized with Hypnorm 0.5 mg and Dormicum 0.25 mg per 100 g body weight (Hypnorm: Dormicum: sterile water = 1:1:2; subcutaneous injection). Two-centimeter segments of esophagus, duodenum, jejunum, ileum, and colon were excized. The esophageal segment was taken from the distal end of esophagus; the duodenal segment from 5 cm distal to pylorus sphincter; the jejunal segment from 5 cm distal to the ligament of Treitz; the ileal segment from 5 cm proximal to the ileo-cecal valve; and the colon from the middle part. Residual contents in the lumen were gently cleared using Krebs solution of the following composition (mmol/L): NaCl, 118; KCl, 4.7; NaHCO₃, 25; NaH₂PO₄, 1.0; MgCl₂, 1.2; CaCl₂-H₂O, 2.5; Glucose, 11; ascorbic acid, 0.11 and the wet weight was measured. Thereafter the rats were killed by injecting an overdose anesthetics.

General histological staining

All samples were fixed in 10% phosphate-buffered formalin about 24 h. The specimen were dehydrated in a series of graded ethanol (70%, 96% and 99%) and

embedded in paraffin. Five-micron sections were cut perpendicular to the mucosa surface and the paraffin was cleared from the slides with coconut oil (over 15 min, 60 °C). The sections were rehydrated in 99%, 96% and 70% ethanol followed by a 10 min wash in water and stained with hematoxylin and eosin (HE). The layer thickness was measured by the same pathologist in a blinded review and sixteen determinations were made on each specimen and averaged.

Immunohistochemical staining

Tissue pretreatment: The tissue samples for immunohistochemistry were also fixed in 10% phosphate-buffered formalin about 24 h, embedded in paraffin. Five-micron sections were cut perpendicular to the mucosa surface and placed in a water bath at 40 °C. Thereafter, sections were transferred onto pretreated microscopic slides, which electrostatically attracted formalin fixed tissue and binding them to the slides. After drying the slides completely at room temperature, they were treated in an oven at 37 °C overnight to enhance the attachment of tissue to the slides. The sections were deparaffinized two times in xylene, 15 min per time, and rehydrated in 100%, 95%, 90%, 80%, 70%, 60% and 50% ethanol two times respectively, 3 s per time, followed by rinsing for 10 min and washing in 0.01M PBS (pH 7.4).

AGE: After treatment with H₂O₂ (3% in ethanol, room temperature, 15 min) and proteinase K (100 µg/mL, 100 µL, 37 °C, 20 min), the sections were incubated with 5% BSA-PBS buffer (room temperature, 30 min) for blocking non-specific staining. Afterwards, the sections were incubated with the primary antibody 6D12 [1:100, diluted in 1% bovine serum albumin-Phosphate buffered saline (BSA-PBS)], which has been thoroughly characterized by Ikeda group^[22], or normal mouse IgG (250 µg/mL) pre-treated with excessive CML (1:250, diluted in 1% BSA-PBS, negative control) overnight at 4 °C. The sections were then washed and incubated with LINK (biotinylated anti-rabbit and anti-mouse immunoglobulins) and afterwards with STREPTAVIDIN PEROXIDASE (streptavidin conjugated with horseradish peroxidase) at room temperature for 10 min (both are part of reagents of LSAB2 System-HRP, products of Dako Company, Denmark). Then the peroxidase activity was visualized by incubating the sections in substrate working solution containing hydrogen peroxide and 3,3'-diaminobenzidine tetrahydrochloride at room temperature for 5 min. The sections were rinsed for 10 min, counterstained with Mayer Haematoxylin for 1 min, treated in HCl-ethanol for 3 s, dehydrated in 80%, 90%, 95%, 100% ethanol for 3 s, respectively. Then the slides were immersed in xylene for 15 min two times and mounted.

RAGE: The primary antibody against RAGE was produced in rabbits immunized with a synthetic peptide corresponding to a sequence at the N-terminal of

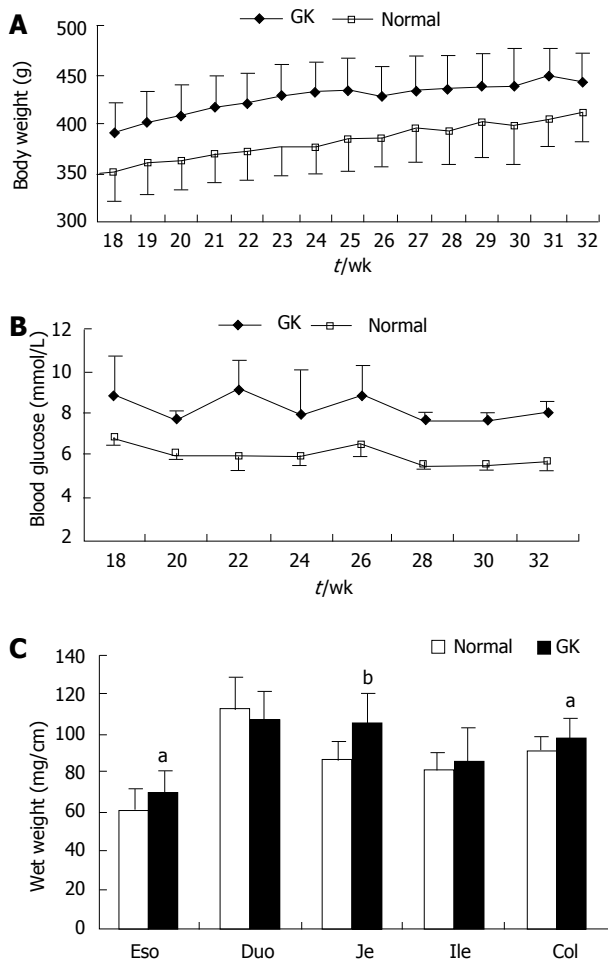

Figure 1 Body weight (A) and the blood glucose level (B) were higher in Goto-Kakizaki group than in the normal group ($P < 0.001$ and $P < 0.01$). The wet weight per unit length of intestinal and colon segments is shown in Figure 1C (compared with normal group: ^a $P < 0.05$, ^b $P < 0.01$). Values are mean \pm SD, $n = 8$ for each group. human RAGE. Only two amino acids are different from the related rat sequence. For RAGE immunostaining, instead of treating sections with proteinase K, the sections were boiled in 10 mmol/L citrate buffer (pH = 6.0) 18 min for retrieving antigen and using normal rat lung as positive control as the RAGE is highly expressed in the lung^[23]. The primary antibody was diluted (1:60) with 1% BSA-PBS and normal rabbit serum (diluted 1:60) pre-treated with excessive soluble RAGE was used as negative control. Other processes were similar to the AGE immunostaining.

Image analysis

To minimize errors, 6 to 10 photographs were randomly taken of different locations of same layer in each slide. After that, images of the different parts such as villus and crypt were saved as individual image files. The region of interest (ROI) was defined using Sigmascan Pro 4.0 image analysis software (Jandel Scientific, Germany). The color due to 3,3'-diaminobenzidine staining was distinguished in the ROI using intensity

thresholds. Finally the images were exported as binary images and the area fraction of AGE or RAGE positive staining was calculated by a MATLAB program (MATLAB 6.5, The MathWorks Inc. United States).

Data analysis

According to the image analysis above, the fraction of AGE in mucosa (villi and crypt were analyzed separately in the intestinal segments), muscle layers, and the fraction of RAGE in the mucosa and muscle layer were computed as: Fraction of AGE or RAGE = immunopositive area/total measuring area. It was difficult to calculate the fraction of RAGE in neurons in the same way. Therefore, the immunoreactivity of RAGE in each neuron was categorized by the stained intensity, *i.e.*, negative, mild, moderate and strong^[24].

Statistical analysis

The results were expressed as mean \pm SD unless indicated in the text. The differences between the diabetes and normal groups were tested using Student's *t* test and Anova. The results were regarded as significant when $P < 0.05$.

RESULTS

General information

The body weight and blood glucose level of GK group were significantly higher than those of the Normal group during the whole experimental period (Figure 1A and 1B, $P < 0.001$ and $P < 0.01$, respectively).

The wet weights per unit length of esophagus, jejunum and colon segments were highest in the GK group (Figure 1C, $P < 0.05$ and $P < 0.01$, respectively). No significant difference were found for duodenum and ileum between the two groups (Figure 1C, $P > 0.05$).

General histological changes

Compared with the Normal group, the full wall thickness of esophagus, jejunum and colon remarkably increased in the GK group (Figure 2A, $P < 0.05$ and $P < 0.01$, respectively). No significant difference was found in duodenum and ileum between two groups. The smooth muscle thickness of esophagus and colon (both circumferential and longitudinal smooth muscle) increased remarkably in GK group. The villous height of jejunum increased in the GK group (Figure 2B-D, $P < 0.05$ and $P < 0.01$). No significant difference was found for other layers.

Distribution of AGE

The immune-positive area of AGE was yellow-brown (Figure 3A and B). These colors were not found in the negative control slides (without primary antibody), demonstrating that the stained color was specific for AGE.

In the esophagus, AGE distribution was inhomogeneous and mainly distributed in striated muscle

and squamous epithelial cells. Compared with normal group, the intensity of immune-staining for AGE was much stronger in the GK group (Figure 3C, $P < 0.01$). No visible stained color was found in submucosa layer (Figure 3A and B).

In the intestine, AGE was mainly distributed in the mucosa layer, especially in epithelial cells of villi (Figure 4A-4E) and crypt. No visible stained color was found in submucosa, smooth muscle and ganglia. The crypt epithelial cells in ileum and colon were slightly stained. The distribution of AGE in the epithelial cells was inhomogeneous, the surface part was much stronger than the bottom part in villous epithelial cells but it showed an opposite pattern in the crypt epithelial cells. The intensity of AGE staining of the epithelial cells in villi was stronger than that in crypts ($P < 0.01$). In the mucosa, the intensity of AGE staining was similar between duodenal and jejunal segments (Figure 4A-C, F, G) but they were stronger than those in colon (Figure 4A, 4C, 4E and 4F). The mucosa of ileum showed the weakest intensity of AGE staining among different

intestinal segments (Figure 4D). Compared with the Normal group, the intensity of AGE staining in mucosa of all segments were stronger in the GK group (Figure 4F and G). Significant difference was found in the epithelial cells of villi and crypt in duodenum (Figure 4F and G, $P < 0.05$).

Distribution of RAGE

The immune-positive area of RAGE also showed yellow-brown color (Figure 5) that was not found in the negative control slides (without primary antibody). Therefore, the stained color was specific for RAGE.

In esophagus, the immune-positive staining for RAGE was mainly observed in the striated muscle cells and mucosa squamous epithelial cells. The RAGE distribution was inhomogeneous in the striated muscle layer and graduated decreased from bottom to surface. No visible stained color was found in the submucosa layer (Figure 5). The intensity of RAGE staining did not differ between Normal and GK group both in the striated muscle cells and mucosa squamous epithelial

Figure 4 Example of advanced glycation end products immune-staining in villi of duodenum (A, normal; B, diabetic), jejunum (C), ileum (D) and mucosa in colon (E). cells ($P > 0.05$).

In the small intestine, the immune-positive staining for RAGE was observed in the epithelial cells of villi (Figure 6A, C, E) and crypts (Figure 6B, D, F), and

in neurons in the myenteric and submucosal plexus (Figure 6G). The RAGE was homogeneously distributed in the cells, as shown in villus and crypt epithelial cells, but the intensity of immune-staining was

Figure 5 Example of receptor of advanced glycation end products immune-staining in normal esophagus. The immune-positive area of RAGE showed yellow-brown color. RAGE: Receptor of advanced glycation end products. Blue arrow: mucosa; Red arrows: Submucosa; Black arrows: Muscle.

much stronger in villous epithelial cells than in crypt epithelial cells. The strongest staining color occurred in duodenum and the weakest in ileum among the three segments (duodenum > jejunum > ileum, Figure 6A-F). In neurons, RAGE distributed both in cytoplasm and cell membrane (Figure 6G). Compared with the Normal group, the intensity of immune-staining for RAGE increased in the neurons for the three segments (Figure 6G and H) in the GK group ($P < 0.05$), but no significant difference was found in other cells between two groups.

In the colon, the immune-positive staining for RAGE was observed in neurons of the myenteric (Figure 7A) and submucosal plexus. It was stronger in the GK group than in Normal group ($P < 0.05$) (Figure 7A and B). Furthermore, a mild positive staining was also observed in mucosa epithelial cells both in the GK and Normal groups (Figure 7C).

DISCUSSION

Our previous study showed that the expression of AGE and RAGE was up-regulated in the small intestine and colon of STZ-induced type 1 diabetic rats^[21]. STZ rats have high blood glucose but formation of free radicals and STZ cytotoxicity plus its direct effects on AGE formation and RAGE expression in GI tract may be questioned. Using the present model, the confounding effect of STZ can be avoided. The major discovery was that the intensity of AGE immune-staining was significantly increased in striated muscle and mucosa layer of esophagus, and in epithelial cells located in intestinal villi and crypts in the GK group compared to normal rats. RAGE was significantly increased in myenteric and submucosa plexus neurons of all intestinal segments in the GK group.

The distribution of AGE and RAGE in normal GI tract

Ling *et al.*^[25] reported the existence of four kinds of AGEs in stomach and small intestinal epithelial cells in normal rats. Our previous study^[21] showed

homogenous AGE distribution in the cytoplasm of smooth muscle cells, epithelial cells, and neurons of the myenteric and submucosal plexus in the layers of colon and small intestine. Furthermore, homogeneous distribution of RAGE was found in epithelial cells and neurons. The present study confirmed the distribution of both compounds in the colon and small intestine as reported from our previous study. Furthermore, we also found that the AGE and RAGE distributed in the striated muscle and squamous epithelial cells of esophagus and also in the stomach (unpublished data). The present study together with our previous study^[21] is the first reports of the localization of AGE and RAGE in the whole rat GI tract. This provides a basis for further comparison study of the distribution of AGE and RAGE on GI tract with diseases, such as diabetes.

AGE and RAGE changes in GI tract of GK diabetic rats

RAGE and AGE distribution in the GI tract of GK rats was similar to that in normal controls. However, compared with the normal controls, the level of AGE and RAGE at some GI locations was increased in GK rats. However, compared with our previous study^[21], the intensity of AGE and RAGE immune-staining were not so strong in the present study. It is well known that the accumulation and production of AGEs and expression of RAGE are associated with blood glucose level^[26]. The blood glucose level is much lower in GK diabetic rats compared to STZ-induced diabetic rats. This is one plausible explanation for the weaker increasing AGE and RAGE in the GK type-2 diabetic rat model.

Histomorphological and biomechanical GI remodeling occurred during the development of diabetes^[27]. For example the esophagus and colon were morphologically and biomechanically remodeled during the development of diabetes^[6,7]. Abnormal levels of AGE and RAGE found in the present study may be associated with the GI remodeling in the GK diabetic rats. In the present study we found that the mucosa of small intestine and muscle layer of all segments proliferated, accordingly the AGE expression is up-regulated in the mucosa in all segments and esophageal muscle layer in the GK diabetic rats. However, the intensity of immune-staining in muscle had no apparent increase in muscle layer of intestine in GK group despite the fact that the muscle layer showed hyperplasia. Therefore it is speculated that in addition to the affection of AGE, other factors may affect the hyperplasia of GI muscle in GK diabetic rats, such as glucagon-like peptide 2^[28].

In the present experiment no direct evidence showed how tissue growth was affected by AGEs and RAGE. From studies in other organs, it is known that AGE through AGE-RAGE-mediated ROS generation activating angiotensin II-tissue growth factor beta (TGF- β)-S-mad signaling can increase renal interstitial fibroblasts mitogenesis and type I collagen production^[29], mesangial cell hypertrophy and fibronectin synthesis^[9], through AGE-RAGE interaction can cause epithelial

Figure 6 Receptor of advanced glycation end products immune-staining in villi (A, C, E) and crypt (B, D, F) of duodenum (A, B), jejunum (C, D) and ileum (E, F) as well as in ileum ganglia (arrowhead; G: Normal group; H: GK group). As shown in the magnification area (big frame vs small frame), the RAGE homogeneously distributed in the epithelia cells. The intensity of immune-staining in ganglia was stronger in the diabetic group (H) than in the normal group (G) (arrowhead). RAGE: Receptor of advanced glycation end products; GK: Inherited type 2 diabetic Goto-Kakizaki rats.

myofibroblast transdifferentiation^[30] and vascular smooth muscle proliferation^[31], and through galectin-3 induce smooth muscle proliferation^[32]. Therefore, it is feasible that GI tissue proliferation at least in part may be induced by AGE accumulation through the same pathways. Further studies must explore mechanisms

for AGE- and RAGE-induced GI tissue growth and the association with the biomechanical remodelling in diabetes.

AGE and RAGE accumulation impact on GI dysfunction

It is well documented that small intestinal epithelial

Figure 7 Receptor of advanced glycation end products immune-staining in colon ganglia (arrow; A: Normal; B: Diabetic) and mucosa (C). The intensity of immune-staining in ganglia was stronger in the GK group (B) than in the normal group (A) (arrow). Big frame area vs small frame area. RAGE: Receptor of advanced glycation end products; GK: Inherited type 2 diabetic Goto-Kakizaki rats.

cells are important for digestion and absorption. Many kinds of enzymes located in the enterocytes lining the intestinal villi brush border are involved in digestion^[33]. Furthermore, the small intestinal mucosa is important for absorptive function^[33]. We demonstrated a stronger intensity of AGE immune-staining in the epithelial cells of intestinal crypts and villi in the diabetes group compared to the normal group. Digestive enzyme activity and cell membrane properties may potentially be affected by AGE accumulation. It is also known that non-enzymatic glycation and oxidative stress are important for changes of brush border membrane fluidity^[34]. Digestion and intestinal transport processes occur at the brush border membrane. Changes in fluidity as well as in the membrane composition can alter the enzyme activity in the villi brush border membrane^[35,36]. Multiple cellular signaling cascades can be activated by binding of AGEs to RAGE^[37]. The increased AGE linking with RAGE may change epithelial cell function. Mechanisms linking AGEs/RAGE compounds to intestinal mucosa function in diabetics need more work.

Numerous studies demonstrated abnormal GI motility in diabetics^[27,38]. Diabetic autonomic neuropathy is considered important in the pathogenesis of sensory-motor disordered function in diabetic patients^[39-41]. AGEs and RAGE likely are key players in development of diabetic neuropathy^[23]. Synergistic action of AGEs and endogenous nitric oxide can lead to neuronal apoptosis *in vitro*^[42]. The neuronal AGE formation and accumulation may account for the development of GI neuropathy, primarily as a direct effect on structural and functional proteins, alternatively by activating RAGE indirectly^[43]. GI nerves express nitric oxide synthase (nNOS), which generates a key transmitter nitric oxide in the regulation of GI motility^[44]. Korenagas group demonstrated that AGEs inhibit *via* RAGE nNOS expression *in vitro*^[45]. The expression and function of neuronal nitric oxide synthase decreased in the stomach of spontaneously diabetic BB-rats^[41] and also decreased in duodenum of STZ-induced diabetic rats, which can be prevented by aminoguanidine (a drug

that prevents AGE formation) and ALT-711 (AGE cross-link breaker)^[8]. In the present study direct evidence was provided that RAGE is localized in myenteric and submucosal plexus neurons in the esophagus and intestine. In addition, DM enhanced RAGE intensity and therefore, AGE-RAGE interaction is likely of importance for GI diabetic autonomic neuropathy. We also demonstrated that the intensity muscle tissue AGE immune-staining was strongest in the diabetic esophagus. The accumulation of AGEs in muscle may alter the architecture and contractile proteins of smooth muscle^[46], resulting in the alteration of muscle contraction properties.

AGE was mainly distributed in striated muscle and squamous epithelial cells in esophagus; in small intestinal epithelial cells of crypt and villi and in epithelial cells in colon and rectum. RAGE was mainly distributed in striated muscle and squamous epithelial in esophagus; in epithelial cells in intestine mucosa and neurons in ganglia. High AGE density was found in striated muscle and mucosa layers in esophagus, and villus, crypt in the GK rat small intestine, and the expression of RAGE in the intestine increased in ganglia of GK rats. Increased expression of AGE and RAGE likely contributes to GI disorders associated with DM.

ACKNOWLEDGMENTS

Technicians Torben Madsen, Ole Sørensen, and Jens Sørensen are thanked for handling the animals.

COMMENTS

Background

In this previous study the authors demonstrated that advanced glycation end products (AGEs) and their receptor (RAGE) were up-regulated in the small intestine and colon of streptozotocin-induced diabetic rats. However, to the best of our knowledge, data on the distribution of AGE and RAGE in the gastrointestinal (GI) tract of type 2 diabetes have never been described.

Research frontiers

Previous studies demonstrated the morphological and biomechanical properties of the GI tract were remodeled during diabetes. However the mechanisms for these changes are not well understood. Therefore, investigation on the

distribution of AGE and RAGE in the GI tract of type-2 diabetes is important for understanding the mechanism of GI remodeling in diabetes.

Innovations and breakthroughs

At present study the authors demonstrated that the AGE and RAGE expression was up-regulated in the GI tract of GK diabetic rats. The increased AGE and RAGE levels may contribute to diabetic GI dysfunction in type 2 diabetic patients.

Applications

The most common type diabetes is type 2 diabetes; therefore it is important to understand the expression of AGE and RAGE in the GI tissues in type 2 diabetes. Knowing the over-expression of AGE and RAGE in the diabetic GI tract may in somehow direct the treatment in the patients suffering from type 2 diabetes.

Terminology

AGEs are formed by non-enzymatic attachment of sugars to the amino groups of various proteins through a series of complex intermediary reactions. Diabetic hyperglycemia accelerates the accumulation of AGEs in the tissues. RAGE is a 55kD transmembrane receptor of the immunoglobulin super family, which binds AGEs. AGEs contribute to diabetic complications through receptor-dependent and -independent pathways.

Peer-review

This is an interesting study. In future, more data should provide to further demonstrate the relationship between increasing AGE and morphological or functional changes in diabetes.

World Journal of Diabetes
Volume 6 Number 5 June 10, 2015

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Cevdet Kaya, MD, Associate Professor, Department of Urology, Haydarpasa Numune Training and Research Hospital, Kadikoy, 34000 Istanbul, Turkey

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

It was previously understood that body weight gain and obesity observed in type 2 diabetes mellitus (T2DM) could be beneficial since body weight increase elevated bone mineral density and thus helped maintain the skeletal framework. However, a number of recent findings in humans and rodents have revealed that T2DM is not only associated with trabecular defects but also increases cortical porosity, and compromised bone cell function and bone mechanical properties. Hyperglycemia and insulin resistance in T2DM may further induce osteoblast apoptosis and uncoupling bone turnover. Prolonged accumulation of advanced glycation end products and diminished activity of lysyl oxidase, an essential enzyme for collagen cross-link, can lead to structural abnormalities of bone collagen fibrils, brittle matrix, and fragility fractures. Our studies in T2DM rats showed that dyslipidemia, which often occurs in T2DM, could obscure the T2DM-associated changes in bone microstructure and osteopenia. Longitudinal bone growth regulated by the growth plate chondrocytes is also impaired by T2DM since differentiation of growth plate chondrocytes is arrested and retained in the resting state while only a small number of cells undergo hypertrophic differentiation. Such a delayed chondrocyte differentiation may have also resulted from premature apoptosis of the growth plate chondrocytes. Nevertheless, the underlying cellular and molecular mechanisms of insulin resistance in osteoblasts, osteoclasts, osteocytes, and growth plate chondrocytes remain to be investigated.

Key words: Advanced glycation end products; Chondrocyte apoptosis; Collagen; Dyslipidemia; Fracture; Growth plate; Type 2 diabetes mellitus; Osteoporosis

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Type 2 diabetes mellitus (T2DM) negatively affects bone density and strength by inducing cellular and extracellular matrix failures. Insulin resistance in T2DM deteriorates osteoblast proliferation and activity, but enhances osteoclast activity, leading to uncoupled bone remodeling. Hyperglycemia also aggravates osteoblast dysfunction, thus contributing to cellular failure. Extracellular matrix failure is caused by abnormal collagen synthesis and aberrant collagen structure and alignment, the latter of which results, in part, from advanced glycation end products (AGEs). With hyperglycemia and AGEs, impaired bone strength may occur despite high bone mineral density. It is, therefore, concluded that T2DM can be considered a cause of osteoporosis and/or poor bone mechanical properties.

Wongdee K, Charoenphandhu N. Update on type 2 diabetes-related osteoporosis. *World J Diabetes* 2015; 6(5): 673-678 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i5/673.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i5.673>

INTRODUCTION

Although type 1 diabetes mellitus (T1DM) is known to compromise bone microstructure^[1,2], how type 2 diabetes mellitus (T2DM) affects bone metabolism has long been debate for decades. It was previously believed that T2DM could be protective against osteoporosis since a number of clinical studies and meta-analyses revealed an increase in bone mineral density (BMD) in T2DM patients^[1,2]. However, several recent lines of evidence in both humans and rodents have corroborated that T2DM is indeed detrimental to bone, leading to impaired osteoblast-mediated bone formation, accelerated bone resorption, microstructural defect, and poor bone quality. The previous controversial data stem from the use of low-resolution X-ray-based techniques, including measurement of areal BMD by dual energy X-ray absorptiometry (DXA), rather than evaluation of high-resolution bone microstructure or bone mechanical properties. This article has updated the recent findings of T2DM-related osteopenia and osteoporosis, as summarized in Table 1.

T2DM INCREASES BONE POROSITY AND DECREASES MECHANICAL BONE STRENGTH

Previous investigations in human mostly focus on trabecular bone changes in T2DM, but recent investigations have moved to the study of cortical changes and mechanical properties. By using more advanced

techniques, such as high-resolution 3-dimensional computed tomography and microindentation, it was found that T2DM negatively affected bone strength despite the presence of relatively high BMD. Several cross-sectional studies in T2DM patients using high-resolution peripheral quantitative computed tomography (HR-pQCT) and magnetic resonance imaging (MRI) consistently revealed quality defects in both cortical and trabecular networks that would increase fracture risk^[3-6]. For instance, Farr *et al.*^[3] by assessing bone quality with HR-pQCT in 30 postmenopausal T2DM patients at distal radius and distal tibia, found lower cortical thickness in T2DM was lower than normal non-diabetic controls, while bone microindentation testing showed lower bone material strength (BMS) in T2DM patients. Moreover, the radius quality evaluated by MRI, showed trabecular network holes being approximately 10% larger in postmenopausal T2DM patients than normal controls^[5]. The cortical part was similarly affected by T2DM^[4]. Patsch *et al.*^[4] investigated changes in bone microarchitecture in postmenopausal T2DM patients with or without fractures at radius and tibia by using DXA and HR-pQCT. Interestingly, they found that T2DM patients with fractures had higher pore-related deficits, *i.e.*, greater cortical pore volume, cortical porosity, and endocortical bone surface, than diabetic patients without fractures^[4], consistent with the previous report in the radii of T2DM patients that having greater cortical pore volume (approximately 150%) and cortical porosity (approximately 125%) than normal individuals^[6]. These cortical defects were often accompanied by impaired mechanical properties, such as increased failure load and low bone bending strength, that led to reduction in overall bone strength and increase in fracture risk^[4,7].

DYSLIPIDEMIA MIGHT OBSCURE T2DM-INDUCED OSTEOPOROSIS

Previously it was believed that greater body weight or obesity associated with T2DM could be beneficial to the skeletal system through increasing BMD and bone mass^[7,8]. However, our group recently reported the possible masking effects of dyslipidemia on diabetic bone in rats^[9]. In our study, we determined the effects of dyslipidemia on bone microstructure were determined in Goto-Kakizaki (GK) diabetic rats treated with high cholesterol diet compared those fed with normal diet. The GK rats-a non-obese T2DM rat model without obesity-induced bone gain-were found to manifest stable fasting hyperglycemia and insulin resistance, while cholesterol-fed GK rats exhibited hypercholesterolemia, hypertriglyceridemia and hyperglycemia without significant weight gain^[10]. Bone histomorphometry revealed that GK rats with T2DM manifested several signs of suppressed osteoblast function, such as decreases in osteoblast surface and bone formation rate, whereas the osteoclast-mediated

Table 1 Recent studies on the type 2 diabetes mellitus-related osteoporosis in humans (2010-2014)

Site of bone	Technique	Subjects	Main findings in T2DM group	Ref.
Distal radius	HR-pQCT	60 postmenopausal women	Low cortical thickness and low trabecular number	[3]
Distal tibia	HR-pQCT		Lower cortical thickness	
Mid-shaft tibia	Microindentation		Poor bone quality (low BMS)	
Distal radius	DXA, HR-pQCT		Higher cortical porosity in T2DM with fractures	
Ultradistal radius	DXA, HR-pQCT	80 postmenopausal women with or without fractures	Higher cortical porosity in T2DM with fractures	[4]
Distal tibia	DXA, HR-pQCT		Lower cortical porosity in T2DM with fractures	
Ultradistal tibia	DXA, HR-pQCT		Lower BMD and cortical porosity in T2DM with fractures	
Distal radius	MRI		Greater trabecular network holes	
Distal radius	HR-pQCT	38 postmenopausal women	Higher cortical porosity	[5]
Tibia	HR-pQCT	1171 men (≥ 65 yr)	Higher volumetric BMD and trabecular thickness	[6]
Mid-shaft radius	pQCT		Lower bone bending strength	
Mid-shaft tibia	pQCT		Lower bone bending strength	

BMD: Bone mineral density; BMS: Bone material strength; DXA: Dual energy X-ray absorptiometry; HR-pQCT: High resolution-peripheral quantitative computed tomography; MRI: Magnetic resonance imaging; T2DM: Type 2 diabetes mellitus.

bone resorption was markedly enhanced. It was noted that, these microstructural changes disappeared after 16-wk of high cholesterol consumption, suggesting that high cholesterol diet and perhaps the resultant dyslipidemia could obscure the T2DM-associated osteopenia and changes in bone microstructural defect^[9]. Thus, the difficulty in detecting bone deterioration in T2DM rats with dyslipidemia could explain, in part, why osteopenia was not observed in some T2DM studies.

T2DM AND LONGITUDINAL BONE GROWTH

Up until now, few studies have investigated relationship between T2DM and longitudinal bone growth. Generally, longitudinal bone growth is controlled by proliferation and differentiation of chondrocytes in the growth plate, which is histologically divided into 3 zones, *i.e.*, resting zone (RZ), proliferative zone (PZ) and hypertrophic zone (HZ). The RZ consists of low mitotic activity stem-like cells that gradually migrate to the PZ where chondrocytes proliferate and align into vertical columns and eventually reach the mature state in HZ. Thereafter, the hypertrophic chondrocytes in HZ undergo apoptosis and are replaced by capillaries and osteoblasts, which later use cartilaginous scaffold as a template for bone formation and bone elongation^[11,12]. Since several investigations reported reduced bone length in diabetic rats compared with normal rats^[9,13], T2DM may be a cause of aberrant growth plate function. Lapmanee *et al.*^[9] examined changes in the growth plate of diabetic GK rats and found impairment of chondrocyte differentiation as indicated by increased RZ height and decreased HZ height. It was possible that differentiation of chondrocyte precursors in T2DM rats were arrested and cells remained in the resting state, with only a small number of proliferating cells undergoing differentiation into hypertrophic chondrocytes^[9].

Aiemlapa *et al.*^[14] further demonstrated the underlying mechanism of delayed growth plate chondrocyte differentiation. By using terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay for apoptosis, they found premature apoptosis of chondrocytes in the HZ and chondro-osseous junction of GK rats. The massive loss of growth plate chondrocytes was accompanied by an increase in serum IGF-1 level, and overexpression of parathyroid hormone related protein (PTHrP), *runx*-related transcription factor (Runx2) and vascular endothelial growth factor (VEGF) in the growth plate, all of which might have been compensatory responses to mitigate excessive loss of chondrocytes due to premature apoptosis^[14]. However, it was possible that the effects of T2DM on the growth plate might be dependent on animal strain and model of DM induction. For instance, Wu *et al.*^[15] found acceleration of longitudinal bone growth as indicated by bone elongation and increased heights of PZ and HZ in insulin resistant mice induced by high fat diet. In this model, insulin might remain to have a stimulatory effect on bone growth *in vivo* similar to its reported stimulatory effect on metatarsal linear growth *in vitro*^[15]. Furthermore, high fat diet-induced dyslipidemia could complicate the matter since 7 α -hydroxycholesterol and oxidized low-density lipoprotein (LDL) have been shown to modulate osteoblast and osteoclast functions, which, in turn, could have effects on bone elongation^[16,17].

POSSIBLE CELLULAR MECHANISMS OF T2DM-RELATED FRAGILITY FRACTURES

The pathogenesis of T2DM-related fragility fracture can be looked upon from 2 aspects, *i.e.*, cellular failure and extracellular matrix failure. At cellular level, T2DM was associated with diminished activities of osteoblasts, osteoclasts and osteocytes, and increased apoptosis of bone cells^[9,18-21]. A decrease in osteocyte density (number of osteocyte-occupied lacunae per unit

area) was conspicuously observed in streptozotocin-induced diabetic rats^[21]. Hyperglycemia-induced insulin resistance is another important factor that cause both osteoblast and osteoclast malfunctions^[22]. Since insulin is a suppressor of osteoclast-mediated bone resorption^[23], T2DM-associated insulin resistance could enhance bone resorption. Moreover, high plasma glucose concentration can induce glucotoxicity in cells including osteoblasts, leading to osteoblast apoptosis^[24]. *In vivo* experiment in transgenic liver-specific S503A CEACAM1 mutant (L-SACC1) mice, a model of impaired insulin clearance in the liver causing hyperinsulinemia and insulin resistance, suggested that the abnormally high bone mass in these mice might have resulted from low bone turnover as indicated by decreases in double-labeled surface (as determined by bone histomorphometry) and TRAP-positive osteoclasts, which represent activities of osteoblast-mediated bone formation and osteoclast-mediated bone resorption, respectively^[22]. In other words, insulin resistance in this model was associated with a slowdown in bone turnover, which could eventually result in inadequate healing of microcracks, poor bone quality and increased fracture risk^[22]. In addition, the experiment in high fat diet-fed Zucker diabetic fatty (ZDF) rats also showed impaired osteoblast function as indicated by downregulation of the expression of osteoblast-specific genes, *e.g.*, bone morphogenetic protein-2 (BMP-2), Runx2, osteocalcin and osteopontin. Suppression of osteoblastogenesis in these ZDF rats possibly compromised bone regeneration capacity. Subcritical bone defect regeneration study further showed that nondiabetic rats filled the defect by 57%, whereas diabetic rats could fill only 21% of bone defect in 12 wk^[18].

T2DM not only caused deterioration of bone cell functions (cellular failure), but it also damaged bone extracellular matrix. Most studies suggested that T2DM caused abnormality in the structure of collagen, which is the most abundant protein in organic bone matrix. García-Hernández *et al.*^[25] reported that high glucose concentration indeed increased biomineralization in human alveolar bone-derived osteoblasts, but the mineral quality was lower than that in low glucose-exposed group. Determination of mineral quality in term of calcium/phosphate (Ca/Pi) ratio in the mineralized extracellular matrix nodules by energy-dispersive X-ray microanalysis (EDX) showed that high concentration of glucose significantly decreased Ca/Pi ratio on day 7 and 14 of treatment. Hammond *et al.*^[26] further studied nanoscale morphology of type I collagen in tibiae of ZDF rats by Raman spectroscopy and reference point indentation (RPI), the latter of which applied a force to determine bone mechanical properties by measuring the relative displacement reference position^[26,27]. RPI analysis revealed that bone matrix of ZDF diabetic rats was more resistant to plastic deformation, which might have resulted from abnormal formation of non-

enzymatic collagen cross-link, toughening of the matrix, or the presence of advanced glycation end products (AGEs).

AGEs are non-enzymatic carbohydrate modifications of extracellular and intracellular proteins accumulated in long-lived tissues, such as skin and bone, and are often present in the plasma proteins of patients with DM and renal failure^[28,29]. A number of investigations have revealed that AGEs are considered a factor that provokes fragility fractures in T2DM by inducing abnormal arrangement of collagen^[26,28,30]. By using scanning electron microscope (SEM) and transmission electron microscope (TEM), Aoki *et al.*^[28] provided evidence that the rats subjected to adenine-induced renal failure exhibited AGEs accumulation and suppression of osteoblast function, similar to that observed in T2DM. SEM showed irregularity in collagen fibril alignment, while TEM revealed a wider diameter of collagen fibril in adenine-treated rats with renal osteodystrophy^[28]. Immunohistochemistry also showed greater accumulation of AGEs in peritrabecular osteoblasts of adenine-treated rats than control rats. Further *in vitro* study in AGEs-treated MC3T3-E1 osteoblast-like cells showed a decrease in protein expression of secreted phosphoprotein 1 and lysyl oxidase, a mature osteoblast marker and essential enzyme for collagen cross-link, respectively. It was thus suggested that suppressed osteoblast differentiation and decreased lysyl oxidase production caused structural abnormalities of bone collagen fibrils leading to bone fragility^[28].

Collagen is the most abundant protein in bone organic matrix, and it undergoes intra- and extracellular post-translational modifications^[31]. To stabilize collagen fibrils, lysyl oxidase catalyzes intra- and intermolecular cross-link between collagen molecules essential for bone strength^[31]. It was reported that glycation of collagen caused abnormal arrangement of collagen leading to brittle matrix and fragile bone^[26,28,30], but little is known whether a decrease in lysyl oxidase-dependent collagen cross-link contributes to diabetic bone fragility and osteoporosis. The underlying mechanism of AGEs-attenuated lysyl oxidase activity was explored in mouse and rat primary osteoblasts and it was found that the carboxymethylated collagen, a form of AGEs, was not able to promote lysyl oxidase-mediated cross-linking due to failure of binding between abnormal collagen and discoidin domain receptor-2^[30].

CONCLUSION

Currently, it can be concluded that T2DM compromises bone microstructure by inducing aberrant bone cell function (cellular failure) and abnormal matrix structure (matrix failure). Regarding the cellular effect, T2DM is associated with increased osteoblast apoptosis, diminished osteoblast differentiation, and enhanced osteoclast-mediated bone resorption, which, in part,

resulted from hyperglycemia and insulin resistance. Prolonged accumulation of AGEs coexisting with a decrease in lysyl oxidase activity causes abnormal structure and alignment of collagen, leading to bone fragility. Several confounding factors in T2DM, particularly body weight gain, obesity, and dyslipidemia, are able to mask the detrimental effects of T2DM, and may delay diagnosis of diabetic osteoporosis. In other words, bone is already damaged in T2DM despite a relatively high BMD. Although deleterious effects of T2DM on bone have been elucidated, the underlying cellular and molecular mechanisms remain unclear. For example, how does insulin resistance occur in osteoblasts and how do phosphorylation of insulin-receptor substrate isoforms (IRSs) and resultant insulin resistance in osteoblasts, osteoclasts and perhaps osteocytes contribute to diabetic bone loss? Indeed, osteocytes residing inside lacunae play an important role in bone remodeling in health and disease since they are responsible for inducing bone loss under certain conditions, such as during lactation^[32,33]. Further investigation is required to demonstrate whether osteocytic dysfunction does exist in T2DM.

Abstract

Macro and microvascular disease are the main cause of morbi-mortality in type 1 diabetes (T1DM). Although there is a clear association between endothelial dysfunction and atherosclerosis in type 2 diabetes, a cause-effect relationship is less clear in T1DM. Although endothelial dysfunction (ED) precedes atherosclerosis, it is not clear whether, in recent onset T1DM, it may progress to clinical macrovascular disease. Moreover, endothelial dysfunction may either be reversed spontaneously or in response to intensive glycemic control, long-term exercise training and use of statins. Acute, long-term and post-prandial hyperglycemia as well as duration of diabetes and microalbuminuria are all conditions associated with ED in T1DM. The pathogenesis of endothelial dysfunction is closely related to oxidative-stress. NAD(P)H oxidase over activity induces excessive superoxide production inside the mitochondrial oxidative chain of endothelial cells, thus reducing nitric oxide bioavailability and resulting in peroxynitrite formation, a potent oxidant agent. Moreover, oxidative stress also uncouples endothelial nitric oxide synthase, which becomes dysfunctional, inducing formation of superoxide. Other important mechanisms are the activation of both the polyol and protein kinase C pathways as well as the presence of advanced glycation end-products. Future studies are needed to evaluate the potential clinical applicability of endothelial dysfunction as a marker for early vascular complications in T1DM.

Key words: Endothelial dysfunction; Type 1 diabetes; Cardiovascular disease

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Endothelial dysfunction is an early finding in the natural history of type 1 diabetes and is predictive for microvascular disease and premature atherosclerosis. Decreased nitric oxide due oxidative stress is the central pathogenetic mechanism. Polyol pathway activation, protein kinase C (PKC) activation and advanced glycation product formation are also important. Long-term hyperglycemia, repeated hypoglycemia and microalbuminuria are factors associated. Intensive glycemic control and exercise training ameliorate endothelial dysfunction. Statins and renin-angiotensin system blockers are partially effective and may be influenced by hyperglycemia. There is a possible clinical benefit for the use of vitamin E and vitamin C that are still to be confirmed. PKC inhibitors are still investigative.

Endothelial dysfunction as a predictor of cardiovascular disease in type 1 diabetes. *World J Diabetes* 2015; 6(5): 679-692 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i5/679.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i5.679>

INTRODUCTION

Micro and macrovascular complications are leading causes of morbidity and mortality in patients with type 1 diabetes mellitus (T1DM)^[1,2]. Subjects with T1DM are prone to accelerated atherosclerosis^[3] and have 3 to 6 times more risk of cardiovascular death than individuals without diabetes. Endothelial dysfunction (ED) is an early event along the natural history of T1DM, indicating a phenotype in risk for accelerated atherosclerosis, that may be independent of the classical cardiovascular risk factors^[4,5]. Interestingly, traditional cardiovascular risk factors altogether can not explain the totality of the cardiovascular risk in T1DM^[6,7]. Chronic hyperglycemia *per se*, although an important predictor of microvascular disease, is a weak predictor of macrovascular complications in both T1DM and T2DM^[8,9]. Thus, much of the residual cardiovascular risk still remains unexplained. In this context, ED becomes a new important risk factor that should be debated in the cardiovascular scenario. In the present review, we discuss recent evidences in the pathogenesis of endothelial dysfunction, its role as a risk factor for cardiovascular disease and the potential interventions for reducing endothelial dysfunction in T1DM.

THE NORMAL ENDOTHELIUM

The vascular endothelium forms the cell layer that is

directly in contact with the vascular lumen, separated from the smooth muscle layer of the basement membrane. Its role is to maintain the homeostasis between the blood and the arterial wall through the synthesis of substances that modulate vascular tone, inhibit platelet aggregation and control the proliferation of vascular smooth muscle cells^[10].

In endothelial cells, nitric oxide (NO) is essential for the maintenance of integrity and homeostasis of endothelium^[11]. NO is synthesized from L-arginine by the action of endothelial nitric oxide synthase (eNOS) in the presence of oxygen, NADP(H) and the NOS co-factor, tetrahydrobiopterin (BH4)^[12]. The synthesized NO diffuses itself quickly into the smooth muscle cell layer and into platelets where it activates guanylate cyclase (GCA), with consequent production of cyclic GMP (cGMP). The presence of cGMP, in turn, promotes vascular relaxation and inhibition of platelet aggregation, keeping the equilibrium between pro and anti-thrombotic factors in the blood and arterial wall. However, as the half-life of NO is very brief, rapidly oxidizing into nitrate, the continuous activation of eNOS becomes the key determinant of NO synthesis and tissue bioavailability^[11]. Normally, eNOS is activated by the turbulent blood flow against the luminal endothelial wall (shear-stress) as well as by the stretch of vascular wall cells and changes in the oxygen tension, promoting vascular muscle relaxation, an effect known as "endothelial-dependent vasodilation"^[13,14].

The stability of the endothelium is also dependent on endothelial repair and regeneration, which are determined by migration and proliferation of surrounding mature endothelial cell resident the vascular wall^[15]. Recently it has been demonstrated that circulating endothelial progenitor cells (EPCs) are important in the endothelial regeneration. EPCs are circulating bone-marrow-derived cells characterized by the expression of varying surface markers that adhere to the damaged endothelium promoting tissue repair^[15]. Circulating EPCs are considered biomarkers of endothelial function and prognostic indicators of cardiovascular morbi-mortality. Endothelial dysfunction represents the breakdown of this endothelium homeostasis, leading to a pro-thrombotic and pro-inflammatory that may lead to progressive atherosclerosis.

METHODS FOR ASSESSMENT OF ENDOTHELIAL FUNCTION

Endothelial function can be investigated through invasively and non-invasively techniques. Coronary arteries can be evaluated invasively through angiography with quantitative measurement of changes in the vascular diameter in response to infusion of acetylcholine^[16] and also through invasive venous occlusion plethysmography^[17], which measures forearm blood flow in response to acetylcholine infusion in the brachial artery. The invasive nature of

these techniques, involving artery cannulation and infusion of vasoactive drugs^[14], make them unfeasible to widespread use in clinical practice.

Non-invasive techniques, on the other hand, are being increasingly used in clinical settings. The flow mediated dilation (FMD) is the most popular technique currently used^[18-20]. The rationale in FMD is based on reactive hyperemia responsive to shear-stress caused by turbulent blood flow, causing NO to be released and promoting endothelium-dependent vasodilation^[14,21]. The measurement of vascular dilation can be done by capturing images of the brachial artery using high-resolution ultrasound^[18]. Reactive hyperemia occurs after a period of ischemia, induced by occlusion of the brachial artery, with a sphygmomanometer cuff inflated with progressive release of vasodilator mediators such as adenosine and ⁺H ions from ischemic tissue. When the release of blood flow occurs, sudden shear-stress is produced in the brachial vein endothelium, which is a strong stimulus for releasing NO^[19]. This mechanism depends on the integrity of eNOs. The lesser the dilation the more severe the dysfunction. Definition of ED is than considered arbitrarily when the increase in dilation is less than 8%^[20].

Other non-invasive techniques are used less frequently. Peripheral artery tonometry induced by reactive hyperemia^[22] assesses endothelial function by a combination of flow-mediated dilation and measurement of the amplitude of the arterial pulse wave expansion through a pneumatic sensor placed on the index finger. The microvascular reactivity on the forearm skin is evaluated with laser Doppler flowmetry, being the the iontophoresis of acetylcholine the endothelium-dependent vasodilator stimulus. The determination of the complacency of the dorsal hand vein is a minimally invasive method described by Aellig^[23] in 1981 which has been used by our group^[24]. It consists in a infusion of vasoactive drugs into the vein surface of the dorsum of the hand to measure endothelium-dependent vasodilation in response to acetylcholine, bradykinin or isoproterenol. The venous occlusion plethysmography can also be used to measure changes in forearm blood flow in response to reactive hyperemia. Finally, the measurement of the thickness of the intima-media layer (IMT) of the common carotid by ultrasound is a structural marker of atherosclerosis and correlates inversely with FMD in the brachial artery^[25]. Increases in the IMT are indicative of early atherosclerosis.

ENDOTHELIAL CHANGES IN DIABETES

Chronic sustained hyperglycemia in diabetes promotes important structural and functional modifications in the endothelium, as reported in both experimental and clinical studies^[26-29]. In the aorta of rabbits with alloxan-induced diabetes, endothelial changes are visible after 2 wk from the onset of hyperglycemia

and become more severe after 6 wk of the diabetes onset^[26]. The findings include adhesion of leukocytes, platelets and fibrin material on the endothelial surface. In mice, 6 wk after the onset of diabetes induced by streptozotocin (STZ), it is possible to observe increased endothelial permeability and endothelial cell apoptosis^[27].

In a classic study using samples of human skin and subcutaneous tissue obtained from autopsies and biopsies of 24 patients with T1DM, which were compared to 9 non-diabetic controls, the most important finding was the increase in the thickness of the basement membrane in T1DM patients compared with non-diabetic subjects^[28]. In another study^[29], the increased thickness of the capillary basement membrane of skeletal muscle from patients with 12 years of T1DM, could be reversed by intensive glycemic control during one year^[29]. In studies using electron microscopy, endothelial cells obtained from umbilical cord blood from pregnant women with T1DM show increased mitochondrial area when compared to pregnant women without diabetes^[28]. The clinical significance of these structural changes, however, is still not clear to predict future atherosclerosis.

Important functional changes occur in the endothelium of T1DM. Hyperglycemia induces excess of electrons that leak from the oxidative chain and are captured by oxygen, generating superoxide excess and oxidative stress. Excessive superoxide production uncouples eNOS, impairing NO production^[29]. The net effect is a reduction of NO production in response to shear stress in the inner vascular wall. By this way, the main determinant of ED is the preponderance of vasoconstrictor factors released by the endothelium in detriment of vasodilators factors due to the decreased availability of NO^[30]. The dysfunctional endothelium leads to a migration of blood cells into the arterial wall, inducing proliferation of smooth muscle cells, platelet aggregation, LDLc oxidation, monocyte adhesion and synthesis of inflammatory cytokines, all factors contributing to atherogenesis^[31].

In patients with T1DM, functional changes in endothelium occurs very early in the natural history of diabetes^[32]. The duration of diabetes is a major determinant for the presence of endothelial dysfunction in T1DM, being inversely correlated with the endothelium-dependent dilation. ED generally occurs in the first decade of T1DM, earlier than increases in the carotid intima-media layer thickness (Table 1).

ED is a common finding in T1DM, generally seen after 4 years of disease. In the study by Singh *et al*^[33], 31 adolescents with 6.8 years of T1DM and poor glycemic control presented both ED and increased intima-media layer thickness of carotid artery, compared with individuals without diabetes. The duration of diabetes was inversely correlated with the endothelium-dependent dilation^[33]. These results were confirmed by other authors^[34-38] and are in accordance

to the concept that endothelial dysfunction is predictive of early atherosclerosis in T1DM.

More recent data indicate that ED can occur even before 4 years of onset of T1DM^[4,39], preceding the onset of microalbuminuria. Järvisalo *et al*^[4] compared non-obese, poor-controlled, recent onset T1DM children with age-matched children without diabetes, with respect to FMD and the thickness of intima-media carotid. They observed the presence of endothelial dysfunction in 36% of cases, a lower peak of flow mediated dilation response and increased intima-media thickness compared with controls. The authors concluded that ED is a common finding in children in the early years of T1DM and may be a predictor for the development of premature atherosclerosis.

The presence of ED, however, is not uncommon before 4 years of T1DM^[32]. We found a prevalence of 35.7% of ED in a sub-group of T1DM patients with less than 5 years of diabetes^[5]. The data from the above studies indicates that it ED may begin to occur 3 to 5 years from the onset of T1DM.

FACTORS ASSOCIATED WITH ED IN T1DM

Gender

The impact of gender in ED is still undefined, but, in one study, boys with T1DM seemed to be at increased risk. Bruzzi *et al*^[40] studied 39 children with T1DM and 45 healthy age-matched controls, evaluated longitudinally with FMD at baseline and 1 year of follow-up^[40]. At baseline, T1DM boys and girls had similar FMD values, however, after 1 year, boys had more endothelial dysfunction than girls. The rationale of this difference is still unknown since multivariate analysis did not identify important predictors of endothelial dysfunction^[40].

Acute hyperglycemia

Acute hyperglycemia is capable to induce reversible

endothelial dysfunction in normal individuals. When non-diabetic subjects are acutely exposed to high concentrations of glucose during dextrose infusion for 6 h, there is an attenuation of the arterial endothelium-dependent vasodilation induced by methacholine (endothelium-dependent vasodilation) while preserving the vasodilator response to nitroprusside (non-endothelium dependent vasodilation)^[41]. This indicates that acute rises in blood glucose in contact to a previous normal endothelium can cause acute endothelial dysfunction, but it is not sufficient to promote vascular smooth muscle dysfunction. In another study in normal subjects^[42], it was also demonstrated that acute hyperglycemia can cause significant hemodynamic and rheological changes such as increases in systolic and diastolic blood pressure, heart rate and plasma catecholamines, while decreasing arterial blood flow to the leg. Platelet aggregation to ADP and blood viscosity also showed increments. When the authors infused the natural precursor of NO formation, L-arginine, blood pressure and artery flow changes were reversed. When they infused the inhibitor of endogenous NO synthesis, N^G-monomethyl-L-arginine (L-NMMA), hemodynamic effects of hyperglycemia were reproduced, indicating that acute hyperglycemia reduces NO availability even in normal subjects^[42].

The effect of acute high glucose in normal endothelium, however, is not observed in all studies. Houben *et al*^[43], studied the effect of acute glucose infusion for 24 h in normal individuals and did not observed changes in vascular dilatation of skin microcirculation induced by acetylcholine (Ach), nitroprusside, norepinephrine or nitric oxide synthase antagonist (L-NMA). The differences between studies may be due to methodological differences. It is accepted, however, that insulin can attenuate acute endothelial dysfunction, promoting compensatory vasodilation which may have biased the studies. In other studies, where the action of insulin was blocked

by octreotide, the effect of acute hyperglycemia alone was evident^[41].

Long-term hyperglycemia

The association between HbA1c and flow-mediated dilation (FMD) is seen in some cross-sectional studies with patients with T1DM. In the study of Ladeia *et al.*^[39], with 19 normo and microalbuminuric T1DM patients, there was a moderate positive correlation between FMD and HbA1c. In another study^[44], patients with T1DM with HbA1c above 6.0% had significant impairment of endothelial function compared to patients with HbA1c below 6%, indicating that chronic mild increases in mean hyperglycemia are also associated to ED in T1DM.

We studied the impact of chronic glycemic control in endothelial function of T1DM in a historical cohort study^[5]. T1DM adolescents under 5 year of disease were evaluated for ED and had their mean HbA1c obtained from medical records in the same institution since their diagnosis. Considering as a whole, the mean historical HbA1c was clearly higher in T1DM patients with endothelial dysfunction compared with T1DM without ED. Interestingly, we observed a moderate inverse correlation between FMD and the historical mean of HbA1c in the first 2 years after the diagnosis of T1DM but not with the more recent HbA1c. The plausible explanation was that endothelial function could be more affected by the long-term than by the short-term glycemic control, supporting the concept of metabolic memory^[45]. Glycation of the endothelium in the first years of T1DM seems, by this way, decisive to determine future endothelial dysfunction in T1DM^[32].

Post-prandial hyperglycemia

The effect of postprandial hyperglycemia in endothelial function was studied by Giugliano *et al.*^[42] in individuals with type 2 diabetes. The combined effect of postprandial glucose and hypertriglyceridemia was associated with increased serum concentrations of adhesion molecules such as ICAM-1, E-selectin and VCAM-1. Markers of oxidative stress such as nitro-tyrosine increased sharply after ingestion of 75 g of oral glucose. This effect was greater when an additional lipid overload was used, indicating that both acute hyperglycemia and hyperlipemia can affect endothelial function in diabetes^[46].

In another study, the same authors^[47] observed that, after a glucose overload, ED accentuates until the second hour, but returns to basal level after 4 h from the beginning of the overload. Though, lipid overload did not change FMD until the fourth hour. These data suggests that the effect of postprandial glycaemia in endothelial function is independent of the postprandial lipemia, although both might be mediated by increased oxidative stress.

Hypoglycemia

Recently, it was demonstrated that repeated episodes of hypoglycemia in subjects with T1DM may be associated with endothelial dysfunction and could be an aggravating factor for preclinical atherosclerosis. In a case-control study^[48], T1DM with repeated hypoglycemia episodes were compared with age and sex-matched T1DM controls who did not have frequent hypoglycemia. Vascular function was assessed by FMD, intimal-media carotid artery thickness (IMT) and endothelial dysfunction markers such as von Willebrand factor (vWf). The group with increased hypoglycemia episodes presented lower percentages of FMD in response to ischemia, increased IMT measures and higher endothelial function markers. In another study^[49], with cross-sectional design, T1DM children and age and gender-matched healthy children were evaluated for vascular function and continuous glucose monitoring system (CGMS) in order to compare the impact of glucose variability and hypoglycemia episodes in vascular function. Subjects with T1DM had significantly lower FMD compared to healthy children. However, when comparing CGMS parameters, the authors found significant inverse relationship between FMD with hypoglycemia indexes but not with variability indexes.

The biological rationale for hypoglycemia inducing endothelial dysfunction in T1DM is that acute hypoglycemia can induce rapid pro-inflammatory, platelet aggregatory, anti-fibrinolytic response, and recurrent hypoglycemia may induce changes in hemostatic factors and viscosity which may decrease perfusion in diabetic microangiopathy^[50].

Glycemic variability

Glycemic variability (GV) is a term exclusively related to blood glucose fluctuations and must be differentiated from post-prandial glucose (PPG). GV is related to glucose variability along the day, while PPG is related to the precise time of glucose rise after a meal. PPG effect in vascular function can also be influenced by other confounders such as hypertriglyceridemia.

Whether GV is an important factor to cause ED is still a matter of debate. The effect of glycemic variability in ED was studied in T1DM with normal urinary albumin excretion^[51]. Patients were exposed to 48 h of good (mean 113 mg/dL) or poor metabolic control (mean 286 mg/dL) and evaluated with FMD and serological markers of endothelial function. Both endothelium-dependent and endothelium-independent vasodilation were significantly impaired after the poor control period in relation to good glycemic control. There was also a significant increase in vWf levels after the deterioration of control. These results indicate that endothelial function may suffer significant impact of acute variability of blood glucose in T1DM, although it

can be reversed with improvement of glycemic control. However this effect was not seen in other studies. In the DCCT study, the GV in glycemic data using 7-point self monitoring blood glucose (SMBG) obtained every 3 mo did not correlated to macrovascular complications^[52]. We were also not able to detect a relationship between FMD and the standard deviation (SD) of glycemia in T1DM, using day 7-point SMBG for 30 d preceding FMD (data unpublished). Finally, in a cohort study of T1DM^[53], the standard deviation of blood glucose, calculated from self-monitoring blood glucose data along 11 years of follow up, was predictive for incident peripheral neuropathy^[53]. The influence of GV in vascular function and future micro or macro vascular complications of T1DM is not yet established.

Microalbuminuria

Microalbuminuria is strongly associated with ED in T1DM. Dogra *et al.*^[34] studied long-term T1DM patients with microalbuminuria with poor glycemic control who were compared to normoalbuminuric T1DM and to non-diabetic individuals. FMD was more severely impaired in T1DM patients with microalbuminuria being albuminuria an independent predictor of ED. In another study, Lekakis *et al.*^[35] observed lower FMD values in microalbuminuric compared with normoalbuminuric patients. In a similar study with children and adolescents with T1DM with less than 5 years of disease^[39], there was a negative correlation between the percent of endothelium-mediated dilation and albuminuria. Mean FMD was also significantly decreased in microalbuminuric. ED is also present in type 2 diabetes patients with normal albuminuria with long duration T2DM during chronic poor glycemic control^[54]. In T1DM patients with normoalbuminuria ED is less common^[40].

MECHANISMS OF ED IN T1DM

Oxidative stress

Children with T1DM have increased oxidative stress and reduction of anti-oxidant defense compared to healthy children and to their parents^[55,56] and these results are similar in adolescents with T1DM^[57]. Moreover, endothelial progenitor cells are also reduced in children with T1DM compared to non-diabetic controls possibly related to oxidative stress^[58].

Hyperglycemia can cause excessive production of superoxide in the mitochondria oxidative chain of endothelial cells. The excess of superoxide reacts rapidly with NO, reducing NO bioactivity and producing peroxynitrite (ONOO⁻). Peroxynitrite is a potent oxidant agent and an activator of the lipid peroxidation which may impair endothelial function by stimulating arachidonic acid metabolism^[59]. The overproduction of superoxide and NO favors the formation of peroxynitrite by interfering with the production of the eNOS cofactor,

tetrahydrobiopterin (BH4)^[60].

NAD(P)H oxidase is a chief determinant enzyme of superoxide production in animal models of vascular diseases, including diabetes^[32]. In arteries of patients with diabetes who were submitted to artery bypass surgery, it was demonstrated that the endothelium can produce superoxide induced by a dysfunctional eNOS. Dysfunctional eNOS is caused by the oxidation of the co-factor BH4 into BH2. The enzymatic uncoupling of eNOS in human endothelium turns eNOS into dysfunctional eNOS which promotes a transition from NO production to superoxide production^[60,61].

Protein kinase C pathway activation

Protein kinase C (PKC) is a cytoplasmic family of enzymes with a wide variety of actions in intracellular signal transduction. The activation of PKC by decreases endothelium derived nitric oxide synthesis, whereas its inhibition increases NO release. The beta isoforms are activated in response to hyperglycemia^[62]. The activation of PKC system is also associated with increased albuminuria in rats^[63].

There are several mechanisms in which PKC may decrease the bioavailability of NO. PKC antagonizes activation of eNOS, decreases NO concentration, and induces NAD(P)H oxidase to produce superoxide, which, in turn, uncouples eNOS, inducing the production of even more superoxide. PKC is associated with various vascular disorders such as a decrease of Na⁺/K⁺ ATPase, increased extracellular matrix, increased vascular permeability, contractility and cell proliferation. The activation of PKC system is also associated with increased albuminuria in rats^[63].

In a randomized double-blind placebo controlled clinical trial, in healthy individuals submitted to acute hyperglycemia with hyperglycemic clamp technique, FMD was attenuated by hyperglycemia and reversed after treatment for 7 d with the PKC beta inhibitor, LY333531, indicating that the PKC-B system is an important regulator of hyperglycemia-induced endothelial dysfunction^[64].

Advanced glycation products

In the presence of sustained hyperglycemia, tissue proteins such as collagen undergo non-enzymatic glycation and formation of cross-links, resulting in advanced glycation end-products (AGEs). AGEs promotes a permanent chemical modification of proteins, stimulating cellular responses through specific anti-proliferative receptors^[65,66]. These receptors were first observed in experiments in mouse peritoneal macrophages^[66], showing ability to remove modified glycated proteins. AGEs may reduce the availability of endothelial NO, and reactive AGE intermediates may compromise their anti-proliferative effect.

Polyol pathway activation

Chronic hyperglycemia increases the activity of aldose reductase enzyme and leads to activation of polyol pathway, transforming glucose into sorbitol and subsequently into fructose. It also induces the consumption of NADP(H), an important cofactor for NO synthesis^[61]. As NADP(H) is an important cofactor for NOS to NO synthesis, its depletion leads to reduction of NO production. It remains uncertain, however, the magnitude of importance in the prevention of human atherosclerosis.

ED AS A MARKER OF CARDIOVASCULAR RISK IN T1DM

Although endothelial dysfunction and chronic low-grade inflammation have been associated with atherothrombotic cardiovascular disease, independently of traditional cardiovascular risk factors in either individuals with or without diabetes, a clear cause-effect relationship with atherosclerosis is not yet established in the natural history of T1DM.

In non-diabetic patients with coronary disease, endothelial dysfunction is predictive for increasing risk of cardiovascular events^[67]. In an observational study, 157 patients with mild coronary disease were classified according to the severity of ED, which was defined by intracoronary ultrasound with vascular reactivity after administration of acetylcholine, adenosine or nitroglycerin^[67]. They were followed by a mean of 28 mo for the assessment of cardiovascular outcomes. At the end of follow up, patients with more severe ED presented 14% of cardiovascular events, while those with mild or no ED had no cardiovascular outcomes ($P < 0.05$)^[67]. This study demonstrated, for the first time, that patients with mild coronary disease but with severe ED were at increased risk for cardiovascular events.

Serum markers of ED

The vWf and C-Reactive protein (CRP) are related to ED and inflammation. In the population-based cohort study, the HOORN study^[68], the predictive value of the serum ED marker, vWf, was evaluated for cardiovascular mortality in T2DM patients. The cohort including 2,484 caucasian individuals with ages between 50-70 years, in which 27% had T2DM and 27% had impaired glucose tolerance, was followed by 5 years^[68]. Patients with vWf levels in the upper tertile had a 3 fold increase in cardiovascular mortality compared to those in the lower tertiles, even after adjustments for age, sex and glucose tolerance status. The relative risk for all-cause mortality associated with vWf was 2.03 (95%CI: 1.19 to 3.47). The predictive value of vWf was not confirmed in ARIC study^[69], however, vWf is also an independent predictor of cardiovascular mortality in specific populations^[70].

CRP is an inflammatory marker and can be increased in T1DM patients without clinical macroangiopathy, compared with healthy subjects^[71]. This increase is greater in the presence of micro or macroalbuminuria compared with normoalbuminuric patients indicating an association between endothelial dysfunction and vascular inflammation^[71].

The mechanisms by which the cardiovascular risk is associated with elevated levels of vWf and CRP are not completely understood. It may reflect generalized endothelial dysfunction, increased prothrombotic state^[71], inflammation and greater risk for developing atherosclerosis^[72]. Von Willebrand factor in combination with *t*-PA measurement may also be an index for endothelial dysfunction^[73].

Markers of endothelial function can also be determinants of inflammation. In the EURODIAB Prospective Complications Study^[74], a nested case-control study of 543 T1DM participants, the levels of serum markers of ED such as E-selectin, vascular adhesion molecule-1 cell (VCAM-1) and inflammatory markers were determined. In this study, endothelial dysfunction was strongly associated with inflammatory activity suggesting that endothelial dysfunction may interact with vascular inflammation in T1DM which potential consequences in accelerating atherosclerosis^[74].

Flow mediated dilation

Impaired flow mediated dilation (FMD) may also predispose to early atherosclerosis in T1DM patients, as seen by the development of increased carotid artery thickness (IMT). In a cross-sectional study, 45 children with T1DM and 30 healthy matched in age, gender and body size were evaluated for FMD and IMT^[75]. Children with diabetes presented lower peak FMD response and increased IMT compared to non-diabetic children. In another cross-sectional study^[75], T1DM adolescents without diabetes complications were compared with healthy age-matched controls in respect to FMD and the presence of diastolic dysfunction with pulse wave Doppler and tissue Doppler echocardiography measurements. ED was associated with segmental diastolic dysfunction. These studies suggest that ED is associated with indirect evidences of premature atherosclerosis, however, long-term prospective studies are still needed to conclude if FMD is predictive for cardiovascular events in early T1DM.

CLINICAL MANAGEMENT OF ED IN T1DM**Intensive insulin therapy and glycemic control**

There are compelling evidences indicating that optimizing glycemic control with intensive insulin therapy reduces the development and progression of microvascular complications^[1]. Although endothelial

dysfunction and oxidative-stress are early changes in T1DM, both conditions are only partially reversed by insulin therapy alone^[76]. In adults with 8 years of T1DM who are in poor glycemic control, acute intravenous insulin infusion can only partially reverse impaired FMD, even after completely normalizing glycaemia. It is likely that a more prolonged treatment is necessary for achieving a reversion to normal functioning of endothelium-dependent vasodilation in T1DM^[76].

In a clinical trial, 92 children and adolescents with T1DM in conventional insulin therapy were randomized for either continuing in conventional insulin therapy or to switch to a more intensive insulin therapy, including insulin infusion pump and multiple insulin injections. After 1 year of intensive insulin therapy, the baseline vascular response to acetylcholine and the levels of E-selectin improved significantly in the intensive group, while no effect was seen in the conventional group. Interestingly, in this study the benefit was independent of HbA1c, suggesting that intensive insulin therapy may confer vascular protection in addition to improving glycemic control^[76].

Exercise

Exercise has a great impact in the mitigation of ED in patients with cardiovascular risk factors both in T1DM and T2DM. In children with T1DM, 30 min of aerobic training, two times a week, for 18 wk can significantly increase flow mediated dilation in around 65%^[77]. In adults with T1DM, 60 min of aerobic training, 2 times a week, significantly improves flow mediated dilation in more than 50% after 24 wk^[78]. In a cross sectional study, T1DM adolescents who did more than 60 min daily of moderate-to-vigorous physical activity have higher flow mediated dilation than inactive patients with diabetes^[79]. Many other studies also show improvement of vasodilator response in T2DM without coronary artery disease, with both aerobic and mixed aerobic/resistance training with 8 to 12 wk of duration^[80-82].

The main mechanism underlying the amelioration of vasodilation in response to exercise is largely related to the increased in nitric oxide (NO) bioavailability, resulted from the increased activity and expression of the eNOS and the diminished degradation of NO due to the action of radical oxygen species (ROS). Cultured cells experiments^[83] indicate that shear-stress can induce eNOS expression and activity due to stabilization eNOS mRNA or increasing its synthesis. In humans with coronary artery disease, it was also demonstrated a two-fold increase in eNOS expression and a 3.2 increase in the phosphorylation of eNOS after 4 wk of regular training^[84]. The increase in antioxidant defenses such as the activity of superoxide dismutase and glutathione peroxidase is another important mechanism underlying the improvement of endothelial function by exercise seen in patients with

heart failure^[85].

Exercise training can increase the number of circulations EPCs in healthy subjects^[86] and coronary artery disease patients^[87] after 4 wk of regular training. EPCs are decreased in patients with T1DM compared to healthy subjects^[83,88]. The effect of exercise impact in EPCs in type 1 patients, however, remains to be clarified.

Anti-oxidants

Experimental studies demonstrated that antioxidants can modulate the response of the endothelium dependent vasodilation, endothelium-leukocyte interactions and the balance of pro and anti-thrombotic factors^[89-91].

In clinical studies, treatment with oral high-dose vitamin E during 6 mo have yielded conflicting results in ED improvement in patients with T1DM. In the first study, Skyrme-Jones *et al.*^[92] compared the effect of vitamin E 1000 UI/d with placebo in a double-blind randomized clinical trial in patients with T1DM in FMD. They found significant increases in FMD after 3 mo in the group receiving vitamin E. They considered that vitamin E decreased the LDLc oxidant capacity, thus reducing ED. In a double-blind randomized clinical trial in adults with both T1DM and T2DM, Beckman *et al.*^[93] compared the use of a combination of vitamin E (800 UI/d) with vitamin C (1000 mg/d) compared to placebo. After 6 mo, FMD increased significantly in the T1DM group but not in T2DM. These data are promising, however, neither all studies confirm these findings. In a randomized clinical trial, Economides *et al.*^[94] studied the effect of high-dose vitamin E (1800 UI) against placebo in T1DM and T2DM along 12 mo but failed to find improvements in ED^[94]. The clinical effectiveness of vitamin E in improving ED and reducing the progression to atherosclerosis remains to be established in larger trials in T1DM.

Ascorbic acid infused together with intravenous insulin with near normalization of glycaemia, can rapidly normalize endothelial dysfunction in T1DM^[75]. This effect is not completely attained, however, when either intensive glycemic control with insulin or ascorbic acid infusions are used alone, indicating that an additive effect of both treatments exist, an effect that may be limited to new-onset type 1 diabetes^[89]. Ascorbic acid can also decrease transcapillary albumin escape^[95] and urinary albumin excretion in T1DM adults^[96]. In children with T1DM, the combined use of ascorbic acid and vitamin E can increase superoxide-dismutase levels^[57].

Low ingestion of antioxidants, especially vitamins, is associated with increased risk of cardiovascular disease and atherosclerosis^[97,98]. The inverse correlation between concentrations of antioxidant agents, vitamins and disease risk could be associated to higher requirement of antioxidant molecules during inflammatory diseases.

Insufficient supply with these compounds may further accelerate disease process^[99]. On the other hand, these data are not yet been convincingly established in clinical trials and are still controversial^[100-102].

Statins

Statins may have benefic effect on endothelial dysfunction in patients with T1DM. In a clinical trial with 204 long-term T1DM randomized to receive atorvastatin 40 mg plus hypolipemic diet or placebo plus hypolipemic diet for 6 mo, FMD increased 44% and PAI-1 was reduced in atorvastatin group compared to placebo^[103]. Similar results were observed in a small cross-over trial including 16 T1DM with microalbuminuria^[104] who received atorvastatin 40 mg or placebo for 6 wk with a 4-wk period of washout. FMD and non-endothelium dependent vasodilation increased significantly while using atorvastatin. In a meta-analysis of 10 studies including 845 patients with both T1DM and T2DM^[105], statin therapy significantly ameliorates FMD in patients with diabetes, although heterogeneity among trials was found. Statins however, improved FMD only in patients with better endothelial function. Factors associated with improvements were: T1DM, younger age, lower baseline lipid levels and blood pressure. Mechanisms enrolled in this effect are not completely known but may be related to reductions in LDLc as well as pleiotropic anti-oxidant effects of statins.

ACE inhibitors

Experimental evidences suggest that ACE inhibition may have benefic effects to the endothelium *in vitro*^[106,107]. In a clinical trial, quinapril showed benefit in coronary endothelial function of non-diabetic patients with CAD^[108]. ACE inhibitors improve FMD in T1DM with microalbuminuria although not in T1DM with normoalbuminuria^[109]. In another small trial with normotensive T1DM patients with microalbuminuria, ACE-I inhibitors improved both FMD and GTN in the femoral artery after 1 wk of treatment^[110].

The direct renin blockade was studied in normo-albuminuric T1DM with the use of aliskiren during 4 wk of monotherapy, followed by 4 wk of a combination of aliskiren and ramipril. In both conditions of hyperglycemia and euglycemia of short duration, obtained through euglycemic clamp and hyperglycemic clamp techniques, ED ameliorated with aliskiren alone and improved further when in combination with ramipril. This effect only occurred in the euglycemic phase of the study. Effects were abolished when patients became hyperglycemic^[111].

PKC inhibitors

Ruboxistaurin (RBX) is an orally administered isoform-selective inhibitor of PKC which was demonstrated to have beneficial effect in experimental models

of diabetic retinopathy^[112] and in hemodynamic retinal abnormalities of patients with diabetes^[113]. The studies PKC-DRS^[114] and PKC DRS2^[115] showed a 50% reduction in vision loss of patients treated with RBX. The effect of RBX was than studied in 2 combined phase 3 trials: MBDL and MBCU. Both were randomized, double-blind, placebo-controlled, clinical trials, including T1DM and T2DM with ages above 18 years. Patients had HbA1c below 11%, blood pressure below 160/90 mmHg and diabetic retinopathy. Patients were submitted to pan-photocoagulation or focal photocoagulation after randomization. Patients were than randomized to RBX 32 mg or placebo and followed by 36 mo (in MBDL) and 48 mo (in MBCU). Altogether, 1040 patients were randomized. Sustained moderate visual loss occurred in 4.4% of placebo vs 2.3% of RBX treated patients ($P = 0.045$). The results were promising, indicating a potential reduction in visual loss of 50% above standard care^[116]. RBX has also been studied in diabetic neuropathy in other smaller studies. In a 6 mo clinical trial, RBX vs placebo in patients with both T1DM and T2DM. Patients who were randomized for RBX presented improvement of neuropathic symptoms and ameliorated decreased skin microvascular blood flow^[117]. Although promising, RBX is not available for clinical use.

CONCLUSION

ED should be a concern for clinicians as an early and common phenomenon in T1DM, which may be predictive for future microvascular disease and early atherosclerosis. The clinical use of endothelial function measurement in clinical practice, specially FMD, is a potential tool to enhance cardiovascular risk prediction. Long-term intensive insulin treatment with optimized glycemic control along with exercise training are essential to prevent ED in these patients. Drugs such as statins and ACE-inhibitors are partially effective and may be influenced by the degree of hyperglycemia, with better response in microalbuminuric patients. There is also a possible benefit in using anti-oxidants such as vitamin E and vitamin C, but there is a clear demand for long-term randomized clinical trials to define their role in ED treatment. New agents such as PKC inhibitors are still investigative, but hold promise for future treatment of ED in T1DM.
