Abstract

Critical illness in patients with pre-existing diabetes frequently causes deterioration in glycaemic control. Despite the prevalence of diabetes in patients admitted to hospital and intensive care units, the ideal management of hyperglycaemia in these groups is uncertain. There are data that suggest that acute hyperglycaemia in critically ill patients without diabetes is associated with increased mortality and morbidity. Exogenous insulin to keep blood glucose concentrations < 10 mmol/L is accepted as standard of care in this group. However, preliminary data have recently been reported that suggest that chronic hyperglycaemia may result in conditioning, which protects these patients against damage mediated by acute hyperglycaemia. Furthermore, acute glucose-lowering to < 10 mmol/L in patients with diabetes with inadequate glycaemic control prior to their critical illness appears to have the capacity to cause harm. This review focuses on glycaemic control in critically ill patients with type 2 diabetes, the potential for harm from glucose-lowering and the rationale for personalised therapy.

Key words: Diabetes; Critically ill; Intensive care; Management; Personalised therapy

Core tip: With diabetes increasing in prevalence, the optimal management of glycaemia in critically ill

patients with pre-existing diabetes remains unknown. Recent data has highlighted therapeutic uncertainties specific to these patients with suggestions that targeted blood glucose concentrations may benefit from consideration of a patient's premorbid glucose state. In patients with uncontrolled type 2 diabetes, it may be safer to target blood glucose concentrations between 10-14 mmol/L, however definitive studies of critically ill patients with poorly controlled diabetes are required. In contrast, in patients with CIAH, or those with well-controlled diabetes (HbA1c < 7.0) have data supporting a more conservative target (6-10 mmol/L).

INTRODUCTION

Patients with diabetes mellitus may develop an acute severe illness that necessitates a level of care that can only be provided within an intensive care unit (ICU)^[1]. In the majority of critically ill patients with pre-existing diabetes, the pathophysiological response to the acute illness or injury, and/or the treatments involved, may lead to deterioration in glycaemic control. Despite the high and increasing prevalence of diabetes (both within the community and in the critically ill), the optimal management of glycaemia in critically ill patients with pre-existing diabetes remains unknown. However, recent data has highlighted the therapeutic uncertainties specific to these patients.

The majority of critically ill patients with diabetes have type 2 diabetes^[2]. The limited information relating to patients with type 1 diabetes precludes speculation as to whether management of glycaemia in this group should be different from that in type 2 diabetes. Accordingly, this review focuses on critically ill patients with type 2 diabetes addressing issues including prevalence, potential rationale for harm and evidence for personalised therapy.

PREVALENCE

In the community type 2 diabetes occurs frequently with global health expenditure estimated at US \$376 billion in 2010, which is expected to rise to US \$490 billion by 2030 due to increasing prevalence^[3,4]. In Australia it is estimated over the last 15 years, the prevalence has increased from 8.5% to 12.0%^[5]. There is a substantial variation in the prevalence of diabetes between countries, peaking in Nauru (31%)^[6]. Factors relating to the increase in prevalence include increasing obesity, increasing age and racial region. A limitation in estimating prevalence is that many patients remain unaware of their diagnosis.

For example, the estimated prevalence in the United States is 13% of the population, of which 40% is unrecognised or undiagnosed^[7].

Diagnosis of diabetes

The prevalence of recognised and unrecognised diabetes varies according to the definitions used, as well as the location and the populations studied. The current diagnostic criteria used by the American Diabetes Association (ADA) involves one of the following; an HbA1c \geq 6.5, a fasting glucose \geq 7 mmol/L, a 2 h post glucose tolerance test following a 75 g oral glucose load of \geq 11.1 mmol/L, or a random blood glucose \geq 11.1 mmol/L with symptoms of hyperglycaemia^[8]. These criteria were ratified by the World Health Organization (WHO) in 2011^[9].

Given each test (HbA1c, fasting, postprandial or random blood glucose) reflects different physiological phenomena, different populations may be diagnosed when using each criterion^[10,11]. Each diagnostic test has advantages and disadvantages. Both the fasting glucose and 2 h post glucose tolerance test are established standards, relatively rapid and easy to perform, and predict microvascular complications. However, these tests are subject to day-to-day variability, require patients to fast and only reflect glucose homeostasis at a single point in time^[12]. HbA1c is convenient (with no fasting required), can predict microvascular complications, is a better predictor of macrovascular disease (than fasting glucose or 2 h post glucose tolerance test) and has low day-to-day variability^[8,12]. Additionally, as the physiological responses to acute illness cause deterioration in glycaemia, estimating glucose control prior to the acute illness - using markers such as HbA1c - to accurately determine which patients have unrecognised diabetes and which patients have "stress hyperglycaemia" is possible^[13]. Weaknesses include variations amongst ethnic groups and age, it may be misrepresentative in certain medical conditions (such as certain forms of anaemia and haemoglobinopathies) and the need for a validated, standardised assay^[12].

Prevalence of diabetes in hospitalised patients

Compared to the general population, the prevalence of diabetes in hospitalised adult patients (*i.e.*, admitted to general wards) is considered to be greater. Depending on the population, estimates range from between 11%-35% of all patients (Table 1).

Numerous studies in the critically ill have evaluated the prevalence of glucose intolerance (Table 1). However, a limitation of the studies reported is that investigators were unable to identify those patients who had so-called "stress hyperglycaemia" (or critical illness associated hyperglycaemia (CIAH) - the condition of acute glucose intolerance that is confined to the period of critical illness) and those who have unrecognised diabetes. Several studies use either fasting blood glucose (\geq 7 mmol/L) and/or random

Table 1 Prevalence of diabetes in hospital population (chronological order)

Ref.	Year	R-D	UR-D	Total study patients	Location	Diabetes diagnosed by	Unrecognised diabetes diagnosed by
Umpierrez <i>et al</i> ^[14]	2002	495 (26%)	223 ¹ (12%)	1886	Atlanta, United States	Admission history	Fasting blood glucose ≥ 7 mmol/L Random blood glucose ≥ 11.1 mmol/L $\times 2$
Wallymahmed <i>et al</i> ^[15]	2005	126 (11%)	13 ¹ (1%)	1129	Liverpool, United Kingdom	Admission history Hospital records	Random blood glucose ≥ 11.1 mmol/L
Wexler <i>et al</i> ^[17]	2008	136 (19%)	33 (5%)	695	Boston, United States	Admission history Hospital records	HbA1c > 6.5
Mazurek <i>et al</i> ^[18]	2010	342 (35%)	152 (16%)	971	New York, United States	Admission history Hospital records Medication review	HbA1c ≥ 6.5
Feldman-Billard <i>et al</i> ^[16]	2013	355 (17%)	156 ¹ (7%)	2141	Multicentre (France)	Admission history	Fasting blood glucose ≥ 7 mmol/L

¹May include patients with stress hyperglycaemia/critical illness associated hyperglycaemia. R-D: Recognised diabetes; UR-D: Unrecognised diabetes.

glucose concentrations (≥ 11.1 mmol/L) for diagnosis of diabetes^[14-16].

Investigators have also measured glycated haemoglobin (HbA1c) on admission to identify hospitalised patients with unrecognised diabetes. A prospective observational study of 695 patients in Boston, Massachusetts^[17], selected a cutoff HbA1c of $> 6.5\%$ to diagnose diabetes, with 19% of patients having diabetes previously diagnosed and 5% having undiagnosed diabetes. Another study of 971 patients admitted to the general medical ward of an urban hospital located in the Bronx, New York^[18] - which may be assumed to admit a larger cohort of lower-income patients - 35% were known to have diabetes, and 16% undiagnosed diabetes, using an HbA1c ≥ 6.5 .

In summary, the prevalence of diabetes in hospitalised patients varies according to geography. In the developed world, diabetes is more prevalent amongst lower socioeconomic groups^[19-21]. Furthermore, diabetes is a risk factor for certain diseases (e.g., cardiovascular disease) and prevalence will be greater if a specific population (e.g., patients presenting with myocardial ischaemia) is studied^[22].

Prevalence of diabetes in patients admitted to ICU

The prevalence of diabetes in patients admitted to the ICU is estimated to be between 12%-40% (Table 2). Similar to the prevalence in hospitalised patients, the wide range reflects the definitions used and the population studied. Multiple single centre observational studies from the United States^[23-25] report prevalence between 13% and 21%, therefore it is likely that the true prevalence is close to this range. More recently, Falciglia *et al*^[26] undertook a retrospective cohort study across 173 ICUs in the United States and reported that 30% of the 259040 patients had a history of diabetes according to ICD-9 codes^[26].

A single centre, observational study from London, United Kingdom^[27], found 16% of patients had a history of diabetes. A retrospective observational study of 4946 patients admitted to one of two hospitals in Melbourne and Sydney, Australia^[28], reported 15%

had diabetes. While a single, mixed medical/surgical ICU from Amsterdam, The Netherlands^[29], found 12% of 5961 patients admitted had a history of diabetes. These data indicate that the prevalence in other developed countries may be similar to, or slightly less than, the United States.

Data from international studies are consistent with this concept. Stegenga *et al*^[30] utilised data collected as part of a randomised interventional study^[31] to evaluate whether diabetes affects the outcome of sepsis in patients admitted to one of 164 ICUs across 11 countries and reported that 23% had pre-existing diabetes. In retrospective observational data derived from 44964 patients admitted to one of 23 ICUs worldwide^[32], 29% had a history of diabetes documented in their medical records, but the prevalence varied substantially according to geography. For example, in an ICU from Geelong, Australia, the prevalence was 14%, while in a hospital < 100 km away (Melbourne) it was 24%, whereas patients admitted to Tampa Bay, United States, the prevalence was 39%.

The prevalence of diabetes in the critically ill varies across studies. Multiple observational studies estimate the prevalence at 12%-30%^[23-29,30,32-35]. However, these studies have significant limitations. Most importantly, the prevalence may be under represented due to diabetes that is either unrecognised or not documented.

A number of interventional studies have also reported diabetes prevalence in ICU patients (Table 2). Two prospective, randomised, controlled studies of surgical and medical ICU patients admitted into the ICU in Leuven, Belgium, compared an intensive insulin therapy (ITT, blood glucose level 4.4-6.1 mmol/L) vs conventional treatment (insulin started if the blood glucose was > 12 mmol/L and maintained between 10-11.1 mmol/L)^[36,37]. These studies reported diabetes at 13% and 17% respectively.

Other interventional studies include single centre^[38,39] and multicentre trials^[40-42], with the largest being in 2009, the NICE-SUGAR (Normoglycaemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation) study. This was conducted across 42 ICUs

throughout Australia, New Zealand and Canada^[41], and noted 20% of its 6029 patients with a history of diabetes, with the majority (92%) having type 2 diabetes.

It should be recognised that there are limitations to using data from these interventional studies. Inclusion into these studies usually requires hyperglycaemia and therefore leads to selection bias, which artificially increases any estimate of prevalence. The interventional trials estimated ICU prevalence at 13%-40%^[36-42].

Prevalence of unrecognised diabetes

Patients may have diabetes that is unrecognised prior to admission^[2]. This may not represent "stress hyperglycaemia" or CIAH - as the hyperglycaemia is chronic rather than acute. Unrecognised diabetes is important as it not only impacts on estimations for the actual prevalence of the condition, but, as a growing

body of evidence suggests, chronic glucose control may have implications on optimal acute glucose ranges in the critically ill.

Hospital and ICU prevalence of unrecognised diabetes can be estimated from the studies mentioned (Tables 1 and 2) along with other studies cited below (Table 3). Hospital prevalence is estimated to be between 5%-16%^[16-18,43] and ICU prevalence between 6%-14%^[34,44]. The prevalence in patients with ischaemic heart disease (*e.g.*, presenting with acute myocardial infarction) appears to be higher^[45,46].

In two European studies, patients with an acute myocardial infarct and without a history of diabetes subsequently underwent an oral glucose tolerance test (OGTT) to diagnose diabetes^[45,46]. The prevalence of diabetes was found to be over 30% at discharge, and between 25%-31% at 3 mo. In London (United Kingdom), Emergency Department patients were

UR-D: Unrecognised diabetes; OGTT: Oral Glucose Tolerance Test; AMI: Acute myocardial infarction.

screened for diabetes *via* fasting blood glucose^[47] and it was reported that 3% patients had unrecognised diabetes.

We recently performed a single centre observational study in a mixed medical/surgical ICU in Adelaide, Australia, and separated patients with diabetes (either known or unrecognised) and CIAH using HbA1c to accurately estimate the prevalence of each condition^[34]. Of 1000 consecutively admitted ICU patients, 22% had known diabetes (5% were type 1) and 6% had unrecognised diabetes (HbA1c \geq 6.5%). The absence of previously diagnosed diabetes was confirmed by a phone call to the patient's usual local medical officer (general practitioner).

Subsequently, Hoang *et al*^[44] also estimated the prevalence of undiagnosed diabetes in a prospective, observational study in a single medical ICU^[44]. All patients with hyperglycaemia and those with known diabetes underwent measurement of HbA1c with diabetes defined as an HbA1c \geq 6.5%. Sixty-six percent of the 299 patients enrolled into the study had a history of diabetes. Of the remaining 102 hyperglycaemic patients without diabetes, 14% had an HbA1c \geq 6.5%.

In summary the prevalence of undiagnosed diabetes is difficult to determine, and as previously noted, depends on the definitions used and the location of the patient population. Current "best estimate", albeit on limited data from single centres, suggest that the prevalence of undiagnosed diabetes is either similar to, or slightly greater than, the background prevalence in the community.

RATIONALE FOR HARM FROM HYPERGLYCAEMIA, HYPOGLYCAEMIA AND GLYCAEMIC VARIABILITY

Hyperglycaemia

Hyperglycaemia in type 2 diabetes reflects the outcome of factors affecting both insulin secretion,

with β -cell dysfunction resulting in a relative insulin deficiency, and insulin resistance as a result of both environmental and genetic factors^[48,49]. However, the pathogenesis of hyperglycaemia in the critically ill patient, either with CIAH, or in those with pre-existing diabetes and experiencing a deterioration in their glucose control, is complex and poorly understood^[2]. Patient predisposition (including insulin resistance and β -cell function), the underlying illness (which can result in catecholamine release, stimulation of the hypothalamic-pituitary-adrenal (HPA) axis, and the release of inflammatory cytokines) and the management involved (including glucocorticoids, vasopressors and nutrition) appear to be of major relevance^[1].

The activation of the HPA axis and the sympathetic system cause the "stress" response. In the majority of patients "stress" hormones (including cortisol and catecholamines) markedly increase. In addition, the underlying illness may stimulate the production of cytokines (such as TNF- α , IL-1 and IL-6)^[1,50]. These three components (HPA axis, sympathetic system and cytokine release) lead to excessive gluconeogenesis, glycogenolysis and insulin resistance, thereby augmenting stress hyperglycaemia^[50]. Glucagon is the major modulator of gluconeogenesis and may be stimulated by TNF- α , however cortisol and adrenaline (epinephrine) are also likely to contribute^[1,51,52].

Insulin resistance is thought to occur due to a number of pathways. Glucose enters cells *via* plasma membrane glucose transporters (GLUTs), which are down regulated in times of stress, possibly due to the presence of TNF- α and IL-1^[50]. Diminished glucose uptake by peripheral tissue may occur due to high cortisol and adrenaline (epinephrine) concentrations^[1,53]. As discussed, acute illness results in increased level of cytokines, which exacerbates hyperglycaemia and stimulates inflammation and oxidative stress^[1].

It should be considered that acute hyperglycaemia may represent a "protective" physiological response of

the host during periods of stress^[50]. An acute rise in glycaemia may facilitate glucose delivery at critical times and promote anti-apoptotic pathways, protecting against cell death^[50]. While uncontrolled acute hyperglycaemia is clearly harmful, the threshold at which harm occurs in the critically ill patient remains to be determined^[2]. The majority of studies that have evaluated this issue have enrolled heterogeneous cohorts - and patients with diabetes only comprised a small proportion of the sample evaluated. Based on recent data it is increasingly likely that the glucose threshold in a patient with diabetes, particularly those with chronic hyperglycaemia, will differ from that in a patient who is naive to hyperglycaemia. A patient with poorly controlled diabetes, i.e., with a history of high blood glucose levels and consequently high HbA1c, will be more tolerant of hyperglycaemia but susceptible to the adverse effects of hypoglycaemia (see below), such that the thresholds for both variables are greater than a patient who is naive to hyperglycaemia - either those with well controlled diabetes or those with CIAH.

Multiple studies have examined the effects of hyperglycaemia on morbidity and mortality in the ICU population with inconsistent and controversial outcomes. Moreover, the majority of these studies have not categorised patients into those with chronic hyperglycaemia or acute glucose intolerance.

There are numerous observational studies (Table 4). In 2005, a case controlled study of 7285 ICU patients reported that in individuals without known diabetes, mortality was increased when blood glucose levels were > 8 mmol/L but this signal was absent in patients with diabetes^[35]. Overall, mortality was significantly greater in patients without diabetes when compared to patients with diabetes. A retrospective study of 2713 patients admitted into ICU^[23] reported an association between mortality and hyperglycaemia in patients without a history of diabetes in the cardiac, cardiothoracic, and neurosurgical intensive care units. In an audit of 5365 ICU

patients evaluated before and after implementation of an intensive glucose control policy^[24], mortality was increased in patients with hyperglycaemia who were not known to have diabetes when compared to those with diabetes. In 2008, Egi *et al.*^[28] reported a retrospective study of 4946 patients in which ICU mortality increased with increasing mean blood glucose level in patients without diabetes but this signal of harm was absent in those with pre-existing diabetes^[28].

A retrospective cohort study of 259040 ICU admissions also reported an association between mortality and hyperglycaemia, with the relationship far stronger in patients without a diagnosis of diabetes when compared to those with pre-existing diabetes^[26]. A retrospective analysis of a previous study^[31] included 830 patients admitted with severe sepsis (defined as sepsis associated with acute organ dysfunction)^[30], and reported that hyperglycaemia was predictive of subsequent death in those patients not known to have diabetes. Additionally, a multicentre retrospective study of 44964 patients divided into 2 cohorts (with and without known diabetes)^[32], reported increased mortality with higher mean blood glucose concentrations (≥ 7.8 mmol/L) when compared to blood glucose concentrations 4.4-7.8 mmol/L in patients without diabetes. In contrast, patients with diabetes were more likely to die when mean blood glucose concentrations were between 4.4-6.1 mmol/L when compared to patients with greater blood glucose concentrations (6.2-10 mmol/L).

A number of interventional studies have evaluated the relationship between chronic and acute hyperglycaemia and outcomes (Table 5). In a pooled analysis of studies conducted in a single centre in Leuven, intensive insulin therapy (ITT, aiming for blood glucose concentrations between 4.4-6.1 mmol/L) was reported to reduce mortality and morbidity in patients without a diagnosis of diabetes, but this was not the case in patients with diabetes, if anything, there was a trend for harm with intensive insulin therapy in patients with diabetes such that mortality was non-significantly greater at a lower mean blood glucose range (6.1-8.3 mmol/L, 21.2% vs < 6.1 mmol/L, 26.2%, $P = 0.4$ and > 8.3 mmol/L, 21.6%, $P = 0.9$)^[54].

Subsequently, a number of interventional, randomised, controlled trials, containing patients with diabetes, comparing ITT to more conventional glucose targets have been published^[38-42]. A trial of 523 mixed (medical and surgical) ICU patients^[39] reported no survival benefit in patients with diabetes with ITT, but ITT was associated with an increased prevalence of hypoglycaemia. The Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP) study assigned 537 ICU patients with severe sepsis to either ITT or more conventional glucose targets while receiving either 10% pentastarch or a modified Ringers lactate in a two-by-two factorial study^[38]. The study was suspended at interim analysis for safety reasons

with ITT being associated with increases in episodes of severe hypoglycaemia and adverse events. De La Rosa *et al.*^[42] also evaluated ITT in 504 ICU patients (61 with diabetes) and there was no mortality or morbidity benefit observed, but an associated increased risk of hypoglycaemia, when administering ITT.

In 2009, the NICE-SUGAR study compared ITT with conventional glucose control in 6029 ICU patients and established that the observations from the initial Leuven studies regarding ITT were not generalisable outside that specialised institution^[41]. However, amongst the 1211 patients with pre-existing diabetes in the NICE-SUGAR study the administration of ITT did not appear more harmful than in patients without diabetes. The Glucontrol study^[40], an international, multicentre trial involving over 1000 ICU patients—was stopped early due to protocol violations, and it was, accordingly, underpowered. However, there was no evidence to suggest any benefit with ITT and data in patients with diabetes were not specifically described.

Recently a number of studies have attempted to measure chronic glycaemia as a dynamic (HbA1c), rather than a binary, variable (*i.e.*, presence of diabetes - yes/no) (Table 6). Egi *et al.*^[55] performed a retrospective observational study of 415 patients with diabetes (from two Australian ICUs) in whom glycated haemoglobin (HbA1c) had been measured within 3 mo of their critical illness and evaluated how this measure of pre-existing glycaemia impacted on the interaction between acute glycaemia and mortality^[55]. It was reported that in patients with elevated preadmission HbA1c levels ($> 7\%$) the number of deaths were significantly fewer when blood glucose concentrations were > 10 mmol/L.

Consistent with this observation, we recently measured HbA1c on admission and glucose concentrations for the first 48 h of ICU admission^[34] and observed that acute peak glucose concentrations were associated with increased mortality only in patients with adequate premorbid glycaemic control (defined as HbA1c $< 7\%$), but not in patients with chronic hyperglycaemia (defined as an HbA1c $\geq 7\%$). This finding was also supported by Hoang *et al.*^[44] who assessed the prevalence of undiagnosed diabetes (*i.e.*, HbA1c $\geq 6.5\%$) among those with hyperglycaemia in a medical ICU. Patients with an HbA1c $\geq 6.5\%$ were found to have significantly lower mortality compared to those with an HbA1c $< 6.5\%$ (11.7% vs 19.3%, $P = 0.038$), despite having greater glucose concentrations.

In summary the outcomes of the largest and most generalisable randomised study are consistent with the concept that the optimal glucose concentrations in unselected critically ill patients are between 6-10 mmol/L^[41]. However, observational data, post-hoc analysis of interventional studies and studies measuring chronic glycaemia as a dynamic variable suggest that patients with pre-existing diabetes may warrant higher targets. Indeed, there is increasing data suggesting that targets should be personalised depending on both

diabetic status and recent glycaemic control.

Hypoglycaemia

In most cases, treatment of hyperglycaemia in the critically ill involves the use of insulin, which is associated with increased risks of both hypoglycaemia and glycaemic variability^[56]. The severity of illness may also result in a hypoglycaemia and therefore it is important to be circumspect when attributing mortality to hypoglycaemia^[57]. Additionally, hypoglycaemia may have adverse biological effects including an increase in systemic inflammatory response, impairment of the sympathetic nervous system, inhibition of the biological response to stress, along with cerebral vasodilation and neural damage^[2,58]. Experimentally, the use of insulin and consequent hypoglycaemia may be associated with hypotension, vasodilation, and reduced autonomic responses to subsequent hypoglycaemic episodes^[58]. Furthermore, critically ill patients may be more prone to the effects of hypoglycaemia itself, which may include cardiac arrest, seizure and coma^[59].

Studies examining the effects of hypoglycaemia in critically ill patients with pre-existing diabetes are limited. Interventional studies describing this relationship have been summarised (Table 6). Of note, post hoc analysis of the NICE-SUGAR data indicate that intensive insulin therapy increases episodes of moderate (2.3-3.9 mmol/L) and severe (\leq 2.2 mmol/L) hypoglycaemia, both of which are associated with increased risk of death^[56]. This relationship was similar among patients with and without a diagnosis of diabetes.

In addition to these studies, there are a number of observational studies that have evaluated this association (Table 7). A retrospective database review of 408 ICU patients (102 index cases, 306 controls) published in 2007^[60] reported that a history of diabetes was associated with severe hypoglycaemia and that a single

Table 6 Observational studies that have recorded chronic glycaemia as a dynamic variable (chronological order)

Ref.	Year	Study pts	Study point	Non diabetic patients	Diabetic patients	Overall message
Egi <i>et al</i> ^[55]	2011	415	Does preexisting hyperglycaemia modulate the association between glycemia and outcome in ICU patients with DM	N/A	Patients with elevated preadmission HbA1c levels (> 7%) showed a mortality benefit when mean ICU glucose concentrations were > 10 mmol/L	Relationship between HbA1c and mortality changed according to the levels of time-weighted average of blood glucose concentrations
Plummer <i>et al</i> ^[34]	2014	1000	Prevalence of CIAH and recognized/unrecognized DM in ICU and to evaluate the premorbid glycaemia on the association between acute hyperglycaemia and mortality	50% had CIAH Risk of death inc by 20% for each increase in acute glycaemia of 1 mmol/L	Well controlled DM (HbA1c < 6%) and adequately controlled (DM 6%-7%) - risk of death as per non diabetic patient HbA1c ≥ 7% (insufficiently controlled DM) had no significance between mortality and acute glycaemia	22% had recognised DM 6% had unrecognised diabetes
Hoang <i>et al</i> ^[44]	2014	299	Prevalance of unrecognized DM amongst those with CIAH and the association between baseline glycaemia and mortality	102 (34%) had no history of DM 14/102 (14%) had unrecognized DM (diagnosed with HbA1c ≥ 6.5)	197 (66%) had a history of DM	Lower HbA1c had inc mortality (in this population of CIAH patients) despite lower median glucose values and less glucose variability Mortality in HbA1c < 6.5 (19%) vs HbA1c ≥ 6.5 (12%), <i>P</i> = 0.04

Inc: Increased; Dec: Decreased; N/A: Not available.

hypoglycaemic episode was associated with an increased risk of mortality (compared with those without an episode of severe hypoglycaemia). Egi *et al*^[61] reported mild or moderate hypoglycaemia was associated with mortality in critically ill patients - with mortality substantially increasing according to severity of hypoglycaemia - and patients with diabetes were more likely to suffer from insulin-associated hypoglycaemia.

The blood glucose threshold that adverse events occur may be greater in patients with pre-existing diabetes. In a retrospective multi-centre observational study^[32] increased mortality was reported in 12880 patients with pre-existing diabetes who had mean glucose concentrations between 4.4-6.2 mmol/L. While the investigators were not able to differentiate between patients with well-controlled or poorly-controlled diabetes, these data support the concept that the threshold for "hypoglycaemia" may be increased in critically ill patients with diabetes when compared to non diabetic patients. For example, if a patient typically has blood glucose concentrations above 10 mmol/L, and, in hospital, insulin is administered to achieve blood glucose concentration of about 6 mmol/L, this may result in a "relative" hypoglycaemia.

Glycaemic variability

Glycaemic variability (GV) describes the fluctuations in blood glucose concentrations, as marked fluctuations may be associated with multiple adverse effects such as apoptosis, cytokine production and increased markers of oxidative stress^[59]. Oxidative stress markers have been shown to increase with glucose fluctuations^[62,63]. GV may be assessed by a number of methods. Techniques to quantify variability are reviewed

elsewhere^[64].

Multiple studies in the critically ill have established as an association with poor outcomes and GV^[44,65-71], however the evidence in patients with pre-existing diabetes is limited and inconsistent (Table 8). In 2006, Egi *et al*^[65] published a retrospective, electronic database analysis of 7049 ICU patients in 4 centres around Australia, using standard deviation as a marker of glucose variability, and focusing on the association of blood glucose variability and mortality^[65]. Both mean and standard deviation of blood glucose were independently associated with mortality.

A retrospective, single center cohort study of patients admitted with sepsis reported that GV was also independently associated with increased mortality and importantly, that this was independent of hypoglycaemia and the presence of diabetes^[66]. Another retrospective study of 3252 patients reported that increased GV was associated with mortality^[67] and diabetes was associated with greater GV. A prospective, observational study of 42 patients used non-linear dynamics to measure glycaemia in time series^[69]. Patients underwent continuous glucose monitoring system measuring interstitial glucose concentrations every 5 min for 48 h. The authors reported greater variability was associated with increasing mortality, even in patients with diabetes. However, given the small cohort, these results must be treated with caution.

Other studies have reported no relationship between mortality and GV in patients with diabetes. A retrospective, observational study of 4084 critically ill patients (942 with known diabetes)^[68] reported that GV was associated with mortality in patients without diabetes, but not in patients with diabetes. More

Table 7 Observational studies and outcomes related to hypoglycaemia (chronological order)

Ref.	Year	Study pts	Study point	Non diabetic patients	Diabetic patients	Overall message
Krinsley and Grover ^[60]	2007	408	Risk factors for developing hypoglycaemia in ICU and outcomes	Severe hypoglycaemia associated with septic shock. Renal insufficiency, mechanical ventilation, illness severity and use of ITT	Associated with inc risk of severe hypoglycaemia ($P < 0.01$) DM had no association with mortality	Mortality in severe hypoglycaemia cohort 56% <i>vs</i> control cohort 40%, $P < 0.01$
Egi <i>et al</i> ^[61]	2010	4946	Hypoglycaemia <i>vs</i> risk of death in critically ill patients	Mild or moderate hypoglycaemia was associated with mortality in critically ill patients Mortality increases as severity of hypoglycaemia increases	Diabetic patients more likely to suffer from insulin-associated hypoglycaemia	22% of total patients had one episode of hypoglycaemia Hospital mortality: hypoglycaemic cohort 37% <i>vs</i> control cohort 20%, $P < 0.01$
Krinsley <i>et al</i> ^[33]	2011	6240 ¹	Mild hypoglycaemia (blood glucose level < 3.9 mmol/L) <i>vs</i> risk of mortality in critically ill patients.	Mild hypoglycaemia was associated with a significantly increased risk of mortality	The association between hypoglycaemia and mortality was independent of diabetic status	Inc severity of hypoglycaemia was associated with inc risk of mortality Hypoglycemic patients had higher mortality regardless of diagnostic category and ICU LOS
Krinsley <i>et al</i> ^[32]	2013	44964	Hyperglycaemia, hypoglycaemia, and glycemic variability <i>vs</i> mortality (and how DM effects this)	Inc mortality with higher mean blood glucose (≥ 7.8 mmol/L) Dec mortality with lower blood glucose (4.4-7.8 mmol/L)	Inc mortality with mean blood glucose between 4.4-6.1 mmol/L Dec mortality when blood glucose were higher (6.2-10 mmol/L)	Hyperglycaemia, hypoglycaemia, and increased glycemic variability are independently associated with mortality in ICU patients Diabetic status tempers these relations

¹Contains partial data from one prospective RCT (Glucontrol trial) and complete data from two observational cohorts (United States and The Netherlands). Inc: Increased; Dec: Decrease; LOS: Length of stay.

recently in the study by Hoang *et al*^[44] of 299 patients there was no association between GV and mortality in their entire cohort, however the group with diabetes (128 patients) had a lower rate of mortality despite having a higher GV. Additionally, a retrospective analysis of 2782 ICU patients, comparing different GV indices and mean glucose concentrations to predict mortality and ICU acquired infections^[70] reported that while GV was associated with infections and mortality in patients without pre-existing diabetes, in those with diabetes GV was greater but was not associated with either mortality or infection.

In summary, there is a strong relationship between GV and mortality in critically ill patients that has been confirmed in multiple studies. However, with respect to patients with diabetes, data are inconsistent. This may be due a number of factors, including small numbers studied resulting in lack of power, or that patients with chronic hyperglycaemia are protected somewhat by glycaemic excursions during acute illness. Research is warranted to further understand whether GV is harmful in patients with pre-existing diabetes.

RATIONALE FOR PERSONALISED THERAPY AND THAT THE HARM FROM EACH OF THESE DOMAINS MAY VARY ACCORDING TO PRE EXISTING PHYSIOLOGY

Diabetes is known to be associated with a large burden

of illness in the outpatient setting and is associated with increased mortality^[72]. Paradoxically, as discussed, multiple studies exist suggesting that acute hyperglycaemia in critically ill patients without diabetes (*i.e.*, patients with CIAH) is associated with increased mortality and morbidity when compared to those with known diabetes^[73]. There is growing evidence that chronic hyperglycaemia may lead to cellular conditioning, and that in fact, may be protective against acute hyperglycaemia mediated damage during an episode critical illness^[1]. These outcomes suggest that current target glucose levels in patients naïve to hyperglycaemia, or those suffering from CIAH, may be harmful to those with chronic hyperglycaemia or poorly controlled diabetes.

CONCLUSION

This review articulates the need for further research to be done to identify the ideal glucose targets in critically ill patient with pre-existing diabetes. Not only does hyperglycaemia occur frequently in this group, but, recent data suggests that targeted blood glucose concentrations may benefit from consideration of a patient's premorbid glucose state.

Our recommendations are to avoid treating patients with diabetes as a homogenous group. Treatment of the critically ill patient with type 2 diabetes should be personalised to their internal milieu. There is preliminary evidence suggesting that higher blood glucose concentrations (*e.g.*, up to 14 mmol/L) in patients with uncontrolled type 2 diabetes may not be

Table 8 Observational and interventional studies and outcomes related to glycaemic variability (chronological order)

Ref.	Year	Study pts	Study point	Non diabetic patients	Diabetic patients	Overall message
Egi <i>et al</i> ^[65]	2006	7049	GV (measured by SD and %CV) <i>vs</i> mortality (hospital and ICU)	Both mean and GV of blood glucose were significantly and independently associated with ICU and hospital mortality GV was a stronger predictor of ICU mortality than mean glucose concentration	Inc mortality when comparing highest and lowest glucose SD No other significant relation with blood glucose (SD and mean) and ICU/hospital mortality Logistic regression: DM associated with decrease OR for ICU mortality Mortality rise remained even after adjusting for a diagnosis of diabetes	The mean \pm SD of blood glucose: Survivors 1.7 ± 1.3 mmol/L <i>vs</i> Non survivors 2.3 ± 1.6 mmol/L ($P < 0.001$) Post logistic regression analysis, both mean and SD of blood glucose were significantly associated with ICU and hospital Higher observed mortality with increasing levels of variability Higher odds of hospital mortality with lower mean blood glucose + high GV or higher mean blood glucose + lower GV
Ali <i>et al</i> ^[66]	2008	1246	GV <i>vs</i> hospital mortality in septic ICU patients	GV is independently associated with hospital mortality in sepsis	Mortality rise remained even after adjusting for a diagnosis of diabetes	Amount of GV had a significant effect on mortality - <i>e.g.</i> , patients with mean blood glucose $3.9\text{--}5.5$ mmol/L mortality: Lowest GV 6% while high GV 30% Attempts to minimize GV may have a significant beneficial impact on outcomes of critically ill patients without diabetes
Krinsley ^[67]	2008	3252	GV <i>vs</i> mortality in ICU patients	Inc GV conferred a strong independent risk of mortality	Multivariable regression analysis demonstrated that diabetes had an independent positive correlation to SD Higher measures of GV	
Krinsley ^[68]	2009	4084	Impact of DM or its absence on GV as a risk factor for mortality	Low GV was associated with increased survival High GV was associated with increased mortality	No association between GV and mortality among diabetics	
Lundelin <i>et al</i> ^[69]	2010	42	Glycemic dynamics (measured <i>via</i> non-linear dynamics) <i>vs</i> mortality in ICU patients	Loss of complexity (therefore higher variability) in glycaemia time series is associated with higher mortality	This association persisted in diabetics No difference in DFA (detrended fluctuation analysis a measure of complexity) between DM and nondiabetics	In critically ill patients, there is a difference in the complexity of the glycaemic profile between survivors and nonsurvivors Loss of complexity correlates with higher mortality Increased glucose amplitude variation was associated with mortality, irrespective of blood glucose level Lower HbA1c had inc mortality (in this population of CIAH patients) despite lower median glucose values and less glucose variability Mortality in HbA1c < 6.5 (19%) <i>vs</i> HbA1c ≥ 6.5 (12%), $P = 0.04$
Meyfroidt <i>et al</i> ^[71]	2010	2748	Blood glucose signal characteristics <i>vs</i> hospital mortality	GV was independently associated with hospital mortality	Increased mortality was seen in both diabetics and non diabetic patients.	
Hoang <i>et al</i> ^[44]	2014	299	Prevalence of unrecognized DM amongst those with CIAH and the association between baseline glycaemia and mortality	102 (34%) had no history of DM 14/102 (14%) had unrecognized DM (diagnosed with HbA1c ≥ 6.5)	197 (66%) had a history of DM	
Donati <i>et al</i> ^[70]	2014	2782	GV and mean BGIs <i>vs</i> mortality and intensive care unit-acquired infections	High GV is associated with higher risk of ICU acquired infection and mortality	Diabetic patients had higher mean BGL and GV No change in mortality or infections	Mean BGL was not associated with infections and mortality

harmful. For this reason it may be safer to target blood glucose concentrations between 10–14 mmol/L in this group. However, definitive studies of critically ill patients with poorly controlled diabetes are required before this approach is incorporated into clinical practice. In contrast, in patients with CIAH, or those with well-controlled diabetes (HbA1c < 7.0), a more conservative target (6–10 mmol/L) is supported by considerable data.

Abstract

The co-occurrence of celiac disease (CD) and type 1 diabetes (T1DM) has been reported as 5-7 times more

prevalent than CD alone. The clinical presentation and natural history of CD in patients with T1DM may vary considerably. Less than 10% of patients with T1DM and CD show gastrointestinal symptoms. Therefore, experts support screening for CD in T1DM patients, though there is no consensus as to the recommended frequency of screening. When stratified by time since CD diagnosis, longer follow-up and coexistence of CD are associated with significant increased risk of diabetic associated morbidity and mortality. Early CD diagnosis and treatment with a gluten-free diet are essential.

Key words: Type 1 diabetes mellitus; Celiac disease; Glycemic control; Gluten free diet; Pediatrics

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Increased prevalence rates of celiac disease (CD) are described among individuals with type 1 diabetes mellitus (T1DM). Specifically celiac disease is more prevalent in females with T1DM. Less than 10% of patients with T1DM and CD show gastrointestinal symptoms therefore screening is necessary. The significant increase of diabetic associated morbidity and mortality, emphasize the importance of early diagnosis of CD and appropriate treatment with gluten-free diet.

INTRODUCTION

Celiac disease

Celiac disease (CD), previously known as celiac sprue, affects 0.6%-1.0% of the population worldwide, with wide geographic variation, for unknown reasons^[1,2]. The autoimmune disorder is triggered in genetically

predisposed patients by gluten ingestion^[1-4]. Symptoms of CD include malabsorption and malnutrition, vitamin deficiencies, iron deficiency anemia, failure to thrive, short stature, diarrhea, anorexia, constipation, vomiting, and abdominal distension. Other complications associated with untreated CD include osteoporosis, obstetric complications, and neurologic disorders, as well as enteropathy-associated T-cell lymphoma and adenocarcinoma of the jejunum^[5,6]. However, several reports in the literature state that many cases of CD are asymptomatic or associated with mild symptoms^[7-9]. Diagnosis of CD is based on intestinal biopsy and the presence of specific antibodies; however, most cases of CD remain undiagnosed^[10,11]. Currently, the only effective treatment for CD is a lifelong gluten-free diet (GFD), which results in resolution or improvement for most individuals^[12].

Epidemiology of T1DM and CD

The association between CD and T1DM was first described in the late 1960s^[13]. Studies published during the last few years have demonstrated elevated prevalence rates of CD among individuals with T1DM: 4.4% in the United Kingdom, 3.7% in Israel, 4.8% in Greece, and 6.4% in Germany; and as high as 10.5% in Brazil and 11.1% in India^[14-19].

The incidence of T1DM is rapidly increasing in children and adolescents, with a reported increase of 3% annually^[20,21]. Similarly, a longitudinal study documented an increase in the prevalence of CD in the mid 1990s, from 3.3% to 10.6%, most probably due to changes in environmental factors^[22].

CD is a female predominant disease, and is 2-3 times more common among females^[23]. Although there is no gender difference in the prevalence rates of T1DM, CD is also more prevalent in females than in males with T1DM. The etiological risk factors for developing antibodies against the small bowel are thought to be different from those for T1DM^[24-26].

Genetics

Genetic background plays a key role in the predisposition to CD, as suggested by higher prevalence among family members and higher concordance rates in monozygotic than dizygotic twins (over 80% compared with 11%)^[27].

The human leukocyte antigen (HLA) plays a key role in the genetic predisposition to CD, as there is a strong association between both *HLA-DQ2* and *HLA-DQ8*, and between CD. The negative predictive value of HLA typing is high, as CD is extremely rare in patients carrying neither *DQ2* nor *DQ8* alleles^[28,29].

An overlap in the genetic susceptibility conferred by *HLA-DQ2* is the basis for the increased prevalence of CD in patients with T1DM. Over 90% of those with CD express *HLA-DR3/DQ2* haplotype, as well as 55% of those with T1DM, compared with less than 25% of the general population^[30]. Bakker *et al.*^[31] confirmed

the high prevalence of *HLA-DQ2* haplotypes in patients with both T1DM and CD, and reported that *HLA-DQ2* homozygosity confers the highest risk for CD among patients with CD. *DQ2* has been cited by a number of studies as the major susceptibility factor for CD. *HLA-DQ8*, another important allele for CD, is considered a stronger susceptibility factor for T1DM. *DQ8* heterozygosity is claimed to be the strongest risk factor for the development of T1DM^[32,33]. Trynka *et al.*^[34] reported 57 independent CD association signals from 39 non-HLA genes that confer a predisposition to CD. However, although genetic predisposition is essential, it is not sufficient for the development of CD, as the pathogenesis of CD involves an external trigger, namely gluten.

SCREENING AND DIAGNOSIS

In the general population

According to the modified guidelines of the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)^[10], testing for CD is recommended in children and adolescents with otherwise unexplained signs and symptoms suggestive of CD, and among asymptomatic children and adolescents with an increased risk for CD, such as patients with T1DM or first-degree relatives with CD.

Diagnosis of CD is based on the presence of villous atrophy and crypt hyperplasia by intestinal biopsy and the presence of antibodies against tissue transglutaminase (TTG) or endomysium (EMA). The diagnosis is confirmed by an antibody decline to a GFD. According to ESPGHAN guidelines, in patients with suspected CD and certain conditions (typical symptoms, high titer of TTG antibodies and predisposing HLA genotypes), there is no obligation to complete duodenal biopsy and histology^[10].

Finally, potential CD, a term coined by Ferguson in the 1990s, refers to patients with positive CD-associated antibodies, but with normal, or almost normal, jejuna mucosa^[35]. These patients usually have mild symptoms, if any, of CD. The number of patients diagnosed with potential CD is increasing, following the raised attention for CD and screening tests of high-risk populations^[36]. Numerous studies in the general population demonstrate that CD is often only diagnosed after several years of CD related complaints^[37-39]. Some reported that diagnosis of irritable bowel syndrome preceded the correct diagnosis of CD in many patients^[40,41].

CD in T1DM patients

Less than 10% of patients with T1DM and CD show gastrointestinal symptoms^[42]. Therefore, most professional societies recommend screening of patients with T1DM for CD. However, there is no consensus regarding the recommended screening tests and the frequency of screening^[43].

Recommended screening test: Most guidelines support screening based on TTG IgA (confirmed by EMA), or TTG IgG in patients with IgA deficiency, because of its high sensitivity and specificity^[44,45]. Most experts argue that in patients with CD-associated antibodies, it is mandatory to perform esophagoduodenoscopy with small bowel biopsies to confirm the diagnosis^[10].

Timing and frequency of screening: Neither in the guidelines issued by ESPGHAN nor those issued by the National Institute for Health and Clinical Excellence, is the timing of screening specified. As for the frequency of screening, ESPGHAN guidelines recommend retesting at intervals, with no firm evidence, but opinion is every 2-3 years^[10]. NICE guidelines state that the evidence is insufficient to make a recommendation regarding the frequency of screening for CD in patients with T1DM^[10,46]. The International Society for Pediatric and Adolescent Diabetes recommends screening for CD at diagnosis of T1DM, every year in the first five years of follow-up, and less frequently in successive years^[4,47,48].

Bakker *et al.*^[31] reported that almost 50% of T1DM patients diagnosed with CD in adulthood had CD related complaints for over 5 years prior to the diagnosis of CD. Furthermore, their findings demonstrated a bimodal distribution of the age of diagnosis of CD in patients with T1DM, with peak incidence rates at the ages of 10 and 45 years.

CLINICAL PRESENTATION OF CD IN PATIENTS WITH T1DM

CD diagnosis most often follows the diagnosis of T1DM, and only a minority of patients were diagnosed first with CD^[7,31,49].

Age of onset

The mean age at onset of T1DM is younger in those with both T1DM and CD, than in those with only T1DM^[25,50]. In an observational cohort study of 4379 people aged ≤ 18 years from Australia, the mean age at T1DM onset was 6.6 ± 4.0 years in those with T1DM and CD, compared with 8.4 ± 4.1 years in those without CD^[51].

Signs and symptoms

The natural history of CD in patients with T1DM may vary considerably, as the diagnosis of CD can precede the diagnosis of T1DM, or be established at the onset of T1DM, during routine screening tests at follow-up. Accordingly, the presentation of CD varies greatly, from asymptomatic or mild symptoms to poor growth and considerable morbidity^[7-9,44]. In individuals with diabetes, symptoms of CD may be divided into two main categories, those directly associated with CD and those related to the impact of CD on diabetes.

Signs and symptoms directly associated with CD

These include malabsorption and malnutrition, vitamin deficiencies, iron deficiency anemia, failure to thrive, short stature, diarrhea, anorexia, constipation, vomiting, and abdominal distension.

Growth in children with CD and T1DM compared to children with T1DM alone: As stated above, differences between reports may be due to whether CD diagnosis results from routine screening or is prompted from signs and symptoms.

Body weight was found to be significantly lower among children with T1DM with screening-identified CD compared to those with T1DM only; however, there was no difference in height^[52]. Of 41951 children and adolescents surveyed in Germany, only 22273 (53%) had been screened for CD. Those with both T1DM and CD had a significantly lower weight standard deviation and height standard deviation score (SDS)^[50]. In a subgroup of 183 patients, those with both diseases had significantly lower height and weight SDS after 5-year follow-up^[53]. Previously, we demonstrated a higher prevalence of growth impairment among patients with both CD and T1DM, compared to patients with T1DM alone. Patients with CD were, on average, significantly shorter than their genetic target height potential, compared to patients with T1DM alone. Furthermore, poor adherence to GFD resulted in continuous growth impairment, compared to steady improvement among those with good adherence to a GFD^[16]. Of note, patients with CD who do not improve their growth velocity after GFD should be evaluated for growth hormone deficiency secondary to autoimmune hypophysitis^[54].

Signs related to the impact of CD on diabetes at diagnosis of CD

Glycemic control: Data remain inconsistent regarding glycemic control in patients with dual diagnosis of CD and T1DM. Data may differ based on the points of time HbA1c levels were assessed (at diagnosis vs at follow-up), whether diagnosis was based on routine screening or on symptoms, and in longitudinal studies whether adherence to GFD was assessed in parallel.

(1) HbA1c levels at diagnosis of CD. Malabsorption of nutrients may cause a reduction in HbA1c levels. In a controlled study in children mean age 10 years with T1DM duration of about 4 years, HbA1c levels at baseline did not differ significantly between patients with T1DM and CD, and between those with T1DM alone^[55]. Yet, among adult T1DM patients who were newly diagnosed with CD, glycemic control was significantly worse than for those with T1DM alone, 8.2% vs 7.5%, $P = 0.05$ ^[56]. The difference between these studies may reflect the impact of delayed diagnosis of CD.

(2) HbA1c levels at follow-up. In a controlled prospective 2-year follow-up study, mean HbA1c

levels did not differ significantly between patients with both T1DM and CD and between those with T1DM alone^[57]. Similarly, in a large cohort from 297 centers in Germany and Austria, no statistically significant differences were found in mean HbA1c levels, between children with and without CD, mean age of 13.7 after 5 years of follow-up^[50].

Acute events-hypoglycemic and diabetes keto-acidosis: CD is associated with mucosal changes that may interfere with the absorption of carbohydrates, even without leading to true malabsorption. An increased risk for symptomatic hypoglycemia was reported in the 6 mo before and after diagnosis of CD^[58]. However, during long-term follow-up and under GFD, no differences were found in the numbers of severe hypoglycemic episodes^[50]. There are no reports of increased risk of DKA episodes in individuals with both T1DM and CD^[50].

Insulin requirements: One study reported significantly lower insulin requirements among patients with T1DM and CD than among those with T1DM alone^[52]; yet the mean insulin requirement increased significantly from 0.88 to 1.1 units/kg per day after 12 mo GFD. In another study, there was no difference in insulin dosage per kilogram per day between patients with both T1DM and CD, mean CD duration of 3 years, and those without CD^[59].

Other autoimmune diseases: Patients with CD are at increased risk for other autoimmune diseases, such as autoimmune thyroid disorders. Thyroid disorders have been reported to be an important risk factor for the development of CD among patients with T1DM^[49,60].

COMPLICATIONS IN PATIENTS WITH T1DM AND CD

Complications may be divided into two main categories, those directly associated with CD and those related to the impact of CD on diabetes.

The long term complications associated with untreated CD include osteoporosis, obstetric complications, and neurologic disorders, as well as enteropathy-associated T-cell lymphoma and adenocarcinoma of the jejunum^[2,6].

Diabetes associated complications in patients with CD

As for long-term complications among patients with T1DM and CD, the data are conflicting: some report that CD increases rates of complications^[56], some show no difference, and others suggest lower incidence of complications^[61]. These discrepancies may be due to differences in duration of undiagnosed CD.

Prevalence of complications in patients with T1DM and newly diagnosed CD

Among adults with T1DM duration of over 20 years, those with newly diagnosed CD had worse glycemic control and a significantly higher prevalence of retinopathy (58.3% vs 25%), nephropathy (41.6% vs 4.2%), and peripheral neuropathy (41.6% vs 16.6%)^[56]. In contrast, Picarelli *et al*^[61] reported significantly lower prevalence of nephropathy and retinopathy among adult T1DM aged about 50 years, with T1DM duration of about 18 years and newly diagnosed CD. The difference between these studies may be due to the unknown duration of undiagnosed CD, and to the difference in HbA1c levels between studies. In the latter, only those with HbA1c levels < 7.5% were included.

The prevalence of complications in patients with T1DM and CD: Long-term follow-up

A lower prevalence of retinopathy was reported in individuals with median durations of T1DM and CD of 27 and 3 years respectively, compared with controls (38.7% vs 67.4%). However, no difference in the prevalence of nephropathy was found between the groups^[59]. The duration of CD was found to be correlated with the risk of diabetic retinopathy. When stratified by time since CD diagnosis, individuals with T1DM and CD were at a lower risk of retinopathy in the first 5 years after CD diagnosis, followed by a neutral risk in years 5 to 10. However, with longer follow-up, coexisting CD was a 2.83 increased risk factor for diabetic retinopathy at 10 to 15 years of follow-up, and a three-fold risk after 15 years of follow-up^[62].

Patients with both T1DM and CD were reported to have more severe subclinical atherosclerosis than those presenting with only T1DM or CD. Among patients with both T1DM and CD, mean age of 39 years, mean T1DM duration of 18 years and CD duration of 8.5 years, carotid intima-media thickness was significantly greater in those with both T1DM and CD than in those with either T1DM or CD, suggesting that the association of these autoimmune diseases might accelerate the atherosclerotic process^[63].

Finally, mortality in patients with both T1DM and CD was studied in 960 individuals aged 30 years, compared with 4608 with T1DM alone, matched for sex, age and disease duration. CD was not a risk factor for death in patients with T1DM during the first 5 years after CD diagnosis, but thereafter the hazard ratio for mortality increased as a function of follow-up time. Having a CD diagnosis for > 15 years was associated with a 2.80-fold increased risk of death in individuals with T1DM^[64].

TREATMENT

The standard therapy for CD is GFD, which requires

avoiding wheat, rye, barley and oats. Patients with CD must follow this strict diet for their entire life. Delay in starting GFD increases the risk of osteoporosis, gastrointestinal malignancies, iron deficiency anemia, infertility, and other autoimmune disorders. Adherence to GFD augments the restrictions required by a diabetic dietary regimen.

GFD impact on glycemic control

Good glycemic control is essential to reduce the risks of T1DM related complications. However, many specially prepared gluten-free foods have high glycemic indices, and thus affect glucose levels, insulin requirements, lipid profiles and body mass indices (BMI). GFD may worsen glycemic control and can thus increase the difficulties of disease management for patients with T1DM and CD^[42]. Numerous studies have evaluated the effect of CD and GFD on the metabolic control of patients with T1DM. Some reported better metabolic control with GFD among CD patients with T1DM^[65,66]. Others did not show any change in HbA1c levels with GFD^[67-72], and some reported worse glycemic control with GFD^[73].

GFD impact on weight and height

Data on weight gain in patients with CD are inconsistent. Some studies report that treatment with GFD promotes a significant catch-up growth while others show no difference. The time of follow-up, age and stage of puberty of patients in different studies may explain the discrepancies. Twelve months after commencement of GFD, one study showed no statistically significant change in the SDS for height, weight and BMI of the 23 children assessed^[74]. In a separate study, children with T1DM and CD had lower SDS for height and weight at CD diagnosis. After 2 years of follow-up, SDS was significantly increased for weight, and for height in prepubertal children^[57].

Adherence to GFD

The compliance rates to GFD among patients with CD and T1DM is less than 60%, compared with about 80% among those with CD only^[75]. The more severe problems of GFD adherence usually occur during adolescence^[44].

QUALITY OF LIFE IN CHILDREN WITH T1DM

Families of children with both CD and T1DM report a higher burden than those affected by T1DM only. Similarly, health care providers perceived family burden to increase over time^[76]. Yet, among children aged 8-18 years, no significant differences in quality of life were observed. However, parents of children with both CD and T1D did express greater concern about their children's social functioning. Adults (mean age 49 years) with both CD and T1DM scored lower in

general health perception, social functioning and role limitation, as a result of physical health and emotional problems. In addition, concerns about diabetes related and social problems were significantly higher in those with both diagnoses^[77].

Abstract

Diabetic complications including diabetic nephropathy, retinopathy, and neuropathy are as major causes of morbidity and mortality in diabetes individuals worldwide and current therapies are still unsatisfactory. One of the reasons for failure to develop effective treatment is the lack of fundamental understanding for underlying mechanisms. Genetic studies are powerful tools to dissect disease mechanism. The heritability (h^2) was estimated to be 0.3-0.44 for diabetic nephropathy and 0.25-0.50 for diabetic retinopathy respectively. Previous linkage studies for diabetic nephropathy have identified overlapped linkage regions in 1q43-44, 3q21-23, 3q26, 10p12-15, 18q22-23, 19q13, 22q11-12.3 in multiple ethnic groups. Genome-wide association studies (GWAS) of diabetic nephropathy have been conducted in several populations. However, most of the identified risk loci could not be replicated by independent studies with a few exceptions including those in *ELMO1*, *FRMD3*, *CARS*, *MYO16/IRS2*, and *APOL3-MYH9* genes. Functional studies of these genes revealed the involvement of cytoskeleton reorganization (especially non-muscle type myosin), phagocytosis of apoptotic cells, fibroblast migration, insulin signaling, and epithelial clonal expansion in the pathogenesis of diabetic nephropathy. Linkage analyses of diabetic retinopathy overlapped only in 1q36 region and current results from GWAS for diabetic retinopathy are inconsistent. Conclusive results from genetic studies for diabetic neuropathy are lacking. For now, small sample sizes, confounding by population stratification, different phenotype definitions between studies, ethnic-specific associations, the influence of environmental factors, and the possible contribution of rare variants may explain the inconsistencies between studies.

Key words: Microvascular complications; Nephropathy; Retinopathy; Neuropathy; Diabetes

Core tip: Most risk genetic loci identified by genome-wide association studies (GWAS) for diabetic nephropathy could not be replicated by independent studies with a few exceptions including those in *ELMO1*, *FRMD3*, *CARS*, *MYO16/IRS2*, and *APOL3-MYH9* genes. These findings highlighted the importance of cytoskeleton reorganization, phagocytosis of apoptotic cells, fibroblast migration, insulin signaling, and epithelial clonal expansion in the pathogenesis of diabetic nephropathy. Conclusive results from GWAS for diabetic retinopathy and diabetic neuropathy are currently lacking.

INTRODUCTION

The prevalence of diabetes mellitus is increasing globally, especially in developing countries^[1]. This surge of diabetes mellitus prevalence poses a serious threat to the public and diabetic complications are ranked as major causes of morbidity and mortality worldwide. Several common mechanisms underlying these microvascular complications including the polyol pathway, advanced glycation end products pathway, protein kinase C pathway, the hexosamine pathway, and cytokines such as nuclear factor- κ B, tumor growth factor- β , and vascular endothelial growth factor are well described and the unifying mechanism of superoxide production have been proposed^[2]. Nevertheless, therapies targeting these pathways have not been very successful^[3-5]. One of the reasons is the lack of fundamental understanding for underlying mechanisms.

Genetic studies provide a powerful tool to the understanding of disease mechanism. Previous family linkage analyses have successfully identified mutations responsible for high-penetrating monogenetic disease. Some discoveries, for example, the identification of *PCSK9* mutation through linkage analyses in hypercholesterolemic families, have resulted in major breakthroughs in therapy^[6,7]. However, family linkage analysis is generally not adequately powered to detect genetic loci of complex disease. Over the last few years, the advent of genome-wide association studies (GWAS) have launched a great leap toward the genetic basis of complex diseases such type 2 diabetes mellitus, cancers, and psychiatric diseases. Intriguingly, many of the identified genetic loci were not previously considered to be related to these diseases and the discoveries indeed illuminated

important pathophysiological pathways to these complex diseases. Diabetic microvascular complications are complex traits influenced by both environmental and genetic factors, and compelling evidences indicate that diabetic microvascular complications are heritable^[8-12]. Here in this review, we only summarized the progress in the genetics for diabetic microvascular complications.

GENETICS STUDIES OF DIABETIC NEPHROPATHY

Linkage studies of diabetic nephropathy

The heritability (h^2) of diabetic nephropathy (DN) defined by reduced glomerular filtration rate (GFR) or albuminuria was estimated to be 0.3-0.44 in multiple Caucasian diabetic populations^[8-10]. Previous linkage studies have repeatedly identified linkage region in 1q43-44, 3q21-23, 3q26, 10p12-15, 18q22-23, 19q13, 22q11-12.3 in multiple ethnic groups (Figure 1, Table 1)^[13-24]. However, these linkage regions usually spanned over megabases and therefore exact locus or risk gene is unclear. In contrast, the resolution of linkage disequilibrium mapping (also called association mapping) is much higher than linkage studies. The distinction between linkage and association mapping is that family linkage mapping use the small amount of recombination events that occurs in each generation within a pedigree to localize a chromosomal region, which usually contains hundreds of genes; while population-based case-control association mapping uses large amount of recombinations that occurred during the evolutionary history of a population to locate the risk loci, which generally did not extend over a few genes. However, population-based case-control association studies are susceptible to the population stratification and independent replication is essential to confirm the result of association studies.

Association studies of DN in type 2 diabetic patients

Several GWAS of DN have been conducted in several ethnic populations (Table 1, Figure 1). *ELMO1* (the engulfment and cell motility 1 gene) was first found to be associated with diabetic nephropathy in a GWAS in Japanese 2 diabetic patients (546 DN cases and 334 type 2 diabetic controls)^[25]. Replication studies in the GoKinD collection (558 DN cases and 820 type 2 diabetes controls)^[26], two African American cohorts [1136 end-stage renal disease (ESRD) diabetes cases and type 2 diabetic 1160 controls]^[27], a Chinese population (123 DN cases and 77 type 2 diabetic controls)^[28], and a Caucasian GWAS (547 ESRD and 549 type 1 diabetic controls)^[29] confirmed this finding although the risk SNPs are not exactly the same with those reported in the original Japanese population (intron 16-20 in original Japanese GWAS, intron 16-20 in GoKinD, intron 13 in African Americans, intron 18 in Chinese). In a large meta-analysis of the GENIE

consortium (including UK-ROI, FinnDiane, and GoKinD US) involving 2966 DN cases and 3399 type 1 diabetic controls, an expanded investigation of the *ELMO1* locus yielded only nominal associations with DN^[30]. Furthermore, another replication studies in Pima Indians of Arizona involving 248 DN cases and 524 diabetic controls found significant association of SNPs in intron 13 but the associations were in the opposite direction from those observed in African Americans^[31], and another study in 455 Mexican-American patients with DN and 437 controls failed to replicate the association^[32].

A GWAS in Pima Indians comparing 105 diabetic ESRD and 103 controls identified plasmacytoma variant translocation (*PVT1*), an lncRNA gene, was associated with DN in type 2 diabetic patients^[33]. Another large GWAS in an initial set of 965 African American type 2 diabetic patients with ESRD and 1029 controls without type 2 diabetes or kidney disease and further replication studies in 1246 type 2 diabetic patients identified *SASH1* (SH3 Domain Containing 1), *RPS12* (ribosomal protein S12), *AUH* (AU RNA binding protein/enoyl-CoA hydratase), *MSRB3* (methionine sulfoxide reductase B3), *LIMK2* (LIM domain kinase 2), *SFI1* (Sfi1 homolog, spindle assembly associated),

¹Overlapped region. MLS: Maximum LOD score; DN: Diabetic nephropathy; ESRD: End-stage renal disease; GFR: Glomerular filtration rate; ACR: Albumin-to-creatinine ratio; DR: Diabetic retinopathy.

APOL3 (apolipoprotein L, 3), and *MYH9* (myosin, heavy chain 9, non-muscle) genes as risk loci^[34]. Among them, the association of *MYH9* risk variants has been replicated in another study involving 1963 European Americans diabetic patients^[35]. Compelling evidence demonstrated that *APOL3-MYH9* gene clusters are also associated with non-diabetic nephropathy including focal segmental glomerulosclerosis and hypertensive nephropathy in African American as well as other ethnic populations^[36-38].

Association studies of DN in type 1 diabetic patients

A large GWAS in a initial set of 820 DN cases and 885 type 1 diabetic controls in the GoKinD study and a replication set of 1304 participants in the Diabetes Control and Complication Trial/Epidemiology of Diabetes Control and Complication (EDIC) identified *FRMD3* (FERM domain containing 3), cysteinyl-tRNA synthase (*CARS*), carboxypeptidase, vitellogenic-like (*CPVL*)/chimerin 2, and intergenic region at 13q33.3 between *MYO16* and insulin receptor substrate 2 (*IRS2*) associated with DN^[39]. Interestingly, another genome-wide linkage analysis and regional association fine

mapping in 1007 general Mongolian also identified SNPs in the *FRMD3*, glycine amidinotransferase, and spermatogenesis associated 5-like 1 genes associated with estimated glomerular filtration rate^[40]. A family-based candidate-gene association study involving 798 type 2 diabetic members in the Joslin Study of Genetics of Nephropathy replicated the association of SNPs in the *FRMD3*, *CARS*, and 13q33.3 between *MYO16* and *IRS2* genes^[41]. Another GWAS in 547 Caucasian ESRD cases and 549 type 1 diabetic controls identified *ZMIZ1* (zinc finger, MIZ-type containing 1) gene is associated with DN^[29]. This study also observed significant association of 13q33 variant near the *MYO16/IRS2* genes^[29]. However, in a large replication study of 1535 Japanese type 1 and 2 diabetic patients, only variants in 13q33.3 between *MYO16/IRS2* gene but not those in *FRMD3*, *CPVL/CHN2*, or *CARS* are significantly associated with DN^[42]. Furthermore, a large meta-analysis of the GENIE consortium (UK-ROI, FinnDiane, and GoKinD US) involving 2966 type 1 diabetic cases with DN and 3399 type 1 diabetes controls failed to replicate the association between SNPs in the *FRMD3*, *CARS*, and 13q33 loci near *MYO16*

¹Loci that could be replicated in independent studies. T1DM: Type 1 diabetes mellitus; T2DM: Type 2 diabetes mellitus; DN: Diabetic nephropathy; ESRD: End-stage renal disease; GFR: Glomerular filtration rate; DR: Diabetic retinopathy; NPDR: Non-proliferative diabetic retinopathy; PDR: Proliferative diabetic retinopathy.

and *IRS2* genes^[30].

A recent huge meta-analysis involving 4315 type 1 diabetic nephropathy and ESRD cases and 8568 type 1 diabetic controls of the GENIE consortium and subsequent replication analyses in 9 independent cohorts (1880 cases and 6656 controls) revealed risk SNPs in the *AFF3* (AF4/FMR2 family, member 3) and *ERBB4* (v-erb-b2 avian erythroblastic leukemia viral oncogene homolog 4) genes and an intergenic SNP between *RGMA* (repulsive guidance molecule family member a)/*MCTP2* (multiple C2 domains, transmembrane 2) genes^[43]. Another large GWAS for 24-h urine albumin excretion rare in type 1 diabetic patients including an initial set of 1925 patients (FinnDiane) and 3750 additional patients from 7 follow-up studies (Steno Diabetes Center, Italian individuals from the Milano region, Umea Diabetes Study from Sweden, Scania Diabetes Registry, NFS-ORPQ, UK-ROI) identified the strongest signal from the *PSD3* (pleckstrin and Sec7 domain containing 3)/*SH2D4A* (SH2 domain containing 4A) genes^[44].

Collectively, current data from GWAS are not very consistent and only genetic loci in the *ELMO1*, *FRMD3*, *APOL3-MYH9*, *CARS*, and 13q33 between *MYO16* and *IRS2* genes have been successfully replicated in independent studies.

GENETIC STUDIES OF DIABETIC RETINOPATHY

Linkage studies of diabetic retinopathy

The heritability of diabetic proliferative retinopathy is estimated to be 0.25-0.50 in Caucasian populations^[11,12]. Previous results of three family linkage analyses for diabetic retinopathy (DR) are summarized in Table 1 and Figure 1^[18,45,46]. However, the only overlapped region is 1q36 between Pima Indians (LOD: 3.1) and Mexican Americans (LOD: 1.24) studies^[45,46].

Association studies of DR

Four GWAS of DR have been published till now (Table 2, Figure 1). A large meta-analysis of GWAS in the GoKinD and EDIC cohorts involving 2829 cases of severe diabetic retinopathy defined by proliferative retinopathy and macular edema and 1856 type 1 diabetic controls identified several possible loci including intergenic SNPs between *AKT3/ZNF238*, *LEKR1/CCNL1*, *KRT18P34/VEPH1* and SNP in the *A2BP1* genes with *P*-value less than 10⁻⁶^[47]. After excluding cases with concomitant nephropathy to identify DR-specific genes, SNPs in the intergenic region between *LOC728275/LOC728316*, the *CCDC101/NUPR1/SULT1A2/SULT1A1* gene clusters, the *FAM18B*,

C

Figure 2 Possible molecular mechanisms. Possible molecular mechanisms by which *ELMO1* (A), *IRS2* (B), and *MYH9* (C) regulate diabetic nephropathy. TRIO: Triple functional domain (PTPRF interacting); RhoG: Ras homolog family member G; GDP: Guanosine diphosphate; GTP: Guanosine triphosphate; MMP: Matrix metalloproteinases; Crk II: V-Crk Avian Sarcoma Virus CT10 Oncogene Homolog II; TGF- β : Transforming growth factor beta; AKT: Protein kinase B; mLSTs: Mammalian lethal with SEC13 protein 8; mTOR: Mammalian target of rapamycin; mTORC2: Mammalian target of rapamycin complex 2; mSin1: Mammalian SAPK interacting protein; PKC: Protein kinase C; SGK1: Serum- and glucocorticoid-induced kinase 1.

AKAP11/FABP3P2/TNFSF11 gene cluster, and intergenic region between *COX5BL1/LOC441026*, *ZNRF1*, *PCSK2*, *C10orf112* genes were found to be associated with DR^[47]. A GWAS for DR involving 174 Taiwanese type 2 diabetic non-proliferative and proliferative retinopathy cases and 575 controls identified several genetic loci with *P*-value less than 10^{-6} , including *MYSM1*, *FSTL5*, *C5orf21*, *PLXD2*, *ARHGAP22*, and *HS6ST3*^[48]. Another GWAS in Taiwanese identified three risk loci in *TBC1D4-COMMD6-UCHL3*, *LRP2-BBS5*, and *ARL4C-SH3BP4* genes in the initial set of 437 cases of proliferative retinopathy and 570 type 2 diabetic controls. However, none of them were replicated in another 585 Hispanic diabetics^[49]. A smaller GWAS comparing 103 Mexican-American type 2 diabetics with severe retinopathy and 183 type 2 diabetics identified suggestive signals in the *CAMK4* and *FMN1* genes^[50]. However, the results from these 4 GWAS did not overlap with each other.

GENETIC STUDY OF DIABETIC NEUROPATHY

There was no heritability estimation for diabetic neuropathy in human and no family linkage study for

diabetic neuropathy. Only GWAS comparing 572 diabetic neuropathic pain cases defined by treatment for diabetic neuropathic pain and positive monofilament test and 2491 diabetic controls in the Genetics of Diabetes Audit and Research Tayside (GoDARTS) identified potential signals from *GFRA2* gene^[51] (Table 2, Figure 1).

PHYSIOLOGICAL INSIGHT FROM GENETIC STUDIES

The *ELMO1* gene encode for a signaling molecule involved in phagocytosis of apoptotic cells^[52,53], fibroblast migration^[52,54,55], cytoskeleton reorganization^[56], and lymphocyte infiltration^[57] through interaction with DOCK2 and DOCK180 (Figure 2A). *ELMO1* expression was found to be elevated in cells cultured under high glucose conditions and in the kidney of diabetic mice, but was weakly detectable in tubular and glomerular epithelial cells in normal kidney^[25].

The *FRMD3* gene encodes for a member of the protein 4.1 superfamily. *FRMD3* has been demonstrated to be silenced in lung cancer tissue in genomic screening. *FRMD3* overexpression in different epithelial cell lines decreased clonal expansion, indicating *FRMD3*

as a potential tumor suppressor gene^[58]. The *CARS* encodes for a cysteinyl-tRNA synthetase, which is a frequent gene fusion partner of anaplastic lymphoma kinase found in anaplastic large-cell lymphoma and inflammatory myofibroblastic tumor^[59,60]. However, the link between *FRMD3* or *CARS* and diabetic nephropathy is currently poorly understood.

The 13q33 risk loci lie between the *MYO16* and *IRS2* genes. The *MYO16* gene encodes a novel unconventional myosin with divergent tails that is presumed to bind to membranous compartments and interact with actin filaments. *MYO16* has also been shown to be expressed during brain development and regulate neuronal morphogenesis through interaction with protein phosphatase and modulation of phosphoinositide 3-kinase signaling^[61]. A GWAS for autism has identified risk loci within an intergenic region between the *MYO16* and *IRS2* genes^[62]. A genome-wide linkage study and regional fine mapping for schizophrenia^[63] and another GWAS of the Framingham Heart Study for pulse pressure^[64] have identified *MYO16* as risk loci, indicating *MYO16* may play pleiotropic functions.

The *IRS2* gene encodes for an adaptor protein that interacts directly with the insulin receptors and the insulin-like growth factor I receptor and is a key mediator of insulin signaling. *IRS2* was expressed in renal epithelial and tubular cells. Deletion of *Irs2* causes reduced kidney size and reduced glomerular number in mice^[65]. A study of transcriptome and metabolome profiles of the primary cultured inner medullary collecting duct cells grown in hyperosmolar culture medium identified *IRS2* levels to be significantly altered^[66]. *IRS2* expression in kidney tubules has also been shown to be elevated nine fold in human diabetic nephropathy patients^[67]. Transforming growth factor (TGF)- β 1 is the primary cytokine shown to induce fibrosis. *IRS2* has been shown to mediate TGF- β 1 signals in kidney epithelial cells^[68]. *IRS2* has also been shown to interact with nuclear complex of rictor to regulate albuminuria in diabetic mice^[69] (Figure 2B).

Mutations in *MYH9* results in a familial autosomal dominant syndrome characterized by a variety of clinical features, including macrothrombocytopenia, deafness, nephritis, and cataract^[70]. GWAS also identified common *MYH9* polymorphism as risk loci for non-diabetic nephropathy including focal segmental glomerulosclerosis and hypertensive nephropathy^[36,27]. *MYH9* encodes the non-muscle myosin heavy chain 9, which, with other subunits, forms myosin II. Myosin II is a motor protein that binds actin to regulate cellular motility. *MYH9* is expressed in the podocytes, as well as in mesangial cells and arteriolar and peritubular capillaries in kidneys^[71]. Classical deletion of *Myh9* in mice results in embryonic lethality due to loss of cell-cell adhesion and loss of cell movement during gastrulation. Podocyte-specific deletion of *Myh9* in C57BL/6 mice results in susceptibility to experimental doxorubicin hydrochloride glomerulopathy^[71]. Several

strains of *Myh9* knockin mice showed macrothrombocytopenia, premature cataract formation, kidney abnormalities, including albuminuria, focal segmental glomerulosclerosis and progressive kidney disease, and mild hearing loss^[72,73] (Figure 2C).

LIMITATIONS AND PROSPECTIVE

The major limitation of family linkage studies is their low resolution and power to detect variants with small effects, especially for complex genetic diseases. GWAS is a hypothesis-free and unbiased tool with finer resolution and greater power to detect risk loci. However, false positivity often results from population admixture or stratification in GWAS. Therefore, independent replications are essential for genetic association studies. However, current results from GWAS are not consistent since most identified loci are not reproducible except for a few genes such as *ELMO1*, *CARS*, *FRMD3*, *MYO16/IRS2*, and *APOL3/MYH9*. Small sample sizes, different phenotype definitions between studies, population-specific associations, and strong influence of environmental factors (medications, co-morbidities) may explain the failure of GWAS for diabetic complications. While GWAS are usually designed for common variants, rare variants with intermediate effects within should also be pursued with next-generation sequencing. The interaction with environmental factors should also be taken into account.

Abstract

Müller cells are macroglia and play many essential roles as supporting cells in the retina. To respond to pathological changes in diabetic retinopathy (DR), a major complication in the eye of diabetic patients, retinal Müller glia produce a high level of vascular endothelial growth factor (VEGF or VEGF-A). As VEGF is expressed by multiple retinal cell-types and Müller glia comprise only a small portion of cells in the retina, it has been a great challenge to reveal the function of VEGF or other globally expressed proteins produced by Müller cells. With the development of conditional gene targeting tools, it is now possible to dissect the function of Müller cell-derived VEGF *in vivo*. By using conditional gene targeting approach, we demonstrate that Müller glia are a major source of retinal VEGF in diabetic mice and Müller cell-derived VEGF plays a significant role in the alteration of protein expression and peroxynitration, which leads to retinal inflammation, neovascularization, vascular leakage, and vascular lesion, key pathological changes in DR. Therefore, Müller glia are a potential cellular target for the treatment of DR, a leading cause of blindness.

Key words: Müller glia; Vascular endothelial growth factor; Protein modification; Inflammation; Blood-retina barriers; Diabetic retinopathy

Core tip: Diabetic retinopathy is a disorder of blood-retina barriers (BRBs) and neurons. Anti-vascular endothelial growth factor (VEGF) drugs are explored

for treating BRB breakdown in the disease. As VEGF is also potentially beneficial, it is essential to understand the cellular and molecular mechanisms of VEGF action in the retina. Discussion is centered on the usefulness of conditional gene targeting mice in dissecting the function of globally expressed VEGF and in identifying significant roles for Müller glia-derived VEGF in diabetes-induced changes in protein expression/modification, inflammation, and BRB lesions and leakage.

INTRODUCTION

Müller cells, the principal macroglia of mammalian retina, span from the vitreal surface to subretinal space and cover all retinal layers. This structural arrangement is ideal for them to serve as major supporting cells in regulating physiological and pathological responses in retinal vasculature and neurons. In the retina, Müller glia play many essential roles in metabolism, functions, maintenance, and protection by providing trophic factors, removing metabolic wastes, controlling extracellular space volumes and ion and water homeostasis, participating visual cycles, releasing neurotransmitters, regulating blood-retina barrier (BRB) function, and modulating innate immunity^[1]. Müller glia is also a major respondent to various stresses by reactive gliosis which involves in morphological, biochemical, and physiological changes. Under some pathological conditions, uncontrollable alteration in growth factor production, such as overexpression of vascular endothelial growth factor (VEGF-A or VEGF) in diabetic retinopathy (DR), results in a detrimental effect and causes vision loss. In this mini-review, we will discuss the general role of VEGF in DR and the function of Müller cell-derived-VEGF (MCD-VEGF) in protein expression/modification, inflammation, BRB function, and vascular and neuronal integrity in diabetic animals.

DIABETIC RETINOPATHY

DR is a leading cause of blindness in working-age people in industrialized countries and is traditionally regarded as a microvascular complication in the eye of diabetic patients due to an apparent breakdown of the endothelial barrier, which is formed by orderly arranged tight junction proteins. The structural interactions between these tight junction proteins control the fluid flow through the barrier^[2]. Patients with endothelial barrier breakdown demonstrate the following key clinical characteristics: retinal

hemorrhages, microaneurysms, cotton-wool spots, lipid exudates, macular edema, capillary occlusion, and retinal neovascularization^[2]. Studies with retinal pigment epithelium (RPE) barrier by others and us suggest that the breakdown of the tight junctions in the RPE barrier may contribute substantially to diabetes-induced blood-content leakage^[3-5], which is responsible for at least some form of macular edema^[6]. Therefore, DR is not just a microvascular disease, but rather a disorder of BRB. Macular edema resulted from BRB breakdown and retinal neovascularization are two most devastating causes of vision loss in diabetic patients. On the other hand, it is increasingly recognized that the loss of retinal neuronal function and viability occurs before the onset of BRB abnormalities in diabetic patients and in experimental animals^[7-11]. Perhaps neuronal and BRB disorder is a more appropriate description for DR.

VEGF IN REGULATING BLOOD-RETINA BARRIER FUNCTION

VEGF-A or VEGF, a heparin-binding homodimeric glycoprotein^[12,13], belongs to a family of seven members, including VEGF-A to -F and placental growth factor and (PlGF). Each of them may also have several isoforms due to alternative splicing, which affects their solubility, and thus is responsible for their cellular localization. The most intensively studied and predominant isoform of VEGF-A in humans is VEGF-A₁₆₅. VEGFs exert their function through complicated receptor- and co-receptor-mediated signaling cascades, which involves VEGF receptor-1 (VEGFR1), VEGFR2, VEGFR3, neuropilin-1, neuropilin-2, vascular endothelial cadherin, and integrin^[14]. Much of the literature information regarding VEGFs in the eye is centered on the pathobiology of VEGF-A due to its high relevance to the pathogenesis of DR, retinopathy of prematurity (ROP), and age-related macular degeneration (AMD), leading causes of blindness.

VEGF is a potent mitogenic factor for endothelial proliferation and migration and tube formation during vessel development and is a major stimulator for embryogenesis, vasculogenesis, and angiogenesis^[13,15]. Disruption of a single VEGF allele is lethal in mice at embryonic day 11-12^[16,17]. VEGF is a major regulator of pathological neovascularization in proliferative DR^[18]. VEGF blockade has been shown to inhibit hypoxia-induced retinal angiogenesis^[19-21]. Due to its potent activity in inducing blood barrier hyperpermeability^[22-25], VEGF is regarded as a major contributor to the high level of blood-content leakage in DR^[26,27]. Overexpression of VEGF or its receptors, which causes disorganization of endothelial and RPE tight junctions^[25,28,29], is associated with diabetic macular edema^[30].

A major regulator for VEGF signaling is oxygen tension and VEGF expression is induced by hypoxia,

a pathological condition occurs after early stages of DR^[31]. While hypoxia-inducible factor-1 (HIF-1) is a critical regulator in this response^[32], its degradation is controlled by von-Hippel-Lindhal (VHL) suppressor protein^[33]. Therefore, HIF-1 (perhaps other HIFs) and VHL are key upstream regulators for VEGF-induced BRB breakdown in DR through VEGFR2^[13,15,34]. Although VEGF signaling may be a major pathogenic mechanism for DR, various growth factors, inflammatory cytokines, and prostaglandins may also affect the disease through VEGF signaling-dependent or independent mechanisms^[35-38]. As a result of intensive effort in VEGF pathobiology and pharmacology, anti-VEGF agents are utilized as a major strategy for the treatment of retinal neovascularization, BRB breakdown, and macula edema in DR.

CONDITIONAL VEGF DISRUPTION IN MÜLLER GLIA

VEGF is produced by several retinal cell-types. Müller glia and RPE cells are thought to produce high levels of VEGF^[39]. Indirect evidences obtained from *in vivo* localization and molecular biology approach with cell cultures suggest a significant role for VEGF in regulating BRB function in DR^[40,41]. However, the importance of MCD-VEGF in DR remained unclear for a long time after the initial discovery of VEGF as a potential pathogenic factor in DR. A major reason for this is that Müller glia only comprise a small portion of retinal cells and VEGF is expressed by multiple cell-types, which makes it difficult to detect Müller cell-specific VEGF expression by immunohistochemistry (IHC) or immunoblotting (IB). Additionally, more and more “new” VEGF functions have been identified since the discovery of its involvement in BRB function in the mid-1990s^[27,42]. While other retinal cells may not produce a high level of VEGF at a given time, it is almost impossible to pinpoint the local effect of VEGF produced by these cells, if VEGF action is blocked globally by genetic, immunological, biochemical, or pharmacological approaches. Therefore, cell-specific approach may be the “only” way to delineate the precise function of Müller cell-derived VEGF (MCD-VEGF). As Müller glia play such a critical role in general health and functions of the retina, a better understanding of their biology is paramount to the prevention and treatment of retinal diseases^[43]. For this purpose, several laboratories developed cell-specific genetic tools for Müller glia^[44], which is very helpful for dissecting the specific function of globally expressed proteins, such as VEGF, in Müller cells.

In a serendipity fashion while developing inducible Cre/*lox* system for the RPE using the promoter of human vitelliform macular dystrophy-2 (*Vmd2*) gene^[45,46], we identified one transgenic founder mouse that was capable of carrying out productive Cre-mediated excise recombination in Müller glia. This transgenic Cre-drive line provides an opportunity to generate conditional VEGF

Table 1 Alteration in protein expression/modification in diabetic or hypoxic Müller cell-specific KO mice

Model/time	Proteins/modification	Alteration
STZ-induced diabetes/6 mo	Albumin	Decrease (59%)
STZ-induced diabetes/2 mo	ICAM1	Decrease (62%)
STZ-induced diabetes/2 mo	Nitrotyrosine	Decrease (19%)
STZ-induced diabetes/6 mo	Occludin	Increase (60%)
STZ-induced diabetes/2 mo	pNF-κB p65	Decrease (48%)
STZ-induced diabetes/2 mo	TNFα	Decrease (53%)
STZ-induced diabetes/6 mo	VEGF	Decrease (51%)
STZ-induced diabetes/6 mo	ZO1	Increase (130%)
Oxygen-induced retinopathy	Albumin	Decrease (56%)
Oxygen-induced retinopathy	VEGF	Decrease (45%)
Oxygen-induced retinopathy	Occludin	Increase (35%)

STZ: Streptozotocin; VEGF: Vascular endothelial growth factor; ICAM1: Intercellular adhesion molecule-1; TNFα: Tumor necrosis factor-α; NF: Nuclear factor; ZO1: Zonula occludens-1.

knockout (CVKO) mice that disrupt VEGF expression mainly in Müller glia. The CVKO mice were generated by breeding this Müller glial Cre-drive line with a mouse line carrying *loxP*-flanked VEGF gene (*VEGF^{ff}*), called floxed VEGF mice^[45,47,48]. The degree of VEGF disruption in the Müller glia was assessed by IB with primary Müller cell cultures derived from the CVKO mice, which reduced VEGF production by 66%. This degree of VEGF knockout (KO) caused a near 50% reduction of total retinal VEGF in CVKO mice under normal conditions^[48,49]. To ascertain whether the production of MCD-VEGF was substantially decreased in CVKO mice in disease models^[49], we examined VEGF expression in diabetic and hypoxic models (see detail below). While diabetes and hypoxia doubled retinal VEGF in WT mice, the deletion of MCD-VEGF caused a near 50% decrease of VEGF overexpression in the retina under hypoxic or diabetic conditions (Table 1). These data were corroborated by IHC with CVKO mice^[48,49]. Considering the fact that Müller cells only comprise a small portion of retinal cells, our data undisputedly suggest that Müller glia are a major cellular origin of VEGF in mouse retinas.

MÜLLER CELL-DERIVED VEGF IN PROTEIN EXPRESSION/MODIFICATION AND RETINAL INFLAMMATION

To determine whether deletion of MCD-VEGF resulted in any significant changes in DR-associated gene expression, we performed IB analysis with retinal extracts from CVKO mice after diabetes was induced with streptozotocin (STZ). HIF1α is a major parameter for oxygen tension and the induction of HIF1α contributes to the increase in VEGF^[50]. To delineate the regulatory mechanisms between HIF1α and VEGF, we examined the expression level of HIF1α in hypoxic and diabetic CVKO mice. Although HIF1α was up-regulated significantly in hypoxic retinas at P14 (see detail below) and diabetic retinas (two month post-STZ injection) in WT controls, there was no apparent

Table 2 Pathological changes in diabetic or hypoxic Müller cell-specific KO mice

Model	Pathological changes	Alteration
STZ-induced diabetes	Leukocytosis	Decrease (75%)
STZ-induced diabetes	Vascular leakage	Decrease (60%)
STZ-induced diabetes	Acellular capillaries	Decrease (45%)
STZ-induced diabetes	Vascular leakage	Decrease (60.0%)
Oxygen-induced retinopathy	Pre-retinal neovascularization	Decrease (34%)
Oxygen-induced retinopathy	Neovascularization area	Decrease (40%)
Oxygen-induced retinopathy	Vaso-oblivation area	Decrease (30%)

STZ: Streptozotocin.

difference in the levels of retinal HIF1 α between the CVKO mice and WT controls under hypoxic and diabetic conditions^[48,49], suggesting that hypoxia/HIF1 α is an upstream regulator of VEGF produced by Müller glia.

Nuclear factor-kappa-B (NF- κ B) is a transcription factor and a major player in inducing early pathological changes, such as inflammation, in DR^[51,52]. To explore if MCD-VEGF regulated NF- κ B in diabetic retina, we examined the expression/phosphorylation of NF- κ B p65 subunit. While there was no detectable change in the total NF- κ B p65 level between the CVKO mice and WT controls, the loss of MCD-VEGF caused a dramatic decrease (48%) of phosphorylated (activated) NF- κ B p65 in the retina 2 mo after STZ-injection (Table 1). This result suggests that activated p65 is downstream of MCD-VEGF in DR^[49]. Nitric oxide (NO) is an important inflammatory mediator and its level is a representation of oxidative stress in the retina of diabetic patients and animals^[53-55]. Peroxynitrite is a highly reactive oxidant, which is formed by the rapid combination of NO with superoxide. Increased peroxynitrite formation may be directly linked to diabetes-induced VEGF overexpression and there is a possible loop effect of VEGF signaling and peroxynitrite formation^[56,57]. To determine the role of MCD-VEGF in protein nitration, we examined the level of nitrotyrosine, a biomarker of peroxynitrite, in retinal protein extracts from CVKO and control mice 2 mo after STZ-injection. The retinal extracts from diabetic CVKO mice demonstrated a 19% decrease of proteins with nitrotyrosine (Table 1), indicating that the disruption of MCD-VEGF reduced oxidative stress.

Inflammation is an early pathological response in DR. To identify the role of MCD-VEGF in retinal inflammation in DR, we examined the levels of pro-inflammatory markers in CVKO mice by IB analysis for intercellular adhesion molecule-1 (ICAM1) and tumor necrosis factor- α (TNF α), 2 mo after STZ-injection. Compared with controls, the CVKO mice showed 62.3% and 52.9% reduction of ICAM1 and TNF α (Table 1), respectively. These results suggest that the deletion of MCD-VEGF substantially inhibits inflammation in diabetic retinas^[49]. This notion is reinforced by the result from the leukostasis assay

showing a 75.0% reduction of adherent leukocytes, a cardinal feature of retinal inflammation in DR, in the retinal microvasculature of the CVKO mice 2 mo after STZ injection (Table 2). Collectively, these data point to a major role for MCD-VEGF in developing inflammation in DR.

MÜLLER CELL-DERIVED VEGF IN BRB FUNCTION AND INTEGRITY

As diabetic rodents usually do not develop retinal neovascularization^[58], the closest way to investigate this is to utilize oxygen induced retinopathy (OIR), a model mimicking an infant blinding disease, ROP. To examine the effect of MCD-VEGF on BRB function, the severity of retinal neovascularization was examined in CVKO mice subjected to OIR. The CVKO mice were placed in hyperoxia (75% oxygen) from postnatal day 7 (P7) to P12 and were then kept under normoxia for up to 5 d. In OIR model, the retina was relatively hypoxic at P14 (compared with that at P7-12), as judged by the abundance of HIF1 α . The level of retinal VEGF in hypoxic CVKO mice was decreased by 45% (Table 1). At P17, fluorescein angiography was performed and OIR-treated CVKO mice demonstrated 40% and 30% reductions in areas of retinal neovascularization and of vaso-oblivation, respectively (Table 2). Retinal sections from OIR-treated CVKO mice also showed a 34% reduction in the number of pre-retinal neovascular endothelia (Table 2). As a consequence of decreasing retinal neovascularization and unhealthy microvasculature, we observed a 56% reduction of OIR-induced vascular leakage in CVKO mice (Table 1), judged by IB for albumin. This observation was supported by IHC data^[48].

IB analysis with retinal and vitreous extracts prepared from PBS-perfused diabetic WT mice demonstrated a 1.5-fold increase in extravascular albumin 6 mo after STZ-injection. However, the disruption of MCD-VEGF caused a near 60% reduction of albumin leakage in age-matched diabetic mice (Table 1). Such a reduction can be visualized in the retinal flat-mounts of diabetic CVKO mice by intravenously injected fluorescein isothiocyanate-labeled albumin^[49].

To delineate the mechanistic insights of MCD-VEGF in diabetes-induced vascular leakage, we analyzed the levels of occludin and Zonula occludens-1 (ZO1), two major tight junction proteins, in the retina^[49]. While diabetes resulted in 39% and 58% decreases of occludin and ZO1, respectively, in WT animals, no alteration in occludin and ZO1 expression was observed in diabetic CVKO mice. As a result, the diabetic CVKO mice had 60% and 130% upregulation of occludin and ZO1 (Table 1), compared with that of diabetic WT controls. Our data indicated that the disruption of MCD-VEGF resulted in a significant reduction of diabetes-induced retinal vascular leakage by attenuating the depletion of occludin and ZO1. This result was supported by a 36% increase in the level

Figure 1 A simplified schematic diagram for the potential roles of Müller cell-derived-vascular endothelial growth factor in diabetic retinopathy. Alteration in pathological characteristics caused by MCD-VEGF is indicated in italic. Potential functions without direct proof by experimental and clinical data are indicated with a question marker. MCD-VEGF plays a significant role in causing retinal inflammation, neovascularization, vascular leakage, vascular lesion, and protein alteration and modification in the pathogenesis of DR. MCD-VEGF: Müller cell-derived-VEGF; DR: Diabetic retinopathy; VEGF: Vascular endothelial growth factor.

of occludin in the retina (Table 1) and by qualitative evidence from IHC in hypoxic CVKO mice generated with OIR^[48]. Collectively, our data suggest that MCD-VEGF was a major inducer of vascular leakage in OIR-treated hypoxic mice and in diabetic mice through VEGF signaling-induced decrease of tight junction integrity.

To assess retinal vascular lesions in diabetic CVKO mice, the number of acellular capillaries in trypsin digested retinal flat-mounts was examined 6 mo after diabetes was induced^[49]. The diabetic CVKO mice had 45% fewer acellular capillaries than that in controls (Table 2), suggesting that the loss of MCD-VEGF had a protective effect on retinal microvasculatures, which reduced vascular leakage through the endothelial barrier in DR.

MÜLLER CELL-DERIVED VEGF IN RETINAL DEVELOPMENT AND INTEGRITY

Disruption of MCD-VEGF in the CVKO mice did not affect the development of retinal and choroidal vasculatures and overall retina^[48], as determined by morphological analysis in retinal sections with light microscopy, functional test with electroretinography, and retinal and choroidal vascular density and morphological examination in retinal and RPE/choroidal flat-mounts with IHC and fluorescein angiography. Although negative results from conditional gene KO studies are not conclusive, our observation is somewhat expected as Müller glia are one of the last few cell-types to develop and KO of VEGF in neural retina during embryonic development results in abnormal retinal vessels^[59]. In our study, the loss of MCD-VEGF did not

affect retinal integrity in the aging CVKO mice under normal and diabetic mice^[49]. This result is seemingly contradictory to the observation that VEGF is a survival factor for retinal ganglion cells, photoreceptors, and Müller glia^[60,61]. The following may account for the “discrepancy”: the disruption of MCD-VEGF in the CVKO mice did not remove VEGF completely as several types of retinal cells produce permeable VEGF and a basal level of VEGF may be sufficient for physiological VEGF function, such as neuronal function and integrity in the retina. In addition, our studies did not blocked VEGF signaling in any retinal cells. However, the result that MCD-VEGF had no apparent role in retinal development and integrity provides an advantage to investigating the role of MCD-VEGF in CVKO mice. Since there was no distinguishable defect in the animals under normal conditions, any phenotypical difference between the CVKO and control mice can be attributed to the defects from deleting MCD-VEGF.

CONCLUSION

Work from others and our laboratories demonstrated a major role for MCD-VEGF in DR, as summarized in Figure 1. Our data clearly pinpoint that MCD-VEGF plays a major role in protein alteration/modification, inflammation, neovascularization, vascular leakage, and vascular lesion in DR. Our study also suggests that MCD-VEGF may be a downstream regulator of DR-related master regulator, such as HIF1 α /hypoxia, but upstream regulator for others, such as NF- κ B and peroxynitrite. We also need to keep in mind that DR is a multifactorial disease. Other growth factors and pro-inflammatory mediators may be involved in developing DR in a VEGF-independent manner. A better understanding of VEGF-dependent and -independent pathways is the key to new therapeutic strategies for intervening multiple drug targets simultaneously, since anti-VEGF strategy alone cannot prevent DR completely. The CVKO mice provide an excellent animal model in this new endeavor.

VEGF is a neural protectant and it has been shown to modulate neuronal function in the brain^[62]. Potentially, MCD-VEGF may also be involved in regulating neuronal integrity. With the development of tools in studying Müller glia and their relationship with neuronal survival in diabetes and hypoxia^[44,63,64], the role of MCD-VEGF in neuroprotection in the retina should be sorted out shortly. Current literature suggests that MCD-VEGF may have a critical role in maintaining Müller glia through autocrine in hypoxia and diabetes. However, it is not clear whether MCD-VEGF acts solely as trophic factor in the maintenance of Müller glia. Other mechanism, such as proliferation (Müller cell self-renew), may also be potentially important to the maintenance of retinal integrity. In principles, mammalian Müller cells are capable of dedifferentiation, proliferation, and differentiation into various retinal neurons under various conditions and

are considered as a major retinal stem cell^[65]. It will be fascinating if MCD-VEGF can act similarly as other growth factors in differentiating Müller cells to neurons for neuro-protection^[66].

Although there are many publications on VEGF or MCD-VEGF in DR, little is known about its actually signaling pathways. As discussed earlier, the presence of at least seven VEGF receptors and co-receptors accounts for the difficulties in revealing their mechanisms. Additionally, VEGF is a secreted protein and loss of VEGF produced by a single cell-type can be compensated by others. Delineating detailed mechanisms may greatly enhance our understanding to the pathogenesis, treatment, and neuronal function in DR, which is critical to the improvement and safety of current anti-VEGF strategy and to the design of new treatments for the disease.

ACKNOWLEDGMENTS

We thank Dr. Gennadiy P Moiseyev for critical reading of this manuscript and members of our laboratories for providing data and helpful discussions.

Abstract

In the epidemiologic context of maternal obesity and type 2 diabetes (T2D), the incidence of gestational diabetes has significantly increased in the last decades. Infants of diabetic mothers are prone to various

neonatal adverse outcomes, including metabolic and hematologic disorders, respiratory distress, cardiac disorders and neurologic impairment due to perinatal asphyxia and birth traumas, among others. Macrosomia is the most constant consequence of diabetes and its severity is mainly influenced by maternal blood glucose level. Neonatal hypoglycemia is the main metabolic disorder that should be prevented as soon as possible after birth. The severity of macrosomia and the maternal health condition have a strong impact on the frequency and the severity of adverse neonatal outcomes. Pregestational T2D and maternal obesity significantly increase the risk of perinatal death and birth defects. The high incidence of maternal hyperglycemia in developing countries, associated with the scarcity of maternal and neonatal care, seriously increase the burden of neonatal complications in these countries.

Core tip: Increased mortality and morbidity are historically attributed to neonates of diabetic mothers. A discerning analysis of the literature shows that these adverse outcomes are uncommon among infants born from "pure" gestational diabetes mellitus (GDM) mothers, well managed during pregnancy. Macrosomia is the predominant adverse outcome and the main factor linked to neonatal complications. Poor maternal glycemic control, especially in the context of maternal type 2 diabetes and obesity increases the risk of all adverse neonatal outcomes, most strikingly the risk of perinatal mortality and birth defects. Developing strategies for screening and managing women with GDM must be encouraged notably in middle and low income countries and, also to limit the adverse effects on global health population in the future.

What neonatal complications should the pediatrician be aware of in case of maternal gestational diabetes? *World J Diabetes* 2015; 6(5): 734-743 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i5/734.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i5.734>

INTRODUCTION

Gestational diabetes mellitus (GDM) is defined as a glucose intolerance of any degree with onset or first recognition during pregnancy. In high income countries, but also in middle and low income countries, because of the spreading of industrialized lifestyle, the incidence of obesity and type 2 diabetes (T2D) has dramatically increased, and subsequently the incidence of GDM^[1].

In high-resource countries, progress has been made during the past fifty years regarding preconceptional care, screening and management of GDM. However, in low and middle-income countries, quality of antenatal care to detect and manage GDM, are often poorly available. As a consequence, the prenatal and neonatal burden of GDM may be paradoxically higher in these countries, although this point is not well documented^[2].

Much of the currently available knowledge on the consequences of maternal diabetes on the offspring has been provided by studies on type 1 diabetes (T1D), while the risks related to GDM, which is much more frequent, need to be clarified in order to improve and to adapt neonatal management^[3]. Moreover, extensive data suggest that the offspring of diabetic mothers is furthermore exposed to an increased risk of developing chronic, non-communicable diseases at adulthood^[4].

Neonatologists are facing first-line this new epidemiologic setting. This review addresses the currently available knowledge on short term consequences of GDM in neonates and focuses on situations with increased risks of neonatal adverse outcomes.

SHORT TERM OUTCOMES

Macrosomia

Macrosomia is the most constant complication in GDM. The concept of excessive fetal growth is expressed either by the word "macrosomia" or by the expression "large for gestational age" (LGA). Macrosomia is defined by a birth weight (BW) of 4000 or 4500 g and more, depending on the authors. However, in this definition, gestational age (GA) is not taken into account. The term LGA corresponds to a BW \geq 90th percentile or $> +2SD$ ($> 97^{\text{th}}$ percentile) for GA. This definition allows premature newborns with excessive fetal growth to be identified. Macrosomia in newborns of diabetic mothers is characterized by excess body fat, an increased muscle mass and organomegaly, without increase in brain size.

The Pedersen-Freinkel's hypothesis, expressed sixty years ago, suggested that fetal overgrowth is related to increased transplacental transfer of maternal glucose, which stimulates the release of insulin by fetal pancreatic beta cells^[5]. Insulin is a major factor of fetal growth and it up-regulates the Insulin-like Growth Factor (IGF) system, subsequently leading to fetal macrosomia. According to this hypothesis, different studies have characterized the link between maternal glycemia and neonatal macrosomia or fat mass^[6,7].

The HAPO study showed a continuous, positive association between maternal glycemia, fetal hyperinsulinism and BW^[8]. A linear and continuous relationship between body fat percentage in newborns, maternal glycaemia and fetal insulin levels has been found in this study^[9]. More recently, other mechanisms that may also contribute to fetal overgrowth were evoked, like maternal metabolic environment and placental modifications^[10]. In particular, maternal lipids availability and transport to the fetus may be enhanced in case of maternal diabetes^[11].

Hence, all types of maternal diabetes are risk factors for macrosomia. As discussed below, macrosomia is *per se* a cause increased neonatal adverse outcome and this point emphasizes the importance of recognizing the excess of growth, even in preterm infants. Treatment of GDM significantly reduces the rate of macrosomia^[12,13].

Preterm birth

A number of studies have reported an increased risk of preterm births in case of diabetes. However, data are not always available on the respective proportion of induced and spontaneous births, considering the increased maternal and fetal morbidity of diabetes during pregnancy. The benefits of early delivery to avoid fetal death or shoulder dystocia must be balanced against the morbidity linked to preterm birth, especially the respiratory morbidity.

The link between GDM and spontaneous preterm birth is still controversial. Hedderson *et al.*^[14] showed in a large cohort study that GDM was an independent risk factor for spontaneous preterm birth (RR = 1.42, 95%CI: 1.15-1.77). On the other hand, Yogeve *et al.*^[15] found that the rate of spontaneous preterm delivery was not increased in GDM compared to non-GDM patients. Nevertheless, both studies found a relationship between higher glucose values in the oral glucose tolerance test (OGTT) or higher mean blood glucose levels and preterm birth.

Metabolic disorders

Hypoglycemia: The link between macrosomia, increased cord C-peptide levels that reflects fetal insulin secretion, and neonatal hypoglycemia has long been known. The data collected by the HAPO study confirmed this relationship: neonatal hypoglycemia was strongly associated with elevated cord serum C-peptide levels^[16]. The infant of a diabetic mother is

at risk of transient hyperinsulinism, which prevents at birth the normal activation of metabolic pathways producing glucose and ketone bodies, and causes increased glucose consumption by tissues^[17].

The exact incidence of hypoglycemia in case of maternal diabetes is difficult to assess due to the various definitions used for neonatal hypoglycemia in the literature. The rate of intravenously treated hypoglycemia was reported between 5% to 7% in two large studies^[18,19]. Comparisons with the risk observed in healthy newborns are difficult also because monitoring of blood glucose at birth was different according to the mother was diabetic or not in most of the studies. At last, in many studies, blood glucose level in neonates is checked soon after birth, although the pathologic significance of low blood glucose levels immediately after birth, in the absence of specific symptoms, is still questioned. Indeed, an immediate fall in blood glucose concentration is observed after birth because of the interruption of placental supply, reaching a nadir between 1 and 2 h in healthy term infants^[20]. Normal levels at this period cannot be distinguished from abnormal ones in asymptomatic infants and the incidence of hypoglycemia is likely to be overestimated^[21]. From 3 h of age, blood glucose then rises spontaneously, even in the absence of any nutritional intake, due to the activation of metabolic regulatory pathways. Therefore, in the absence of abnormal clinical signs, the first blood glucose measurement is recommended after the second feed, which generally allows infants who cannot manage adequate early glucose homeostasis to be identified^[21].

There is currently no consensus on the indications for systematic glucose blood monitoring in asymptomatic infants born to diabetic mothers. It seems reasonable to consider that LGA or growth restricted infants (< 10th percentile) born to diabetic mother may benefit from blood glucose concentration check at 3 to 6 h intervals during the first day of life. On the other hand, normal-grown infants of mothers with diet-controlled GDM should not be monitored^[22].

For newborns with no clinical signs, therapeutic intervention can be considered starting at a threshold value of 0.36 g/L (2.0 mmol/L). Early and frequent breastfeeding remains the key in preventing hypoglycemia, whatever the infant's BW, as far as he/she is able to feed autonomously. Therefore, infants of diabetic mothers should be kept aside their mother, in the absence of significant complications requiring a transfer to a special care neonatal unit. Even in mildly or moderately symptomatic infants with low blood glucose levels, sustained breastfeeding, or eventually formula supplements should be tried first, provided a satisfactory clinical response is obtained^[22]. In case the infant is unable to feed, an IV glucose supplementation (3-6 mg/kg per hour) should be provided at constant rate of infusion, in order to avoid rebound hypoglycemia.

Hypocalcemia: Hypocalcemia can be defined by

plasma calcium concentration below 2 mmol/L or ionized calcium concentration below 1.1 mmol/L, regardless of GA or BW. Transient neonatal hypocalcemia has been mainly reported in neonates of pre-gestational insulin dependent- diabetic mothers and may be partly related to maternal hypomagnesemia and subsequent fetal hypomagnesemia. The severity of hypocalcemia also appeared to be related to the severity of maternal diabetes, as calcium concentration in the neonates was negatively related to maternal HbA1c levels^[23].

It seems that hypocalcemia is rarely of clinical significance, particularly in case of GDM, unless other complications are associated^[24].

The mechanism is still unclear but seems to involve an abnormal calcium phosphorus metabolism during pregnancy with a decrease in calcium and vitamin D concentrations especially during the third trimester. Some studies have reported an association between GDM and low maternal vitamin D status, particularly with poor blood glucose control. Conversely, there are growing evidences that women who develop GDM are more likely to be vitamin D deficient^[25]. Other factors like prematurity and perinatal asphyxia can contribute to low calcium levels^[26].

Therefore, there is no indication to screen healthy baby for hypocalcemia and hypomagnesemia. When treatment is indicated, it consists to give oral vitamin D supplements and calcium gluconate orally or intravenously (40-60 mg/kg per day) and magnesium treatment according to plasma level.

Hyperbilirubinemia: Hyperbilirubinemia is more frequently observed in infants born to diabetic mothers. It is not a serious complication if non-toxic levels are diagnosed and treated, which is usually the case. The risk of nuclear icterus, the severe form of hyperbilirubinemia, is not reported in cases of diabetes as being more frequent. In the HAPO study, hyperbilirubinemia was weakly associated with maternal blood glucose levels^[8]. Polycythemia could be one of the reasons, but additional mechanisms, such as preterm birth, poor liver conjugation are likely to be involved.

Hematologic disorders

It has been reported that infants of diabetic mothers may have polycythemia [hematocrit (Ht) higher than 65%]. Mechanisms evoked are reduced transplacental oxygen transport to the fetus and increased fetal oxygen consumption due to fetal hyperinsulinism. This may lead to fetal hypoxia and increased levels of fetal erythropoietin. However, no consistent correlation between plasma erythropoietin level and polycythemia has been reported in human. Increased insulin and IGFs levels can also increase red blood cells production. A strong positive correlation between maternal β -hydroxybutyrate levels and polycythemia was observed in a small observational study^[27].

Normovolemic polycythemia seen in infants from diabetic mother can lead to hyperviscosity. Early symptoms are unspecific, feeding problems, plethoric aspect, acro-cyanosis, lethargy, hypotonia, respiratory distress, jitteriness and irritability, seizure (due to multiple cerebral infarcts), necrotizing enterocolitis, hyperbilirubinaemia and hypoglycemia have all been found associated. Polycythemia may also favor deep vessels thrombosis. Hypoglycemia may be aggravated in infants from diabetic mothers in case of polycythemia, due to increased glucose consumption by the increased red cell mass. Partial exchange transfusion with saline solution should be performed in symptomatic infants according to the formula (volume exchanged in mL): $(Ht-55) \times \text{weight (kg)} \times 80/Ht$.

Respiratory disorders

The rate and the risk of respiratory distress syndrome (RDS) in cases of GDM cannot be accurately established, due to insufficient precise data^[28]. In a recent study from the French birth cohort in 2011, including 474 614 births, the risk for neonatal respiratory disorders was slightly but significantly increased in case of GDM [OR adjusted on mother's age and gestational age, 1.2 (1.1-1.3)] (personal data not yet published).

It is generally recognized that, besides RDS, infants born to diabetic mothers are exposed to increased risk of transient tachypnea of the newborn. This is more likely to happen after caesarian section due to delayed reduction of alveolar fluid at birth and when the infants have macrosomia. This was clearly showed in infants of T1D mothers^[29].

Diabetes, but also maternal body mass index (BMI), is associated with a higher risk of persistent pulmonary hypertension (PPH). However, other independent risk factors like macrosomia and caesarean deliveries might be in the causal pathway between diabetes, overweight and PPH^[30].

Cardiac disorders

Hypertrophic cardiomyopathy: Fetuses exposed to maternal hyperglycemia and hyperinsulinism, are prone to develop hypertrophic cardiomyopathy. It primarily affects the interventricular septum, but can extend to the myocardium in more severe cases^[31].

Myocardial hypertrophy has been reported in both pregestational diabetes and GDM with a wide range of frequencies (between 25% to 75% of infants born to diabetic mothers)^[32,33]. The incidence was lower in case of pure GDM comparing to pregestational diabetes^[34]. The most recent studies showed that good maternal glycemic control does not entirely prevent interventricular septum hypertrophy and minor fetal cardiac function impairment, regardless of the type of diabetes^[35,36]. Although myocardial hypertrophy is associated with an overall decrease in ventricular compliance and an increase in contractility of the left and right ventricles, it is most often asymptomatic. It can sometimes lead to severe morbidity and mortality,

according to the severity and the extension of cardiac hypertrophy. Major septal hypertrophy can lead to subaortic stenosis and secondary mitral insufficiency. It is usually considered that heart hypertrophy resolves anatomically within few months. However, the long term effect of diabetic cardiomyopathy on heart function remains to be elucidated.

Cardiac malformations: Some data supports that GDM carries a small but significantly increased of congenital defects (ORs between 1.1 and 1.3), but it is much lower than in women with pregestational diabetes^[37]. The malformations described are similar to those reported in pregestational diabetes, especially cardiovascular defects and anomalies involving the musculo-skeletal and central nervous systems^[38,39].

The most commonly reported cardiac malformations include transposition of the great arteries, double outlet right ventricle, truncus arteriosus, hypoplastic left heart syndrome and ventricular septal defects^[40].

Antenatal ultrasounds play an important role in monitoring fetal cardiac anatomy and function. Antenatal diagnosis of cardiac malformation is helpful to decide the place of birth when specific neonatal cardiologic care is needed. Babies of women with GDM should have an echocardiogram in the presence of clinical signs at birth associated with congenital heart malformations (cyanosis, murmur) or cardiomyopathy (heart failure).

Neurological impairments

Infants of diabetic mothers are prone to neurologic impairments, mainly due to perinatal asphyxia, birth traumas and metabolic disorders.

Perinatal asphyxia: Increased risk of perinatal asphyxia has been reported in diabetic pregnancies in a number of studies. The risks of perinatal asphyxia are increased in case of macrosomia, particularly when there is a shoulder dystocia^[28,41]. Impaired fetal environment characterized by fetal hypoxia has also been evoked as a contributing factor.

However, in cases of GDM, the incidence of perinatal asphyxia, defined by a 5-min Apgar score < 7, was very low (1%-2%) in a study including more than a thousand neonates of GDM mothers^[18]. In another study, umbilical arterial pH < 7.2 was about 15% in GDM group, comparable to the non-diabetic group^[42]. In both studies, the incidence was not influenced by the treatment of maternal diabetes.

Metabolic disorders: Glucose is the main energy substrate for the brain. In newborns, hypoglycemia can lead to the situation where brain energy metabolism cannot be sustained. The consequences of low blood glucose levels depend on the availability of other substrates, such as lactate and ketone bodies also used by the brain to provide energy. These alternative substrates are not routinely measured, and the normal

threshold values are unknown. Their availability also depends on the clinical and nutritional status of the infant.

For infants presenting with clinical signs compatible with hypoglycemia, like apnoea, hypotonia, jitteriness, apathy, hypothermia, tremors and seizures, treatment must ensure that blood glucose levels remain above 0.45 g/L (2.5 mmol/L). An IV bolus dose of glucose (150-200 mg/kg) should be administered urgently, followed by a constant rate infusion. It is necessary to check that thereafter blood glucose concentrations stabilize within normal ranges (20). In case of clinical signs, Cornblath *et al.*^[43] have suggested that the Whipple triad should be fulfilled: a low blood glucose concentration; signs consistent with hypoglycemia; and resolution of signs and symptoms after restoring blood glucose concentrations to normal values. Therefore, if symptoms persist despite adequate treatment, other causes should be investigated, since these symptoms are not specific.

Symptoms from hypocalcemia are similar to those observed in hypoglycemia, but usually present later, between 24-72 h of life^[31]. Then, blood calcium concentration should also be measured in the presence of symptoms suggestive of hypocalcemia.

Brachial plexus injuries: The spinal cord is vulnerable to birth trauma with symptoms related to palsies of the brachial plexus.

The most common type of brachial plexus injury, also called Erb's palsy, involved the cervical roots C5 to C7. The infant presents with internally rotated arm and flexed wrist. The second most common type called total plexus palsy involves cervical roots C5-C8 and sometimes thoracic root T1. The infant presents with a flaccid and insensitive arm and with clawed hand. Paralysis of the hemi-diaphragm is also observed when phrenic nerve is involved, leading to respiratory insufficiency and requirement of mechanical ventilation^[44].

Incidence of brachial plexus palsy in newborns of diabetic mothers is low, between 0.2% and 3%. As a consequence, the risk could not be accurately measured^[28].

Poor suckling: It has been shown in the early nineties that maternal GDM may impair neonatal behavior, leading to lethargy and hypotonia related to delayed neural maturation. More recently, poorer suckling patterns were found at day 3 only among infants of insulin-managed GDM mothers, but not in the diet-managed mothers^[45]. This study confirmed some degree of neurologic immaturity during the early neonatal period.

Digestive impairment

Apart from the difficulties to feed because of poor suckling pattern, neonates of diabetic mothers may also exhibit neonatal small left colon, a cause of

functional lower intestinal obstruction that can mimic Hirschsprung disease. The pathophysiology is unknown but it is significantly associated with maternal diabetes. The treatment is always conservative as long as intestinal perforation does not happen. Contrast enema is both diagnostic (abrupt transition zone at the splenic flexure) and curative, promoting the evacuation of meconium relieving the intestinal obstruction^[46].

FACTORS THAT INFLUENCE THE SEVERITY OF NEONATAL ADVERSE OUTCOME IN GDM

The adverse neonatal outcomes described above are not constant in all cases but they are significantly influenced by the quality of maternal care and by maternal health. Furthermore, most of these complications are more likely to happen in macrosomic infants.

Maternal conditions and neonatal outcomes

Impact of maternal blood glucose levels and pregestational T2D on neonatal outcomes:

Perinatal death, malformations and prematurity are mainly influenced by maternal glucose levels. As discussed above, there is also a linear relationship between glucose maternal level and the frequency of macrosomia^[8]. Furthermore, the analysis of the risk of fetal malformation and perinatal death in case of GDM shows that undiagnosed pre-pregnancy T2D has a substantial impact on these serious perinatal complications.

There is a relationship between the malformation rate and maternal fasting blood glucose level^[39,47]. This risk also increases with maternal BMI, and when GDM is diagnosed during early pregnancy^[48,49]. Most major malformations occur very early in gestation during the embryonic stage. In diabetic pregnancies, they are attributable to unstable periconceptional glycemia. Maternal hyperglycemia results in excess glucose metabolism in the developing embryo that may alter various molecular chain reactions: (1) altered cell lipid metabolism, notably the production of prostaglandin E2 involved in the patency of the ductus arteriosus in utero^[50]; (2) high glucose levels induce an excess production of reactive oxygen species which has been shown to cause oxidative stress and subsequently increase the risk for fetal malformations, notably neural tube defect^[51]; and also (3) high glucose levels induce the activation of many proteins involved in apoptotic cell death, including members of the caspase families^[52]. Although data on the molecular basis of diabetic embryopathy have improved during the last years, mechanisms are still incompletely understood^[53].

These clinical and physiopathologic data suggest that the increased risk of congenital defects in GDM reported in some studies is likely to be related to the inclusion of women with undiagnosed T2D in the GDM

groups^[54].

Unlike in pregestational diabetes, the increased rate of fetal deaths in the 2nd and 3rd trimesters of pregnancy is debatable in cases of GDM^[55,56]. In a large cohort study, the rate of mortality was 16.2/1000 in the GDM group vs 12.5/1000 in the general population. Six weeks after delivery, women diagnosed with GDM were re-classified by a post-partum glucose tolerance test. Women having diabetes on post-partum test were considered as "newly presenting T2D". When those women were excluded from the GDM group, perinatal mortality was 8.9/1000 in the "true" GDM group, which was similar to the general population. Mortality was the highest in the groups with T2D diagnosed before and after pregnancy (respectively, 39.1/1000 and 56.2/1000)^[57]. These data demonstrated that the increased risk of perinatal death reported in case of GDM in some studies, seems to be attributable to undiagnosed T2D.

Prematurity is one of the leading causes of neonatal death. As discussed above, higher maternal glucose levels were observed in case of prematurity in GDM pregnancies. Furthermore, one of the main causes of induced preterm delivery is maternal pre-eclampsia which is more commonly associated with T2D pregnancies^[58].

Impact of maternal obesity in the complications of GDM: Maternal obesity is associated with worse perinatal outcome even in glucose-tolerant women. Macrosomia is the main complication reported in overweight or obese women, independently of diabetes^[59-62]. It is well recognized that neonates born to obese women, even if normal glucose tolerant, have increased fat mass^[63]. As in GDM, increased adiposity at birth is related to maternal excess of glucose and lipids availability, and placental transfer to the fetus^[11].

The risk of fetal and infant deaths are two to three times greater for women with preconceptional obesity, after excluding pregnancies affected by congenital anomalies or pregestational diabetes^[64]. It was recently showed that even modest increases in maternal BMI were associated with increased risk of fetal death, stillbirth, and neonatal, perinatal, and infant death. The relative risk per 5-unit increase in maternal BMI ranged from 1.15 to 1.24^[65]. Maternal obesity is also associated with an increased risk of a range of structural anomalies, with the higher risk for neural tube defects^[66,67]. It is interesting to note that the risk of particular malformations such as omphalocele and diaphragmatic hernia is increased in obese pregnant women, but not in case of diabetes^[68,69].

There is a tight link between maternal obesity and diabetes in pregnancy. Indeed, the risk of GDM increases with maternal BMI^[70]. The overall population-attributable fraction of GDM related to overweight was estimated at 46.2%^[71].

The benefit effect of treatment of diabetes on neonatal outcomes is lower in obese women, even

if targeted levels of glycemic control are achieved. Furthermore, when GDM is untreated or poorly controlled, overweight and obese women have a higher risk of poor neonatal outcome, compared to normal weight GDM women^[42,72].

The combination of GDM and obesity shows a greater impact on pregnancy outcomes than either GDM or obesity alone. This cumulative risk was shown for macrosomia, newborn percent body fat and birth trauma^[73]. It was also reported for a composite neonatal outcome (BW > 4000 g, birth trauma, shoulder dystocia, hypoglycemia, or jaundice)^[74].

Effects of macrosomia on neonatal outcomes

It has long been reported that the delivery of macrosomic infants is associated with a higher risk for adverse neonatal morbidity such as birth injury, respiratory distress and hypoglycemia. Macrosomia (BW > 4500 g), regardless of the cause, is also in itself a risk factor for asphyxia and perinatal death^[75].

Macrosomia increases the risk of shoulder dystocia, regardless of the cause. In the study by Zhang *et al.*^[75], the risk of birth injury was the highest for infants with a birth weight 4500-4999 g and ≥ 5000 g, [ORs 2.4 (2.2-2.5) and 3.5 (3.0-4.2), respectively].

In the case of GDM, there is a particularly high risk of respiratory distress in newborns with a BW ≥ 4000 g, compared to those with a BW of less than 4000 g [OR = 3.1 (1.11-8.65)]^[76]. In the other study, the risk of respiratory complications increased with increasing BW ≥ 4000 g, irrespective of maternal diabetic status^[22]. Furthermore, it seems that clinically significant hypertrophic cardiomyopathy without concomitant fetal macrosomia is rarely observed^[40].

The analysis of the data collected by the HAPO study showed that neonatal hypoglycemia was strongly related to elevated cord C-peptide levels. High C-peptide levels are related to the importance of fetal hyperinsulinemia that favors fetal excess of growth. Therefore, infants with excessive size at birth are prone to develop hypoglycemia^[16]. It was shown that when BW was ≥ 4000 g the risk of hypoglycemia increased, but the risk was higher when BW ≥ 4000 g was associated with maternal GDM^[76]. In another study, the risk of hypoglycemia increased with increasing BW, irrespective of maternal diabetic status^[77].

SIZE OF THE BURDEN IN LOW INCOME COUNTRIES

The prevalence of risk factors for diabetes during pregnancy are increasing all around the world because of increasing incidence of T2D and obesity and the shift of age at onset of diabetes to younger age groups. T2D is an occult disease that can remain undiagnosed, especially in young women of reproductive age. A recent study reported an estimated global prevalence of hyperglycemia in pregnancy worldwide of 170/1000

live births in 2013. A majority of cases occurred in low and middle income countries (91.6%). The prevalence varies widely around the world. The South-East Asia region had the highest prevalence with 23% of live births, followed by the Middle East and North Africa region with 22%^[78].

A community-based prospective program in India, with universal screening for GDM, showed that the prevalence of GDM was 13.9%. The frequency varied widely across urban, semi-urban and rural areas, respectively 17.8%, 13.8% and 9.9%. The prevalence also varied according to maternal BMI. For BMI ≥ 25 mg/m², the incidence was up to 28.4%, 23.8% and 16.1% in urban, semi-urban and rural areas, respectively^[79].

A recent analysis of data from World Health Organization (WHO)'s Global Survey on maternal and perinatal outcomes in 23 developing countries described the prevalence of macrosomia, one of the main complications of maternal diabetes and obesity^[80]. There was a large variation in the prevalence of babies with BW ≥ 4 kg, ranging from 0.5% in India, to 15% in Algeria. Maternal diabetes and increased gestational BMI were significantly associated with macrosomia in all regions. For example, in Algeria, where 15% of the babies had a BW ≥ 4 kg, 25% of the mothers were obese (BMI ≥ 30 kg/m²). In Latin America countries, frequency of maternal obesity was more than 30% (Argentina, Mexico, and Paraguay).

It can then be estimated that the burden of neonatal complications is higher in developing countries than in high-income countries, because of the high incidence of maternal hyperglycemia and the absence of screening and treatment of maternal diabetes, and finally because of substandard neonatal care. This is probably even worst within the rural areas, because of limited financial and human resources.

CONCLUSION

It is indisputable that diabetes during pregnancy exposes the fetus and the neonates to increased adverse outcomes. These risks mainly depend on maternal health condition. Thus, awareness of maternal health prior and during pregnancy is essential to pediatricians to anticipate the severity of neonatal adverse outcome. Health systems in low income countries are often insufficiently structured to provide adequate screening and care to diabetic mothers. Such situations seriously increase the burden of adverse fetal and neonatal outcomes, probably still underestimated.

The current definition of GDM does not allow identifying pregestational diabetes from true GDM. The WHO recently proposed new criteria for the diagnosis and definition of hyperglycemia first detected in pregnancy which distinguishes the more serious diabetes in pregnancy from GDM^[81]. This is a considerable advance as we say that risks of serious complications for fetuses and the neonates are much

higher in true diabetes than in GDM. This will help to better understand the burden of hyperglycemia in pregnancy and its relationship with the growing prevalence of T2D. This will also probably allow in the future to determine precisely the risks linked to GDM compared to those linked to T2D. Such distinction will subsequently help better identifying risks in the neonatal period, but also later in life. Indeed, offspring of diabetic and obese women, or macrosomic infants, are more likely to be obese and to have diabetes and cardiovascular diseases in adulthood^[3,4]. These long-term consequences of diabetes in pregnancy are going to be the burden of further generations.

Abstract

Type 2 diabetes mellitus and Alzheimer's disease are both associated with increasing age, and each increases the risk of development of the other. Epidemiological, clinical, biochemical and imaging studies have shown that elevated glucose levels and diabetes are associated

with cognitive dysfunction, the most prevalent cause of which is Alzheimer's disease. Cross sectional studies have clearly shown such an association, whereas longitudinal studies are equivocal, reflecting the many complex ways in which the two interact. Despite the dichotomy, common risk and etiological factors (obesity, dyslipidemia, insulin resistance, and sedentary habits) are recognized; correction of these by lifestyle changes and pharmacological agents can be expected to prevent or retard the progression of both diseases. Common pathogenic factors in both conditions span a broad sweep including chronic hyperglycemia *per se*, hyperinsulinemia, insulin resistance, acute hypoglycemic episodes, especially in the elderly, microvascular disease, fibrillar deposits (in brain in Alzheimer's disease and in pancreas in type 2 diabetes), altered insulin processing, inflammation, obesity, dyslipidemia, altered levels of insulin like growth factor and occurrence of variant forms of the protein butyrylcholinesterase. Of interest not only do lifestyle measures have a protective effect against the development of cognitive impairment due to Alzheimer's disease, but so do some of the pharmacological agents used in the treatment of diabetes such as insulin (especially when delivered intranasally), metformin, peroxisome proliferator-activated receptors γ agonists, glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase-4 inhibitors. Diabetes must be recognized as a risk for development of Alzheimer's disease; clinicians must ensure preventive care be given to control and postpone both conditions, and to identify cognitive impairment early to manage it appropriately.

Core tip: Type 2 diabetes mellitus is a risk factor for future development of Alzheimer's disease, the most prominent cause of cognitive failure in the elderly. Common pathogenic mechanisms underpin both

conditions. Therapeutic strategies in prevention (lifestyle changes) and pharmacological agents (biguanides, intranasal insulin, thiazolidinediones, glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase-4 inhibitors could also be useful against Alzheimer's disease.

INTRODUCTION

The prevalence of diabetes mellitus is inexorably rising as evidenced by data from local, national and international studies^[1-3]. Improved care of diabetes as well as general increase of longevity are predictive of greater proportion of elderly in the general population. It is well known that the critical problems of the aged relate to impaired activities of daily living and of cognitive decline. It is also recognized that compared to persons without diabetes, those with diabetes have dementia two to three times more commonly^[4]. The economic and social burden on the health-care system as well as on care-providers would be enormous. It is essential if methods are available, to prevent or postpone the onset of both conditions; lifestyle changes appear to be effective in preventing both conditions^[5].

CAUSES OF DEMENTIA

Dementia may be broadly classed into Alzheimer's disease, vascular dementia, dementia with Lewy bodies and frontotemporal dementia^[4]. Of these, Alzheimer's disease is the most common type^[6].

Dementia in diabetes: Epidemiological studies

A number of epidemiological studies have shown an association of dementia with diabetes. In the Hisayama study (1995), the relative risk (RR) of Alzheimer's disease was 2.18 (95%CI: 0.97-4.9) and of vascular dementia 2.77 (95%CI: 2.59-2.97)^[7]. A later publication from the same study group (2011) showed an RR of 2.05 (95%CI: 1.18-3.57) for Alzheimer's disease and 1.82 for vascular dementia (95%CI: 0.89-3.71)^[8]. The Rochester Study (1997) reported differences in the risk of Alzheimer's disease based on gender: RR was 2.27 for men (95%CI: 1.55-3.31) and 1.37 for women (95%CI: 0.94-2.01)^[9]. The well cited Rotterdam Study (199) showed a relative risk of 1.9 for Alzheimer's disease (95%CI: 1.2-3.1)^[10] (Table 1).

Conflicting results: Cross sectional vs longitudinal studies

Although there is a consensus from cross-sectional

Table 1 Dementia and diabetes

Relative risk of AD	Relative risk of vascular dementia	Ref.
2.18	2.77	[7]
2.05	1.82	[8]

AD: Alzheimer's disease.

studies that hyperglycemia causes cognitive impairment, results from longitudinal studies are conflicting^[4]. Two recent longitudinal studies show up differences in the occurrence of Alzheimer's disease and glucose tolerance.

The Baltimore Longitudinal Study of aging prospectively assessed a cohort of community-dwelling individuals. An investigation was made to relate serial glucose intolerance, insulin resistance with brain β amyloid burden measured *in vivo* using carbon 11-labelled Pittsburgh Compound B. The latter is utilized to image β -amyloid ($A\beta$) *in vivo* with PET scan; ¹¹C-Pittsburgh compound-B (11C-PiB), a PET $A\beta$ ligand, is widely employed for early diagnosis of Alzheimer disease. It allows quantitative analysis of $A\beta$ burden. Derived as a carbon-11 labelled thioflavin-T amyloid dys, it binds to $A\beta$ plaques with high specificity and affinity. ¹¹C-Pittsburgh compound-B (11C-PiB), correlates with the rate of cerebral atrophy. Pathological process for Alzheimer's disease was established at autopsy^[11]. Analysis was carried out using grouped and continuous mixed-models analyses. The key result of the study was, there was *no* significant correlation of brain markers of Alzheimer with insulin resistance or glucose intolerance during the follow up period of 22.1 years (SD:8.0)^[11].

In contrast, a group from the University of Washington, which evaluated whether higher glucose levels increase the risk of dementia in those without diabetes, found that they did^[12]. Participants, without dementia were drawn from the Adult Changes in Thought study (839 men, 1228 women, mean baseline age 76 years). In all 35264 glucose levels and 10208 glycosylated hemoglobin levels were analyzed. They were followed up for a median of 6.8 years. 524 subjects developed dementia (74 of 243 with diabetes and 450 of 1228 without diabetes). Higher levels of average glucose levels were related to development of dementia in both groups, ie those with and without known diabetes. The authors conclude that "higher glucose levels may be a risk factor for dementia, even among persons without diabetes"^[12].

Can the conflicting results of these two rigorous, well-designed studies be resolved? The Baltimore study used both neuroimaging as well as autopsy to identify Alzheimer's pathological processes. The Adult Changes in Thought study performed a 6 year follow up in a large group of well-defined elderly. In the former, insulin resistance and glucose intolerance were not a risk factor for Alzheimer's changes; in the

latter, higher glucose levels even among those without diabetes may be a risk factor for dementia.

The apparent differences can be attributed to the variety of pathological changes in diabetes leading to dementia including Alzheimer's disease: chronic hyperglycemia, hypoglycemia (acute and recurrent), glycosylated of proteins, vascular disease, endothelial dysfunction, inflammation, altered blood brain barrier, dyslipidemia, insulin resistance, genetic predisposition, amyloid deposition and depression, among others^[13]. More sensitive methods of measuring brain volume as a surrogate of cognitive function may throw light^[4]. In addition, there is a flaw in using brain markers such as plaques in diagnosis of Alzheimer's disease: subjects may have amyloid plaques, yet display no symptoms of Alzheimer's disease throughout their life. This discrepancy between the presence of plaques and Alzheimers could play a role for a lack of finding a link between diabetes and Alzheimer's disease.

Hyperglycemia

Hyperglycemia is a recognized risk factor for cognitive impairment as shown by the ACCORD-MIND study and others^[14,15]. Biological reasons for such changes were ascribed to neural damage following advanced glycosylated end products and oxidative stress, osmotic stress damaging the blood brain barrier and resultant leak of toxic substances leading to further damage of nervous structures^[4]. In addition to chronic hyperglycemia as assessed by glycated hemoglobin, glycemic variability was also proposed to contribute to cognitive dysfunction. Measurements by continuous glucose monitoring revealed cognitive function was better correlated with diurnal variation in blood glucose^[16]. Post prandial glucose levels could also be a contributing factor, acting *via* oxidative stress^[4].

Hypoglycemia

Although severe hypoglycemia was shown to be associated with dementia in the elderly^[17], when hypoglycemia is avoided by careful treatment as in the DCCT/EDIC study, there was no association between hypoglycemia and cognitive dysfunction^[18]. In the elderly however, hypoglycemia, when coupled with atherosclerosis leads to organic brain damage which is often irreversible^[4].

Role of insulin in brain

Cognition may be affected not only by alterations in the level of glucose, but also *via* the action of insulin. Upon transport through the blood brain barrier, insulin binds to its receptors, and is involved in modulating cognitive function. A large number of insulin receptors occur in brain areas related to memory such as the hippocampus and cerebral cortex. In addition it also aids the release of β -amyloid peptide extracellularly, and increases the expression of the enzyme which degrades insulin, insulin degrading enzyme (IDE)^[4]. As the latter also degrades β -amyloid peptide, insulin deficiency results in accumulation of β -amyloid peptide.

Both hyperinsulinemia and hyperglycemia were shown to increase neuritic plaque formation^[19].

Information is being available about the origin of insulin in the brain and its role in cognition. Originally, brain was considered to be insulin insensitive because insulin did not influence the glucose uptake by the bulk brain. However insulin has been shown to be a neuroregulatory peptide playing a role in food intake and in monitoring the energy stores of the body^[20]. Interestingly a role for insulin in modulation of memory and cognition is also emerging. Its action has been observed in regions associated with reward recognition such as hippocampus, and in global cognition and memory. Rather than passing across the blood brain barrier from the periphery, insulin appears to be produced locally for action as a neurotransmitter, regulated by glucose levels. In addition a para-arteriolar pathway for transport at the level of microvasculature has been proposed^[20].

The role of insulin in the pathogenesis of Alzheimer disease has been described. Insulin can modulate A β peptide *in vitro*. The peptide is well known as a neuropathological hallmark of AD. Low levels of insulin in the brain can decrease the A β release into extracellular compartments. In addition hypoinsulinemia in the central nervous system can lower the levels of insulin-degrading enzyme, thereby impairing A β clearance. In all, chronic hyperinsulinemia in the peripheral circulation, along with decreased uptake of insulin into the brain can lead to dysregulation of A β and inflammation^[21,22].

Role of microvascular disease in cognitive decline

Studies have shown that retinopathy and nephropathy are associated with impairment of cognition^[22,23]. Small vessels in both organs arise from a similar embryonic antecedent and share similar structures; it is conceivable therefore that insults (*e.g.*, increased polyol pathway activity, myo-inositol dysmetabolism) result in similar adverse reactions in frontal lobe of the cerebral cortex leading to cognitive decline^[4]. However, evidence is not unequivocal. Retinopathy is related to microvascular changes in diabetes. Because the retina shares many features with the brain, both developmental, anatomical (*e.g.*, microvascular bed) and physiological (*e.g.*, blood-tissue barrier), changes in retina were suggested to presage brain pathological processes. Alzheimer's disease is known to involve the retina, such as the macula and the optic disc. It has been suggested that pathological changes in the retina such as macular deposits, reduced thickness of retinal nerve, cupping of optic disc and retinal microvascular changes may be related to cognitive dysfunction and Alzheimer disease^[24].

Insulin resistance and Alzheimer's disease

Downstream insulin signaling acts through a complex interplay involving phosphatidylinositol 3-kinase (P13K0 and mitogen activation protein kinase (MAPK).

The latter is associated with most metabolic effects of insulin. Unlike its peripheral effects, the action of insulin in the central nervous system is dependent on its crossing the blood brain barrier *via* direct transfer^[25] through an insulin receptor protein, which is selectively distributed. In addition there is also local synthesis of insulin in the CNS. Unlike peripheral insulin receptors, those in the CNS differ in terms of structure, function and size. They are highly populated in the olfactory bulb, hypothalamus, cortex, cerebellum, hippocampus and are expressed in both neurons and glia^[26].

The physiological effects of insulin in the brain are unlike those in the periphery: in an animal model it suppressed food intake and increased the level of glucose^[27], acting in a way as its own counterregulation^[25]. Compared to its weight, the brain depends on a larger amount of glucose for its metabolic needs compared to other tissues. Glucose reaches it *via* facilitated diffusion transported by glucose transport proteins. In the brain, insulin does not have a major effect on either the transport of glucose to the brain or its basal metabolism^[28,29]. While it is not a major regulator of glucose metabolism in the brain, insulin indirectly affects neurons by modulating neurotransmitter release, neural growth, tubulin activity, nerve survival and synaptic plasticity^[26]. In humans, insulin improves cognition independent of its effects on peripheral glucose^[30].

Whereas acute increases of insulin improve cognition, chronic hyperinsulinemia can adversely affect neuronal function *in vitro* by increasing susceptibility to toxin and stress-induced effects^[31]. Glycated proteins and inflammatory mediators could also have a pathogenic role^[25].

Protein aggregation, diabetes and Alzheimer's disease

Protein aggregation has been suggested to be an underlying pathogenic factor between type 2 diabetes and Alzheimer's disease^[32]. A number of hypotheses were proposed to explain why a biological protein can be transformed into a pathological entity with the ability to self-assemble: aging, high concentrations of the protein, mutation of amino acids or abnormal post-translational modification, modulated by environmental factors^[32].

Alzheimer's disease is associated with accumulation of neurofibrillary tangles and amyloid fibers leading to neuronal cell loss. Amyloid β peptides form from cleavage of amyloid β -protein precursor seen in plaques. It is organized as amyloid fibrils, which are linear aggregates^[32]. Diabetes is also characterized by localized and progressive amyloid deposition in the pancreatic β cell islets^[33]. Common features of amyloid deposited in both Alzheimer's disease and diabetes include: linear appearance, with a beta-sheet structure, which begin to form from spherical oligomers that can self-assemble^[34]. The islet amyloid peptide is secreted by β cells of the pancreas and

consists of 37 amino acids.

ApoE- ϵ 4

Expression of ApoE- ϵ 4, which is related to diabetes as well, increases the risk of early onset Alzheimer's disease. It has increased ability to deposit A β , which is neurotoxic, and also impair its clearance^[35]. ApoE- ϵ 4 is less protective against oxidative stress and leads to cholinergic dysfunction seen in Alzheimer's disease, besides modifying the cholesterol transporter protein ABCA1.

Other potential associations

In addition other associations are also being recognized as risk factors for both diabetes and Alzheimer's disease: weight gain, acting perhaps through defective leptin signaling and increased formation of advanced glycation end products, which could have a pathogenic role in the amyloid plaques deposited in the brain^[35]. Other emerging associations include disturbances in sleep and the circadian rhythm^[36,37], and iron overload in brain among persons with obesity^[38].

Insulin like growth factor

Animal studies have provided intriguing evidence that loss of insulin-like growth factors, along with insulin could lead to age-dependent brain atrophy with cognitive decline^[39]. Insulin and its growth factors maintain brain protein content; their replacement can prevent brain protein loss, cell degeneration and demyelination. Lack of insulin and growth factors, which are common to type 2 diabetes and to Alzheimer's disease could therefore play a role in their pathogenesis and provide therapeutic targets in their treatment^[39].

Butyrylcholinesterase

Butyrylcholinesterase, belonging to the esterase family of enzymes that also contain acetylcholinesterase^[40] has been evaluated in relation to insulin resistance, cardiovascular disease, obesity and dyslipidemia^[36]. Variant forms of the enzyme with little or no activity exist in isolated geographic populations^[41] with apparently no adverse health effects^[42]. Butyrylcholinesterase was studied in relation to both type 2 diabetes mellitus and to Alzheimer's disease^[43-45], with studies suggesting a possible protective effect against Alzheimer's disease and risk for fronto-temporal dementia^[46].

A number of hypothesis were put forward for the association of butyrylcholinesterase with type 2 diabetes mellitus and Alzheimer's disease^[33,36]. Plaques in the brains of individuals with dementia had higher levels of butyrylcholinesterase, which is also localized in neurofibrillary tangles. It was also shown to attenuate amyloid formation^[47].

Similarly in type 2 diabetes, butyrylcholinesterase may modify the expression of insulin resistance or by way of amyloid fibril deposition in β cells of the pancreas^[33]. It was shown to interact with amylin

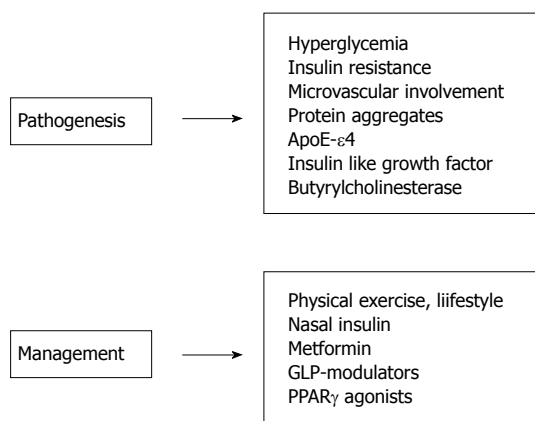

Figure 1 Links between Alzheimer's disease and type 2 diabetes mellitus.

and attenuate the formation of amylin fibril as well as its oligomer. When applied to cultured β cells, it was protective against amylin cytotoxicity^[47]. Butyrylcholinesterase was shown to participate in the progression of metabolic syndrome to type 2 diabetes mellitus. A majority of subjects with type 2 diabetes show extracellular deposits formed by islet amyloid polypeptide (IAP), adjacent to the β cells. Elevated levels of IAP are found in conditions of insulin resistance. Disturbed balance of sympathetic and parasympathetic nervous system could participate in metabolic syndrome. Lower vagal activity could in part be caused by increased hydrolysis of acetylcholine mediated by increased butyrylcholinesterase^[48]. Lowering of acetylcholinesterase results in reduced parasympathetic signals and increased ratio of sympathetic signals^[48]. In addition BChE was reported to attenuate the formation of A β amyloid fibrils^[47]. Essentially subjects with metabolic syndrome had elevated levels of BChE compared to those with type 2 diabetes and with controls. *In vitro* interaction of BChE was observed with amylin. It interacted with amylin, and attenuated the formation of both amylin fibril and oligomer formation, showing that it can protect cultured β cells from cytotoxicity due to amylin^[47]. Thus increased BChE seen in metabolic syndrome could protect pancreatic β cells by reducing toxic amylin oligomer formation^[47].

A bioinformatics study suggested the following sequences ($E < e^{-5}$) were associated with both type 2 diabetes and Alzheimer's disease: butyrylcholinesterase precursor K allele (NP_000046.1), acetylcholinesterase isoform E4-6 precursor (NP_000656.1) and apoptosis-related acetylcholinesterase (1B41|A). In an animal study, streptozotocin-induced diabetes was associated with elevated butyrylcholinesterase activity, lowered superoxide dismutase and impaired cognitive function assessed by Morris water maze method^[49]. Being low-grade inflammatory conditions, both type 2 diabetes mellitus and Alzheimer's may be target conditions for utilization of butyrylcholinesterase as a biomarker^[50], as well as a treatment target^[33].

The principal drugs currently available to manage

Alzheimer's disease act *via* modifying butyrylcholinesterase levels. Renewed interest in the possible role of "missing genes" in people who are apparently healthy may aid in uncovering new treatment modalities^[51]. Individuals with variant butyrylcholinesterase activity genes may be a potential group for such long-term follow up studies vis a vis their propensity or protection against diabetes and Alzheimer's disease^[40].

THERAPEUTIC IMPLICATIONS

The interest of linking type 2 diabetes mellitus and Alzheimer's disease lies not in science, but more in translational science: how understanding the common pathogenesis can help in prevention and treatment of both conditions. Other than the scope for future therapies, evidence is now available for the currently available drugs used in diabetes^[52] to have a modulatory effect on the cognitive decline due to Alzheimer's disease. Along with its action on AMPK, metformin has been recently shown to influence the incretin system by increasing the secretion of glucagon-like peptide-1 (GLP-1)^[53]. GLP-1 and GIP receptors are known to be expressed in the brain, and direct activation of these receptors may be a potential strategy to treat Alzheimer's disease^[54]. In addition, metformin also influences gut microbiome along with its other putative actions in the management of diabetes mellitus^[55]. The use of drugs used in diabetes mellitus such as metformin, GLP-1 mimetics (exenatide and liraglutide) and peroxisome proliferator-activated receptors γ agonists may all be of potential benefit in the prevention and management of Alzheimer disease^[56].

When a theoretical basis for insulin to affect brain responses was studied in clinical practice, a recent review of 8 published studies on effect of intranasal insulin on cognition, comprising 328 participants showed first of all, no significant adverse effects. Generally the authors concluded that "the limited clinical experience suggests potential beneficial cognitive effects of intranasal insulin"^[57]. In a single study, use of 20 IU intranasal insulin showed improved immediate recall in Apo ϵ 4(-) subjects but not in Apo ϵ 4(+) subjects.

Other than correcting hyperglycemia, some of the conventional antidiabetic agents were shown to affect cognition. Metformin protected brain against oxidative stress in rats, and by preventing apoptosis^[54]. However caution must be exercised because of metformin leading to increased biogenesis of Alzheimer's amyloid peptides^[58] and increased risk of cognitive impairment^[59]. Thiazolidinediones, which act at the nuclear receptors of insulin-sensitive tissues, affect transcription of genes affecting lipid and glucose metabolism. Early studies suggested that this group of drugs may favourably affect cognition, before the clinical use tapered due to their adverse drug effect profile.

Pharmacological agents modulating the incretin

system have now become mainstream in many markets world-wide. Pathological studies showed that sitagliptin lowered APP and A β deposition in the hippocampus of transgenic Alzheimer's disease mice^[53]. However whether it does so by lowering glucose levels or independently remains to be clarified. Interest arises because liraglutide, another drug in the same group had similar protective effects (Figure 1).

CONCLUSION

In conclusion, diabetes mellitus and Alzheimer's disease are both common and increasing in incidence in the aging population. Recent evidence has shown common pathogenic factors operating in both conditions. Thereby common preventive and therapeutic agents may be used in their prevention and treatment. Physicians caring for the elderly must be aware of the increased risk of the other when one condition is present. Common pathogenesis and therapeutic agents make it possible to manage both using similar lifestyle changes and pharmacological agents.

Abstract

AIM: To study the acceptability of incentives for behavior

changes in individuals with diabetes, comparing financial incentives to self-rewards and non-financial incentives.

METHODS: A national online survey of United States adults with diabetes was conducted in March 2013 ($n = 153$). This survey was designed for this study, with iterative testing and modifications in a pilot population. We measured the demographics of individuals, their interest in incentives, as well as the perceived challenge of diabetes self-management tasks, and expectations of incentives to improve diabetes self-management (financial, non-financial and self-rewards). Using an ordered logistic regression model, we assessed the association between a 32-point score of the perceived challenge of the self-management tasks and the three types of rewards.

RESULTS: Ninety-six percent of individuals were interested in financial incentives, 60% in non-financial incentives and 72% in self-rewards. Patients were less likely to use financial incentives when they perceived the behavior to be more challenging (odds ratio of using financial incentives of 0.82 (95%CI: 0.72-0.93) for each point of the behavior score). While the effectiveness of incentives may vary according to the perceived level of challenge of each behavior, participants did not expect to need large amounts to motivate them to modify their behavior. The expected average amounts needed to motivate a 5 lb weight loss in our population and to maintain this weight change for a year was \$258 (interquartile range of \$10-100) and \$713 (interquartile range of \$25-250) for a 15 lb weight loss. The difference in mean amount estimates for 5 lb and 15 lb weight loss was significant ($P < 0.001$).

CONCLUSION: Individuals with diabetes are willing to consider financial incentives to improve diabetes self-management. Future studies are needed to explore incentive programs and their effectiveness for diabetes.

Key words: Patient incentives; Diabetes self-management; Motivation; Weight loss; Patient engagement

Core tip: Patient incentives have shown potential in modifying behaviors such as smoking cessation or weight loss. This online survey for individuals with diabetes explores their attitude towards incentives (financial, non-financial and self-rewards) for diabetes self-management. Although nearly all participants showed positive expectations about financial incentives, they favored financial incentives for less challenging behaviors, and non-financial incentives for more challenging behaviors. This survey also enquired about expected amount of incentives, in particular for a 5 lb weight loss, maintained over a year.

INTRODUCTION

Behavioral changes are key part of diabetes self-management^[1], but they are difficult to implement and maintain. Setting goals is a key step to behavior change. Findings from a group of Swedish investigators about patients' willingness to pay to improve their diabetes self-management emphasize the importance of certain goals for patients, such as weight loss, less frequent or severe hypoglycemic events and lower HbA1c levels^[2].

Financial incentives have shown potential in supporting patients to modify their behaviors^[3], such as for smoking cessation^[4] or weight loss^[5,6]. Acceptability and feasibility of incentives may vary with different health behaviors, as the complexity of the behaviors vary widely. The effect and type of incentives for one-time vaccinations^[7] may differ from incentives for repeated, constant efforts for weight loss^[8]. Financial incentives for health and wellness are being used by a rapidly growing number of employers, with nearly 90% companies using such measures in the 2013 survey from Fidelity Investments and the National Business Group on Health (57% increase since 2009)^[9]. While some authors have suggested using financial incentives for diabetes self-management behaviors, evidence for incentivized diabetes self-care is still scarce^[10]. There is to our knowledge only one study on patient incentives for diabetes self-management, comparing incentives to peer mentors or usual care^[11]. Although this study did not find a significant benefit, the sample was small and the reward design was solely based on the outcome (change in HbA1c value).

Incentives programs can reward different types of goals. Some programs provide outcome-based incentives, where rewards are given for achieved final results (e.g., HbA1c or BMI, body mass index). These outcome-based rewards can favor individuals who are healthier at baseline. Other programs reward the total amount of behavior change-related results, thus favoring individuals who are more obese, for example, who then have more weight to lose. Finally, some incentive programs reward the process, such as attendance at group sessions, or tracking and reporting results. These are more equitable, because it is more attainable for all participants. Furthermore, prior research suggests that process-based rewards may be more effective than outcome-based rewards, and that associating them could have an additional effect.

Incentives programs also differ in the rewards that are given. Some programs have financial incentives, others offer vouchers and discounts^[12], and yet others propose badges and stars without financial stakes. Self-rewards are another type of reward, which one gives oneself for reaching self-defined goals. Rewards are typically used to address present bias, the tendency to value small immediate rewards over large rewards in the distant future. Controversies about using financial incentives for long-term behavior change have been raised due to the "undermining effect"^[13,14]. Long-term behavior changes are driven by intrinsic motivation, or inherent motivation, rather than by extrinsic motivation, which are rewards that are external to the behavior^[15]. Prior studies on rewards have shown that the removal of extrinsic rewards can result in a decrease in intrinsic motivation, the so-called undermining effect^[13,14].

The goal of this study was to explore patients' expected responses to financial and non-financial incentives to improve their diabetes self-management. We hypothesized that expected responses to the type of incentive (financial, non-financial or self-reward) would differ with the perceived level of challenge of the incentivized behavior. We also wanted to explore the amount of money participants considered necessary to motivate behavior change. These results can help guide the creation and implementation of new patient-centered approaches for diabetes self-management.

MATERIALS AND METHODS

Setting

The survey was developed by the authors through an iterative process of editing and was tested on two groups of altogether 15 students and faculty at the University of Washington. The feedback led to modifications to simplify the survey, and resulted in a final set of 10 questions in addition to demographic information. Two individuals of the test groups had diabetes. The survey was available in English.

This online survey was launched to a panel of

Table 1 Overview of survey questions

Survey question themes
Three most difficult and three easiest diabetes self-management tasks:
Tracking health parameters
Choosing foods
Adapting medications or insulin
Affording healthcare
Adjusting meds and diet around unexpected events
Perceived challenges for living with diabetes (detailed in Table 2)
Perceived helpfulness of incentives for motivating healthier behaviors:
Cash rewards (weekly, monthly or yearly)
Tangible rewards, e.g., vouchers (weekly, monthly or yearly)
Decrease in future insurance premium
Non-financial rewards (badges, stars)
Social support (sharing with friends)
Self-reward (setting money aside for a self-set goal)
Potential sources of funding for the rewards (employer, insurance, self-paid)
Estimated amount needed to lose weight and keep it off for a year:
To lose 5 lb
To lose 15 lb

three hundred members of a commercial survey website in March 2013. This company has a large panel of international volunteer members who can be filtered according to personal information such as age or country of residence. Eligible members receive recruitment emails, and choose freely whether to respond or not. All participants gave their informed consent prior to their inclusion in the study. Participants who complete the proposed surveys receive website points, which can be exchanged for tangible gifts.

Recruitment

Our survey was administered in English, and was restricted to United States residents. It was open until 300 participants responded. We also filtered out individuals younger than 18 years old. The survey was open to individuals with type 1 or type 2 diabetes, but excluded those with gestational diabetes. We did not offer any supplementary compensation for completing the survey. (We had no involvement with the reward points that are part of the website). The study was approved by the Institutional Review Board of the University of Washington.

Measures

Participants completed the 10-question survey on diabetes self-management, goals and barriers (Table 1). We asked them to identify the three most difficult and the three easiest barriers among the following diabetes self-management tasks: tracking health, choosing foods, cooking appropriate meals, adapting medications or insulin, affording healthcare, adjusting meds and diet around unexpected events. We then asked them which diabetes-related behaviors were challenging: structuring a daily routine around diabetes management, impact on social relationships, thinking about diabetes all the time, social support from family, friends and workplace, changing foods, seeing

how others think of them, and understanding the relationships between glucose, diet and exercise.

We asked the participants to anticipate their responses to different rewards to help improve diabetes self-management: financial rewards, non-financial rewards and self-rewards. For the financial rewards, we asked participants to estimate the helpfulness of rewards, according to their frequency (weekly, monthly or annual) and type (cash, vouchers or reduced annual insurance premium) to improve their health behaviors. We used a 4-point scale with our predicted small sample to avoid having a neutral option. For the non-financial rewards, we enquired about the anticipated effect of receiving stars or badges, or sharing results with friends, in helping improve their behavior. Finally, we asked participants about the helpfulness of self-paid rewards (e.g., setting money aside for a self-set goal) in improving health behaviors.

We explored who the participants thought should pay for the rewards to improve their health behaviors (health insurance companies, employers or self-paid rewards). We adapted two questions from Long *et al*^[16]'s survey instrument, which were: "If you were overweight, how much money would you need to receive to persuade you to lose 5 pounds and keep it off for 1 year?" and likewise for a 15-pound weight loss. Finally, we explored their use of mobile technology (in general and for diabetes).

Statistical analysis

We conducted descriptive analyses describing means and distributions. We defined financial incentive as any cash incentive (weekly, monthly or yearly), any voucher or reduction in insurance premium. We considered recognition by badges or stars and sharing results with friends as a non-financial incentive. Helpfulness of incentives was a binary variable, defined as not helpful or helpful (somewhat helpful to very helpful). To explore associations between diabetes tasks and type of reward, we used a logistic regression model to compare expectations of self-management tasks perceived as difficult or easy. We proceeded similarly for the behaviors that are related to diabetes self-management, separating not helpful or somewhat challenging behaviors from those that are challenging. We then created a score ranging from 0 (easy) to 24 (hard) based on how difficult these behaviors were perceived to be (Table 2). Using a logistic regression model, we studied the association between the score and the three types of reward. In this model, we also analyzed the effect of age and of weight loss motivation, using the estimated amount needed to lose 5 lb and keep it off during a year. We used a cutoff of \$30000 to avoid bias from outliers in these analyses.

The percentage of complete cases was 76%. Missing covariate data were infrequent ($\leq 3\%$) other than for income (7%). Missing data were multiple-

Table 2 Challenges of diabetes self-management behaviors

Behavior	n (%)
Having to structure my daily routine around diabetes management	77 (50.3)
Coping with the impact of diabetes on my social relationships	64 (41.8)
Thinking about diabetes all the time	74 (48.4)
Having insufficient support from family and/or friends	52 (34.0)
Having insufficient support from my workplace	51 (33.3)
Seeing how other people think of me	88 (57.5)
Having to change what I eat	49 (32.0)
Understanding the relationships between glucose, diet and exercise	72 (47.1)
Overall mean	65.9 (43.1)

For the score, each behavior was rated 0 to 3 points (total of 0 to 24 points).

Table 3 Participant characteristics by type of diabetes

Diabetes	Type 1	Type 2 ¹	P-value
Value	17 (11.1)	136 (88.9)

¹Limited to white and black race. Data are expressed as mean ± SD or n (%).

imputed with 10 imputed datasets using imputation by chained-equations^[17]. The imputation model included the covariates used in all our analysis (with dependent variables), as well as the region of residence. Categorical variables were compared using χ^2 tests. *P* values from regression models were derived from Wald tests with robust standard errors. A *P*-value < 0.05 determined statistical significance. No interaction was tested. All analyses were conducted on Stata 11 (Stata Corporation, Texas).

RESULTS

Out of the 300 responders, 153 participants were eligible and consented to participate. Excluded participants differed from the inclusion group only by the higher proportion of female individuals (69.4% vs 50.4%). Age, region of residence, race, ethnicity, type of education and income were not statistically different among inclusion and exclusion groups.

The included participants had a mean age of 44.2

± 1.2 years, with 50.4% women. Graduate school education was achieved by 25.5%, and 34.1% had an annual income of > \$75,000/year. Nearly a quarter of the participants were smokers (23.0%) at the time of the survey. Smartphone ownership was 43.7%. We present the detailed participant characteristics by type of diabetes in Table 3. There were 11.1% individuals with type 1 diabetes and 88.9% individuals with type 2 diabetes. Although the mean age was not statistically different, participants with type 1 diabetes were significantly more likely to have a smartphone. Individuals with type 1 diabetes were located more in the northeast area of the United States. and less in the West and South areas.

Almost all participants (96.7%) had positive expectations from the use of incentives (financial or non-financial) to improve their diabetes self-management. Only six individuals were not interested in incentives. There was no significant difference in demographic characteristics (age, gender, race/ethnicity, education, income) among those interested in incentives or not. While all individuals with type 1 diabetes were interested in incentives, six individuals who were not interested in incentives had type 2 diabetes. Forty-five percent of participants with an interest in incentives were smartphone users, although there was no significant difference in smartphone use between those with or without interest in incentives.

Overall, the participants expected financial incentives to motivate themselves more than non-financial rewards (96.0% vs 60.0%), and 70.2% of individuals expected self-rewards to be helpful in improving diabetes self-management. The self-management tasks rated as the three easiest were: keeping track of health parameters, making food choices and cooking appropriate meals. The tasks considered most difficult were: affording diabetes costs, and adjusting diet and medications around unexpected events. Participants expected financial incentives to help improve food choices and healthcare costs the most, whereas self-rewards were expected to help improve adjustments to unexpected events the most. Non-financial incentives were expected to help improve adapting insulin doses the most.

We studied the participants' responses to the three types of incentives according to whether these factors were considered a challenge for diabetes self-management or not. We found that overall, 94% expected a positive outcome with financial incentives, compared with 60% with non-financial incentives, and 69% with self-rewards. Participants expected financial incentives to help improve the food habit changes the most, whereas non-financial incentives and self-rewards were expected to improve support from the workplace and impact on social relationships the most.

We assess the association of perceived level of challenge (0 is easy, 24 is challenging) and type of incentive (financial, non-financial and self-rewards) in Table 4. We found in the unadjusted analysis that for

Table 4 Effect of behavior score on the 3 types of rewards

Score	OR financial incentive (95%CI)	P-value	OR non-financial incentive (95%CI)	P-value	OR self-reward (95%CI)	P-value
Score	0.82 (0.72-0.93)	0.002	1.06 (1.01-1.10)	0.01	1.00 (0.96-1.04)	0.98
Score adjusted for age	0.82 (0.72-0.93)	0.002	1.06 (1.01-1.11)	0.01	1.00 (0.96-1.05)	0.94
Score adjusted for weight loss motivation ¹	0.83 (0.73-0.95)	0.005	1.07 (1.02-1.11)	0.006	1.01 (0.96-1.05)	0.75

¹Estimated amount needed to lose 5 lb and maintain it for a year.

an increase in the behavior score by one point, the odds ratio comparing expected response to financial incentives with no response to financial incentives would be 0.82 ($P = 0.002$). When comparing expected responses to non-financial incentives to no response to these incentives, we found an OR of 1.05 ($P = 0.01$). The level of perceived difficulty with these behaviors was not associated with expecting to respond to self-rewards in our dataset (OR = 1.00, $P = 0.98$). We obtained similar results when adjusting for age or for the weight loss motivation (assessed by the amount needed to lose 5 lb and keep it off for a year). This means that when these behaviors are perceived to be more difficult, the participant less expected to respond to financial incentives. Yet for non-financial incentives, when more behaviors are perceived to be difficult, participants expected to respond more to non-financial incentives.

We asked participants to provide an estimated amount needed to motivate losing 5 and maintaining it for a year, and the amount for a 15 lb weight loss. We excluded 2 outliers for each analysis, using a \$30000 cutoff. To motivate a 5 lb weight loss, participants gave estimates that ranged from \$0 (12 participants) to \$2.15 billion. On average, the estimated amount to motivate people to lose 5 lb was \$258, with a median of \$50 and interquartile range of \$10 to 100. When asked how much money participants needed to lose 15 lb and keep it off for a year, the range of responses was identical. They expected themselves to be motivated with an average of \$713 (median of \$100, IQR \$25-250). Only 8 participants responded with \$0 for this question. The difference between these two estimates was statistically significant ($P < 0.001$).

DISCUSSION

In this national web-based survey of individuals with diabetes, we explored perceptions of financial and non-financial incentives to improve diabetes self-management. We found that nearly all surveyed individuals were interested in incentives, with no difference in socioeconomic status, or demographic features (age, race, gender and SES). In fact, the only significant difference was in the type of diabetes, as all individuals with type 1 diabetes were interested in incentives.

Smartphones offer a unique opportunity to monitor behaviors^[18] and provide rewards. Smartphone use was

reported by nearly half of surveyed individuals interested in incentives and smartphone adoption is increasing rapidly^[19]. The easy availability of smartphones creates opportunities for low-effort tracking and immediate gratification through smartphone applications with reward systems. This short delay favors the efficacy of feedback for behavior changes^[20], and is a unique possibility offered by these devices. Many applications already exist for diabetes management^[21,22], including applications with non-financial reward systems^[23]. Applications with financial rewards are also available to motivate users to exercise, and recent developments like near field communication technologies facilitate money management on mobile devices. Using a smartphone app could also allow for better individualization of the reward program, by adapting to each user's stage of disease and self-management, and by identifying areas that are more challenging for each person.

Individuals overall were optimistic about the effectiveness of incentives, and expected financial incentives to be a stronger motivation than non-financial incentives for behavior change. Furthermore, when considering how difficult behavior changes were perceived to be, using a 32-point score, we found that participants expected to be significantly less likely to use financial incentives for more challenging behavior changes in the unadjusted analysis. In fact, participants were more likely to use non-financial incentives when facing the difficult behaviors. Interestingly, the perceived level of difficulty for behavior change was not associated with the use of self-rewards. These findings persisted after adjusting for age and weight loss motivation.

Our findings suggest that financial incentives could have a potential role to play in motivating select behavior changes for diabetes self-management. The different response by perceived level of challenge suggest that perhaps a combination of incentives is needed to improve the various self-management skills. In Polonsky *et al*^[24]'s recent study about perceived obstacles for glucose self-monitoring, avoidance behaviors (including forgetting, lack of time or reminders of diabetes) were predictors of a low frequency of glucose testing. Whether avoidance also predicts low success of other self-care behaviors is uncertain. Based on our findings, avoidance behaviors that are perceived to be less challenging could have a positive response to financial incentives, while more

challenging behaviors would require the use of non-financial incentives.

The amounts of financial incentives are important to consider. An interesting finding from our survey is the relatively low amounts of money that participants expected as incentive for weight loss (\$258 for the 5 lb weight loss and \$713 for the 15 lb weight loss), particularly if we consider that current out-of-pocket costs for diabetes are estimated at \$350-500/mo^[25,26]. This concurs with findings from another study which explored the use of financial incentives in diabetes, where participants suggested \$25 per month for tracking and reporting glucose results^[27]. Employers typically employ similar amounts for action-based incentives, or rewards for taking action (joining a weight loss program, for example) after going through a risk assessment^[28]. Prior research has found that very large amounts can lead to lower performances, because the individual feels pressure to perform well. Likewise, amounts that are too small lead to lower performances, even lower than those who do not have any incentive^[29]. These considerations suggest that our participants' intuitions about the reward amounts are in the right ballpark, although this needs to be evaluated empirically.

The strengths of our study include its focus on the use of incentives, both financial and non-financial, in a diabetic population. Although the relatively moderate number of participants may limit its generalizability, its web-based modality allowed us to recruit nationwide. This modality however also has its limitations, as the participants are self-selected, and received tokens in exchange for taking part in the survey (no compensation was given by the investigators, this was solely a feature of the survey company). Our population may therefore be disproportionately biased in their interest in incentives. A final limitation to our study lies in its design as a survey, as we assess the participants' expected response to incentives, which may differ from their actual response to incentives. Future studies are needed to confirm our findings, and to further explore the acceptability and feasibility of incentives for diabetes self-management in a larger population.

According to our nationwide survey, patients with diabetes are willing to consider using incentives, both financial and non-financial, to improve diabetes self-management. While the financial incentives may be more effective for behavior changes that are perceived as less challenging, non-financial incentives may be useful for the more challenging behaviors. Participants did not expect to need large amounts to motivate them to modify their behavior. Our findings suggest that the effectiveness of incentives could vary, and may depend on the perceived difficulty of the incentivized task. Future studies are needed to confirm these results in interventional studies on larger populations.

ACKNOWLEDGMENTS

I acknowledge Klasnja P, Pratt W and the rest of the iMed team for their help in preparing the survey.

COMMENTS

Background

Financial incentives have shown potential for modifying behaviors such as smoking cessation. Diabetes self-management requires many behavior changes, which may benefit from such incentives. Little is known about patient attitudes in response to incentives for diabetes self-management.

Research frontiers

Although incentives have been studied for certain behaviors, the current research hotspot is patient acceptance of incentives for diabetes self-management, in particular for the goals, type (financial, non-financial or self-reward) and amount of incentives.

Innovations and breakthroughs

Beyond patient attitudes and expectations about their response to incentives, this survey provides suggestions about goal-setting in reward programs, in relation to the perceived level of challenge of certain behaviors. Individualization of goals and rewards could be feasible with the exponential adoption of mobile devices, which could both track and reward behaviors ubiquitously.

Applications

The results of this study can help guide future interventional studies with incentives, both in goal-setting in terms of types of behaviors, types of rewards, and amounts for financial incentives.

Terminology

Financial incentives include all rewards relating to monetary rewards or equivalents such as vouchers (cash or discount for a future purchase, for example). Non-financial incentives are rewards such as badges or stars in social networks that provide recognition from others for an achieved feat. Self-rewards are rewards that a person gives themselves when they reach a predefined goal, often planned as small rewards that accumulate to reach a large, final reward.

Peer-review

In this well-written paper, the author investigates the patient willingness to change diabetes self-management behaviors in response to rewards. The reviewers found this approach to improve patient engagement interesting. The results can help guide the creation and implementation of new patient-centered approaches for diabetes self-management.

Abstract

AIM: To determine the prevalence and incidence of diabetic nephropathy in Africa.

METHODS: We performed a systematic narrative review of published literature following the MOOSE Guidelines for Meta-Analysis and Systematic Reviews

of Observational Studies. We searched PubMed-MEDLINE for all articles published in English and French languages between January 1994 and July 2014 using a predefined strategy based on the combination of relevant terms and the names of each of the 54 African countries and African sub-regions to capture the largest number of studies, and hand-searched the reference lists of retrieved articles. Included studies reported on the prevalence, incidence or determinants of chronic kidney disease (CKD) in people with diabetes within African countries.

RESULTS: Overall, we included 32 studies from 16 countries; two being population-based studies and the remaining being clinic-based surveys. Most of the studies (90.6%) were conducted in urban settings. Methods for assessing and classifying CKD varied widely. Measurement of urine protein was the most common method of assessing kidney damage (62.5% of studies). The overall prevalence of CKD varied from 11% to 83.7%. Incident event rates were 94.9% for proteinuria at 10 years of follow-up, 34.7% for end-stage renal disease at 5 years of follow-up and 18.4% for mortality from nephropathy at 20 years of follow-up. Duration of diabetes, blood pressure, advancing age, obesity and glucose control were the common determinants of kidney disease.

CONCLUSION: The burden of CKD is important among people with diabetes in Africa. High quality data from large population-based studies with validated measures of kidney function are still needed to better capture the magnitude and characteristics of diabetic nephropathy in Africa.

Core tip: Chronic kidney disease is a serious health threat for people with diabetes in Africa, with prevalence

figures ranging from 11% to 83.7%. The incidence estimates suggest that 95% of people with diabetes may have proteinuria after 10 years from diabetes diagnosis; about 35% may develop end-stage renal disease after 5 years and 18% die from nephropathy after 20 years of disease duration. Hypertension, obesity, poor glycemic control and diabetes duration are the main risk factors of chronic kidney disease among diabetic patients in Africa. High quality data are needed to refine the epidemiology of diabetic nephropathy on the continent.

INTRODUCTION

Africa, like the rest of the world, is experiencing an increasing prevalence of diabetes alongside other non-communicable diseases, mainly as a result of urbanization, sedentary lifestyles, obesity and population growth and ageing^[1]. Estimates for 2013 by the International Diabetes Federation (IDF) indicate that the number of adults with diabetes in the world will expand by 55%, from 381.8 million in 2013 to 591.9 million in 2035^[2]. The largest increase of the population with diabetes will occur in sub-Saharan Africa, with a projected growth of 109.6%, from 19.8 million in 2013 to 41.5 million in 2035^[2].

Diabetes causes significant morbidity, disability and early mortality. Diabetes has been identified as a major contributor in several other important diseases, both non-communicable diseases such as cardiovascular disease and renal disease^[3,4], and communicable diseases such as invasive bacterial infections^[5,6]. Mortality attributable to diabetes in sub-Saharan Africa was estimated to account for 8.6% of the total death in 2013^[7]. Diabetic nephropathy (DN) is one of the most common complications of diabetes. The prevalence of DN is increasing steeply along with the diabetes epidemic^[8]. Approximately one third to half of patients with diabetes develops renal manifestations^[8-11]. DN is associated with increased premature mortality, end-stage renal disease and need to renal replacement therapy, cardiovascular diseases, and escalating health-care costs^[8].

DN has been suggested to be more frequent among patients with diabetes in Africa as compared to those in the developed world due to delayed diagnosis, limited screening and diagnostic resources, poor control of blood sugar and other risk factors, and inadequate treatment at an early stage^[7,12,13]. However, evidence to support the burden of kidney diseases in people with diabetes in Africa remains very patchy, and

we are not aware of any effort to synthesize existing data on the occurrence of kidney disease in African populations with diabetes. Accordingly, the aim of this review is to provide a comprehensive overview of the published evidence on the occurrence of nephropathy in African people with diabetes.

MATERIALS AND METHODS

Data sources and search strategy

A systematic narrative review of published literature was performed following the MOOSE Guidelines for Meta-Analyses and Systematic Reviews of Observational Studies^[14]. We searched MEDLINE *via* PubMed for articles published in English and French on DN in Africa between January 1994 and July 2014, using a predefined strategy based on the combination of relevant terms and the names of each of the 54 African countries and African sub-regions to capture the largest number of studies. The data search was limited to human studies. The last search date was October 22, 2014. Search histories are provided in Table 1. Once duplicate references were removed the titles and abstracts of the references were screened. The references of included articles were scanned to identify additional articles of interest.

Study selection and data extraction

We included cross-sectional, case-control or cohort studies of subjects with diabetes mellitus resident in African countries reporting the prevalence or incidence or progression of DN. We excluded studies of populations of African origin residing outside Africa; case series (sample size less than 50 subjects), letters, comments and editorials; studies not published in English or French. Two investigators (JJNN, APK) independently identified articles and sequentially screened them for inclusion (Figure 1). Disagreements were solved by a third investigator (JN). Full text articles were reviewed by two investigators (JJNN and APK) who independently extracted data regarding study setting and design, study population characteristics and prevalence or incidence of DN.

RESULTS

We identified 730 articles, of which 73 were reviewed in full-text; 32 met the inclusion criteria (Figure 1)^[15-46].

Characteristics of included studies

Characteristics of the included studies are summarized in Table 2. The 32 studies were performed in 16 countries, with a geographical distribution covering all the African regions. However, more than half the studies [18 (56.3%)] were from South Africa (five), Nigeria (four), DR Congo (three) and Ethiopia (three).

Only two population-based studies were identified. In Democratic Republic of Congo, between March and April 2007, Makulo *et al*^[35] studied pathologic

Figure 1 Flow diagram of study selection.

albuminuria among 81 diabetic patients identified through a population-based survey on the prevalence of diabetes involving 1898 participants^[35]. Pruijm *et al*^[39] in Seychelles in 2004, conducted a large-scale population-based estimate of the prevalence of microalbuminuria among 1218 adults. All other studies were clinic-based surveys conducted mostly in

diabetic clinics. There were three cohort studies (two prospective and one retrospective), one case-control study and the other 28 studies were cross-sectional with non-random sampling. Only three (9.4%) studies were conducted in rural settings.

Methods of assessment and classification of chronic kidney disease (CKD) varied widely. The studies assessed kidney function by urine protein [20 (62.5%) studies], urine albumin-to-creatinine ration (ACR) [9 (28.1%) studies], and estimation of glomerular filtration rate (GFR) by Cockcroft-Gault formula [3 (9.4%) studies] or by MDRD formula [4 (12.4%) studies]. Six studies (18.8%) measured kidney function by two methods, and renal biopsy was not performed in any study.

Prevalence of CKD

As depicted in Table 3, the overall prevalence of CKD varied from 11% in Tunisia to 83.7% in Tanzania^[20,29]. In studies where proteinuria was used to assess CKD, the prevalence varied from 5.3% in South Africa to 53.1% in Cameroon (study with a small sample size)^[32,44]. When considering the estimation of the GFR, the prevalence ranged from 4.6% in Tanzania to 43.1% in Nigeria (study with a small sample size)^[15,33].

Incidence of CKD

A study in South Africa investigated the long-term incidence of proteinuria among T2DM patients. After 12 years of follow-up or death, 94.9% (56/59) had a proteinuria with a mean duration from diabetes onset to proteinuria of 9.7 (5.9) years^[31]. In another study in South Africa, found that 18.4% of T1DM patients had

ACR: Albumin-to-Creatinine Ratio; T1DM: Type 1 diabetes mellitus; T2DM: Type 2 diabetes mellitus; CKD: Chronic kidney disease; eGFR: Epidermal growth factor receptor.

died from renal nephropathy after 20 years of follow-up^[28]. In a recent study in Morocco, the incidence of end-stage renal disease after 5 years was 34.7%^[19].

Risk factors of CKD

Twenty studies (62.5%) reported factors associated with CKD in diabetic patients (Table 4). However, in most studies the method to assess this association was imprecise. In cross-sectional studies, correlates of CKD included systolic and diastolic high blood pressure, long duration of diabetes, older age, dyslipidemia, obesity^[16-22,25,26,29-31,33,36,40,42-44,46]. In a study in Cameroon, T2DM patients with systolic hypertension and diastolic hypertension were respectively 1.45 (95%CI: 1.15-1.84; $P = 0.006$) and 1.33 (95%CI: 1.06-1.66; $P = 0.026$) times more likely to have nephropathy^[22]. Two studies in Rwanda and South Africa respectively showed that a one year increase in the duration of T1DM increased by 0.86 (95%CI: 0.77-0.96; $P = 0.008$) the odds of microalbuminuria^[36], and that T1DM and T2DM patients with a duration of diabetes greater than 10 years were 4.19 times (95%CI: 1.93-9.10; $P < 0.001$) more likely to have microalbuminuria^[43]. Poor glycemic control as measured by HbA1c was also a strong predictor of nephropathy. For instance, HbA1c level greater than 10% and 14% were respectively associated with a 2.6 fold (95%CI: 1.1-6.4) and a 4.69 (95%CI: 1.65-13.3; $P = 0.004$)^[42,43]. A 1 g/dL decrease in hemoglobin level has been found to be associated with end-stage renal disease (OR 3.18, 95%CI: 1.47-6.87; $P = 0.003$)^[19]. Studies in Nigeria showed that left ventricular hypertrophy, stroke, myocardial infarction and peripheral arterial disease were more frequent in T2DM patients with nephropathy, especially those with advanced stages^[17,18].

plication of diabetes and the leading cause of CKD in the developed world. The lack of renal registries means that there are no reliable statistics about the burden of CKD in people with diabetes in the majority of African countries. The current systematic review identified 32 relevant studies published over the last 20 years on kidney diseases in people with diabetes residing in Africa. Prevalence rates ranged from 11% to 83.7% for the overall CKD, 5.3% to 53.1% for CKD based on proteinuria, and 4.6% to 43.1% for CKD based on eGFR. Incident event rates were 94.9% for proteinuria at 10 years for follow-up, 34.7% for ERSD at 5 years of follow-up and 18.4% for mortality from nephropathy at 20 years of follow-up. Diagnosed duration of diabetes, blood pressure variables, advancing age, obesity and to some extent glucose control were the common determinants of kidney disease in people with diabetes. Studies were overwhelmingly hospital-based studies; half of them originated from four countries while variable definitions and methods for assessing nephropathy had been used across studies.

The most recent overview of CKD in populations within Africa was completed in 2012, and was restricted to sub-Saharan African Countries^[47]. This review identified 90 articles representing data from 21 countries, with over half of the studies originating from South Africa, Nigeria and Ethiopia alones. Across 21 studies deemed to be of medium to high quality by the investigators, the pooled prevalence of CKD was 13.9% (95%CI: 12.2-15.7), with substantial heterogeneity across studies. The prevalence in people with diabetes ranged from 4% to 24% based essentially on proteinuria defined CKD^[47]. In our review without applying quality criteria, we found much higher prevalence of CKD, regardless of the definition. In four studies published in 2013 for instance, the prevalence of microalbuminuria ranged between 21% and 45%. Although issues with the quality of the studies preclude direct comparisons, it is likely that nephropathy is

DISCUSSION

Diabetic nephropathy is a common and morbid com-

Table 4 Risk factors for chronic kidney disease in people with diabetes

CKD: Chronic kidney disease; BMI: Body mass index; ACR: Albumin-to-Creatinine Ratio; T1DM: Type 1 diabetes mellitus; T2DM: Type 2 diabetes mellitus; eGFR: Epidermal growth factor receptor.

more frequent in population with diabetes within Africa than in developed countries. The review by Stanifer *et al.*^[47] also identified many challenges and limitations, which largely apply to the current study.

The most important aspect in assessing incidence and prevalence of diabetic nephropathy in Africa is currently different diagnostic criteria for CKD. There are no clear definitions on DN. The 2012 KDIGO CKD classification assesses diabetes related kidney changes according to urinary albumin-to-creatinine ratio based on early morning spot urine samples^[48]. Quantification of proteinuria in assessing CKD is controversial as no optimal test exists. The National Institute for Health and Clinical Excellence (NICE) guidance has recommended that an early morning urinary ACR should be preferred to other tests of proteinuria, because ACR offers greater sensitivity for the detecting lower, but clinically significant, levels of proteinuria^[49]. Almost all the studies included in our review utilized urine tests to diagnose CKD, but only nine studies used ACR. Inconsistencies in the way and manner of reaching a diagnosis of DN in Africans are explained at least in part by issues relating to availability and accessibility of screening or diagnostic tools. Swanepoel *et al.*^[50] have reviewed in detail some of the problems associated with nephrology in Africa and discussed the role of lack of amenities in diagnosing renal diseases. Another challenge to making the diagnosis of diabetic nephropathy in Africa is the degree to which other causes of chronic kidney disease have been excluded. A standard armamentarium of tests would include tests looking for HIV, hepatitis B and C, brief collagen screen, syphilis exclusion and other tests would have to be based on history and physical exam.

The classification of CKD is important in the definition of DN and has a few limitations that are universally acknowledged: eGFR underestimates kidney function and there is discordance in the estimates across different estimators^[51]; isolated microalbuminuria is a normal feature of aging, inflammation, vascular pathologies, smoking, diet and obesity which are all frequent in diabetes; decline in kidney function is an expected phenomenon with advanced age, just like diabetes risk increases with age. Further considerations to CKD classifications and DN definition limitations is that current guidelines take no notice of the single most important risk factor associated with CKD namely hypertension, which is present in over 50% of people with type 2 diabetes.

Risk factor association was not assessed in 12 of the 32 studies, however common risk factors included were hypertension, raised BMI, HbA1c and duration of diabetes. Despite advances in management over the last three decades, many people with diabetes still develop CKD. This may be partly explained by the poor achievement of blood pressure and blood glucose targets. Recently the JNC 8 guidelines have added to the controversy of various blood pressure targets needed for diabetic patients that would

assist in preventing progression to CKD. Optimal targets when reached, however have shown to aid in progression to progression. Another risk factor pertinent to the developing world is the socioeconomic status of individuals in the causative role of diabetic nephropathy. Weil *et al.*^[52], in 2010 reviewed factors associated with disadvantage that may increase the risk of diabetic kidney disease, and the barriers to care that hinder attempts to provide an adequate therapeutic response^[52].

Several mechanisms underlying the pathogenesis of diabetic nephropathy have been suggested and include glomerular hyperfiltration; hyperglycemia and the increased production of advanced glycation end products; hypoxia-inflammation and the activation of cytokines. Hyperfiltration commonly occur in early in the course of diabetes and involves glucose-dependent dilation of the afferent arteriolar dilation, and the enhanced filtration area secondary to the increase in the number of mesangial cells and capillary loops. Molecular level action involves vasoactive mediators like insulin-like growth factor 1, transforming growth factor beta, nitric oxide, prostaglandin, glucagon and vascular endothelial growth factor^[53]. Other hallmarks of diabetic nephropathy include nodular diabetic glomerulosclerosis and diffuse glomerulosclerosis, mediated at least in part by inflammatory processes and immune cells activity^[53]. Interstitial fibrosis and tubular atrophy are also seen early in DN, with the underlying pathogenetic mechanism being similar to those in progressive non diabetic renal disease^[54].

Diabetic nephropathy ultimately occurs only in susceptible individuals with diabetes; which susceptibility is determined by the combined effect of genetic predisposition and non-genetic factors. Genetic susceptibility to diabetic nephropathy is by nature polygenetic. Whole-genome scanning studies have identified several chromosomal regions linked with diabetic nephropathy; however, the pathophysiologic function of such genetic regions has yet to be fully elucidated. Genetic polymorphisms may explain the familial clustering of diabetic nephropathy^[55]. Some studies have suggested some detrimental effect of the double-deletion (DD) polymorphism of the angiotensin-converting enzyme (ACE) genotype on disease progression^[56]. Non-genetic determinants of diabetic nephropathy include among others socioeconomic factors, dietary factors, poor hyperglycemic control, hypertension, obesity and early life factors^[57,58]. Hypertension appears to be a strong correlate of disease progression in Black people^[59,60].

The current review has some limitations. Included studies were mostly based on small samples, with different study designs and most of the studies were cross sectional with only two being retrospective cohorts and one case-control. A large proportion were based in urban clinics with and most of the populations studied were that attending a general diabetic clinic and the results may not be generalizable

to primary care populations. Ideally chronic kidney disease should not be diagnosed on the basis of single measurements of serum creatinine and albuminuria, and standard baseline investigations are needed to exclude other causative kidney disease, although there is precedence for this in other studies in the West as well. Finally, detection of microalbuminuria was one the most frequent method to assess the presence of diabetic nephropathy. As microalbuminuria is more a quantitative estimate of endothelial/vascular dysfunction than of diabetic nephropathy, the incidence and prevalence rate of diabetic nephropathy have probably been overestimated when assessing kidney function by urine protein.

In conclusion, the current review gives a small glimpse of the larger numbers of CKD in diabetics in Africa compared to Western society. CKD is a substantial health burden among diabetic patients on the African continent, with prevalence varying from 11% to 83.7% depending on the method of assessment. Estimates suggest that 95% of diabetics may have proteinuria after a 10 years duration of diabetes, about 35% may have an end-stage renal disease after 5 years and 18% die from nephropathy after 20 years of disease duration. Risk factors of CKD include mainly hypertension, obesity, poor glycemic control and disease duration. Better surveillance of diabetes is a necessary first step toward its prevention and control, which is now recognized as an urgent priority. An electronic database in African regions would be ideal to assist in this entity although it is presumed that we are light years away from that. At a primary care level it is very plausible that with early detection, proper screening, and management, the impact of diabetic nephropathy may be better mitigated to lessen its impact on society and healthcare.

COMMENTS

Background

African countries are experiencing an epidemics of diabetes mellitus. Diabetic nephropathy is one the most frequent complications of diabetes mellitus. Several studies on the epidemiology of diabetic nephropathy have been conducted in Africa, but there is no previous published work which synthesizes evidences from this study to provide an overview of the disease on the continent.

Research frontiers

Epidemiological data on diabetic nephropathy in Africa are sparse. These data are important to quantify the magnitude of the disease and assist the formulation of strategies to reduce the impact of nephropathy on people with diabetes in Africa.

Innovations and breakthroughs

This review is the first to synthesize relevant data on diabetic nephropathy in Africa. The authors performed extensive electronic and manual bibliographic searches to determine the prevalence and incidence of diabetic nephropathy on the continent. Although the quality of data was not optimal, estimates suggest that the prevalence of diabetic nephropathy vary between 11%-83.7%. About one third of diabetic patients have end-stage renal disease after 5 years and about one fifth die from nephropathy after 20 years of disease duration. Hypertension, obesity, poor glycemic control and disease duration are the main risk factors of chronic kidney disease among diabetic patients in Africa.

Applications

This review shows that the burden of chronic kidney disease is important among people with diabetes in Africa. The findings will have implications for policy, practice and future research on diabetic nephropathy on the continent.

Terminology

Diabetic nephropathy is an alteration of the function of the kidneys due to diabetes mellitus. It is associated with substantial morbidity and mortality.

Peer-review

The authors of the present manuscript performed extensive electronic and manual bibliographic research to determine the prevalence and incidence of kidney disease in people with diabetes mellitus within countries in Africa. Overall the review is well written.

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Wayne H-H Sheu, MD, PhD, Professor, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung 40705, Taiwan

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulin resistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Incretin-based therapies have revolutionized the medical management of type 2 diabetes mellitus (T2DM) in the 21st century. Glucagon-like peptide-1 (GLP-1) suppresses appetite and gastric motility, and has trophic effects on pancreas, cardio-protective and renal effects. GLP-1 analogues and dipeptidyl peptidase-4 inhibitors form the incretin-based therapies. Significant reduction of hemoglobin A1c when used as monotherapy and in combination regimens, favorable effects on body weight, and low risk of hypoglycemia are their unique therapeutic benefits. Their safety and tolerability are comparable to other anti-diabetic medications. Concern about elevated risk of pancreatitis has been discarded by two recent meta-analyses. This article discusses the therapeutic manipulation of incretin system for the management of T2DM.

Key words: Incretin hormones; Incretin-based therapies; Glucagon-like peptide-1 analogues; Dipeptidyl peptidase-4 inhibitors; Pancreatitis

Core tip: Development of multiple pharmaceutical agents by the manipulation of incretin hormone system provided the global scientific fraternity several drugs for the management of type 2 diabetes mellitus (T2DM) in recent years. These agents, the glucagon-like peptide-1 analogues and dipeptidyl peptidase-4 inhibitors, form the incretin-based therapies that benefited T2DM patients with significant reduction of hemoglobin A1c, low risk of hypoglycemia, favorable effects on management of overweight and obesity, and enhanced efficacy in combination regimens for glycemic management with other anti-diabetics. Two recent meta-analyses discarded the concern about elevated pancreatitis risk. The article discusses the incretin-based therapies for the management of T2DM.

Pappachan JM, Raveendran AV, Sriraman R. Incretin manipulation in diabetes management. *World J Diabetes* 2015; 6(6): 774-781 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/774.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i6.774>

INTRODUCTION

Incretins are gut hormones secreted in response to meals that modify the biological mechanisms of glucose homeostasis in the body mainly through their effects on the pancreatic endocrine function^[1,2]. Glucose-dependent insulintropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) are the two major incretin hormones identified to have major effects on carbohydrate metabolism. Although the concept of incretin effect on glucose homeostasis was introduced as early as 1930s^[3], the biological effects of incretins were well-established only in the past 3-4 decades^[2]. Approximately 70% of β -cell insulin secretion is controlled by GIP and GLP-1^[2]. Native GLP-1 has a very short biological half-life (1-2 min only) being rapidly degraded by the enzyme dipeptidyl peptidase-4 (DPP-4) to an inactive molecule that terminates its incretin effect. Research on the biological manipulation of incretin system in animal models in the past few decades showed promising results with development of multiple pharmaceutical agents quite useful in the management of obesity, type 2 diabetes mellitus (T2DM) and metabolic syndrome towards the turn of 20th century. This paper discusses an overview of incretin manipulation for the management T2DM.

BIOLOGICAL EFFECTS OF GLP-1

GLP-1 is a peptide hormone secreted from the entero-endocrine L cells located within the gastrointestinal mucosa (mainly the ileum) that act as nutrient sensors, which release GLP-1 in response to luminal nutrients such as sugars, amino acids, and fatty acids^[4]. The secreted GLP-1 binds to the GLP-1 receptors (GLP-1R) distributed widely in various body tissues such as the pancreatic islets, brain, heart, kidney, and the gastrointestinal tract. The binding of GLP-1 to islet cell GLP-1R results in amplification of insulin secretion by the pancreas. This property of augmented insulin secretion in response to gut hormone release related to meal intake is termed as "the incretin effect"^[4]. However, the effects of GLP-1R activation in most other tissues still remain elusive.

GLP-1 also has trophic effects on the pancreatic β -cells^[4,5]. It has been found to stimulate beta-cell proliferation, enhance the differentiation of progenitor cells in the pancreatic duct epithelium into new β -cells, and inhibit apoptosis of the β -cells^[4]. Fasting and meal-related hyper-secretion of glucagon was demonstrated in patients with T2DM, and GLP-1 was found to be

a strong inhibitor of glucagon secretion^[4]. The exact mechanism of this effect is unknown. Local increase in insulin levels around the α -cells in response to GLP-1R stimulation and the GLP-1-stimulated somatostatin secretion are thought to be responsible for the inhibition of glucagon secretion^[4].

GLP-1 possesses the property of inhibition of gastric motility, gastrin-induced acid secretion in the stomach, and the pancreatic secretion^[4,6]. The gastric inhibitory effects of GLP-1 are thought to be mediated through the vagus nerve. GLP-1 also possesses central effects in the brainstem and hypothalamus through which it modulates the appetite, satiety and eating behavior in animals and human beings^[4]. GLP-1 also has cardio-protective and renal effects. The physiological aspects of incretin bio-effects are depicted diagrammatically in the Figure 1.

PHARMACOLOGICAL MANIPULATION OF INCRETIN SYSTEM

Attempts for the pharmacological manipulation of GLP-1 and DPP-4 molecules were areas of immense research interest among the scientific fraternity over the past few 3 to 4 decades that resulted in development of multiple medications, which revolutionized the modern management of T2DM. Through the bio-modulation of GLP-1 molecules to counteract the ultra-short half-life of native GLP-1, a class of drugs termed GLP-1 analogues was invented (also termed as incretin mimetics or incretin analogues). Development of inhibitors of the DPP-4 enzyme resulted in production of multiple drugs that prolong the effects of endogenously synthesized incretin molecules termed as incretin enhancers. These two classes of drugs form the incretin-based therapies which are commonly used in the management of T2DM.

With a significant effect on reduction of hemoglobin A1c (HbA1c), favorable effects on body weight especially in obese T2 diabetic, and a relatively low risk of hypoglycemia^[7], these drugs were well accepted by diabetologists and internists in the past few years^[1]. The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) recently recommended incretin-based therapies as important second line agents for management of T2DM^[7,8]. Newer molecules with different therapeutic and pharmacodynamic profiles are being added to this class of drugs.

GLP-1 ANALOGUES

Native GLP-1 is 30 amino acid polypeptide hormone that is rapidly degraded by the DPP-4 enzyme. To counteract the ultra-short half-life, alterations in the molecular structure of GLP-1 were attempted resulting in successful invention of a few GLP-1 analogues in

Figure 1 Physiological aspects of incretin hormones in the body. GLP-1: Glucagon-like peptide-1; GIP: Glucose-dependent insulinotropic polypeptide.

recent years.

Exenatide

Exenatide is the first among these molecules that gained approval from the United States Food and Drug Administration (FDA) in 2005^[9]. The drug, isolated from saliva of the reptile Gila monster (*Heloderma suspectum*), has 39 aminoacids with a 53% structural homology to natural GLP-1^[9,10]. It has a plasma half-life of 3-4 h, and is excreted by glomerular filtration with subsequent degradation^[10].

Exenatide improved glycemic control in patients with T2DM, not responsive to lifestyle modification, and medications such as sulfonylureas, metformin and thiazolidinediones, either alone or in combinations^[9,11]. Exenatide treatment showed improvements in both the fasting and post-prandial hyperglycemia in T2DM patients^[12]. In a recent meta-analysis examining the efficacy of the drug compared to placebo from nine clinical trials, the weighted mean difference of mean variation of hemoglobin A1c (Δ HbA1c) for all included data for exenatide 5 μ g twice daily or its equivalent long acting dosage form was -0.68% [95%CI: -0.89 to -0.48 ($P < 0.0001$)] and for exenatide 10 μ g twice daily or its equivalent long-acting dosage form was -0.99% [95%CI: -1.18 to -0.8 ($P < 0.0001$)]^[13]. The weighted mean difference of mean variation of BW (Δ BW) for

5 μ g twice daily or its equivalent long acting dosage form in eight of the trials was -0.56 kg [95%CI: -0.07 to -0.06 ($P = 0.0002$)] and for exenatide 10 μ g twice daily or its equivalent long-acting dosage form in twelve trials was -1.24 kg [95%CI: -1.69 to -0.78 ($P < 0.0001$)]. Other observed benefits were reduction of systolic and diastolic blood pressures, and total cholesterol and low density lipoprotein (LDL)^[13].

Being structurally different from native GLP-1, development of antibodies to exenatide on long-term treatment is common. Low-titre anti-exenatide antibodies were observed in 32% of cases on twice daily regimen and in 45% cases on once weekly regimen^[14]. However, a significant effect on therapeutic efficacy was not evident in most cases. Higher antibody titres were less common (5% and 12% respectively), and increasing titres were associated with a reduction in average efficacy that was statistically significant for exenatide once weekly preparation^[14]. Apart from injection-site reactions, there were no observed safety issues with anti-exenatide antibodies.

Liraglutide

The drug is manufactured using recombinant DNA technology, and is with a 97% structural homology to human GLP-1^[15]. Therefore, the molecule can be used effectively in patients with reduced response

to exenatide therapy after prolonged use because of antibody production. The estimated mean differences in HbA1c reduction with liraglutide 1.2 mg and 1.8 mg daily compared to placebo were -1.01% (95%CI: -1.18 to -0.85) and -1.18% (95%CI: -1.32 to -1.04) respectively in a recent meta-analysis^[16]. The Liraglutide Effect and Action in Diabetes (LEAD) program trial showed that mono-therapy with 1.2 mg and 1.8 mg of the drug was associated with a mean 2.1 kg and 2.5 kg weight reduction respectively, compared with a mean 1.1 kg weight gain among patients on glimepiride ($P < 0.001$) treatment^[17].

The other observed benefits were: a mean reduction in systolic blood pressure of 2.59 mmHg ($P = 0.0008$) and 2.49 mmHg ($P = 0.003$) from baseline for liraglutide 1.2 mg and 1.8 mg respectively at 26 wk of treatment^[15], improvement of β -cell function^[18], reduction of total cholesterol and LDL, improvement of non-alcoholic fatty liver disease (NAFLD)^[19], and improvement of cardiovascular risk markers^[15].

Lixisenatide

Plasma half-life of lixisenatide is 3 h similar to that of exenatide^[20], although it can be used as a single daily subcutaneous injection. Treatment with the drug resulted in a HbA1c reduction of 0.9%, body weight reduction of -3.62 kg (95%CI: -5.86 to -1.36) without significant risk of hypoglycemia compared to insulin^[21]. Lixisenatide was also shown to improve NAFLD (number needed to treat: 14 patients, $P = 0.042$)^[22]. Although slightly less effective than exenatide in terms of lowering HbA1c levels and weight reduction, lixisenatide use can be more convenient in comparison to exenatide as it has less hypoglycemia risk and gastrointestinal side effects, and the ease of once-daily administration^[23].

Albiglutide

Albiglutide is a DPP4-resistant human GLP-1 manufactured by fusion of the molecule with recombinant human albumin^[24]. With a plasma half-life of approximately 5 d, the drug has the advantage of being administered once weekly. The drug recently received FDA approval in the United States for management of T2DM. Albiglutide can be used as a monotherapy or as an add-on therapy to metformin, sulfonylureas, insulin glargine and thiazolidinediones. Superior clinical efficacy compared to sitagliptin, and glimepiride, and non-inferiority to insulins (glargine and lispro) with HbA1c reduction of 0.55% to 0.9% and weight reduction up to 1.21 kg were reported with the use in T2DM cases^[25]. Although gastrointestinal side effects were less common, efficacy in reducing HbA1c and body weight were less pronounced compared to liraglutide.

Dulaglutide

This new long acting GLP-1 analogue received recent

FDA approval for use in T2DM. The plasma half-life of dulaglutide is approximately 4 d, with a once weekly dosing advantage^[26]. Efficacy of once weekly regimen was reported to be superior to: metformin monotherapy, sitagliptin as add-on to metformin, and exenatide as add-on to metformin and pioglitazone, with a safety profile similar to other GLP-1 analogues^[27]. The plasma half-lives, dosage range and common side effects of GLP-1 analogues are shown in Table 1.

DPP-4 INHIBITORS

DPP-4 inhibitors increase the endogenously secreted GLP-1 and GIP concentrations by inhibiting the bio-degradation of these hormones by the DPP-4 enzyme, and thereby enhancing the incretin effect. In patients with T2DM these drugs are effective both as monotherapy and as add-on therapy to sulphonylureas, metformin, thiazolidinediones and insulin. In general, DPP-4 inhibitors are weight neutral, making them favorable options in the management of overweight and obese T2DM patients.

Sitagliptin

Sitagliptin is first among the DPP-4 inhibitors that received FDA approval in 2006. The drug has good oral bio-availability, a half-life of 10-12 h (with once daily dosing advantage), and is eliminated mainly through the kidneys necessitating dose reduction in renal impairment^[28]. Sitagliptin improves both fasting and postprandial hyperglycemia in T2DM patients. HbA1c reduction of up to 0.94% has been reported when sitagliptin is used as a monotherapy and better reduction in combination regimens. A recent meta-analysis concluded that sitagliptin had comparable efficacy to metformin in reduction of HbA1c and body weight, and improvement of β -cell function, although inferior to metformin in improvement of insulin sensitivity^[29].

Vildagliptin

When used as a monotherapy, this molecule showed glycemic control comparable to sulfonylureas and thiazolidinediones, with the advantages of fewer hypoglycemic episodes and lesser body weight gain^[30]. Additional favorable effects on pancreatic α - and β -cell function compared to sulphonylureas were noted with the drug. The plasma half-life of vildagliptin is 1.5-4.5 h and the elimination is mainly through hepatic hydrolysis^[28]. HbA1c reduction of 0.5%-1% has been reported with the drug use in T2DM. Use in combination with metformin, further improves glycemic control when metformin monotherapy is insufficient, with good tolerability and safety^[30]. Combination regimens with other oral anti-diabetic medications and insulins are also effective and well tolerated.

Table 1 Plasma half-lives, dosage range, average hemoglobin A1c and body weight reduction, and common side effects of glucagon-like peptide-1 analogues

Drug	Plasma $\frac{1}{2}$ -life	Dosage	HbA1c reduction	Weight reduction	Adverse effects	Other special features
Exenatide	3-4 h	5-10 mcg twice daily s.c, 60 min prior to meal	0.68%-0.99%	0.56-1.24 kg	Nausea, diarrhoea, headache, pancreatitis, injection site nodule/reaction, formation of anti-exenatide antibody	Not recommended if Creatinine clearance is < 30 mL/min
Exenatide ER	2 wk	2 mg s.c once weekly	0.99%	1.24 kg	Nausea, diarrhoea, vomiting, pancreatitis, injection site nodule/reaction	Injection at any time independent of meals
Liraglutide	13 h	0.6-1.8 mg s.c once daily	1.01%- 1.18%	2.1-2.5 kg	Nausea, diarrhoea, headache, pancreatitis, injection site reaction, formation of anti-liraglutide antibody and naso-pharyngitis	Store in refrigerator (36-46 ° F) Injection at any time independent of meals
Lixisenatide	3 h	20 mcg, once daily s.c	0.90%	3.62 kg	Nausea, diarrhoea, vomiting, pancreatitis	
Albiglutide	5 d	30-50 mg s.c once weekly	0.55%- 0.9%	1.21 kg	Upper respiratory infection, diarrhoea, injection site reaction, hypersensitivity, pancreatitis	Administer on the same day of the week
Dulaglutide	4 d	0.75-1.5 mg s.c once weekly	0.99%- 1.3%	-	Nausea, diarrhoea, vomiting, increased amylase and lipase levels, abdominal pain, injection site reaction, hyper-sensitivity and pancreatitis	

HbA1c: Hemoglobin A1c.

Saxagliptin

The drug received FDA approval in 2009 for use in patients with T2DM. When used as monotherapy at a maximum dose of 5 mg, saxagliptin caused a mean HbA1c reduction of 0.8% with significant improvement of fasting hyperglycemia, and with other categories of oral anti-diabetics, an additional mean HbA1c reduction by 0.6%-0.7%^[31]. The plasma half-life is 2.5 h and elimination is mainly by hepatic and renal clearance^[28].

Linagliptin

Linagliptin is primarily excreted *via* bile and therefore safe to be used in T2DM patients with renal impairment. With a reasonable safety profile, low hypoglycemia risk, HbA1c reduction ranging from 0.6% to 0.8% and weight neutrality, the drug became popular in the recent years^[32]. Additional benefits such as improvement of wound healing, reduction of hepatic steatosis, decrease in the infarct size following myocardial infarction and ischemic stroke, improvement of vascular function, and reduction of albuminuria are claimed with linagliptin use in pre-clinical studies that needs further research in large randomized controlled trials. Linagliptin has relatively low oral bio-availability compared to other DPP-4 molecules (15%-50%) and the plasma half-life of the drug is 12 h^[32].

Alogliptin

This new DPP-4 molecule has a plasma half-life of about 21 h, and can be administered once daily^[33]. Elimination is mainly through kidneys that necessitates dose reduction in advanced renal disease. Alogliptin is safe and well tolerated. A mean HbA1c reduction of 0.6% is reported with monotherapy^[28,33], and additional reduction in combination regimens with other anti-

diabetics^[33].

Teneligliptin

Teneligliptin is one of the latest additions to the class of DPP-4 inhibitors. A recent study revealed that the drug administration was associated with significant elevations of postprandial active GLP-1 and GIP levels, lowering of postprandial hyperglycemia, 24-h mean blood glucose levels, and mean amplitude of glycemic excursions without hypoglycemia^[34]. A significant elevation in early-phase insulin release and a reduction in postprandial glucagon surge were also observed. Even short-term teneligliptin treatment was found to be beneficial in patients with T2DM. HbA1c reduction of about 1%, improvement of β -cell function, insulin sensitivity, and adverse lipid parameters are the benefits claimed in a clinical trial^[35].

Anagliptin

The drug is still being evaluated in phase III clinical trials and is expected to be available for clinical use soon. Mean HbA1c reduction of $-0.85\% \pm 0.70\%$, reduction in the fasting proinsulin/ insulin ratio, and improvement of insulin secretion were observed when used as an add-on therapy to metformin (all effects comparable with sitagliptin) in a recent multi-center clinical trial^[36]. Safety profile and efficacy were also comparable with sitagliptin.

The dosage ranges and common side effects of DPP-4 inhibitors are shown in Table 2.

SAFETY ISSUES/CONCERNS ABOUT INCRETIN-BASED THERAPIES

A lot of discussions on the safety of incretin-based

Table 2 Plasma half-lives, dosage ranges, average hemoglobin A1c reduction and common side effects of dipeptidyl peptidase-4 inhibitors

Drug	Plasma half-life	Dose	HbA1c reduction	Adverse effects	Other remarks
Sitagliptin	12.4 h	100 mg PO daily	0.94%	Nasopharyngitis, diarrhea, headache, constipation, oedema, hypersensitivity, pancreatitis, elevation of hepatic enzymes	Use with caution in renal, hepatic or cardiac failure
Vildagliptin	90 mts - by terminal elimination	50-100 mg/ daily PO	0.5%-1%	Headache, nasopharyngitis, cough, constipation, dizziness, and increased sweating	Dose reduction with CYP450 3A4/5 inhibitors
Saxagliptin	2.5 h	2.5-5 mg/PO daily	0.8%	Urinary and upper respiratory infections, headache, edema, purpuric rash, hypersensitivity, pancreatitis and angio-edema	
Linagliptin	12 h	5 mg PO daily	0.6%-0.8%	Nasopharyngitis, dyslipidemia, pancreatitis	Monitor LFT and stop if elevated
Teneligliptin	24.2 h	20-40 mg PO daily	0.78%	Constipation, QT interval prolongation, hypoglycaemia and elevation of alanine aminotransferase and γ -glutamyltransferases	
Alogliptin	21 h	25 mg PO daily	0.6%	Hypoglycemia, nasopharyngitis, headache and pancreatitis	
Anagliptin	4.37 h - by terminal elimination	100 mg PO daily	0.85%	Not available	

HbA1c: Hemoglobin A1c.

therapies occurred recently following multiple case reports and the data from the United States FDA adverse events reporting system about the risk for pancreatic damage^[1]. Two recent meta-analyses showed reassuring results without significant risk of pancreatitis favoring incretin-based therapies^[37,38]. However, the potential long-term effects of chronic GLP-1R stimulation and its effects on pancreatic enzyme synthesis and the probability of evoking inflammatory response in the pancreas are not clear at the moment.

The other important concern is about the potential to induce neoplasia by these drugs. Significant β -cell hyperplasia, co-expression of insulin and glucagon from β -cells, hyperplasia of α -cells, increased proliferation markers, and excess prevalence of pre-neoplastic lesions were found in pancreas specimens of organ donors previously treated with incretin-based medication for T2DM^[39]. Concerns about elevated risk of pancreatic and thyroid cancer in animal models and human beings^[40] need further clarification by long-term studies and drug safety monitoring.

CONCLUSION

Incretin-based therapies are promising tools for the management of T2DM, especially in overweight and obese individuals. Favorable effects on body weight, significant reduction of HbA1c levels and the relatively low risk of hypoglycemia make them attractive therapeutic options in the day to day management of T2DM patients. Newer GLP-1 analogues and DPP-4 inhibitors are being added to this class of medications recently. Concern about elevated risk of pancreatitis is not obvious at the moment, based on results from two large meta-analyses. However, long-term effects of

these medications on pancreatitis risk and cancer risk still need vigilant monitoring.

ACKNOWLEDGMENTS

We are thankful to Blessen P George for his valuable help for the construction of the figure in this article.

Abstract

The approach to screening and diagnosis of gestational diabetes mellitus (GDM) around the world is disorderly. The protocols for diagnosis vary not only in-between countries, but also within countries. Furthermore, in any country, this disparity occurs in-between its hospitals and often exists within a single hospital. There are many reasons for these differences. There is the lack of

an international consensus among preeminent health organizations (*e.g.*, American College of Gynecologists and World Health Organization). Often there is a disagreement between the country's national diabetes organization, its local health society and its regional obstetric organization with each one recommending a different option for approaching GDM. Sometimes the causes for following an alternate approach are very obvious, *e.g.*, a resource strapped hospital is unable to follow the ivory-tower demanding recommendation of its obstetric organization. But more often than not, the rationale for following or not following a guideline, or following different guideline within the same geographic area is without any perceivable explanation. This review is an attempt to understand the problems afflicting the screening and diagnosis of GDM globally. It traces the major temporal changes in the diagnostic criteria of (1) some respected health organizations; and (2) a few selected countries. With an understanding of the reasons for this disparity, a way forward can be found to reach the ultimate goal: a single global guideline for GDM followed worldwide.

Key words: Gestational diabetes; Criteria; Screening; Diagnosis; Global

Core tip: Globally, the screening and diagnosis of gestational diabetes mellitus (GDM) is idiosyncratic. This disarray is independent of whether a country is affluent (*e.g.*, Denmark) or relatively poor (*e.g.*, Bangladesh). The reason is that not just the international but also the national medical and obstetric organizations in a country advise a multitude of approaches to GDM. This confuses the primary providers of obstetric care, who need one clear, evidence-based, global recommendation. Despite all the differences, in the near future, the light at the end of the tunnel for providing such a universal global GDM guideline is bright.

Agarwal MM. Gestational diabetes mellitus: An update on the current international diagnostic criteria. *World J Diabetes* 2015; 6(6): 782-791 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/782.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i6.782>

INTRODUCTION

Since it is one the commonest metabolic problems of pregnancy, an accurate diagnosis of gestational diabetes mellitus (GDM), *i.e.*, high plasma glucose first identified during pregnancy, is critical to the care of pregnant women. Five decades ago, GDM was used to detect pregnant women who were at a higher risk of developing type 2 diabetes mellitus (DM2) after childbirth^[1]. Currently, GDM is used to predict morbidity in index pregnancy; many trials have confirmed that it is related to multiple maternal and fetal complications like preeclampsia, caesarean sections and birth injuries^[2]. Thus, missing GDM has grim implications, personal for individual women and epidemiological for the entire population. Women with diabetes mellitus who become pregnant have more harmful complications (due to the severe hyperglycemia since early pregnancy) compared to pregnant women developing mild hyperglycemia in late pregnancy. The former have diabetes in pregnancy while the latter are diagnosed with GDM. Thus, GDM implies a milder form of hyperglycemia seen generally in late pregnancy, which usually, but not always, reverts to normal after delivery.

The screening of GDM is done by assessing the clinical risk factors or by the 50-g glucose challenge test (GCT). The diagnosis of GDM is made by the 75-g or 100-g oral glucose tolerance test (OGTT). A screen followed by the diagnostic OGTT (in screen positive patients) is called the two-step approach, while OGTT directly without screen is called the one-step approach. The two-step and the one-step screening methods are also known as the selective and universal screening methods, respectively. The various preeminent health organizations recommend different glucose cut-offs for the OGTT; as a result, there many international diagnostic criteria are available for diagnosis^[3]. More often than not, the gynecologic, medical and health associations within any one country support distinctly diverse schemes for GDM causing major differences in the approach to GDM. Thus, the scourge of gestational diabetes mellitus (GDM) is the diversity of processes accessible for its screening and diagnosis. The variation in the diagnostic thresholds advocated by these venerable organizations, when applied to the same OGTT, results in major discrepancies in prevalence and the women classified with GDM^[3]. Misclassifying women with GDM will result in excessive treatment of many women without GDM and no treatment of many

women with GDM again iterating the need for correct classification.

This review traces the progress in the major international diagnostic criteria worldwide. It looks at the changes in practices of GDM screening and diagnosis in selected countries of the world to show that most countries face similar problems caused by the multitude of criteria available. An understanding of the reasons for the disparity is critical to formulate plans for the ideal goal: a single global approach to GDM.

MAJOR GDM DIAGNOSTIC CRITERIA: DEVELOPMENT

World Health Organization criteria

The World Health Organization (WHO) provides guidelines for numerous communicable and non-communicable diseases. GDM is no exception and due to the worldwide reach and authority of the WHO, the WHO criteria for GDM^[4] are popular globally. In 1965, the WHO Expert Committee on Diabetes Mellitus published the first guideline on diabetes mellitus. They defined gestational diabetes as "hyperglycemia of diabetic levels occurring during pregnancy". After these initial attempts to define GDM, new follow-up WHO guidelines were published in 1980, 1985, 1999 and 2013.

In 1980, the WHO recommended the OGTT for diagnosis of DM2 in non-pregnant adults using 2 values: fasting plasma glucose and the 2-h plasma glucose levels after 75-g of oral glucose. For convenience, common thresholds were applied to both pregnant women and non-pregnant adults; thus, the diagnosis of GDM was applied if a woman was pregnant instead of DM2 for the non-pregnant. In 1985, the glucose values were made more precise by rounding to the nearest tenth of a millimole (rather than the nearest millimole). In 1997, for the diagnosis of diabetes, the ADA lowered the fasting plasma glucose (FPG) cut-off to 7.0 mmol/L (from 7.8 mmol/L). In 1999, the WHO followed suit applying the same FPG criteria as recommended by the ADA to the OGTT. The WHO has always applied the same criteria to the pregnant and non-pregnant women even though common thresholds for pregnant and non-pregnant have been shown to be erroneous^[5]. However, due to the ease of use, simplicity and global clout, the WHO criteria for have remained popular in most countries of the world.

The current global diabetes epidemic has resulted in many younger women in the child bearing age to get DM2. Due to the more severe fetal and maternal complications resulting from such diabetes mellitus antedating pregnancy, in 2013, the WHO^[6] has divided hyperglycemia in pregnancy as follows: (1) Diabetes in pregnancy: Pre-gestational diabetes (PGD) or

pregnancy occurring in a women with known diabetes, and Overt diabetes - diabetes first detected during pregnancy; and (2) Gestational diabetes mellitus.

Essentially, this latest WHO 2013 guideline has endorsed the International Association of Diabetes and Pregnancy Study Groups (IADPSG 2010) criteria (see below).

International Association of Diabetes and Pregnancy Study Groups criteria

In 1998, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) were created to find a common consensus between many national and international groups addressing diabetes in pregnancy. Delegates from over 40 countries met to review the results of the elaborate Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study^[7].

In 2010, IADPSG recommended universal screening of all pregnant women with the 75-g oral glucose tolerance test (OGTT)^[8]. They used 1.75 odds of having complications seen in the HAPO study and proposed new thresholds for the 75-g OGTT. Thus, the IADPSG criteria had the possibility to be accepted all by the preeminent medical, endocrine and health organizations worldwide. However, as of 2014, as will be pointed out, despite the IADPSG guideline being agreed to by many global health groups, one worldwide guideline remains elusive.

American Diabetes Association criteria

Due to its geographical location and authority, the American Diabetes Association (ADA) criteria are widely used in United States, Canada and Mexico. In 1964, O'Sullivan and Mahan^[9] recommended using the 4 sample, 3-h 100-g OGTT for diagnosis of GDM; the glucose thresholds were established from a cohort involving 752 women. With time, as glucose measuring techniques evolved, Carpenter and Coustan (C and C)^[10] modified O'Sullivan's recommended glucose thresholds by adjusting for (1) the non-glucose reducing elements in blood; and (2) converting whole blood glucose values to the higher plasma glucose values. So the C and C thresholds were modified to be aligned to the newer glucose enzymatic methods for quantifying plasma glucose. The ADA incorporated the C and C thresholds for the 100-g, 3-h OGTT in their recommendations in 2000. Thus, a two-step approach was popular in North America, *i.e.*, 50-g GCT screen followed by 100-g OGTT if the screen GCT was positive. In 2003, the ADA also accepted the one-step approach of using the 75-g OGTT for the screening and diagnosis of GDM, especially in high-risk populations, since it was deemed more cost-effective. For the thresholds, the C and C cut-offs were used leaving the 3-h glucose value of the 100-g OGTT, which is not collected in the 2-h, 75-g OGTT. In 2011, the ADA accepted the recommendations of the

International Association of Diabetes and Pregnancy Study Groups (IADPSG)^[8], *i.e.*, using the 75-g OGTT on all women as a one-step screening and diagnostic method eliminating the need for the 50-g GCT. In 2013, after the American College of Obstetricians and Gynecologists (ACOG)^[11] refused to accept the IADPSG criteria at the conference organized by the National Institute of Health^[12]; in 2014, the ADA relented reversing its earlier stance and accepted both the one-step and two-step as a methods to screen and diagnose GDM agreeing with the ACOG (see below) and IADPSG recommendations.

ACOG criteria

The ACOG has always endorsed the two-step approach to GDM. In 1986, ACOG recommended the 50-g 1-h screening test for "women at risk," which in 2001 was changed to "all" women but excluding women at very low risk. In 2011, though the ADA approved the IADPSG; the ACOG had concerns that GDM prevalence would rise from 5%-7% to 18% - a three-fold increase. The ACOG had doubts that the increase in prevalence would have clinically significant improvements in maternal and neonatal outcomes in the "additional" women identified and treated with GDM. So, in its August 2013 bulletin, it has retained the two-step procedure using the thresholds (for the 100-g OGTT) of the National Diabetes Data Group (NDDG)^[13] or C and C criteria for the 100-g OGTT^[10].

Canadian criteria

In Canada, the Canadian Diabetes Association (CDA)^[14] and the Society of the Obstetricians and Gynecologists of Canada (SOGC) publish recommendations for GDM. Like the ADA and the ACOG in United States, their approaches have been dissimilar though they have shared many common ideas. CDA has been regularly using the latest research to update their recommendations - their latest guidelines were released in 2013^[15]. The SOGC recommendations of 2002 have not been modified; therefore, the SOGC has lagged behind in providing recommendations for GDM after 2002. It advocated either no screening as an option or using screening with a 50-g GCT with women having positive screens to undergo an OGTT (100-g or 75-g). These guidelines are completely out of date and need an update using research from the recent trials.

The CDA has consistently advocated screening all (*i.e.*, universal screening) women as any form of risk-factor screening, though cheaper, would always miss some patients with GDM. The 75-g OGTT CDA thresholds have been much higher than the C and C criteria originally approved by the ADA; thus, the strict CDA criteria for the 75-g OGTT always identified less women with GDM when compared to other criteria^[3]. The latest guideline, CDA 2013, recommends scr-

Table 1 Comparison of screening and diagnostic criteria of gestational diabetes^[58]

Area	Advising body	Year	Advise for screening	Method of screening (positive cut-off \geq)	Glucose load, g	Glucose thresholds (mmol/L)				Number of OGTT values for diagnosis \geq
						Fasting	1-h	2-h	3-h

Global criteria	WHO	2013	All	75-g OGTT	75	5.1	10.0	8.5	-	1

ADA: American Diabetes Organization; ADIPS: Australian Diabetes in Pregnancy Society; BSD: Brazilian Society of Diabetes; CDA: Canadian Diabetes Association; C and C: Carpenter and Coustan; EASD: European Association for the Study of Diabetes; DIPSI: Diabetes in Pregnancy Study group in India; IDF: International Diabetes Federation; FPG: Fasting plasma glucose; JDS: Japan Diabetes Society; NDDG: National Diabetes Data Group; NZSSD: New Zealand Society for the Study of Diabetes; NICE: National Institute for Health and Care Excellence; NS: Not specified; RPG: Random plasma glucose; SOGC: Society of Obstetricians and Gynecologists of Canada; WHO: World Health Organization.

creening high-risk women with the 50-g GCT in early pregnancy. All women should undergo the GCT between 24-28 wk, and if between 7.8-11.0 mmol/L, they should undergo the 75-g OGTT using thresholds recommended by them (Table 1).

The cut-offs of CDA 2013 are similar to the IADPSG 2010 thresholds since they use the odds ratio of 2.0 and 1.75, respectively, based on adverse outcomes of the HAPO data. In their latest guideline^[15] the CDA claims that their 2003 and 2013 thresholds are very similar. However, their resulting prevalence will be very different. The reason for the disparity is that, though the thresholds are similar, the number of thresholds needed for diagnosis are different (one vs two) - a fact not so obvious in their guideline.

Thus, it can be seen the CDA has kept with the evolution of GDM research, suggesting higher thresholds for diagnosis. Though it has reluctantly agreed with the IADPSG as an alternative some of its members have been very skeptical of the IADPSG guidelines^[16]. CDA also differs in that it recommends a 50-g GCT screen on all women followed by the 75-g OGTT.

European Association for the Study of Diabetes criteria

In 1991, the European Association for the Study of Diabetes (EASD) published diagnostic criteria for GDM^[17]. It accepted the 1996 the Pregnancy and Neonatal Care Group^[18] glucose thresholds of the 75-g OGTT (either FPG \geq 6.0 mmol/L or 2-h plasma

venous glucose \geq 9.0 mmol/L) for GDM diagnosis. Nevertheless, the EASD has not recommended any changes in their diagnostic criteria for GDM despite new epidemiological data and numerous randomized trials; thus, the EASD recommendations have not been modified or changed since the last 20 years. Unfortunately, they still are used in some countries of Europe^[19].

Australasian Diabetes in Pregnancy Society criteria

In 1991, the Australasian Diabetes in Pregnancy Society (ADIPS) endorsed its first directives for GDM^[20]. They modified the popular WHO GDM for 75-g OGTT based on opinion of the experts. Subsequently, their recommendations were modified in 1998^[21]. The ADIPS accepted both selective (if the resources were limited) or universal screening (if the resources were adequate) with a 50-g GCT or 75-g OGTT (Table 1). In 2013, the ADIPS issued new guidelines after considering the available evidence like HAPO study and other clinical trials. In fact, they accepted the WHO 2013 (same as IADPSG 2010) with a few caveats. They recommend not using the term "Overt diabetes" as suggested by the IADPSG for marked hyperglycemia first discovered in pregnancy. At booking, they have a list of risk factors for diabetes and recommend that all women with these risk factors undergo a 75-g OGTT and clinical judgment should be used for further work-up^[22].

New Zealand Society for the Study of Diabetes criteria

Until recently, the Australasian (ADIPS) 1998 guidelines were common for both Australia and New Zealand. The excessive number of women diagnosed with GDM would strain the limited resources of New Zealand. So, to diagnose less women with GDM, the New Zealand Society for the Study of Diabetes (NZSSD) raised the 2-h cutoffs for the 75-g OGTT from 8.0 mmol/L to 9.0 mmol/L. This change shows how many changes in the criteria were made on an “ad-hoc” basis.

In 2014, The New Zealand Ministry of Health published a clinical practice guideline: Screening, Diagnosis and Management of Gestational Diabetes in New Zealand^[23]. Twenty international and national guidelines and position statements were identified and critically appraised. Their recommendation: a HbA1c should be ordered at booking and at 24-28 wk, depending on the result of the HbA1c, a 50-g GCT or an OGTT may be done (cut-offs $F \geq 5.5$ mmol/L or 2-h ≥ 9.0 mmol/L) (Table 1). Thus, they have not accepted the WHO 2013/IADPSG 2010 criteria for GDM like the ADIPS, which has accepted them.

Japan Diabetes Society criteria

In Japan, the Japan Diabetes Society (JDS) has kept up with the new research in diabetes and GDM. It published new guidelines three times between 1970-1995 critically evaluating guidelines of major organizations like ADA and WHO. Originally, JDS adhered to local Japanese criteria (derived from healthy pregnancies) suggested by the Committee for Nutrition and Metabolism of the Japan Society of Obstetrics and Gynecology (JSOG)^[24] and the JDS continued endorsing this approach to GDM established in the early 1980s^[24]. In 2013, the JDS released Evidence-based Practice Guideline for the Treatment for Diabetes in Japan 2013^[25]. Essentially, it accepted the IADPSG criteria for the diagnosis of GDM. Hence it can be appreciated that Japan has kept up with the latest developments on GDM something not done by many modern European countries (like Sweden).

Brazilian Society of Diabetes criteria

The Brazilian Society of Diabetes (BSD) accepted the fasting plasma glucose (FPG) as a screening test for GDM at booking and at 24-28 wk gestation^[26]. These recommendations were based on a landmark study published in a preeminent diabetes journal^[27]. As per these recommendations, a FPG ≥ 4.7 mmol/L and < 5.0 mmol/L needed a diagnostic OGTT using the C and C criteria for diagnosis. In 2010, a Brazilian Consensus guideline endorsed these guidelines^[28]. The use of FPG in Brazil has been recently been authenticated by a recent Brazilian study^[29]. The IADPSG has been accepted as the diagnostic method in Brazil^[30].

International Diabetes Federation guidelines

In 2009, the International Diabetes Federation (IDF)^[31]

acknowledged that many strategies were available. It logically stated that any GDM definition must take into account 3 risk factors: perinatal morbidity and mortality in index pregnancy, the mother developing type 2 diabetes, and intra-uterine epigenetic programming of the developing fetus. At that time, it accepted both the two-step or one-step methods of the ADA and WHO, respectively. However, the IDF had a preference for the 75-g OGTT because it used less glucose and was of shorter duration. Currently, they have accepted the current WHO 2013/IADPSG criteria^[30].

GDM APPROACH: CONTINENTS AND SELECTED COUNTRIES

The differences in algorithms for GDM by major international bodies translate into variation in the practices within individual countries. Similar trends are found in most countries for the screening and diagnosis of GDM. The practices in some specific selected countries, segregated by continents, are discussed below.

Europe

Buckley *et al*^[19] reviewed the screening practices all over Europe. They looked at 185 sources of information from 23 European countries. The screening methods varied from risk-factor screening (Norway); 50-g universal GCT (Finland, Poland, Austria); random plasma glucose (United Kingdom, Plymouth). Most countries used WHO 1999 criteria or the Carpenter and Coustan criteria for diagnosis as applied to the 75-g or 100-g OGTT. Some countries (like Hungary) used the universal one-step, 75-g OGTT (WHO 1999) for diagnosis while others (like Italy) used universal one-step, 100-g OGTT (C and C) for diagnosis. The authors conclude that global agreement on screening and diagnostic methods would lead to better detection and treatment; only more well-designed research would inform us about the best practice methods in screening and diagnosis of GDM.

United Kingdom

The national guidelines for GDM in United Kingdom were established only after 2008. The clinician had to decide if screening was needed or not^[32]. The National Institute for Health and Clinical Excellence (NICE) guidelines were originally issued in March 2008. These have been replaced by recommendations in February 2015^[33] and essentially, the NICE does not accept the IADPSG criteria. They continue to recommend using clinical risk factors for screening. GDM is diagnosed if on a FPG ≥ 5.6 mmol/L or a 2-h glucose after a 75-g OGTT is ≥ 7.8 mmol/L (Table 1). The OGTT should be done in the first or second trimester depending on the clinical need. These guidelines have been motivated by

the latest research and cost of treatment of GDM^[33].

The Scottish Intercollegiate Guidelines network (SIGN) in their 2010 recommendations advise (at booking) screening with clinical risk factors, with HbA1c or fasting glucose; at 24-28 wk, while all high-risk women should undergo a 75-g OGTT with the IADPSG criteria used for diagnosis; All low risk women at 24-28 wk, should undergo the fasting plasma glucose^[34].

In January 2011, the Royal College of Obstetricians and Gynaecologists discussed the overall strategies for GDM including NICE and IADPSG. However, they do not provide any recommendations on how to screen and diagnose GDM^[35].

This inconsistency of multiple approaches to GDM is reflected in practices at ground level. In an older United Kingdom survey by mail^[36], the screening practices were very varied: fasting and random plasma glucose and glycosuria were all used showing the heterogeneity in screening for GDM. Various cutoffs were used for diagnosis using the 75-g OGTT - a fact iterated in the latest 2015 NICE guidelines^[33]. Thus, it can be seen that in a country like United Kingdom, which has well-developed health system, there is no consistency in the approach to GDM. However, with time there should be more uniformity in the approach to GDM once there is more international agreement.

Italy

Many Italian organizations like Italian Society of Diabetology (SID) and the Italian Association of Diabetologists (AMD) set standards for diabetes in Italy in 2007^[37]. They agreed to use the C and C criteria for diagnosis, which were also endorsed by the ADA. Currently, the Italian Institute of health recommends using risk-factors for screening of GDM. Thus, even recently, whether universal or risk factors screening should be done has been debated in Italy^[38]. However, currently, the IADPSG guidelines have been accepted in Italy^[31].

Sweden

The screening and diagnostic criteria for GDM in Sweden have been evolving over time. In 1985, repeated random blood glucose measurements were popular for GDM diagnosis. Since 1991, the hand-held Hemocue spectrophotometers have been popular in Sweden. These use capillary whole blood for measuring glucose; even the OGTT samples, instead of plasma venous glucose, tend to utilize capillary whole blood for convenience. Currently, there is no consensus in Sweden and over 4 methods are used to screen and diagnose GDM as shown by a recent study^[39]; the authors recommend that IADPSG should be adapted. Thus in Sweden, even in 2015, there is a huge variation in the approach to GDM; furthermore, popular use of Hemocue complicates the diagnosis of

GDM. Thus, Sweden is no different when compared to other European countries in having no consistency for the diagnosis of GDM.

Belgium

A survey (May 2012-January 2013) of 45 obstetrical centers from Belgium showed that 56% used screening before 24 wk based on clinical methods^[40]. At 24 wk, the commonest strategy (56%) was the two-step method (GCT + 100-g OGTT) with C and C (52%) or NDDG (4%) criteria for diagnosis. The remaining used IADPSG (33%) or WHO 1999 (2%) or C and C (9%). Belgium, like other European countries, also has no uniformity in the approach to GDM.

Germany

Like most other countries, the screening and diagnosis of GDM in Germany has been inconsistent. The German Society of Obstetrics and Gynecology and the German Diabetes Association (DDG) made some attempts at formulation guidelines for GDM in 2001. However, obstetricians either do not screen, or often carry on risk factor screening. Currently, the IADPSG has been approved formally in Germany by the German Diabetes Association^[41]. This should result in consistency in screening and diagnosis of GDM in Germany over time.

Asia

Tutino *et al*^[42] recently reviewed the situation of diabetes and pregnancy in Asia. Since the prevalence in Asia varies extensively due to lack of uniform diagnostic criteria, the authors stress the importance of a unified approach to GDM. Hyperglycemia in pregnancy has its highest prevalence in South-Est Asia, where one-fourth pregnancies are affected vs one-seventh, globally. Asians develop GDM at a lower BMI and type 2 DM occurs at a much younger age. With urbanization, GDM prevalence is becoming an epidemic. The IADPSG has been adapted by some Asian countries, although it remains a challenge to implement in low-resource settings. So, local modifications have been suggested.

China

The Ministry of health in China published its guidelines for testing and diagnosis of gestational diabetes in 2011^[43]. It recommends the fasting plasma glucose or 2-h venous glucose post 75 g OGTT at the first prenatal visit to rule out diabetes antedating pregnancy using standard diagnostic criteria for diagnosis of diabetes in the non-pregnant.

The diagnosis of GDM is made by a single step 75-g 2 h. OGTT done between 24 and 28 wk of gestation. The cut points for diagnosis of GDM are those of the IADPSG.

To reduce the number of OGTTs, it has been suggested that the FPG test may be done first - a

concept originally described by us, which was adapted by the Chinese Ministry of Health. If the FPG value is less than 4.4 mmol/L no further testing is needed. For values above 5.1 mmol/L a diagnosis of GDM is made without an OGTT. Pregnant women with fasting glucose values between 4.4 and 5.1 mmol/L must undergo a 75-g OGTT to further rule in or rule out GDM. This concept has been tested in China^[44]. Using this algorithm, only half of pregnant women would be required to undergo the formal OGTT.

India

Asian Indians are considered to be at the highest risk for gestational diabetes. In India there is a (1) high burden and a rising prevalence of diabetes; (2) constraint of resources; and (3) high rate of deliveries (27 million/year). Considering these factors and using local studies, the Diabetes in Pregnancy Study group in India (DIPSI) has developed practical usable recommendations for diagnosis of GDM in the community^[45]. This guideline has been recognized by the Ministry of Health, Government of India, the Federation of Obstetrics and Gynecological Societies of India (FOGSI) and the Association of Physicians of India (API).

Testing for GDM is recommended twice during antenatal care. The first testing should be done during first antenatal contact as early as possible in pregnancy. The second testing should be ideally done during 24-28 wk of pregnancy if the first test is negative. If women present beyond 28 wk of pregnancy, only one test is to be done at the first point of contact.

A single step is recommended by measuring plasma glucose 2 h after ingestion of 75-g glucose irrespective of the last meal (fasting or non-fasting). In the absence of available laboratory facilities a standardized glucometer may be used to evaluate plasma glucose. A glucose level of ≥ 7.8 mmol/L is the cut off for diagnosis of GDM. This test is called the DIPSI Test.

The older WHO 1999 criteria are very popular in many Asian countries^[46,47]. The latest guidelines of Sri Lanka recommend either the DIPSI or the IADPSG guidelines^[48]. However, other countries like Thailand use mostly use the two-step approach (the diagnostic criteria of the NDDG or C and C) or WHO 1999 criteria (75-g OGTT)^[49]. As can be appreciated in Asia, like the rest of the world, the approach between and within countries is not uniform.

Australia

As detailed earlier, the latest guidelines in Australia have been modified in November 2014. Essentially, with a few caveats, the ADIPS has accepted the guidelines of IADPSG.

Africa

The data from Africa about GDM is limited. Like Asia,

due to its global reach and acceptance, the WHO 1999 criteria are widely used in many African countries^[50-53]. Recently, Macaulay *et al*^[54] reviewed GDM in Africa. They found 14 useful papers from 60 studies. Six African countries, representing 11% of African continent, were Ethiopia, Morocco, Mozambique, Nigeria, South Africa and Tanzania. Major variation in methods was present between countries. Morocco used 100-g OGTT with C and C criteria. Mozambique used their own diagnostic criteria. Much heterogeneity between countries was present within countries. Six studies from Nigeria used 75 or 100-g OGTT for diagnosis with varying criteria. One center used 50-g GCT for diagnosis of GDM. Similar heterogeneity was found in 4 studies from South Africa. The authors conclude that there is a paucity of information about GDM from Africa and stress the importance of more research. This is crucial given the public health burden of obesity and diabetes. Only then, effective public health measures can be planned.

Nigeria

In 2011 (modified 2013), a national guideline on diabetes was published in Nigeria^[55]. The recommendations include (1) risk assessment at booking; (2) A one-step (75-g OGTT) or two-step method (50-g GCT with 100-g OGTT) using C and C criteria for diagnosis. Despite the availability of a guideline on GDM, practice varies across obstetric units in Nigeria. There are many gaps in the guideline as it is not appropriate for use in all circumstances; there is no recommendation on the screening/diagnostic approach for women outside tertiary care facilities as GCT/OGTT are not available in primary health care settings.

Thus, Nigeria reflects some of the problems seen with GDM screening in Africa and stresses the importance of addressing the specific needs of the sub-Saharan Africa region. The critical gaps were potentially due to only endocrinologists in the guideline development team. It also emphasizes that international guidelines cannot just be applied to poor countries in Africa.

South America

Like Africa, there is little published data from South America, which consists of 14 independent countries. However, much data comes from Brazil and Chile, and Argentina^[27,56,57]. In fact, Brazil is the leader in diabetes and gestational diabetes research. A literature search from individual countries from South America (Venezuela, Columbia, Peru, Uruguay, Ecuador, Bolivia, Paraguay) yields almost no results. Thus, it is difficult to get information on the approach to screening and diagnosis to GDM in South America.

WAY FORWARD

As can be appreciated, the availability of multiple criteria for the screening and diagnosis of GDM have resulted in an almost ad-hoc approach to GDM. Most (but not all) organizations have been updating their

criteria over time; however, the hospitals following recommendations of a preeminent association often lag behind in updating their approach to follow the latest guideline. This adds to the already disorderly situation. Major international bodies are aware of this problem. Thus, some of these organizations are working to convince all the major international professional organizations to come to a consensus. A major effort has been undertaken by the International Federation of Gynecology and Obstetrics (FIGO), which has members from 125 gynecology and obstetric organizations worldwide, to achieve consensus on GDM. Ideally, the answer may lie in a well-funded trial like the HAPO. Till that happens, the approach will have to be by consensus. As of 2015, worldwide, the most accepted criterion is of the IADPSG 2010^[30] and as it becomes more approved - we may achieve the much desired consensus for one guideline.

CONCLUSION

As can be appreciated from this review, the screening and diagnostic criteria for GDM throughout the world are summarized by one word: chaotic. Many international and regional guidelines have lagged behind the current research. The need for a single global guideline has been repeatedly stressed^[57] and this consistency is essential to avoid confusing primary care-givers of GDM. The primary care-givers of pregnant women look to the authorities and expert committees for guidance. Unfortunately, the experts continue to provide no clarity. With over five decades of research and hindsight, we must develop a single useful guideline for GDM: it is high-time.

Abstract

Medical imaging technologies are acquiring an increasing relevance to assist clinicians in diagnosis and to guide management and therapeutic treatment of patients, thanks to their non-invasive and high resolution pro-

perties. Computed tomography, magnetic resonance imaging, and ultrasonography are the most used imaging modalities to provide detailed morphological reconstructions of tissues and organs. In addition, the use of contrast dyes or radionuclide-labeled tracers permits to get functional and quantitative information about tissue physiology and metabolism in normal and disease state. In recent years, the development of multimodal and hybrid imaging techniques is coming to be the new frontier of medical imaging for the possibility to overcome limitations of single modalities and to obtain physiological and pathophysiological measurements within an accurate anatomical framework. Moreover, the employment of molecular probes, such as ligands or antibodies, allows a selective *in vivo* targeting of biomolecules involved in specific cellular processes, so expanding the potentialities of imaging techniques for clinical and research applications. This review is aimed to give a survey of characteristics of main diagnostic non-invasive imaging techniques. Current clinical appliances and future perspectives of imaging in the diagnostic and prognostic assessment of diabetic complications affecting different organ systems will be particularly addressed.

Key words: Medical non-invasive imaging; Diabetes; Diabetic complications; Molecular imaging; Multimodal imaging; Hybrid scanners

Core tip: Non-invasive imaging techniques are increasingly employed in every medical field, both for diagnostic purposes and for monitoring of pathological progression and/or efficacy of treatments. Several imaging modalities are currently available to provide structural and functional information about tissue and organ physiology, and thanks to technical improvements and development of hybrid devices, multimodal imaging combining advantages of different techniques offers now new potentialities for research and clinics. Aim of

this review is to overview the principal features of most used diagnostic imaging modalities and to explore main current and forthcoming applications for the study and management of diabetes and its complications.

INTRODUCTION

While X-ray diagnostic imaging has been in use for more than 100 years, it is in the last 40-45 years that imaging has made a great impact on healthcare due to the development of several modalities. Medical imaging technologies may be roughly divided into structural and functional imaging categories. The former entails the assessment of anatomical and morphological features of tissues and organs. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US) scans are the prototypal and the most used non-invasive technologies for this imaging class. However, structural imaging alone may not provide the clinician or researcher with all the necessary information to fully characterize the pathophysiology of diseases. As such, functional imaging has come into existence and is comprised of a multitude of non-invasive, quantitative imaging techniques that are currently in use to study tissue and organ physiology, to probe molecular processes, and to study pathophysiological molecules and metabolites. The parallel development of specific contrast agents has significantly helped to improve the signal to noise ratio of the acquired images, and to gather both structural and functional information during the same scan sequence or within the same modality. Functional imaging is mainly achieved through the use of CT, MRI, and US, as well as through positron emission tomography (PET), single-photon emission computed tomography (SPECT), and optical imaging. Complementary information from structural and functional imaging can assist to determine the nature, location and extent of disease in patients, to guide interventions and to monitor the effects of treatment. Just for an example, MRI can be used to quantitatively determine the three-dimensional structure of an organ or tumour mass and by using the contrast agent, *e.g.*, gadolinium, it is also possible to monitor the blood flow which is an indicator of its functional state.

An accurate visual representation of the anatomy and sometimes of the functional state of the patient has been a goal of clinicians for several decades in many medical fields, although this aspect is often still neglected in diabetic patients. Nevertheless, the rapid rise in the prevalence of diabetes to 382 million

individuals worldwide during the last 20 years and the expected rise to 592 million by 2030^[1] has global implications and requires paradigm-shifting approaches to diagnosis, treatment monitoring, and prevention. Over the long term, hyperglycaemic conditions can lead to serious diseases affecting the cardiovascular system, eyes, kidneys, nerves, and teeth^[2-6]. In addition, people with diabetes also have a higher risk of developing infections, cognitive impairment and dementia^[7,8], and lower limb amputations^[9].

The present review aims to overview the current principal diagnostic appliances of imaging in the field of diabetes and its complications. In addition, mention will be also deserved to molecular and multimodal imaging, the two more recent approaches to non-invasive imaging tests that, by progressing in parallel with advancements in molecular pathology and with refinement of techniques, represent the new frontier of medical imaging and management of patients with diabetes.

DIAGNOSTIC IMAGING APPROACHES

A short analysis and comparison of the most employed techniques in diagnostic imaging can be of help in the evaluation of the approaches deserving advanced research with a view to both present application and future clinical translation. Table 1 sums up the main characteristics of the principal imaging modalities.

SPECT and PET

In nuclear medicine images of various body parts are produced by using small amount of radioactive tracers, administered intravenously or orally. Then, external detectors capture and form images from the radiation emitted by the radiopharmaceuticals.

There are two main nuclear imaging modalities: SPECT and PET, characterized by a very high sensitivity range (femto- to picomolar concentration range) but a limited spatial resolution (Table 1). Typical SPECT radionuclides are γ photon emitters (Table 2) and they are usually employed to label tracers of blood flow such as N-isopropyl-¹²³I-iodoamphetamine (¹²³I-IMP) and ^{99m}Tc-hexamethyl-propylene amine oxime (^{99m}Tc-HMPAO). Different SPECT radioisotopes can have one or more energy emission lines, therefore several processes can theoretically be imaged simultaneously by setting SPECT scanners at different energy windows. Among the limits of SPECT imaging there are the low temporal resolution, the limited number of available radiopharmaceuticals, and the difficulty to achieve absolute quantitative information due to lack of attenuation and scatter corrections necessary at the time of image reconstruction^[10].

PET differs from SPECT in that it relies on nuclides that are neutron-deficient, positron (β^+) emitters, with shorter half-lives (Table 2). It offers several advantages over SPECT. First of all, the large number of available

Table 1 Relevant features of the most common imaging modalities

Imaging modality	Anatomy	Metabolism/function	Spatial resolution	Weakness
SPECT	Poor	Yes	0.3-3 mm	Radiation
PET	Poor	Yes	1-4 mm	Radiation
CT	Yes	Yes	0.5-1 mm	Radiation
MRI	Yes	Yes	50-500 μ m	Expensive
Ultrasound	Yes	Yes	Approximately 200 μ m	Poor depth penetration
Optical	Poor	Yes	0.1-10 mm	Poor depth penetration

SPECT: Single-photon emission computed tomography; PET: Positron emission tomography; CT: Computed tomography; MRI: Magnetic resonance imaging.

radiolabeled compounds allows to image a large variety of functional cellular processes such as glucose and amino acid metabolism, neurotransmission, receptor affinity, gene expression, cell and molecular targeting. Moreover, the possibility of corrections at the time of image reconstruction allows quantitative measurements^[11]. However, one of the main disadvantages of PET is that all radionuclides decay at the same energy (photon energy of 511 KeV)^[11]. Therefore, it is not possible to simultaneously discriminate between different radiotracers at different energy windows. Furthermore, the short half-life of radioisotopes restrains the clinical use of PET mainly at those clinical centers which are equipped with a cyclotron. For this reason, radiopharmaceuticals with longer half-lives, such as ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) and ¹⁸F-fluoro-6-thia-heptadecanoic acid (¹⁸F-FTHA), have been implemented to assess glucose and fatty acid metabolism, respectively^[12].

X-ray CT

A CT scan consists of an X-ray beam (generated by an external source) passing through the body where a portion of the X-rays are either absorbed or scattered by the internal structures and organs, while the remaining X-ray pattern is transmitted to a rotating detector along multiple linear paths to create cross-sectional pictures of the body^[13]. CT scan involves a higher radiation dose than the conventional radiography. However, the radiation dose for a particular study depends on multiple factors: volume scanned, number and type of scan sequences, the desired resolution and image quality.

On the basis of the high spatial resolution (Table 1), CT scans can provide detailed information to diagnose, plan treatment for, and evaluate many conditions in adults and children. Additionally, the detailed images provided by CT scans may eliminate the need for exploratory surgery. CT scans are very good at imaging bone, soft tissue and blood vessel, even if the use of dyes with high atomic numbers is sometimes useful to

Table 2 Main nuclides used in nuclear medicine to label radiopharmaceuticals

SPECT			PET		
Nuclide	Half-life	γ (KeV%)	Nuclide	Half-life	β^+ (KeV%)
^{99m} Tc	6.02 h	89	¹⁸ F	109.8 min	96.9
¹¹¹ In	2.83 d	90.2	¹¹ C	20.4 min	99.7
¹²³ I	13.2 h	83	¹³ N	9.98 min	99.8
¹²⁵ I	60.14 d	6.5	¹⁵ O	2.03 min	99.9
			¹²⁴ I	4.18 d	25.0
			⁶⁴ Cu	12.7 h	17.9
			⁶⁸ Ga	68 min	90.0
			⁸² Rb	1.2 min	99.9

Radiation types: γ : Isomeric transition (gamma) decay; β^+ : Positron decay; KeV%: Percentage of energy per decay. SPECT: Single-photon emission computed tomography; PET: Positron emission tomography.

improve soft tissue contrast. Iodine-based compounds (classified into non-ionic and ionic) are mainly used as water soluble CT contrast agent to be injected intravascularly or into any sinus or body cavity, and can also give an indication of the renal function (*e.g.*, kidney filtration). Concerns about CT scans include the risks from exposure to ionizing radiation and possible allergic or toxic reactions to the intravenous contrast agents. The overall adverse reactions occur in 1% to 3% of people with non-ionic contrast agents and in 4% to 12% with ionic contrast agents^[14]. Skin rashes may appear within a week to 3% of people^[15].

Two of the most prevalent clinical and diagnostic applications, especially on the cardiovascular field, are the CT angiogram (CTA) and artery calcium scoring. The former can be used to view arteries and veins and requires contrast dye injected into the bloodstream. CTA images can be 3D reconstructed to overview all the organ vasculature and can be rotated and viewed from all angles.

As the artery calcium score test is concerned, it does not use X-ray contrast, and pictures are taken to look for the presence of calcium depots in the blood vessels, mainly in the coronary arteries. Calcium deposits are a very specific sign of coronary artery disease, as they are associated with cholesterol and scar tissue buildup in the arteries. While the amount of calcium in the arteries increases with age, patients who have significantly elevated amounts of calcium depots are at increased risk to heart attacks or other cardiovascular complications^[16].

Magnetic resonance

MRI uses strong magnetic fields and pulses of radio waves to produce cross-sectional images of organs and internal structures in the body at high spatial resolution (Table 1). Because the signal detected varies depending on the water content and local magnetic properties of a particular area of the body, MRI provides an excellent soft tissue contrast. Unfortunately, its sensitivity is low (micro- to millimolar

concentration range) and at present there are a limited number of ligands. The physical basis of magnetic MRI is the quantum interaction between a nuclear spin of certain atoms (^1H , ^{13}C , ^{19}F , ^{23}Na , ^{31}P and others) and an external magnetic field. MRI scanner detects the radio frequency signal which is emitted only by excited atoms in the body, when they are perturbed by an applied pulse in the range of the radio waves. Image contrast depends on three parameters: the proton density, the longitudinal relaxation time which corresponds to the energy transfer between excited spins and tissue (T1, spin-lattice relaxation time), and the transverse relaxation time which is related to the decay of magnetization by interaction between nuclei (T2, spin-spin relaxation time)^[17]. Variable image contrast can be achieved by using different pulse sequences and by changing the imaging parameters. Signal intensities on T1, T2, and proton density-weighted images relate to specific tissue characteristics. Moreover, it is possible to employ contrast agents that magnetically modify the proton spin environment to provide a positive enhancement (T1-targeted), mostly achieved by gadolinium chelates, or negative enhancement (T2- and T2*-targeted probes), by using paramagnetic ultra-small particles of iron oxide (USPIOs)^[18].

In 1990, Ogawa *et al.*^[19] discovered that deoxy-hemoglobin acts as a natural contrast agent to study brain activity on the basis of changes in blood flow, thus providing a functional value to MRI. Functional MRI based on the blood-oxygen-level-dependent (BOLD) contrast is applied both in the research field and, to a lesser extent, in the clinical arena. In this latter case, it is used to anatomically map the brain and detect the effects of tumors, stroke, head and brain injury, or diseases such as Alzheimer's^[20-22].

Although MRI does not use ionizing radiation and no harmful side-effects are known to be associated with temporary exposure to the strong magnetic field, there are important safety concerns to consider before performing or undergoing an MRI scan. The magnet, indeed, may cause pacemakers (and any other implanted medical devices that contain metal) to malfunction or heat up during the exam.

While MRI provides information on the spatial location and local chemical environment of protons, proton magnetic resonance spectroscopy (^1H -MRS) is a non-invasive technique providing biochemical information about tissues. ^1H -MRS is based on the principle that the resonance frequency of protons is also dependent on their chemical environment (e.g., protons have a slightly different resonance frequency in lipids than in water). Therefore, protons can be visualized at a specific chemical shift (peak position along the X-axis) depending on their chemical environment. The panel of metabolites that can be recognized by MRS include some amino acids, neurotransmitters, choline, lactate, lipids, creatinine, and myo-inositol. MRS is currently used to investigate brain and metabolic disease^[23-25].

Ultrasound imaging

Diagnostic ultrasound, or US, is an imaging method that uses high-frequency sound waves (1 to 12 MHz) and their echoes to produce relatively precise images of structures within the body (Table 1). The transducer probe is the main part of an ultrasound machine. It generates and receives sound waves using a principle called the piezoelectric effect. The sound waves travel into the body and hit a boundary between tissues (e.g., between fluid and soft tissues or between soft tissues and bone). Some of the sound waves get reflected back to the probe, while some others travel on further until they reach another boundary and get reflected. The machine calculates the distance from the probe to the tissue or organ (boundaries) by using the speed of sound in tissue and the time of each echo's return, and then displays a 2D-image based on the echoes' intensity. Transducer probes come in many shapes, sizes and frequency of emitted sound waves. This latter parameter determines how deep the sound waves penetrate into the body, and so affects the resolution of the image.

Contrast enhanced ultrasound extends ultrasound techniques to the exploitation of gas-filled microspheres [microbubbles (MB)] as an ultrasound contrast medium. MB are commercially available for clinical use in cardiovascular imaging, being confined by their size to the intravascular space. Their proven clinical tolerability, along with the advantages of real-time imaging, high spatial resolution, and the relatively low cost of equipment renders molecular targeting of MB an attractive option for future development from its current preclinical stage to the actual clinical application^[26-29]. A variant of US is based upon the Doppler effect (Doppler US). When the object reflecting the ultrasound waves is moving, it changes the frequency of the echoes as a function of its velocity. Doppler US measures the change in frequency of the echoes to calculate how fast the object is moving, and it is mostly used to measure the rate of blood flow.

Optical imaging

Optical imaging is based on the detection of molecular emission in the electromagnetic spectrum (visible and near-infrared) by a high sensitive and high resolution charge-coupled device digital camera. It extends over a wide range on the imaging resolution scale (Table 1) and is often complementary to other imaging modalities.

Optical imaging offers a number of important advantages over the existing radiological imaging techniques. It uses non-ionizing radiation, which significantly reduces patient radiation exposure, provide high sensitivity detection (pico- to nanomolar concentrations) and allows for repeated studies over time. Moreover, optical imaging has the potential to differentiate among soft tissues, and between native tissues and tissue labeled with contrast media (either endogenous or exogenous compounds), using their

different photon absorption or scattering profiles at different wavelengths. Optical imaging encompasses a host of light-based imaging modalities, including diffuse optical tomography (DOT), optical coherence tomography (OCT), and hyper-spectral imaging, that holds great potential for improving disease prevention, diagnosis, and treatment in healthcare facilities.

DOT modality utilizes red and near-infrared light (λ 650-900 nm) to probe the optical properties of tissues. By measuring the spatio-temporal variations of transmitted and back-scattered light intensities, it is possible to image regional variations in the chemical concentration of specific molecules to detect cellular physiological changes (e.g., neuronal activation). The limited spatial resolution (approximately 1 cm) of DOT is balanced by a high temporal resolution (approximately 10 ms), a potential large optical penetration depth (up to several cm) which depends on the characteristics of the light source and by the light-transmittance of the tissue, a high intrinsic contrast associated with hemoglobin (contrast factor of 10-100 in most soft tissues), and the capability of spectral discrimination of multiple chromophores. DOT has been used in multiple thick tissue imaging appliances, including brain functional imaging, breast cancer imaging, and tissue oxygenation analysis. Methods to improve DOT imaging performance by combining multi-modality information such as from X-ray, CT and MRI are also being explored^[30-33].

OCT detects light that has been back-scattered from structures at a particular depth by exploiting constructive and destructive interference between the returning light and a reference beam. It is a technique for obtaining sub-surface images (up to 2 mm), now in use in a variety of applications, including art conservation, artery disease, and diagnosis of diabetic retinopathy^[34].

HIS imaging, or imaging spectroscopy, represents a hybrid modality for optical imaging which combines the power of conventional digital imaging and spectroscopy. Indeed, it provides a three-dimensional matrix, or image cube, merging information coming from every pixel of the entire 2D-image with the optical spectrum over a large number of wavelengths (typically tens to hundreds)^[35]. The high spatial and spectral resolution offered by HIS allows to detect and quantify tissue environment in the early stages of disease progression. In the medical and clinical scenarios, HIS has exhibited a great potential in the early diagnosis of several forms of cancer, peripheral artery disease, burn wounds, diabetic foot, and ischemic tissue pathology^[36-39].

Hybrid techniques for multimodal imaging

To overcome single modality limitations (e.g., the strong variation in sensitivity, spatial and/or temporal resolution, and quantitative analysis capabilities), multimodal imaging which combines techniques

with complementary strength has grown up fast in clinical practice. Most of the examinations, however, are performed on separate machines, with some drawbacks that can impact on the diagnostic accuracy: an inaccurate anatomic matching due to patient repositioning, side-by-side or co-registration of images, time-consuming and expensive processes. In the last decade, the development of combined PET-CT integrated systems has revolutionized the concept of hybrid imaging^[40]. On the success of PET-CT hybrid scanners, more recently also SPECT-CT hybrid devices have been introduced^[41]. However, there are also some negative aspects in using CT as complementary anatomical imaging modality, such as the additional radiation to the patient and the poor soft tissue contrast in the absence of contrast agents. These shortcomings do not apply to MRI and, hence, the idea to combine PET and MRI in a unique device. Hybrid PET-MRI scanners are currently available mainly for preclinical studies on small animals, and in a proof-of-principle phase for clinical applications. Hybrid bimodal PET-MRI imaging is attracting great interest because, unlike PET-CT that requires sequential acquisition of PET and CT images, it makes available the simultaneous acquisition of PET and MRI images, and potentially performs dynamic imaging to obtain valuable functional information within an accurate anatomical framework^[42-44].

Targeted molecular imaging

The significant advancement provided by molecular targeting of imaging probes with respect to the traditional diagnostic techniques of morphological, functional or metabolic imaging runs parallel to the advancements in the hybrid imaging systems^[45,46]. Molecular imaging approach allows the selective *in vivo* targeting of biomolecules that are specifically expressed in cellular processes contributing to the development of a variety of disease states. It requires the availability of appropriate molecular probes, composed by a label system that can be visualized by imaging devices and a ligand that recognizes and binds the molecular target (e.g., antibody, peptide, small synthetic or natural molecules). The application of targeted molecular imaging has already proven valuable in clinical oncological practice for early detection and diagnosis as well as in prognosis^[47]. Despite its great capability, however, molecular imaging approach in other medical fields is still mainly confined to the laboratory settings and almost exclusively used in preclinical studies. Many areas of research are very active in this field, especially studies centered on the detection of pre-disease states or molecular states that occur before typical disease symptoms are overt^[48,49]. Other important areas of interest are the imaging of gene expression and the development of novel biomarkers^[50,51]. Nevertheless, at present there are some barriers to a widespread clinical translation

Table 3 Synopsis of imaging modalities and their applications in diabetes

of molecular imaging: the paucity of approved molecular imaging agents; the difficulty of combining the suitable characteristics of the probe (feasibility of synthesis, pharmacokinetics, high binding efficacy and specificity) with the lack of toxicity in patients; the reduced interest for industrial investment considering that, by its very nature, molecular imaging (as well as personalized medicine) decreases the size of the possible patient set from a commercial point of view^[52,53].

MEDICAL AND CLINICAL APPLICATIONS OF IMAGING IN DIABETES

A general view of the different non-invasive imaging approaches and their applications on the medical and clinical settings is offered in this section. Some advantages and drawbacks of alternative or combined approaches are also described. Table 3 sums up the most employed imaging modalities in the diagnosis and monitoring of diabetic complications and end-organ damage.

Pancreatic islet and beta cells imaging

The loss of functional β -cells is decisive in the development of both type 1 (T1D) and type 2 (T2D) diabetes. T1D is characterized by an autoimmune reaction against pancreatic β -cells, while T2D leads to β -cell dysfunction due to insulin resistance^[54,55].

The possibility to non invasively imaging the severity and the extent of a critical mass of β -cell destruction could significantly aid in the diagnosis and treatment of diabetes. However, imaging of β -cells is a major challenge due to the small size of pancreatic islets, the low density distribution of islets throughout the pancreas, and the scarce inherent contrast from the surrounding tissues.

A variety of currently available imaging techniques, including MRI^[56,57], bioluminescence imaging^[58,59], and nuclear imaging (PET and SPECT) have been tested for the study of β -cell diseases^[60]. The majority of the

cited studies was carried out on animal models, and even though the translational potential of some of the methods is hampered by the depth of the pancreas in the human body, in many cases the possibility of a clinical transfer embodies a real opportunity.

Since zinc plays a critical role in the biosynthesis and secretion of insulin, Lubag *et al.*^[61] demonstrated the feasibility of utilizing zinc-responsive T1-contrast MRI for monitoring islet β -cells function in animal models. Currently, there are two approaches that have been developed for monitoring β -cell function using MRI: manganese-enhanced and a zinc-responsive contrast agent^[62].

Moreover, MRI proved to be useful at diagnosing and monitoring immune cell infiltration of the pancreas^[63-66] by using superparamagnetic iron oxide nanoparticles as T2-weighted negative contrast agent.

Very recent preclinical studies proposed the use of PET imaging to evaluate the loss of pancreatic islet cells in a rodent model of T1D, using $[^{18}\text{F}]$ -fallypride, a dopamine D2/D3 receptor radiotracer^[67].

Finally, PET, MRI and US have been used in several trials to investigate the efficacy of different imaging modalities for visualizing transplanted islets^[68]. Since these methodologies have different advantages and disadvantages, their use in combination is recommended for accurate assessment of the condition of transplanted islets^[69].

Diabetic nephropathy and kidney imaging

In diabetic patients, renal functional deterioration is the result of heterogeneous renal structural changes and represents 35%-40% of new cases of renal insufficiency requiring dialysis. Renal damage occurs in multiple stages and diagnostic tests that help to identify early stages of kidney alterations will provide significant benefits to get the disease under control. In the early stages of diabetic nephropathy, kidney size may be enlarged from hyperfiltration^[70-72]. With progression of kidney disease in diabetes, the kidneys diminish in size due to glomerulo-sclerosis^[70]. US

imaging is typically performed to assess kidney size^[73]. Moreover, a renal ultrasound examination can reveal hyperechogenicity that is suggestive of chronic kidney disease, and can assist in ruling out any obstruction. In addition, Doppler US can support in both the evaluation of renal parenchymal perfusion and the computation of renal resistance parameters to assess endothelial dysfunction and microvascular impairment in the kidneys of diabetic patients^[74].

Also quantitative diffusion-weighted MRI and BOLD-MRI can play a role in the evaluation of renal disease^[75-77] and may facilitate the development of more effective follow-up and treatment modalities^[78].

Brain imaging in diabetes

The technique of choice to image the brain is MRI that spans from coarse anatomical studies of atrophic areas to the more detailed investigations of both functional and structural alterations in both gray and white matter of specific cerebral areas. It has been suggested that the risk of decreases in cognitive ability, usually associated with aging, is increased in type 2 diabetic patients. Some recent and comprehensive reviews focused on the relationship between diabetes and brain abnormalities^[22,79]. A consistent number of studies were aimed to measure volumetric differences in diabetic population by MRI. During aging, a global brain atrophy with an average decline in the brain volume of 0.1%-0.5% per year is physiological^[80,81]. However, brain volume in T2D patients is reduced of 0.5%-2.0% relative to controls^[22], correspondent to an extra 2-5 years of normal aging. Brain atrophy can be generalized or focal, with the medial temporal lobe mainly involved^[22], and can be related to either the white or the gray matter, or both. Ryan *et al.*^[79] reported that insulin resistance is a predictor of gray matter atrophy and cognitive impairment. Moreover, the analyses of T2-weighted MR brain images of diabetic patients revealed micro- and macrovascular alterations induced by the chronic inflammation associated with hyperglycemia, which could play a role in the hyperintense lesions of the white matter observed^[82]. Several MRI studies indicated a significant correlation between T2D and brain infarct, mostly lacunar necrosis^[22], and such parameters as insulin resistance, nephropathy, diabetes duration and high systolic blood pressure are suggested as main determinants of the increased occurrence of brain infarcts in the diabetic population^[22].

At present, there are few studies on brain metabolism of diabetic patients by MR spectroscopy^[23-24,83]. They were mainly addressed to determine the alterations of the resonance peaks of brain metabolites and neurotransmitters under different conditions of cognitive impairment^[22].

Brain microvascular function can be investigated by imaging of cerebral blood flow and cerebrovascular reactivity. The former is assessed by SPECT (using

¹²³I- or ⁹⁹Tc- labeled tracers), MRI (phase-contrast or arterial spin-labeling modalities) and transcranial Doppler US. Cerebrovascular reactivity, assessed by MRI or transcranial Doppler US, is the measure of the microvascular reserve defined as the increase of blood flow under maximal cerebral vasodilation induced by acetazolamide or CO₂. At present, however, studies on cerebral blood flow and cerebrovascular reactivity in patients with T2DM show conflicting results^[22].

Imaging of vasculature and vascular changes

Non-invasive techniques provide information on macrovascular anatomy, as well as on functional parameters concerning vessel flows, tissue perfusion, microcirculation, all of which are affected by complications concurring in the high morbidity and mortality on diabetic patients.

Ultrasonography is mainly used to assess the atherosclerotic burden in non coronary arteries. Doppler US has been successfully employed for an early and accurate characterization of the vasculopathy of lower limb arteries (a strong risk factor in the development of diabetic foot ulcers)^[84], thus favoring the prevention or delay of foot complications, especially amputation. Moreover, the measurement of the carotid intima-media thickness (IMT) by US has been demonstrated a useful marker of the progression of atherosclerosis throughout the body, and an excellent predictor of cardiovascular events even in diabetic population^[85,86]. Furthermore, carotid IMT can be used to evaluate the efficacy of new treatments^[87-90].

At present, techniques based on CT technology, such as coronary artery calcium scoring and coronary multi-slice CT angiography, are considered the most robust imaging techniques for non-invasive visualization of coronary atherosclerosis, assessment of plaque composition and level of calcification^[91-93]. Also MRI is emerging as an important modality to assess atherosclerotic plaque burden and morphology in non coronary arteries^[94,95].

Nevertheless, because altered vessel morphology may be ambiguous, the ability to non invasively evaluate molecular and cellular pathological processes becomes crucial in terms of early detection and preventive treatment. The use of functional and molecular imaging approaches will provide valuable diagnostic tools. Recently, by using MRI in experimental studies on rodent diabetic models, Medarova *et al.*^[96] evaluated pancreatic vascular volume, microvascular flow, and permeability, that are common disease biomarkers for both T1D and T2D^[97-99].

Moreover, PET imaging studies reported a strong relation between peripheral artery atherosclerosis and increased regional ¹⁸F-FDG uptake (glycolytic metabolism) in subjects presenting impaired glucose tolerance and T2D^[100,101]. In addition, inflammatory condition associated with atheroma or atherosclerosis progression has been investigated by both single and

dual-modal imaging, using ^{18}F -FDG-PET/CT^[102], USPIO-MRI^[103-105], nanoparticle PET-CT^[106]. Finally, it is very promising, but mainly limited to the preclinical field, the use of nanoparticles appropriately functionalized with ligands or antibodies vs cell membrane molecules (VCAM-1, PECAM-1, E-selectin, P-selectin) to detect activated endothelial cells in different imaging modalities (OCT, MRI, enhanced US, PET)^[107-109], or even in the same acquisition session (hybrid MRI or PET-CT and MRI-PET scanners)^[110,111] in order to obtain a molecular contrast.

Imaging of ulcerations and diabetic foot

Lower extremity and particularly foot ulcers are among the most frequent complications of diabetes. It is estimated that 15%-25% of T1D and T2D patients are affected by skin ulcers in their lifetime^[112]. Factors as peripheral neuropathy and vascular disease contribute to the development of skin ulcerations. Some valuable information on vasculopathy can be provided by Doppler US examination in patients with diabetic foot^[113]. Moreover, in the last few years hyperspectral imaging (HIS) has been launched as a useful diagnostic tool to monitor microvascular changes and tissue perfusion impairment associated with diabetic ulcer formation and healing^[114]. By selecting proper wavelengths within the visible and very near infrared region (400-1000 nm) of the electromagnetic spectrum, HIS allows to acquire spatial maps of oxy- and deoxyhemoglobin and, thus, to quantify tissue oxygenation. In the management of diabetic foot ulcers, it represents a valuable tool in the assessment of wound healing potential and in guiding the proper therapy in order to prevent infections and amputations. If left untreated, a relevant cases of foot ulcers lead to infection, limited joint mobility, muscular alterations and deep-tissue necrosis^[112]. Bones may also be involved in two different clinical conditions associated with diabetic complications, such as osteomyelitis and Charcot osteoarthropathy^[115]. The former is mainly due to direct bone contamination from a soft-tissue ulcer and accounts for approximately one third of diabetic foot infections, whereas the latter is a chronic and progressive inflammatory disease affecting the bone and joints. Both osteomyelitis and Charcot foot are conditions with an increased risk of lower limb amputation from 25% to 50%. It has been suggested that about 50% of those amputations could be avoided by an early diagnosis and a multidisciplinary approach. The major diagnostic difficulty is in distinguishing osteomyelitis from non-infectious bony disorders as Charcot foot^[115].

X-ray planar radiographs are relatively inexpensive and readily available, but their sensitivity is quite poor and false negative results are not so rare, especially in the first stages of osteomyelitis. Bone biopsy is considered the technique of choice for detection of osteomyelitis, however conventional imaging (MRI, SPECT and hybrid SPECT/CT) are valuable

support in the early diagnosis of infections and their accurate anatomical localization^[116]. In addition, due to their non-invasive nature, imaging studies proved particularly useful in monitoring the progression of the disease and the efficiency of specific treatments. Valabhji *et al.*^[117] show the effective role of MRI also in guiding the time course of the antibiotic therapy in the management of diabetic foot complicated by osteomyelitis. Unfortunately, the major limitation of MRI imaging is its inability to accurately differentiate osteomyelitis from other inflammatory bone disease. Similarly, the use of SPECT imaging modality that combines technetium methyl-diphosphonate ($^{99\text{m}}\text{Tc}$ -MDP) bone scan with technetium hexamethylpropylene amine oxime ($^{99\text{m}}\text{Tc}$ -HMPAO)-labeled leukocytes scan is adequate for osteomyelitis diagnosis^[118], but is poor in the anatomical localization of the infection, due to the limited spatial resolution of nuclear imaging.

Recently, new hybrid imaging technologies combining SPECT localization of $^{99\text{m}}\text{Tc}$ -HMPAO-labeled leukocytes and high resolution X-ray CT have been introduced and provided effective in the differential diagnosing of osteomyelitis in patients with diabetes^[116]. The use of ^{18}F -FDG-PET has emerged as a possible alternative nuclear imaging modality combined with CT in the diagnosis of bone infection secondary to diabetic ulcerations. However, at present, the data on the role of PET and PET/CT in the evaluation of diabetic foot infections are limited and the results reported are rather inconsistent, especially in the absence of an appropriate reference standard^[119].

Imaging of diabetic cardiomyopathy

Accumulating data from experimental, pathological, epidemiological, and clinical studies have shown that diabetes mellitus results in cardiac functional and structural changes, independent of hypertension, coronary artery disease or any other known cardiac disease, which support the existence of diabetic cardiomyopathy. The pathophysiology of diabetic heart disease is likely multifactorial, involving altered myocardial metabolism, endothelial dysfunction and vascular disease, autonomic neuropathy, and increased myocardial fibrosis. Most of the conventional non-invasive imaging modalities can provide valuable insights into the disease process and can be useful for monitoring disease progression and evaluating the effectiveness of medical interventions.

Ventricular function and perfusion: Conventional diagnostic imaging modalities currently aids in non-invasive assessment of both systolic and diastolic dysfunction in diabetic patients. Pulsed wave Doppler studies measuring transmitral inflow, deceleration time and isovolumic relaxation time are the gold standard to diagnose ventricular diastolic dysfunction^[120,121]. Moreover, tissue Doppler imaging and strain rate imaging are considered more sensitive for detection

of LV dysfunction than conventional trans-thoracic echocardiography, especially in the early stages of diabetes in which the sole sub-endocardial dysfunction is overt. Cardiac MRI has recently emerged as a very good imaging tool for the diagnosis of structural and functional disorders of the myocardium. Gadolinium-enhanced cardiac MRI has been found to be useful in the prediction of major adverse cardiac events in diabetic patients without previous history of ischemic heart disease^[95,122]. Cardiac MRI is also useful to detect diastolic dysfunction and myocardial steatosis^[95]. Among the available imaging modalities, only PET allows quantitative assessment of myocardial blood flow using radiotracers kinetics^[95,123,124]. The combined images by MRI and PET provide a high spatial resolution detection of myocardial metabolic abnormalities and currently represent the more valuable imaging analysis in the diagnosis and prognosis of diabetic disease. Unfortunately, many diabetic patients with advanced stages of cardiomyopathy have had mechanical interventions that have inserted metallic devices into the heart (e.g., defibrillators, left ventricular assist devices) that preclude the possibility to use MRI. Under these circumstances, the low anatomical (spatial) resolution of PET can be compensated by the combined PET/CT imaging. This recent hybrid modality is also particularly indicated in the case of diabetic patients with or at risk of coronary artery disease, since CT is currently considered very reliable in evaluating coronary artery calcium plaque burden and, with the aid of contrast agents, it provides an accurate coronary angiogram^[125,126].

Cardiac autonomic neuropathy in diabetes: It is one of the diabetic complications that increase the risk of myocardial infarction and sudden death in diabetic patients. The need of an early diagnosis of cardiac autonomic neuropathy (CAN) for clinical decision-making of these patients is evident considering that it was estimated that the 5-year mortality rate is 5 times higher in diabetic patients with CAN compared with patients without evidence of CAN^[127]. CAN detection requires several indirect tests to assess the activity of both the parasympathetic and the sympathetic branches of the autonomic system. However, the only direct method to assess cardiac autonomic activity is by using nuclear imaging. Currently, either SPECT and PET clinical imaging is limited to assess sympathetic activity and innervation, with parasympathetic imaging limited mostly to preclinical and translational studies^[95]. Cardiac sympathetic imaging is focused on synaptic junction, and in particular on the pre-synaptic endings, where the norepinephrine transporter (NET) protein, also known as uptake 1, is localized^[128]. NET is responsible for the most part of the re-uptake of synaptic norepinephrine that is released following sympathetic nerve endings stimulation. Several studies used radiolabeled analogs of norepinephrine

to evaluate the cardiac neuronal activity and function. The most commonly used is metaiodobenzylguanidine (MIBG), a molecule that is taken up by NET protein but that is not catabolized by monoamine oxidase or catechol-o-methyltransferase, thus allowing to accumulate into the sympathetic synaptic endings^[129]. MIBG can be easily labeled with the radionuclide ¹²³I, a γ photon emitter and, thus, imaged by SPECT scanner. Besides, some PET tracers have also been developed based on molecules sharing similarities with norepinephrine, including ¹¹C-meta hydroxyephedrine (¹¹C-HED), ¹¹C-epinephrine (¹¹C-EPI) and ¹¹C-guanyl-meta-octopamine (¹¹C-GMO). Both clinical and experimental studies with these tracers have provided significant information on cardiac sympathetic dysfunction in many diseases, diabetes included^[130-132].

More recently, experimental and pre-clinical studies tested a new ¹⁸F-labeled NET substrate (namely, ¹⁸F-LMI1195) designed to allow PET cardiac neuronal imaging with high sensitivity and resolution^[133].

Altered myocardial metabolism: It is commonly accepted that one of the mechanism leading to diabetic cardiomyopathy is the accumulation of fatty acids in myocardial tissue (myocardial steatosis). When the fatty acid uptake oversteps the oxidative capability of myocyte, the exceeding fatty acids are stored in the cell cytoplasm as triglycerides. Intracellular triglycerides are inert *per se*. However, a proportional part of them are transformed in toxic intermediates through non-oxidative pathways. At present, myocardial triglycerides can be quantified (thus having an estimate of their toxic metabolites) by means of ¹H-MRS scanners with field strength ≥ 1.5 Tesla. Several experimental and clinical studies have used ¹H-MRS to correlate the increased myocardial triglyceride content and ventricular dysfunction in diabetes^[95]. Magnetic resonance spectroscopy is also suitable to monitor the effect of pharmacological treatment of diabetes on intra-myocardial triglyceride accumulation^[134,135].

Measuring of visceral and liver fat

Excessive body fat is a major risk factor for several diseases, including insulin resistance, T2D, and cardiovascular disease. In addition, fat accumulation in specific body tissues and/or organs (named, ectopic fat) such as visceral, intrahepatic and intramuscular lipid stores, pericardial, perivascular and perirenal fat depots, is considered an important predictor of cardiometabolic and vascular risk^[136,137]. Therefore, regional fat distribution might be a more predictive factor for specific risks than obesity itself and an accurate measurement of fat accumulation might represent an additional prognostic value in the risk assessment of patients. Dual energy X-ray absorptiometry (DEXA) is considered the reference choice to evaluate body composition^[138]. It measures three different compartments: fat mass,

non-bone lean mass and bone mineral content. DEXA is accurate, time and cost effective, widely available, and has low radiation exposure but is, on the whole, unable to discriminate among fat depots, except for a software that has been recently proposed to quantify the visceral fat compartment^[139]. For this reason, MRI and CT are currently considered the gold standard methods to measure adiposity and accurately distinguish between subcutaneous and ectopic visceral fat. However, the use of CT for fat distribution analysis is discouraged, especially in children, due to the high levels of radiation exposure. More recently, several studies have reported grey-scale and/or contrast-enhanced US as a promising technique to measure subcutaneous adipose tissue thickness and abdominal visceral fat^[140,141]. Moreover, a strong correlation between US and CT assessment of fat depots was found^[140]. If adequately validated, US might represent the clinical standard methodology for longitudinal studies on fat content and distribution in response to treatment^[142]. In addition, contrast-enhanced US showed a good sensitivity (> 95%) and specificity (> 90%) even in revealing fatty liver^[143,144]. However, as hepatic fat quantification is concerned, also CT, dual-energy CT (80 and 140 kVp), MRI and ¹H-MRS perform very well, with high specificity, and are considered the front runners in the non invasive diagnosis and quantification of moderate to severe liver steatosis^[145-147].

CONCLUSION

Considering the current trends in medicine, it can be expected that diagnostic non-invasive imaging techniques, particularly multimodal hybrid devices, will become increasingly available in the clinical arena and assume an always more important role in supplementing the clinical evaluation of the diabetic patient.

The challenge is to combine the diagnostic utility of imaging tools with therapeutic entities ("theranostics") in order to improve risk stratification and personalized therapy for diabetes management. It poses both scientific and technical problems: molecular and cellular biology and pathology on one side, and physical and chemical methodologies on the other. As for the contribution of medicinal chemistry, it is required the use of nanometer-scale materials to provide molecular imaging with simultaneous treatment. The nanomaterial platforms have to integrate molecular targeting ligands, therapeutic moieties and complementary imaging (multi)-modalities. Recently, Arifin *et al.*^[148] have introduced a biohybrid theranostic agent composed by human pancreatic islets encapsulated in a porous matrix together with functionalized Gd-gold nanoparticles which could serve as a contrast agent for three complementary imaging modalities (MRI, CT and US). They found that

microcapsules containing islet cells were able to restore normoglycemia in a mouse diabetic model and could be tracked by trimodal non-invasive imaging. Analogously, Barnett *et al.*^[149] reported the theranostic capabilities of functionalized magneto-capsules containing human pancreatic islet β -cells in mouse and swine pre-clinical models. Moreover, dextran-coated iron oxide nanoprobe, suitable for MRI, have been functionalized with small interfering RNA^[150,151] to silencing specific genes of choice. Although important in proving new principles, at present these contributions are still in an exploratory, preclinical stage. Future studies should be performed in models endowed with increased power of predicting human efficacy and safety, thus warranting clinical translation and development in a demanding regulatory environment.

Abstract

Long-acting glucagon-like peptide-1 (GLP-1) analogues marketed for type 2 diabetes (T2D) treatment have been showing positive and protective effects in several different tissues, including pancreas, heart or even brain. This gut secreted hormone plays a potent insulinotropic activity and an important role in maintaining glucose homeostasis. Furthermore, growing evidences suggest the occurrence of several commonalities between T2D and neurodegenerative diseases, insulin resistance being pointed as a main cause for cognitive decline and increased risk to develop dementia. In this regard, it

has also been suggested that stimulation of brain insulin signaling may have a protective role against cognitive deficits. As GLP-1 receptors (GLP-1R) are expressed throughout the central nervous system and GLP-1 may cross the blood-brain-barrier, an emerging hypothesis suggests that they may be promising therapeutic targets against brain dysfunctional insulin signaling-related pathologies. Importantly, GLP-1 actions depend not only on the direct effect mediated by its receptor activation, but also on the gut-brain axis involving an exchange of signals between both tissues *via* the vagal nerve, thereby regulating numerous physiological functions (*e.g.*, energy homeostasis, glucose-dependent insulin secretion, as well as appetite and weight control). Amongst the incretin/GLP-1 mimetics class of anti-T2D drugs with an increasingly described neuroprotective potential, the already marketed liraglutide emerged as a GLP-1R agonist highly resistant to dipeptidyl peptidase-4 degradation (thereby having an increased half-life) and whose systemic GLP-1R activity is comparable to that of native GLP-1. Importantly, several preclinical studies showed anti-apoptotic, anti-inflammatory, anti-oxidant and neuroprotective effects of liraglutide against T2D, stroke and Alzheimer disease (AD), whereas several clinical trials, demonstrated some surprising benefits of liraglutide on weight loss, microglia inhibition, behavior and cognition, and in AD biomarkers. Herein, we discuss the GLP-1 action through the gut-brain axis, the hormone's regulation of some autonomic functions and liraglutide's neuroprotective potential.

Core tip: Glucagon-like peptide-1 (GLP-1) physiological responses are dependent on a gut-brain axis and receptor (GLP-1R) activation. GLP-1Rs are widely expressed throughout the body, including several brain areas. GLP-1 may readily diffuse across the blood-brain-barrier, activating neuroprotective pathways. Given the native GLP-1 short half-life, liraglutide has been developed with a highly increased half-life, allowing its use to treat type 2 diabetes (T2D). Given T2D patients increased risk for obesity and dementia [*e.g.*, Alzheimer disease (AD)], and evidence from preclinical studies, whereby liraglutide showed impressive neuroprotective effects, clinical studies are underway to test the role of liraglutide on weight control and AD.

INTRODUCTION

The incretin effect was first discovered when experiments were conducted to evaluate the possibility that food ingestion would lead to hormone secretion by the gut into the bloodstream to modulate pancreatic insulin secretion and lower blood glucose levels^[1-3]. Shortly after, glucose-dependent insulinotropic polypeptide (GIP) and gastrointestinal glucagon-like peptide-1 (GLP-1) were described as the incretin hormones secreted by intestinal cells that were responsible for a potent insulinotropic activity upon elevated plasma glucose (70% of the postprandial insulin secretion)^[4-7]. More recently, in an increased number of studies directed to the analysis of incretins effects in patients with type 2 diabetes (T2D), impaired interactions between mediators such as insulin, glucagon and incretin hormones have been increasingly suggested to underlie the development of T2D^[8].

In this review, we will focus primarily on the complex interaction between gut and central nervous system (CNS), particularly in the regulation of appetite and body weight. More specifically, we will briefly overview the role of the increasingly used anti-T2D drug from the incretin/GLP-1 mimetics class liraglutide in brain, with a special emphasis on its anorectic and potential neuroprotective effects on T2D-associated neurodegeneration.

INCRETIN HORMONES IN BRAIN: A PIVOTAL ROLE FOR GLP-1

Despite the known GIP action in inhibiting gastric acid secretion and gastrointestinal motility, as well as in the stimulation of insulin release^[6,7], it was observed that not only GLP-1 is more insulinotropic in hyperglycemic conditions than GIP^[9,10], but also that GIP insulinotropic activity was diminished in T2D patients^[11,12]. Thus, as the GIP secretion was maintained normal or even increased, such apparently reduced β -cell response to GIP might result from a down-regulation of GIP receptor expression/activity^[13,14]. This was further reinforced by the observation that, despite no changes in GLP-1-related insulinotropic activity in diabetic patients, their impaired insulin secretion could be associated with a decreased incretin effect^[15-17]. Importantly, in addition to its insulinotropic effects, GLP-1 has been also involved in the suppression of postprandial glucagon secretion, delaying gastric emptying, promoting early satiety (and the subsequent decrement in food intake), slowing the rate of endogenous glucose production and, ultimately, promoting weight loss, particularly in diabetic conditions^[4,18,19]. Moreover, it has been reported that, by stimulating cell proliferation and protecting against apoptosis, GLP-1 also enhanced pancreatic β -cell mass^[20,21]. In this perspective, it has been suggested that the combination of these effects may contribute to the normalization of blood glucose levels in T2D patients^[19,22], thus rendering the GLP-1

hormone (instead of GIP) a very attractive target for the treatment of T2D.

The gut-to-brain GLP-1-dependent axis: GLP-1 synthesis and secretion

As previously referred, GLP-1 is primarily synthesized and secreted from the intestine (ileum and colon) enteroendocrine L cells and, to a lesser extent, from pancreatic α -cells and from neurons located at the nuclei of brainstem [solitary tract nucleus (NTS), caudal brainstem and area postrema (AP)]^[23-25].

This hormone arises from the post-translational cleavage of proglucagon (catalyzed by the prohormone convertase) and, depending on the tissue, proglucagon may originate different products^[26]. For instance, in pancreas the major products are glucagon, glycentin related polypeptide and a major proglucagon fragment, containing the GLP-1 and GLP-2 sequences, whilst in brain and gut proglucagon processing liberates GLP-1, GLP-2 (which is not an incretin, as it is deprived from insulinotropic and glucose lowering properties), IP-2, glicentin, and oxyntomodulin^[23,26]. Additionally, recent studies showed that multiple forms of GLP-1 are secreted by humans, including GLP-1 (1-37) and GLP-1 (1-36) amides (synthesized as immature forms), as well as the bioactive forms glycine-extended form GLP-1 (7-37)-amide and the GLP-1 (7-36)-amide (this being the predominant form in plasma and brain)^[23,27].

Most GLP-1 is secreted postprandially, particularly after fat- and carbohydrate-rich meals. Interestingly, this secretion is proportional to the size of the meal and may reach 10-30 pM^[4,19]. Individual nutrients, including glucose and other sugars, fatty acids, essential amino acids and dietary fibers also stimulate GLP-1 release^[28]. Amongst these, the glucose and fructose mechanism of stimulation have been the more explored and it has been shown that, in humans, oral (but not intravenous) glucose administration stimulates GLP-1 secretion^[4,26]. Moreover, basal secretion of GLP-1 may even occur as a product of glucagon secretion in fasting state and reach 5-10 pM, being essential for maintaining glucose homeostasis^[4,25]. Interestingly, plasma GLP-1 (7-36)-amide increases rapidly (within just a few minutes) through a biphasic pattern of secretion and release after oral glucose absorption, composed by an early phase within 10-15 min followed by a prolonged second phase at 30-60 min^[28,29].

Although the majority of secreting L-cells are located in the distal small intestine, they can be found also throughout the entire length of the small intestine^[30,31]. Interestingly, these cells may contact with different regions, being stimulated by a variety of mediators. For instance, L-cells can contact directly with nutrients at their luminal surface and with vascular tissue through their basolateral surface, as well as with the enteric and the CNS *via* the vagus nerve^[31,32]. Hence, evidence suggests that early and late phases of GLP-1 secretion may be generated either through

(1) the direct nutrient stimuli to L-cells (particularly those located in more proximal regions of the small intestine, being at least partially responsible to induce the first phase of GLP-1 secretion); or (2) *via* the indirect action of neural and endocrine factors^[19,30,32]. More specifically, it has been hypothesized that the early GLP-1 secretion in rodents and humans may be indirectly regulated by the autonomic nervous system and neurotransmitters and peptides [e.g., gastrin-releasing peptide, acetylcholine, γ -aminobutyric acid (GABA), calcitonin gene-related peptide and GIP], with the vagus nerve playing an essential role herein^[31,33]. Additionally, others proposed that non-nutrient factors, as leptin and insulin, could also contribute to the rapid release of GLP-1^[33,34].

Intracellular signaling pathways underlying brain GLP-1 synthesis, secretion and action

Importantly, brain GLP-1 can be peripherally originated (from the intestine), reaching the CNS through leaks in the blood-brain barrier (BBB) (at the level of area postrema and subfornical organs), whereby it may readily diffuse across the BBB (GLP-1 is a relatively small molecule), and may also influence the activity of afferent vagal neurons^[35]. However, as previously referred, GLP-1 synthesis can also occur locally in brain, in a process dependent on the complex brainstem-hypothalamic-preproglucagon system. More specifically, in preproglucagon neurons from the CNS, proglucagon is processed to GLP-1 in neuronal cell bodies^[36]. First evidence showed that the largest population of GLP-1 immunoreactive innervations occurred in the dorsomedial and paraventricular nuclei of the hypothalamus, and to a lesser extent in the cortex and hindbrain^[37,38]. Then, others reported that preproglucagon neurons are primarily located in the lower brainstem, particularly in the caudal NTS and AP, some cell bodies being also found in the dorsomedial part of the medullary reticular nucleus^[37,39,40]. Besides this, both the NTS and AP appear to receive visceral sensory inputs generated by the vagal nerves that innervate the gastroduodenal tract^[41]. Indeed, it has been described that sensors in the hepatic portal vein may activate the vagus nerve, initiating a neural signal to the NTS/AP in the brainstem, which in turn transmits the information through axons to the hypothalamic nuclei^[42]. Intracellularly, GLP-1 secretion may be mediated by several signaling pathways. In general, these include the activation of protein kinases A (PKA) and C (PKC) and mitogen-activated protein kinase (MAPK), as well as an increase in intracellular calcium (Ca^{2+})^[43]. More specifically, upon a meal, the increase in blood glucose is accompanied by its uptake into the cells (namely *via* sodium/glucose transporters) and subsequent metabolism. As a result, the increment in ATP levels may lead to the closure of ATP-linked potassium channels and, ultimately, GLP-1 secretion^[33,43]. Conversely, inhibition of GLP-1 secretion

in gut has been described to involve a negative feedback, probably *via* GLP-1-mediated stimulation of somatostatin secretion^[34,44]. Interestingly, the neuropeptide galanin has been also identified as an inhibitor of GLP-1 secretion from intestinal L-cells, both *in vitro* and *in vivo*^[26,34].

Physiological responses of GLP-1 are elicited upon binding of the hormone to its receptors belonging to the class B family of 7-transmembrane heterotrimeric expressed G-protein-coupled receptors, a family that also includes receptors for glucagon, GLP-2, and GIP^[45,46]. Increasing evidence points towards an ubiquitous expression of GLP-1 receptor (GLP-1R), in tissues ranging from pancreas (α , β , and δ cells), lung, heart, kidney, stomach, intestine, pituitary, skin and ganglion neurons of the vagus nerve, to multiple regions of CNS (including brainstem, hypothalamus, hippocampus and cortex)^[26,30]. Importantly, GLP-1R expression was detected in mammalian brain neurons, astrocytes, microglia and endothelial cells^[47] and, even more strikingly, GLP-1Rs have been identified in lipid rafts, where they interact with caveolin-1, thereby regulating receptor subcellular localization, trafficking, and signaling^[48].

Interestingly, rat and human GLP-1Rs are polypeptide chains with 463 amino acids and share 90% sequence homology^[19]. Structurally, GLP-1R possesses a long N-terminal extracellular region responsible for peptide recognition and binding, and a cytoplasmic C-terminal containing the components for specific G protein coupling, thus having a major influence in signaling specificity and transmission^[49,50]. Once activated, GLP-1R stimulates the adenylyl cyclase system, increasing intracellular cyclic adenosine monophosphate (cAMP) levels and, subsequently, activating the downstream PKA and exchange protein activated by cAMP-2 (Epac2) pathways^[4,29]. Alternatively, GLP-1R activation may also increase intracellular Ca^{2+} and phospholipase C levels, or stimulate other signal transduction pathways, depending on the activated tissues, including phosphoinositide 3-kinase (PI3K), insulin receptor substrate-2, epidermal growth factor receptor transactivation, PKC, MAPK, cyclic AMP response element binding protein (CREB), pancreatic duodenal homeobox-1, and glucose transporter-2^[26,51,52].

Importantly, some authors suggested that at least part of GLP-1-associated endocrine effects (e.g., GLP-1R-dependent insulin secretion) may be indirectly mediated by neural mechanisms^[42]. This appears to be supported by the increasing notion that GLP-1R activation may generate new signals to guide the energetic flux towards tissues (*via* the autonomic nervous system) and ultimately regulating a diverse array of homeostatic functions (Figure 1)^[23,53,54].

The short-half life of GLP-1: Inactivation by dipeptidyl peptidase-4

Concerning the use of incretin-based anti-T2D therapy, we must bear in mind that a continuous GLP-1 ad-

ministration would be required to effectively maintain glucose homeostasis. In fact, given the native GLP-1 short half-life of less than 2 min [the hormone is rapidly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4)]^[55,56], this would render its therapeutic use unfeasible, as we will discuss later.

DPP-4 is a ubiquitous and multifunctional enzyme that can be found either solubilized in blood or membrane-anchored in many cell types^[57]. This glycoprotein is widely expressed in multiple tissues, including kidney, lung, adrenal gland, pancreas, liver, thymus, lymph node, uterus, placenta, prostate and on the surface of lymphocytes, macrophages and endothelial cells^[58,59]. More relevant herein, DPP-4 appears to be also expressed in several brain areas (e.g., hypothalamus, hippocampus, circumventricular organs, choroid plexus, and leptomeninges)^[60,61]. And besides its well known role in GLP-1 inactivation, DPP-4 has been also implicated in numerous pleiotropic cellular processes involving cell cycle regulation, proliferation, adhesion, immunomodulation and apoptosis^[62-64].

Molecularly, DPP-4 is able to specifically cleave different dipeptides possessing an alanine, proline or hydroxyproline in the penultimate N-terminal position. These substrates include fibronectin, substance P, chemokines, neuropeptide Y (NPY), peptide YY (PYY), and the best validated *in vivo* substrates: GLP-1, GLP-2 and GIP^[62,63]. The resulting GLP-1 (7-36)-amide is metabolized to GLP-1 (9-37) or GLP-1 (9-36)-amide, which has a 1000-fold reduced affinity for GLP-1R and thus completely blunts its insulin-releasing activity^[56,57]. Besides DPP-4, another relevant step in GLP-1 inactivation process can be catalyzed by the neutral endopeptidase (NEP), a membrane-bound zinc metallopeptidase expressed in both the periphery and CNS, that is responsible for GLP-1 (7-36)-amide hydrolysis into smaller peptides^[65,66]. Therefore, as most of GLP-1 passing the portal circulation has been already degraded by DPP-4, GLP-1 (9-37) and GLP-1 (9-36)-amide constitute the major circulating forms of the hormone (with an estimated half-life of 8-10 min, as a result of renal clearance)^[25]. Apparently, this suggests that, after GLP-1 secretion and release by intestinal L-cells, DPP4 starts to continuously degrade the incretin hormone, thus accounting for 50% of GLP-1 inactivation^[30,67]. Then, after its passage through the liver, another large amount of the remaining intact bioactive form of the peptide is further inactivated, thus culminating in less than 10% of active GLP-1 reaching the blood circulation^[30].

INCRETIN-BASED THERAPIES: THE FUTURE OF ANTI-T2D AND NEURODEGENERATIVE DISEASES?

The management of T2D through a patient's lifetime is often difficult and frequently renders the achievement of therapeutic goals unsuccessful. However, this

Figure 1 The gut-brain axis for the actions of glucagon-like peptide-1. After a meal ingestion, gastrointestinal (GI) tract is rapidly stimulated and glucagon-like peptide-1 (GLP-1) is secreted in the gut lumen by enteroendocrine L-cells. Besides the direct interaction of nutrients with L-cells, neural (acetylcholine) and endocrine (gastrin-releasing peptide, somatostatin and leptin) mechanisms are also involved in the control of GLP-1 secretion after food intake. Bioactive GLP-1 diffuses into the capillaries, immediately beginning to be degraded by dipeptidyl peptidase-4, so that more than 50% of the hormone is inactivated before reaching the portal circulation. In the liver, a further large amount is truncated, thus only 10% of the secreted GLP-1 leaves the liver and enters the systemic circulation and may reach the pancreas, the brain and other tissues via the endocrine pathway. However, the passage of GLP-1 through the hepatoportal vein activates vagal afferents nerves that initiate a neural signal towards the brain. In the central nervous system, the metabolic information is received by the solitary tract nucleus and the AP in the brainstem, which synthesize and project the GLP-1 to the hypothalamus. The GLP-1 receptor signaling is involved in the central control of energy homeostasis and food intake, and several autonomous functions, such as glucose-dependent stimulation of insulin secretion and inhibition of glucagon secretion in the pancreas, cardiovascular effects, regulation of gastric emptying and of endogenous glucose production in liver and glucose uptake and storage in muscle and adipose tissue. GRP: Gastrin-releasing peptide; ACh: Acetylcholine; SS: Somatostatin; DPP-4: Dipeptidyl peptidase-4; AP: Area postrema.

scenario has been increasingly challenged in the recent years, due not only to the promising results obtained with GLP-1-related therapy in T2D, but also to its widespread beneficial effects on body weight and metabolic parameters where other promising anti-T2D approaches failed^[68]. Altogether, this rendered the GLP-1R-mediated intracellular signaling one of the most appealing targets in the development of therapies for diabetes management. Importantly, and despite GLP-1's pharmaceutical promise, the first crucial step was the need to overcome its rapid degradation by DPP-4, thereby enhancing the hormone's action time^[69-71]. In this regard, two novel classes of glucose lowering agents, the DPP-4-inhibitors and the GLP-1R agonists (GLP-1RAs) have been intensively developed over the last years^[72].

DPP-4-inhibitors and GLP-1R agonists: The future therapeutic dream team?

DPP-4-inhibitors are orally-given small molecules that

compete with DPP-4 substrates for the active site of the enzyme, thus avoiding the inactivation of native bioactive GLP-1 and, therefore, extending its half-time and increasing its levels in circulation^[73,74]. Currently, there are three inhibitors approved for treatment of T2D in the United States and Europe: sitagliptin, saxagliptin and linagliptin^[74]. Besides these, vildagliptin is another DPP-4 inhibitor also available only in Europe^[73].

On the other hand, given the peptidic nature of GLP-1RAs, it is necessary to administer them by subcutaneous injection^[75]. These molecules have been developed based on the effects of native GLP-1 (binding to GLP-1R and activating similar glucoregulatory effects), but with a high resistance to DPP-4 degradation, thereby increasing the systemic GLP-1 activity^[73]. Currently, three GLP-1RAs are commercially available: exenatide twice daily (EBID), liraglutide once daily, and exenatide once weekly (EQW)^[74]. Importantly, most of these incretin-based therapies

have been approved as a second line therapy, in dual or triple combination with other anti-diabetic therapies, including metformin, sulphonylureas (SU) and thiazolidinediones (TZD)^[75].

Since the endogenous levels of incretin hormones appear to be reduced in T2D patients, increasing evidence points towards a higher effectiveness of GLP-1RAs-based therapies in glycemic control than the use of DPP-4-inhibitors, particularly in reducing glycated hemoglobin A_{1c} (HbA_{1c}) and postprandial glucose levels^[8,11]. Furthermore, contrary to GLP-1RAs, DPP-4-inhibitors appear to be weight neutral, with no effect in gastric emptying, and with less described positive cardiovascular effects^[76,77]. And although some adverse events have been reported in both therapeutic subclasses [namely an increased risk for infections with DPP-4 inhibitors and common gastrointestinal side effects (predominantly nausea) with GLP-1RAs], the overall tolerability was comparable and general positive results were described for both classes of incretin-related therapy, with no episodes of major hypoglycemia documented in patients on either therapy^[8,78]. Thus, it is not surprising that, in the last years, the incretin-based therapies (and particularly GLP-1RAs) have been increasingly faced as the potential “dream team” not only for the treatment of T2D and its associated complications, but also for other disorders involving changes in glucose homeostasis and metabolism [e.g., neurodegenerative diseases, as Alzheimer disease (AD)].

GLP-1R agonists: Exenatide and liraglutide

As previously referred, the main advantage of GLP-1RAs over DPP-4 in terms of T2D treatment appears to be the fact that these patients often present lower circulating incretins' levels^[8,11]. Although comparative clinical efficacy data are still limited to support the use of one GLP-1RA molecule over another, some comparative studies have already shown some differences between the two main GLP-1RAs, exenatide and liraglutide. First, liraglutide has been considered a true GLP-1 agonist, sharing 97% sequence identity with human GLP-1, while exenatide is a mimetic isolated from the saliva of the Gila monster (*Heloderma suspectum*) that shares only 53% structural similarity with native GLP-1^[79-83]. Additionally, the long-acting GLP-1 analog liraglutide, Arg³⁴,Lys²⁶-{N-ε-[γ-Glu(N-α-hexadecanoyl)]}-GLP-1 (7-37), has a substitution of a lysine residue with arginine at position 34 and a 16-carbon fatty acid chain *via* a glutamic acid spacer attached to lysine at position 26, thereby promoting the noncovalent binding of liraglutide to serum albumin that not only confers its DPP-4 enzyme resistance and protection from renal clearance, but also allows liraglutide molecules to form heptamers, slowing its absorption rate from injection site and increasing its half-life in plasma to 13 h (in contrast with the 2 h half-life of exenatide)^[84-86]. And although the efficacy of peptide injection into the organism may be partially

compromised by the formation of antibodies against GLP-1RAs, given its protein sequence differences liraglutide appears to be less immunogenic than exenatide^[75,87,88]. Indeed, the Liraglutide Effect and Action in Diabetes-6 (LEAD-6) study reported that 61% of T2D patients treated with exenatide developed antibodies compared to only 2.6% of patients given liraglutide^[89,90]. Importantly, this trial also showed that, during the 26-wk study, liraglutide was significantly more efficient than exenatide BID in reducing HbA_{1c} levels (1.12% vs 0.79% respectively) and in improving HOMA-β (homeostasis model assessment of β-cell function) index in T2D patients, thereby suggesting that liraglutide may also induce a better improvement in β-cell function^[89,90]. But, to us, the most striking point from the LEAD-6 clinical trial was that, in a 14-wk extension, patients who started and responded well to exenatide BID treatment could even further ameliorate some parameters when switching to liraglutide. For instance, these patients further reduced HbA_{1c} levels by 0.32%, body weight by 0.9 kg and systolic blood pressure by 3.8 mmHg^[89,90]. In another comparative study between liraglutide and exenatide QW - the DURATION-6 trial -, the first was shown to decrease HbA_{1c} levels by 1.48% in T2D patients compared to the 1.28% lowering achieved with exenatide QW^[91]. Additionally, in this study more patients submitted to liraglutide therapy were able to achieve HbA_{1c} < 7% than with exenatide QW^[91]. And, as in LEAD-6, weight loss was greater among patients receiving liraglutide (-3.58 kg vs -2.68 kg). Interestingly, 94% of the liraglutide-treated T2D patients from the DURATION-6 trial were satisfied with their treatment compared with 86% of those receiving exenatide^[91]. To further complete this comparative overview on both drugs, we must refer that, since the primary route of exenatide clearance from the body is through renal excretion, this may pose some risk of accumulation in patients with renal disease, and, thus, exenatide is not recommended for patients with hepatic impairment^[79,92,93]. Conversely, liraglutide (as GLP-1) is almost exclusively enzymatically degraded by DPP-4 and NEP, and therefore, renal impairment should not affect liraglutide efficacy^[94].

The actions of liraglutide in peripheral diseases:

T2D is mainly characterized by hyperglycemia and an impaired insulin action. However, T2D most dangerous and devastating consequences may arise from the development of long-term complications (e.g., retinopathy, nephropathy, cardiovascular disease, stroke, neuropathy, cerebrovascular disease), which in most cases are already installed by the time of diagnosis^[95].

As previously discussed, the first characteristic that turned GLP-1 into an ideal candidate for T2D treatment was its property to enhance glucose- induced insulin release and overcome insulin desensitization^[6,7]. However, over time GLP-1 has been shown to exert

T2D: Type 2 diabetes; AD: Alzheimer disease.

many other interesting (and potentially therapeutically relevant) effects in the organism^[96] and, in this perspective, the GLP-1RA liraglutide may have also a significant impact (rather than the “mere” GLP-1R activation), not only in periphery, but also in CNS and in other pathologies besides T2D (Table 1), as we will further discuss.

Regarding the role of liraglutide in the periphery

and the progressive loss and dysfunction of pancreatic β -cells that constitutes one of the key features of T2D, several recent studies have shown that the drug was able not only to protect (through anti-apoptotic effects), preserve and enhance β -cell mass, but also to improve β -cell function [seen in the *db/db* and in the transient receptor potential melastatin 2 (TRPM2)-deficient mice models], thereby improving glucose control, and insulin secretion and sensitivity^[97-99].

It is well known that chronic hyperglycemia and poor blood glucose control may also underlie cardiovascular dysfunction and development of cardiovascular disease, thus rendering T2D a risk factor for cardiovascular disease^[100]. Therefore, it is not surprising that emerging data from animal and human studies also point towards a liraglutide-mediated reduction in systolic blood pressure and improvement in lipid profiles (decreased low-density lipoprotein cholesterol and triglycerides levels, and increased high-density lipoprotein cholesterol)^[99,101,102]. Moreover, Liu *et al.*^[103] demonstrated that liraglutide improves cardiac function in diabetic rats, probably due to a decreased expression of proteins involved in the endoplasmic reticulum stress pathway. Accordingly, recent studies also associated liraglutide treatment with a significant decrease in several cardiovascular risk biomarkers, such as plasminogen activator inhibitor-1, B-type natriuretic peptide^[104-106], interleukin-6 (IL-6) and tumor necrosis factor- α ^[107,108]. Besides cardiovascular function, liraglutide was also shown to reduce endothelial cell dysfunction in a process probably mediated by its anti-oxidant and anti-inflammatory effects^[107]. Moreover, other tissues can be directly or indirectly affected by GLP-1RA therapies, including muscle, liver and kidney^[109-111], thus rendering them highly promising against other pathologies than T2D. However, some caution must be used and further clarification is needed as, *e.g.*, was recently reported that, albeit rare the aggravation of an existing nephropathy in T2D patients submitted to GLP-1RA treatment may be due to external factors (*e.g.*, other medications), but if related with this therapy it may probably arise from gastrointestinal problems^[112,113]. Nevertheless, recent data also showed that liraglutide was able to counteract renal impairment in a mouse model that also displayed chronic hyperglycemia and increased renal oxidative stress^[114]. According to these authors, such protection was due to liraglutide-mediated inhibition of NAD(P)H oxidase and activation of cAMP-PKA pathway, thus suppressing the progression of renal failure^[114].

Concerning the effects of GLP-1 analogues in hepatic impairment, there is currently an increasing interest mostly due to the lack of effective therapies against hepatic diseases. Amongst them, the non-alcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver diseases, being strongly related with insulin resistance, metabolic syndrome, cardiovascular disease, cerebral vessel

disease and T2D^[115]. In a recent pilot study involving patients diagnosed with diabetes complicated by NAFLD/non-alcoholic steatohepatitis (NASH), liraglutide (0.9 mg/body per day) was given for 24 wk^[116]. Data suggested that liraglutide significantly improved liver function (as given by the decreased serum levels of alanine aminotransferase, aspartate aminotransferase, ferritin and C-reactive protein) and histological changes in NASH patients^[116]. Besides this, data from LEAN-2 study demonstrated that liraglutide combined with metformin also exerted positive effects in liver enzymes and hepatic steatosis in T2D patients^[117].

Regarding the impact of liraglutide on muscle, Li *et al.*^[118] showed recently that this drug increases cAMP and AMP-activated protein kinase (AMPK) signaling pathways, which may in turn induce GLUT4 translocation in mouse skeletal muscle cells.

The role of liraglutide in appetite and weight loss: A centrally-regulated peripheral anorectic effect:

Unhealthy lifestyle, weight gain and obesity are intimately related with the increased prevalence of T2D worldwide, being estimated that 60%-90% of T2D patients are overweight^[119-121]. Importantly, weight gain has been also described as a common side-effect of standard anti-T2D therapies. Therefore, weight management should be an important issue herein, as it not only may interfere with treatment, but may also increase the risk for the development of long-term complications (*e.g.*, cardiovascular disease)^[120,122]. However, the control of body weight and energy balance is a complex process, involving different tissues and pathways, such as gut, adipose tissue, pancreas and brain^[30,123]. For instance, gut-derived hormones (*e.g.*, GLP-1, PYY, ghrelin, cholecystokinin and oxyntomodulin) are known to play a major role in feeding regulation, at least partially by relaying to the CNS information on nutritional status^[123]. On the other hand, GLP-1's well known anorectic properties have been suggested to arise from the combination of both central and peripheral effects, *via* another gut-brain connection^[23,124]. More specifically, GLP-1-mediated satiating effect requires primarily the activation of peripheral GLP-1Rs located on vagal sensory afferents in the gut and in the hepatportal region of the liver; after the transmission of the metabolic signals into the brain c-fos expression is increased in NTS neurons^[124,125]. Once activated, these neurons act on brain neuronal circuits from the brainstem and several other areas involved in appetite control, where GLP-1R are also expressed. These include the ventral tegmental area (VTA), nucleus accumbens (NAc) and hypothalamus^[37,39,123]. In the hypothalamus, GLP-1R are highly expressed in the paraventricular nucleus, dorsomedial hypothalamus and the arcuate nucleus (ARC) [where they overlap with the pro-opiomelanocortin (POMC) neurons (anorexigenic neurons)], being present at a lesser extent in agouti-related peptide (AgRP)/NPY neurons (orexigenic

neurons)^[23,126,127]. At this respect, Seo *et al.*^[128] demonstrated that intracerebroventricular (icv) infusion of GLP-1 stimulates the synthesis of anorexigenic peptides (POMC and cocaine- and amphetamine-regulated transcript), and simultaneously decreased the synthesis of NPY and AgRP in rodents. Accordingly, while effects on hypothalamic and brainstem circuits may regulate food intake, the inhibitory effect of GLP-1 on the rewarding value of food appears to be regulated by the regions of VTA and NAc (mesolimbic reward system)^[123,124]. This hypothesis was supported by the finding that the administration of the GLP-1R antagonist, exendin 9-39, into the NAc promoted hyperphagia in rats^[129]. After hypothalamic and brainstem (dorsal motor nuclei) stimulation, efferent impulses depart from these brain areas to regulate the gastrointestinal tract, pancreas and other peripheral organs, by slowing gastric emptying and acid secretion, and decreasing gut motility, thereby further controlling the feeding behavior and glucose metabolism^[39,124]. Although such slowed gastric emptying may also arise from a direct activation of gastric inhibitory GLP-1Rs, this appears to be more visible with long-acting GLP-1RAs, particularly liraglutide (whose potent gastric emptying capacity has been increasingly described)^[104]. Importantly, the rate of gastric emptying may also influence stomach distension, thereby stimulating gastric mechanoreceptors, with the subsequent activation of the nodose ganglion (inferior ganglion of vagus nerve) that may *per se* culminate in the activation of NTS neurons to induce satiety^[123]. Besides this, a direct central action of GLP-1 in satiation signaling was also demonstrated by an inhibition of food intake by pathways independent of the vagal afferents^[130-132].

As T2D-associated postprandial hyperglycemia may be further aggravated by an accelerated gastric emptying, it is not surprising that GLP-1RAs drugs have been successful in attenuating postprandial blood glucose levels also by slowing gastric emptying^[133]. And although this is not considered the main mechanism by which these drugs regulate appetite and weight loss, it has been widely described that the incidence of gastrointestinal adverse events (such as nausea and vomiting, which albeit transient may affect nearly 50% of treated patients) is often accompanied by a decrease in food intake and body weight. Despite the limited knowledge on the mechanisms involved, it is plausible that a direct effect on gastrointestinal system and a central action producing conditioned taste aversion may play a role herein^[104,123,134].

In recent clinical trials, T2D patients treated with liraglutide (either as a monotherapy or in combination therapies) have shown a weight loss, in contrast with the weight gain associated with SU, TZD and insulin^[119,121]. More strikingly, both people with or without T2D, treated with clinically relevant doses of liraglutide for 20 to 30-wk presented significant reductions in body weight (from 1 to 3 kg)^[99,135].

Importantly herein, despite the increased GLP-1 levels in response to the amount of nutrient intake, obese people were shown to have lower basal GLP-1 levels^[136]. Accordingly, a negative relation was also established between body mass index (BMI) and GLP-1 oral stimulation^[17]. Moreover, the SCALE Maintenance study reported a loss of 5.9 kg in obese patients treated with 3.0 mg liraglutide for 56-wk vs placebo-treated ones^[137]. Interestingly, even a study case involving the Prader-Willi syndrome (PWS) (a rare genetic disorder characterized by an extreme and insatiable appetite that ultimately leads to morbid obesity), described that a 25-year-old female hyperglycemic PWS patient submitted to liraglutide therapy, not only improved her glycemic control, but was also able to control hyperphagia and to decrease plasma ghrelin levels and her BMI^[138].

From the above, such consistent weight loss observed with liraglutide and other GLP-1RAs, not only in T2D patients, but also in non-T2D people has aroused the interest for the use of GLP-1RAs as promising pharmacotherapies for weight management. To further potentiate this interest, we must bear in mind that, to date, only one medical therapy against obesity is approved in Europe, with most current anti-obesity pharmacological drugs having serious undesirable side effects^[135]. In this regard, the use of these drugs in obese people is currently being tested in several clinical trials^[139-141].

The neuroprotection in type 2 diabetic and degenerative brain: Insulin and liraglutide: (1) Pathological commonalities between T2D and neurodegenerative diseases: neuroinflammation and brain dysfunctional insulin/ insulin-like growth factor-1 (IGF-1).

Obesity, hypertension, dyslipidemia and T2D all constitute risk factors, particularly vascular, for cognitive dysfunction^[142]. Numerous experimental data indicated a decrease in cognitive function in T2D patients, which is often accompanied by impairments in memory, attention, intelligence, processing speed and executive functions, as well as by brain atrophy (particularly in cortical, subcortical and hippocampal areas) and white matter abnormalities^[143,144]. Interestingly, the well described cell loss that occurs in T2D pancreas appears to be accompanied by cell loss also in the CNS upon disease progression^[145,146]. Indeed, the pathological progression of T2D and, more specifically, its associated glucose toxicity, insufficient insulin action, neuroinflammation and general aging, amongst others, can slowly lead to nervous damage and may ultimately result in diabetic neuropathy and diabetic encephalopathy, thus increasing the risk for dementia in diabetes^[147-149]. In line with this, chronic inflammatory response in brain has been suggested to play a pivotal role in propagating T2D-mediated injury. This may probably occur *via* activation of microglia and other immune cells, with the subsequent

release of neurotoxic amounts of proinflammatory cytokines and free radicals and ultimately leading to neurodegeneration and brain disease upon T2D progression^[150-152]. Additionally, similarly to desensitization of IR from peripheral tissues of T2D patients, increasing evidence also point towards the impairment of brain insulin signaling in AD^[153,154]. As a consequence, it has been increasingly suggested that brain insulin resistance could be a potential link between T2D and AD^[95,151]. This hypothesis has been supported by numerous evidences, *e.g.*, (1) a decrease in IR expression in brains from AD patients; (2) an inverse correlation found between AD Braak stage and the levels of such receptors; (3) the accumulation of hyperphosphorylated tau (a neuropathological hallmark of AD) upon insulin signaling impairment and the consequent inhibition of GSK-3 β phosphorylation and of tau protein phosphatase 2A^[155,156]; (4) the increased A β accumulation and decreased insulin degrading enzyme (IDE) levels in AD patients displaying also brain insulin resistance^[157]; and (5) the memory enhancement and protection against A β toxicity in AD patients submitted to insulin therapy^[158]. These and other *in vivo* and *in vitro* findings have been also corroborated and extended by epidemiological studies showing an increased risk for T2D patients to develop AD and *vice versa*. According to a very recent study, T2D patients have a 65% increased risk to develop AD later in their life^[155], whereas others found that 85% of AD patients had either T2D or increased fasting glucose levels^[159].

Parkinson disease (PD) is the second most common neurodegenerative disorder after AD, the most common form of parkinsonism (motor syndrome) and, pathophysiologically, is the predominant form of synucleinopathies, which are characterized by an abnormal accumulation of α -synuclein (α -syn) protein^[160]. PD is characterized by the neuronal accumulation of Lewy bodies (containing deposits of α -syn) and the progressive loss of dopaminergic neurons (particularly in substantia nigra) that may culminate in multiple motor (tremor, rigidity, slowness of movement, and postural instability) and non-motor (autonomic dysfunction and neuropsychiatric problems) symptoms occurring throughout the course of the disease^[161]. Nowadays, an increasing amount of evidence points towards several similar biochemical changes between PD and T2D, leading to the idea that dysfunctional insulin signaling might be at the center of those alterations^[162]. Amongst such commonalities are, *e.g.*, the increased serum IGF-1 levels in PD patients^[163,164], both the insulin and IGF-1 resistance found in basal ganglia and substantia nigra from PD^[165,166], the impaired dopaminergic signaling observed in a rat model of T2D^[167], and the observation that activation of PI3K/Akt pathway was able to rescue α -syn toxicity *in vitro*^[168].

Stroke (or cerebrovascular accidents) is considered the third most common cause of death in

developed countries and may develop as a long-term complication in comorbid diseases, such as T2D^[169,170]. Indeed, epidemiological studies point towards a 2- to 6-fold increased risk of T2D patients to development of stroke, whereas stroke victims often present impaired glucose tolerance^[171,172]. It is well known that this disease arises from a disturbance in the blood supply to the brain (due to ischemia or hemorrhage), thus resulting in neurological deficits and a loss of brain function^[173]. Interestingly, stroke has been regularly associated with increased neuroinflammation markers^[174], thereby rendering GLP-1 analogues an appealing therapeutic strategy, as we will discuss later.

Strikingly, such correlation between T2D, AD, PD and stroke appears to be also applicable to a wide range of other neurodegenerative diseases, including vascular dementia or Huntington disease (HD)^[95,170], thereby suggesting that T2D is a risk factor for at least some of these brain pathologies.

(2) Brain insulin/IGF-1 as metabolic and body weight regulators.

As it is well known, the primary regulators of glucose homeostasis and metabolism involve insulin/IGF-1 signaling pathways responsible for the control of both peripheral signals and CNS effects^[155]. Although most of the brain insulin is primarily secreted by the pancreas (whereas IGF-1 comes from the liver), being then transported by cerebrospinal fluid (CSF) and crossing the BBB into the brain, numerous evidence also points towards their local synthesis (particularly in brain cortex, olfactory bulb, hippocampus, hypothalamus, and amygdala)^[175]. Once bound to their receptors, the insulin and IGF-1 receptors (IR and IGF-1R, respectively) that are ubiquitously expressed in brain (particularly neurons), many physiological functions are activated, such as neuronal outgrowth and survival, enhancement of attention, memory formation and cognition, food intake and weight maintenance, synaptic protection and sexual regulation^[170,176,177]. Of these, food intake and energy homeostasis are the most directly related also with GLP-1R-mediated signaling, being mediated by a specialized group of hypothalamic glucosensing neurons that appear to be able to detect and respond to even small variations in glycemia^[130]. Such anorexigenic effect of insulin signaling depends on a strict control of the hypothalamic PI3K/protein kinase B (Akt) signaling pathway, on the inhibition of NPY and AgRP expression and on the induction of POMC neurons^[178,179].

From the above, it is not surprising that changes in body weight, hyperinsulinemia and insulin resistance may arise from alterations in the homeostatic balance, thus culminating in injurious effects on the organism^[180,181]. Indeed, hyperinsulinemia has been widely associated to a downregulation of insulin transport across the BBB, thus decreasing its uptake and levels in the brain, as well as the subsequent IR activity, ultimately leading to a brain insulin resistance^[182,183]. Moreover, insulin resistance and

subsequent impairment in glucose supply, transport and utilization may lead to glucose dysmetabolism that may be also accompanied by a decrease in cerebral flow and damaging effects to intracellular organelles, including mitochondria^[184-186]. As brain mitochondria are particularly susceptible to metabolic impairment, situations like brain insulin resistance may lead to dysfunctional respiratory chain and phosphorylation system, and alterations in mitochondrial dynamics and biogenesis that may significantly compromise ATP production and mitochondrial membrane potential. As a result, mitochondrial permeability transition pore may open and ultimately activate apoptotic cell death^[184]. Thus, defects in brain insulin/IGF-1 signaling may raise a deleterious vicious cycle involving metabolic impairment and mitochondrial dysfunction, that in turn generate a wide range of harmful effects (e.g., increased oxidative stress, advanced glycation end-products formation, inflammatory response, excitatory neurotransmitter release)^[175,187]. Altogether, these alterations can be responsible for a decrease in neuronal function and survival, and impaired synaptic activity and plasticity, that may be also accompanied by a decrease in neurogenesis, leading to impaired memory formation and storage, and learning potential, culminating in cognitive decline^[188]. To further intricate this subject, as we detailed above, both T2D and neurodegenerative diseases share several common features that together with the neuroprotective effects demonstrated by many of the already marketed anti-T2D therapeutic agents have potentiated the recent investigations worldwide on the potential beneficial role of such drugs also in the context of neurodegeneration^[96,189].

(3) Restoration of insulin/IGF-1 action as a potential therapeutic target in neurodegenerative diseases: what can we count on in a near future?

Preclinical studies involving insulin and IGF-1 to treat animal models of neurodegenerative diseases revealed promising results. In this regard, our group showed that insulin was able to protect against oxidative stress and a decline in mitochondrial oxidative phosphorylation efficiency induced by the amyloid β -peptide (A β , one of the main players in AD pathology) in streptozotocin (STZ)-induced type 1 diabetic rats^[190]. Similarly, Quesada *et al.*^[191] reported that IGF-1 treatment significantly increases tyrosine hydroxylase (TH) positive neurons and improves motor performance of the medial forebrain bundle 6-hydroxydopamine (6-OHDA) lesion rat model of PD, in a PI-3K/Akt-dependent manner. Additionally, we and others showed that by increasing blood insulin and brain IGF-1 levels, the *in vivo* peripheral administration of IGF-1 was not only able to protect against peripheral glucose intolerance^[192], but also to rescue motor deficits and brain glucose dysmetabolism upon HD^[193]. Molecularly, these observations were further supported and extended by a recent study using an *in vitro* model of human HD, in which insulin- and IGF-1-mediated

PI3K/Akt activation was able to improve mitochondrial function and decrease mitochondrial reactive oxygen species (ROS) formation^[194].

Even though insulin therapy can be very useful to prevent or slow the progression of long-term complications of diabetes and others pathologies, as diseases progress not only the hormone's beneficial effects may be lost (including glycemic control), but also it may increase the risk for severe hypoglycemic episodes, which have been also associated with increased brain damage. As a result this may further increase neuronal and cognitive dysfunction^[195]. Alternatively, the use of insulin sensitizers (another commonly prescribed class of anti-T2D drugs, whose most widely used member is metformin, a first line pharmacological approach against the pathology) could provide a reliable therapeutic alternative also in the context of neurodegenerative diseases^[154,196]. Indeed, metformin was demonstrated to protect the brains of the non-obese T2D Goto-Kakizaki rat models against oxidative imbalance, by decreasing oxidative stress markers and increasing antioxidant defenses^[197]. Additionally, Gupta *et al.*^[198] reported that metformin ameliorates neuronal insulin resistance and AD-associated characteristics in an *in vitro* model of the so-called "type 3 diabetes". Nevertheless, we must bear in mind that metformin presents several controversial side effects, and some authors suggested that metformin therapy and subsequent AMPK activation may even exacerbate previously existing impairments^[199-201].

From all the above, and given also the previously mentioned actions in the brain, the native GLP-1 hormone would be considered the "almost perfect" alternative to restore insulin action in CNS, either in T2D, neurodegenerative diseases or simply in normal aging. And this has been widely corroborated by its rapid capacity to cross the BBB when injected peripherally, acting as a growth factor in brain, whereby the hormone has been shown to stimulate the metabolism, the expression of genes associated with cell growth, repair and replacement and to protect against oxidative injury, neuroinflammatory response and apoptosis, thus exerting beneficial effects in neuronal health and cognition^[155]. However, given the previously described limited half-life of the native GLP-1, recent research interests have been mostly focused on the neuroprotective potential of DPP-4 inhibitors and GLP-1RAs.

Regarding DPP-4 inhibitors, their beneficial roles in CNS have been intensively analyzed and appear to constitute promising candidates for the treatment of CNS disorders. In this regard, sitagliptin (the first DPP-4 inhibitor approved for T2D treatment), has been recently shown to positively affect working and reference memories, and to increase the hypothalamic acetylcholine content and adiponectin receptor 1 expression in T2D Sprague-Dawley rats^[202]. Additionally, vildagliptin (another DPP-4 inhibitor)-

mediated decrease in A β , tau protein phosphorylation and neuroinflammatory markers levels were also accompanied by an amelioration in memory retention capacity in a STZ-induced AD rat model^[203].

On the other hand, and similarly to the native GLP-1, liraglutide and the other synthetic GLP-1RAs are able to readily cross the BBB, reaching the brain almost intact and thereby exerting neuroprotective effects^[204]. Therefore, it is not surprising that most of the preclinical studies that reported such protective effects were performed in T2D, AD, PD and also in stroke models^[205]. For instance, liraglutide has been increasingly suggested to prevent or attenuate T2D-associated neuronal and cognitive deficits^[206]. Although the underlying mechanisms remain unclear, Hamilton *et al.*^[207] proposed that such protection could rely on the activation of stem cells and neuronal progenitor cells to counteract T2D-induced neurodegeneration. Indeed, these authors reported that liraglutide was able to promote neurogenesis [as given by the increase in the number of 5'-bromo-2'-deoxyuridine (BrdU)-positive cells dividing progenitor cells and doublecortin-positive young neurons] in the dentate gyrus of three different types of obese T2D mouse models. Additionally, other authors observed that liraglutide administration in 2 mo-old pre-diabetic UCD-T2D rats (a polygenic obese model of T2D) reduced energy intake and body weight, improved insulin sensitivity and reduced triglycerides, thus delaying diabetes onset by about 4 mo compared to controls^[208,209]. Moreover, these authors reported that liraglutide normalized brain metabolic homeostasis (as given by TFAM, SIRT1, and AMPK phosphorylation), decreased hippocampal lipid oxidation (upon determination of 4-hydroxynonenal levels), improved brain mitochondrial regulation (*via* PGC-1 α) and preserved synaptic plasticity (as given by the BDNF-TrkB signaling) in the UCD-T2D rats over the disease progression^[208,209]. These results appear to be in line with previous evidences that GLP-1R activation may be involved in memory and learning^[210]. In fact, During *et al.*^[211] demonstrated that GLP-1R activation was correlated with an enhancement of associative and spatial learning, as GLP-1R-deficient mice exhibited a learning deficit phenotype. Strikingly, liraglutide (25 nmol/kg, once daily *i.p.*, for 30 d) has been also demonstrating potent anti-inflammatory effects in brains from a mouse model irradiated with 6Gy (X-ray, a model of chronic inflammation), as given by a reduction in microglia activation in cortex and dentate gyrus, and a decrease in mean astrocyte load after irradiation (by massively reducing the total GFAP load), in pro-inflammatory cytokines (IL-6, IL-12p70, IL-1 β) and in total nitrite levels^[212]. Moreover, liraglutide was able to decrease cerebral edema, and to ameliorate both neurobehavioral deficits (in modified Garcia test and wire hanging test) and inflammatory parameters (given by an increased brain phosphorylated AMPK and reduced neutrophil infiltration) in an intracerebral hemorrhage-induced

brain injury mouse model (strongly associated with inflammatory mechanisms)^[47].

Therefore, given also the pathological commonalities between T2D and AD, it is plausible that a therapeutic approach involving incretin analogues might be beneficial against the cognitive deficits occurring in AD.

The neuroprotective potential of liraglutide in AD has been increasingly analyzed. In one of the first studies, McClean *et al.*^[213] reported that liraglutide significantly affects brain neurotransmission and modulates synaptic plasticity by enhancing long-term potentiation (LTP) mechanisms. More recently, Han *et al.*^[214] observed that pre-treatment with liraglutide dose-dependently protected against the impairment in learning and memory (as given by the dysfunctional spatial memory and hippocampal late-phase LTP) induced by a bilateral intrahippocampal injection of A β in adult male Sprague-Dawley rats, suggesting a possible preventive strategy against the development of AD in T2D patients. Strikingly, McClean *et al.*^[215], Long-Smith *et al.*^[216] and McClean *et al.*^[217] described that once daily intraperitoneally (*i.p.*)-injected liraglutide for 8 wk was able to reduce brain amyloid plaque formation by 30%-50%, as well as the levels of soluble amyloid oligomers (by 25%) and amyloid precursor protein (APP) in the APP/PS1 AD mouse model (which expresses the human Swedish mutated form of APP and a mutated human form of presenilin-1). Additionally, these authors observed that chronic liraglutide administration blunted the A β -associated changes in neuronal IR localization and IRS-1 phosphorylation at serine 616 (a key marker of insulin resistance), increased IDE levels, reduced microglia activation by up 50%, decreased the A β -associated astrocytic activation, enhanced LTP and synaptophysin levels, and increased hippocampal neuronal progenitor cells, thus indicating a protection against neuroinflammation, synapse loss and deterioration of synaptic plasticity that may culminate in the restoration of memory function, particularly in object recognition and water maze tasks. Interestingly, Parthasarathy *et al.*^[218] also reported that chronic treatment with liraglutide-mediated increase in neurogenesis in an AD mouse model was accompanied by an increased differentiation of newly generated cells into mature neurons. Concerning abnormal tau protein phosphorylation (another neuropathological hallmark of AD), liraglutide treatment has been able to reduce both brain tau protein phosphorylation at different residues (Ser199, Ser202, and Ser396) and phospho-tau immunoreactivity in T2D rats, which also displayed a reduction of HOMA-IR close to control levels and a normalization of brain insulin signaling (as given by the activation of Akt and subsequent inhibition of GSK-3 β at Ser9)^[219]. Altogether, these results strongly suggest that liraglutide may be able to prevent and/or reverse the major pathological hallmarks of AD. In line with this, two clinical trials are

underway to assess the effects of liraglutide in AD. In a small randomized clinical trial at the University of Aarhus (Denmark)^[220], 17 early-onset AD patients were treated with liraglutide (1.8 mg, once a day, 26 wk) and the already available results point towards an effect of liraglutide on cerebral amyloid deposits in the brain (assessed by Pittsburgh compound B PET scan), but more novelties are expected soon. The second trial, at the Imperial College of London and launched in June 2013^[221], is a large-scale Phase 2 clinical trial involving 206 early AD patients treated with liraglutide (1.8 mg/d, for 12 mo), that aims to use fluorodeoxyglucose-PET scan to detect changes in cerebral glucose metabolic rate, microglia activation, CSF markers, and amyloid and tau levels, to correlate with eventual Alzheimer Disease Assessment Scale Executive (ADAS) and Magnetic resonance imaging (MRI) changes. Interestingly, another ongoing, Phase 2, randomized, double-blind clinical trial sponsored by the National Institute on Aging and aiming at analyzing the action of the long-acting GLP-1RA exendin-4 (Ex-4) in AD^[222] will end by December 2015 and involves the evaluation of patients' performance in the Clinical Dementia Rating scale sum-of-boxes, ADAS (cognitive sub-scale), behavior and cognition, changes on structural and functional MRI and magnetic resonance spectroscopy, hormonal and metabolic changes, as well as alterations in CSF and plasma AD biomarkers.

Regarding the protective potential of GLP-1 analogues against PD, evidences are still relatively scarce and mostly relying on preclinical assessing the role Ex-4 in PD. Upon a 3 wk, twice daily *i.p.* administration of Ex-4, it was observed a significant increase in the number of TH-immunoreactive neurons and of dopamine levels that, together with a reduction of amphetamine-induced rotations in the 6-OHDA rat model of PD, suggest that Ex-4 may have beneficial cellular and functional properties in this model of PD^[223,224]. Similar effects were also reported in another rat model of PD involving a lipopolysaccharide-induced lesion to substantia nigra^[224]. Moreover, Li *et al.*^[225] observed that Ex-4 protected against the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, another PD-like phenotype inducer)-associated loss of nigral neurons and striatal dopaminergic fibers, preserved dopamine levels and improved motor function. With all this in mind, in a recent randomized Phase 2 clinical trial, Ex-4 safety and efficacy was evaluated in 21 PD patients, which received 5 mg b.i.d for 1 mo or 10 mg b.i.d for 11 mo^[226]. The main observations herein included a good tolerability to Ex-4, improved motor scores [from the Unified Parkinson's Disease Rating Scale (MDS-UPDRS)] at 12 mo (a mean improvement of 2.7 vs a 2.2 point decline in control group) and cognitive efficiency (using the Mattis dementia rating scale 2) (a mean improvement of 2.8 vs a 3.5 point worsening in control group)^[226].

Given the previously mentioned increasing interest on the potential therapeutic use of GLP-1 analogues

Figure 2 Overview of the main pathways induced by a peripheral administration of liraglutide in neurons. When liraglutide enters the body, it will move through the bloodstream and activate glucagon-like peptide-1 receptors (GLP-1R) widely expressed throughout tissues. In pancreas, GLP-1R activation exert insulinotropic effects, thus increasing insulin levels, which may migrate into the brain, crossing the blood-brain-barrier (BBB) and will activate insulin receptor (IR) or insulin-like growth factor-1 receptors (IGF-1R) expressed in neurons. Liraglutide by itself may also cross the BBB and activate GLP-1R present in the brain. Neuronal IR/IGF-1R and GLP-1R mediated intracellular signaling transduction pathways show several overlapping downstream targets. Activation of these pathways may mediate several biological responses in the central nervous system, such as control of cell metabolism and energy homeostasis, inhibition of apoptosis, reduction of inflammatory responses, modulation of synaptic neurotransmission, regulation of gene transcription, cell growth, synapse growth, cell repair and regeneration, facilitation of long-term potentiation and memory formation, among others. AC: Adenyl cyclase; Akt: Protein kinase B; Bcl-2: B-cell lymphoma 2; BAD: (Bcl-2) antagonist of death; Bcl-XL: B-cell lymphoma extra-large; Ca²⁺: Calcium; cAMP: Cyclic adenosine monophosphate; CREB: cAMP response element-binding protein; Foxo: Forkhead box O; GLUT: Glucose transporter; GRB2/SOS: Growth factor receptor-bound protein 2/son of sevenless; GSK-3 β : Glycogen synthase 3 beta; GTP: Guanosine triphosphate; IRS-1: Insulin receptor substrate 1; IRS-2: Insulin receptor substrate 2; JNK: C-Jun N-terminal kinase; MAPK: Mitogen associated protein kinase; mTOR: Mammalian target of rapamycin; NF- κ B: Nuclear factor kappa-light-chain-enhancer of activated B cells; PI3K: Phosphoinositide 3-kinase; PKA: Protein kinase A; Shc: Src homology-2/ α -collagen-related protein.

for stroke treatment, in a recent study Sato *et al.*^[227] demonstrated that liraglutide was able to ameliorate behavioral scores, to reduce brain infarct volumes at 24 h, to decrease the levels of ROS derivatives and to upregulate vascular endothelial growth factor in brain cortex of a rat model for stroke (90 min transient middle cerebral artery occlusion and 1 h reperfusion). Similarly, neuroprotective effects upon stroke and ischemia were also reported for Ex-4^[225,228,229].

From the above, as exenatide and liraglutide are the currently marketed GLP-1RAs for the treatment of T2D, and since preclinical studies have demonstrated remarkable and consistent neuroprotective effects, some clinical trials are underway to assess the effect and efficacy of Ex-4 and liraglutide in AD and PD patients. And although the underlying molecular mechanisms (particularly those focused on the liraglutide's neuroprotective and anti-inflammatory potential) remain mostly unknown, a recent study on human neurons shed some light on this issue. Indeed,

Sharma *et al.*^[230] suggested that liraglutide-mediated neuroprotection may involve the PI3K/Akt pathway and its subsequent regulation of mammalian target of rapamycin; however, it is also plausible that GLP-1R activation under such circumstances may also activate the alternative extracellular signal-regulated kinase signaling. Traditionally, liraglutide-mediated activation of GLP-1R may further activate adenyl cyclase and increase cAMP content, leading to the subsequent activation of PKA and CREB, and ultimately contributing to cell survival, inhibition of apoptosis, activation of Ca²⁺ channels, cell growth, repair and regeneration, as well as regulation of translation/transcription processes in response to stress (Figure 2).

CONCLUSION

As the quote "the key to one's heart is through his stomach", the gut hormone GLP-1 (and, more specifically, its long-lasting synthetic analogs) may

hold the key for promising therapeutic effects against diseases affecting such different tissues, as the heart, pancreas, kidneys, liver, brain, and all the other tissues where we can find GLP-1Rs. It is plausible that this hormone, mainly secreted from L-cells, may exert its influence on the activities of several organs *via* complex axis involving the gut. And despite the still limited knowledge on this matter, we believe that the clarification of the molecular mechanisms involved herein might be of the outmost relevance in the context of the promising preventive/therapeutic potential of the long-acting GLP-1RAs against the development of long-term complications of several diseases. As a novel GLP-1RA and already marketed anti-T2D drug, and given the strong association between T2D and numerous neurodegenerative pathologies, liraglutide has been extensively investigated for such purpose in the recent years and has shown remarkable effects, not only peripherally, but also in CNS upon a wide range of diseases, including T2D, AD, PD and stroke. As liraglutide's positive effects in brain, we emphasize its promotion of neuronal survival, protection from apoptosis, regulation of neuroinflammatory response and modulation of stress response, thereby suggesting a strong neuroprotective potential. And this might be of a pivotal relevance, in our ever increasingly aged world and societies, characterized by an exponential increase in age-related diseases that still lack effective (or at least with a minimum of serious side-effects) preventive or therapeutic approaches, thereby posing an enormous socio-economic burden and urging the seek for an effective cure or delay in such diseases. Thus, the limited preclinical and clinical findings already available strongly suggest that liraglutide may emerge as a potential mono- or combined therapy against most of the common diseases afflicting the brain.

Abstract

A complex interaction of genetic and environmental factors can trigger the immune-mediated mechanism responsible for type 1 diabetes mellitus (T1DM) establishment. Environmental factors may initiate and possibly sustain, accelerate, or retard damage to β -cells. The role of environmental factors in this process has been exhaustively studied and viruses are among the most probable ones, especially enteroviruses. Improvements in *enterovirus* detection methods

and randomized studies with patient follow-up have confirmed the importance of *human enterovirus* in the pathogenesis of T1DM. The genetic risk of T1DM and particular innate and acquired immune responses to enterovirus infection contribute to a tolerance to T1DM-related autoantigens. However, the frequency, mechanisms, and pathways of virally induced autoimmunity and β -cell destruction in T1DM remain to be determined. It is difficult to investigate the role of enterovirus infection in T1DM because of several concomitant mechanisms by which the virus damages pancreatic β -cells, which, consequently, may lead to T1DM establishment. Advances in molecular and genomic studies may facilitate the identification of pathways at earlier stages of autoimmunity when preventive and therapeutic approaches may be more effective.

Key words: Virus; *Enterovirus*; *Coxsackievirus*; Type 1 diabetes mellitus; Auto-immune diabetes; Pathogenesis

Core tip: A complex interaction of genetic and environmental factors can trigger the immune-mediated mechanism responsible for type 1 diabetes mellitus (T1DM) establishment. The role of environmental factors in this process has been exhaustively studied and viruses are among the most probable ones, especially enteroviruses. Improvements in enterovirus detection methods and randomized studies with patient follow-up have confirmed the importance of these viruses in the pathogenesis of T1DM. However the frequency of viruses induces autoimmunity or β -cell destruction and the mechanisms and pathways how they increment the autoimmunity in T1DM still to be determined. Here, we review these mechanisms and all evolution in enterovirus studies and T1DM. Advances in molecular and genomic studies may facilitate the identification of pathways at earlier stages of autoimmunity when preventive and therapeutic approaches may be more effective.

INTRODUCTION

Type 1 diabetes mellitus (T1DM) is a chronic endocrine disorder that is caused by the progressive destruction of pancreatic β -cells, which results in insulin deficiency. A complex interaction between genetic and environmental factors may trigger this immune-mediated mechanism^[1]. The most important T1DM susceptibility genes are located in the *HLA-DR* and *DQ* loci^[2]. However, T1DM is not induced by genetic susceptibility alone, and environmental factors may initiate and possibly sustain, accelerate, or retard the damage to β -cells^[3,4]. The role of environmental factors in the development of T1DM has been suggested because of the seasonal variation in the incidence of T1DM^[5] and the conspicuous variation in the incidence of T1DM between different countries^[6,7]. Immigrants often acquire a level of risk for developing T1DM that is typical for their new home country^[8]. In addition, the incidence of T1DM has rapidly increased during the last decade^[9-11] despite the increased prevalence of protector genes for T1DM and a concomitant decrease in high-risk genes^[12,13]. Changes in the environment and how individuals respond to these variations have been indicated as being responsible for this increase in T1DM.

The following environmental factors have been suspected to contribute to the development of T1DM: dietary factors, such as cow's milk proteins^[14,15], vitamin D deficiency^[16,17] and gluten^[18]; pancreatic toxins^[19,20], such as streptozotocin and nitrites; psychological factors^[21]; and viral infection factors^[22]. Viruses are among the most probable environmental factors in the development of T1DM, including rubella virus^[23], rotavirus^[24], mumps virus, cytomegalovirus and enteroviruses^[25-27]. Recent studies using different approaches have suggested that the most promising candidates for viral triggers with clinically significant associations with T1DM development are enteroviruses^[28-31].

However, it has been difficult to establish viruses as the inducers of T1DM. First, the link between infections and autoimmunity is multifactorial^[32]. Several infections may act together or in an appropriate temporal sequence to trigger clinical autoimmunity. Furthermore, the particular virus that is involved in triggering T1DM may be hard to detect systemically or in the target organ after the initiation of the autoimmune response^[33]. Second, the long duration of time between the possible triggering effect and the onset of the clinical symptoms of diabetes makes it difficult to establish a direct relationship. Third, T1DM

patients and healthy individuals undergo multiple viral infections during their lifetime, and several of these viruses may even protect individuals from autoimmune disease^[34,35]. Fourth, the "fertile field hypothesis" suggests that viral infections render tissue a "fertile ground" for autoaggressive lymphocytes to invade and expand, which leads to T1DM^[36,37]. Therefore, the activation of the immune system may have a role in the pathogenesis of this disease^[38].

In this review, the potential mechanisms of enterovirus infections in the establishment of T1DM will be discussed.

ENTEROVIRUSES

The *Enterovirus* genus of the *Picornaviridae* family consists of small, non-enveloped, positive, single-strand RNA viruses, including *polio viruses* (PVs), *Coxsackie viruses* A and B (CVA and CVB), *echoviruses* (EVs) and new enteroviruses. Three different PVs (types 1-3) and more than 60 non-polio enteroviruses cause disease in humans. These human *enteroviruses* (HEVs) include 23 CVAs (types 1-24; type 23 does not exist), 6 CVBs (types 1-6), 28 EVs (types 1-33; types 10, 22, 23 and 28 do not exist) and 4 other enteroviruses (EV 68-71)^[39].

Enterovirus infections are transmitted from person to person by fecal-oral and, less commonly, respiratory routes, which indicates that these infections usually begin in the gastrointestinal or respiratory mucosa. After replicating in the mucosa, the virus spreads through the lymphatic system into the circulation after a brief viremic phase at secondary replication sites, which determines the types of symptoms^[40].

Most *enterovirus* infections are asymptomatic or produce subclinical or mild symptoms, such as nonspecific febrile disease, muscle pain, sore throat, gastrointestinal distress, headache and abdominal discomfort. However, a wide variety of symptoms that affect various organs may occur, such as hand, foot and mouth disease; acute hemorrhagic conjunctivitis; aseptic meningitis; myocarditis; severe neonatal sepsis-like disease; and acute flaccid paralysis^[41].

Independent of location and symptom intensity, viral replication is continuous in the lymphatic tissue. The incubation period varies from 2-30 d, and enteroviruses can be detected in various types of biological specimens from humans. Enteroviruses may be detected most readily in stools for up to 3-4 wk but rarely more than 2-3 mo. Serologic diagnoses in the acute phase are difficult because most cases are asymptomatic^[42].

Systemic *enterovirus* infection may lead to viral dissemination to other target organs, and *enterovirus* RNA and protein may be detected in intestinal, heart or pancreatic tissues by reverse transcription-polymerase chain reaction (RT-PCR), immunohistochemistry or *in situ* hybridization^[43].

ASSOCIATION BETWEEN ENTEROVIRUSES AND T1DM: A HISTORICAL OVERVIEW

There are convincing experimental results for the role of *EV* infection in T1DM development using mouse models^[44-46], and some mechanisms of beta cell damage have been proposed based on experiments with non-obese diabetic (NOD) mice^[47].

In humans, *enterovirus* infection has been suspected to be involved in the pathogenesis of T1DM since the late 1960s, when Gamble *et al.*^[45] described a seasonal variation in the incidence of T1DM following *enterovirus* infection^[48] and demonstrated that the frequency of neutralizing antibodies against the *CVB4* serotype was increased in newly diagnosed T1DM patients^[49]. A *CVB4* virus was subsequently isolated from the pancreas of a child who died from diabetic ketoacidosis, and this virus strain caused diabetes in a susceptible mouse strain^[50]. However, subsequent studies failed to replicate this result.

In many serological studies, *enterovirus* antibodies have been more prevalent in diabetic patients than in healthy children^[51]. However, critics have questioned these data because control patients were not matched for HLA risk alleles, and the detection methods for *enterovirus* cannot differentiate between HEV types. Several reports have not presented the same outcome, and the role of *enterovirus* infection in the development of T1DM has remained controversial^[52].

Oikarinen *et al.*^[53] analyzed the role of past exposure to different *CVB* serotypes by measuring neutralizing antibodies specifically against each of the six serotypes in 249 children who were newly diagnosed with T1DM and in 249 control subjects from five European countries. Antibodies against *CVB1* were more frequently detected in diabetic children than in the control group. This study suggests that coxsackie virus B may include a diabetogenic virus group and indicates that *CVB1* may be a member of this group. However, because of the cross-sectional study design, the findings do not support a causality link between *enterovirus* infection and T1DM. Nevertheless, the same virus type has recently been observed to increase the risk of T1DM in the prospective Diabetes Prediction and Prevention (DIPP) study as a potential initiator of the β -cell-damaging process^[54].

Much attention has been paid to the possible immunological cross-reactivity that is induced by a homology sequence in the 2C non-structural *CVB* protein and a principal diabetes autoantigen glutamic acid decarboxylase (GAD65), which share a common amino acid sequence^[55,56]. GAD65 is an important target antigen in the pathogenic process of diabetes. In mice, the insulinitis establishment coincides with GAD65 specific reactivity, and tolerance induction to GAD65 can prevent the disease^[57,58]. Humoral and cellular responses have been detected against GAD65 before

the onset of clinical diabetes^[59], and auto antibodies are positive several years before diagnosis^[60]. The importance of this homology in T1DM pathogenesis is supported by data showing that T cells that respond to this sequence are present both in NOD mice and T1DM patients^[61,62]. This mechanism will be discussed below.

In more recent studies, RT-PCR has been used to detect *CVB*-specific RNA in the sera of newly diagnosed T1DM patients^[63]. Yeung *et al.*^[64] conducted a useful systematic review and meta-analysis of observational molecular studies on the detection of *enterovirus* in T1DM patients. Observational case-control studies measured *enterovirus* RNA or viral protein in the blood, stool or tissue of prediabetic and diabetic patients by molecular methods. The 24 selected papers and two abstracts demonstrated a clinically significant association between *enterovirus* infection and autoimmunity/T1DM (odds ratios ranging from 5.5 to 17.4).

Human studies on the relationship between *enterovirus* and T1DM have been retrospective and based on the detection of virus infections in newly diagnosed T1DM patients. However, this study design does not allow for the evaluation of possible causal associations. To overcome this issue, several prospective studies have been performed to assess the role of *CVB* and other *HEV* infections in the induction and acceleration of T1DM and islet autoimmunity. These studies include the Childhood Diabetes in Finland (DiMe) study^[65,66], the DIPP study^[67,68], and the Trial to Reduce T1DM in the Genetically at Risk (TRIGR)^[69], which were conducted in Finland; the BABYDIAB^[70] and Babydiat^[71] studies in Germany; the Diabetes and Autoimmunity Study in the Young (DAISY)^[72,73] in Colorado, United States; and the Environmental Triggers of Type 1 Diabetes (MIDIA)^[74] in Norway. These studies included children with an increased risk of T1DM, which was defined as a first-degree family history of T1DM, HLA susceptibility genes or both. The sampling frequency and the method of *enterovirus* detection varied between these studies (Table 1).

A positive association between *EV* infections and a rapid progression from autoimmunity to clinical T1DM was observed both in the DiMe study as well as in the DAISY follow-up study (human longitudinal studies). However, there was no agreement in the studies' conclusions between *EV* infection and islet autoimmunity development.

The results of these prospective studies may be controversial due to heterogeneity in the study design, the small number of patients in each study and the low sensitivity of the methods used to detect *enterovirus* infection. Another important confounding factor is the frequency of sampling because *EV* RNA can rarely be found continuously in stool samples for more than 3 mo, and it is found for a shorter time in serum samples^[75]. The studies that indicated a positive association between *enterovirus* infection and T1DM used smaller sampling intervals and a wider panel

Table 1 Longitudinal studies evaluating the association between enterovirus infection and autoimmunity/type 1 diabetes mellitus

Study	Enterovirus infection and autoimmunity/T1DM	Cases/controls	Infection diagnose method	End point	Ref.
DiMe	+	22/110	Antibody assays	Diabetes	[65]

of *enterovirus* assays than the studies that indicated no association. Similarly, most *enterovirus* infections are asymptomatic, and a negative result for the virus at diagnosis does not mean that its contribution is meaningless.

The prevalence of *EV* infections varies in populations, and independent of this, the vast majority of people infected will not develop autoimmunity or T1DM, as illustrated by Sarmineto^[76]. This study showed that in Cubans that were exposed to an echovirus epidemic, a large number of patients seroconverted to islet autoantibody positivity, but T1DM prevalence has not increased. It remains to be determined how often enteroviruses induce β cell damage, autoimmunity development and clinical diabetes.

ENTEROVIRUSES AND THE DEVELOPMENT OF T1DM

Hygiene hypothesis

The hygiene hypothesis was first proposed by Strachan^[77] to explain the increasing rates of asthma in highly developed countries, suggesting that contacts with a high number of infections early in life could properly modulate the adaptive immune system, and the significant changes in human living standards and the improvement of sanitary conditions meant that people had less exposure to infection, favoring an impaired immune response to environmental triggers^[35,78]. This concept may be applied to many autoimmune diseases, but it does not explain all of these diseases, as there is a complex interplay between environmental exposure, the host, and other confounding variants^[78-80].

Exposure to HEV, which is typically transmitted through a fecal-oral pathway, becomes less common as individual age, and infection with *HEV* later in life could result in an unbalanced immune response. In other words, where *enterovirus* infections are frequent,

children develop an efficient immune response to these viruses, and when they are exposed in the future, the effects are not exacerbated or harmful. This may explain the rising worldwide incidence of T1DM over the last decade, mainly in developed societies where *enterovirus* infections are less prevalent^[81-83].

The age when individuals are first exposed to enteroviruses may be critical in determining how the virus interacts with the host immune system (as recently demonstrated in a NOD mouse model^[84]) and ultimately, whether T1DM develops. *Enterovirus* infections during the first year of life have been correlated with protection from the onset of T1DM^[85]. A study of *enterovirus*-specific cellular immunity in Estonian and Finnish children at 9 mo of age found that *enterovirus* infections were inversely correlated with T1DM risk^[86]. Estonian children who were immunized with live-attenuated *PV* at early ages had stronger T cell responses to *CVB4* and *PV* type 1 compared with Finnish children who were immunized with inactivated *PV*. This stronger T cell immunity led to higher cross-reactivity with other *enterovirus* serotypes. Despite the higher incidence of *enterovirus* infections in Estonia, the incidence of T1DM is five times lower than that in Finland^[87]. In addition, the frequency of T1DM is higher in the firstborns of multiplex families than in younger children, which could be explained by a lower exposure of firstborns than siblings to infections^[88]. Therefore, viral infections during childhood may protect individuals from developing T1DM or may delay disease onset.

Implication of HEV in T1DM

CVB infections may have two different roles in the etiology of T1DM in humans: protective or triggering^[89]. These proposed models are based on observations that *CVBs* do not replicate productively in healthy, non-inflamed pancreatic islets from NOD mice^[90]. In individuals who are genetically predisposed to T1DM but not to insulinitis, *CVB* infection may induce a protective

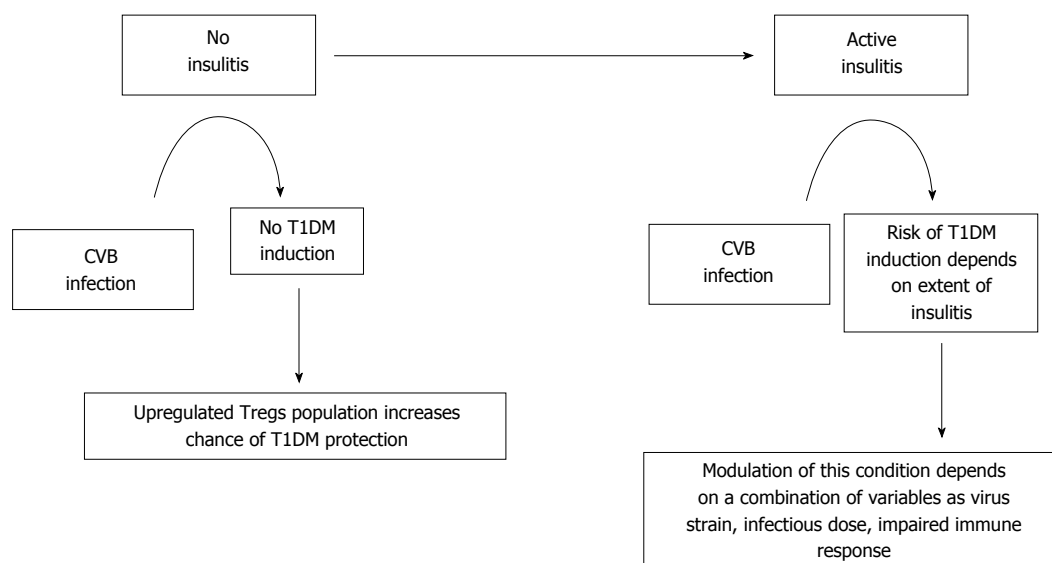

Figure 1 Enterovirus infection pathways on type 1 diabetes mellitus pathogenesis (adapted from Tracy *et al*^[47]). T1DM: Type 1 diabetes mellitus; CVB: Coxsackie viruses.

Treg population that prevents the development of pathogenic autoimmune islet-specific T cells, thereby reducing the risk of autoimmune T1DM. However, in the absence of a protective Treg population, the extent of insulinitis tends to increase with the depletion of β -cells and results in an elevated risk of developing autoimmune diabetes. The likelihood of developing T1DM requires a basic condition of genetic predisposal with the presence of anti-islet autoimmunity due to a particular virus strain and infectious dose in addition to extensive insulinitis at the time of infection. A significant number of β -cells must be destroyed before the adaptive immune system may be activated. Therefore, depending on the host environment during infection, the virus may either induce protection against autoimmune T1DM onset or, with significant insulinitis, may induce T1DM development (Figure 1)^[89].

Autoimmune islet inflammation may facilitate productive virus replication and induce β -cell damage^[47].

Roles of enteroviruses in β -cell injury mechanisms that lead to the development of T1DM

Several hypotheses have been proposed to explain how enteroviruses affect T1DM (Figure 2)^[28,40,89]. The mechanisms differ for each *enterovirus*; however, their coexistence is supported^[33]. Enteroviruses have a strong pancreotropism^[91]; human islets express coxsackie virus receptor^[92], and beta cells are susceptible to enteroviruses *in vitro*^[93]. During *enterovirus* infection, pancreatic islet cells may exhibit cytolysis, which exposes previously hidden self-components^[94,95]. Dotta *et al*^[96] detected *enterovirus* in three of six pancreatic tissue samples from patients with T1DM. Additionally, Coxsackie viruses lead to direct pancreatic injury. Elshebani *et al*^[97] demonstrated that enteroviruses that were isolated from patients who were newly diagnosed with T1DM

infected induced the destruction of human pancreatic islets *in vitro*.

Alternatively, β -cell damage may result from a virus-induced inflammatory reaction in the exocrine pancreas compartment. Viral infections often lead to the production of proinflammatory cytokines and the activation of antigen-presenting cells (APCs). In addition, these infections may cause tissue damage and may expose endogenous antigens that are presented by APCs. In individuals who are genetically predisposed to T1DM, viral infections may result in the impaired activation of self-reactive T cells through a mechanism that is independent of specific T-cell receptor (TCR) stimulation^[98,99]. This process, called "bystander activation", does not require specific TCR stimulation and was supported by a study of *CVB4* infection in transgenic mice that resulted in the activation of circulating naive islet-specific T cells and clinical diabetes development^[100].

Furthermore, the mechanism of cell destruction may be based on molecular mimicry^[101]. The activation of a T-cell population against an environmental antigen results in the development of autoimmune disease if the epitope recognized shows sequence or structural similarity with a self-protein. Although virus-specific T lymphocytes are activated during an infection, antibody responses are critical in the defense against enteroviruses and are responsible for the clearance of the infection. Neutralizing antibodies are directed against the capsid surface of *CVB* and nonstructural proteins. These proteins are produced exclusively during the replication of the virus and are released as a consequence of the lysis of the infected cells. Directly linked to T1DM triggering was an observation of the amino acid sequence similarity between *CVB4* nonstructural protein 2C and GAD65 (PEVEKEK), which suggests that the cellular anti-viral response

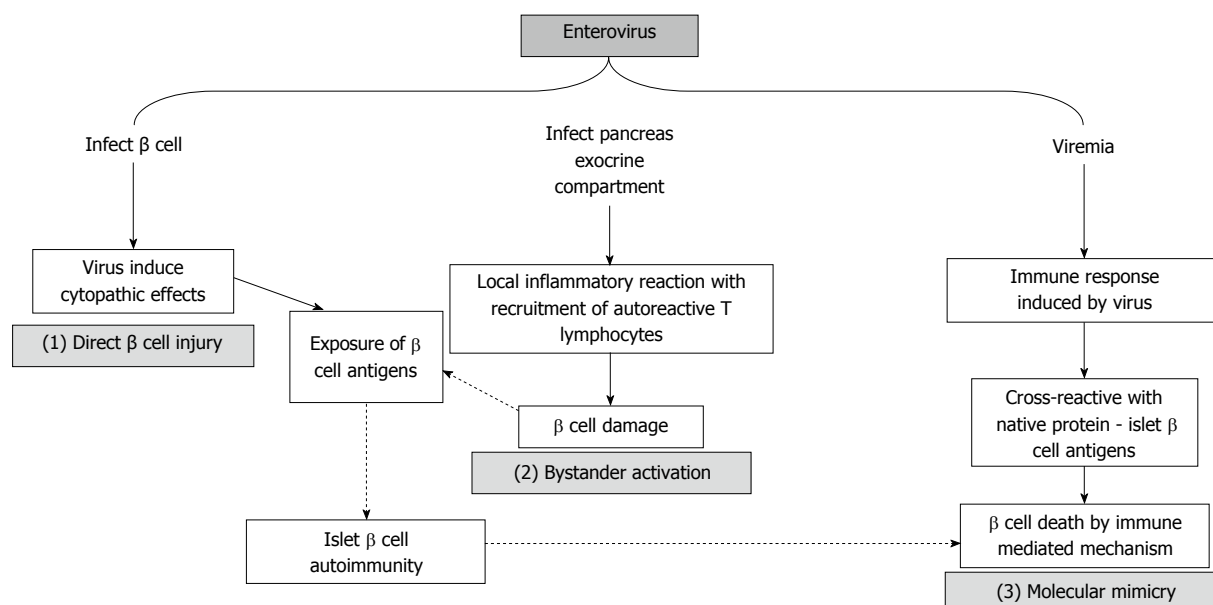

Figure 2 Schematic representation of possible injury mechanisms from enterovirus infection in type 1 diabetes mellitus development (adapted from Roivainen^[40]).

may cross-react with the native protein, inducing an autoimmune response^[102].

However, in several studies, the molecular mimicry hypothesis has been controversial because healthy control groups presented reactivity to the molecular section of GAD65^[103]. In addition, molecular mimicry is extremely common in nature, which suggests that an impaired immune response may be crucial for β -cell damage in contrast with molecular mimicry^[103].

All these mechanisms described may occur simultaneously. In fact, inflammatory conditions induced by virus infection will trigger autoimmunity resulting in T1DM only in susceptible individuals^[38]. This hypothesis, Fertile Field, postulates that following the inflammation caused by virus infection, autoreactive T cells may be generated by bystander activation or molecular mimicry or both. The damage of beta cells and its presentation to immune system lead to antigenic epitope spreading, which explains the broad autoreactive T-cell repertoire in T1DM patients. This hypothesis may be of interest because *enterovirus* infection activates a strong innate immune response^[104,105].

Innate and acquired immunity

Immune responses against infection by microbes are highly complex, and recent advances in the understanding of innate immunity components have elucidated the integration of innate immunity and acquired immunity. Innate immunity has limited specificity for microbes and works in a similar manner against most infectious agents. The main components of the innate immune system are physical and chemical barriers, blood proteins, including the complement system and other inflammatory mediators, such

as phagocytes (neutrophils and macrophages) and natural killer cells. In contrast with the innate immune system, the acquired immune system consists of defense mechanisms with remarkable specificity for distinguishing molecules. The acquired immune response increases in magnitude with successive exposure to a specific microbe. Acquired immunity develops as a response to infection. The components of the acquired immune system are lymphocytes and their products, which are known as antibodies.

The innate immune response provides the initial defense against infectious agents. Pathogen recognition by the innate immune system is usually mediated by receptors that recognize the molecular patterns of different organisms. Recent studies have demonstrated that this recognition is mainly mediated by Toll-like receptors (TLR)^[106,107]. TLR2 detects lipoproteins, lipoteichoic acid and zymosan. TLR3 recognizes dsRNA, and TLR4 recognizes lipopolysaccharide (LPS). Additionally, flagellin is detected by TLR5, ssRNA by TLR7/8 and CpG DNA by TLR9. TLRs are expressed in multiple tissues, predominantly in the cells of the immune system, particularly APCs^[108].

TLR signaling induces the expression of costimulatory molecules and the production of inflammatory cytokines, such as interferons (IFNs) and interleukins (ILs), which activate both the innate and acquired immune responses. An intact innate immune response is critical for host survival during *enterovirus* infection. The rapid induction of IFNs is important for protection against infection. A recent study found a high rate of mortality in mice that were unresponsive to type I IFNs or lacked IFN- β after CVB infection. In addition, mortality occurred early in these mice^[109].

Figure 3 Hypothetic relationship between innate immune response to enterovirus and type 1 diabetes mellitus risk. T1DM: Type 1 diabetes mellitus.

Viral infection, innate immunity and T1DM

Viruses activate the innate immune response and induce the production of proinflammatory cytokines^[98,110,111]. Enteroviruses demonstrate a tropism for the pancreas. However, the mechanism of β -cell damage is unclear^[112].

CVB4 infection induces the production of pro-inflammatory cytokines, such as interleukin-1 β (IL-1 β) and tumor necrosis factor α (TNF- α)^[113]. These cytokines are involved in the host defense response against infection; however, recent studies have suggested that pro-inflammatory cytokines that are activated in response to viral infections may play a role in the pathogenesis of T1DM^[114,115]. TNF- α may be involved in β -cell damage^[116].

Using RT-PCR, Wen *et al.*^[117] recently isolated pancreatic islet β -cells from different species of mice and detected TLR2, 3, 4 and 9 in the islet cells of normal mice but a higher expression of TLR2, 3 and 4. The same methodology was applied in a study of pancreatic β -cells from three healthy human donors, and a higher expression of TLR3 was found in these cells. However, after treatment with microbial stimuli, LPS from gram-negative bacteria and CpG oligonucleotide DNA increased the expression of TLR2, 4 and 9. Moreover, viral stimulation with poly (I:C), a synthetic dsRNA that is capable of triggering immune responses, TLR2, 3, 4 and 9 expression was observed. The same microbial stimuli were assessed *in vivo*, and only the viral stimulus poly (I:C) triggered diabetes mellitus.

In NOD mice, CVB can induce diabetes because of the framework that is established by insulinitis, which is caused by the increased expression of TLR4 and 8 by dendritic cells^[118]. A study in human pancreatic cells demonstrated that CVB4 leads to the production of inflammatory cytokines, particularly IL-6 and TNF α . TLR4 is necessary for triggering this immune response; however, this response is independent of CVB4 internalization and replication. Therefore, the interaction between TLR4 and CBV4 in pancreatic cells may induce an innate immune response^[119].

Studies in experimental models have demonstrated that the innate immune response is crucial for host survival during *enterovirus* infection. A weak innate immune response may allow unrestricted replication and the systemic spread of the virus. Tissue damage may ensue as a direct effect of the infecting virus, and an inefficient immune response may enable viral persistence. A robust innate immune response will limit early viral replication and diminish virally instigated damage, thereby allowing the host to mount an adaptive immune response. However, autoimmune pathologies may arise in the wake of a very potent immune response. In this scenario, the innate immune response to infection triggers the activation of self-reactive T cells^[120]. Many autoimmune diseases are associated with the excessive production of IFNs^[121]. Therefore, Lien *et al.*^[122] postulated that the relationship between viruses and TLRs in the development of diabetes in BioBreeding diabetes-resistant (BBDR) rats is a complex process that involves the modulation of auto-reactive T cells. In response to pathogenic microorganisms, the innate immune response that is mediated by TLR may lead to the bystander activation of auto-reactive T cells, the release of pro-inflammatory cytokines and the impairment of pancreatic islet cells^[123,124].

In contrast, a strong immune response is more likely to prevent the virus from productively infecting host cells and is more likely to hinder virus access to the pancreas. However, an inefficient response enhances the risk for systemic viral spread and the induction of an innate immune response in tissues that are targeted by the virus. Therefore, viral infection with a weak initial immune response may result in higher systemic levels of pro-inflammatory cytokines and the activation of auto-reactive T cells^[120] (Figure 3).

Interferon transcriptional signature

Two studies were recently conducted with children from the BABYDIET cohort^[125] and the DIPP study^[126] who were genetically predisposed to T1DM. Using targeted and genome-wide transcriptomics, the expression of IFN signatures during the onset of autoimmunity and the progression to clinical T1DM was investigated. An IFN signature was first characterized in systemic lupus erythematosus disease in which IFN was found to be correlated with disease severity.

In these two studies, both research groups identified an IFN signature in the children before the development of islet autoimmunity. Ferreira *et al.*^[125] found that the IFN signature was increased before seroconversion in predisposed patients and corresponded with two or more episodes of respiratory infection, suggesting that the IFN signature is related to viral infections. The expression was intermediate in samples that were collected postseroconversion and in children with clinical T1DM.

The increased expression of type 1 IFN is a normal

response to viral and bacterial infections in healthy individuals, but the pattern of expression and the presence of an IFN signature in peripheral blood may be a marker of a recent antiviral immune response. In individuals with a genetic risk for T1DM, an altered response to viral infection with unbalanced effector and regulatory cells may result in an overreaction. Importantly, the expression of an IFN signature is consistent with the activation of innate immune pathways during the initiation of islet autoimmunity and may be the first sign of this process.

CONCLUSION

Extended and cumulative discussions have been conducted on the role of *enterovirus* infection in the etiopathogenesis of T1DM, and substantial supporting evidence has been found. Improvements in *enterovirus* detection methods and randomized studies with patient follow-up have confirmed the importance of HEV in T1DM development and progression. However, the frequency, mechanisms, and pathways of virally induced autoimmunity and β -cell destruction in T1DM remain to be determined. In this way, the causal link between EV and T1DM involves a complex interplay between viruses, β -cells, innate and acquired immune systems in the particular genetic context of an individual. The influence of these several concomitant mechanisms by which the virus damages pancreatic β -cells, which, consequently, may lead to T1DM establishment makes investigating the role of *enterovirus* infection quite difficult. It will be extremely important to design prospective studies with large study populations, more frequent sampling of various specimens and a standardized methodology to detect *enterovirus* infection, linking it to islet autoimmunity or T1DM and controlling for confounding factors. Advances in molecular and genomic studies may facilitate the identification of pathways at the earlier stages of autoimmunity when preventive and therapeutic approaches may be more effective.

REVIEW CRITERIA

The databases that were searched in this study included PubMed and Embase. Papers that were published from 2004-2014 were included in the study, with a particular interest in papers that were published after 2009. The search terms were "virus", "*enterovirus*", "*coxsackievirus*", "type 1 diabetes mellitus", "auto-immune diabetes", and "insulin-dependent diabetes". The selected publications were full-text papers that were published in English. Additional references were selected from the reference lists of the selected article.

Abstract

Although several previous studies have been published on the effects of dipeptidase-4 (DPP-4) inhibitors in diabetic hemodialysis (HD) patients, the findings have yet to be reviewed comprehensively. Eyesight failure caused by diabetic retinopathy and aging-related dementia make multiple daily insulin injections difficult for HD patients. Therefore, we reviewed the effects of DPP-4 inhibitors with a focus on oral antidiabetic drugs as a new treatment strategy in HD patients with diabetes. The following 7 DPP-4 inhibitors are available worldwide: sitagliptin, vildagliptin, alogliptin, linagliptin, teneligliptin, anagliptin, and saxagliptin. All of these are administered once daily with dose adjustments in HD patients. Four types of oral antidiabetic drugs can be administered for combination oral therapy with DPP-4 inhibitors, including sulfonylureas, meglitinide, thiazolidinediones, and alpha-glucosidase inhibitor. Nine studies examined the antidiabetic effects in HD patients. Treatments decreased hemoglobin A1c and glycated albumin levels by 0.3% to 1.3% and 1.7% to 4.9%, respectively. The efficacy of DPP-4 inhibitor treatment is high among HD patients, and no patients exhibited significant severe adverse effects such as hypoglycemia and liver dysfunction. DPP-4 inhibitors are key drugs in new treatment strategies for HD patients with diabetes and with limited choices for diabetes treatment.

Key words: Dipeptidase-4 inhibitors; Hemodialysis; Diabetes mellitus; Blood glucose-related factors; Anti-inflammatory effects

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Until now, the effectiveness of dipeptidase-4 (DPP-4) inhibitors on diabetic hemodialysis (HD) patients has not been reviewed. All 7 DPP-4 inhibitors are available for HD patients; administration is once daily with dose adjustments. The effectiveness of DPP-4 inhibitor treatment in HD patients is high, and adverse events do not increase as a result. DPP-4 inhibitors may prevent inflammation and atherosclerosis, which are principal prognostic factors for HD patients. In summary, DPP-4 inhibitors are key drugs in new treatment strategies for HD patients with diabetes and limited choices for its treatment.

Diabetes therapies in hemodialysis patients: Dipeptidase-4 inhibitors. *World J Diabetes* 2015; 6(6): 840-849 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/840.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i6.840>

INTRODUCTION

Diabetes is the biggest cause of renal failure worldwide^[1,2]. Diabetes treatment is an very important factor in the overall survival of hemodialysis (HD) patients^[3,4]. While insulin therapy is the primary treatment for HD patients, impaired eyesight caused by diabetic retinopathy and aging-related dementia make multiple daily insulin injections difficult for many patients^[5]. Moreover, in HD patients, many diabetes oral medicines cause serious side effects such as hypoglycemia and lactic acidosis. Hence, the development of new diabetes oral medicines with little or no side effects is needed for these patients.

Dipeptidase-4 (DPP-4) inhibitors are the most highly used diabetic drugs and show both a lower incidence of hypoglycemia and good safety^[6]. In addition, they induce an ingestion control effect and may also prevent atherosclerosis and reduce cardiovascular events^[7,8]. Therefore, these medications are strongly expected to improve the quality of life and prognosis of diabetic HD patients.

As a new class of diabetic medications, sodium-glucose co-transporter 2 (SGLT2) inhibitors both inhibit glucose reabsorption in renal tubules and increase glucose excretion, but cannot be administered to dialysis patients. G-protein-coupled receptor 40 (GPR40) agonist, GPR119 receptor agonist, and glucokinase activators are new antidiabetic medications currently in clinical trials and thus are not yet available. Therefore, DPP-4 inhibitors have been the mainstay drugs during the past several years for HD patients with diabetes. Accordingly, a comprehensive research of the pharmacokinetics and pharmacodynamics of DPP-4 inhibitors in HD patients is important. Some reports have investigated the effectiveness of DPP-4 inhibitors in HD patients^[9-18]. However, there has

been no review of new treatment strategies for HD patients who have diabetes and limited choices for its treatment. Therefore, this review evaluated the effects of DPP-4 inhibitors as a new therapeutic strategy for diabetic patients.

SEARCH STRATEGY

A MEDLINE search (1966 to July 2014) for published clinical studies and pertinent review articles published in English was conducted with the following keywords: "DPP-4 inhibitor", "hemodialysis", "end stage renal disease", "sitagliptin", "vildagliptin", "alogliptin", "linagliptin", "teneligliptin", "anagliptin", "saxagliptin", "glucagon-like peptide-1 (GLP-1)", "insulin", "glucagon", and "insulin resistance". References of identified articles were searched for additional relevant sources. Articles relevant to the efficacy, safety, and pharmacology of DPP-4 inhibitors in HD patients were also identified from the references cited in works obtained from the MEDLINE search results.

SEVEN DPP-4 INHIBITORS

At present, 7 DPP-4 inhibitors are available worldwide: sitagliptin, vildagliptin, alogliptin, linagliptin, teneligliptin, anagliptin, and saxagliptin. All DPP-4 inhibitors are available to HD patients, and administration is once daily. However, the dose adjustments are different for each DPP-4 inhibitor. Five DPP-4 inhibitors are excreted renally (*i.e.*, sitagliptin, vildagliptin, alogliptin, anagliptin, and saxagliptin). Meanwhile, both linagliptin and teneligliptin are excreted through bile; therefore, a reduction of the dose is unnecessary for HD patients. In particular, the renal excretion rate of linagliptin is 5%, which is the lowest among the DPP-4 inhibitors^[19]. Therefore, linagliptin is easy to use in patients with renal failure including HD patients. DPP-4 inhibitors interact with dipeptidase-4 in 2 different ways^[20]. The inhibition of DPP-4 by vildagliptin and saxagliptin is a 2-step process entailing the formation of a reversible covalent enzyme-inhibitor complex; this is characterized by slow rates of inhibitor binding and inhibitor dissociation, and results in the enzyme equilibrating slowly between its active and inactive forms^[21,22]. In contrast, the other DPP-4 inhibitors form noncovalent bonds (*i.e.*, hydrogen bonds) with residues present in the catalytic site^[23-25]. Some metabolites of DPP-4 inhibitors have drug activities. For example, 5-hydroxysaxagliptin is a metabolite of saxagliptin and has a half of the activity of the original drug^[26]. Therefore, unchanged substances are not representative of the effects of all drugs (Table 1).

Sitagliptin

The molecular weight of sitagliptin is 523.32 Da, and the administration therapeutic dosage is 25 mg once daily in HD patients. The bioavailability of this medicine is 87%^[27], and the protein-binding rate is 38%^[28]. Hepatic metabolism by CYP3A4 and CYP2C8 is low,

Table 1 Seven dipeptidase-4 inhibitors

Dose and pharmacokinetics	Sitagliptin	Vildagliptin	Alogliptin	Linagliptin	Teneligliptin	Anagliptin	Saxagliptin
Daily dose (mg)	25	50	6.25	5	20	100	2.5
Molecular weight (Da)	523.32	303.4	461.51	472.54	628.86	383.45	333.43
Bioavailability	87%	85%	100%	30%	Unknown	73.2%	Unknown
Protein binding	38.0%	9.3%	28.2%-38.4%	> 80%	77.6%-82.2%	37.1%-48.2%	Negligible
C _{max} (<i>vs</i> healthy volunteer)	1.4 fold	1.4 fold	3.2 fold	1.5 fold	1.0 fold	1.4 fold	Unknown
AUC (<i>vs</i> healthy volunteer)	4.5 fold	2.0 fold	3.8 fold	1.5 fold	1.5 fold	3.2 fold	2.1 fold
t _{1/2} (h) (<i>vs</i> healthy volunteer)	2.2	2	Unknown	Unknown	1.0 fold	0.9 fold	Unknown
Dialyzability	13.50%	3.00%	7.20%	Unknown	15.60%	Unknown	4.00%

C_{max}, AUC and t_{1/2} were measured under different dose conditions. AUC: Area under the curve.

and active metabolites are not produced. Therefore, most sitagliptin is excreted unchanged in the urine (87%) and feces (13%)^[29]. After the administration of sitagliptin 50 mg, compared to cohorts with normal renal function, HD patients had 1.4-fold higher observed plasma maximum concentration (C_{max}) levels, 4.5-fold higher area under the curve (AUC), and a 2.2-fold higher half-life (t_{1/2})^[28,30]. Furthermore, 13.5% of this drug is excreted by 4 h of HD^[31].

Vildagliptin

Vildagliptin has a molecular weight of 303.40 Da and is administered therapeutically at a dosage of 50 mg once daily in HD patients. The bioavailability and protein binding rate are 85%^[32,33] and 9.3%^[33,34], respectively. The mean elimination t_{1/2} after intravenous administration is short (about 2 h), and the amount of renal excretion of unchanged vildagliptin is 23% of the oral administration dose^[34,35]. Relative to cohorts with normal renal function, HD patients who received an administration of vildagliptin 50 mg had 1.4-fold and 2.0-fold higher C_{max} levels and AUC, respectively. Following the administration of vildagliptin 100 mg, HD patients had 2.0-fold higher t_{1/2} as compared to those with normal renal function. Additionally, 3% of this drug is removed by 4 h of HD^[34].

Alogliptin

At a molecular weight of 339.39 Da, alogliptin is administered at a therapeutic dosage of 6.25 mg once daily in HD patients. Its bioavailability is 100%, and the protein-binding rate is 28.2%-38.4%^[36]. In comparison to cohorts with normal renal function, HD patients had 3.2-fold and 3.8-fold higher C_{max} levels and AUC, respectively, following administration of alogliptin 50 mg. The t_{1/2} is unknown in HD patients. Furthermore, 7.2% of this drug is removed by 4 h of HD^[36,37].

Linagliptin

Linagliptin has a molecular weight of 472.54 Da, and the therapeutic dosage is 5 mg once daily in HD patients. Its bioavailability and protein binding rate are 30%^[38,39] and > 80%^[19], respectively. Relative to cohorts with normal renal function, the HD patients

showed 1.5-fold higher C_{max} levels and 1.5-fold higher AUC after the administration of linagliptin 5 mg. The t_{1/2} and dialyzability are unknown in HD patients^[40,41].

Teneligliptin

The molecular weight of teneligliptin is 628.86 Da, and the therapeutic dosage is 20 mg once daily in HD patients. Its bioavailability is unknown, and the protein-binding rate is 77.6%-82.2%^[42]. Compared to cohorts with normal renal function, HD patients had 4.5-fold higher AUC after teneligliptin 20 mg administration. The C_{max} levels and t_{1/2} in HD patients are the same as those in subjects with normal renal function after teneligliptin 20 mg administration. Furthermore, 15.6% of this drug is removed by 4 h of HD^[42].

Anagliptin

Anagliptin has a molecular weight of 383.45 Da, and is administered at a therapeutic dose of 100 mg once daily in HD patients. Its bioavailability and protein-binding rate are 73.2% and 37.1%-48.2%, respectively^[43]. Relative to cohorts with normal renal function, HD patients had 1.4-fold higher C_{max} levels, 3.2-fold higher AUC, and 0.9-fold higher t_{1/2} after anagliptin 400 mg administration^[43]. The dialyzability of this drug in HD patients is unknown.

Saxagliptin

At a molecular weight of 333.43 Da, saxagliptin is administered at a therapeutic dosage of 2.5 mg once daily in HD patients. Its protein-binding rate is negligible^[44]. Compared to cohorts with normal renal function, HD patients had a 2.1-fold higher AUC after saxagliptin 10 mg administration^[45]. The C_{max} levels and t_{1/2} are unknown in HD patients. Furthermore, 4.0% of this drug is removed by 4 h of HD^[45].

COMBINATION THERAPIES OF ORAL ANTIDIABETIC DRUGS WITH DPP-4 INHIBITORS IN HD PATIENTS

At present, 7 types of oral antidiabetic drugs are

Table 2 Combinations of oral antidiabetic drugs with dipeptidase-4 inhibitors

Class	Action mechanism	Glucose target	Drug	Daily dose (mg)
Sulfonylurea	Increases insulin secretion	Fasting and postprandial	Glipizide	2.5-10
			Gliclazide	40-240
			Gliquidone	45-60
Meglitinide	Increases insulin secretion	Postprandial	Repaglinide	0.5-12
Thiazolidinediones	Insulin sensitizer	Fasting and postprandial	Mitiglinide	7.5-15
			Rosiglitazone	4-8
			Pioglitazone	15-45
Alpha-glucosidase inhibitor	Delays carbohydrate absorption	Postprandial	Voglibose	0.6-0.9
			Acarbose	75-300
			Miglitol	150-225

available worldwide: sulfonylureas, meglitinides, biguanides, thiazolidinediones, alpha-glucosidase inhibitors, SGLT2 inhibitors, and DPP-4 inhibitors. Beyond agreement on DPP-4 inhibitors, the guidelines differ with respect to the oral diabetes therapeutic drugs that can be administered to HD patients, and countries vary as to recommendations on oral antidiabetic medicines^[46]. According to the Kidney Disease Outcomes Quality Initiative (KDOQI), glipizide (sulfonylurea), gliclazide (sulfonylurea), repaglinide (meglitinide), and thiazolidinediones can be administered to HD patients. In the guideline of the Japanese Society for Dialysis Therapy, HD patients can take repaglinide (meglitinide), mitiglinide calcium hydrate (meglitinide), and alpha-glucosidase inhibitor. Some reports state that gliquidone can be administered to HD patients^[47]. Many oral diabetes therapeutic drugs induce serious side effects in HD patients. In particular, sulfonylureas, biguanides, and thiazolidinediones can induce hypoglycemia, lactic acidosis, and fluid retention, respectively. Only a few oral antidiabetic drugs can be administered to HD patients before the use of DPP-4 inhibitors. Therefore, the side effects of drugs administered concomitant with DPP-4 inhibitors must be examined in detail (Table 2).

Sulfonylureas

With progressive decreases in kidney function, the clearance of sulfonylureas and their active metabolites decrease, and the $t_{1/2}$ is prolonged^[48-51]. First-generation sulfonylureas should generally be avoided in HD patients because they depend on the kidney to eliminate both the original drug and active metabolites. Accordingly, the $t_{1/2}$ and risk of hypoglycemia increase. According to the KDOQI, glipizide and gliclazide are among the usable second-generation sulfonylureas because they do not produce active metabolites or increase the risk of hypoglycemia in patients with decreased renal function. Glipizide and gliclazide are administered at a dose of 2.5-10 mg/d^[47] and 40-240 mg/d^[47,52], respectively. There are also reports of the administration of gliquidone in HD patients at a more than twice daily dose of 45-60 mg^[47].

Meglitinides

According to the KDOQI and guideline of the Japanese

Society for Dialysis Therapy, repaglinide and mitiglinide calcium hydrate (mitiglinide) can be administered to HD patients. In those with an estimated glomerular filtration rate (eGFR) of < 30 mL/min, repaglinide results in a 4-fold increase in the $t_{1/2}$ after 1 wk following its administration, as well as increase in AUC, in comparison to subjects with no renal failure. However, no changes are seen in the maximal plasma concentration, suggesting chronic kidney disease (CKD) influences both the metabolism and hepatic clearance of this medicine rather than bioavailability^[47,53]. Furthermore, active metabolite concentrations do not increase with repaglinide^[1]. Therefore, there is no relationship between renal failure and risk of hypoglycemia for this medicine in treated patients^[54]. Repaglinide is usually taken preprandially at each meal at a dose of 0.5-12 mg/d^[47,55]. Mitiglinide acts on liver metabolism^[56]; hence, the metabolites of mitiglinide calcium hydrate have no antidiabetic effects. Therefore, the risk of hypoglycemia from this drug is low in HD patients. Accordingly, HD patients can take this drug preprandially at each meal at a dose of 7.5-15 mg/d.

Thiazolidinediones

As rosiglitazone is metabolized in the liver, it is not necessary to reduce its dose in patients with renal failure^[57], since it does not increase the risk of hypoglycemia in CKD patients. Meanwhile, pioglitazone shows similar pharmacokinetic properties between patients with or without CKD because of its high molecular weight, protein-binding competency, and hepatic metabolism, and there is no effect in HD patients^[58,59]. Therefore, it is not necessary to adjust the dose in CKD patients. Pioglitazone is administered once daily at a dose of 15-45 mg. There are no specific data regarding fluid retention in CKD patients. Nevertheless, there is the potential risk of congestive heart failure by fluid overload, particularly in those patients with both renal and cardiac failure.

Alpha-glucosidase inhibitors

Alpha-glucosidase inhibitors increase glucagon-like peptide-1 levels and reduce gastric inhibitory polypeptide responses after eating. Therefore, combination therapies

with DPP-4 inhibitors may be more effective^[60].

The guideline of the Japanese Society for Dialysis Therapy states that all 3 types of alpha-glucosidase inhibitors can be administered in HD patients. Voglibose is not absorbed in the blood and is orally administered before each meal at 0.6-0.9 mg/d^[61]. The plasma levels of acarbose and its metabolites increase several fold in patients with renal failure. The peak plasma concentration and exposure of this drug in patients with severe renal impairment (eGFR < 25 mL/min) are 5- and 6-fold higher than in patients with normal renal function, respectively^[46,48]. However, only a small amount of acarbose is absorbed, since its bioavailability is very low^[62]. Additionally, its metabolites have very small antidiabetic effects. Acarbose is orally administered before each meal at 75-300 mg/d. Miglitol accumulates with a decrease in renal function. Those patients with an eGFR of < 25 mL/min and taking 75 mg miglitol (25 mg three times a day) have double the plasma exposure as subjects with an eGFR of > 60 mL/min^[46]. However, miglitol has no antidiabetic effects. The molecular weight of miglitol (383.45 Da) is low, and its protein binding rate is < 3.9%. Therefore, miglitol is eliminated by HD treatment. Miglitol is orally administered at 150-300 mg/d, usually before each meal^[47,63].

EFFICACIES OF DPP-4 INHIBITORS IN HD PATIENTS

The effectiveness of DPP-4 inhibitors is summarized in Table 3. DPP-4 inhibitor treatment decreases hemoglobin A1c (HbA1c) and glycated albumin (GA) levels by 0.3%-1.3% and 1.7%-4.9%, respectively. It is difficult to compare the effects of DPP-4 inhibitors, because the strength and selectivity of DPP-4 inhibition are related to their respective therapeutic effects. Moreover, the curative effects of these drugs might be related to ethnicity. For example, some studies report

greater effectiveness of DPP-4 inhibitor treatment in Japanese patients with diabetes based on the evaluation of GA levels^[64-66].

Monotherapy

Eight studies have investigated the diabetes therapeutic effects of DPP-4 inhibitors only in HD patients and not CKD patients. Of these, seven studied the antidiabetic effectiveness of only DPP-4 inhibitor monotherapy (*i.e.*, sitagliptin, vildagliptin, alogliptin, linagliptin, and teneligliptin) (Table 3). However, there have been no studies of anagliptin or saxagliptin monotherapy.

Arjona Ferreira *et al*^[9] investigated the efficacies of sitagliptin monotherapy in 64 diabetic HD patients. All patients were administered sitagliptin 25 mg once daily for the monotherapy research. Forty patients newly started sitagliptin therapy, and 24 switched from other medications. Mean HbA1c and fasting plasma glucose levels decreased from 7.95% to 7.2% and from 159 to 133 mg/dL, respectively, 12 mo after treatment initiation.

Three studies have evaluated vildagliptin monotherapy in HD patients. Of these, 2 studied only vildagliptin monotherapy, while the other was a sub-analysis study in which the patients were categorized into either vildagliptin monotherapy or combination therapy groups. Ito *et al*^[10] investigated the efficacies of vildagliptin monotherapy in 5 diabetic HD patients who were following diet and exercise regimens. All patients were administered vildagliptin 50 mg once daily for the monotherapy research. At 6 mo after treatment, HbA1c and GA levels had decreased from 6.0% ± 0.3% and 21.8% ± 2.6% to 5.5% ± 0.6% and 19.7% ± 3.3%, respectively. Kume *et al*^[11] investigated the efficacies of vildagliptin monotherapy in 26 diabetic HD patients. Sixteen patients newly started sitagliptin therapy, and 7 patients switched from other oral antidiabetic drugs (3 patients were

Table 4 Efficacies of both monotherapies and combination therapies with dipeptidase-4 inhibitors

						GA	Unknown	Unknown	Unknown

HbA1c: Hemoglobin A1c; GA: Glycated albumin.

unknown). All patients were administered vildagliptin 50 mg once daily for the monotherapy research. Mean GA and postprandial plasma glucose (PPG) levels had decreased from 23.8% to 21.2% and 204 to 157 mg/dL respectively, 6 mo after treatment initiation. In the subanalysis study, all 9 patients were administered an initial dose of vildagliptin 50 mg once daily. Thereafter, if 8 wk of continuous vildagliptin administration did not result in the target HbA1c value (< 7.0%) or GA value (< 21.0%) being achieved, the vildagliptin dose was increased to 100 mg daily from week 8. The HbA1c, GA, and PPG levels showed mean changes of -0.7%, -4.6%, and -54 mg/dL in the monotherapy group^[12].

Nakamura *et al*^[13] investigated the diabetes therapeutic effects of alogliptin and linagliptin monotherapy in HD patients in 2 studies. In the study of alogliptin monotherapy, 16 diabetic HD patients were eligible based on diet and exercise regimens. All patients were administered alogliptin 6.25 mg once daily. At 2 years after treatment initiation, the HbA1c and GA levels had decreased from 7.1% ± 0.2% to 5.8% ± 1.6% and from 22.5% ± 0.7% to 19.6% ± 0.6%^[13]. In the study of linagliptin monotherapy, 21 diabetic HD patients were eligible based on diet and exercise regimens. All patients were administered linagliptin 5 mg once daily. GA levels decreased from 21.3% ± 0.6% to 18.0% ± 0.6% 6 mo after treatment initiation^[14].

Otsuki *et al*^[15] investigated the efficacies of teneligliptin monotherapy in 14 diabetic HD patients. All patients were administered teneligliptin 20 mg once daily. Seven patients newly started teneligliptin therapy, and 7 patients switched from other medications. The mean changes in HbA1c and GA were -0.3% to -0.8% and -1.7% to -2.3% after treatment^[15].

Monotherapy and combination therapies

Two studies have evaluated the combined efficacies of both monotherapy and combination oral diabetic therapy with DPP-4 inhibitors in HD patients. In the evaluation of combination therapy with vildagliptin, 30 HD patients with diabetes were eligible to participate. All patients were administered vildagliptin 50 mg once daily as an initial dose. Nine patients newly started vildagliptin therapy, and 21 patients switched from other medications. Thereafter, if 8 wk of continuous

vildagliptin administration did not result in the target HbA1c value (< 7.0%) or GA value (< 21.0%) being achieved, the vildagliptin dose was increased to 100 mg daily from week 8; this was done in 19 patients. Another 11 patients were administered 50 mg daily. Mean HbA1c, GA, and PPG decreased from 6.7% to 6.1%, 24.5% to 20.5%, and 186 to 140 mg/dL, respectively, 6 mo after treatment initiation^[12].

In the study of combination therapy with alogliptin, 30 HD patients with diabetes were eligible. All patients were administered alogliptin 6.25 mg once daily. Fifteen patients newly started sitagliptin therapy, and 15 patients switched from other medications. Mean HbA1c, GA, and PPG decreased from 7.1% to 6.3%, 25.6% to 20.7%, and 212 to 156 mg/dL, respectively, 12 mo after treatment initiation. When patients were divided into the alogliptin monotherapy and combination (alogliptin plus mitiglinide and/or voglibose) therapy groups (*n* = 15 each), the mean changes in GA and PPG were greater in the monotherapy group (the specific decreases are unclear)^[16].

There is one subanalysis study of DPP-4 inhibitors that included only HD patients from among those with CKD. A total of 19 HD patients with diabetes were eligible. All patients were administered saxagliptin 2.5 mg once daily. The diabetes treatments before saxagliptin therapy were unknown. Mean HbA1c and PPG decreased from 8.75% to 7.5% and 177 to 138 mg/dL, respectively, 12 mo after treatment initiation (the details of monotherapy and combination therapies are unclear)^[17,18] (Table 4).

Glycemic control parameters

Blood glucose is a principal parameter for assessing the effects of diabetes therapy. Blood is collected at 3 time points: PPG, fasting plasma glucose, and the start of HD treatment. Therefore, it is difficult to compare blood glucose levels among studies. GA may more accurately reflect glycemic control, because HbA1c, the more general available parameter, is falsely low in HD patients^[67-69]. This probably results from the shortened survival time of erythrocytes in CKD patients, as well as the reduced time for the glucose-hemoglobin chemical reaction to occur^[70]. Another reason underlying the falsely low HbA1c levels in HD patients is related to the erythropoietin injections and

resultant increase in younger erythrocytes^[71]. GA is a predictor of death, hospitalization, and cardiovascular events in HD patients with diabetes^[72,73].

IMPACTS OF DPP-4 INHIBITORS ON BLOOD GLUCOSE-RELATED FACTORS IN HD PATIENTS

Some studies have investigated the impacts of DPP-4 inhibitors on blood glucose-related factors (*i.e.*, insulin, glucagon, and insulin resistance) in HD patients. In the study of sitagliptin, HOMA-IR increased 12 mo after sitagliptin treatment, while fasting insulin, proinsulin, proinsulin/insulin ratio, and HOMA-IR showed no changes from baseline^[9]. Meanwhile, the study of vildagliptin investigated insulin and C-peptide but observed no significant differences for these parameters from baseline after 6 mo^[11]. The study of alogliptin investigated insulin, C-peptide, and glucagon monthly for 3 mo. However, they were not significantly different before and after alogliptin treatment^[13]. In the study of teneligliptin, C-peptide level at baseline was 4.94 ng/mL and increased significantly to 5.96 ng/mL after 5 mo of treatment^[15]. Three studies assessed active GLP-1 levels before and after DPP-4 inhibitor treatment in HD patients. Samples were taken before the start of HD treatment, and active GLP-1 levels increased 2-3 fold after DPP-4 inhibitor therapy^[11,13,14].

ANTI-INFLAMMATORY EFFECTIVENESS OF DPP-4 INHIBITORS IN HD PATIENTS

Inflammation is an important prognostic factor in HD patients^[74]. Therefore, if DPP-4 inhibitors prevent inflammation and atherosclerosis, they may improve the prognosis of HD patients. However, almost no research has investigated the anti-inflammatory or anti-atherosclerosis efficacies of DPP-4 inhibitors in HD patients. Only 2 reports have assessed the anti-inflammatory efficacies of DPP-4 inhibitors in HD patients. In the study of vildagliptin, interleukin-6 levels decreased after 6 mo, although not significantly^[11]. In the study of linagliptin, PGE2 and interleukin-6 levels decreased significantly^[14]. Four mechanisms have been proposed to underlie the anti-inflammation properties of linagliptin: increased GLP-1^[75,76], DPP-4 (CD26) suppression^[77,78], xanthine-related skeletal structure, and a diabetic therapy effect^[79,80]. Increased GLP-1, DPP-4 suppression, and an antidiabetic effect are the effects that are common among all DPP-4 inhibitors. However, among the 7 DPP-4 inhibitors, linagliptin is the only one with xanthine-related skeletal structure effects. The pharmacological anti-inflammatory mechanisms of xanthine-related skeletal structure are unknown. The meta-analysis of the cardiovascular events with DPP-4 inhibitors examined 73678 patients in a total of 82 randomized controlled

trials including the SAVOR-TIMI 53 and EXAMINE trials^[81-83]. Only linagliptin reduced major adverse cardiovascular events compared to placebo/alternative diabetes therapy. This suggests the anti-inflammatory effectiveness of linagliptin may be involved in its anti-atherosclerotic effects.

SAFETY/TOLERABILITY

Hypoglycemia is the most serious general side effect of diabetes treatment. In clinical trial data, the incidence of hypoglycemic events due to DPP-4 inhibitors ranges from < 0.1%-5%. Meta-analysis of data from clinical trials indicated few hypoglycemic events due to vildagliptin and sitagliptin^[6]. Adverse events other than hypoglycemia due to DPP-4 inhibitors include rash, hives, abdominal fullness, pancreatitis, constipation, headache, giddiness, nasopharyngitis, headache, and upper respiratory tract infection. However, the occurrence of these side reactions is low^[84].

One study reports higher incidences of cellulitis and headache (6.3%) with sitagliptin compared to glipizide^[9]. One patient experienced a drug-related rash^[13], and another experienced constipation^[15]. However, in 8 studies that evaluated the diabetes therapeutic effects of DPP-4 inhibitors in HD patients, no patients showed severe side effects (*e.g.*, hypoglycemia and liver dysfunction). Therefore, adverse events resulting from DPP-4 inhibitor treatments do not occur at a higher incidence than in HD patients.

CONCLUSION

Treating HD patients with DPP-4 inhibitors does not result in an increased incidence of adverse events. Furthermore, DPP-4 inhibitors are strongly anticipated to be effective in HD patients with diabetes. Moreover, drugs with anti-inflammatory and anti-atherosclerotic effects are attractive options for HD patients, whose prognosis is associated with inflammation and atherosclerosis. DPP-4 inhibitors are key drugs that are part of new treatment strategies for HD patients with diabetes, whose choices for diabetes treatment are limited. A once-weekly oral DPP-4 inhibitor, SYR-472^[85], which could reduce the number of required administrations, might be approved in the future. Therefore, the number of treatment options for HD for diabetic patients is anticipated to increase.

Diabetes mellitus: The epidemic of the century

Akram T Kharroubi, Hisham M Darwish

Akram T Kharroubi, Department of Medical Laboratory Sciences, Faculty of Health Professions, Al-Quds University, Jerusalem 91000, Palestine

Hisham M Darwish, Department of Biochemistry, Faculty of Medicine, Al-Quds University, Jerusalem 91000, Palestine

Author contributions: Kharroubi AT and Darwish HM contributed equally to the writing of the review article; Kharroubi AT wrote the classification, diagnosis, and etiology of diabetes; Darwish HM wrote the molecular genetics of diabetes.

Abstract

The epidemic nature of diabetes mellitus in different regions is reviewed. The Middle East and North Africa

region has the highest prevalence of diabetes in adults (10.9%) whereas, the Western Pacific region has the highest number of adults diagnosed with diabetes and has countries with the highest prevalence of diabetes (37.5%). Different classes of diabetes mellitus, type 1, type 2, gestational diabetes and other types of diabetes mellitus are compared in terms of diagnostic criteria, etiology and genetics. The molecular genetics of diabetes received extensive attention in recent years by many prominent investigators and research groups in the biomedical field. A large array of mutations and single nucleotide polymorphisms in genes that play a role in the various steps and pathways involved in glucose metabolism and the development, control and function of pancreatic cells at various levels are reviewed. The major advances in the molecular understanding of diabetes in relation to the different types of diabetes in comparison to the previous understanding in this field are briefly reviewed here. Despite the accumulation of extensive data at the molecular and cellular levels, the mechanism of diabetes development and complications are still not fully understood. Definitely, more extensive research is needed in this field that will eventually reflect on the ultimate objective to improve diagnoses, therapy and minimize the chance of chronic complications development.

Core tip: Diabetes mellitus is rising to an alarming epidemic level. Early diagnosis of diabetes and prediabetes is essential using recommended hemoglobin A1c criteria for different types except for gestational diabetes. Screening for diabetes especially in underdeveloped countries is essential to reduce late diagnosis. Diabetes development involves the interaction between genetic and non-genetic factors. Biomedical research continues

to provide new insights in our understanding of the mechanism of diabetes development that is reviewed here. Recent studies may provide tools for the use of several genes as targets for risk assessment, therapeutic strategies and prediction of complications.

Kharroubi AT, Darwish HM. Diabetes mellitus: The epidemic of the century. *World J Diabetes* 2015; 6(6): 850-867 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/850.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i6.850>

DEFINITION OF DIABETES MELLITUS

Diabetes mellitus is a group of metabolic diseases characterized by chronic hyperglycemia resulting from defects in insulin secretion, insulin action, or both. Metabolic abnormalities in carbohydrates, lipids, and proteins result from the importance of insulin as an anabolic hormone. Low levels of insulin to achieve adequate response and/or insulin resistance of target tissues, mainly skeletal muscles, adipose tissue, and to a lesser extent, liver, at the level of insulin receptors, signal transduction system, and/or effector enzymes or genes are responsible for these metabolic abnormalities. The severity of symptoms is due to the type and duration of diabetes. Some of the diabetes patients are asymptomatic especially those with type 2 diabetes during the early years of the disease, others with marked hyperglycemia and especially in children with absolute insulin deficiency may suffer from polyuria, polydipsia, polyphagia, weight loss, and blurred vision. Uncontrolled diabetes may lead to stupor, coma and if not treated death, due to ketoacidosis or rare from nonketotic hyperosmolar syndrome^[1-3].

CLASSIFICATION OF DIABETES MELLITUS

Although classification of diabetes is important and has implications for the treatment strategies, this is not an easy task and many patients do not easily fit into a single class especially younger adults^[1,4-6] and 10% of those initially classified may require revision^[7]. The classical classification of diabetes as proposed by the American Diabetes Association (ADA) in 1997 as type 1, type 2, other types, and gestational diabetes mellitus (GDM) is still the most accepted classification and adopted by ADA^[1]. Wilkin^[8] proposed the accelerator hypothesis that argues "type 1 and type 2 diabetes are the same disorder of insulin resistance set against different genetic backgrounds"^[9]. The difference between the two types relies on the tempo, the faster tempo reflecting the more susceptible genotype and earlier presentation in which obesity, and therefore, insulin resistance, is the center of the hypothesis. Other

predictors of type 1 diabetes include increased height growth velocity^[10,11] and impaired glucose sensitivity of β cells^[12]. The implications of increased free radicals, oxidative stress, and many metabolic stressors in the development, pathogenesis and complications of diabetes mellitus^[13-18] are very strong and well documented despite the inconsistency of the clinical trials using antioxidants in the treatment regimens of diabetes^[19-21]. The female hormone 17- β estradiol acting through the estrogen receptor- α (ER- α) is essential for the development and preservation of pancreatic β cell function since it was clearly demonstrated that induced oxidative stress leads to β -cell destruction in ER- α knockout mouse. The ER- α receptor activity protects pancreatic islets against glucolipotoxicity and therefore prevents β -cell dysfunction^[22].

TYPE 1 DIABETES MELLITUS

Autoimmune type 1 diabetes

This type of diabetes constitutes 5%-10% of subjects diagnosed with diabetes^[23] and is due to destruction of β cells of the pancreas^[24,25]. Type 1 diabetes accounts for 80%-90% of diabetes in children and adolescents^[2,26]. According to International Diabetes Federation (IDF), the number of youth (0-14 years) diagnosed with type 1 diabetes worldwide in 2013 was 497100 (Table 1) and the number of newly diagnosed cases per year was 78900^[27]. These figures do not represent the total number of type 1 diabetes patients because of the high prevalence of type 1 diabetes in adolescence and adults above 14 years of age. One reported estimate of type 1 diabetes in the United States in 2010 was 3 million^[28,29]. The number of youth in the United States younger than 20 years with type 1 diabetes was estimated to be 166984 in the year 2009^[30]. The prevalence of type 1 diabetes in the world is not known but in the United States in youth younger than 20 years was 1.93 per 1000 in 2009 (0.35-2.55 in different ethnic groups) with 2.6%-2.7% relative annual increase^[26,31]. Type 1 diabetes is mainly due to an autoimmune destruction of the pancreatic β cells through T-cell mediated inflammatory response (insulinitis) as well as a humoral (B cell) response^[25]. The presence of autoantibodies against the pancreatic islet cells is the hallmark of type 1 diabetes, even though the role of these antibodies in the pathogenesis of the disease is not clear. These autoantibodies include islet cell autoantibodies, and autoantibodies to insulin (IAA), glutamic acid decarboxylase (GAD, GAD65), protein tyrosine phosphatase (IA2 and IA2 β) and zinc transporter protein (ZnT8A)^[32]. These pancreatic autoantibodies are characteristics of type 1 diabetes and could be detected in the serum of these patients months or years before the onset of the disease^[33]. Autoimmune type 1 diabetes has strong HLA associations, with linkage to *DR* and *DQ* genes. HLA-DR/DQ alleles can be either predisposing or protective^[1]. This autoimmune type 1 diabetes is

Table 1 Number of subjects with type 1 diabetes in children (0-14 years), with diabetes in adults (20-79 years) and with hyperglycemia (type 2 or gestational diabetes) in pregnancy (20-49 years)

Region	Type 1 diabetes in children (0-14 yr)		Diabetes in adults (20-79 yr)				Hyperglycemia in pregnancy (20-49 yr)

Data extracted from International Diabetes Federation Diabetes Atlas, 6th ed, 2013.

characterized by the absence of insulin secretion and is more dominant in children and adolescents.

In addition to the importance of genetic predisposition in type 1 diabetes, several environmental factors have been implicated in the etiology of the disease^[9,33]. Viral factors include congenital rubella^[34,35], viral infection with enterovirus, rotavirus, herpes virus, cytomegalovirus, endogenous retrovirus^[36,37] and Ljungan virus. Other factors include low vitamin D levels^[38], prenatal exposure to pollutants, improved hygiene and living conditions decreased childhood infections in countries with high socioeconomic status leading to increased autoimmune diseases (hygiene hypothesis), early infant nutrition such as using cow's milk formula instead of breast feeding^[39] in addition to insulin resistance in early childhood due to obesity or increased height growth velocity. The role of environmental factors remains controversial^[40]. Recent evidence supported the causative effect of viral infections in diabetes^[41-43].

Type 1 diabetes often develops suddenly and can produce symptoms such as polydipsia, polyuria, enuresis, lack of energy, extreme tiredness, polyphagia, sudden weight loss, slow-healing wounds, recurrent infections and blurred vision^[27] with severe dehydration and diabetic ketoacidosis in children and adolescents. The symptoms are more severe in children compared to adults. These autoimmune type 1 diabetes patients are also prone to other autoimmune disorders such as Graves' disease, Hashimoto's thyroiditis, Addison's disease, vitiligo, celiac sprue, autoimmune hepatitis, myasthenia gravis, and pernicious anemia^[1]. The complete dependence on insulin of type 1 diabetes patients may be interrupted by a honeymoon phase which lasts weeks to months or in some cases 2-3 years. In some children, the requirement for insulin therapy may drop to a point where insulin therapy could be withdrawn temporarily without detectable hyperglycemia^[44].

Idiopathic type 1 diabetes

A rare form of type 1 diabetes of unknown origin (idiopathic), less severe than autoimmune type 1 diabetes and is not due to autoimmunity has been reported. Most patients with this type are of African or Asian descent and suffer from varying degrees of insulin deficiency and episodic ketoacidosis^[45].

Fulminant type 1 diabetes

This is a distinct form of type 1 diabetes, first described in the year 2000, and has some common features with idiopathic type 1 diabetes being non-immune mediated^[46,47]. It is characterized by ketoacidosis soon after the onset of hyperglycemia, high glucose levels (≥ 288 mg/dL) with undetectable levels of serum C-peptide, an indicator of endogenous insulin secretion^[48]. It has been described mainly in East Asian countries and accounted for approximately 20% of acute-onset type 1 diabetes patients in Japan (5000-7000 cases) with an extremely rapid and almost complete beta-cell destruction resulting in nearly no residual insulin secretion^[48,49]. Both genetic and environmental factors, especially viral infection, have been implicated in the disease. Anti-viral immune response may trigger the destruction of pancreatic beta cells through the accelerated immune reaction with no detectable autoantibodies against pancreatic beta cells^[48,50]. Association of fulminant type 1 diabetes with pregnancy has also been reported^[51].

TYPE 2 DIABETES MELLITUS

The global prevalence of diabetes in adults (20-79 years old) according to a report published in 2013 by the IDF was 8.3% (382 million people), with 14 million more men than women (198 million men vs 184 million women), the majority between the ages 40 and 59 years and the number is expected to rise beyond 592 million by 2035 with a 10.1% global prevalence.

Figure 1 Comparative prevalence of diabetes in adults (20-79 years) in countries with high prevalence ($\geq 10\%$). Data extracted from International Diabetes Federation Diabetes Atlas, 6th ed, 2013.

With 175 million cases still undiagnosed, the number of people currently suffering from diabetes exceeds half a billion. An additional 21 million women are diagnosed with hyperglycemia during pregnancy. The Middle East and North Africa region has the highest prevalence of diabetes (10.9%), however, Western Pacific region has the highest number of adults diagnosed with diabetes (138.2 millions) and has also countries with the highest prevalence (Figure 1)^[27]. Low- and middle-income countries encompass 80% of the cases, “where the epidemic is gathering pace at alarming rates”^[27]. Despite the fact that adult diabetes patients are mainly type 2 patients, it is not clear whether the reported 382 million adults diagnosed with diabetes also include type 1 diabetes patients.

More than 90%-95% of diabetes patients belong to this type and most of these patients are adults. The number of youth (less than 20 years) with type 2 diabetes in the United States in the year 2009 was 0.46 in 1000 and accounted for approximately 20% of type 2 diabetes in youth^[26]. The increased incidence of type 2 diabetes in youth is mainly due to the change in the lifestyle of the children in terms of more sedentary life and less healthy food. Obesity is the major reason behind insulin resistance which is mainly responsible for type 2 diabetes^[52-54]. The ADA recommends screening of overweight children and adolescence to detect type 2 diabetes^[55,56]. The prevalence of obesity in children is on the rise^[6] which is probably the main reason for the increased incidence of type 2 diabetes in the young (30.3% overall increase in type 2 diabetes in children and adolescence between 2001 and 2009)^[26].

Insulin resistance in type 2 diabetes patients increases the demand for insulin in insulin-target

tissues. In addition to insulin resistance, the increased demand for insulin could not be met by the pancreatic β cells due to defects in the function of these cells^[18]. On the contrary, insulin secretion decreases with the increased demand for insulin by time due to the gradual destruction of β cells^[57] that could transform some of type 2 diabetes patients from being independent to become dependent on insulin. Most type 2 diabetes patients are not dependent on insulin where insulin secretion continues and insulin depletion rarely occurs. Dependence on insulin is one of the major differences from type 1 diabetes. Other differences include the absence of ketoacidosis in most patients of type 2 diabetes and autoimmune destruction of β cells does not occur. Both type 1 and type 2 diabetes have genetic predisposition, however, it is stronger in type 2 but the genes are more characterized in type 1 (the *TCF7L2* gene is strongly associated with type 2 diabetes)^[58]. Due to the mild symptoms of type 2 diabetes in the beginning, its diagnosis is usually delayed for years especially in countries where regular checkup without symptoms is not part of the culture. This delay in diagnosis could increase the incidence of long-term complications in type 2 diabetes patients since hyperglycemia is not treated during this undiagnosed period.

In addition to diabetes, insulin resistance has many manifestations that include obesity, nephropathy, essential hypertension, dyslipidemia (hypertriglyceridemia, low HDL, decreased LDL particle diameter, enhanced postprandial lipemia and remnant lipoprotein accumulation), ovarian hyperandrogenism and premature adrenarche, non-alcoholic fatty liver disease and systemic inflammation^[6,54]. The presence of type 2 diabetes in children and adolescence who are

not obese^[59-61], the occasional severe dehydration and the presence of ketoacidosis in some pediatric patients with type 2 diabetes^[55] had led to the misclassification of type 2 to type 1 diabetes.

Some patients with many features of type 2 diabetes have some type 1 characteristics including the presence of islet cell autoantibodies or autoantibodies to GAD65 are classified as a distinct type of diabetes called latent autoimmune diabetes in adults (LADA)^[62]. People diagnosed with LADA do not require insulin treatment. In a recent study, Hawa *et al.*^[63] reported 7.1% of European patients with type 2 diabetes with a mean age of 62 years, tested positive for GAD autoantibodies and the prevalence of LADA was higher in patients diagnosed with diabetes at a younger age. This classification of LADA as a distinct type of diabetes is still controversial^[6,64-66].

Insulin resistance and signaling

Defects in the insulin-dependent substrate proteins IRS-1 and IRS-2 mediated signaling pathway are implicated in the development of metabolic disorders, mainly diabetes. This pathway mediates the cellular response to insulin and involves a large array of insulin-stimulated protein kinases including the serine/threonine kinase AKT and protein kinase C (PKC) that phosphorylate a large number of Ser/Thr residues in the insulin receptor substrate (IRS) proteins involved in the metabolic response to insulin^[67]. In addition, other non-insulin dependent kinases including the AMP-activated protein kinase, c-Jun N-terminal protein kinase and G protein-coupled receptor kinase 2 that are activated under various conditions can phosphorylate the two insulin responsive substrates^[67-71]. Disruption in the AKT and PKC kinases is central to the development of diabetes^[72] and is associated with all major features of the disease including hyperinsulinemia, dyslipidemia and insulin resistance^[73]. Replacing the wild type IRS-1 with a mutant version of the protein having alanine instead of tyrosine in three locations using genetic knock-in approach provided evidence to the central role of IRS-1 phosphorylation in the development of insulin resistance^[74]. Using a similar approach to generate IRS-1 mutant with a single mutation involving a specific tyrosine residue, confirmed the role of IRS-1 phosphorylation in the development of insulin resistance pathogenesis^[75]. The large cumulative evidence indicates a complex array of factors including environmental factors^[76] and a wide range of cellular disturbances in glucose and lipid metabolism in various tissues^[77] contribute to the development of insulin resistance. This condition generates complex cellular metabolic changes in a variety of tissues, mainly liver and muscles, that include the inability of the liver to transport and dispose glucose, control glucose production *via* gluconeogenesis, impaired storage of glucose as glycogen, *de novo* lipogenesis and

hypertriglyceridemia^[77]. Among the factors implicated in the development of insulin resistance, obesity is the most predominant risk factor leading to insulin insensitivity and diabetes which involves several mechanisms that participate in the pathogenesis of the disease^[78]. Obesity-induced insulin resistance is directly linked to increased nutrient flux and energy accumulation in tissues that directly affect cell responsiveness to insulin^[77]. However, it seems that other insulin-independent mechanisms are involved in the overall metabolic disturbances of glucose homeostasis and diabetes including activities in extra-hepatic tissues in addition to the central role of liver.

OTHER TYPES OF DIABETES MELLITUS

Monogenic diabetes

Characterization of the genetic etiology of diabetes enables more appropriate treatment, better prognosis, and counseling^[79]. Monogenic diabetes is due to a genetic defect in single genes in pancreatic β cells which results in disruption of β cell function or a reduction in the number of β cells. Conventionally, monogenic diabetes is classified according to the age of onset as neonatal diabetes before the age of six months or Maturity Onset Diabetes of the Young (MODY) before the age of 25 years. However, certain familial defects are manifested in neonatal diabetes, MODY or adult onset diabetes^[2,9,80]. Others believe that classification of diabetes as MODY and neonatal diabetes is obsolete and monogenic diabetes is currently used relating specific genetic etiologies with their specific treatment implications^[79]. Beta cell differentiation depends on the expression of the homeodomain transcription factor PDX1 where mutation in the gene results in early onset diabetes (MODY) and its expression decreases before the onset of diabetes^[81]. The angiopoietin-like protein 8 (ANGPTL8) may represent a potential "betatrophin" that acts to promote the proliferation of beta cells, however, studies using mice lacking the ANGPTL8 active gene or overexpressed protein indicated that it did not seem to play a role in beta cells proliferation^[82].

Mitochondrial diabetes is due to a point mutation in the mitochondrial DNA associated with deafness and maternal transmission of the mutant DNA can result in maternally-inherited diabetes^[1,83].

Mutations that result in mutant insulin or the inability to convert proinsulin to insulin result in glucose intolerance in some of these cases. Genetic defects in the insulin receptor or in the signal transduction pathway of insulin have been demonstrated to result in hyperinsulinemia and modest hyperglycemia to severe diabetes^[1].

Disease of the exocrine pancreas

Damage of the β cells of the pancreas due to diffused injury of the pancreas can cause diabetes. This damage

could be due to pancreatic carcinoma, pancreatitis, infection, pancreatectomy, and trauma^[1]. Atrophy of the exocrine pancreas leads to progressive loss of the β cells^[84]. Accumulation of fat in the pancreas or pancreatic steatosis could lead to diabetes due to decreased insulin secretion but may require a long time before the damage to β cells occurs^[85]. In most cases, extensive damage of the pancreas is required before diabetes occurs and the exocrine function of the pancreas is decreased in these patients^[86]. Cirrhosis in cystic fibrosis may contribute to insulin resistance and diabetes^[2].

Hormones and drugs

Diabetes has been found in patients with endocrine diseases that secrete excess hormones like growth hormone, glucocorticoids, glucagon and epinephrine in certain endocrinopathies like acromegaly, Cushing's syndrome, glucagonoma, and pheochromocytoma, respectively^[1]. Some of these hormones are used as drugs such as glucocorticoids to suppress the immune system and in chemotherapy and growth hormone to treat children with stunted growth.

Genetic syndromes

Diabetes has been detected in patients with various genetic syndromes such as Down syndrome, Klinefelter syndrome, Turner syndrome and Wolfram syndrome^[1].

PREDIABETES

Individuals with prediabetes do not meet the criteria of having diabetes but are at high risk to develop type 2 diabetes in the future. According to the ADA Expert Committee, individuals are defined to have prediabetes if they have either impaired fasting plasma glucose (IFG) levels between 100-125 mg/dL (5.6-6.9 mmol/L) or impaired glucose tolerance test (IGT) with 2-h plasma glucose levels in the oral glucose tolerance test (OGTT) of 140-199 mg/dL (7.8-11.0 mmol/L). The World Health Organization (WHO) still adopts the range for IFG from 110-125 mg/dL (6.1-6.9 mmol/L). Prediabetes has been shown to correlate with increased cardiovascular mortality^[87,88] and cancer^[89]. The definition of prediabetes with the indicated cut off values is misleading since lower levels of glucose in the normal range are still correlated with cardiovascular disease in a continuous glycemic risk perspective^[90]. In accordance with the recommendation of the ADA in 2009 to use hemoglobin A1c (HbA1c) to diagnose diabetes, ADA also recommended the use of an HbA1c (5.7%-6.4%) to diagnose prediabetes^[91]. The number of people with IGT according to IDF was 316 million in 2013 (global prevalence 6.9% in adults) and is expected to rise to 471 million in 2030^[27]. According to a report in 2014 by the Center for Disease Control and Prevention, 86 million Americans (1 out of 3) have prediabetes^[92]. Four of the top ten countries with the

highest prevalence of prediabetes are in the Middle East Arab States of the Gulf (Kuwait, Qatar, UAE and Bahrain with prevalence of 17.9%, 17.1%, 16.6% and 16.3%, respectively)^[27]. The number of people diagnosed with prediabetes is different according to the method and criteria used to diagnose prediabetes. The number of people with prediabetes defined by IFG 100-125 mg/dL is 4-5 folds higher than those diagnosed using the WHO criteria of 110-125 mg/dL^[93]. Diabetes and prediabetes diagnosed using an HbA1c criteria give different estimates compared to methods using FPG or OGTT. Higher percentages of prediabetes were diagnosed using HbA1c compared to FPG^[94-96]. Prediabetes is associated with metabolic syndrome and obesity (especially abdominal or visceral obesity), dyslipidemia with high triglycerides and/or low HDL cholesterol, and hypertension^[97]. Not all individuals with prediabetes develop diabetes in the future, exercise with a reduction of weight 5%-10% reduces the risk of developing diabetes considerably (40%-70%)^[98]. Individuals with an HbA1c of 6.0%-6.5% have twice the risk of developing diabetes (25%-50%) in five years compared to those with an HbA1c of 5.5%-6.0%^[99].

DIAGNOSTIC CRITERIA FOR DIABETES MELLITUS

Diabetes mellitus is diagnosed using either the estimation of plasma glucose (FPG or OGTT) or HbA1c. Estimation of the cut off values for glucose and HbA1c is based on the association of FPG or HbA1c with retinopathy. Fasting plasma glucose of ≥ 126 mg/dL (7.0 mmol/L), plasma glucose after 2-h OGTT ≥ 200 mg/dL (11.1 mmol/L), HbA1c $\geq 6.5\%$ (48 mmol/mol) or a random plasma glucose ≥ 200 mg/dL (11.1 mmol/L) along with symptoms of hyperglycemia is diagnostic of diabetes mellitus. In addition to monitor the treatment of diabetes, HbA1c has been recommended to diagnose diabetes by the International Expert Committee in 2009^[100] and endorsed by ADA^[101], the Endocrine Society, the WHO^[102] and many scientists and related organizations all over the world. The advantages and disadvantages of the different tests used to diagnose diabetes have been reviewed by Sacks *et al.*^[103]. The advantages of using HbA1c over FPG to diagnose diabetes include greater convenience and preanalytical stability, lower CV (3.6%) compared to FPG (5.7%) and 2h OGTT (16.6%), stronger correlation with microvascular complications especially retinopathy, and a marker for glycemic control and glycation of proteins which is the direct link between diagnosis of diabetes and its complications^[104-109]. It is recommended to repeat the HbA1c test in asymptomatic patients within two weeks to reaffirm a single apparently diagnostic result^[110].

A cut off value for HbA1c of $\geq 6.5\%$ (48 mmol/mol) has been endorsed by many countries and dif-

ferent ethnic groups, yet ethnicity seems to affect the cut off values to diagnose diabetes^[111,112]. Cut-off values of 5.5% (37 mmol/mol)^[113] and 6.5% (48 mmol/mol)^[114] have been reported in a Japanese study, 6.0% (42 mmol/mol) in the National Health and Nutrition Examination Survey (NHANES III), 6.2% (44 mmol/mol) in a Pima Indian study, 6.3% (45 mmol/mol) in an Egyptian study as reported by Davidson^[105]; and three cut-off values for Chinese^[112]. The Australians recommended the use of two cut-off values: $\leq 5.5\%$ to “rule-out” and $\geq 7.0\%$ to “rule-in” diabetes^[115]. Variations in the prevalence of diabetes^[94,116-119] and prediabetes^[120] due to ethnicity have been documented. Most studies diagnosed less subjects with diabetes using HbA1c compared to FPG or OGTT^[121-123]. Yet, other studies reported more subjects diagnosed with diabetes using HbA1c^[96,124-126].

GESTATIONAL DIABETES

Hyperglycemia in pregnancy whether in the form of type 2 diabetes diagnosed before or during pregnancy or in the form gestational diabetes has an increased risk of adverse maternal, fetal and neonatal outcome. Mothers with gestational diabetes and babies born to such mothers have increased risk of developing diabetes later in life. Hyperglycemia in pregnancy is responsible for the increased risk for macrosomia (birth weight ≥ 4.5 kg), large for gestational age births, preeclampsia, preterm birth and cesarean delivery due to large babies^[127]. Risk factors for gestational diabetes include obesity, personal history of gestational diabetes, family history of diabetes, maternal age, polycystic ovary syndrome, sedentary life, and exposure to toxic factors^[3].

Diagnosis of type 2 diabetes before or during pregnancy is based on criteria mentioned before. Fasting plasma glucose ≥ 126 mg/dL (7.0 mmol/L) or 2-h plasma glucose ≥ 200 mg/dL (11.1 mmol/L) after a 75 g oral glucose load. However, gestational diabetes has been diagnosed at 24-28 wk of gestation in women not previously diagnosed with diabetes using two approaches: the first approach is based on the “one-step” International Association of the Diabetes and Pregnancy Study Groups (IADPSG) consensus^[128] and recently adopted by WHO^[129]. Gestational diabetes is diagnosed using this method by FPG ≥ 92 mg/dL (5.1 mmol/L), 1-h plasma glucose after a 75 g glucose load ≥ 180 mg/dL (10.0 mmol/L) or 2-h plasma glucose after a 75 g glucose load ≥ 153 mg/dL (8.5 mmol/L). This criteria is derived from the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study^[127] even though the HAPO study showed a continuous relationship between hyperglycemia and adverse short-term pregnancy outcome with no threshold reported^[130]. The second approach is used in the United States and is based on the “two-step” NIH consensus^[131]. In the first step 1-h plasma glucose after a 50 g glucose load under nonfasting state \geq

140 mg/dL (7.8 mmol/L) is followed by a second step under fasting conditions after a 100 g glucose load for those who screened abnormal in the first step. The diagnosis of gestational diabetes is made when at least two of the four plasma glucose levels are met. The four plasma glucose levels according to Carpenter/Coustan criteria are: FPG ≥ 95 mg/dL (5.3 mmol/L); 1-h ≥ 180 mg/dL (10.0 mmol/L); 2-h ≥ 155 mg/dL (8.6 mmol/L); and 3-h ≥ 140 mg/dL (7.8 mmol/L)^[1].

The use IADPSG criteria in comparison with the Carpenter/Coustan criteria was associated with a 3.5-fold increase in GDM prevalence as well as significant improvements in pregnancy outcomes, and was cost-effective^[132]. In another retrospective cohort study of women diagnosed with gestational diabetes, Ethridge *et al*^[133] have shown that newborns of women diagnosed with gestational diabetes by IADPSG approach have greater measures of fetal overgrowth compared with Carpenter-Coustan “two-step” approach neonates. A strategy of using fasting plasma glucose as a screening test and to determine the need for OGTT is valid^[134,135]. According to Sacks^[136], correlation of glucose concentrations and the risk of subsequent complications will eventually lead to universal guidelines.

The use of ADA/WHO cut off value of HbA1c $\geq 6.5\%$ (48 mmol/mol) to diagnose gestational diabetes is not recommended by the “one step” IADPSG criteria or the “two-step” NIH criteria. Further investigation is required in light of recent reports on HbA1c in combination with OGTT and its usefulness to predict adverse effect of gestational diabetes or obviate the use OGTT in all women with gestational diabetes^[137-141].

DIABETES AND GENETICS

Diabetes is a complex disease that involves a wide range of genetic and environmental factors. Over the past several years, many studies have focused on the elucidation of the wide spectrum of genes that played a role in the molecular mechanism of diabetes development^[142-144]. However, despite the vast flow of genetic information including the identification of many gene mutations and a large array of single nucleotide polymorphisms (SNPs) in many genes involved in the metabolic pathways that affect blood glucose levels, the exact genetic mechanism of diabetes remains elusive^[145,146]. Evidently, a major complication is the fact that a single gene mutation or polymorphism will not impose the same effect among different individuals within a population or different populations. This variation is directly or indirectly affected by the overall genetic background at the individual, family or population levels that are potentially further complicated by interaction with highly variable environmental modifier factors^[147,148].

Molecular genetics and type 2 diabetes

One of the major focuses of biomedical research is to delineate the collective and broad genetic variants in the

human genome that are involved in the development of diabetes. This major effort will potentially provide the necessary information to understand the molecular genetics of the different forms of diabetes including type 1, type 2 and monogenic neonatal diabetes among individuals of all populations and ethnic groups. Despite the fact that linkage and association studies allowed the identification and characterization of many candidate genes that are associated with type 2 diabetes^[144,149,150], however, not all of these genes showed consistent and reproducible association with the disease^[151]. Genome wide association studies (GWAS) in various populations identified 70 loci associated with type 2 diabetes and revealed positive linkage of many mutations and SNPs that influence the expression and physiological impact of the related proteins and risk to develop type 2 diabetes. One study involved several thousand type 2 diabetes patients and control subjects from the United Kingdom allowed the identification of several diabetes putative loci positioned in and around the *CDKAL1*, *CDKN2A/B*, *HHEX/IDE* and *SLC30A8* genes in addition to the contribution of a large number of other genetic variants that are involved in the development of the disease^[152]. Two similar studies from the Finns and Swedish populations and the United States resulted in the identification of similar single nucleotide variants^[153] that are linked to the risk of acquiring type 2 diabetes^[154,155]. The study in the United States population included in addition to type 2 diabetes, the association of the identified SNPs with the level of triglycerides in the tested subjects^[155]. These SNPs are located near several candidate genes including *IGFBP2* and *CDKAL1* and other genes in addition to several other variants that are located near or in genes firmly associated with the risk of acquiring type 2 diabetes. Other GWAS analysis studies were performed in the Chinese, Malays, and Asian-Indian populations which are distinct from the European and United States populations in addition to meta-analysis of data from other populations in the region revealed relevant findings among patients with European ancestry^[156]. The results of the combined analysis showed significant association of SNPs in the *CDKAL1*, *CDKN2A/B*, *HHEX*, *KCNQ1* and *SLC30A8* genes after adjustment with gender and body mass index. More recently, meta-analysis of GWAS data involving African American type 2 diabetes patients identified similar loci to the previous studies with the addition of two novel loci, HLA-B and INS-IGF^[157]. These results provide strong evidence of common genetic determinants including common specific genes that are linked to diabetes. A small list of specific genetic markers seem strongly associated with the risk of developing type 2 diabetes including the *TCF7L2*^[158] and *CAPN10*^[159,160] genes which also play a significant role in the risk and pathogenesis of the disease^[158,159]. The association of *TCF7L2* gene variants with type 2 diabetes and its mechanism of action received special attention by several investigators^[161,162]. Over expression of

the protein was shown to decrease the sensitivity of beta islet cells to secrete insulin^[163,164] and was more precisely involved in the regulation of secretory granule fusion that constitute a late event in insulin secretion pathway^[165]. The role of *TCF7L2* in insulin secretion was partially clarified^[166] that involves modifying the effect of incretins on insulin secretion by lowering the sensitivity of beta cells to incretins. Several other genes have been found to be significantly associated with the risk of developing type 2 diabetes including a specific SNP in a hematopoietically-expressed homeobox (*HHEX*) gene^[167]. The islet zinc transporter protein (*SLC30A8*)^[168] showed positive correlation with the risk of developing type 2 diabetes where variant mutations in this gene seem protective against the disease which provides a potential tool for therapy^[169]. More recently, a low frequency variant of the *HNF1A* identified by whole exome sequencing was associated with the risk of developing type 2 diabetes among the Latino population and potentially may serve as a screening tool^[170]. Genetic variants and specific combined polymorphisms in the interleukin and related genes including interleukin-6 (*IL-6*), tumor necrosis factor- α and *IL-10* genes were found to be associated with greater risk of developing type 2 diabetes^[171], in addition to genetic variants in the genes for *IL12B*, *IL23R* and *IL23A* genes^[172]. In a study involving the hormone sensitive lipase responsible for lipolysis in adipose tissues, a deletion null mutation, which resulted in the absence of the protein from adipocytes, was reported to be associated with diabetes^[173]. Nine specific rare variants in the peroxisome proliferator-activated receptor gamma (*PPARG*) gene that resulted in loss of the function of the protein in adipocytes differentiation, were significantly associated with the risk of developing type 2 diabetes^[174]. In addition, certain SNPs in the alpha 2A adrenergic receptor (*ADRA2A*) gene, involved in the sympathetic nervous system control of insulin secretion and lipolysis, were found to be associated with obesity and type 2 diabetes^[175]. Link analysis between the melatonin MT2 receptor (*MTNR1B*) gene, a G-protein coupled receptor, identified 14 mutant variants from 40 known variants revealed by exome sequencing, to be positively linked with type 2 diabetes^[176]. The authors suggested that mutations in the *MT2* gene could provide a tool with other related genes in modifying therapy for type 2 diabetes patients based on their specific genetic background to formulate personalized therapies which potentially may ensures the optimum response. Interestingly, mutations in the clock^[177,178] and *Bmal1*^[179] transcription factor genes which are involved in beta cells biological clock affecting growth, survival and synaptic vesicle assembly in these cells, resulted in reduced insulin secretion and diabetes. Evidently, prominent metabolic functions involve the production of specific reactive metabolites, leading to oxidative stress, which affect lipids, proteins and other biological compounds leading to serious damage in

various tissues and organs. Mutations and SNPs in the antioxidant genes, including superoxide dismutase, catalase and glutathione peroxidase, that decrease their activity are implicated in the risk and pathogenesis of type 2 diabetes^[180]. The metabolic syndrome was shown to be associated with the development of type 2 diabetes in a population that is described as highly endogenous especially in individuals over 45 years of age^[181]. Since consanguinity marriages is high in this population, screening for this syndrome among families could provide an informative marker on the risk of developing type 2 diabetes^[181].

Molecular genetics of type 1 diabetes

Even though type 1 diabetes is basically described as an autoimmune disease that results in the destruction of pancreatic beta cells, however, single gene mutations and SNPs have been found to be associated with the susceptibility to this type of diabetes. Initially, two gene mutations were linked to the development of type 1 diabetes including the autoimmune regulator (*AIRE*) gene which affect the immune tolerance to self antigens leading to autoimmunity^[182] and the *FOXP3* gene which results in defective regulatory T cells^[183]. In addition, a mutation in the histone deacetylase *SIRT1* gene predominantly expressed in beta cells involved in the regulation of insulin secretion^[184] and played a role in modulating the sensitivity of peripheral tissues to insulin^[185] was detected in type 1 diabetes patients^[186]. Recently, additional mutations and SNPs in the *CTLA-4 +49A/G* and *HLA-DQB1* and *INS* gene VNTR alleles were found to be associated with type 1 diabetes, which have the advantage of differentiating between Latent autoimmune type 1 diabetes and type 2 diabetes^[187]. The *HLA-DQB1*, in combination with *HLA-DR* alleles and a polymorphism in *PTPN22* gene seem to be associated with the age onset of late type 1 diabetes^[188,189]. Two specific polymorphisms in the promoter region of a transmembrane protein (*DC-SIGN*) gene expressed in macrophages and played an important role of T- cell activation and inflammation were found to be protective against type 1 diabetes^[190]. An innovative non-parametric SNP enrichment tool using summary GWAS DATA allowed the identification of association between several transcription factors and type 1 diabetes and are located in a type 1 diabetes susceptibility region^[191]. Nine SNP variants in several genes associated with type 1 diabetes, not including the major histocompatibility gene region, were identified using extensive GWAS analysis^[192]. Furthermore, several novel SNPs in a region in chromosome 16 located in the *CLEC16A* gene were shown to be associated with type 1 diabetes and seem to function through the reduced expression of *DEX1* in B lymphoblastoid cells^[193]. Since more than 40 regions in the human genome were identified to be associated with the susceptibility to type 1 diabetes^[194-196], a weighted risk model was developed utilizing selected

genes SNPs could be used for testing infants for these genetic markers that could provide insights in the susceptibility to type 1 diabetes development or safe prevention of the disease among young children^[197].

Molecular genetics of monogenic diabetes

A large array of genes were identified to be involved in the development of monogenic diabetes^[80] which represent about 2%-5% of diabetes patients. Monogenic diabetes results primarily from gene defects that lead to a decrease in beta cell number or function. Monogenic diabetes genes were identified using linkage studies or code for proteins that directly affected glucose homeostasis. The majority of genes responsible for monogenetic diabetes code for either transcription factors that participate in the control of nuclear gene expression or proteins that are located on the cell membrane, cytoplasm and endoplasmic reticulum, proteins involved in insulin synthesis and secretion, exocrine pancreatic proteins and autoimmune diabetes proteins^[80]. The collective function of these proteins is their participation in glucose metabolism at different levels. Evidently, the hierarchy of a specific gene in the overall glucose metabolism pathway determines the onset of diabetes in the patient and whether it is neonatally expressed or have late onset expression (adulthood). Consequently, molecular defects in the structure and function of these genes lead to the disturbance of plasma glucose level, the primary pathological sign of diabetes. The molecular mechanism of permanent neonatal diabetes mellitus (PNMP) in addition to *MODY* explains the observed phenotype of monogenetic diabetes that involves loss of function of the expressed mutant protein. The first gene implicated in monogenic diabetes was the glucokinase (*GCK*) gene^[198] which functions as a pancreatic sensor for blood glucose where more than 70 mutations in the gene were identified that affected its activity^[199]. A recent study on *GCK* gene mutations causing neonatal and childhood diabetes showed that the majority of mutations resulted in the loss of the enzyme function primarily due to protein instability^[148,150]. Two hepatocytes nuclear factor genes that code for the *HNF4A* and *HNF1A* transcription factors were closely associated with *MODY1* and *MODY2*^[148,149]. Definitely, a whole list of other genes involved in monogenic diabetes are either overlooked or included in the genetic determinants of type 1 and type 2 diabetes which will be identified and clarified through more careful future studies.

MOLECULAR GENETICS OF DIABETES COMPLICATIONS

In addition to the genetic determinants of diabetes, several gene mutations and polymorphisms have been associated with the clinical complications of diabetes. The cumulative data on diabetes patients with a

variety of micro- and macrovascular complications support the presence of strong genetic factors involved in the development of various complications^[200]. A list of genes have been reported that are associated with diabetes complications including *ACE* and *AKR1B1* in nephropathy, *VEGF* and *AKRB1* in retinopathy and *ADIPOQ* and *GLUL* in cardiovascular diseases^[200]. A study on Chinese patients revealed a single SNP in the promoter region of the smooth muscle actin (*ACTA2*) gene correlates with the degree of coronary artery stenosis in type 2 diabetes patients^[201]. Furthermore, the alpha kinase 1 gene (*ALPK1*) identified as a susceptibility gene for chronic kidney disease by GWAS^[202], was demonstrated in type 2 diabetes patients^[203]. Three additional genes have been strongly correlated with this risk of diabetic retinopathy (DR) including the vascular endothelial growth receptor, aldose reductase and the receptor for advanced glycation products genes^[204] where specific polymorphisms in these genes seem to increase the risk of DR development in diabetes patients^[204]. A significant differential proteome (involving 56 out of 252 proteins) is evident that characterizes vitreous samples obtained from diabetes patients with the complication in comparison to diabetes patients without the complication and control individuals^[205]. Interestingly, a large portion of these proteins (30 proteins) belong to the kallikrein-kinin, coagulation and complement systems including complement C3, complement factor 1, prothrombin, alpha-1-antitrypsin and antithrombin III that are elevated in diabetic patients with retinopathy^[205]. In addition, 2 single nucleotides polymorphisms in the human related *B7-I* gene seem to mediate podocyte injury in diabetic nephropathy^[206]. Furthermore, increased concentration of the ligand of B7-1 correlates with the progression of end-stage renal disease (ESRD) in diabetes patients^[206]. These results indicate that B7-I inhibition may serve as a potential target for diabetes nephropathy prevention and/or treatment. Recently, it was shown that direct correlation is evident between circulating levels of tumor necrosis factors 1 and 2 and increased risk of ESRD in American Indian patients^[207]. The link between diabetes and proper bone development and health is evident. Studies using animal models with major significant reduction in insulin receptor (IR) in osteoprogenitor cells resulted in thin and rod-like weak bones with high risk of fractures^[208]. Similar findings were observed in animal models with bone-specific IR knockdown animals which points to the central role of IR in the proper development of bones^[208]. Type 2 diabetes is also associated with mitochondrial dysfunction in adipose tissues. Using knockout animal models of specific mitochondrial genes led to significant reduction in key electron transport complexes expression and eventually adipocytes death^[209]. These animals exhibited Insulin resistance in addition to other complications that can potentially lead to cardiovascular disease^[209].

CONCLUSION

Diabetes mellitus is the epidemic of the century and without effective diagnostic methods at an early stage, diabetes will continue to rise. This review focuses on the types of diabetes and the effective diagnostic methods and criteria to be used for diagnosis of diabetes and prediabetes. Evidently, diabetes is a complex disease with a large pool of genes that are involved in its development. The precise identification of the genetic bases of diabetes potentially provides an essential tool to improve diagnoses, therapy (more towards individualized patient targeted therapy) and better effective genetic counseling. Furthermore, our advanced knowledge of the association between medical genetics and the chronic complications of diabetes, will provide an additional advantage to delay or eradicate these complications that impose an immense pressure on patient's quality of life and the significantly rising cost of health-care services.

Abstract

Diabetes mellitus (DM) is a highly prevalent condition affecting about 347 million people worldwide. In addition to its numerous clinical implications, DM also exerts a negative effect on patient's sleep quality.

Impaired sleep quality disrupts the adequate glycemic control regarded as corner stone in DM management and also lead to many deleterious effects causing a profound impact on health related quality of life. This article outlines various factors leading to impaired sleep quality among diabetics and delineates how individual factor influences sleep. The article also discusses potential interventions and lifestyle changes to promote healthy sleep among diabetics.

Key words: Diabetes mellitus; Sleep quality; Quality of life; Obstructive sleep apnea; Nocturnal hypoglycemia

Core tip: Diabetes mellitus (DM) is one of the common chronic medical conditions affecting approximately 347 million people worldwide. Studies have shown that up to one third of patients with DM suffer from concomitant sleep disorder. Factors associated with disrupted sleep among diabetic patient include nocturia, nocturnal hypoglycemia, peripheral neuropathy, restless leg syndrome and sleep disordered breathing. These conditions, when associated with diabetes can cause fragmented sleep and poor quality of life. It is imperative for the primary care physicians and health care providers to address this important issue among the diabetic patients during their visit.

INTRODUCTION

Sleep is a prerequisite for healthy functioning of human mind and body. It is generated based on a circadian rhythm and homeostatic pressure that follows a period

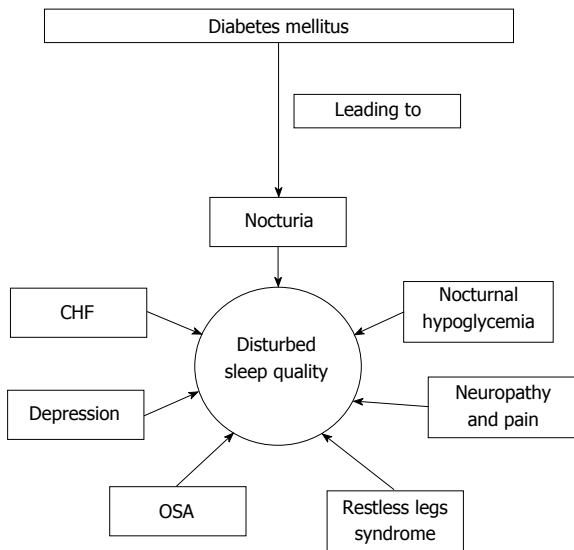

Figure 1 Illustration how different conditions associated with diabetes mellitus affects the sleep quality. OSA: Obstructive sleep apnea; CHF: Congestive heart failure.

of wakefulness. Poor or impaired sleep has not only being associated with various diseases and conditions but also led to poor performance and occupational accidents. Medical literature regarding sleep sciences reveals numerous studies that characterize sleep quality and determine various factors leading to impaired sleep among different patient populations^[1-6]. Based on findings from these studies, it is inferred that in addition to many behavioral factors including poor sleep habits and hygiene, various pathological conditions have been recognized that adversely affect the sleep. Most notable among these conditions are obstructive sleep apnea, chronic insomnia and restless legs syndrome.

Diabetes mellitus (DM) is being increasingly recognized as a significant health burden. Based on recent data published by World Health Organization (WHO), it is estimated that approximately 347 million people are suffering from diabetes worldwide, 90% of who have type 2 diabetes. Patients with DM, by virtue of its numerous clinical and associated implications, suffer a poor quality of life^[7,8]. It is not surprising that sleep quality among these patients are significantly impaired. Patients with DM can experience challenges to their sleep and wakefulness due to physiological imbalance and co-morbid sleep pathologies. In this review we attempted to present several factors, which directly affect the sleep quality among patients with DM (Figure 1).

DIABETES AND SLEEP

The significance of good sleep cannot be over emphasized when it comes to chronic medicinal condition like DM. Poor sleep quality, apart from its usual effect of daytime sleepiness, has ramifications that

affect every aspects of life. The pertinent ones are: exacerbation of seizures, short-term memory deficits, long-term cognitive effects and headache. These, when combine to “already worsened” quality of life in patients with chronic diseases, can have several deleterious consequences in an individual’s life.

Clinical research has shown that up to one third of patients with DM suffered from concomitant sleep disorders, as compared with 8.2% of controls without DM^[9]. In another study, more than half of the patients with type 2 DM are likely to report being “poor sleepers”, according to a research poll conducted at University of Pittsburgh. The patients with type 2 DM were more likely to have low Pittsburgh Sleep Quality index (PSQI)^[10]. (PSQI is a validated tool which measures sleep quality and pattern in older adults. It discriminate poor sleepers from normal by assessing seven components of sleep over a one month time interval)^[10]. Part of the components of these index’s metrics are common insomnia variables, such as sleep latency and efficiency. The same study also showed that the sleep quality correlated well with other diabetic quality of life scores^[11]. In general, patients with other chronic medical conditions are also more likely to experience insomnia. In a large community-base sample of 3282 adults, polysomnographic data was analyzed along with self-reported sleep habits and current health. The adjusted odds ratio for insomnia was 1.4 in patients with DM, compared with people without the disorder. Even when data obtained on polysomnography was adjusted for age, gender and apnea-hypopnea index, patients with diabetes mellitus and insomnia had lower sleep efficiency than those without the disease^[12]. Sleep deprivation and sleep fragmentation has been shown to correlate with insulin resistance in obese individuals^[13]. Poor sleep quality has implications on diabetes self-management. Adult diabetic patients, who reported poor quality sleep underwent completion of questionnaires measuring diabetes control, sleep quality and daytime sleepiness. The patients with poor sleep were found to have difficulty with diabetes control, other demographic factors such as education, age, gender, were measured and these were not found to be associated with diabetes control problems^[14]. Studies have linked poor sleep and insomnia to be associated with decrease in gamma-aminobutyric acid (GABA). A lower level of GABA is also seen in the patients with depression^[15]. GABA is produced in significant levels in pancreas. It has also been shown to be inhibiting apoptosis of the rodent beta cells. The glutamate decarboxylase the primary enzyme (GAD) involved in the synthesis of GABA has been linked with type 1 DM^[16,17]. It is possible that GABA is one of the neurotransmitter involved in the sleep quality among diabetics, when in low levels. Orexins also has been associated with sleep, arousal, energy balance and feeding. Orexins have been implicated in the metabolism of glucose.

Its expression is inhibited by obesity, obstructive sleep apnea and depression^[18]. The pathogenetic link between sleep deprivation and DM has been further elucidated in a recent cross over study involving fourteen healthy subjects who underwent 4 h sleep restriction. This sub-chronic sleep restriction led to a reduction in peripheral insulin sensitivity but interestingly the hepatic insulin sensitivity did not decrease. There was no significant reduction in slow wave sleep associated with it. There was a modest increase in cortisol and catecholamines. This increases lipolysis. Fasting non-esterified fatty acids and β -OH butyrate levels were elevated indicating an increase in lipolysis and hepatic fatty acid oxidation. The resting energy expenditure was unchanged but the respiratory quotient decreased consistent with fat oxidation. The elevated non-esterified fatty acids may modulate hepatic metabolism. Thus the insulin resistance is driven by extrahepatic tissue^[19].

NOCTURIA

Nocturia is defined by waking up at night to void and is considered clinically meaningful if it occurs two or more times per night. Patients report nocturia as a leading cause of sleep disturbance, affecting both sleep onset and maintenance^[20]. Polyuria, defined as 24-h urine output of more than 2800 mL (or above 40 mL/kg per 24 h)^[21]. Polyuria may cause nocturia through generally increased urine production wherein nocturnal urine output exceeds functional bladder capacity (FBC). However, polyuria and nocturnal polyuria are not mutually inclusive.

Nocturia in persons with DM can occur in association with polyuria, and the mechanism is solute diuresis, but can also be associated with frequently comorbid sleep-breathing disorder, such as obstructive sleep apnea. It has been postulated that in patients with obstructive sleep apnea, the negative intrathoracic pressure and stretching of the myocardium releases atrial natriuretic peptide (ANP). This, in turn, causes vasodilatation and inhibits aldosterone resulting in excess sodium and water excretion. When a sleep disorder is suspected, for example in patients with complaints of snoring, gasping for breath when sleeping, or with daytime sleepiness, a nocturnal polysomnography should be performed^[22]. In a study conducted in Australia with 74 patients with type 2 DM, nocturia was correlated with sleep maintenance difficulties^[23].

NOCTURNAL HYPOGLYCEMIA

Nocturnal hypoglycemia can lead to sleep disruption and can be regarded as one of the many factors leading to poor sleep quality among diabetics. Longer intervals between self-monitoring glycemia are generally seen during the night and this period is

associated with the highest sensitivity to insulin. Studies observing continuous glucose monitoring have shown that in patients with diabetes mellitus type 1 spent on average of 2.3 h per day with glucose levels below 70 mg/dL, and most of the hypoglycemic values occur at night^[24]. These findings were corroborated by another study with same principles of continuous monitoring, showing that in more than half of the nights studied, nocturnal hypoglycemia occurred^[25]. Moreover, various insulin regimens can also predispose a diabetic patient to nocturnal hypoglycemia. In a study comparing bedtime insulin NPH (neutral protamine hagedorn) and bedtime insulin glargine, the incidence of nocturnal hypoglycemia was statistically significant with bedtime insulin NPH (24% vs 9.9%)^[26].

RESTLESS LEGS SYNDROME

Restless legs syndrome is a sensorimotor-related sleep disorder and can be either primary or secondary, when related to other conditions such as anemia, pregnancy, or end-stage renal disease, among others. The International Restless Syndrome Study Group (IRLSSG) has published four essential criteria to diagnose patient with restless leg syndrome. It includes: Presence of an urge to move the legs the legs accompanied by an unpleasant sensation (creeping, crawling, painful, itching or jittering feeling in the legs), relieved by movement, aggravated by rest (*i.e.*, when patients lie down to attempt to fall asleep) and worsening of symptoms in the evening or at night^[27]. Other body parts such as the upper extremities can also be involved. Females suffer from RLS twice as much as their male counterparts across all different populations and ages^[28]. There is evidence linking an increased risk for RLS in patients with diabetes mellitus^[29,30]. Several diabetic patients with RLS also suffer from peripheral neuropathy^[29]. Diabetic patients who suffer from RLS are more likely to report worse sleep quality, have longer sleep latency and worse sleep efficiency, and experience more daytime dysfunction compared with diabetic controls without RLS^[31]. RLS can be treated with non-pharmacologic methods which include implementing lifestyle changes such as regular physical activity, restriction on all caffeinated food and drinks, using pneumatic compression devices applied to the thigh and leg during sleep, massage therapy, soaking the legs in warm water^[32]. Pharmacotherapy can be achieved with dopamine agonists, such as pramipexole and ropinirole, anticonvulsants, such as gabapentin, opiates, benzodiazepines, minerals and vitamin supplementation, particularly oral iron in patients with low serum ferritin levels below 50 μ g/L^[32]. Several pharmacological agents have been implicated in worsening symptoms of RLS. Selective serotonin receptor inhibitors, antihistamines, dopamine agonists and sympathomimetic agents are common drug associated with RLS^[33]. These include antihistamines,

dopamine antagonist, sympathomimetic agents, caffeine, nicotine and alcohol^[33]. Attempt should be made in avoiding the medications, which can worsen the RLS, and in turn impair the sleep quality in those patients.

SLEEP DISORDERED BREATHING

Obstructive sleep apnea (OSA) is a complex disorder characterized by recurrent episodes of pharyngeal obstruction during sleep, leading to repeated episodes of intermittent hypoxia, arousals from sleep, which in turn can lead to sleep fragmentation, decreased total sleep time and daytime hypersomnolence^[34]. Obesity is a risk factor for both obstructive sleep apnea and insulin resistance. Foster *et al* found that in a population comprising patients with obesity and type 2 DM in whom the impact of lifestyle changes were being studied, obstructive sleep apnea was highly prevalent, with only 13.4% of patients not having some degree of OSA on a home-based portable monitoring sleep test. Among obese adults with type 2 diabetes, half the patients had moderate or severe OSA (apnea-hypopnea index above 15 events per hour)^[35]. The interactions between obstructive sleep apnea and insulin resistance and glucose intolerance mellitus are being investigated. It has been postulated that there could be a causal effect for the development of insulin resistance in patients with chronic intermittent hypoxia (as it occurs during episodes of obstructive apneas and hypopneas). Possible mechanisms implicated include higher levels of cytokines in patients with OSA (plasma IL-6 and TNF- α), increase in sympathetic neural traffic and the release of gluco-regulatory neuroendocrine hormones such as cortisol^[36]. In a murine model of obese animals, chronic intermittent hypoxemia exacerbated fasting hyperglycemia, glucose intolerance and insulin resistance^[37]. A more recent study of patients with poorly controlled DM (HbA1C \geq 7%) revealed that intermittent hypoxia which is a consequence of sleep apnea, is frequent in these patients (37.2%). Furthermore, it was strongly associated with poor glycemic control (OR: 2.31, 95%CI: 1.06-5.04)^[38]. However, it is still unclear whether OSA may lead to the development of DM over time and more studies are needed to evaluate this possible causal relationship.

DIABETES AND HEART FAILURE

The lifetime risk of cardiovascular diseases in individuals with DM is high, ranging from 55%-79%. The risk is further accentuated with increasing adiposity^[39]. In a study conducted by Nicholas GA and colleagues, it was estimated that 11.8% subjects with baseline diabetes developed heart failure compared 7.7% without DM^[40]. Diabetic patients developing heart failure experiences disturbed sleep by several mechanisms including: Sleep disordered breathing

Cheyne Stokes breathing and Obstructive sleep apnea, effects of medicines, symptom of heart failure (dyspnea, orthopnea and paroxysmal nocturnal dyspnea) and health problems including pain and depression^[41].

The treatment of impaired sleep quality and sleep fragmentation should involve the education of the patients regarding the sleep hygiene techniques, behavioral modification, cognitive behavioral therapy and pharmacological therapies. The detail discussion of which is beyond the scope of this manuscript. In addition the specific etiologies, which are specific for the sleep fragmentation, poor sleep quality and insomnia among diabetics as nocturia, pain related to diabetic neuropathy, restless leg syndrome, obstructive sleep apnea, heart failure and nocturnal hypoglycemia should be addressed and treated.

CONCLUSION

DM is one of the most common diseases worldwide. DM, in addition to causing direct sleep disturbances as a result of nocturia, polyuria, diabetic neuropathy and neuropathy pain, has also been associated with several chronic illness as obstructive sleep apnea, cardiovascular complications, hypertension, cerebrovascular accidents and depression which can impair sleep and quality of life. The patient may not bring the sleep issues during their visit to healthcare providers, with acute issues taking precedence during their visit. It is important for the health care providers treating the patient with DM to address their sleep issues and the impaired quality of life due to inadequate and fragmented sleep, as it may be severely affect their recovery, control of diabetes as well as quality of life. Sleep education should also be considered an essential part in the diabetic management armamentarium.

Abstract

With the rising global prevalence in diabetes, healthcare

systems are facing a growing challenge to provide efficient and effective diabetes care management in the face of spiralling treatment costs. Diabetes is a major cause of premature mortality and associated with devastating complications especially if managed poorly. Although diabetes care is improving in England and Wales, recent audit data suggests care remains imperfect with wide geographical variations in quality. Diabetes care is expensive with a sizeable amount of available expenditure used for treating the complications of diabetes. A target driven, long-term, multifactorial intervention in patients with type 2 diabetes has been shown to reduce mortality and morbidity. The alphabet strategy is a novel approach to effective diabetes care provision, aiming to address patient education and empowerment, provide consistent comprehensive care delivered in a timely fashion, and allowing multidisciplinary team work.

Key words: Alphabet strategy; Diabetes care management; Checklist; Multifactorial intervention; Chronic disease management

Core tip: The alphabet strategy is a novel approach to effective diabetes care provision, using a checklist approach to delivering multifactorial intervention. The aim is to address patient education and empowerment, provide consistent comprehensive care delivered in a timely fashion, and allow multidisciplinary team work. In this article, we demonstrate evidence for its clinical effectiveness.

Alphabet Strategy for diabetes care: A multi-professional, evidence-based, outcome-directed approach to management. *World J Diabetes* 2015; 6(6): 874-879 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/874.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i6.874>

INTRODUCTION

The increasing global prevalence of diabetes has been described by many as an current epidemic^[1]. The causes are complex but they are largely due to adverse lifestyle factors such as obesity and physical inactivity, as well as poverty. Although no country will be immune from the epidemic, most of the increase is expected to occur in low and middle income countries that are poorly set-up to manage the crisis^[2]. Diabetes care is expensive, with current direct costs estimated to be £9.8 billion in the United Kingdom, or approximately ten percent of the total healthcare expenditure. Treatment of complications account for 80% of this expenditure^[3].

No short-term cure exists for diabetes. Patients need to work closely with multidisciplinary teams to control risk factors in order to prevent or delay the advent of recognised complications. However diabetes care management remains imperfect with substantial variations in care quality. Data from the National Diabetes Audit from England and Wales found that on average under two-thirds of people received all eight recommended healthcare checks, with a range of performance from 18% to 78%^[4]. Such variation in routine healthcare performance also exists at a geographical level. For target care process achievement, only an average of 61% and 60% of subjects achieved their blood pressure and cholesterol goals respectively. Internationally, our own Global Alphabet Strategy Implementation Audit project across 45 single centres in 28 countries demonstrated considerable variations in care quality closely linked to each country's economic prosperity and healthcare spend^[5].

Our objective from the outset was to develop a diabetes strategy that would address the variation in care ensuring "simple things are done right all the time", promoting a consistent approach to management^[6]. It would involve the participation of patients in their own care, especially for their education and empowerment in disease management issues. The strategy had to be applicable in all clinical settings, allowing multidisciplinary teamwork across primary and secondary care interfaces. Finally, it had to be evidence-based, and simple to use and recall for both healthcare professionals and patients.

THE ALPHABET STRATEGY

Our framework is called the alphabet strategy, a mnemonic-based checklist incorporating the core components for comprehensive diabetes care^[7]. Its elements consist of: (1) Advice, specifically on avoidance of smoking, encouraging regular physical activity and judicious dietary choices leading to optimal weight attainment, and individualised recommendations such as influenza vaccination; (2) Blood pressure, with targets guided by co-morbidities; (3)

Cholesterol measurement, with targets determined by co-morbidities - Creatinine/microalbuminuria evaluation; (4) Diabetes glucose control, with target HbA1c individualised according to co-morbidities and aiming for avoidance of hypoglycaemia; (5) Eye exam, performed yearly, with prompt referral for intervention as clinically indicated; (6) Foot exam, conducted at least yearly, with prompt appropriate referral as indicated; and (7) Guardian drugs: opportune use of aspirin, ACE inhibitors or angiotensin receptor blockers, and statins protective against cardiovascular disease and other diabetes complications.

A substantial diabetes evidence base exists for each element of the checklist^[8-11]. Overall, the use of a multifactorial targeted intervention such as that used in the Steno-2 study resulted in significant reductions in macrovascular and microvascular complications as well as cardiovascular mortality^[12].

The aim of this paper is to outline the evidence-base and the potential for use of the alphabet strategy in clinical practice. We hope that this will lead to a reduction in diabetes complications and provide an education strategy for both patients and healthcare professionals in diabetes care.

CLINICAL IMPACT - PRACTICE OF EVIDENCE-BASED MEDICINE 1 AUDIT

To determine the clinical impact of the alphabet strategy in the care of our patients with type 2 diabetes, pre and post checklist implementation audits were conducted on over 400 consecutive patients attending our diabetes outpatient clinic^[13].

The average age of our cohort was 58 years, with mean duration of diabetes being 6 years. 54% were male. Ethnically, 87% were White Caucasian, 11% of South Asian (Indo-Asian) origin, and the remainder being of African-Caribbean. The average follow-up period between the two audits was 5 years.

Use of alphabet strategy resulted in significant improvements in average blood pressure, mean total and HDL cholesterol, performance of eye and foot examinations, and uptake of guardian drugs. Ninety-seven percent of subjects on lipid lowering agents in the post implementation audit were on statins. Significant deterioration was seen in glycaemic control over the mean 5 year follow-up, which can be partly explained by the effect of progressive ageing on glycaemic control^[8]. When adjusted for duration of diabetes, an improvement in HbA1c was seen. No significant change was seen in the number of smokers (Table 1).

CONTINUED BENEFITS - PRACTICE OF EVIDENCE-BASED MEDICINE 2

A repeat audit of subjects with T2DM attending the clinic was performed two years later to determine if the

Table 1 Effect of the Alphabet Strategy on change in achievement of target care processes

Alphabet strategy	Pre implementation	Post implementation	P value
A Smoking (%)	18.2 (77)	15.7 (66)	NS
B Blood pressure (mmHg)	146/82	140/76	< 0.0001
C Total cholesterol (mmol/L)	5.7	4.9	< 0.0001
HDL cholesterol (mmol/L)	1.1	1.39	< 0.001
D HbA1c (%)	7.9	8.3	< 0.0001
E Eye examination (%)	85.0	95.5	< 0.001
F Foot examination (%)	69.8	83.5	< 0.001
G Aspirin (%)	29.0	83.5	< 0.001
ACEI/ARB (%)	32.0	73.0	< 0.001
Lipid lowering (%)	16.8	55.0	< 0.001

NS: Not significant.

Table 2 Comparison of achievement of Alphabet Strategy components between practice of evidence-based medicine audits

Alphabet strategy	POEM 1 n = 420	POEM 2 n = 1071	P value
A Smoking status (%)	15.5	14.7	0.83
B Blood pressure (mmHg)	141/77	136/76	0.007
C Total cholesterol (mmol/L)	4.9	4.5	< 0.001
LDL cholesterol (mmol/L)	2.5	2.4	< 0.001
Creatinine (mmol/L)	109	105	0.036
D HbA1c (%)	8.3	7.9	0.09
E Eye examination (%)	95.5	97.1	0.72
F Foot examination (%)	83.5	97.3	< 0.001
G Aspirin (%)	83.5	88.0	0.20
ACEI/ARB (%)	73.0	74.4	0.75
Lipid lowering (%)	55.0	73.4	< 0.001

POEM: Practice of evidence-based medicine.

use of the AS continued to provide meaningful clinical benefits. Data on over 1000 subjects was collected^[14].

Performance of each essential care process according to the alphabet strategy was over 92%. Comparison of target care process achievement with the original Practice Of Evidence-based Medicine (POEM) audit is shown in Table 2. Improvements in all AS measured components were seen (Table 1).

ACHIEVING CLINICAL TRIAL STANDARDS IN ROUTINE PRACTICE

The clinical outcomes delivered by the alphabet strategy are comparable to those achieved in published landmark studies^[15]. Blood pressure, glycaemic and cholesterol targets in the Steno-2 study, The United Kingdom Prospective Diabetes Study (UKPDS), and the POEM audits are shown in Table 3. Table 4 shows

Table 3 Clinical trial standards of United Kingdom Prospective Diabetes Study and Steno-2 compared to those in practice of evidence-based medicine studies

Variable	Steno-2 (intensive arm)	UKPDS	Alphabet strategy	
			POEM	POEM2004
Systolic BP (mmHg)	≤ 130	≤ 144	≤ 140	≤ 130
Diastolic BP (mmHg)	≤ 80	≤ 82	≤ 80	≤ 80
HbA1c (%)	≤ 6.5	≤ 7	≤ 7	≤ 7
Cholesterol (mmol/L)	≤ 4.5	NA	≤ 5	≤ 4

POEM: Practice of evidence-based medicine; UKPDS: United Kingdom Prospective Diabetes Study.

Table 4 Percentage of practice of evidence-based medicine cohort attaining trial standards compared to original study treatment arms

	Intensive arm	POEM 1 post implementation	POEM 2	P value (intensive vs POEM 2)
Steno-2				
SBP ≤ 130 mmHg	45%	34%	36%	0.07
DBP ≤ 80 mmHg	70%	67%	67%	0.51
TC ≤ 4.5 mmol/L	72%	36%	54%	< 0.001
HbA1c ≤ 6.5%	15%	13%	15%	1.000
Aspirin	73%	83%	88%	< 0.001
Statin	71%	52%	69%	0.66
ACEI	66%	66%	58%	0.09
ARB	39%	10%	20%	< 0.001
Either ACEI/ARB	58%	73%	74%	0.001
UKPDS				
SBP ≤ 144 mmHg	50%	58%	73%	< 0.001
DBP ≤ 82 mmHg	50%	73%	74%	< 0.001
HbA1c ≤ 7%	50%	22%	29%	< 0.001

POEM: Practice of evidence-based medicine; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; UKPDS: United Kingdom Prospective Diabetes Study.

the proportion of people achieving these targets in the original studies compared to those in the POEM audits.

The percentage of POEM subjects reaching trial targets was comparable to those in the UKPDS and Steno-2 for the majority of categories. Significantly less people reached the total cholesterol target compared to Steno-2, but in a re-audit in 2013, 75% of our subjects achieved this goal. There were fewer people on ARBs, but individuals using either ACEI or ARB were higher than for Steno-2.

Almost three quarters of the POEM 2 population reached the UKPDS blood pressure target, but achieving an HbA1c of ≤ 7% was more difficult. Indeed in the recent National Diabetes Audit, centres with over 50% of their submitted cohorts achieving the slightly higher target HbA1c of ≤ 7.5% numbered only 10 out of 77 centres^[16]. However, it must be understood that our hospital provides secondary care for people with diabetes. Therefore our patient population is predominantly patients that cannot be managed in

Table 5 Change in care process performance following implementation of the alphabet strategy in a low-resource diabetes clinic

	Elements	Pre implementation	Post implementation	P value
A	Body mass index	99%	99%	NS
	Smoking status	99%	99%	NS
	Smoking cessation	100%	100%	NS
B	Blood pressure	99%	99%	NS
C	Total cholesterol	60%	99%	< 0.001
	Lipid profile	10%	64%	< 0.001
	Creatinine	5%	49%	< 0.001
	Proteinuria	48%	93%	< 0.001
D	Fasting and postprandial glucose	41%	97%	< 0.001
E	Eye examination	98%	100%	NS

G	Aspirin therapy	6%	71%	< 0.001
	ACEI/ARB therapy	7%	57%	< 0.001
	Statin therapy	5%	38%	< 0.001
	All three	2%	20%	< 0.001

NS: Not significant.

primary care alone.

NATIONAL DIABETES AUDIT 2011/12 - SECONDARY CARE UNITS

In this national audit, the clinical effectiveness of the alphabet strategy was reflected in the beneficial showing of George Eliot Hospital in comparison with other hospitals. Performance of each of the seven out of eight NICE recommended processes occurred in 100% of our submitted cohort, a feat that no other trust achieved. Overall, 85.7% of the submitted cohort received all eight recommended care processes, placing it third out of seventy seven. For target care process achievement, George Eliot scored above average in all categories other than for HbA1c $\leq 6.5\%$ ^[16].

IMPLEMENTATION IN A NON-HIGH INCOME COUNTRY

A beneficial clinical change in care process performance was also demonstrated when the alphabet strategy was applied to a resource poor setting in India. An outpatient diabetes clinic run by a single diabetologist with the aid of a dietician and a nurse was selected for the study. The checklist was adapted for use to the limited local resources. Pre and post-implementation audits were conducted on 100 randomly chosen patients with type 2 diabetes. Principle improvements occurred in the assessments of cholesterol, creatinine and proteinuria, glycaemia, and the use of statins (Table 5).

QUESTIONNAIRE STUDY

As part of the Global Alphabet Strategy Implementation

Audit project, a questionnaire study was performed to gauge the opinions of healthcare professionals and patients on the potential of the alphabet strategy as a management checklist, as a patient-held diabetes care plan, and an education tool. Completed forms were available from 44 single centres located in 27 countries.

Most of the respondents considered the alphabet strategy an evidence-based and practical tool (98% and 91% respectively replying positively). Eighty-five percent of respondents thought that its use would potentially improve outcomes in their clinical practice. Over 70% said they would be likely to adopt the checklist in their clinical practice, although just over half thought it could be applied in their economic background. The strategy was regarded as a useful instrument for patient education. Indeed, over two-thirds of patient responders suggested that patients themselves should use it. However, there were some concerns about the checklist's indirect costs: HbA1c, creatinine, and lipid profile assessments together with the cost of statin implementation are prohibitive in low resource countries, with the expense borne entirely by the patient in private healthcare systems.

CHECKLISTS - ENGAGEMENT IS KEY

Interest has been gathering in the use of checklists and care bundles as a means of improving healthcare quality and lowering patient risk. However, there are many issues associated with their application and adoption, particularly social and cultural difficulties^[17]. After the adoption of the WHO Surgical Safety Checklist, several reports described a range of barriers including confusion regarding its proper use, lack of resource availability in low income countries, and individual personal beliefs and attitudes^[18]. The solutions provided by checklists should not be considered magic bullets. Mere provision of the WHO checklist to hospitals did not culminate in immediate clinical benefits, but rather months of groundwork to organisational systems and personnel were required to aid effectual implementation^[19].

The successful outcomes associated with the use of the alphabet strategy suggests it presents a technical solution to the complicated task of achieving effective diabetes care. Implementation of the alphabet strategy initially in our hospital trust was relatively uncomplicated. There was then one consultant diabetologist supported by an able diabetes team keen for patient-centred and evidence-based care. There now exists four consultant diabetologists, all with varying degrees of engagement with the alphabet strategy. Indeed a recent audit assessing care process performance showed considerable variation by consultant (Table 6).

Consultant A, the author of the alphabet strategy, achieved performance of all nine care processes in 80.8% of all patients directly seen. All other doctors fared significantly worse in performance of all care

Table 6 Care process performance by consultant, registrars, and junior doctors

Care process	Cons A/% n = 125	Cons B/% n = 132	Cons C/% n = 36	Cons D/% n = 101	Junior drs/% n = 86	Registrars/% n = 70

processes, except interestingly for the junior doctors.

ALPHABET STRATEGY MATERIALS

Our healthcare education talks are centred around the alphabet strategy approach. A one-day alphabet strategy workshop has previously been delivered nationally in the United Kingdom and internationally under the auspices of the United Nations Development Programme in Bahrain (twice). Course evaluations have been consistently positive^[20].

A series of posters and leaflets discussing each of the elements of the alphabet strategy have proved popular and effective in group and individual education. The education posters were also rated favourably in our questionnaire study by healthcare professional and patients. As a result, they have been translated into French, Somali, Telugu, and Gujarati. Other patient resources include a "patient passport" - a diabetes care plan in the alphabet strategy format that allows people to track their clinical and biochemical data and identify management targets. Culturally adapted materials ensure that the key messages of the alphabet strategy are relayed to members of the South-Asian (Indo-Asian) community residing in our locality. For Muslim patients, Ramadan advice leaflets prepare individuals on self-management issues during their month of fasting.

Finally, clinical letters based on the strategy communicating treatment plans to primary care have been developed to facilitate shared management.

CONCLUSION

When used appropriately, the alphabet strategy can consistently deliver excellent clinical outcomes comparable to trial standards in landmark studies. We achieved these benefits despite a considerable outpatient workload and low levels of human resources: the average patient was seen two to three times per year in our unit, approximating a total of 45 min with a healthcare professional. The positive

improvements with the checklist have been achieved because healthcare providers and patients all subscribe to one methodical approach to diabetes care.

We believe diabetes care, like all forms of healthcare provision, should be effective, professional, responsible, and accountable. Our philosophy for the alphabet strategy is that it should follow the "POETIC" vision: (1) Patient-focused, Public health centred to improve outcomes, and Professionally guided and inspired; (2) Outcome-based, delivering relevant clinical improvements based on real and assessable outcomes; (3) Evidence-based, rooted in clinical evidence, up to date, and influenced by local audit; (4) Team-focused, allowing multidisciplinary cooperation and intervention to improve patient care; (5) Integrated across primary and secondary care, and other related health services; and (6) Cost efficient, using limited resources appropriately.

The alphabet strategy concept is freely available and not under copyright. All materials (lecture slides, patient education posters, patient held care plans, Ramadhan advice leaflets, clinic letter template) are available in the public domain, free to download and use, and easily adaptable to local resources and requirements. All patients with diabetes should be offered the foremost healthcare that resources allow, with none being refused effective or affordable care or therapy. The alphabet strategy can deliver real clinical benefits in diabetes care and has the scope to be adopted extensively across different economies.

Abstract

AIM: To perform a systematic review of reported
 neonatal and pregnancy outcomes of Indigenous
 Australians with diabetes in pregnancy (DIP).

METHODS: Electronic searches of PubMed and Web of
 Science were carried out. Articles were selected if they
 contained original data on DIP outcomes in Indigenous
 Australians. There were no specific exclusion criteria.

RESULTS: A total of eight articles, predominantly from
 Queensland and Western Australia were identified
 once inclusion criteria were applied. Birth data from
 midwifery registries or paper charts encompassing
 years 1985-2008 were used. A total of 465591 pregnant
 women with and without DIP were included in the eight
 studies, with 1363 being Indigenous women with DIP.
 Indigenous Australians experienced increased rates
 of many known adverse outcomes of DIP including:
 macrosomia, caesarean section, congenital deformities,
 low birth weight, hypoglycaemia, and neonatal trauma.
 There were regional differences among Indigenous
 Australians, particularly regional/remote vs metropolitan
 populations where the regional/remote data showed
 worse outcomes. Two of the articles did not note a
 difference between Aboriginals and Caucasians in
 the rates of measured adverse outcome. Studies
 varied significantly in size, measured outcomes, and
 subsequent analysis.

CONCLUSION: The health disparities between In-
 digenous Australians and non-Indigenous Australians
 are further evidenced by poorer outcomes in DIP.
 This has broader implications for Indigenous health in
 general.

Core tip: A review of all published data in Australia concerning diabetes in pregnancy outcomes in Indigenous Australians was performed. Of the eight articles identified, Indigenous Australians were shown to have higher rates of adverse outcomes compared to the non-Indigenous population. Living in a remote region appeared to increase the risk of an adverse outcome. This article highlights further health disparities between Indigenous and non-Indigenous, but also exposes gaps in regional data.

Duong V, Davis B, Falhammar H. Pregnancy and neonatal outcomes in Indigenous Australians with diabetes in pregnancy. *World J Diabetes* 2015; 6(6): 880-888 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i6/880.htm> DOI: <http://dx.doi.org/10.4239/wjcd.v6.i6.880>

INTRODUCTION

It is well documented that diabetes during pregnancy poses multiple risks for the developing foetus as well as adverse outcomes for both mother and newborn^[1-4]. Common adverse pregnancy outcomes include foetal macrosomia, caesarean delivery, shoulder dystocia, congenital malformations, preterm delivery, neonatal hypoglycaemia, respiratory distress and hyperbilirubinaemia^[5-7].

Type 2 diabetes (T2DM) has been reported to be up to four times more prevalent in Indigenous Australians compared to non-Indigenous Australians^[8,9]. Furthermore, T2DM occurs at younger ages and complications occur earlier in addition to being more severe than in non-Indigenous Australians^[10,11]. There are parallels that can be drawn with Indigenous populations in overseas countries, with studies conducted in North America showing that the First Nations people also suffer an increased prevalence of diabetes and are subject to increased adverse outcomes as a result of diabetes during pregnancy, compared to non-Indigenous citizens^[12-14]. The high rates of T2DM in the Indigenous populations is thought to be related to obesity, high fat and carbohydrate dense dietary changes combined with a more sedentary lifestyle compared to the traditional hunter-gatherer lifestyle^[15]. As obesity is a risk factor for developing T2DM it has been hypothesised to be a cause of increased rates of gestational diabetes and pre-existing diabetes in women of childbearing age^[16].

The Indigenous population is spread out across Australia and a large proportion reside in communities located in rural or remote areas^[17] (Figure 1). Australia has two distinct Indigenous populations: Australian Aborigines and Torres Strait Islanders, the combined population estimated to be 669881 at the

2011 census, of which 90% were of sole Australian Aboriginal origin^[18]. Torres Strait Islanders are ethnically distinct from Australian Aborigines as they are primarily of Melanesian descent. They originate from the Torres Strait region, a region consisting of hundreds of islands between the tip of Cape York on the Australian mainland and Papua New Guinea^[19]. The Torres Strait diaspora are scattered all over Australia in present times. Indigenous women living in remote areas of Australia have been shown to be at greater risk for developing T2DM^[20]. This is related to obesity, physical inactivity, to poor food quality, availability and cost, in addition to poor economic disposition and genetic predisposition. Access to, and quality of services provided to rural and remote communities are frequently lacking due to the transient nature of health professionals working in these areas. Moreover, Indigenous women often present late for antenatal care, increasing the risk of an adverse pregnancy outcome.

The aim of this study was to conduct a systematic review of the current literature surrounding pregnancy and neonatal outcomes in DIP experienced by Indigenous Australian women.

MATERIALS AND METHODS

For this systematic review, the PRISMA guidelines for literature search and reporting were adhered to where they were applicable^[21]. PubMed searches were performed using the search terms "Aboriginal", "Torres Strait Islander", "Indigenous", "diabetes", "pregnancy", "gestational" and "Australia" (Figure 2). Relevant combinations of these terms returned around 40 unique articles. A MeSH search was then carried out using the combination of subject headings: "Pregnancy in Diabetics" or "Diabetes, Gestational" and "Australia". This returned a higher yield, with 185 articles identified. The Web of Science database was also searched using each of the initial PubMed search terms, however this did not reveal any further articles of interest. The last search was performed in November 2014. Papers which mentioned diabetes, pregnancy, outcomes or made reference to Indigenous Australians in their titles and abstracts were downloaded for further evaluation. Around 20 articles were identified, which involved Indigenous Australians and DIP. The references of these articles were screened to identify any further publications that may have been missed in the search, however this did not reveal any additional studies. Of the papers that were downloaded, prevalence of DIP was the topic of focus in roughly half of the articles, leaving a total of eight suitable papers focusing specifically on outcomes in Indigenous women with DIP (Figure 2). Inclusion criteria were articles that reported on pregnancy and neonatal outcomes in DIP experienced by Indigenous Australian women. There were no specific exclusion criteria. A quality analysis of each study was also

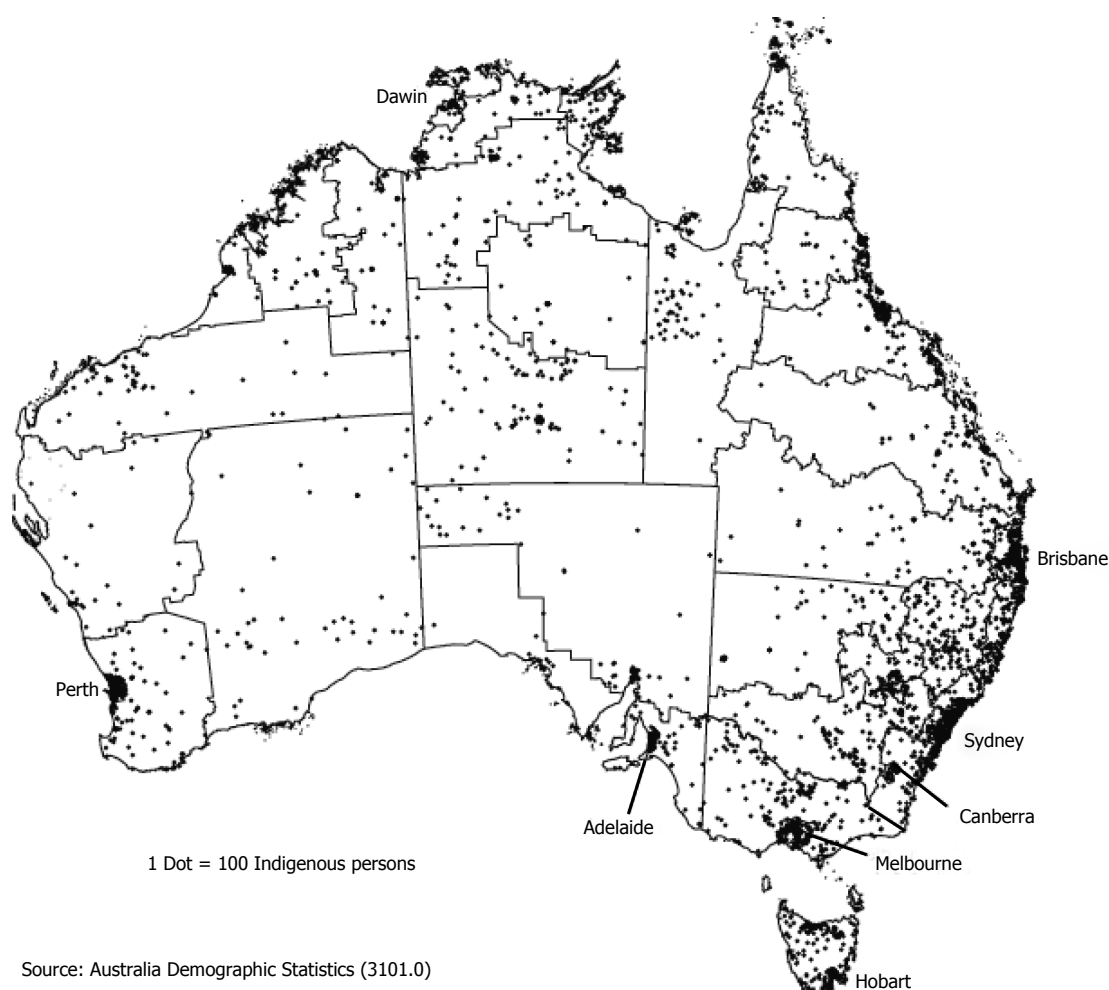

Figure 1 Graphic demonstrating the distribution of Indigenous Australians throughout Australia. Obtained from the Australian Human Rights Commission under Creative Commons^[17].

performed, outlining merits and limitations of each.

RESULTS

The eight articles gathered from the PubMed database were published between 1985 and 2013. Most were state-wide studies, with three from Queensland (Qld), four from Western Australia (WA) and one from South Australia (SA). All were audits of paper charts or birth registers; in essence, retrospective cohort studies (Table 1). A total of 465591 pregnant women with and without DIP were included in the eight studies, with 1363 being Indigenous women with DIP. Outcomes were usually quoted in terms of rates of incidence, or sometimes where comparison to non-Indigenous was available, risk ratios. The quality of included studies varied (Table 2).

Our search revealed that Indigenous women experienced higher rates of most recordable complications of diabetes than non-Indigenous women, regardless of type 1, 2, or gestational diabetes (GDM). There were two exceptions. Sharpe *et al*^[22] found in their large cohort study in SA that although Aboriginal women had

Table 1 List of included studies, all describing pregnancy and neonatal outcomes in Indigenous Australians with diabetes in pregnancy

Ref.	Year	Title	Study region	Years studied	Total study size	Total women with DIP	Number of Indigenous women with DIP	Outcome measured	Findings
Stanley <i>et al</i> ^[25]	1985	Congenital malformations in infants of mothers with diabetes and epilepsy in Western Australia, 1980-1982	WA	1980-1982	62265	225	52	Congenital anomalies	Relative risk of malformations in Aboriginal DIP - 5.6 compared to 1.9 in non-Aboriginal DIP. Attributable risk however, is low
Bower <i>et al</i> ^[24]	1992	Birth defects in the infants of Aboriginal and non-Aboriginal mothers with diabetes in Western Australia	WA	1980-1984	111019	427	98	Congenital anomalies	Prevalence ratio for birth defects in Aboriginal children is 4.85 for insulin dependent DM and 3.64 for non-insulin dependent DM, compared to 2.08 and 3.64 respectively for non-Aboriginal children
Blair ^[23]	1996	Why do Aboriginal newborns weigh less? Determinants of birthweight for gestation	WA	1980's	1301	672	159	Birth weight	Aboriginal newborns weigh 180 g less than non-Aboriginal (DIP and non-DIP)
Sharpe <i>et al</i> ^[22]	2005	Maternal Diabetes and Congenital Anomalies in South Australia 1986-2000: A Population-Based Cohort Study	SA	1986-2000	282260	7681	432	Congenital anomalies	Congenital anomalies significantly higher in mothers with DIP, relative risk 2.01. No difference with ethnicity
Davis <i>et al</i> ^[28]	2009	Maternal and neonatal outcomes following diabetes in pregnancy in Far North Queensland, Australia	North Queensland	2004	50683 ¹	136	59	C-section, hypoglycaemia, resp distress, abnormal birth weight, term delivery	Compared with non-Indigenous women, Indigenous women had smaller babies, less term deliveries, more severe neonatal hypoglycaemia. Worse outcomes than national and state data
Falhammar <i>et al</i> ^[19]	2010	Maternal and neonatal outcomes in the Torres Strait Islands with a sixfold increase in type 2 diabetes in pregnancy over six years	North Queensland	1999, 2005/2006	454	37	32	C-section, large baby, neonatal trauma, hypoglycaemia	DIP infants heavier (700 g), taller (1.9 cm), more neonatal trauma and hypoglycaemia
Porter <i>et al</i> ^[26]	2011	What is the impact of diabetes for Australian Aboriginal women when pregnant?	WA	2000-2007	81617	5987	531	Birth weight, C-section, stillbirth	Indigenous infants' high birth weight, stillbirth rate = 22/1000 for GDM and 53/1000 for pre-existing DM, compared with 3/100 and 11/1000 for Caucasians
Davis <i>et al</i> ^[29]	2013	A threefold increase in gestational diabetes over two years: Review of screening practices and pregnancy outcomes in Indigenous women of Cape York, Australia	North Queensland	2006, 2008	261	31	31	C-section, birth weight, hypoglycaemia	Higher rates of C-section (66 vs 25%), higher birth weight and increased rate of hypoglycaemia (> 40%) in DIP vs non-DIP Indigenous mothers and babies

¹136 local mothers were compared to diabetic mothers in a national benchmark study ($n = 496$) and to all pregnant data in Queensland 2004 ($n = 50051$).
DIP: Diabetes in pregnancy; C-section: Caesarean section.

Table 2 Quality analysis of included studies, detailing strengths and limitations of each

Ref.	Title	Strengths	Limitations
Stanley <i>et al</i> ^[25]	Congenital malformations in infants of mothers with diabetes and epilepsy in Western Australia, 1980-1982	Large sample size	Retrospective cohort study Only one outcome measure (congenital malformations) Low number of Indigenous women with DIP Time period may not be relevant to modern era
Bower <i>et al</i> ^[24]	Birth defects in the infants of Aboriginal and non-Aboriginal mothers with diabetes in Western Australia	Large sample size	Retrospective cohort study Only one outcome measure (birth defects) Low number of Indigenous women with DIP
Blair ^[23]	Why do Aboriginal newborns weigh less? Determinants of birth weight for gestation	Large sample size	Retrospective cohort study DIP outcomes not main focus of paper
Sharpe <i>et al</i> ^[22]	Maternal Diabetes and Congenital Anomalies in South Australia 1986-2000: A Population-Based Cohort Study	Large sample size	Retrospective cohort study Only one outcome measure (congenital anomalies) Comparison between diabetic and non-diabetic with ethnic background as secondary comparator
Davis <i>et al</i> ^[28]	Maternal and neonatal outcomes following diabetes in pregnancy in Far North Queensland, Australia	Study question aligned with our study question, <i>i.e.</i> , outcomes of DIP in Australian Aboriginal women Large sample size	Retrospective cohort study Low number of Indigenous women with DIP
Falhammar <i>et al</i> ^[19]	Maternal and neonatal outcomes in the Torres Strait Islands with a sixfold increase in type 2 diabetes in pregnancy over six years	Assessment and comparison between two time periods	Retrospective cohort study No comparison with non-Indigenous women Low number of Indigenous women with DIP
Porter <i>et al</i> ^[26]	What is the impact of diabetes for Australian Aboriginal women when pregnant?	Study question mirrors ours Large sample size spanning 7 yr	Retrospective cohort study
Davis <i>et al</i> ^[29]	A threefold increase in gestational diabetes over two years: Review of screening practices and pregnancy outcomes in Indigenous women of Cape York, Australia	Comprehensive analysis of outcomes in Indigenous women with DIP	Retrospective cohort study No comparison with non-Indigenous women Low number of Indigenous women with DIP

DIP: Diabetes in pregnancy.

higher rates of pre-existing diabetes and gestational diabetes than Caucasian women, their rate of birth deformities was only slightly higher compared to the Caucasian group. Blair^[23] found that the increased presence of diabetes, urogenital infections, alcoholism and leprosy contributed to most of the lower birth weight in Indigenous children, but did not observe a higher impact of this compared to non-Indigenous children with similarly affected mothers. There was, however, a discrepancy of 180 g between pure-descent Aboriginal infants and Caucasian infants that was not accounted for by these conditions. Incomplete data on the pathologies and non-medical factors in Aboriginal women were cited as the cause of the discrepancy.

In contrast to the study by Sharpe *et al*^[22], Bower *et al*^[24] discovered in their analysis of midwifery data in WA from 1980-1984 that compared to non-diabetic Aboriginal mothers, birth defects in infants of Aboriginal women with pre-existing DM or gestational diabetes were over three times more common. Similarly, the risk in the Caucasian pre-existing diabetic population was 2.0-3.5 times higher but not increased at all in the gestational diabetes group compared to their non-diabetic counterparts. Thus, if Aboriginal diabetic mothers were compared directly to Caucasian diabetic mothers, there was a 10% increased prevalence of birth defects, which was statistically significant for gestational diabetes ($P = 0.02$) but not for pre-existing diabetes. In a cohort from WA with data from

1980-1982, Stanley *et al*^[25] in their analysis of diabetic and epileptic mothers showed a relative risk of 5.1 (95%CI: 2.6-13.0) for diabetic Aboriginal mothers having children with birth defects, in contrast with 1.7 (95%CI: 0.8-3.5) for Caucasian diabetic vs Caucasian non-diabetic women. There may be some overlap of data in these two similar studies, as the same state-wide database was used in overlapping time periods.

Porter *et al*^[26] in their analysis of the midwifery database in WA from 2000-2007, determined that for the time period studied, Aboriginal infants not only had greater birth weights compared to Caucasian infants when both had mothers with GDM, but when the mother had pre-existing diabetes the Aboriginal infants were smaller. Rates of elective caesarean section in Aboriginal women were 10% lower than for Caucasian women with diabetes, and were even found to be slightly lower than healthy Caucasian women. The other significant adverse outcome was that stillbirths were reported to be extremely high in both Aboriginal women with GDM or pre-existing diabetes (22/1000 and 53/1000 births respectively), while Caucasian women with GDM or pre-existing diabetes only had slightly higher rates (3/1000 and 11/1000 births respectively) compared to their non-diabetic counterparts (2/1000 births). The stillbirth rate in Aboriginal women with DIP was similar or even worse than some of the highest stillbirth rates worldwide in southern Africa and Asia (25 to 35/1000 births)^[27].

Falhammar *et al.*^[19] reported birth data from the Torres Strait Islands, obtaining information from two discrete time periods six years apart. The conclusions drawn were that Torres Strait Islander mothers with DIP experienced higher rates of expected complications compared to Torres Strait Islander mothers without DIP. Hypertension and previous spontaneous abortions were more prevalent, as were caesarean sections, with a fivefold elevation compared to the non-diabetic group in the latter year studied. Infants born to diabetic mothers were also heavier, longer, experienced more neonatal trauma, hypoglycaemia and IV dextrose use.

Two other studies originating from North Queensland examined maternal/neonatal outcomes in Indigenous women. Both included the Torres Strait Islander group in the analysis while recognising the ethnically distinct origin. Davis *et al.*^[28] in 2009 compared local DIP outcomes in Far North Queensland to state-wide and national outcomes. They found that Indigenous women with DIP had smaller babies, less term deliveries and more severe neonatal hypoglycaemia than the non-Indigenous cohort. Importantly, when comparing local and national Indigenous data, locals showed worse outcomes with more premature deliveries and lower APGAR scores. There were no significant differences between the two local populations of Aboriginals and Torres Strait Islanders.

Davis *et al.*^[29] in 2013 examined solely DIP vs non-DIP outcomes in the Indigenous Aboriginal population of Cape York in North Queensland. Analysis was done for two discrete years, 2006 and 2008. DIP women were found to have higher rates of caesarean section, higher birth weight and hypoglycaemia. Outcomes such as mean APGAR score and respiratory distress showed improvement in the latter studied year, after a period of intensive education on GDM screening and management protocols between the two years.

DISCUSSION

While it is widely acknowledged that Indigenous Australians suffer poorer health across a variety of disciplines, this is the first systematic review focusing specifically on outcomes related to hyperglycaemia in pregnancy. The studies identified from our literature search contained much variability in research focus and outcome measurement. Six out of eight studies were in accordance that Indigenous Australian women and their babies are subject to worse outcomes in DIP than their non-Indigenous counterparts, or at least their Indigenous counterparts without DIP. Maternal complications such as delivering prematurely or *via* caesarean section occurred at a higher rate. Neonatal complications including hypoglycaemia, macrosomia or low birth weight, and trauma were also increased to significant levels. The studies were equivocal as to whether there was a higher rate of birth defects compared to non-Indigenous babies. These complications for the infant correspond to poorer

health in adulthood, most importantly an increased risk of developing impaired glucose tolerance, obesity or the metabolic syndrome^[30-34]. For the mother, developing GDM in pregnancy places her at a higher risk of developing T2DM later in life and with subsequent pregnancies^[35]. Furthermore, experiencing a caesarean section may involve undue emotional distress, which is also financially and logistically disruptive as many Indigenous women live in remote communities and are relocated to larger regional centres for delivery. It also exposes them to the range of complications possible from undergoing a surgical procedure and places them at higher risk for future pregnancies. However, one study did show a lower frequency of elective caesarean sections in Indigenous mothers with DIP compared to Caucasian mothers with but also without DIP suggesting that inequality in the health care delivery exists, as discussed below. This may explain some of the differences found in outcomes.

In addition to poorer outcomes compared to non-Indigenous women, there is evidence to suggest that perinatal outcomes for Indigenous women living in rural or remote regions are poorer still, particularly in comparison to those women living in metropolitan areas^[19,28,36]. Two of the three studies performed in northern Queensland had shown that compared to state-wide statistics, people living in the study region experienced worse outcomes. This demonstrates that remoteness is likely to be a compounding factor towards a negative outcome in DIP, for reasons including limited food supply, substandard housing and living conditions, poor access to medical services and financial factors. Cultural barriers for women's non-engagement with mainstream health services in remote areas is multifaceted and incorporates cultural beliefs, conflicting cultural responsibilities, fear, guilt, shame, perceptions of culturally insensitive Western practices in pregnancy care and cultural indifference in health care providers^[37].

This review strikes similarities with Indigenous populations abroad, with a study conducted in Ontario, Canada showing that First Nations women received less antenatal and postpartum care, and that those with DIP were subject to higher birth weights and higher rates of jaundice, neonatal hypoglycaemia and shoulder dystocia^[12]. A separate investigation conducted in Alberta, Canada also confirmed worse perinatal outcomes due to DIP in First Nations women, however found that the prevalence of adverse outcomes varied between different provinces^[13]. Aljohani *et al.*^[14] found that in Manitoba, having gestational diabetes and First Nation status compounded the risk of shoulder dystocia. These similarities to other nations with Indigenous populations allow us to draw on and potentially apply any conclusion obtained from studies performed overseas, and vice-versa.

Early in our search it became apparent that literature focusing on pregnancy and neonatal outcomes in Indigenous Australians with DIP was scarce. Half

Table 3 Indigenous population by state as of 2011

State	Indigenous population	Proportion of total population
New South Wales	208000	2.9%
Victoria	47000	0.9%
Queensland	189000	4.2%
Western Australia	88000	3.8%
South Australia	37000	2.3%
Tasmania	24000	4.7%
Australian Capital Territory	6000	1.7%
Northern Territory	69000	29.8%

Source: Adapted from Australian Bureau of Statistics, Estimates of Aboriginal and Torres Strait Islander Australians, June 2011^[18].

of the studies that were eventually included in our analysis focused on one particular complication of pregnancy and assessed predisposing factors, with DIP and Indigenous status being a variable that may lead to the outcome in question. This limits the perspective on the full spectrum of outcomes of DIP, but also introduces an additional form of bias. Due to the variability of the research focuses and outcomes, detailed statistical analysis and direct comparisons, for instance performing a meta-analysis was not possible.

A point worth noting is that while the Northern Territory (NT) has the highest proportion of Indigenous Australians per capita, comprising 29.8% of the NT population at the 2011 census^[18], there were no studies originating from the NT. In both Queensland and Western Australia Indigenous people make up a much lower 4.8% and 3.2% respectively of the total population, however in some remote regions they make up 50%-90% of the population. These states were the biggest contributors to the data on diabetes in Aboriginal women and their pregnancy outcomes (Table 3). To alleviate the disparity in data output across states, an upcoming NT-based study will analyse many different aspects of DIP in Indigenous Australians^[38].

Due to the limited data available, not all of the known adverse outcomes of pregnancy in a diabetic mother could be fully assessed. Pre-eclampsia is known to occur at a higher rate in mothers with pre-existing diabetes^[5], however has not yet been analysed. Stillbirth, perinatal mortality and transient cardiomyopathy are significant recognised complications^[5,39,40], that require further study. Other complications with lacking data include biochemical derangements with uncertain long-term effects such as low iron stores, hyperbilirubinaemia and hypocalcaemia^[41-43]. With more research on the topic, we will be able to paint a clearer picture of specific outcomes that Indigenous women and their offspring may be more prone to developing. This may in turn be used as endpoints to gauge efficacy of management protocols and allocation of resources.

Diabetes in pregnancy presents itself as one of the many health disparities between Indigenous and non-Indigenous Australians. The rising prevalence of the disease and demonstrated poor outcomes com-

pared to non-Indigenous Australians ensures that this problem will remain topical until it is dealt with effectively. In addition, mothers and their infants who are affected by diabetes suffer consequences, which may not manifest until later in life. The main challenges that face Australian healthcare professionals are twofold: incorporating strict antenatal care into the cultural, spiritual and religious framework of Indigenous Australians, and dealing with the difficulties of delivering evidence-based medical care in rural and remote communities. More research into trends, specific outcomes and data from different regions of Australia will aid in building a clear image of the task at hand, as current data is limited. This will in turn assist in identifying novel intervention strategies to employ, and outcome measures by which to judge the effectiveness of these methods.

COMMENTS

Background

It is well recognised that in general, health outcomes of Indigenous Australians are inferior to those of non-Indigenous Australians. Complications related to having diabetes in pregnancy (DIP) are no exception to this trend. However, no systematic review has previously been performed to summarise the current state of pregnancy and neonatal outcomes experienced by Indigenous Australians with DIP.

Research frontiers

Although Indigenous Australians are known to suffer poorer obstetric outcomes compared to non-Indigenous Australians, less is known of specific outcomes and their relative prevalence.

Innovations and breakthroughs

Previous studies have been small or only investigated few outcomes. This systematic review included in total a large number of pregnant women with and without DIP in eight studies, and many were Indigenous women with DIP. Indigenous Australian mothers with DIP and their offspring experienced increased rates of macrosomia, caesarean section, congenital deformities, stillbirth, low birth weight, hypoglycaemia, and neonatal trauma. There were regional differences among Indigenous Australians, particularly regional/remote vs metropolitan populations, where the regional/remote data showed worse outcomes. However, two of the articles did not note a difference between Indigenous and non-Indigenous in the rates of measured adverse outcome.

Applications

This article summarises the main adverse outcomes that are experienced by Indigenous Australians with DIP. These outcomes can in turn be used as endpoints in assessing the impact of new interventions or policies to improve Indigenous health.

Terminology

Diabetes in pregnancy encompasses all conditions that may result in hyperglycaemia in pregnant women. This includes gestational diabetes mellitus diagnosed during pregnancy, or previously diagnosed type 1 or 2 diabetes mellitus.

Peer-review

The paper appears interesting and very well written paper.

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Guo-Ping Shi, DSc, Associate Professor of Medicine, Cardiovascular Medicine, Brigham and Women's Hospital, Harvard Medical School, NRB-7, 77 Avenue Louis Pasteur, Boston, MA 02115, United States

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Despite large improvements in the management of glucose levels and in the treatment of cardiovascular risk factors, the mortality rate in individuals with type 1 diabetes (T1D) is still high. Recently, Lind *et al* found that T1D individuals with glycated hemoglobin levels of 6.9% or lower had a risk of death from any cause or from cardiovascular causes that is twice as high as the risk for matched controls. T1D is a chronic disease with an early onset (*e.g.*, pediatric age) and thus in order to establish a clear correlation between death rate and the glycometabolic control, the whole history of glycemic control should be considered; particularly in the early years of diabetes. The switch from a normo- to hyperglycemic milieu in an individual with T1D in the pediatric age, represents a stressful event that may impact outcomes and death rate many years later. In this paper we will discuss the aforementioned issues, and offer our view on these findings, paying a particular attention to the several alterations occurring in the earliest phases of T1D and to the many factors that may be associated with the chronic history of T1D. This may help us to better understand the recently published death rate data and to develop future innovative and effective preventive strategies.

INTRODUCTION

Whether mortality in type 1 diabetes mellitus (T1D) is improved by intensive glycemic therapy has not been clarified yet. A number of studies have recently been published claiming that mortality rate is still higher than in age-matched controls without diabetes, despite improvements in management of glucose levels and treatment of cardiovascular risk factors^[1-3]. Lind *et al.*^[1] reported data on current life expectancy for adults with T1D in a population-based sample using Swedish national registries of adults with and without diabetes. The Authors found that individuals with T1D and glycated hemoglobin (HbA1c) level of 6.9% or lower had a risk of death from any cause or from cardiovascular causes that was twice as high as the risk for matched controls. The multivariable-adjusted hazard ratios for death from any cause according to the HbA1c level for individuals with T1D as compared with controls are reported in Table 1.

Livingstone *et al.*^[2] report data on current life expectancy for adults with T1D in a population-based sample using Scottish national registries of adults with and without diabetes. At the age of 20 years, women and men with T1D could expect to live 12.9 years (95%CI: 11.7-14.1) and 11.1 years (95%CI: 10.1-12.1), respectively, less than aged-matched adults without it. Finally, Orchard *et al.*^[3] report survival data on the selective cohort of North Americans with T1D who participated in the Diabetes Control and Complications Trial (DCCT)^[4] and its observational follow-up study, Epidemiology of Diabetes Interventions and Complications (EDIC)^[5]. They found that 27 years after entry into the trial, 6.5 years of initial intensive diabetes therapy was associated with a modestly lower all-cause mortality rate when compared with conventional therapy. Few editorials accompanied^[6] or commented^[7] these data, without suggesting any conclusive hypothesis about the reason why this happens. T1D is known to be associated with an increased risk of premature mortality among the affected individuals, as documented by a

recent systematic review on this topic by Morgan *et al.*^[8]. Authors identified thirteen relevant publications with mortality data, describing 23 independent studies. Standardized mortality ratios varied markedly ($P < 0.0001$). The increased mortality in childhood/adolescent-diagnosed with T1D was apparent across countries worldwide. Excesses were less marked in more recent studies and in countries with lower infant mortality and higher health expenditure. Given that good metabolic control has been shown to be effective reducing microvascular and macrovascular complication rates, one should expect that also the mortality rate might be reduced, but this is not the case^[4,5]. Therefore, we would like to propose our appraisal to these important findings.

THE IMPORTANCE OF CHILDHOOD YEARS OF T1D

All studies reporting mortality rates in T1D refer to adult individuals, most of the time with a diabetes which occurred in childhood. For instance all individuals studied in the Lind paper were at least 18-year-old at the moment of enrollment, with a mean age at baseline of 35.8 years and mean diabetes duration of 20.4 years^[1]. This implies that the average age for the onset of diabetes was 15.4 years, during their adolescence. The study does not provide any information at all with respect to HbA1c levels between diabetes onset and the time of data collection (on average 40 to 50 years after T1D diagnosis). From previous studies, (e.g., DCCT and EDIC), we know how “metabolic memory” provides an important footprinting to future long-term complications^[4,5,9]. We can thus argue that “metabolic memory” may partially be accounted for the higher death rate observed in individuals with T1D, whose onset was during childhood or adolescence. This aforementioned aspect reinforces the important of obtaining an optimal glycometabolic control in the first years of T1D. This is an important issue, since T1D incidence rate increases from birth, and peaks between the ages 10-14 years^[10], with an even increased incidence especially marked in the youngest children (0-4 years)^[11], making T1D the second most frequent chronic disease of childhood, after asthma. Further emphasis should be pointed to vascular complications, which start at the onset of the disease^[12], although the consequences become clinically evident later in adulthood^[13,14]. Once again, we may speculate that the reported excess mortality in adult individuals showing HbA1c < 6.9% in the study by Lind *et al.*^[1], may be the residual effect of previous cardiovascular insults started in infancy, childhood or adolescence. It is still unclear and partially unexplained why cardiovascular complications start so early in the disease history of T1D; indeed we can only speculate that a chronic state of mild hyperglycemia might be the culprit of cardiovascular morbidity, and thereby of excess death, as unaccounted in the Swedish observational trial^[1].

Table 1 Adjusted hazard ratios for death from any cause and death from cardiovascular disease among individuals with type 1 diabetes *vs* control according to the glycated hemoglobin

Mean HbA1c	Hazard ratios	
	Death from any cause	Death from cardiovascular disease
≤ 6.9%	2.36 (95%CI: 1.97-2.83)	2.92 (95%CI: 2.07-4.13)
7.0%-7.8%	2.38 (95%CI: 2.02-2.80)	3.39 (95%CI: 2.49-4.61)
7.9%-8.7%	3.11 (95%CI: 2.66-3.62)	4.44 (95%CI: 3.32-5.96)
8.8%-9.6%	3.65 (95%CI: 3.11-4.30)	5.35 (95%CI: 3.94-7.26)
≥ 9.7%	8.51 (95%CI: 7.24-10.01)	10.46 (95%CI: 7.62-14.37)

Adapted from Lind *et al*^[1]. HbA1c: Glycated hemoglobin.

Indeed, according to the A1c-Derived Average Glucose study group, a HbA1c value of 6.9% indicate an average glucose level as high as 151 mg/dL (8.4 mmol/L)^[15].

Additionally, the HbA1c measurement has some limitations itself. It has been shown to be unreliable in several different clinical scenarios, such as anemia or hemolysis, in presence of implanted mechanical heart valves, hypothyroidism, or during the use of medications such as erythropoietin^[16]. Moreover, there is a recognized biological variability in the glycation process of the hemoglobin molecule in response to hyperglycemia. This is the result of a different glycation rate in "high glyating" *vs* "low glyating" subjects, where the same mean blood glucose was associated with an HbA1c level of 9.6% *vs* 7.6%, respectively^[17]. To summarize, besides the issues related to the use of HbA1c, multiple factors contributed to the augmented risk of death in T1D individuals despite a good metabolic control. Indeed, several challenges are offered by the constantly evolving age-appropriate care needed by diabetic individuals transitioning from infancy to adulthood^[18].

ENDOTHELIAL DYSFUNCTION AND EARLY ATHEROSCLEROSIS

Several different systems show altered homeostasis early along the course of diabetes^[19-21]. Among them, the endothelium is definitely one of the most important and earlier targeted organs. Evidence suggests that impairment in nitric oxide-mediated smooth muscle vasodilation is an early pathophysiologic process and underlies the onset endothelial dysfunction, a key event for the development of atherosclerosis^[22]. Among factors that may worsen endothelial function in individuals with T1D, we should mention: a long disease duration^[23], a severely altered glycemic control^[24], high low density lipoprotein cholesterol levels^[25], high levels of advanced glycated end products^[26], and altered mitochondrial dynamics^[27]. Our group recently observed a high prevalence of endothelial dysfunction (76.7%) in adolescents with T1D for a mean duration of 9 years, particularly in those individuals with impaired glycometabolic control, subclinical signs of autonomic neuropathy and sedentary lifestyle. We did not observe any correlations between endothelial dysfunction and diabetes duration or individuals' age. A

HbA1c below 7.5% (58 mmol/mol) and regular physical activity of at least 4 h per week, were indeed associated with better endothelial function. Atherosclerosis, the late event of endothelial dysfunction, is frequently linked to the likelihood of death from cardiovascular origin, especially in individuals with T1D. Compared to non-diabetic subjects, individuals with T1D show an increased risk up to 10-fold to develop atherosclerotic plaques, starting since childhood and adolescence^[28]. Furthermore, intima media thickness measurement of the carotid artery is considered another valid surrogate marker for cardiovascular risk allowing assessment of atherosclerotic changes at a very early stage^[29]. Finally, Paroni *et al*^[30] showed that hyperhomocysteinemia in individuals with T1D may further increase the risk of endothelial dysfunction.

CARDIOVASCULAR AUTONOMIC NEUROPATHY

Cardiac autonomic neuropathy is an often overlooked and common complication of diabetes mellitus and by itself it is associated with increased cardiovascular morbidity and mortality^[31], together with cardiac abnormalities typical of individuals with diabetes^[32,33]. Data demonstrate the dual (vagal and sympathetic) control of heart rate and the dominant role of respiration in the genesis of heart rate and blood pressure fluctuations, suggesting that reduced vagal control of the sinoatrial node and impaired vascular regulation are the two main pathophysiological alterations^[34]. Few years ago, our group investigated the autonomic performance of 93 children and adolescents with uncomplicated well-controlled T1D compared to age-matched controls. We found a significant increase in arterial blood pressure, a blunted baroreceptor reflex, and an increase of the low-frequency component of systolic arterial pressure variability. These findings entail the simultaneous impairment of the capability of the vagal system to influence the heart function, together with an increased sympathetic vasomotor regulation^[21]. A follow-up study conducted 1-year later showed further impairment of the neuro vegetative performance, thereby suggesting early progression of the autonomic disturbance^[21]. Interestingly, a small weekly increase in exercise in these same individuals can greatly help to improve cardiac autonomic neuropathy.

INFLAMMATION AND OXIDATIVE STRESS

In the last fifteen years several groups worked in the direction of uncovering the association between the increased cardiovascular risk in individuals with T1D and inflammation. Schaumberg *et al*^[35] measured levels of inflammatory biomarkers at baseline and after a 3-year follow-up in a random sample of 385 participants of the DCCT cohort. Results were controversial and emphasized the extremely complex interaction between

inflammation, T1D and insulin therapy. Some of the inflammation indexes were high in both intensive and conventional insulin treatment groups; others were higher in the intensive insulin therapy group, others in the conventional one. What seemed to be linked to increased inflammation status in individuals using intensive insulin therapy was the weight gain they showed^[35], underlining the need for a more effective weight control in individuals with T1D. Indeed, a recent study by Valerio *et al.*^[36] found that T1D adolescents, particularly females, showed a considerable occurrence of abdominal adiposity and metabolic syndrome. That is why pediatric diabetologists need to make every effort to achieve normal weight and better health outcomes in their young T1D patients. Davì *et al.*^[37] found that newly T1D diagnosed individuals showed significantly augmented lipid peroxidation and platelet activation, paralleled by a higher degree of systemic inflammation. This data strongly support the idea of a significantly noxious effect of even the earliest form of damage triggered by the disease. The biochemical picture depicted is suggestive of a true acute inflammatory response accompanying the disease in its very earliest, hence pediatric, phase^[37]. The SEARCH Case-Control Study showed that young individuals with T1D, when compared to healthy controls, were characterized by excess inflammation despite good glycemic control^[38]. Interestingly, Folli *et al.*^[39] demonstrated that persistent cellular changes of anti-oxidative machinery and of aerobic/anaerobic glycolysis are present in individuals with T1D (with or without end-stage renal disease), and these abnormalities may play a key role in the pathogenesis of hyperglycemia-related vascular complications. Restoration of euglycemia and removal of uremia with kidney pancreas transplant can correct these abnormalities. Some of these identified pathways may become potential therapeutic targets for a new generation of drugs^[39].

HYPOGLYCEMIC EVENTS

Another possible explanation for the increased death rate in individuals with T1D despite good glycemic control may be hypoglycemia. The T1D Exchange Registry seems to confirm this hypothesis^[40]. Elderly individuals and children younger than 5 years seem to be the two populations at greater risk^[41,42]. A value of HbA1c in the low range ("good" metabolic control) may not only be associated with well controlled glucose control but with recurrent episodes of hyper/hypoglycemic oscillations. We may speculate that, in the study by Lind *et al.*^[41], one of the factors potentially explaining the persistence of a sizeable mortality hazard ratio in individuals with low HbA1c could be a high rate of hypoglycemic events in those individuals.

HOW TO IMPROVE OUTCOMES

T1D is a complex disease whose management may be extremely awkward and demanding^[43]. Diet and

exercise, in combination with a correct insulin therapy, play a pivotal role in obtaining and maintaining the best glycemic control possible. In the evaluation of a subgroup of individuals from the treatment group of the DCCT cohort, Delahanty *et al.*^[44] established the relation between diet and glycemic control beyond the sole intensive insulin therapy. A higher content of total and saturated fat, associated with a lower carbohydrate intake are linked to worse glycemic control, thereby further increasing the cardiovascular risk^[44]. Adequate fibers intake, usually lower than suggested, is also recommended. Indeed, fibers offer a beneficial dietary profile: (1) by reducing or at least delaying the overall glucose absorption; (2) by blunting post-prandial glycemic peaks, and finally (3) by impacting low-density lipoproteins by enhancing biliary acid secretion. For the aforementioned reasons, a proper nutritional education is a crucial part of diabetes management and needs to be promoted in all pediatric individuals with T1D and their families^[45]. Interestingly, recent study reported that children with T1D show less healthy food habits than same age healthy subjects^[46].

Routine physical exercise is known to have beneficial effects on the cardiovascular system in the general population, and even more in individuals with T1D^[47]. For this reason, we should strongly encourage individuals with T1D to participate in regular physical activity since childhood. One hour of moderate, aerobic exercise every day is currently recommended. Lucini *et al.*^[48] recently found the favorable effects of moderate increase (10%) in spontaneous exercise load in adolescents with T1D. Similarly, in children with T1D (mean age 11 years old), 60 min per day of exercise improves endothelial dysfunction, a well-known risk factor for cardiovascular diseases^[49]. Moreover, in the recent years, technology has helped to reduce the impact of T1D especially in children^[50]. Continuous glucose monitoring has emerged as one of the most significant innovation in the management of children with T1D. The combination of continuous glucose monitoring and insulin pumps, provides better glycemic control with less hypoglycemic episodes^[51,52]. The ultimate technological advance of such automated insulin administration systems, currently under development, is the completely automated glycemic management, the closed-loop system also known as "external artificial pancreas"^[53].

Finally, we would like to highlight recent stem cell-based trials, for which expectations in the scientific community and among individuals with T1D are high^[54]. One of the most promising is cord blood stem cells that have been demonstrated to become a powerful tool not only for regenerative medicine but for autoimmune (e.g., T1D) and inflammatory diseases as well^[55,56]. Recently, a novel hematopoietic stem cell-based strategy has been tested in individuals with new-onset T1D, suggesting that remission of the disease is possible by combining hematopoietic stem cell transplantation and immunosuppression; however safer hematopoietic stem cell-based therapeutic options are required^[57].

MORTALITY IN INDIVIDUALS WITH TYPE 2 DIABETES

As the prevalence of type 2 diabetes (T2D) continues to increase worldwide, diabetes-related morbidity and mortality increase as well. There is scarce evidence on the effect of HbA1c reduction on mortality rate in T2D individuals. Recently a study by Skriver *et al.*^[58] in a large cohort ($n = 11205$) of Danish individuals with T2D, showed that HbA1c variability was associated with mortality irrespective of the magnitude of absolute change in HbA1c. An increased mortality was observed even in those individuals with a HbA1c $\leq 8\%$ if presenting a higher HbA1c variability^[58]. However, in T2D individuals many factors other than glycometabolic control may contribute to increase the mortality rate (e.g., hypertension, obesity, dyslipidemia, elevated uric acid and insulin resistance). Therefore, an early diagnosis and a prompt management of T2D comorbidities is required^[59-62].

CONCLUSION

In conclusion, the recent findings describing an increased mortality in individuals with T1D as compared to age-matched population, even in the presence of on-target HbA1c, are important. Whenever the outcomes of a chronic disease like T1D are being studied, it is important to acquire data from the onset. Indeed, any events in the early phase may affect its future course and especially its final outcome (*i.e.*, death rates). A better understanding of the several alterations occurring in the earliest phases of T1D and of the factors that may be associated with the chronic history of T1D may help us to develop future innovative and effective preventive strategies.

Abstract

Despite the well-recognised role of vitamin D in a wide range of physiological processes, hypovitaminosis is common worldwide (prevalence 30%-50%) presumably arising from inadequate exposure to ultraviolet radiation and insufficient consumption. While generally not at the very low levels associated with rickets, hypovitaminosis D has been implicated in various very different, patho-physiological processes. These include putative effects on the pathogenesis of neoplastic change, inflammatory and demyelinating conditions, cardiovascular disease (CVD) and diabetes. This review focuses on the association between hypovitaminosis D and the metabolic syndrome as well as its component characteristics which are central obesity, glucose homeostasis, insulin resistance, hypertension and atherogenic dyslipidaemia. We also consider the effects of hypovitaminosis D on outcomes associated with the metabolic syndrome such as CVD, diabetes and non-alcoholic fatty liver disease. We structure this review into 3 distinct sections; the metabolic syndrome, vitamin D biochemistry and the putative association between hypovitaminosis D, the metabolic syndrome and cardiovascular risk.

Key words: Vitamin D; Hypovitaminosis D; Metabolic syndrome; Type 2 diabetes mellitus; Insulin resistance; Cardiovascular disease; Atherogenic dyslipidaemia; Hypertension; Non-alcoholic fatty liver disease

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The metabolic syndrome is common, affecting about 40% of Americans. It is defined by combinations of risk factors for cardiovascular disease (CVD) including insulin resistance and abdominal obesity. Research implicates hypovitaminosis D in the causation and phenotype of the syndrome and we present relevant data. While hypovitaminosis appears a risk factor for components of the syndrome and its outcome, the mechanism is unclear. The risks associated with varying

levels of hypovitaminosis and the benefits of vitamin replacement are unknown. However, unravelling the association between hypovitaminosis and the syndrome is warranted as even a modest decrease in CVD risk would confer substantial benefits.

INTRODUCTION

Much research over the last 30 years has shown that the pleiotrophic actions of 1, 25 dihydroxy-vitamin D [$1,25(\text{OH})_2\text{D}$] are central to cell, organ and organism homeostasis. Thus, along with its historic functions as a mediator of calcium and bone metabolism, $1,25(\text{OH})_2\text{D}$ has effects on a wide range of physiological processes. It is perhaps surprising, given its perceived importance to public health, to find that hypovitaminosis D is common worldwide (prevalence 30%-50%). This deficiency presumably arises from failure to firstly, ensure adequate exposure to ultraviolet radiation (UVR) because of skin cancer fears and secondly, consume food with sufficient levels of the vitamin. Vitamin D status is identified by low serum levels of biologically inactive 25-hydroxylated vitamin D [$25(\text{OH})\text{D}$]. While generally not at the very low levels associated with rickets, hypovitaminosis D has been implicated in various very different, pathophysiological processes. These include a putative effect on the development of neoplastic, inflammatory, demyelinating, cardiovascular and diabetic conditions. While the impact of hypovitaminosis D on health remains unclear, accumulating data indicates it confers increased disease risk and in some cases worse outcome.

In the context of this review, the finding that hypovitaminosis D is associated with impaired glucose homeostasis is of particular interest. A meta-analysis of 28 studies demonstrated that higher serum $25(\text{OH})\text{D}$ levels were associated with a 55% reduction in diabetes, a 51% decreased risk of the metabolic syndrome and a 33% lower risk of cardiovascular disease (CVD)^[1]. Further, treatment with vitamin D supplements over 2 mo improved fasting glucose levels and insulin resistance homeostasis model assessment for insulin resistance (HOMA-IR) in 100 patients with type 2 diabetes^[2]. It is suggested that the mechanism for this latter finding involves improved sensitivity of target tissues such as the liver, muscle and bone to insulin as well as enhanced beta cell function. Given that many risk factors for CVD are clustered in the highly prevalent metabolic syndrome, which is characterised by insulin resistance and abdominal obesity, it is reasonable to speculate a significant role for the vitamin in the development of the syndrome and its sequelae of diabetes and CVD.

In this review we focus on the association between hypovitaminosis D and the metabolic syndrome and how this may contribute to increased CVD risk. We present 3 sections describing firstly, the metabolic syndrome, secondly, vitamin D biochemistry and thirdly, the putative association between hypovitaminosis D, the syndrome and CVD risk.

METABOLIC SYNDROME; HOW IT WAS IDENTIFIED

The relationship between sensitivity to insulin, obesity and glucose homeostasis was first observed by the Swedish physician Eskil Kylin^[3]. He described a syndrome comprising hyperglycaemia, hypertension and hyperuricaemia and suggested insulin resistance as a possible causative factor^[3]. Subsequently Himsworth *et al.*^[4] laid the foundations for the classification of type 1 and 2 diabetes by showing that while some patients were insulin sensitive (younger, normal weight and blood pressure) others are insulin insensitive (older, more obese, hypertensive and atherosclerotic). Vague, in studies on gender-related obesity patterns described android obesity (now termed central obesity and linked with diabetes and atherosclerosis) and suggested a hormonal aetiology with over-activity of the pituitary-adrenal axis playing a key role^[5].

Such observations were brought together by Reaven^[6] in his Banting Lecture to the American Diabetes Association in 1988. He termed the combination of hypertension, dyslipidaemia and glucose intolerance as syndrome X and proposed that this mix of phenotypes provided a pathophysiological basis for atherosclerosis. Obesity, was also seen as a further essential component and following a number of iterations (dyslipidaemic hypertension, deadly quartet, insulin resistance, hazardous waist), the combination of phenotypes is now termed the metabolic syndrome^[7] with the International Classification of Disease code of 277^[7,8].

Classification of the metabolic syndrome

Various groups including the World Health Organisation^[9], European Group for the Study of Insulin Resistance^[7], American Association of Clinical Endocrinologists^[10], National Cholesterol Education Program - Adult Treatment Panel III^[11] and, more recently, the International Diabetes Federation (IDF)^[12,13] have provided definitions of the metabolic syndrome (Table 1). While all are based on the characteristics presented by Reaven^[6], there are various inclusion thresholds. A form of consensus was arrived at in 2009^[14] with the IDF, National Heart, Lung and Blood Institute, American Heart Association, World Heart Federation, International Atherosclerosis and the International Association for the Study of Obesity agreeing on threshold levels that were similar to those originally proposed by the IDF. Guidelines for classifying metabolic syndrome in children over 10 years of age were also issued^[15] and population and gender specific

ACR: Albumin creatinine ratio; BMI: Body mass index; DBP: Diastolic blood pressure; F: Female; IFG: Impaired fasting glucose; IGT: Impaired glucose tolerance; IR: Insulin resistance; SBP: Systolic blood pressure; M: Male; T2DM: Type 2 diabetes mellitus; W:H: Waist to hip ratio; WHO: World Health Organization; HDL: High density lipoprotein; IDF: International Diabetes Federation; EGIR: European Group for the Study of Insulin Resistance; NCEP: National Cholesterol Education Program; AACE: American Association of Clinical Endocrinologists; BP: Blood pressure; IR: Insulin resistance.

waist circumference thresholds were published to define central obesity^[13]. The prevalence for the metabolic syndrome varies between countries. Based on the IDF classification a 40% prevalence in the United States has been reported^[16].

Is there a clinical value in identifying the metabolic syndrome: It is not surprising, given the presence of known risk factors, to find that the metabolic syndrome confers an approximately two-fold increased relative risk of CVD^[17]. However, it is important to determine whether this impact is the effect of the metabolic syndrome (added risk due to a clustering of risk factors) or just the sum of its defining phenotypes. Studies using different CVD endpoints indicate the latter is the case. For example, Eddy *et al.*^[18] used data from NHANES III (third national health and nutrition survey) to simulate a population matching that of the United States, estimated its metabolic syndrome prevalence (using the various definitions) and associated this with CVD. While the number of individuals identified by the various metabolic syndrome classifications differed, they reported that fasting glucose levels > 110 mg/dL (6.1 mmol/L) were a better predictor of CVD than the presence of the metabolic syndrome classified by any of the definitions^[18]. Further, using change in atheroma volume as an endpoint, Bayturan *et al.*^[19] reviewed 3459 patients enrolled in 7 trials that used intravascular ultrasonography to measure plaque progression. While the metabolic syndrome was significantly associated [odds ratio (OR)

= 1.29, 95%CI: 1.09-1.53] with increased atheroma volume, the relationship was not significant (OR = 1.04, 95%CI: 0.79-1.37) when adjusted for its individual components; serum triglycerides ≥ 150 mg/dL (1.7 mmol/L), body mass index (BMI) ≥ 30 kg/m², high density lipoprotein cholesterol (HDL-C) < 40 mg/dL (1.0 mmol/L) in men or < 50 mg/dL (1.3 mmol/L) in women, blood pressure ≥ 135/85 mmHg or treatment of hypertension^[19]. In this multifactorial model, only serum triglyceride concentrations (≥ 150 mg/dL) remained significantly associated with plaque progression^[19].

These findings (and others) question the clinical value of identifying the metabolic syndrome in patients. Indeed, the identification is dependent on the thresholds of each of the contributing factors. Thus, for example, if age-related thresholds were used there would be a marked change in the numbers of affected individuals. While in theory its identification does not appear to add anything to prognosis in an individual patient, we and others^[20] argue that it has clinical value. As the metabolic syndrome is based on related and modifiable CVD risk factors, its identification encourages a holistic approach rather than a focus on the individual aspects (glycaemia, dyslipidaemia, weight reduction and blood pressure management) of the patients' condition. It therefore, has value in encouraging the clinician to address CVD risk using a multifactorial approach. It is also arguably useful in a research setting when considering the role of possible risk factors.

We also believe it is important to consider the

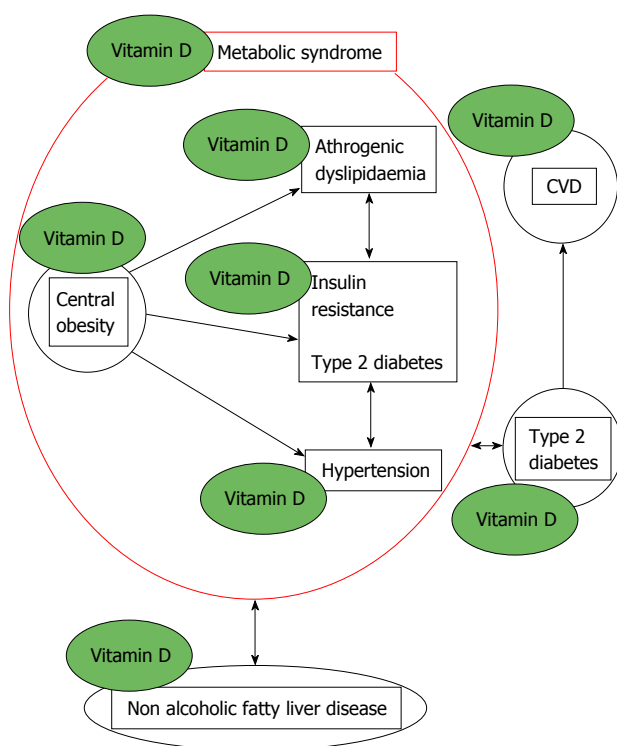

Figure 1 Simplified illustrations of the component risk factors of the metabolic syndrome, the complex relationships between them and the outcomes leading to increased morbidity and mortality. We also identify the areas that may be affected by hypovitaminosis D which are covered in this review. CVD: Cardiovascular disease.

metabolic syndrome as a heterogeneous entity. Indeed, in patients with the syndrome, we have shown that following treatment with statins and fibrates, outcomes can vary considerably indicating the presence of subgroups both known (gender, baseline lipids, and concurrent therapy) and unknown^[21-24].

Metabolic syndrome - putative pathway to CVD:

While it is accepted that central obesity and insulin resistance are core drivers of the metabolic syndrome, the timescale and inter-relationships between these and other factors that lead to an individual being classified with the syndrome and the consequent increased risk of CVD remain unclear^[25-27]. Clearly, while obesity and insulin resistance are common in adults worldwide they are rare in childhood indicating that environmental factors interacting with a genetic predisposition drive the development of the syndrome from birth through childhood to its identification in adulthood. Once an individual develops the metabolic syndrome, the combination of risk factors leads to an increased risk of CVD (Figure 1).

Obesity is a recognised risk factor associated with mortality, this probably due to the link between obesity and risk of developing diabetes, hypertension, atherogenic dyslipidaemia and CVD^[28]. However, the National Health and Nutrition Examination Survey (NHANES) indicated that individuals with a BMI between 30 and 35 kg/m² demonstrated only a modest increase

in mortality compared to those with BMI 18.5-25 kg/m²^[27,29]. These findings suggest the presence of a subgroup of obese individuals who are not at high risk of metabolic disturbances or increased mortality. Their presence may be a reason for the relatively modest increase in overall mortality in obese subjects. It has been speculated that the link between obesity and CVD may be *via* insulin resistance^[27]. Individuals with high insulin sensitivity and not fulfilling the ATP III metabolic syndrome criteria are considered to be a "metabolically healthy obese" group^[29].

The concept that not all obesity is bad in the context of developing CVD is interesting. Abdominal obesity, visceral as opposed to subcutaneous fat, appears to be critical in the development of insulin resistance^[30]. Abdominal adipose tissue was initially considered an inert storage depot for triglycerides (glycerol and fatty acids). The current view however, is that it is also an active endocrine organ. Intra-abdominal obesity, a classifying characteristic of the metabolic syndrome promotes insulin resistance (the reverse of insulin sensitivity), perhaps by secreting metabolically active substances (adipokines) and making available an increased quantity of free fatty acids^[30,31].

Insulin resistance, the other key factor in the metabolic syndrome, is defined as a condition where greater than normal levels of the peptide are needed to clear a glucose load (and effect its other metabolic actions). Thus, for a given blood glucose level the amount of insulin secreted is high. Impairment of sensitivity appears to be a contributing factor to all of the features of the metabolic syndrome in addition to having a direct causative role in the pathogenesis of type 2 diabetes. It can be considered a pre-diabetic state in non-diabetic patients, conferring a 5 fold increased risk of developing diabetes^[32]. Insulin resistance has also been demonstrated to be associated with hypertension, atherogenic dyslipidaemia and higher amounts of the atherogenic small dense low density lipoprotein cholesterol (LDL-C), features associated with the metabolic syndrome^[20,33].

Thus, in addition to weight reduction measures, reducing insulin resistance, a feature that may be an intermediate factor linking obesity with morbidity and mortality, must be addressed in patients with the metabolic syndrome. Apart from abdominal obesity there are other factors that may modify insulin resistance. Physical fitness (as measured by aerobic capacity) has been seen to increase insulin sensitivity^[34].

VITAMIN D BIOCHEMISTRY

Vitamin D, in addition to its role in calcium and bone metabolism, has pleiotrophic effects in many cell types in many life forms. These include a potential role in the actions of insulin and development of obesity (Figure 1). Thus, not surprisingly hypovitaminosis D has been linked with hypertension, atherogenic dyslipidaemia and increased CVD risk (Figure 1). An association has

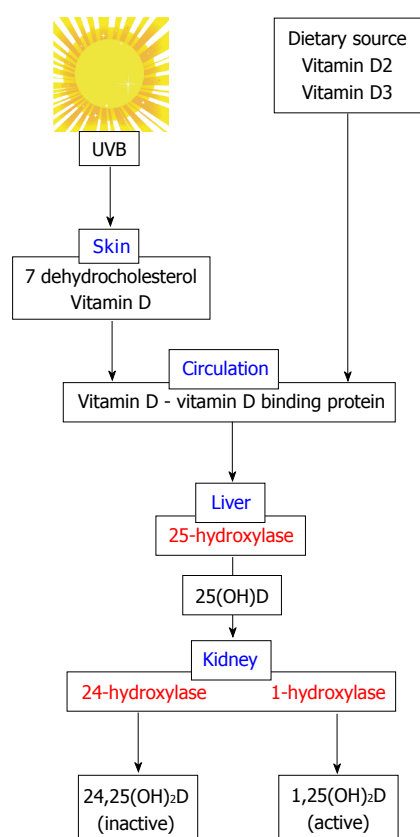

Figure 2 Simplified synthetic pathway leading to the formation of the active metabolite 1,25(OH)₂D. UVB: Ultraviolet B.

also been noted with non-alcoholic fatty liver disease independent of the features classifying the metabolic syndrome. Hypovitaminosis D can be addressed by both lifestyle measures and supplementation; hence, it is important to understand the relationship between vitamin D and the metabolic syndrome at both mechanistic and epidemiological levels.

Vitamin D synthesis

Bioactive vitamin D, 1,25(OH)₂D is synthesised in a pathway involving different organs and intermediates (Figure 2). Some inactive chemicals are produced that may have a regulatory role but will not be considered further. The first step in the pathway is the photochemical production of cholecalciferol in the skin from 7-dehydrocholesterol. Thus, production of bioactive 1,25(OH)₂D can only be initiated in skin *via* a photochemical process. Accordingly, animals have to eat foods containing the vitamin or be exposed to sunlight to allow its photosynthesis in skin.

Cholecalciferol is produced in the stratum basale and stratum spinosum layers of skin following reaction of 7-dehydrocholesterol with ultraviolet B (UVB) (270–300 nm). It is noteworthy that the concentration of 7-dehydrocholesterol falls with increasing age resulting in reduced capacity to synthesise vitamin D₃. This effect is marked; for example, the skin of a 70-year-old subject has approximately 25% of the 7-dehydrocholesterol compared with that of a young adult^[35]. Cholecalciferol

(and ergocalciferol) is carried in blood to the liver and hydroxylated at position 25 to form 25(OH)D. The final step in the pathway is hydroxylation of circulating 25(OH)D at the 1 position to form biologically active 1,25(OH)₂D. This occurs in the kidney, and other tissues, and is followed by its release into blood bound to vitamin D binding protein and transported to target organs.

How vitamin D works

Systemic or locally produced 1,25(OH)₂D binds to the vitamin D receptor (VDR), a nuclear receptor that dimerises with the retinoid X receptor and, in turn, becomes a regulator of transcription^[36]. Dimerisation allows interaction with the vitamin D response element on target genes initiating transcription^[37]. The VDR is a member of the steroid receptor superfamily and is responsible for regulating transcription in many responsive genes. Indeed, more than 200 genes, including those that regulate cell differentiation and proliferation as well as multiple metabolic systems, are targets for vitamin D.

Skin pigmentation, UVR and vitamin D

Vitamin D photosynthesis is long-established among animals implying a key role in metabolism. Phytoplankton in the sea have synthesised vitamin D for more than 500 million years and land vertebrates for more than 350 million years. Further, the sophisticated biochemical systems used by humans to balance the harmful and beneficial effects of sunlight demonstrate the evolutionary pressures on these processes. Protection from UVR has been provided by the development of a sunscreen; eumelanin. Eumelanin absorbs UVR, reducing its penetration and, thereby, formation of potentially harmful free radicals (reactive oxygen species) in the skin. The migration of humans from Africa to environments of often low and highly seasonal UVR placed pressure on the original constitutive, dark-skinned phenotype^[38]. Thus vitamin D₃ synthetic ability, following movement into higher latitudes, was enabled by polymorphic change in genes that determine skin pigmentation, such as melanocortin 1 receptor, with the resulting development of partially depigmented phenotypes capable of tanning. Thus, the present range of skin pigmentation results from a requirement to promote cutaneous UVR-induced vitamin D₃ synthesis (depigmented phenotype) and simultaneously prevent UVR-induced damage (pigmented phenotype)^[38].

Studying the relationship between UVR exposure, vitamin D status, skin type and disease risk is complicated by historical and recent population movements resulting in many people living under solar regimes very different to those in which their ancestors developed mechanisms to balance sunlight's harmful and beneficial effects. The health penalties of these movements are still under assessment though the potentially serious consequences of chronically low exposure are now being recognised. This of course, does not mitigate the need to ensure that the risks associated with inappropriate and excessive UVR exposure in terms of skin and other

cancers continues to be emphasised.

Environmental factors affecting exposure to UVR

The amount of UVR reaching earth varies with the angle at which radiation passes through the atmosphere (solar zenith angle), its path length through air, the presence of clouds and pollution in the lower atmosphere^[39,40]. Consequently, place and time of day and season are important. Outside of tropical latitudes, ensuring a year-round, adequate level of vitamin D synthesis is problematic because large solar zenith angles and long path lengths result in increased absorption and scattering of UVR. During the year the availability of vitamin D₃-inducing UVB wavelengths varies with latitude and outside the tropics there is little or no UVB in sunlight except at high altitudes for much of the year. For example, the equator sees only about a 20% variation while 50° N (circle of latitude that crosses the English Channel, Belgium, Czech Republic, Russia, Mongolia and Canada) sees around 250% variation. Indeed, between November-February, people living at latitude 50° N and higher receive no effective vitamin D₃-inducing UVB and can effect no vitamin synthesis^[39,40]. This latitude effect is compounded by dark skin pigmentation; the higher the eumelanin content the lower the vitamin D₃ production. Thus, for many individuals there is insufficient UVB over the year to allow adequate vitamin D synthesis and therefore a need to consume vitamin D₃-rich foods such as oily fish. An additional problem in ensuring adequate vitamin D status, particularly away from the equator, is presented by modern urban lifestyles. Exposure to UVR is limited by clothing, shade-seeking behaviour, often because of skin cancer fears, and occupations that result in 80%-90% of work time being spent indoors.

Assessing vitamin D status and defining hypovitaminosis

Exposure to sunlight or dietary intake of vitamin D increases the serum concentration of 25(OH)D making this a ready indicator of body vitamin D status. Establishing a link between chronic hypovitaminosis and disease risk clearly requires definition of a normal serum concentration of 25(OH)D. The serum 25(OH)D concentrations that identify hypovitaminosis D are not fully defined though the following ranges have been suggested; deficiency: ≤ 12 ng/mL (30 nmol/L), insufficiency: 12-20 ng/mL and satisfactory status: ≥ 20 ng/mL (50 nmol/L). However, given the well-recognised seasonal variation in vitamin synthesis, particularly in northerly latitudes, any reference range needs to be considered in the context of season. Recently Tandeter described an Individual Mean Annual vitamin D level termed the "IMAD level" and a recovery formula "RF" that may be used to calculate a mean that encompasses values from four seasons^[41].

Relationship between season and vitamin D status

Understanding the temporal relationship between

seasons, solar radiation and vitamin D photosynthesis is important if epidemiological approaches are used to establish associations between these variables, disease risk and outcome. Furthermore, the impact of relative acute or chronic hypovitaminosis on the relationship between seasons and disease pathogenesis is unclear. For example, if chronic hypovitaminosis D was pathological, a visible consequence might take some time to be clinically evident and therefore not easily associated with the seasons^[42].

Surprisingly given the potential impact of vitamin D on public health, there is little data on the relationship between seasons, serum vitamin concentrations and lag time between firstly, solar radiation and building up of adequate levels of the vitamin and secondly, which chronic patterns of hypovitaminosis have most impact on the pathogenesis of particular diseases^[42]. Thus, while the causal link between skin exposure to solar UVR and serum vitamin D cyclicity is recognised, neither the mathematical relationship between the peaks and troughs of serum 25(OH)D concentrations during the year nor how (or if) particular patterns affect disease risk have been well defined. Kasahara *et al.*^[42] also provide a model describing the seasonality of serum 25(OH)D concentrations in the United States that could be extrapolated to other studies^[41]. They argued that in the temperate northern hemisphere, serum 25(OH)D concentrations vary during the year because production is determined by the area of skin exposed to UVR and the intensity of the radiation. Thus, serum vitamin concentrations demonstrate maximum levels in late summer and lowest in late winter. This presumably reflects significant photosynthesis and gradual accumulation of vitamin D during the early spring months and a gradual use of reserves in months immediately after photosynthesis ceases when there is little sunlight. Thus, serum vitamin D concentrations demonstrate a seasonal lag pattern that is influenced by how much atmosphere sunlight must pass through before reaching the human body.

ASSOCIATION BETWEEN HYPOVITAMINOSIS D, THE METABOLIC SYNDROME AND CVD RISK

Importance of vitamin D: Population studies using mortality/morbidity as outcome

Many studies suggest that low serum vitamin D concentrations, even when above those associated with rickets, are deleterious. A variety of criteria have been used as clinical endpoints. For example, Schöttker *et al.*^[43] studied the association between serum 25(OH)D concentrations and mortality in a meta-analysis of data from eight prospective cohort studies involving 26018 men and women aged 50-79 years from Europe and the United States. The outcome measures were all-cause, cardiovascular, and cancer mortality. As expected, 25(OH)D concentrations were higher in summer and in

men. During follow-up a total of 6695 study participants died; 2624 of these subjects died of CVDs and 2227 of cancer. Despite levels of 25(OH)D strongly varying with country, gender and season, the association between 25(OH)D concentration and all-cause and cause-specific mortality was consistent^[43]. The lowest 25(OH)D quintile was associated with increased all-cause mortality, cardiovascular mortality and cancer mortality (in those with a history of cancer)^[43]. The inverse association across quintiles was consistent across countries, genders, season and age groups despite 25(OH)D cut-off values varying according to these characteristics^[43].

Associations between UVR exposure and disease risk and outcome have been reported for a wide range of pathologies, although in most cases conflicting data have also presented. Corresponding studies using serum 25(OH)D also show conflicting data. For example, we have presented data indicating that UVR may influence disease risk by a vitamin D mediated mechanism in the pathogenesis of prostate cancer^[44,45] and multiple sclerosis^[46] though we emphasise that these associations remain unproven and any mechanistic basis is uncertain^[47].

Metabolic syndrome and seasons

Clearly, any suggestion that risk of the metabolic syndrome is partly determined by vitamin D status would be helped by evidence that the incidence of the syndrome, and/or its component phenotypes, is linked with availability of the vitamin and/or the seasons. Some evidence supporting this view is available. Kamezaki *et al.*^[48] reported such links in 1202 Japanese males (44 ± 10 years) who were assessed in summer and winter in 2008 for the metabolic syndrome defined using the criteria proposed by the NCEP, the IDF and the Japanese Society of Internal Medicine (JSIM). The prevalence rates of NCEP, IDF, and JSIM defined metabolic syndrome in winter were 3.8%, 15.1% and 12.4% and in summer, 3.2%, 10.7% and 8.4% respectively^[48]. Blood pressure changes were most significantly correlated with this seasonal variation in metabolic syndrome prevalence^[48].

However, inconsistent results regarding the putative association of key components of the metabolic syndrome with season have been reported including more insulin resistance and higher triglyceride concentrations during the summer in some, winter in others and some showing no significant seasonal variation. Taiwanese subjects described by Chen *et al.*^[49] were studied in winter (January and February) and summer (July and August) in 2002. They found higher levels of fasting insulin, HOMA-insulin resistance and triglycerides, but lower levels of HDL-C in summer compared with winter. The prevalence of metabolic syndrome in summer was higher than in winter; difference of 7.7% in both genders ($P = 0.0092$ in men, $P = 0.0037$ in women). After controlling for BMI and other risk profiles, summer was independently and positively associated with fasting insulin and insulin resistance regardless of metabolic syndrome^[49].

A further interesting association between the meta-

bolic syndrome and season is the report by Rintamäki *et al.*^[50] showing a significant association between seasonal changes in mood and behaviour and the metabolic syndrome. Individuals with the syndrome had greater seasonal changes in mood and behaviour.

Metabolic syndrome and vitamin D status: Observational studies

Considerable research has focussed on associations between vitamin D levels and the prevalence of the metabolic syndrome and its component features. Many studies demonstrate an inverse relationship between serum 25(OH)D and diabetes, metabolic syndrome, insulin resistance and beta cell function^[51,52]. The NHANES data confirmed the inverse relationship between 25(OH)D levels and diabetes and insulin resistance in the non-Hispanic white and Mexican American, but not in the non-Hispanic black populations^[53,54].

A meta-analysis of 28 studies (between 1990 and 2009) including 99745 participants (age range: 40.5-74.5 years) by Parker *et al.*^[1] investigated the effects of vitamin D on the risk of CVD, diabetes and the metabolic syndrome^[1]. Higher levels of vitamin D were seen to be associated with reduction of all the outcomes studied among middle aged and elderly individuals. The 28 studies reported 33 ORs when considering the association between 25(OH)D and cardiometabolic outcomes; 29 of these ORs suggested an inverse relationship with 3 indicating an opposite effect with 1 analysis remaining non-significant^[1]. The pooled OR was 0.57 (95%CI: 0.48-0.57). Prevalence of the metabolic syndrome was the outcome in 8 of the studies; all these showing a significant association between high 25(OH)D levels and reduced metabolic syndrome prevalence (OR = 0.49, 95%CI: 0.38-0.64).

Ju *et al.*^[55] studied the relationship between serum 25(OH)D levels and metabolic syndrome in the general adult population using a dose-response meta-analysis based on studies reporting risk ratios for metabolic syndrome in categories of serum 25(OH)D concentrations. The pooled OR for the metabolic syndrome per 25 nmol/L (10 ng/mL) increment in the 25(OH)D concentration was 0.87 (95%CI: 0.83-0.92), based on 16 cross-sectional studies and 1.00 (95%CI: 0.98-1.02) for 2 cohort and nested case-control studies^[55]. The dose-response meta-analysis showed a generally linear, inverse relationship between 25(OH)D levels and the metabolic syndrome in the cross-sectional studies [probability (P) value for linear trend < 0.001]. They concluded that vitamin D status was associated with metabolic syndrome risk in cross-sectional but not longitudinal studies^[55].

Song *et al.*^[56] reported a cross-sectional study comprising 778 Korean adults. Metabolic syndrome was defined according to the American Heart Association/ National Heart, Lung, and Blood Institute criteria and the Korean Society for the Study of Obesity. The overall prevalence of the metabolic syndrome was 18.9%^[56]. After multiple adjustments, compared with the highest

quartile serum 25(OH)D level group (19.9-55.9 ng/mL), the OR for metabolic syndrome in the lowest level group (4.2-9.7 ng/mL) was 2.44 (95%CI: 1.32-4.48). The intermediate quartiles (9.8-14.1 ng/mL) and (14.3-19.8 ng/mL) had ORs of 2.20 (95%CI: 1.24-3.90) and 1.81 (95%CI: 1.02-3.20) respectively when compared to the highest quartile. Among the components of metabolic syndrome, the adjusted ORs for elevated blood pressure and high triglycerides in the lowest 25(OH)D level were 1.81 (95%CI: 1.15-2.85) and 2.74 (95%CI: 1.64-4.57) respectively^[56].

Thus, it is clear from these observational surveys that a relationship may exist between 25(OH)D levels and glucose homeostasis, metabolic syndrome and type 2 diabetes. These population studies do not hint as causation as 25(OH)D status and other established risk factors were not measured at or prior to diagnosis. Thus, prospective studies are required that take into account other confounding factors such as serial weight measurements, physical activity and family history.

Metabolic syndrome and vitamin D status: Prospective studies

A number of prospective studies have also presented data that support the proposal that low serum 25(OH)D concentrations are associated with increased risk of the development of the metabolic syndrome. For example, Gagnon *et al.*^[57] studied 4164 adults (mean age 50 years; 58% women; 92% Europeans). Over the following 5 years, 528 incident cases (12.7%) of the metabolic syndrome were identified^[57]. Compared with the reference category [highest quintile 25(OH)D ≥ 34 ng/mL], the metabolic syndrome risk was significantly higher in people with 25(OH)D in the first (< 18 ng/mL) and second (18-23 ng/mL) quintiles [OR = 1.41 (95%CI: 1.02-1.95) and 1.74 (95%CI: 1.28-2.37) respectively]^[57]. Serum 25(OH)D was inversely associated with waist circumference ($P < 0.001$), triglycerides ($P < 0.01$), fasting glucose ($P < 0.01$), and HOMA-IR ($P < 0.001$) but not with 2-h plasma glucose ($P = 0.29$), HDL-C ($P = 0.70$), or blood pressure ($P = 0.46$)^[57].

More recently Kayaniyil *et al.*^[58] examined the prospective association of 25(OH)D with the metabolic syndrome in a multi-ethnic cohort of non-diabetic adults with pre-existing risk factors in Ontario, Canada. Of 654 participants enrolled at baseline, 489 attended a 3 year follow-up visit. Multivariate logistic regression analyses indicated a decreased risk of the metabolic syndrome at follow-up per standard deviation increase in baseline 25(OH)D after adjustment for sociodemographics, season, baseline and change in supplement use, physical activity and insulin resistance (OR = 0.63, 95%CI: 0.44-0.90)^[58].

Associations between the defining components of the metabolic syndrome and vitamin D status:

Observational, prospective and interventional studies

The observational and prospective studies previously

described demonstrate associations between 25(OH)D concentrations and the metabolic syndrome, but were not designed to explore mechanistic aspects. We now review the effect that 25(OH)D levels may have on the defining characteristics of the metabolic syndrome; abdominal adiposity, insulin resistance (and beta cell function), hypertension and atherogenic dyslipidaemia.

Karatas *et al.*^[59] investigated the association between 25(OH)D levels and all components of the metabolic syndrome in 287 Turkish subjects. Of these, 214 participants were either obese (BMI ≥ 30 kg/m²) or overweight (BMI: 25-29.9 kg/m²). Metabolic syndrome was classified using IDF criteria. Multiple logistic regression analyses were carried out with metabolic syndrome, abdominal obesity, low HDL-C, hypertriglyceridaemia and hypertension as the dependent variable and with 25(OH)D as a continuous independent variable in one set of analyses and 25(OH)D levels stratified as deficiency (< 20 ng/mL), insufficiency (20-29.9 ng/mL) and sufficient (reference level) groups as a factorised independent variable in further analyses. The analyses were corrected for age, gender and season. Hypovitaminosis was significantly more common in the overweight/obese individuals with and without the metabolic syndrome^[59]. There was a significant inverse relationship between triglyceride levels and serum 25(OH)D concentration. No significant associations between 25(OH)D and HDL-C, hypertension and insulin resistance were observed.

Obesity has been associated with hypovitaminosis D, perhaps *via* multiple mechanisms^[60,61]. The nature of this association was investigated by a bi-directional genetic study that suggested higher BMI resulted in lower 25(OH)D levels but with the reverse effect being small^[62]. They concluded that weight reducing interventions would be expected to reduce the prevalence of hypovitaminosis D^[62]. In contrast Salehpour *et al.*^[63] carried out a 12 wk study following cholecalciferol supplementation and showed a significant decrease in body fat mass in both healthy and obese women compared to the placebo arm^[63]. These conflicting findings make it essential that both interventions (weight reduction and vitamin D replacement) are studied in detail with suitably designed trials. Other studies investigating mechanisms, unlike Vimalleswaran *et al.*^[62], have indicated a bi-directional association between obesity and hypovitaminosis D. It has been seen from animal studies that vitamin D may play a part in adipogenesis and energy metabolism. The VDR is expressed in adipose tissue pre-maturation^[64] and in early adipogenesis^[65]. The presence of a role in adipogenesis is also suggested by adipocyte atrophy seen in VDR knockout mice^[66].

The relationship between volume of adipose tissue and vitamin D status, at least as reflected in serum 25(OH)D concentrations, is unclear. Vitamin D is sequestered in adipose tissue and it has been speculated that obesity, by increasing the volume of distribution of available adiposity, will lead to lower serum vitamin D levels^[67,68]. This view is contradicted by Pramyothin *et al.*^[69] who measured vitamin D levels in the subcutaneous

abdominal fat of 17 patients undergoing gastric bypass. Vitamin measurements were made at surgery and over a 12 mo follow-up period^[69]. It was found that vitamin D levels in adipose tissue varied considerably and no significant change in serum 25(OH)D was noted during follow-up despite intake of supplements (> 2500 U/d).

There has been speculation that behaviour traits associated with obesity, such as reduced outdoor exercise levels, could be associated with decreased exposure and reduced vitamin D synthesis. Results from studies investigating this possible association have varied^[70,71]. Thus, although a clear association is evident between adiposity and vitamin D levels the nature of this association has yet to be determined. It is important to establish this relationship as central adiposity is a key driver in the development of the metabolic syndrome.

Dysfunction of insulin secretion by pancreatic beta cells and insulin resistance are considered to be causative drivers in the aetiology of type 2 diabetes^[26]. Insulin secretion may be affected by lipotoxicity, due to increased free fatty acids, and glucotoxicity, due to elevated serum glucose and lipid accumulation within the beta cells^[72]. We have seen that insulin resistance is a core component of the metabolic syndrome. Contrasting findings are evident in observational studies investigating the relationship between 25(OH)D levels and insulin sensitivity. Chiu *et al.*^[52], in Californian students of mixed ethnicity, and Kamycheva *et al.*^[73], in a study of patients with hyperparathyroidism, [patients grouped by the median 25(OH)D concentration] noted a positive correlation between insulin sensitivity and 25(OH)D levels. However, there have been other studies which have not shown the above association, these having been carried out in patient groups characterised by obesity^[74], non-diabetic status^[75] and the metabolic syndrome^[76]. A prospective study of 524 non-diabetic individuals by Forouhi *et al.*^[77] showed an inverse association between 25(OH)D levels and the risk of insulin resistance and elevated blood sugars^[77]. However, the Mini-Finland Health Survey did not demonstrate a significant correlation between 25(OH)D quartiles and the onset of diabetes when the analysis was corrected for BMI and activity^[78].

Vitamin D supplementation has been seen to alter insulin sensitivity in non-diabetic patients, but not in patients diagnosed with type 2 diabetes^[79,80]. Pittas *et al.*^[81] demonstrated that, when compared to placebo, vitamin D had a positive effect on insulin resistance and glycaemic control (non-primary outcome) in a randomised controlled study of patients with impaired fasting glucose^[81]. A complex mechanism is suggested by the SURAYA trial of obese south Asian women as insulin resistance was seen to improve only when supplementation elevated the 25(OH)D concentration above 80 nmol/L this perhaps indicates either a dose response or threshold effect^[82].

Given the association between 25(OH)D levels and obesity it is expected that there would be a similar

relationship with the lipid concentrations; however, study results have varied. A large study in Norway, both longitudinal ($n = 2159$) and cross sectional ($n = 10105$) demonstrated that higher levels of cholesterol, HDL-C and LDL-C and lower levels of triglyceride were associated with reduced 25(OH)D concentrations^[83]. A survey of 108711 patients who had multiple 25(OH)D and lipid profiles measured revealed a similar relationship between 25(OH)D and cholesterol and LDL-C levels^[84]. Further, optimal levels of 25(OH)D were associated with higher HDL-C^[84]. More confusion has arisen as vitamin D supplementation following their cross sectional survey in patients with hypovitaminosis did not lead to consistent changes in the lipid profile^[84]. Jorde *et al.*^[85] reviewed the findings of 22 cross sectional and 10 placebo controlled double blind randomised controlled trials and concluded that, while the cross sectional studies demonstrated a uniform inverse relationship between 25(OH)D and triglyceride levels, the intervention studies with vitamin D supplementation have led to varied results. They concluded that these intervention studies were not adequately designed to specifically investigate the relationship between 25(OH)D and lipids and speculated that the relationship between 25(OH)D and lipids could be either direct or *via* changes in parathyroid hormone and/or calcium concentrations^[85].

Many studies using mouse and human hepatoma cell lines^[86,87] and VDR knockout mice^[88] have been carried out to understand the observed associations between 25(OH)D and lipid concentrations. Some have examined the effect of VDR on bile acid synthesis, and cholesterol levels, once again with inconsistent results^[89].

Hypertension, one of the defining components of the metabolic syndrome, has been reported to display a seasonal and geographical variability raising the possibility of sun exposure having a role^[90]. Even before this observation Resnick *et al.*^[91] in 1986 suggested that vitamin D metabolites were associated with hypertension potentially *via* the renin-angiotensin system^[91]. Both animal and cross-sectional human studies have suggested vitamin D to be an inhibitor of the renin-angiotensin system in VDR knockout^[92] and 1α -hydroxylase knockout^[93] mice with significantly raised renin activity and plasma angiotensin 2 concentrations. The effects were reversed in the 1α -hydroxylase knockout mice by administration of $1,25(\text{OH})_2\text{D}$ ^[93]. Vascular smooth muscle and endothelial cells express VDR and the 1α -hydroxylase enzyme indicating that vitamin D may influence endothelial function which could lead to arterial stiffness and hypertension, in addition to plaque formation^[94]. The change in endothelial function could be due to either a direct effect or *via* improved blood pressure.

Most of the surveys such as NHANES III^[95], the German National Health Interview and Examination Survey^[96] and the 1958 British Birth Cohort^[97] investigating the relationship between vitamin D and hypertension have pointed to an inverse association. However, there have been studies that have not shown this

association^[98,99]. Once again the mixed findings could have been due to confounding variables common in multifactorial pathology. Similarly prospective studies too have not been consistent with regards to outcome^[100,101]. Further, interventional trials have also resulted in varied results^[102,103]. A meta-analysis of 11 interventional trials showed a modest reduction in diastolic blood pressure (3.1 mmHg), but this was not accompanied by any significant change in systolic blood pressure^[104]. It was evident that most of the studies were not designed to investigate the association in question. Although observational studies have suggested endothelial dysfunction in individuals with hypovitaminosis D^[105,106] results following vitamin D supplements have been missed. While some intervention trials have shown a beneficial effect on endothelial function^[107,108] others have not^[109,110]. Thus, it is clear that although most studies indicate an association between vitamin D status and blood pressure the findings from observational, prospective and interventional studies have not been unanimous.

We have seen that much of the work presented above, with the exemption of Karatas *et al.*^[59], has focussed on individual associations between hypovitaminosis D, vitamin D supplementation and components of the metabolic syndrome. As evident from Figure 1 these factors are inter-related and it is essential that future studies take this into account.

Benefits in mortality, CVD and onset of type 2 diabetes observed following vitamin D supplements

As we have seen previously there is considerable evidence that hypovitaminosis D is associated with increased CVD risk although the mechanisms still remain largely unclear. It is essential to determine if this increase in risk can be reversed by supplements. Many questions remain that can only be answered by long term intervention studies. It is important to estimate benefit in the overall study group as well as subgroups based on age, gender, ethnicity, CVD risk, vitamin D levels and other baseline characteristics. Further, benefit associated with different replacement dosage must be evaluated. To this date no large intervention trial fulfilling the above criteria has reported findings.

Vacek *et al.*^[111] in 2012 carried out an observational retrospective study of 10889 patients seen in a secondary care cardiology setting. Hypovitaminosis (< 30 ng/mL) was diagnosed in 70.3% of this cohort. Vitamin D supplements were taken by 31.6% of the vitamin D deficient patients and 21.3% of patients with normal values and the association between treatment and all-cause mortality studied. Hypovitaminosis D was significantly associated with mortality in patients not on vitamin D replacement (OR = 3.72, 95%CI: 2.563-5.396)^[111]. In contrast hypovitaminosis was not significantly associated with mortality in patients on supplements (OR = 1.46, 95%CI: 0.760-2.799). This analysis was not carried out with CVD mortality and morbidity as an outcome measure. It must be noted

that this study was in a selected population and was retrospective and observational. Gotsman studied the impact of vitamin D supplements on mortality in 3069 patients with heart failure^[112]. Supplementation was associated with significantly reduced mortality (HR = 0.68, 95%CI: 0.54-0.85). However, no convincing data exists regarding the benefits in mortality that may be related to vitamin D supplements in a healthy population.

There are very few studies examining CVD risk reduction following vitamin D supplementation. A systematic review of 17 prospective and randomised trials using vitamin D and/or calcium supplements showed vitamin D supplements, at approximately 1000 IU/d, caused a 10% relative risk reduction that was not significant when compared to placebo^[113]. When the analysis was restricted to the 5 prospective studies of patients receiving vitamin D a reduction in CVD related mortality was observed. It must be noted that 4 of these studies consisted of patients receiving dialysis, a high risk group. Interestingly calcium supplementation did not appear to influence any of the outcome measures.

No large randomised control trial has been carried out with onset of metabolic syndrome/diabetes as the primary outcome. The RECORD study where patients were randomised to receive 800 IU/d of vitamin D recorded onset of type 2 diabetes as a secondary outcome (primary outcome was fracture rate)^[114]. A non-significant 33% relative risk reduction was seen. Similarly, onset of diabetes was the monitored outcome in the Womens Health Initiative Calcium/Vitamin D Trial with 33951 women randomised to either 400 IU/d of vitamin D or placebo for 7 years and no significant benefit was observed^[115]. Most other studies have included smaller patient numbers and have not demonstrated reduced incidence of type 2 diabetes or the metabolic syndrome. Further, no convincing evidence exists that supplementation reduces the progression from the metabolic syndrome to type 2 diabetes.

Mixed results have been observed when insulin sensitivity has been determined following treatment with vitamin D. Mitri *et al.*^[116] demonstrated a significant improvement in insulin secretion in 92 individuals at high risk of developing diabetes following randomisation to either 2000 IU/d of vitamin D supplements or placebo. Nagpal *et al.*^[117] determined the effect vitamin D supplementation (3 doses of 120000 IU) had on insulin sensitivity compared to placebo in 71 healthy male volunteers with central obesity. Insulin sensitivity was seen to improve in the treatment arm^[117]. However, there have been other trials demonstrating no improvement in insulin sensitivity. Luo *et al.*^[118] treated 21 Chinese patients with type 2 diabetes and hypovitaminosis D (≤ 50 nmol/L) with 2000 IU/d of vitamin D for a 3 mo period. No changes were observed in any of the metabolic syndrome parameters, HbA1c or in insulin requirements^[118]. George *et al.*^[119] published a systematic review of 15 trials assessing the effects of vitamin D supplementation compared to placebo on fasting glucose,

glycaemic control and insulin resistance. When all the studies were combined no significant improvement in outcomes was observed. When the analyses were restricted, to patients with diabetes or impaired glucose tolerance, significant but small improvements were observed in both fasting glucose and insulin sensitivity, but no changes seen in HbA1c^[119].

All the studies described above leave an impression that vitamin D supplementation could potentially be beneficial. However, current evidence does not allow us to identify patient groups that would benefit maximally.

Vitamin D and type 2 diabetes

We have focussed this review on hypovitaminosis D in the metabolic syndrome and its defining components as well as CVD. We have described that hypovitaminosis D appears to be related to the metabolic syndrome, potentially a pre-diabetic state and its component characteristics such as obesity and insulin resistance. Thus, we would expect there to be a relationship between vitamin D levels and type 2 diabetes. We have also described current evidence as to the effects of vitamin D supplementation on diabetes control. In addition to actions that may be mediated *via* obesity and insulin resistance which we have described above, hypovitaminosis D appears to have a direct effect on glycaemic control. It has been suggested that vitamin D could have a role in ensuring calcium influx into cells which may be essential to the actions of insulin in skeletal muscle and adipocytes^[120]. There have been hints that elevated parathyroid hormone levels may blunt the actions of insulin^[121]. Although outside the boundaries of this review, an association between type 1 diabetes and hypovitaminosis D also suggests at a direct action of vitamin D on insulin action that may also be relevant to type 2 diabetes^[122].

Vitamin D and non-alcoholic fatty liver disease

Individuals with the metabolic syndrome of long duration are considered to be at greater risk of developing hepatic steatosis^[123]. A two or three hit hypothesis has been proposed^[124]. The first hit is considered to be the damage caused by fatty infiltration associated with insulin resistance and obesity^[124]. The second and third hits are thought to be due to hepatic injury resulting from mechanisms linked to oxidative stress and impaired cellular regeneration^[124]. Hepatic fatty infiltration could progress through non-alcoholic steatohepatitis and liver fibrosis to liver cirrhosis. Management of this spectrum has focused on improving the metabolic syndrome phenotype with weight reduction and management of dyslipidaemia and hyperglycaemia^[125].

As hypovitaminosis D is related to the metabolic syndrome we would expect an association with non-alcoholic fatty liver disease. A review of 6800 patients on the NHANES III database showed that those with an elevated serum alanine transaminase activity were seen to have lower vitamin D concentrations compared to matched controls with normal enzyme levels, the analysis

being corrected for the metabolic syndrome^[126]. This association (independent of age, gender, triglycerides and insulin resistance) was also observed by Barchetta *et al.*^[127] in a study of 262 patients. Further, vitamin D levels were lower in patients with non-alcoholic fatty liver disease diagnosed by liver biopsy^[128]. Hypovitaminosis D has been associated with altered regulation of inflammatory and anti-oxidant pathways in addition to influencing the metabolic syndrome phenotype; all the hits postulated in the aetiology of steatosis^[129]. At present there is no conclusive evidence that vitamin D supplementation could lead to clinical improvement of hepatic steatosis. Interestingly treatment with agents such as ursodeoxycholic acid, which increases vitamin D concentrations, has shown some improvement in non-alcoholic steatohepatitis with alanine transaminase levels used as the outcome^[130]. However, ursodeoxycholic acid may possess direct anti-inflammatory anti-oxidant properties which may be significant confounding factors.

CONCLUSION

It is clear that hypovitaminosis D has extra-skeletal effects that impact on the development of various pathologies including those that make up a large majority of morbidity and mortality; cancer, CVD and diabetes. In this review we have focussed on the association between hypovitaminosis D and the metabolic syndrome. Recently there has been a significant increase in the number of individuals with the metabolic syndrome. Indeed, as much as 40% of the United States population suffers from the condition comprising some or all of a cluster of CVD risk factors. Although the metabolic syndrome does not confer additional risk compared to the component risk factors we believe it helpful to the clinician and researcher to classify patients because it encourages a holistic approach to CVD risk reduction and study of the inter-relationships between the different relevant factors respectively.

There is considerable confusion surrounding the association between vitamin D and the metabolic syndrome, its component factors, CVD and mortality. Although studies have not been unanimous in their findings we are left with the impression that hypovitaminosis D is probably associated with all the above outcomes. However, the nature of this relationship in subgroups (*e.g.*, gender, age groups, ethnicity, *etc.*) is not clear. The risk associated with varying levels of vitamin D has not been estimated. Mechanisms that lead to increased prevalence of the components of the metabolic syndrome and its associated risk have not been worked out. Even more confusing is whether there is any benefit in vitamin D replacement therapy as trials have been contradictory.

However, there appears to be sufficient evidence to make the unravelling of the association between hypovitaminosis D and the metabolic syndrome a priority. Today both conditions are of high prevalence. This suggests that even if a modest decrease in CVD risk is

observed following vitamin D replacement it will translate to substantial overall benefits. Due to the modest price of supplements and relative safety, the cost benefits could be in favour of vitamin D replacement.

What is required are well designed studies, both prospective and intervention. In addition to estimating overall benefit, they must be sufficiently powered to study subgroups as well as risk and benefits at varying serum vitamin D concentrations as well as replacement regimes. It is only following the availability of this data that clear recommendations can be made with regards vitamin D replacement in patients with the components of the metabolic syndrome.

Abstract

Hypoglycemia unawareness (HU) is defined at the onset of neuroglycopenia before the appearance of autonomic warning symptoms. It is a major limitation to achieving tight diabetes and reduced quality of life. HU occurs in approximately 40% of people with type 1 diabetes

mellitus (T1DM) and with less frequency in T2DM. Though the aetiology of HU is multifactorial, possible mechanisms include chronic exposure to low blood glucose, antecedent hypoglycaemia, recurrent severe hypoglycaemia and the failure of counter-regulatory hormones. Clinically it manifests as the inability to recognise impending hypoglycaemia by symptoms, but the mechanisms and mediators remain largely unknown. Prevention and management of HU is complex, and can only be achieved by a multifactorial intervention of clinical care and structured patient education by the diabetes team. Less known regarding the impact of medications on the development or recognition of this condition in patients with diabetes. Several medications are thought to worsen or promote HU, whereas others may have an attenuating effect on the problem. This article reviews recent advances in how the brain senses and responds to hypoglycaemia, novel mechanisms by which people with insulin-treated diabetes develop HU and impaired counter-regulatory responses. The consequences that HU has on the person with diabetes and their family are also described. Finally, it examines the evidence for prevention and treatment of HU, and summarizes the effects of medications that may influence it.

Key words: Hypoglycemia unawareness; Impaired awareness of hypoglycemia; Hypoglycemia associated autonomic failure; Diabetes mellitus; Counter-regulation

INTRODUCTION

Hypoglycemia is usually defined as a plasma glucose level < 70 mg/dL (3.9 mmol/L)^[1]. Since the brain is permanently dependent on glucose, strong counter-regulatory mechanisms exist to quickly increase glucose levels to protect the human body from the negative consequences of hypoglycemia. Counter-regulatory response to hypoglycemia (Figure 1) includes inhibition of the endogenous insulin secretion and stimulation of glucagon, catecholamines (norepinephrine, epinephrine), cortisol and growth hormone secretion, which all together stimulate hepatic glucose production and cut down glucose utilization in peripheral tissues, increasing in this way plasma glucose levels. As glycaemia comes down, the activation of the autonomic nervous system leads to neurogenic symptoms (palpitations, sweating, hunger, anxiety, tremors, etc.), which allows the perception of hypoglycaemia (hypoglycaemia awareness) (Figure 2).

Hypoglycemia unawareness (HU) is defined as the onset of neuroglycopenia before the appearance of autonomic warning symptoms^[2] or as the failure to sense a significant fall in blood glucose below normal levels^[3]. In patients with type 1 (T1DM) or type 2 diabetes mellitus (T2DM), recurrent hypoglycemia has been shown to reduce the glucose level that precipitates the counter-regulatory response necessary to restore euglycemia during a subsequent episode of hypoglycemia^[4,5].

HU was observed in 40% T1DM patients^[6] and less frequently in T2DM patients with low C-peptide levels. The presence of HU increases the risk of severe hypoglycaemia (six-fold for T1DM^[7] and 17-fold for T2DM^[8]). HU is more common in individuals with longer duration of diabetes, history of recent and/or recurrent hypoglycaemic events, patients with intensive glycaemic therapy and in advanced age^[9].

Presently, the major risk factors for the development of HU are duration of the disease and improved metabolic control. The severity of HU was associated with longer diabetes duration and with a history of frequent low glycaemic levels^[6], whereas aging and the blood glucose decreasing rate using professional continuous glucose monitoring systems (CGMS), which falls from near blood glucose level, were risk of severe HU^[10]. Data from Pittsburgh Epidemiology of Diabetes Complications^[11] showed that diabetes duration, HbA1c and intensive insulin therapy predicted HU in men, whereas severity and frequency of hypoglycemia, QTc interval and hypertension predicted HU in women. Thus, women are more likely to have HU, which unlike in men, is also marginally related to hypertension, QTc interval

and hypoglycemia. On the other hand, in patients with T1DM, HU was 3.4-fold more common among patients homozygous for Gly16 than among patients with other variants of the Arg16Gly polymorphism, so that T1DM patients who carry two alleles of the Gly16 variant of ADRB2 are at increased risk of developing HU^[12]. Finally, in both T1 and T2DM patients with impaired HU, hypoglycemia-induced electroencephalogram changes, such as increased theta band amplitude, were not affected by antecedent hypoglycemia^[13].

This article reviews recent advances in how the brain senses and responds to hypoglycemia, novel mechanisms by which people with insulin-treated diabetes develop HU and impaired counter-regulatory responses. The consequences that HU had on the person with diabetes and their family is also described. Finally, it examines the evidence for prevention and management of HU, and summarizes the effects of medications that may influence it.

MECHANISMS OF HU

Aberrant glucose counter-regulation (as a result of a failure in the reduction of insulin production and an increase in glucagon release), and HU (as the result of an attenuated increase in sympathoadrenal activity) are the components of hypoglycemia-associated autonomic failure (HAAF) in diabetic patients. HAAF is most often caused by recent/recurrent iatrogenic hypoglycemia, and indeed HAAF is maintained by recurrent hypoglycemia^[14,15] (Figure 3).

Diverse causes of HAAF and HU in diabetes^[16]

Catecholamines: Previous hypoglycemia leads to a blunted catecholamine response to a following episode of hypoglycemia. This has been demonstrated in several studies; for example Ramanathan *et al.*^[17] showed that intravenous infusion of adrenergic blockers on one day of a hypoglycemia prevent the counter-regulatory failure in the response on the next day of hypoglycemia. This study implicates that HAAF needs a previous hypoglycemia (with its sympathoadrenal responses). If we use this hypothesis to think in a possible pharmacologic treatment, we can conclude that blocking the action of catecholamines we can limit the development of HAAF and protect against subsequent hypoglycemia; but unfortunately, blocking the action of catecholamines in periphery we would tend to an increase in the severity of hypoglycemia. We would need to develop a selective adrenergic receptor modulators that favourably change central nervous system response without modify the beneficial peripheral effects of the sympathoadrenal response.

Sleep: Sleep is a peripheral mediator of HAAF linked with catecholamine response. Patients with T1DM, while they are sleeping, they have a significantly decreased epinephrine response to hypoglycemia^[18], and also a

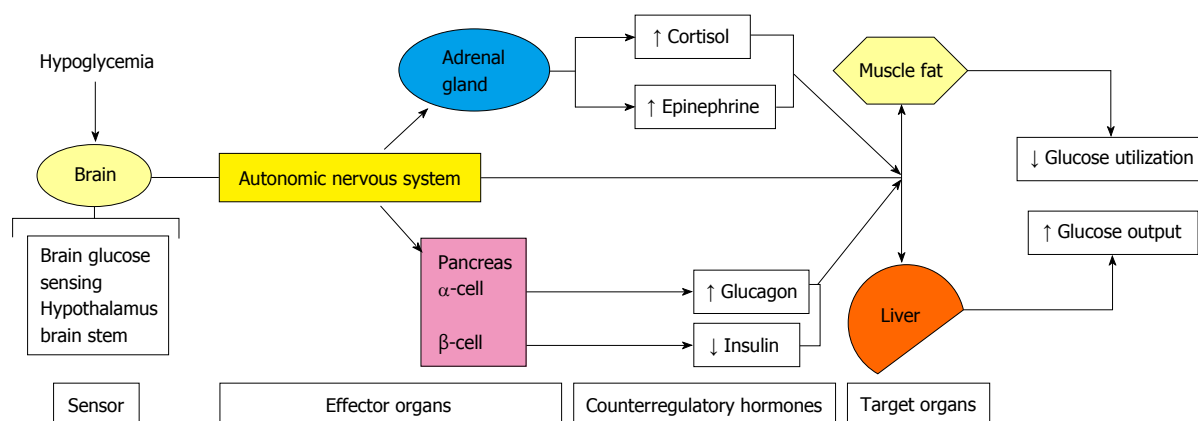

Figure 1 Counter-regulatory response to hypoglycemia.

Figure 2 Symptoms and signs associated with progressive hypoglycemia. ACTH: Adrenocorticotrophic hormone; GH: Growth hormone.

reduced awakening from sleep during hypoglycemia^[19]. So, because of the HU and the impaired adrenomedullary response, we can explain some of the overnight deaths of healthy young people with T1DM.

Cortisol: Hypoglycemia is associated with an elevation in systemic corticosteroids, and this has been proposed to feedback to the hypothalamus contributing to HAAF^[20-22]. However it remains controversial if the endogenous hypercortisolemia is of sufficient magnitude to blunt the counter-regulatory response to hypoglycemia^[23,24]. It has been shown that corticotrophin releasing hormone agonist impair the counter-regulatory response to a subsequent hypoglycemia, suggesting a possible role in HAAF^[25].

Opioids: Preclinical and clinical studies with opioids demonstrated a rise in endogenous opioids during hypoglycemia, for example naloxone (an opioid receptor blocker), increased the sympathoadrenal response to hypoglycemia, and when is infused during previous hypoglycemia, it prevent HAAF^[26,27]. Hence there is a potential therapeutic function for opioid receptor blockade to protect against HAAF.

Exercise: The inability to reduced circulating insulin during exercise, lead T1DM patients, at an increased risk for hypoglycemia during or after exercise. In addition to, during exercise the opioid beta endorphin is released to activate the sympathoadrenal response. In a recent study, healthy individuals who exercised and elevated endorphin levels, they had reduced catecholamine response during hypoglycemia in the next day^[28], suggesting that endogenous opioids, again, play a role in HAAF, and that blocking their action may protect against exercise-autonomic failure.

Recurrent hypoglycemia and HU

Clinically HAAF can be viewed as both, maladaptive or adaptive response^[29]. At one end, patients with T1DM and HU make tests of cognitive function during hypoglycemia better than patients with HU. Additionally, the time necessary for complete cognitive recovery after restoration of normoglycemia is faster in patients who have HU^[30]. HAAF in humans may be similar than in rats; rats with recurrent moderate hypoglycemia had less brain cell death^[31] and less mortality during or following marked hypoglycemia than those without recurrent hypoglycemia. On the other hand, HAAF is without doubt a maladaptive response if we consider that defective glucose counter-regulation and HU rise the risk of severe hypoglycemia with its morbidity and potential mortality^[32].

Although it is well established that recurrent hypoglycemia leads to HU, the mechanism responsible for this are unknown. Several current mechanistic hypotheses are discussed below.

The brain glucose transport or glucose metabolism hypothesis

Several studies have identified specific brain regions that exhibit decrease glucose uptake. In diabetic patients with and without HU, the effects of acute moderate hypoglycemia and the condition of HU on regional brain uptake of the labeled glucose analog [(18)F]fluorodeoxyglucose (FDG) using positron emission tomography were examined^[33,34]. In the group with hypoglycemia awareness, there was an increase

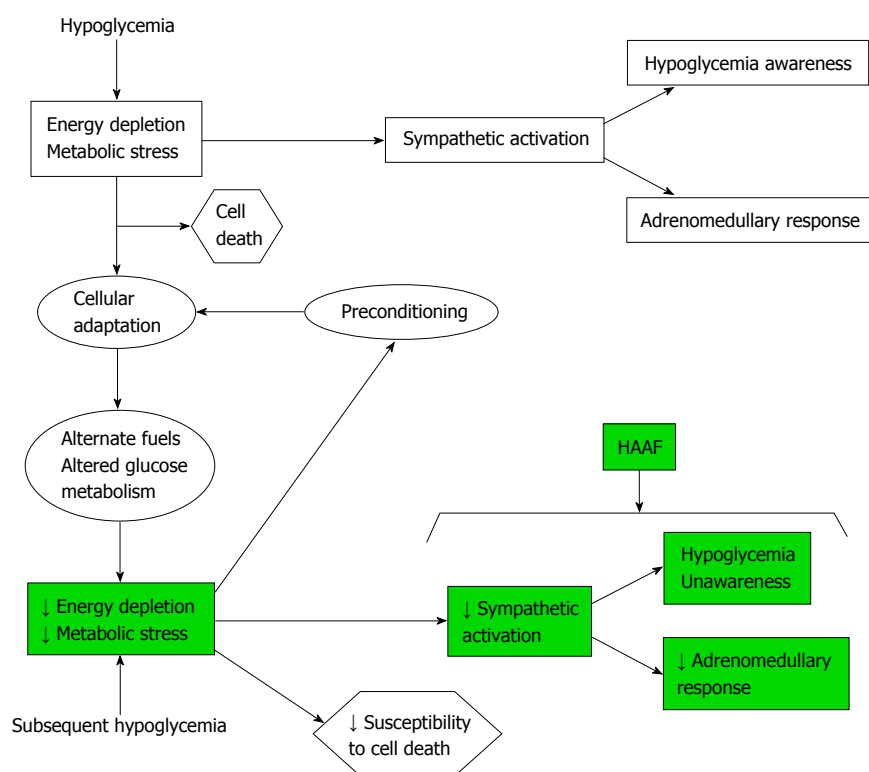

Figure 3 Recurrent hypoglycemia leads to cellular adaptation and hypoglycemia-associated autonomic failure. HAAF: Hypoglycemia-associated autonomic failure.

in the normalized FDG uptake in a subthalamic brain region^[33], in left amygdale and in bilateral ventral striatum^[34] in response to hypoglycemia; whereas in the group with HU the uptake in these brain regions fell significantly^[33,34]. Reduced responses in these brain regions in HU, suggest habituation of higher behavioral responses to hypoglycemia as a basis for unawareness, and demonstrated a change in its metabolic function associated with the failure to trigger a counter-regulatory response. On the other hand, in subjects with T1DM and HU a positive correlation was observed between thalamic response and epinephrine response to hypoglycemia, suggesting that this brain region may be involved in the coordination of the counter-regulatory response to hypoglycemia^[35]. During recurrent hypoglycemia, cerebral blood flow reduced significantly in the thalamus and hypothalamus of T1DM subjects, compared to healthy controls^[36], suggesting that there is reduced neuronal activation in these brain regions that participate in glucose sensing and/or coordination of counter-regulation response in subjects with T1DM that likely contributes to the development of HU.

It has been hypothesized that recurrent hypoglycemia leads to HU through an alteration in the glucose transport or metabolism. Altered glucose transport or metabolism as a cause of HU is less substantiated in humans. Subjects with T1DM and HU had significantly higher brain glucose concentrations compared to that in controls under the same conditions^[37]. These data suggest that changes in brain glucose transport or metabolism may occur as a result of recurrent hypoglycemia.

The brain glycogen supercompensation hypothesis:

It has been hypothesized that increased brain glycogen contributes to the development of HU and impaired sympathoadrenal responses by providing energy for the brain during periods of systemic hypoglycemia. Experimental studies and in humans have shown that after one or more episodes of hypoglycemia, increased glycogen content in the brain^[38,39]. Subsequent studies indicated lower glycogen content in brain of humans with T1DM, implying that glycogen supercompensation does not contribute to the development of HU^[40]. The most important question to resolve is whether changes to brain glucose levels, physiologically or pharmacologically induced, may provide people who suffer from recurrent hypoglycemia a therapeutic benefit to preserve both the sympathoadrenal response and HU.

The brain fuel hypothesis:

When there is a decrease in the supply of glucose from the periphery, the brain may be able to keep your metabolic processes by increasing uptake of alternative carbon fuels such as lactate or ketones. Plasma lactate concentrations are approximately tenfold higher than those of acetate, making it a primary candidate as an alternative brain fuel during hypoglycemia. On the other hand, increased of blood-brain barrier monocarboxylic acid (MCA) transport and metabolism among T1DM individuals with HU may be a mechanism to supply the brain with non-glucose fuels during episodes of acute hypoglycemia and may contribute to the maintenance of brain energetic during hypoglycemia and to the syndrome of HU, independent

of diabetes^[41]. Finally, in T1DM patients with HU, upregulation of the MCA transporter promotes increased brain lactate uptake^[42].

The brain neuronal communication hypothesis:

Neuronal communication relies on the release of classical neurotransmitters, such as Gamma-Aminobutyric Acid (GABA), a potent inhibitory neurotransmitter. GABA levels in ventromedial hypothalamus (VMH) interstitial fluid are decreased during acute hypoglycemia^[43]. Recurrent hypoglycemia leads to a significant increase in VMH GABA concentrations^[44], that fail to decrease normally during subsequent hypoglycemia, and which correlates with the reduced glucagon and epinephrine responses^[45]. These data suggest that recurrent hypoglycemia results in increased VMH GABA inhibitory tone, and that altered GABA tone may be an important common mediator in the development of HAAF, especially in diabetic patients.

CONSEQUENCES OF HU

Consequences of HU on morbidity, mortality, and cardiovascular outcomes

People who have HU have a much greater risk of severe hypoglycemia, up to six fold, with its attendant morbidity^[46,47]. HU may result in many serious forms of morbidity including seizure, coma, fractures and joint dislocation and cardiac arrhythmias, and is occasionally fatal.

Severe episodes of hypoglycemia or HU requiring the assistance of another have been shown to be associated with an increased risk of mortality in both the Action to Control Cardiovascular Risk in Diabetes (ACCORD)^[48] and the Action in Diabetes and Vascular Disease^[49] studies. On the other hand, *post hoc* analysis of the ACCORD study cohort, to examine the relationship between frequent and unrecognized hypoglycemia and mortality, 10096 ACCORD study participants were included. In this study, recognized and unrecognized hypoglycemia was more common in the intensive group than in the standard group; and in the intensive group, a small but statistically significant inverse relationship was identified between the number of hypoglycemic episodes and the risk of death among participants^[50]. This latter finding does not mean that we should change our clinical practice and include frequent episodes of hypoglycemia in the targets of T2DM patients and cardiovascular risk factors. Instead, we must strive to achieve optimal glycemic control in our patients, without episodes of hypoglycemia.

Consequences of HU on adults with T1DM

Several prospective studies as the Diabetes Control and Complications Trial^[51] and the Stockholm Diabetes Intervention Study^[52] suggests that cognitive function does not deteriorate in patients with T1DM who suffer recurrent hypoglycemia, at least less than 10 years of these studies.

Gold *et al.*^[53] to compare the degree of cognitive

dysfunction experienced by T1DM patients who had normal awareness of the onset of hypoglycemia with patients who had history of impaired awareness of hypoglycemia, found that T1DM patients with HU exhibited more profound cognitive dysfunction during acute hypoglycemia which persisted for longer following blood glucose recovery. Intellectual activity is likely to be affected and cause sub-optimal performance during this recovery period. Recent investigations with advanced imaging techniques have demonstrated that adults with T1DM appear to call upon a greater volume of the brain to perform a working memory task during hypoglycemia^[54]. These findings suggest that adults with T1DM must recruit more regions to preserve cognitive function during hypoglycemia than adults without the disease.

Evidence of clinical audit in T1DM patients with intensive insulin therapy with HU showed that these patients had less adhesion to changes in insulin regimens to compare them with patients with hypoglycemia awareness, despite the observed increase in clinical contacts^[55]. Neuroimaging studies have shown that patients with HU showed a reduced activation in appetitive motivational networks associated with integrated behavioral responses to hypoglycemia^[34]. This may suggest that in some patients with HU behavioral strategies are more important than educational strategies; however treatment of HU will require a combination of both strategies, behavioral and educational, along with the use of technology, such as therapy with continuous insulin pump and online glucose monitoring^[56].

Consequences of HU in children and adolescents with T1DM

A significant proportion of children and adolescents with T1DM have HU. Screening for HU is an important component of routine diabetes care and can identify patients at increased risk of severe hypoglycemic events^[57]. The youngest patients are most vulnerable to the adverse consequences of hypoglycemia. Ongoing maturation of the central nervous system puts these children at greater risk for cognitive deficits as a consequence of HU^[58]. HU is a significant problem for children and adolescents with T1DM and the major risk factor for development of hypoglycemia^[57]. Those children with T1DM diagnosed before age of 6, who suffer repeated and severe episodes of hypoglycemia may have more increased range of cognitive dysfunction, brain abnormalities^[59], structural brain changes^[60], lower mental abilities latter on in life, and behavior problems than those who do not have HU until latter^[61,62].

Consequences of HU on subjects with T2DM

HU is less common in T2DM patients. Two retrospective surveys of subjects with insulin-treated T2DM showed that only 8% and 9.8% respectively had HU estimated by a validated scoring system^[8,46]. However, in the patients with HU the incidence of severe hypoglycemia was nine-fold and 17-fold higher respectively than

those with normal hypoglycemia awareness^[8,46]. In several studies, using continuous monitoring system, asymptomatic hypoglycemia was detected in 47%^[63] and 56%^[64] of subjects with T2DM, treated with different treatment regimes. These findings suggest that HU may be more prevalent in T2DM than is appreciated.

Severe hypoglycemia, due to HU, was associated in T2DM patients with cardiovascular and neurological complications^[1,48]. In patients with T2DM and coronary artery disease, severe hypoglycemia was associated with ischemic electrocardiogram changes and chest pain, and may account for sudden mortality^[65,66]. In a retrospective study in T2DM subjects, the patients who experienced outpatient severe hypoglycemia were also shown to have a 79% higher odds ratio of experiencing acute cardiovascular events than patients without severe hypoglycemia^[67]; and a case-control study in patients with T2DM showed a 65% increase in the odds of myocardial infarction with severe hypoglycemia within the previous two weeks; the risk of myocardial infarction persisted elevated for up to six months following a hypoglycemic event^[68].

Behavioral changes, cognitive impairment, seizures, coma and a mortality rate estimated at between 4.9% and 9% are well-known neurological complications of severe and prolonged hypoglycemia secondary to HU^[69-71]. Severe hypoglycemia secondary to HU can cause neuronal cell death and may damage regions of the brain that oversee memory, especially in older people with T2DM^[72].

Finally, a frequently problem in T2DM is nocturnal hypoglycemia. Undetected nocturnal hypoglycemia often contributes to HU. Nocturnal hypoglycemia has been associated with cardiac arrhythmias resulting in sudden death^[73].

Consequences of HU on the elderly

Patients in the older age-groups are especially vulnerable to HU. Aging modifies the cognitive, symptomatic, and counter-regulatory hormonal responses to hypoglycemia^[74]. Older adults with diabetes are at much higher risk for the geriatric syndrome, which includes falls, incontinence, frailty, cognitive impairment and depressive symptoms^[75]. In the elderly subjects, episodes of severe hypoglycemia are more likely to be followed by changes in the blood brain circulation which may further increase the risk of neurological damage in this population^[76,77]. In older patients with T2DM, Whitmer *et al.*^[72] found a significant association between the number of severe hypoglycemic episodes and dementia; with ≥ 3 episodes almost doubling the risk more episodes of severe hypoglycemia secondary to HU had increasing likelihoods of being subsequently diagnosed with dementia. Another authors also found an association between severe hypoglycemia and cognitive impairment in these patients^[78]. These reports suggest that severe hypoglycemia and HU in older people with

diabetes may be associated with cognitive decline^[79].

Consequences of HU during pregnancy

Pregnancy is associated with a high risk of severe hypoglycemia in diabetic subjects. History of HU has been documented as risk factors of severe hypoglycemia during pregnancy^[80-82]. Reduced sympathoadrenal responses during hypoglycemia may contribute to defective glucose counter-regulation and HU^[83,84]. In pregnant woman severe hypoglycemia episodes and HU occur three to five times more frequently in first trimester than third trimester when compared with the incidence in the year preceding the pregnancy^[80,81,85] and may lead to severe morbidity and even death^[86].

Consequences of HU on quality of life and social impact

Hypoglycemia and HU are associated with significant reductions in quality of life measures in both T1DM and T2DM patients^[87-89]. The wellbeing of patients may be affected both from the effects of hypoglycemia and from fear of recurrence^[89,90]. A positive association was found between severity and/or frequency of hypoglycemic events and greater fear of hypoglycemic episodes^[71]. As a result fear of hypoglycemia makes the patients to promote compensatory behaviors in a way to have less episodes of hypoglycemia such as decreased insulin doses resulting in negative glycemic control, and an increased risk of serious health consequences^[91]. Patients with recurrent hypoglycemia and HU were more likely to have a lower quality of life in several parameters including depression and anxiety^[89,92,93], increased pain and limitations in mobility and usual activities^[89], and decline in the quantity and quality of sleep^[94]. On the other hand, young adults with T1DM reported the presence of interpersonal conflict, and difficulty talking about issues related to hypoglycemia with significant others^[95], that may carry over to their work life, where hypoglycemia has been linked to reduced productivity^[88].

Despite that many countries require documentation that severe hypoglycemia and HU is not occurring before persons with diabetes are permitted to have a license to operate a motor vehicle; HU has not consistently been associated with an increased risk of car collisions^[96-98].

Consequences of HU on family members

In the subjects with diabetes, HU can have a profound impact on the lives of their family members, and are often reliant on immediate relatives or partners to detect and treat hypoglycemia episodes. A recent study based in-depth interviews with 24 adult family members of persons with T1DM and HU, showed that family members restricted their own lives in order to help the person with HU to detect and treat hypoglycemia^[99]. In this study, some family members of people with HU, report that they are afraid of their partners, during episodes of hypoglycemia because of their aggressive behavior and their personality changes, making it difficult managing their treatment. The study showed that family

members of patients with HU restricted their own lives in order to help the person with HU to detect and treat hypoglycemia, and felt anxious about the safety of the person with HU; which sometimes leads family members to neglect their own health, leading to resentment over time^[100]. On the other hand, personality changes during hypoglycemia events of the person with diabetes, such as aggression, also caused, in some family members, physical fear of your partner or relative, and made treatment difficult. Family members emphasized that there is an unmet need for information and emotional support for caregivers, and the researchers suggest that proactive support for the families of patients with diabetes and HU should be considered and provided by healthcare professionals^[99].

Psychological consequences of HU

The psychological consequences of HU include subsequent fear to hypoglycemia, and secondary poor treatment compliance, increased anxiety and decreased levels of satisfaction and happiness. Fear of hypoglycemia will be a barrier to achieving good glycemic control. The hypoglycemia fear survey (HFS) used to measure behaviors (HFS-B) and worries (HFS-W) related to hypoglycemia in adults with T1DM, such as maintaining higher blood glucose levels than recommended, and limiting exercise or physical activity, or concerns may have about hypoglycemic episodes, such as nocturnal episodes; have been shown to be significantly higher in women than in men and among patients who have experienced severe hypoglycemia in the past compared with those that have not^[100]. If patients experience repeated severe hypoglycemic events, both the patient's and the physician's subsequent treatment policy are affected. In one study that reviewed hospital records and examined daily insulin doses and HbA1c levels before and after an episode of severe hypoglycemia in patients with insulin-dependent diabetes, it was found that, in 69% of these cases, either the physician or patient or both decreased the daily insulin dose. Furthermore, physicians decreased the insulin dose in a third of patients in whom the cause of hypoglycemia was preventable and due to a cause other than erroneous administration of excess insulin^[101].

Economic consequences of HU

The economic consequences of severe hypoglycemia events and HU in patients with diabetes are higher than that of a mild episode and have been examined in a number of studies in Europe and United States^[102-105]. Reported costs of a severe hypoglycemic event varied from approximately \$80 to \$5000, depending on the requirement for resources including hospitalization, emergency services, healthcare professionals and diagnostic test.

A United Kingdom study estimated the total cost of emergency treatments of 244 episodes of severe hypoglycemia in 160 patients with T1DM and T2DM over the course of one year. The total cost was approximately

£92078 (£400 per episode)^[102]. On the other hand, in a Swedish study the total cost (direct and indirect) of severe hypoglycemia in T2DM patients was between \$12.90 and \$14.10 for one month period^[90].

An analysis of several United States studies, the estimated annual total cost attributable to severe hypoglycemia was between \$1400 and \$1500^[106]. In this analysis the estimated work days lost per hypoglycemic event was between 0.22 and 6.60 d^[103]. A recent study estimated that in patients with diabetes who experienced severe hypoglycemia, the lost of productivity ranged from \$15.26 to \$93.47 per severe hypoglycemic event, representing 8.3-15.9 h of lost work time per month^[106]. Among the patients who experimented a severe hypoglycemic event at work, 18.3% missed work for a mean duration of 9.9 h, whereas the patients who had severe hypoglycemic event outside working hours, 22.7% arrived late for work or missed a full day^[104]. If the hypoglycemia has occurred during the night, the number of working hours lost increased to 14.7 h^[104].

PREVENTION AND MANAGEMENT OF HU

Prevention of HU

Prevention of HU is an important part of modern day intensive diabetes therapy. To prevent HU, the goal is the complete avoidance of hypoglycemia, which is very difficult to achieve^[105]. Blood glucose monitoring, individualized targets and educational programs are important in the bid to prevent and manage HU.

Blood glucose monitoring: CGMS, that can detect hypoglycemia, represents an important technological advance on the methods used for self-monitoring of blood glucose, and they are welcome to both patients and clinicians^[106]. The ability of CGMS systems is to advise patients when glucose levels fall too low or rise too high, and has the potential to reduce the duration of hypoglycemia and hyperglycemia events^[107,108]. Also, CGMS can be used for objective detection of patients with HU^[109]. In adult patients with long-standing T1DM, a fasting level of C peptide of ≤ 0.6 ng/mL, and a HbA1c $\leq 9\%$, hypoglycemic episodes with a duration more than 90 minutes detected by CGMS, identified patients who had HU with an 88% specificity and 75% sensitivity^[109]. On the other hand, the epinephrine response to hypoglycemia in adolescents patients with T1DM with HU was greater after the use of real-time CGMS with low glucose alarms than with standard medical therapy alone^[110]. This suggests that real-time CGMS is a useful clinical tool to improve HU in adolescents with T1DM^[110]. Choudhary *et al.*^[111] assessed the effect of CGMS on the frequency of severe hypoglycemia episodes, using the Gold scoring method^[46] in 35 people with T1DM who have HU, *via* retrospective audit. A significant decline was observed in the mean rate of severe hypoglycemia (8.1 to 0.6 events per year) and also in HbA1c level

(8.1% to 7.6%), between its initiation and the end of the 1-year follow-up period; while the mean Gold score did not change significantly^[111]. These results support previous reports that CGMS can lower the incidence of severe hypoglycemia in patients with T1DM and HU, with no impact on the severity of HU over a 1-year period. A randomized cross-over study to assess the effects of CGMS use on glycemic levels and quality of life in patients with T1DM and HU, using the change in the Gold scoring as one of the secondary endpoints, is currently in progress and the results will not be available until 2015^[112].

The impact of closed-loop CGMS, which link CGM technology with insulin pumps, whereby insulin infusion is programmed to stop automatically when glucose levels drop below a pre-determined glycemic threshold, on reducing the incidence of hypoglycemia events appears to be limited and so their usefulness in improving HU is debatable^[16].

Individualized targets: In diabetic patients with HU blood glucose targets should be relaxed but not abandoned. Appropriate targeting of plasma glucose may help patients and practitioners achieve HbA1c goals, reduce excessive self-testing and minimize the occurrence of severe hypoglycemic events^[113]. Glycemic goals should be individualized with some degree of safety particularly for patients with long duration of diabetes, patients who have a high risk of HU and severe hypoglycemia development, and/or subjects with multiple co-morbidities^[114,115]. Basically, an HbA1c goal of less than 7% remains recommended, but is there a safe range for HbA1c? In patients with T1DM undertaking insulin therapy, the rates of severe hypoglycemia were increased among those with HbA1c < 6% and therefore it was suggested that using current therapy, an HbA1c of between 6%-7% represents the best compromise between the risk of severe hypoglycemia and that of developing microvascular complications^[116].

Educational programs: The central objective of a hypoglycemia-reversal program is to prevent any period of hypoglycemia for at least four weeks. In diabetic patients with HU an appropriate educational program includes an emphasis on regular snacks at right times, warnings to take special care at periods of greater risk such as before lunch, moderation in alcohol intake and about the danger of delayed hypoglycemia after heavy alcohol intake or prolonged exercise. Diabetes self-management education can have physical and psychosocial benefits, and results in behavior changes with positive influence in outcome. A self-awareness intervention of 8 sessions, each lasting 3 h, was designed to determine whether there are psychosocial and physical benefits of self-awareness intervention in 29 adults with T1DM and HU. Post-intervention the participants detected more cues of euglycemia and hypoglycemia and experienced significant increases in integration and metabolic control^[117].

In a randomized, prospective multi-centre trial, the effect of a specific training program for patients with hypoglycemia problem was compared with a control group receiving a standardized education program aiming of at avoidance of hypoglycemia by optimization of insulin therapy^[118]. Compared to control group, the specific training program demonstrates additional benefits in terms of improving HU, reducing mild hypoglycemia, and detecting and treating low blood glucose^[118]. In the Dose Adjustment for Normal Eating-Hypoglycemia Awareness Restoration study, a 6-wk pilot intervention using motivational interviews and cognitive behavioral techniques around hypoglycemia, in 23 people with HU; support the importance of educational programs to improve HU. One year after the intervention HU had improved, mean rates of severe hypoglycemia fell from 3 to 0 per person per year, and worry and behavior around hypoglycemia improved^[119]. In a sub-study of HypoCOMPASS trial aimed to assess the restoration of impaired hypoglycemia awareness and defective hypoglycemia counter-regulation by an educational strategy targeted at hypoglycemia avoidance, in 18 adults patients with T1DM; following the 6-mo intervention the mean glucose concentration at which participants first experienced symptoms of hypoglycemia significantly increased from baseline (from 2.6 to 3.1 mg/dL), and counter-regulatory responses to hypoglycemia were also enhanced^[120].

Jointly, the results of these three studies suggest that interventions that include education around hypoglycemia avoidance may help to decrease HU.

Treatment of HU

The treatment options for the management of HU are listed in Table 1.

Optimizing insulin treatment: It is important that in patients with a history of recurrent hypoglycemia and HU, the time of episodes be identified and the treatment regimen be adjusted accordingly^[121]. Compared with regular insulin, rapid-acting insulin analogs have a more rapid onset of action, higher peak action, and shorter duration of action, which more closely approximates endogenous mealtime insulin response, allowing more flexibility in the time of meals and exercise, and, consequently, a lower risk of severe hypoglycemic events^[122]. Similarly, long-acting insulin analogs exhibit a more consistent, longer, and flatter action profile than NPH insulin, and demonstrate a lower risk of hypoglycemia, particularly nocturnal^[123,124]. In diabetic patients with HU substitution of regular insulin with rapid-acting insulin analogs (aspart, lispro or glulisine) reduces frequency of daytime hypoglycemia; and substitution of long-acting insulin analogues (detemir or glargine) for intermediate-acting insulin (NPH or premix) reduces the frequency of nocturnal and day time hypoglycemia^[121,125]. Compared with insulin glargine, the newest basal analog insulin degludec offers a more constant time-action profile, a long duration of action, and a lower risk of

Table 1 Treatment options for the management of hypoglycemia unawareness and mechanisms of action

Treatments options	Mechanism of action
Optimizing insulin treatment	Avoidance of hypoglycemia
Pharmacological therapy	
β 2-adrenergic agents	Enhancement of adrenaline effect
Methylxanthine derivatives (caffeine, theophylline)	Central nervous system stimulation
Serotonin reuptake inhibitors (fluoxetine, sertraline, paroxetine)	Unknown. It has been hypothesized that the effect could be mediated by an atypical presentation of serotonin syndrome that will lead to autonomic dysfunction
KATP channel modulators	Modulation of hypoglycemia sensing
Other treatments	
Islet cell transplantation	Improving metabolic control
Fructose	Modulation of hypoglycemia sensing

hypoglycemia^[126,127]. While clinical experience with insulin degludec is limited, a meta-analysis evaluating 5 clinical trials of 3372 subjects with T2DM demonstrated a 17% lower rate of overall hypoglycemia and a 32% lower rate of nocturnal hypoglycemia with insulin degludec, compared with insulin glargine^[128]. These characteristics may facilitate the achievement of glycemic control with insulin degludec with fewer hypoglycemic events in patients with HU.

An alternative approach is to use continuous subcutaneous insulin infusion (CSII). A study was designed by Giménez *et al*^[129] to evaluate the effect of CSII on hypoglycemia awareness and on glucose profile in a cohort of T1DM subjects in which 95% had established HU and had experienced two or more episodes of severe hypoglycemia in the preceding two years, for a 24-mo period. Severe hypoglycemic episodes fell from 1.25 per subject-year to 0.05 after 24 mo, an improvement in all the aspects of quality of life, and an improved symptomatic response to experimentally-induced hypoglycemia was observed^[130]. Previous studies^[130-132] have also shown a reduction in hypoglycemia with CSII, particularly when a short-acting insulin analogue is used^[2,133]. The decrease is partly due to better pharmacokinetic delivery of insulin and a 15%-20% reduction in insulin requirements compared with multiple doses of insulin^[134]. Substitution of CSII for NPH insulin in patients with T1DM, especially at bedtime, resulted in a lower frequency of hypoglycemic episodes, and improved counter-regulatory and symptomatic responses during subsequent acute hypoglycemia^[135]. On the other hand, administration of bolus doses of glucagon at times of impending hypoglycemia during CSII lowered the frequency of hypoglycemia^[136].

Pharmacological therapy: β -adrenergic antagonists or β -blockers alter the effects of epinephrine and could have potential effects on glucose homeostasis and the hypoglycemic counter-regulatory system. The more troubling concern regarding β -blockers is their potential effect on HU and blunting of the return to euglycemic levels after hypoglycemia has occurred, through the suppression of all adrenergically mediated symptoms of hypoglycemia. In patients with T1DM without HU, adrenergic symptoms did occur at lower glucose levels

when subjects were treated with β -blockers^[137]. Cardio-selective β -blockers cause less alteration in the perception of hypoglycemia and may have an effect on correction of hypoglycemia than do their noncardioselective counterparts^[138]. These agents should not be avoided in patients with diabetes but should be used with the same caution as when any new medication is added to a patient's therapeutic regime.

It has been suggested that people with HU may have reduced β -adrenergic sensitivity, and this can be reversed by strict avoidance of hypoglycemia^[139]. In T1DM patients, the use of β -adrenergic agonist terbutaline was associated with statistically significant higher glucose levels compared to control subjects during the first half and second half of the night, and with reduction of nocturnal hypoglycemic episodes (22 in the control group vs 1 in the group of terbutaline). β -adrenergic agonist had therefore been suggested as possible therapeutic options for HU, at the cost of inducing morning hyperglycemia. One of the concerns about using β -adrenergic agonist for the treatment of HU was associated with reduced β_2 sensitivity observed *in vitro*. A recent study from De Galan *et al*^[140] showed that sensitivity to β_2 -adrenergic receptor agonist stimulation is preserved in T1DM patients with HU. No long-term clinical trials to evaluate the usefulness of β -adrenergic agonist in the prevention of HU have been reported.

Several studies have evaluated the effects of the methylxanthines derivatives caffeine and theophylline on HU and the counter-regulatory response to hypoglycemia. Both have been shown to augment symptom intensity and improve counter-regulatory responses in patients with T1DM with and without HU^[2,141]. Using functional magnetic imaging, caffeine can restore regional brain activation normally lost during acute hypoglycemia^[142]. In another trial designed to assess the impact of caffeine on the frequency and perception of hypoglycemia over a 3-mo period; patients receiving caffeine (200 mg/twice-daily) had statistically significant more symptomatic hypoglycemia episodes and more intense warning symptoms than patients receiving placebo^[143]. These results suggest that modest amounts of caffeine enhance the sensitivity of hypoglycemia warning symptoms in patients with T1DM without increasing the incidence of severe hypoglycemia. de Galan *et al*^[144] planned one

study to evaluate the impact of theophylline on the response to hypoglycemia in 15 patients with T1DM who had a history of HU and 15 matched healthy control subjects. When compared with placebo, theophylline (2.8 mg/kg) improves the counter-regulatory response to a perception of hypoglycemia in the group with T1DM with HU^[144]. Although modest doses of caffeine and theophylline may be effective at reducing HU in patients with T1DM at a low cost and without significant toxicity, larger doses may carry risk, and large trials are needed to determine efficacy, toxicity and dose-response curves.

The development of HU was associated with the use of selective serotonin reuptake inhibitors (SSRIs) in three patients with T1DM treated with different SSRIs (fluoxetine, sertraline and paroxetine) for depression and who were previously able to recognize and treat hypoglycemia symptoms^[145]. HU occurred in all three patients within weeks of starting SSRI therapy. HU reversed after discontinuation of SSRI therapy^[145]. The mechanism by which SSRIs might be associated with HU is unknown, but it has been hypothesized that the effect could be mediated by an atypical presentation of serotonin syndrome that will lead to autonomic dysfunction^[146]. These observations suggest that in some patients, treatment with SSRIs may alter the perception of hypoglycemia, and should be used with caution in diabetic subjects with HU.

Infusion of the opioid-receptor antagonist naloxone increases the plasma epinephrine response to hypoglycemia and, when administered during hypoglycemia prevents attenuation of the plasma epinephrine response to subsequent hypoglycemia in humans^[26,27].

Administration of a selective Kir6.2/SUR-1 K_{ATP}-channel agonist increases the epinephrine response to hypoglycemia in rats^[147]. However, systemic administration of the nonselective K_{ATP}-channel agonist diazoxide suppresses the glucagon response and has no effect on the epinephrine response to hypoglycemia in nondiabetic humans^[148]. These results suggest that K_{ATP}-channel modulators are not effective in humans, possibly due to inability to cross blood-brain barrier.

Other treatments: Islet cell transplantation (ICTx) prevents severe hypoglycemia^[149], and restores some counter-regulatory hormone secretion^[150]. In a retrospective study conducted in 31 T1DM recipients of ICTx, HU was assessed using the Clark hypoglycemic score (minimum = 0; maximum = 7; no hypoglycemia = 0; HU \geq 4)^[151] twice. A reduction in the proportion of patients with HU was observed post-ICTx (pre vs post-ICTx: 87% vs 13%) and a significant increase in glucose threshold that resulted in symptoms (pre vs post-ICTx: 41.4 mg/dL vs 58.4 mg/dL)^[152]. These results were sustained even after the patient's stratification based in islet function, graft dysfunction and graft failure^[152]. These results suggest that improved metabolic control achieved with ICTx can restore hypoglycemia awareness in patients with T1DM, persisting even after islet graft failure.

Fructose infusion amplifies epinephrine and glucagon responses and increases glucose production during hypoglycemia in humans^[153]. Fructose is a promising treatment but has not been tested in clinical trials.

CONCLUSION

HU is a complex, difficult-to-study phenomenon that carries with it great risk to patients. HU is common in people with T1DM and is observed with less frequency in insulin-treated T2DM. Exposure to antecedent hypoglycemia, especially repeated episodes, is an important factor in the pathogenesis of HU. Although enormous advances have been made in our knowledge of the mechanisms of HU, further research is needed to elucidate the pathophysiology of counter-regulatory impairment and HU, and enable the development of more targeted strategies that support glucose counter-regulation and consequently reduce hypoglycemia. Numerous research studies have begun to uncover the mechanisms by which the central nervous system responds and adapts to hypoglycemia. Understanding these mechanisms will lead to better management and therapies that reduce the risk for hypoglycemia. Studies aiming to improve or even reverse HU have met with variable success and a number of research groups are considering new candidate pathways to develop a therapy. Therefore, until effective measures are developed to reverse HU, part of the role of the healthcare professional should be to educate people with diabetes on the risks associated with HU and should discuss hypoglycemia prevention strategies with their patients, so that they can have a better chance of achieving their glucose control goals while avoiding the morbidity and mortality associated with hypoglycemia.

Abstract

Periodontal disease is a high prevalent disease. In the United States 47.2% of adults ≥ 30 years old have been diagnosed with some type of periodontitis. Longitudinal studies have demonstrated a two-way relationship between diabetes and periodontitis, with more severe periodontal tissue destruction in diabetic patients and poorer glycemic control in diabetic subjects with periodontal disease. Periodontal treatment can be successful in diabetic patients. Short term effects of periodontal treatment are similar in diabetic patients and healthy population but, more recurrence of periodontal disease can be expected in no well controlled diabetic individuals. However, effects of periodontitis and its treatment on diabetes metabolic control are not clearly defined and results of the studies remain controversial.

Key words: Diabetes; Diabetes mellitus; Periodontitis; Periodontal disease; Periodontal treatment; Scaling and root planning; Non surgical periodontal treatment; Antibiotic; Glycosylated hemoglobin; C-reactive protein

diabetes and periodontal infection. *World J Diabetes* 2015; 6(7): 927-935 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i7/927.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i7.927>

PERIODONTAL DISEASE

What is periodontal disease?

Periodontal disease is the destruction of the tissues that support the tooth by accumulation and maturation of oral bacteria on teeth.

Periodontal diseases include two major entities, gingivitis and periodontitis. Gingivitis is characterized by reversible inflammation of periodontal tissues whereas periodontitis also presents destruction of tooth supporting structures, and may lead to tooth loss. Existing evidence indicates that gingival inflammation (gingivitis) is required for periodontitis, however some gingivitis never transform to periodontitis^[1,2]. This is because bacterial plaque accumulation is necessary for the onset of both entities but individual susceptibility is required to develop periodontitis^[2,3].

The currently used classification of periodontal diseases was introduced by the 1999 International Workshop for a Classification of Periodontal Diseases and Conditions^[4]. Since the current classification has been used only in the last years, a substantial part of the existing literature on the prevalence and extent of periodontal diseases in various populations is still based on earlier classification systems.

Due to its high prevalence in current populations, it has become a public health priority. Epidemiologic studies have determined that about 50% of the population suffer from gingivitis and approximately 14% show periodontitis^[5]. This percentage was higher in a recent study on United States population, which showed that 47.2% of adults ≥ 30 years old had periodontitis. Prevalence of periodontitis increased with age up to the point that 70.1% of adults ≥ 65 years old were affected by periodontal disease^[6]. Men exhibit worse periodontal status than women [(56.4% vs 38.4%), as well as those with limited education (66.9%) and income (65.4%)]. These factors, together with cigarette smoking are increased risk factors for periodontal progression^[7].

Etiology and pathogenesis of periodontal disease

Microorganisms in combination with individual host susceptibility and environmental factors are the main etiologic factors of periodontal diseases.

Plaque accumulation on teeth produces gingivitis, but the degree of inflammation and destruction of the alveolar bone that supports teeth depend on the host susceptibility^[8].

Oral bacteria can damage periodontal tissues through the action of matrix-degrading enzymes and molecules that affect host cells. The transition from gingivitis to

periodontitis involves the spreading of the inflammatory front to deeper areas in the connective tissue. However the reason why this happens is not well established. One etiopathogenic mechanism could involve the presence of bacteria or their products, such as lipopolysaccharides, in the periodontal connective tissue. They may induce an immune response with production of interleukins and tumor necrosis factor (TNF), which play an important role in the regulation of inflammatory processes. This inflammation stimulates the production of secondary mediators, which amplify the inflammatory response. Simultaneously, the presence of these cytokines reduces the ability to repair damaged tissue by cells such as fibroblasts, and finally, bacterial products and this inflammatory cascade stimulate osteoclastogenesis, leading to alveolar bone destruction^[9,10] (Figure 1).

Several studies have shown how gingival inflammation can be modulated by a number of conditions. Systemic diseases, steroid hormones variations, nutritional deficiency, the intake of drugs, diabetes, tobacco smoking and other conditions have comprehensive and profound effects on the host, resulting in an increased response to bacterial plaque accumulation^[10].

The high prevalence of *Helicobacter pylori* (*H. pylori*) among the microorganisms isolated from the oral environment induce to think that it may have an effect in the development of periodontal disease. Umeda *et al.*^[11] determined that periodontal patients showed a higher level of *H. pylori* than healthy subjects but, there was no significant correlation between the presence of *H. pylori* and the severity of periodontitis^[12]. The addition of periodontal treatment to eradication therapy may reduce *H. pylori* recurrence compared with eradication therapy alone in periodontal patients suffering from gastric diseases associated with *H. pylori*^[13].

Clinical manifestation of periodontal disease

Clinical signs of gingival inflammation (gingivitis) involve enlarged gingival contours due to edema or fibrosis, color transition to a red and/or bluish red hue, elevated sulcular temperature, bleeding upon probing and, increased gingival exudates (Figure 2).

Periodontitis clinical features include clinical attachment loss (CAL), alveolar bone loss (BL), periodontal pocketing and gingival inflammation. In addition, enlargement or recession of the gingiva; increase tooth mobility, drifting, and even tooth exfoliation may occur (Figure 3)^[14].

Diagnosis of periodontal disease

Clinical evaluation includes periodontal probing (Figure 4) to evaluate: (1) Probing depth: the distance a periodontal probe penetrates into a periodontal pocket measured from the gingival margin to its bottom; (2) Clinical attachment level: The distance from the cemento-enamel junction to the bottom of the periodontal pocket; (3) Bleeding on probing. Bleeding after probing to the base of the periodontal pocket has been

a common way to identify presence of subgingival inflammation; and (4) Tooth mobility and furcations. The movement of a tooth in its socket resulting from an applied force can be classified into three categories. Furcation involvement is defined as BL affecting the base of the root trunk of a tooth where two or more roots meet.

Radiographic evaluation will show if alveolar bone that support tooth roots is lost. In a healthy situation alveolar bone will remain 1-2 mm below the crown of

the teeth. If bone is located further from the crown, it means that loss has occurred (Figure 5).

Classification of periodontal disease

In 1999, the American Academy of Periodontology organized an international symposium with the aim of reaching a consensus regarding the classification of periodontal diseases and disorders, resulting in eight categories: gingival diseases, chronic periodontitis, aggressive periodontitis, periodontitis as manifestation of systemic diseases, necrotizing periodontal diseases, periodontal abscesses, periodontitis associated with endodontic lesions and, developmental or acquired deformities and conditions^[4,15,16].

It is possible to include in this classification additional subcategories such as "diabetes mellitus-associated chronic periodontitis" and "diabetes mellitus-associated aggressive periodontitis" under the category of periodontitis as manifestation of systemic diseases.

INTERRELATIONSHIP BETWEEN PERIODONTITIS AND DIABETES

Investigations have demonstrated associations between periodontitis and various systemic diseases^[17,18] such as cardiovascular disorders^[19,20], respiratory diseases^[21,22], osteoporosis^[23,24], immunodeficiencies^[25] and also diabetes

Figure 5 Radiographic diagnosis of periodontitis.

Figure 6 Clinical features of acute pseudomembranous candidiasis.

mellitus^[26].

As already mentioned, longitudinal studies have demonstrated a two-way relationship between diabetes and periodontitis, with more severe periodontal tissue destruction in diabetic patients and poorer glycemic control in diabetic subjects with periodontal disease^[27-30].

Effect of diabetes on periodontal disease and periodontal treatment

Diabetes has been associated to different oral diseases such as salivary and taste dysfunction, oral bacterial and fungal infections (*i.e.*, candidiasis), and oral mucosa lesions (*i.e.*, stomatitis, geographic tongue, traumatic ulcer, lichen planus,...)^[31,32]. Diminished salivary flow and burning mouth are other oral characteristics in diabetic patients with poor glycemic control. Also, different oral pathologies such as, lichen planus, leukoplakia and lichenoid reactions are associated to diabetic subjects due to immunosuppression and/or drugs used. In addition, delayed mucosal wound healing, mucosal neuro-sensory disorders, decay lesions and tooth loss have been reported in diabetic patients^[33]. Xerostomia is a frequent symptom found in diabetic patients on oral hypoglycemic agents, and it may facilitate the onset of some fungal opportunistic infection. Candidiasis has been reported in patients with poorly controlled diabetes (Figure 6).

Evidence suggests that diabetes leads to worsening of periodontal disease, and a significant association between

diabetes and periodontitis has been demonstrated. Periodontal disease has a higher incidence in diabetic patients, and it is more prevalent and severe if compared with a healthy population^[27,34]. Lalla *et al.*^[35] determined the prevalence of periodontitis in different age cohorts. It was 4.8 times higher among diabetic patients compared to non diabetics when the 15 to 24-year age cohort was considered, and 2.3 higher in the 25-34 year group. Also, CAL was higher in diabetic patients when the 15 to 55-year age cohort was considered. Lim *et al.*^[36] estimated that the glycemic control was the most important risk factor related to severity and extent of periodontitis. Other authors like Lalla *et al.*^[37] established that the rate of periodontal destruction is related to inappropriate glycemic control in diabetic patients so that accurate metabolic control could be important to prevent periodontal complications. Thus, glycemic control and the diabetes onset are critical factors in periodontal disease progression but it should be considered that substantial heterogeneity exists within diabetics^[38].

Glycosylated hemoglobin (HbA1c) allows the control of serum glucose levels in an interval of 120 d and is a useful decision-making tool. Diabetes micro- and macrovascular complications are related to increased levels of HbA1c. The risk of periodontitis is 3-fold times higher among diabetic patients^[39], being its prevalence and severity even greater in diabetic patients presenting elevated HbA1c levels^[40].

Different hypotheses have been proposed to explain the influence of diabetes mellitus on periodontitis but they are all currently under investigation and remain somewhat controversial. Two similar but distinct pathogenic pathways may justify the biologic plausibility, a possible common origin of the two diseases which results in a host susceptible to either diseases^[41], or a direct causal relationship in which, through the effects of advanced glycosylation end products (AGEs), diabetes triggers an increased inflammatory phenotype in cells^[5,27]. Studies have shown how chronic hyperglycemia produces AGEs that can bind to specific receptors (RAGE) on different cells such as fibroblast, endothelial cells and macrophages^[42]. Thereby, macrophages are transformed into hyperactive cells that produce pro-inflammatory cytokines such as interleukins 1 β and 6 (IL-1 β , IL-6)

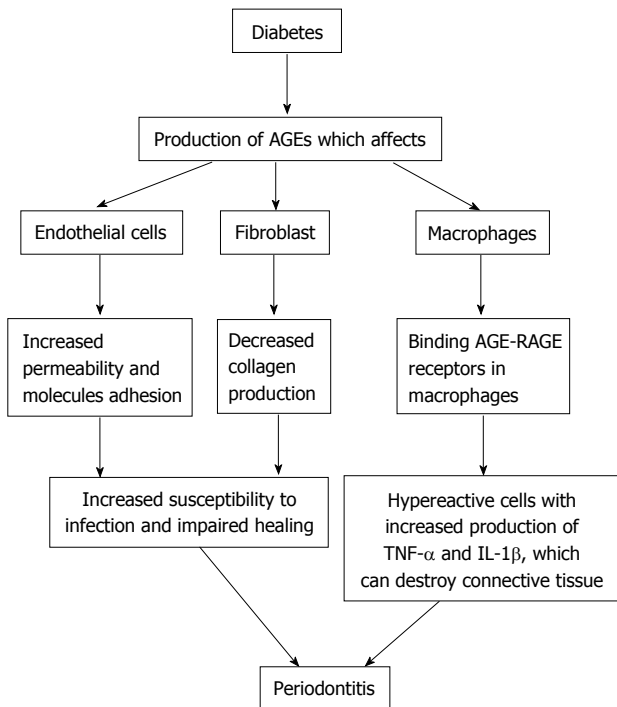

Figure 7 How diabetes mellitus could contribute to the development of periodontal disease (Llambés F, Caffesse R, Arias S). TNF: Tumor necrosis factor; IL-1 β : Interleukins 1 β ; AGE: Advanced glycosylation end product; RAGE: Receptors AGE.

and TNF- α . AGEs can also alter endothelial cells which will become hyperpermeable and hyperexpressive for adhesion molecules, while fibroblasts will show decreased collagen production^[43]. Therefore, AGEs produced by chronic hyperglycemia can produce hyper inflammatory responses, vascular modifications, altered healing and increased predisposition to infections (Figure 7). Lalla *et al.*^[44] supported the hypothesis that the activation of RAGE contributes to pathogenesis of periodontitis in diabetic patients. Increased accumulation of AGEs and their interaction with RAGE in diabetic gingiva leads to hyper production of proinflammatory cytokines, vascular dysfunction, and loss of effective tissue integrity and barrier function.

Despite these facts, periodontal treatment can be successful in diabetic patients. Short term effects of periodontal treatment are similar in diabetic patients and healthy population^[45-47] but, more recurrence of periodontal disease can be expected in non well controlled diabetic individuals^[26].

Effect of periodontal disease and its treatment on diabetes

The National Health and Nutrition Examination Survey 2009-2010 reported that prevalence of diabetes was 12.5% among periodontal patients, but only 6.3% in subjects without periodontitis^[48].

If diabetic individuals are at a higher risk for periodontitis, it is also important to determine what effects periodontitis and its treatment may have on diabetes. It would be reasonable to think that perio-

dontal inflammation, as any other infections, can have an adverse effect on diabetes glycemic control, compromising diabetes management in these individuals. Most evidence on this issue is derived from interventional and observational studies, indicating that periodontitis affects the glycemic control of diabetic patients. HbA1c values < 7% are related with proper glycemic levels whilst > 8% values represents poorly controlled glycemia.

Longitudinal studies have demonstrated that severe periodontitis is associated with poorly controlled glycemia, higher HbA1c levels and development of diabetic systemic complications^[1,30,49]. It also has been reported that periodontitis is associated with a slight elevation of HbA1c in non-diabetic subjects (periodontitis may potentially increase the incidence of diabetes), although a clear-cut association could not be established^[50].

Studies assumed that periodontal infection may impair glycemic control by increasing insulin tissue resistance^[26]. Hence, glycemic level could be improved by non-surgical periodontal treatment removing bacterial plaque accumulation and decreasing gingival inflammation. This assumption is based on studies that observed an improvement in diabetes glycemic control following periodontal therapy^[46,51]. It should be considered that other studies did not find such causal relationship, maybe due to inadequate time for periodontal tissues healing, or because periodontitis had not been properly resolved^[30,52]. Another reason may be the influence of factors such as diet, physical exercise or use of antidiabetics that can alter significantly HbA1c, and make more difficult to observe the metabolic effect of periodontal treatment^[45].

Effect of non-surgical periodontal therapy on diabetes glycemic control

Several studies have investigated the effect of non-surgical periodontal therapy on the glycemic control of diabetic patients. Both non-diabetic and diabetic patients show similar short-term outcomes after non-surgical periodontal therapy in terms of probing depth reductions, gain in CAL and changes in subgingival microbiota^[53]. If glycemic control is considered as treatment outcome after non-surgical periodontal therapy, results vary (Table 1).

Different studies on patients with type 1 diabetes mellitus have not found an additional beneficial effect of periodontal treatment in glycemic control. Llambés *et al.*^[45] obtained changes in mean HbA1c of about 0.07%, without statistical significant difference after non-surgical periodontal treatment in type 1 diabetic patients after 3-mo. Similarly, Seppälä *et al.*^[54] reported that in poorly-controlled type 1 diabetic patients, non-surgical periodontal therapy had no effect on HbA1c. The same results were observed in the study performed by Aldridge *et al.*^[55] who stated no changes in HbA1c levels after non-surgical periodontal therapy in 22 type 1 diabetics with severe periodontitis.

On the other hand, Faria-Almeida *et al.*^[46] reported

Table 1 How periodontal therapy affects diabetes glycemic control

	Ref.	Design	Sample	Follow-up	Outcome	Results
Type 1	Aldridge <i>et al</i> ^[55]	Randomized clinical trial	23 subjects	2 mo	HbA1c	No changes
	Smith <i>et al</i> ^[47]	Controlled clinical trial	18 subjects	2 mo	HbA1c	No changes
	Christgau <i>et al</i> ^[53]	Cohort study	7 subjects	4 mo	HbA1c	No changes
	Llambés <i>et al</i> ^[45]	Randomized clinical trial	30 subjects	3 mo	HbA1c	0.06% reduction (no changes)
Type 2	Stewart <i>et al</i> ^[75]	Controlled clinical trial	72 subjects	10 mo	HbA1c	6% reduction
	Kiran <i>et al</i> ^[51]	Randomized clinical trial	44 subjects	3 mo	HbA1c	0.8% reduction
	Faria-Almeida <i>et al</i> ^[46]	Cohort study	20 subjects	6 mo	HbA1c	5.7% reduction
	Dağ <i>et al</i> ^[56]	Controlled clinical trial	45 subjects	3 mo	HbA1c	No changes
	Auyeung <i>et al</i> ^[57]	Cohort study	75 subjects	12 mo	HbA1c	No changes
	Engelbreton <i>et al</i> ^[58]	Randomized clinical trial	257 subjects	6 mo	HbA1c	No changes
	Gay <i>et al</i> ^[59]	Randomized clinical trial	126 subjects	4 mo	HbA1c	No changes

that non-surgical periodontal therapy significantly reduce HbA1c levels about 5.7% in type 2 diabetics, while Dağ *et al*^[56] and Auyeung *et al*^[57] reported that this therapy alone significantly reduced HbA1c levels only in well-controlled diabetics. Smith *et al*^[47] reported that mechanical periodontal therapy alone did not produce a significant change in glycemic control in diabetic patients.

Recently, Engelbreton *et al*^[58] indicated that non-surgical periodontal therapy in type 2 diabetics with chronic periodontitis did not improve diabetes glycemic control. According to these findings the use of nonsurgical periodontal treatment in order to reduce levels of HbA1c would not be justified. Lately, Gay *et al*^[59] in a randomized clinical trial where 152 type 2 diabetic patients with periodontitis were treated, determined that no statistically significant differences were found in the changes of HbA1c levels.

Furthermore, current systematic reviews report glycemic control improvement, with a HbA1c reduction of approximately 0.4%, after non-surgical periodontal treatment^[60]. A mean reduction of -0.36% of glycosylated HbA1c in subjects with type 2 diabetes has been determined recently^[61]. However, the clinical significance of this effect is still unknown. It has been reported that each 1% reduction of HbA1c may be associated with 35% reduction in the risk of microvascular complications^[62]. To the best of our knowledge, no studies have evaluated changes in HbA1c levels in non-diabetic patients after non-surgical periodontal therapy.

Effect of non-surgical periodontal therapy in combination with antimicrobials on diabetes glycemic control

Two studies have examined the added benefit of chlorhexidine as adjunct to non-surgical periodontal therapy in diabetic patients. Christgau *et al*^[53] demonstrated that non-surgical periodontal therapy in combination with subgingival irrigation with 0.2% chlorhexidine did not improve HbA1c levels. The same results were achieved when 0.12% chlorhexidine was considered^[63].

Iwamoto *et al*^[64] demonstrated a 0.8% reduction in HbA1c in type 2 diabetics after non-surgical periodontal

therapy and subgingival use of minocycline gel.

Studies in which systemic antibiotics were used along with mechanical therapy showed a significant improvement in glycemic control in diabetic patients. This may be due to the additional benefits of systemic antibiotics, such as their antimicrobial and host modulation effects, as well as their inhibition of non-enzymatic glycosylation^[63,65-67].

Non-surgical periodontal therapy combined with 100 mg doxycycline is associated with a mean HbA1c reduction of 0.6% in type 2 diabetics patients^[65]. There is not enough evidence about the use of tetracyclines but it seems to play a role in limiting tissue destruction. Lately, a modest improvement in glycemic control was detected after nonsurgical therapy plus azithromycin^[68]. However, Llambés *et al*^[45] show that non-surgical periodontal treatment combined with systemic doxycycline has no effect on HbA1c of type 1 diabetic patients^[43].

Effect of surgical periodontal therapy on diabetes glycemic control

Scarce available evidence makes it impossible to determine the response after periodontal surgical treatment in diabetic patients. Diabetic subjects usually show improved periodontitis after surgical periodontal treatment. However, if poor diabetic control is present, more recurrence of periodontal pockets and unfavorable long term response is expected after surgical treatment^[53,69]. Effects of surgical periodontal treatment on HbA1c are currently unknown.

The exact mechanism linking periodontitis/periodontal inflammation and HbA1c levels is still not clearly known. In periodontitis, there is an increased production of pro-inflammatory mediators, such as TNF- α , IL-6, IL-1 β and interferon gamma (IF- α), and increased levels of acute-phase proteins, such as C-reactive protein (CRP). All these mediators have important effects on glucose and lipid metabolism. TNF- α , IL-6 and IL-1 β are insulin antagonist and lipid metabolism is hampered by TNF- α . Elevated levels of CRP lead to insulin resistance. IF- α induces apoptosis of pancreatic β cells^[70]. Non-enzymatic glycosylation of hemoglobin is not induced by inflammation, but rather results from hyperglycemia caused by insulin resistance^[44]. Thus, this could explain

why subjects with periodontitis have high HbA1c levels.

According to these reports, it can be presumed that control of periodontal inflammation after therapy may reduce the levels of local and circulatory mediators, such as IL-6 and TNF- α . Both may trigger acute phase proteins such as CRP, and impair intracellular insulin signaling. Consequently, if these mediators were reduced by periodontal treatment, this could theoretically, help in diabetes control. However, this mechanism remains to be confirmed. Some studies have shown that periodontal disease severity is correlated with blood CRP levels in diabetic patients^[71,72], however CRP levels are not reduced after periodontal treatment^[73,74].

CONCLUSION

Within the limits of this review we can conclude that: Periodontitis is a highly prevalent infectious disease that relates to some systemic disorders, including diabetes mellitus.

Diabetes has been associated to different oral diseases such as: xerostomia, neuro-sensory disorders, several oral mucosa diseases, tooth decay and periodontal disease. It is well documented in the literature that periodontal disease is more prevalent and severe in diabetic individuals than in healthy subjects. However, it has to be kept in mind that the level of metabolic control and duration of diabetes appear to influence the risk for periodontal disease, with a significant heterogeneity among diabetic individuals.

Periodontal treatment is effective in diabetic patients, but more long-term recurrence can be expected when diabetes is not well controlled.

Severe periodontitis is more frequently found in diabetic subjects with high HbA1c levels and systemic diabetic complications; however, the influence of periodontal treatment on HbA1c is not that well established. The beneficial effects of periodontal treatment on HbA1c levels seem to be more apparent in type 2 diabetics and when antibiotics are associated to local periodontal therapy, although other reports did not find any improvement in diabetes control after periodontal treatment. More research on type 1 and type 2 diabetic subjects will be needed to know how periodontal treatment affects diabetes metabolic control. In those, it will be paramount to control other factors that may affect HbA1c levels, such as diabetic medication, diet and physical exercise.

HbA1c reduction after periodontal treatment is usually less than 0.5%. New studies are needed to evaluate the clinical significance of this improvement.

Additionally, it may be necessary to explore the effects of different modalities of periodontal therapy in patients with different types of diabetes and different degrees of metabolic control.

Further analysis of inflammatory mediators, such as CRP, may help to explain the relationship between diabetes and periodontal disease, and the individual variations detected in samples from different severities

of diabetes and periodontal disease.

Any improvement in the control of diabetes and/or periodontal disease has the potential to improve significantly the quality of life in diabetic subjects.

Abstract

Polycystic ovary syndrome (PCOS) is a common endocrine disorder that affects up to 6.8% of reproductive age women. Experimental research and clinical observations suggest that PCOS may originate in the very early stages of development, possibly even during intrauterine life. This suggests that PCOS is either genetically-transmitted

or is due to epigenetic alterations that develop in the intrauterine microenvironment. Although familial cases support the role of genetic factors, no specific genetic pattern has been defined in PCOS. Several candidate genes have been implicated in its pathogenesis, but none can specifically be implicated in PCOS development. Hypotheses based on the impact of the intrauterine environment on PCOS development can be grouped into two categories. The first is the "thrifty" phenotype hypothesis, which states that intrauterine nutritional restriction in fetuses causes decreased insulin secretion and, as a compensatory mechanism, insulin resistance. Additionally, an impaired nutritional environment can affect the methylation of some specific genes, which can also trigger PCOS. The second hypothesis postulates that fetal exposure to excess androgen can induce changes in differentiating tissues, causing the PCOS phenotype to develop in adult life. This review aimed to examine the role of fetal programming in development of PCOS.

Core tip: Polycystic ovary syndrome (PCOS) is a highly complex and heterogeneous disorder that is significantly influenced by genetic and environmental factors. There is some evidence that the development of PCOS may begin during the intrauterine period. Fetuses exposed to intrauterine nutritional restriction often have lowered insulin secretion and, as a compensatory mechanism, insulin resistance, which is known as the "thrifty" phenotype. Additionally, an impaired intrauterine nutritional environment can affect the methylation of some specific genes, which can trigger PCOS. The other hypothesis postulates that fetal exposure to excess androgen can induce changes in differentiating tissues, causing the PCOS phenotype and related disorders to develop in adult life.

INTRODUCTION

Polycystic ovary syndrome (PCOS) is a complex disorder characterized by defects in primary cellular control mechanisms that can result in hyperandrogenemia, hyperinsulinemia, insulin resistance, and chronic anovulation. PCOS is the most common endocrinologic disorder among women of reproductive age. Its prevalence typically ranges between 4% and 8% in diverse populations, but it has been reported to be as high as 25%^[1]. The variations in the reported prevalence of PCOS have been attributed to the use of different diagnostic criteria. Three main diagnostic criteria systems that are currently accepted for PCOS are those from the National Institutes of Health (NIH, 1990), Rotterdam (ASRM/ESHRE, 2003), and Androgen Excess Society (AES, 2006). According to the Rotterdam criteria, the diagnosis of PCOS is based on the presence of at least two of the following three clinical features: polycystic ovarian morphology, oligo/amenorrhea and hyperandrogenism. However, the NIH criteria require only oligo/amenorrhea and hyperandrogenism for a diagnosis, while the AES criteria require a combination of biochemical or clinical hyperandrogenism along with chronic anovulation or polycystic ovarian morphology^[1,2]. Although it is considered to be a disorder of reproductive age women (based on its classical symptoms of amenorrhea, hirsutism, and infertility), it can affect a woman any time during her life. Affected persons have a lifetime risk of disorders, including glucose metabolism, cardiovascular diseases, endometrial hyperplasia and/or cancer^[2].

The underlying causes of PCOS are not known. However, its signs and symptoms typically appear during or close to the onset of puberty. Signs of precocious pubarche and adolescent hyperandrogenemia with or without insulin resistance may indicate the early stages of PCOS^[3]. Further, epidemiologic studies have shown that adolescents with the aforementioned signs of PCOS had lower birth weights than those of controls^[4]. These results suggest the hypothesis that PCOS is a continuum of a process that begins during intrauterine life.

PCOS is also believed to be caused by several genetic and environmental factors. The prevalence of PCOS has risen in populations where the gene pool has been relatively constant, which indicates that environmental factors may be playing a more important role in its development^[5]. Further, obesity has been linked to the development of PCOS in susceptible individuals. A recent study revealed that, when compared with matched controls, non-obese women with PCOS had higher levels of glycotoxins, hyperandrogenemia, and advanced

glycation end products, which were positively correlated with insulin resistance indices^[6]. Some recent animal studies and observational human studies have suggested that impaired nutrition and steroidal environment during intrauterine life may play an important role in the development of PCOS^[7-9].

GENETICS OF PCOS

Although case reports indicate that PCOS clusters within families, genetic studies have been inconclusive^[10]. Twin studies have shown a heritability of 79% for PCOS with a correlation of 0.71 between monozygotic twins and 0.38 between dizygotic twins^[11]. The clinical presentation of PCOS varies widely and there is currently no consensus on its diagnostic criteria^[12,13]. Studies aimed at determining a genetic model of PCOS have produced different results when varying diagnostic criteria were used. For instance, some studies accepted hirsutism and ovaries with a polycystic appearance as diagnostic criteria (Rotterdam criteria) for the disease; these studies suggested that PCOS may have an autosomal dominant or X-linked simple Mendelian trait. Other studies using oligomenorrhea and hirsutism as the diagnostic criteria (NIH criteria) have reported lower genetic penetration rates^[14-17]. On the other hand, some other recent studies have shown that the genetic aspect of insulin resistance is more prominent than that of hyperandrogenism in PCOS patients^[18]. In conclusion, there is not yet a clearly established genetic model of PCOS. This is due to the diversity of both the diagnostic criteria and the clinical presentations of the disease, differences in its prevalence among various ethnic populations, and the limitations of some prior studies with respect to the number of subjects and statistical analyses used^[10].

While the etiology of PCOS remains unclear, intrinsic abnormalities in the synthesis and secretion of androgens, insulin and gonadotropins provide a plausible basis for the syndrome. Therefore, it has been suggested that specific primary enzyme abnormalities in these steroidogenic pathways may be an important cause of PCOS. Many different genes encoding these enzymes have been studied to determine the etiology of PCOS; these genes have altered expression, suggesting that the genetic abnormalities in PCOS affects signal transduction pathways controlling steroidogenesis, steroid hormone action, gonadotropin action and regulation, insulin action and secretion, energy homeostasis, chronic inflammation, and more (Table 1)^[19-27]. These genes may each contribute separately, or they might act collectively. Moreover, different variation in the same gene (allelic heterogeneity) and possible gene-environment interactions may have different effect on gene function. Data suggests that as of yet, there are no gene defects considered to be responsible for the etiology of PCOS; however, several studies have looked at many candidate genes and have suggested that alterations in these genes may contribute to the development of PCOS. Nevertheless, future studies are needed to determine

Table 1 Genetics of polycystic ovary syndrome

The genes associated with PCOS	Genetic mutation (specific enzyme, protein or receptor)
Genes involved in ovarian and adrenal steroidogenesis	CYP11A (P450 cytochrome) CYP21 (21-hydroxylase) CYP17 (17 α -hydroxylase and 17,20-lyase) CYP19 (the enzyme complex aromatase: cytochrome P450 aromatase, the NADPH cytochrome P450 reductase 30, and P450 arom)
Genes involved in steroid hormone actions	AR-VNTR polymorphism (the androgen receptors) 4-kb gene - A pentanucleotide repeat polymorphism (SHBG)
Genes involved in gonadotropin action and regulation	Trp8Arg and Ilg15Thr (the β -subunit of LH)
Genes involved in insulin action and secretion	INS -VNTR (insulin) INSR-SNP (insulin receptor) Gly972Arg for IRS1, Gly1057Asp for IRS2 (insulin receptor substrates) 112/121 haplotype of CAPN10 (calpain-10) ApaI; rs680-SNP (IGF-1, IGF-2)
Genes involved in energy homeostasis	T45G in exon 2 and G276T in intron 2 (adipocytokines)
Genes involved in chronic inflammation	Mutation 308 A alleles (TNF- α) TNFR2, IL-6 signal transducer gp 130, IL-6 receptor genes (type-2 TNF receptor, IL-6) Polymorphism 4G/5G (PAI-1)

PCOS: Polycystic ovary syndrome; PAI-1: Plasminogen activator inhibitor-1; IL-6: Interleukin-6; TNF- α : Tumor necrosis factor α ; IRS: Insulin receptor substrates; INSR: Insulin receptor.

which genes are the most appropriate PCOS biomarkers. In addition, more recent genetic approaches, namely genome-wide association studies, may begin a new era in PCOS research^[28].

EXPERIMENTAL ANIMAL STUDIES

Experimental evidence supports the hypothesis that the phenotypic expression of PCOS is strongly influenced by the intrauterine environment. Initial studies on rats have shown that elevated testosterone (T) levels early in intrauterine life are related to anovulatory sterility and ovarian polycystic changes in offspring^[29-31]. Prenatally T-treated monkeys and sheep serve as good models of PCOS because follicular differentiation in these species is similar to that in humans^[32]. The results of studies on prenatally androgenized rhesus monkeys are summarized as follows: (1) Following cessation of maternal testosterone treatment in the early period (beginning on days 40-44 of gestation; term 165 ± 10 d), fetuses of these mothers had irregular ovulatory menstrual cycles, ovarian hyperandrogenism, enlarged polyfollicular ovaries and luteinizing hormone (LH) hypersecretion, insulin resistance, diminished insulin secretion, increased incidence of type 2 diabetes, visceral adiposity, and hyperlipidemia. These conditions may be related to an increase in Gonadotropin-releasing hormone (GnRH) secretion, a reduced negative feedback effect of steroids on LH release and/or increased gonadotropin response to GnRH^[33,34]. Normally, healthy fetuses undergo a "critical hypothalamic hormonal period" during sexual differentiation. During this period, a sufficient androgenic stimulus in the brain allows for tonic gonadotropin release and contributes to male-type development; on the other hand, an insufficient androgenic stimulation level promotes the development of a female-type synaptology that is characterized by cyclic GnRH release^[35]. An

increased frequency and amplitude of GnRH release increases LH levels and impairs folliculogenesis, resulting in the anovulatory clinical picture that is characteristic of PCOS. Female offspring of monkeys that were androgenized during fetal life and have high LH levels have hormonal profiles similar to those of the normal male-type hormonal profile; (2) female monkeys similarly exposed to androgen excess during late gestation (100-110 gestation days) also exhibit an adult PCOS-like phenotype, but they do not have obvious abnormalities in LH and insulin secretion or in insulin action^[33]; (3) prenatally androgenized monkeys have high blood levels of androstenedione at birth and their androgens of adrenal origin continue to increase for a period of 4-25 mo after birth, suggesting that prenatal androgen exposure may permanently alter adrenal androgen production^[36]; (4) fetuses that are androgenized during the prenatal period have an increased number of primary, growing preantral, and small antral follicles and an accelerated proliferation of granulosa cells. In addition, an excess of prenatal androgen increases the mRNA expression of follicle-stimulating hormone receptor, insulin-like growth factor I (IGF- I) and the IGF- I receptor in granulosa cells. These morphological changes are similar to the increased follicular development from the primordial follicle pool that is seen in PCOS patients. Furthermore, prenatally androgenized fetuses have increased 5 α -reductase and decreased aromatase activities, which are similar to mechanisms involved in the impaired follicular maturation of PCOS patients^[37,38]; (5) prenatally androgenized female monkeys exhibit enhanced insulin secretion in both the fetal and infant zona reticularis. Therefore, an excess of fetal androgen may induce relative insulin hypersecretion in exposed female fetuses and infants, which in turn programs adrenal hyperandrogenism. In addition, the amelioration of impaired insulin action has beneficial

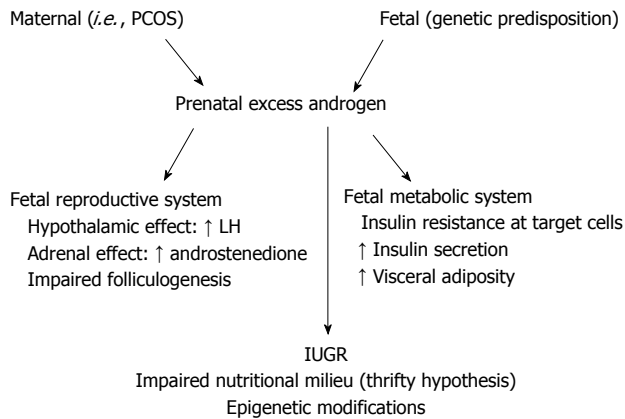

Figure 1 Possible effects of prenatal excess androgen on the fetus. PCOS: Polycystic ovary syndrome; LH: Luteinizing hormone; IUGR: Intrauterine growth restriction.

glucoregulatory effects in both PCOS patients and in prenatally androgenized female monkeys. Treatment with Pioglitazone (a thiazolidinedione-based insulin sensitizer) in prenatally androgenized female monkeys diminishes the aspects of adrenal androgen excess and normalizes menstrual cyclicity^[34]; (6) the hypothesis that metabolic disorders are programmed during the fetal stage is supported by the finding that, despite normal T levels after birth, prenatally androgenized male fetuses have insulin resistance and pancreatic beta-cell defects similar to those observed in females^[39]; and (7) T excess, when introduced prenatally, decreases birth weight in rodent and sheep offspring. In addition, in humans, impaired placental aromatization is accompanied by diminished uteroplacental perfusion and low infant birth weight^[40-44]. It has been suggested that maternal T excess may reduce fetal growth and birth weight *via* impaired placental function (Figure 1).

CLINICAL OBSERVATIONS FOR THE DEVELOPMENTAL ORIGIN OF PCOS

There is some evidence that female fetuses exposed to high androgen levels during the intrauterine period develop the clinical features of PCOS later in life. In humans, it is not possible to perform controlled studies to observe the fetal consequences of maternal androgens; this is left to animal research. However, some observations have been made in humans to support the validity of this hypothesis. Female fetuses having a congenital virilizing tumor or congenital adrenal hyperplasia due to 21-hydroxylase deficiency have been shown to display features of PCOS later in life, even after eliminating the hyperandrogenemia with postnatal therapies^[45]. Similarly, it has been reported that female fetuses of women with defects in the p-450 aromatase gene and sex hormone-binding globulin gene, which are rare conditions that cause androgenization, also develop PCOS later in life^[46]. Furthermore, it has been shown that exposure to androgen-like chemicals (e.g., Bisphenol A)

can lead to PCOS^[47,48].

Another study showed that the maternal androgen level is significantly higher in pregnant mothers with PCOS compared to that in healthy pregnant women^[49]. While the reason for elevated androgen levels in pregnant women with PCOS has not yet been clarified, it is hypothesized that it may be due to hCG-stimulated androgen production in maternal theca cells or the placenta. Under normal conditions, maternal androgens or fetal adrenal androgens are rapidly converted to estrogens by the activity of the placental enzyme aromatase. However, when the activity of this enzyme is inhibited, the availability of androgens may increase. Insulin has been shown to inhibit aromatase activity in human cytotrophoblasts and can stimulate 3-hydroxysteroid dehydrogenase activity^[50]. Therefore, hyperinsulinemia appears to coincide with elevated maternal androgen levels in the development of PCOS in offspring of pregnant women with the same disease. Furthermore, this hypothesis may be supported by the observation that the fetuses of diabetic mothers using insulin have increased levels of macrosomia and fetal pancreatic β -cell hyperplasia, as well as hirsutism, ovarian theca-lutein cysts, ovarian theca cell hyperplasia, and high T and hCG levels in the amniotic fluid^[32].

In addition to having increased androgen levels during pregnancy, women with PCOS may also deliver small-for-gestational age newborns at a higher prevalence than do normal control mothers^[51]. It is hypothesized that prenatal exposure to androgens in the offspring of women with PCOS may cause the development of the PCOS phenotype later in life, and it may also be the reason for low birth weight during the intrauterine period. With this in mind, recent studies in girls have shown that low birth weight is related to the development of premature pubarche followed by functional hyperandrogenism, insulin resistance with hyperinsulinism, and dyslipidemia during adolescence. It has been suggested that these manifestations may have a common early origin^[3,52]. A study in which the authors followed pregnant women during their entire pregnancies reported that pregnant women with PCOS had a progressive increase in both maternal androgens (testosterone and androstenedione) and insulin resistance during their pregnancies, and that these women were exposed to adverse pregnancy-related events significantly more often than those in the control group with a similar body mass index^[49]. Fetuses of mothers with PCOS can have developmental delay, which may be related to an elevated T level and insulin resistance. It has been shown that increased insulin resistance during pregnancy is related to adverse pregnancy outcomes including gestational diabetes, preeclampsia, preterm labor, and intrauterine growth restriction (IUGR)^[53,54]. This hypothesis is also supported by the fact that male children of mothers with PCOS also have increased prevalence of impaired glucose tolerance, insulin resistance, type-2 diabetes, dyslipidemia and pancreatic beta-cell defects later in life^[55].

Another possible mechanism related to the fetal

programming of PCOS involves an impaired intrauterine environment. Independent of elevated androgen levels, intrauterine nutritional insufficiency for any reason may lower insulin secretion and insulin resistance in target tissues as an adaptive mechanism (the thrifty hypothesis). The development of insulin resistance is believed to be directly related to the body "predicting" a life of starvation for the developing fetus. This fetus or infant will have retarded growth and will likely develop PCOS when exposed to nutritional surplus later in life. Epidemiologic studies have demonstrated that babies born with IUGR have an increased prevalence of metabolic syndrome, type-2 diabetes, and hypertension later in life^[48]. A recent study showed that urine from neonatal infants with IUGR contained significantly increased levels of metabolic syndrome-associated markers^[56]. Although conclusive evidence is lacking, it has been suggested that an impaired intrauterine nutritional environment causes epigenetic changes that trigger metabolic disorders in adult life. The best evidence for this is that there is hypomethylation in the 11p15 imprinting center region that is responsible for the etiology of Silver-Russell syndrome, which is characterized by severe IUGR, lack of catch-up after birth, and specific dysmorphisms^[57].

CONCLUSION

In conclusion, PCOS is a highly complex and heterogeneous disorder that is significantly influenced by both genetic and environmental factors. Environmental factors may play a role in the early stages of human development by helping to convert a predisposed genotype to the phenotypic expression of PCOS. In this review, the possible roles of intrauterine environmental factors in PCOS were summarized. Experimental animal studies suggest that maternal hyperandrogenism at a critical stage of fetal development may cause permanent changes in fetal physiology that can trigger PCOS development later in adult life. In humans, it is not possible to perform controlled studies to observe the fetal consequences of maternal androgens; however, some observations have been made in humans to support the validity of this hypothesis. In addition to having increased androgen levels during pregnancy may also deliver small-for-gestational age newborns at a higher prevalence that do normal control mothers. Furthermore, an insufficient intrauterine nutritional environment may also affect PCOS development by affecting cellular metabolism in target tissues or by causing epigenetic alterations to specific genes.

Mechanisms triggering PCOS may be eliminated by making improvements to the maternal hormonal environment and to the intrauterine nutritional environment. Future studies are necessary in order to determine whether insulin-sensitizing treatment of pregnant women with PCOS, or prenatally androgenized animals, will prevent postnatal PCOS in their daughters/female offspring. Results from such studies may help to identify a specific programming mechanism for PCOS.

Abstract

Diabetes mellitus significantly increases the risk of cardiovascular disease and heart failure in patients. Independent of hypertension and coronary artery disease, diabetes is associated with a specific cardiomyopathy, known as diabetic cardiomyopathy (DCM). Four decades of research in experimental animal models and advances in clinical imaging techniques suggest that DCM is a progressive disease, beginning early after the onset of type 1 and type 2 diabetes, ahead of left ventricular remodeling and overt diastolic dysfunction. Although the molecular pathogenesis of early DCM still remains largely unclear, activation of protein kinase C appears to be central in driving the oxidative stress dependent and independent pathways in the development of contractile dysfunction. Multiple subcellular alterations to the cardiomyocyte are now being highlighted as critical events in the early changes to the rate of force development, relaxation and stability under pathophysiological stresses. These changes include perturbed calcium handling, suppressed activity of aerobic energy producing enzymes, altered transcriptional and posttranslational modification of membrane and sarcomeric cytoskeletal proteins, reduced actin-myosin cross-bridge cycling and dynamics, and changed myofilament calcium sensitivity. In this review, we will present and discuss novel aspects of the molecular pathogenesis of early DCM, with a special focus on the sarcomeric contractile apparatus.

Core tip: Pathological changes in cardiac muscle underlie diabetic cardiomyopathy (DCM) independent of hypertension and atherosclerosis. In advanced diabetes, fibrosis, hypertrophy and apoptosis, reduce myocardial compliance, which leads to increased diastolic filling pressures and overt left ventricular diastolic dysfunction. However, detrimental changes in sarcomeric and other cytoskeletal proteins in the cardiomyocytes of animal models of diabetes precede remodeling of the cardiac extracellular matrix, which has until now been considered the main contributor to diabetic diastolic dysfunction. An important target for preventing early DCM are the protein kinase C/rho-kinase pathways that drive oxidative stress and reduce myosin head cycling and prolong Ca^{2+} transients.

Contractile apparatus dysfunction early in the pathophysiology of diabetic cardiomyopathy. *World J Diabetes* 2015; 6(7): 943-960 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i7/943.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i7.943>

INTRODUCTION

Diabetes mellitus is a rapidly escalating global epidemic with the International Diabetes Federation predicting that the incidence of diabetes will rise to 552 million people worldwide by 2030^[1]. Diabetes is a metabolic disorder characterized by hyperglycemia, insulin deficiency and or resistance. Type 1 diabetes mellitus (T1DM) is triggered by an autoimmune mechanism and accounts for approximately 5%-10% of diabetes cases. Type 2 diabetes mellitus (T2DM) represents 90%-95% of diabetes cases and is initiated by the interaction of genetic, environmental and lifestyle factors^[2].

Diabetes is associated with a number of complications such as retinopathy^[3], nephropathy^[4], peripheral neuropathy^[5] and cardiovascular disease, which are similar in their pathophysiological mechanisms in both T1DM and T2DM. Cardiovascular disease is the most common complication of diabetes and a leading cause of morbidity and mortality in patients^[6]. Several lines of evidence have established that chronic diabetes is associated with pathological changes to the cardiac muscle^[7-9], coronary vasculature^[10-12] and cardiac autonomic nerves^[13-15], all of which contribute to the increased risk of cardiovascular disease^[16,17].

Independent of other cardiovascular complications, a large body of evidence indicates that diabetes is associated with a specific cardiomyopathy known as diabetic cardiomyopathy (DCM)^[18-20]. In the long term,

people with diabetes more frequently have cardiovascular complications and double the mortality rate^[21]. Moreover, we have known for some time from the Framingham Heart study that diabetic men and women are 2 and 5 times more likely to develop heart failure respectively, independent of hypertension and coronary artery disease^[22].

Initially, DCM was recognized by impaired myocardial relaxation and left ventricle (LV) stiffening with progressive development of LV interstitial fibrosis and cardiomyocyte hypertrophy^[23]. Although the natural history of DCM has never been directly studied, extensive research utilizing experimental animal models of T1DM and T2DM and advances in clinical cardiac imaging over the past four decades support the notion that DCM is a progressive disease, beginning in the early time course of diabetes^[24].

Clinical investigations indicate that features of DCM are present early after the onset of T1DM. In T1DM patients, early DCM is identified by subtly reduced peak myocardial systolic velocity and early diastolic velocity preceding overt diastolic dysfunction^[25]. Early abnormalities in diastolic function are also apparent in patients with well-controlled T2DM in the absence of LV hypertrophy^[26]. Similarly, in one of the most common animal models, the streptozotocin (STZ) induced diabetic rat, depressed rates of pressure development and decay, reduced end systolic developed pressure and prolonged relaxation times are evident as early as 2-3 wk post diabetes induction^[27,28], prior to LV remodeling^[28].

In the advanced stages of diabetes, a myriad of cellular signaling pathways are chronically activated within the heart, leading to fibrosis, hypertrophy and apoptosis, resulting in inadequate myocardial compliance, increased diastolic filling pressures and the development of overt LV diastolic dysfunction^[24]. There is strong evidence from prevention and intervention studies using animal models that specifically targeting the structural manifestations of advanced DCM improves LV function^[29-31]. However, in the clinical setting, there is still uncertainty as to whether structural remodeling is a cause or consequence of DCM^[32]. Functional abnormalities in isovolumetric contraction and relaxation rates, as well as reduced systolic developed pressure are common to both early and advanced DCM. Moreover, it is not easy to diagnose when structural change has occurred. As these cardiac indices reflect the functional status of mechanisms regulating intracellular events within cardiomyocytes including the initiation and regulation of contraction and relaxation, there is sufficient evidence that demonstrates that subcellular changes to the cardiomyocytes can account for the functional abnormalities observed in early DCM.

In this review, we will focus on and discuss the multiple cellular biochemical derangements, intracellular signaling cascades as well as the structural and functional changes to the cardiomyocyte and sarcomere that establish the beginnings of contractile dysfunction in DCM ahead of myocardial remodeling and overt LV

diastolic dysfunction.

EARLY BIOCHEMICAL DYSFUNCTION AND THE CELLULAR SIGNALING PATHWAYS INVOLVED IN DCM

Diabetes is associated with hyperglycemia, hyperlipidemia, hyperinsulinemia and or insulin resistance. However, unlike T1DM, abnormal glucose homeostasis, hyperinsulinemia and insulin resistance frequently precede development of T2DM^[33]. Regardless of the etiology of the disease, diabetes results in multiple cellular metabolic derangements, including increased production and accumulation of advanced glycation end-products in the extracellular space, increased polyol and hexosamine pathway flux and activation of various protein kinase C (PKC) isoforms^[34] (Figure 1). In the myocardium, these biochemical derangements drive the generation of oxidative stress, a key contributor to the development of DCM^[35] (Figure 1A).

Oxidative stress

The development of oxidative stress has long been recognized as a cardinal molecular event in the initiation and progression of DCM. Importantly, in the long-term, diabetes and insulin resistance induce myocardial oxidative stress from a number of sources leading to enhanced production of reactive oxygen species (ROS) and reactive nitrogen species, whilst also diminishing the heart's antioxidant defense system (reviewed by^[36]). The specific mechanisms of how each of these sources generate oxidative stress are beyond the scope of this review and are described in detail by Huynh *et al.*^[37].

In the setting of chronic experimental diabetes, oxidative stress has been consistently implicated in myocardial remodeling and diastolic dysfunction. Studies conducted by our group and others demonstrate that elevated ROS expression and compromised antioxidant defense are associated with myocardial fibrosis, hypertrophy and diastolic dysfunction in STZ induced T1DM rats^[38,39]. Similar findings have been reported in genetic models of advanced T2DM including the db/db mouse^[40], the Goto Kakizaki (GK) rat^[38] and the Otsuka Long-Evans Tokushima Fatty (OLETF) rat^[41].

A role for oxidative stress in the initiation of DCM has also been shown to occur early after the induction of diabetes in animals. One source of myocardial oxidative stress that certainly plays a role in early DCM is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Inhibition of NADPH oxidase shortly after the onset of diabetes attenuates subsequent interstitial fibrosis and completely restores systolic and diastolic function in diabetic rats^[42]. Three to five weeks post induction of diabetes in rats, there is a significant increase in myocardial oxidative stress (nitrotyrosine and lipid peroxidation), which is associated with contractile dysfunction^[43,44]. Antioxidant treatment with N-acetylcysteine (NAC) significantly improved the prolonged rates of LV pressure decay, but not the rates of

pressure development^[43]. While myocardial remodeling was not directly assessed by Cheng *et al.*^[43], the improvements in LV diastolic indices they observed are most likely caused through actions on cardiomyocyte and sarcomeric function (Figure 1A).

Oxidative stress has been widely reported to induce posttranslational modifications of a large variety of contractile proteins within the sarcomere with redox modifications of such proteins playing a pivotal role in the evolution of heart failure (reviewed extensively by references^[45,46]). Therefore, in early DCM, cardiac contractile dysfunction is likely to arise in some part as a consequence of oxidative stress, through posttranslational modifications of contractile proteins as opposed to myocardial structural alterations derived from the increasing burden of chronic oxidative stress associated with advanced DCM. Two distinct cellular signaling cascades that drive generation of oxidative stress through NADPH production are the renin angiotensin aldosterone system (RAAS)^[47,48] and the PKC β_2 pathway^[49,50] (Figure 1A). Both have been implicated in the early pathogenesis of DCM.

RAAS

It has been known for many years that the RAAS is a key contributor to the development and progression of renal^[51], vascular^[52] and cardiac^[53] complications in diabetic patients, mainly by its effector molecule, angiotensin II (ANG II). Since systemic RAAS activity is unchanged or downregulated in diabetes^[54,55], local RAAS in the heart is thought to be responsible for the local production of ANG II. All the components of the classic RAAS have been identified in the heart including renin, angiotensinogen, ANG I, angiotensin converting enzyme (ACE), ANG II and ANG II type 1 receptors (AT₁R)^[56]. Traditionally, it is accepted that chronic activation of the RAAS in advanced T1DM and T2DM diabetes increases myocardial levels of ANG II. In addition to its potent vasoconstrictor actions, ANG II promotes myocardial remodeling by driving collagen production, extracellular matrix protein accumulation^[57], fibrosis, myocyte hypertrophy, apoptosis, impaired calcium handling, myofibrillar dysfunction and oxidative stress, all of which combine to evoke overt LV diastolic dysfunction^[48,58-65] (Figure 1B). Newer evidence suggests that in addition to the activation of classic RAAS, diabetes sequesters the activity of the cardiac ACE2-ANG-(1-7)-Mas receptor axis (Figure 1B), which opposes the pressor, fibrotic and hypertrophic effects of ANG II (reviewed in references^[66-68]). Although RAAS research in the context of DCM is in its infancy, the few studies conducted have reinforced the notion that diabetes suppresses cardiac ACE2-ANG-(1-7)-Mas receptor pathway in the hearts of rodents with chronic T1DM^[58,69] and T2DM^[62], resulting in myocardial remodeling and diastolic dysfunction in the long term (Figure 1B). Therefore, restoring the balance of the pathological and cardioprotective arms of local RAAS in chronic DCM has been proposed as a novel and more effective therapeutic strategy^[66,68].

In prediabetic, insulin resistant and early T1DM

animal models, there is also a potential role for elevated myocardial ANG II and activation of the classic RAAS arm in the initiation of cardiomyopathy. AT₁R-dependent NADPH oxidase-mediated oxidative stress is apparent in the hearts of insulin resistant, prediabetic OLETF rats^[70]. Normal myocardial nitric oxide production is restored after AT₁R blockade in a dietary induced rat model of obesity and insulin resistance^[71]. Moreover, one week of STZ diabetes in rats significantly increases

intracellular ANG II content in cardiomyocytes and is associated with myocardial oxidative stress and apoptosis^[72]. Unfortunately, as cardiac function was not assessed in these studies, it is not possible to say if the activation of the classic RAAS is responsible for LV contractile dysfunction documented in these early stages of diabetes. However, in support of this possibility, other studies have shown that increased RAAS activity in the hearts of diabetic animals is associated with impaired

calcium handling^[60,73] and reduced myofibrillar ATPase activity^[64]. Thus, there is a strong possibility for an early involvement of the RAAS in the pathogenesis of DCM as these subcellular alterations are often associated with early LV contractile dysfunction in diabetes (Figure 1A, broken line). Further studies are needed to clarify the involvement of classic RAAS and the ACE2-ANG-(1-7)-Mas receptor axis in contractile dysfunction at this time point, and if other angiotensin peptides^[74] and the AT₂R have any role in DCM development.

PKC β_2 pathway

There are multiple PKC isoforms in existence (α , β_1 , β_2 , γ , δ , ϵ , η , θ , ξ , ι/λ), which all regulate a large variety of cellular functions. In diabetes, hyperglycemia causes *de novo* synthesis of diacylglycerols, in turn activating several PKC isoforms in various tissues including the eye, kidney, vasculature and heart (reviewed extensively elsewhere^[75,76]) (Figure 1A). Of particular interest is the PKC β_2 isoform, which is found in the right and left ventricles of the heart^[77]. In rodent models of chronic STZ-induced T1DM, increased PKC β_2 expression and activity results in cardiomyocyte hypertrophy, fibrosis and impaired cardiomyocyte calcium handling capabilities, ultimately prolonging active diastolic relaxation and reducing passive compliance^[78-81] (Figure 1B). Elevated myocardial PKC β_2 expression levels are also reported in a rat model of dietary induced insulin resistance and T2DM^[82].

In the context of early DCM, one month after STZ induced diabetes in pigs, both cardiac PKC β_2 mRNA and protein expression is significantly increased compared to euglycemic controls^[83]. Consistent with this finding, two weeks post STZ diabetes induction, PKC β_2 protein activity is significantly increased in the hearts of rats^[84]. Furthermore, selective PKC β_2 inhibition from shortly after the onset of STZ diabetes prevented cardiomyocyte hypertrophy and NADPH oxidase mediated oxidative stress and thereby restored cardiac function to that of control rats^[85]. A significant finding of that study was antioxidant treatment with NAC had comparable effects to PKC β_2 inhibition in attenuating NADPH induced myocardial oxidative stress and hypertrophy. However, PKC β_2 inhibition was superior in preventing cardiac dysfunction by completely restoring isovolumetric relaxation times^[85]. This suggests that PKC β_2 also acts through oxidative stress independent pathways in the development of LV contractile dysfunction in early diabetes.

The RhoA/Rho kinase pathway axis - a possible mechanism for oxidative stress independent contractile dysfunction in early DCM

The Rho Kinases (ROCK), ROCK1 and ROCK2, are Rho-associated kinases activated by the small GTP-binding protein RhoA. ROCK1 is ubiquitously expressed, whereas ROCK2 appears to be brain and cardiac specific^[86]. The RhoA/ROCK pathway controls a diverse range of cellular processes in the cardiovascular system (see review^[87]), but primary actions of ROCK that are

pertinent to this review are the regulation of actin-myosin interactions^[88] and maintenance of cytoskeletal structure^[89].

A large body of evidence has established that ROCK is a key mediator of diastolic dysfunction in various rodent models of heart disease including hypertensive cardiomyopathy^[90-93], pressure-overload hypertrophy^[94] and myocardial infarction in mice^[95], as well as in patients with chronic heart failure^[96]. As a consequence, ROCK has gained attention as a promising therapeutic target for diabetic patients with diastolic dysfunction and preserved ejection fraction^[97]. In a small cohort of T2DM patients, daily administration of fasudil, a specific ROCK inhibitor, for two weeks significantly improved isovolumetric relaxation time, deceleration time, E/A wave ratio and E/e' wave ratio in comparison to baseline measures and placebo treated patients^[97]. Although not specifically identified in the aforementioned clinical study, elevated ROCK activity leads to diastolic dysfunction in chronic diabetes by inducing fibrosis, hypertrophy and cardiac ultrastructural remodeling^[98,99]. However, considering that ROCK is pivotal in regulating contractility at the level of the sarcomere and given the marked improvement in active diastolic indices in patients treated with fasudil, we speculate that elevated ROCK activity primarily drives diastolic dysfunction by modulation of sarcomeric proteins.

Early ROCK activation may also contribute to the initiation of DCM. Acute inhibition of ROCK in diabetic rats rapidly alleviates cardiac contractile dysfunction and increases developed force^[100], confirming ROCK has a direct interaction with the cardiomyocyte's contractile apparatus. Work conducted by our group demonstrates depressed actin-myosin dynamics and LV contractile dysfunction^[101] is associated with modestly elevated myocardial ROCK1 and ROCK2 expression^[102] suggesting that in the early diabetic rat heart, ROCK may drive contractile dysfunction by impairing actin-myosin interaction. Interestingly, we found all of these changes to occur largely independent of oxidative stress^[102]. Given the recent studies describing complex interactions between PKC β_2 and ROCK in chronic experimental DCM^[103,104] and the hypothesis that PKC β_2 is able to modulate cardiac function by oxidative stress independent mechanisms^[85], it is conceivable that PKC β_2 may indeed be acting through ROCK to prolong diastolic relaxation times (Figure 1A). Thus, there is strong evidence that implicates the PKC β_2 /RhoA/ROCK pathway in the pathogenesis and progression of DCM^[104]. Future investigations that examine the roles of ROCK at the level of the sarcomere in early diabetes may provide a clearer understanding of the initiating factors involved in DCM.

EARLY STRUCTURAL AND FUNCTIONAL CHANGES TO THE CONTRACTILE APPARATUS IN DCM

It has been widely held for some time that the diastolic

Figure 2 Subcellular alterations in various compartments of the cardiomyocyte in diabetic cardiomyopathy. PLB: Phospholamban; SERCA: Sarcoplasmic reticulum Ca^{2+} -ATPase; SR: Sarcoplasmic reticulum; RyR: Ryanodine receptor.

dysfunction associated with DCM is primarily attributed to increased LV fibrosis and hypertrophy, causing stiffening of the myocardium. However, a growing number of research findings provide evidence that insulin resistance and hyperglycemia also alter cardiomyocyte intracellular processes responsible for initiating and regulating cardiac contraction and force development on a beat-to-beat basis (see reviews^[105,106]). These include declines in cardiomyocyte calcium handling abilities, aerobic energy producing enzyme activity, integrity of cytoskeletal structures as well as sarcomeric dysfunction (Figure 2). In the following section we will discuss how all of these subcellular alterations contribute to contractile dysfunction in early DCM in both T1DM and T2DM (Table 1).

Alterations in calcium handling proteins and excitation-contraction coupling

Sufficient and timely transport of calcium ions (Ca^{2+}) in and out of the cardiomyocyte and sarcoplasmic reticulum (SR) is vital for the maintenance of normal cardiac function. During systole, Ca^{2+} enters through sarcolemma L-type Ca^{2+} channels and Ca^{2+} clusters are released spontaneously from the SR Ca^{2+} stores via the ryanodine receptor (RyR). The release of Ca^{2+} clusters causes Ca^{2+} sparks and initiates contraction by excitation-contraction coupling. In diastole, Ca^{2+} is pumped back into the SR via SR Ca^{2+} -ATPase (SERCA) and out of the cytosolic spaces by the $\text{Na}^{+}/\text{Ca}^{2+}$ exchanger, driving myocardial relaxation.

Systolic and diastolic Ca^{2+} handling impairment is characteristic of T1DM, even in the early stages. Three weeks post STZ, SR Ca^{2+} reuptake is prolonged and SERCA activity is decreased in comparison to the control group of normoglycemic rats^[107]. Slowed rates of contraction and relaxation in diabetic rats were attributed to prolonged Ca^{2+} transients and SR reuptake

in isolated papillary muscle preparations^[108]. In the whole heart, Takeda *et al.*^[109] also reported that prolonged myocardial relaxation in early diabetes was associated with depressed sarcolemma Ca^{2+} extrusion and SR Ca^{2+} reuptake, and reduced SERCA activity. More recently, it has been demonstrated that a progressive loss of cardiomyocyte Ca^{2+} handling abilities occurs ahead of LV contractile dysfunction in diabetic rats^[110].

Whether impaired Ca^{2+} handling is also an early event in the insulin resistant state and early T2DM is unclear. For example, in sucrose fed rats with insulin resistance^[111] and early T2DM^[112], impaired ventricular and cardiomyocyte relaxation is associated with decreases in SERCA and RyR expression and prolonged SR Ca^{2+} reuptake. However, in young prediabetic GK rats, appreciable changes in gene expression of Ca^{2+} handling proteins only resulted in moderate prolongation of shortening and a slower decay of Ca^{2+} transients^[113]. Similarly, in cardiomyocytes from young Zucker diabetic fatty (ZDF) rats, prolonged relaxation times cannot be fully explained by disruptions in Ca^{2+} handling^[114]. In stark contrast, Fredersdorf *et al.*^[115] have reported increased SERCA expression and Ca^{2+} sequestration in ZDF rats with early DCM, suggesting enhanced Ca^{2+} handling capabilities may be a compensatory mechanism to preserve cardiac function in the presence of hyperglycemia. Thus, subtle or moderately compromised cardiac contractile performance is not always attributable to changes in Ca^{2+} handling, except in early T1DM. Altered Ca^{2+} handling appears to be more important later in the course of diabetes.

Myosin heavy chain, myofibrillar/myosin ATPases and energy depletion

For cardiac contraction to occur, ATP bound to myosin must be hydrolysed to ADP and phosphate. Once the phosphate is released, ADP causes myosin to be strongly

bound to actin and induces the force-producing power stroke. Therefore, the rate-limiting step of cardiac contraction is ATP hydrolysis by myofibrillar and myosin ATPase^[116]. It has been known for several decades now that reduced myosin and myofibrillar ATPase activity is associated with contractile dysfunction in early diabetes. Three to four weeks post induction of T1DM, myosin and myofibrillar ATPase activities are significantly reduced in diabetic rats compared to normoglycemic, age-matched controls^[117,118]. Other studies have demonstrated that decreased myosin and myofibrillar ATPase activity is associated with *in vivo* contractile dysfunction in early diabetes in rats^[119] and reduced force development in isolated muscle preparations^[120]. Depression of myosin and myofibrillar ATPase activity in the diabetic heart is due to myosin isozyme switching from V₁ to V₃. Myosin isozyme expression is determined by the predominant myosin heavy chain (MHC) dimer^[121]. In the adult rodent heart, the V₁ (MHC_{αα} homodimer, α-MHC) is present^[105], however isozyme switching to the V₃ (MHC_{ββ} homodimer, β-MHC) is commonly exhibited in diabetic rodents. Such a V₃ isozyme shift has been reported along with depressed myosin ATPase activity in early diabetic rats, with some demonstrating a concomitant prolongation of tension development (without change in net tension development) and contraction times in isolated papillary muscle preparations^[117,122]. Notably, it has been shown that marked expression of β-MHC slows actin-myosin kinetics and thereby contributes to contractile dysfunction in early diabetes^[123,124].

Despite these convincing studies using animal

models, clinical experiments utilizing phosphorus magnetic resonance spectroscopy in T2DM patients with early DCM have found no association between diastolic dysfunction and ATP turnover^[125]. Thus, it is unclear if altered energetics of contraction is a cause or consequence of diabetes.

Changes in the structural compliance and order of the cardiomyocyte cytoskeleton network

The cardiomyocyte cytoskeleton is a highly organized and complex subcellular structure. The cytoskeleton can be divided into four main structures, this being the sarcomeric, extra-sarcomeric, membrane-sub-membrane and nuclear cytoskeleton^[126]. Although the cytoskeleton is considered a unified structure throughout the cardiomyocyte, there is a clear functional division between the contractile part, the sarcomere, and the non-contractile parts that transmit the developed power and ensures structural integrity of the cell and the functional syncytium^[127]. Arguably, the extra-sarcomeric cytoskeleton, comprising of microtubules, actin myofibrils and intermediate desmin filaments are as important for myocyte contraction as the sarcomeres, since these structures transfer the power produced by the sarcomeres through tethering of the sarcomere at the Z-disc to the submembrane skeleton and sarcolemma.

In the diabetic heart, there are inconsistent findings concerning the possible involvement of structural alterations to the sarcomere in the development of contractile dysfunction. One study using electron microscopy reported that hearts with advanced DCM

exhibited disarray of normal sarcomeric order, which was associated with contractile dysfunction^[128]. However, others have been unable to corroborate this finding. In contrast, ventricular ultrastructure, and especially the contractile apparatus, remained largely unchanged 8 mo post T1DM induction in rats^[129]. Jackson *et al.*^[130] demonstrated that in the initial stages of DCM sarcomeric and myofibrillar assembly remain unchanged from that of age-matched, normoglycemic controls, despite depressed contractile function. A unique feature of the sarcomeric cytoskeleton is the interaction of a myriad of proteins that provide exceptional stability. One of the major scaffolding proteins within the sarcomere is titin, a giant protein that spans half of the sarcomere from the Z-disc to the M-line, which provides spring-like recoil of the sarcomere to its relaxed length and facilitates power transmission of the sarcomere through the Z-disc. Titin exists in two isoforms; the stiffer N2B and the more elastic N2BA^[131]. The expression ratio and phosphorylation state of both isoforms are tightly controlled to regulate myocyte compliance and sarcomeric order^[132]. In the adult heart, the N2B isoform is predominantly expressed^[133], although a transition toward the N2BA isoform has been observed during the progression to heart failure^[134]. Indeed, titin isoform switching from N2B to N2BA has been demonstrated in the hearts of rats with advanced T1DM and diastolic dysfunction^[135]. Interestingly, in obese rats with T2DM, titin N2B hypophosphorylation contributes to contractile dysfunction in the absence of a change of isoform composition^[136]. Nevertheless, it is plausible that changes in composition and or phosphorylation of sarcomeric cytoskeletal proteins may be more responsible for contractile dysfunction in diabetes as opposed to overt disruption of sarcomeric order and organization.

Diabetes also affects microtubule function in the extra-sarcomeric compartment of the cytoskeleton. Microtubules are hollow protein cylinders created by the polymerization of α and β tubulin heterodimers. Amongst other functions, microtubules regulate the flexibility of the cytoskeleton and thus the contractile capacity^[127]. In the hearts of diabetic rats, microtubule flexibility is diminished^[137,138]. The lack of microtubule flexibility impedes adequate transfer of the power generated by the sarcomere and thus, contributes to contractile dysfunction^[137,138]. Polymerization of cytoskeletal actin filaments is increased in diabetes and essential for activation of the PKC β_2 /RhoA/ROCK pathways^[104]. The contribution of the extra-sarcomeric cytoskeleton is commonly overlooked in the pathogenesis of DCM and warrants further investigation, not only in areas of mechanical power translation but signal transduction between the sarcolemma, sarcomeres and the nucleus.

Actin-myosin cross-bridge dysregulation

The formation and dissociation of the actin-myosin cross-bridges (CBs) in the cardiac sarcomere is a pivotal determinant of force development and contractility. Various experimental approaches including X-ray diffraction^[139], simultaneous recording of heat generation^[140]

and the measurement of the work of isolated muscle^[141] have been used to investigate cardiac performance at the level of the sarcomere and cardiomyocyte. These approaches show that impaired cyclic transfer of myosin heads to actin filaments contributes to contractile dysfunction at the sarcomere level at the onset of diabetes. Moreover, CB dysregulation is also observed in the prediabetic state in the heart of insulin resistant animals.

A significant reduction in CB cycling has been reported in isolated cardiac muscle from early diabetic rats, due to a preferential shift to the less efficient β -MHC isoform^[123,124]. Indeed the time required for CB detachment is inversely related to the proportion of α -MHC expression in isolated ferret papillary muscle, attesting to a clear role for β -MHC content in prolonging CB kinetics^[142]. Joseph *et al.*^[143] demonstrated a reduced rate of CB attachment and detachment due to diabetes in *ex vivo* papillary muscle, as well as a significant reduction in the total number of CBs recruited, without a change in force developed per CB. Impaired CB dynamics in this preparation was attributed to a slower myosin ATPase turnover^[143]. Accordingly, T1DM is claimed to have no discernible effect on CB mechanical efficiency in isolated trabeculae from rats^[144]. Although it is important to recognize that in contrast to Joseph *et al.*^[143], the estimated number of CBs attached during contraction did not differ between control and diabetic rats in the study of Han *et al.*^[144]. Recent X-ray diffraction studies conducted by our group affirm these previous findings when CB dynamics are determined across the different layers of the ventricular muscle *in situ*, in the hearts of early diabetic^[101] and prediabetic insulin resistant rats^[139]. We demonstrated significant myosin head displacement from actin filaments throughout the cardiac cycle, but especially at end diastole, in the rat heart three weeks post STZ induction^[101]. Reduction in the proximity of myosin heads to actin filaments at end diastole was directly correlated with a prolonged LV pressure decay rate in diabetic rats. Further, a transmural gradient was found in actin-myosin separation, being most pronounced in the deeper subendocardial layer^[101]. However, we also found that the change in CB transfer to actin under β -adrenergic stimulation was comparable in control and diabetic rats suggesting that the impairment of the contractile apparatus precedes that of the β -adrenoceptor signaling^[101]. In young prediabetic GK rats, we also found significant myosin head displacement from actin at end diastole in the subendocardial layer of the LV wall^[139]. It is still unclear if these altered CB dynamics translate to significant LV dysfunction, but fiber shortening and Ca²⁺ transients are reported to be more prolonged in young GK rats^[113].

It is noteworthy that X-ray diffraction recordings from the *in situ* beating heart demonstrate in both STZ induced diabetic rats and young prediabetic GK rats that myosin-myosin separation (interfilament spacing) does not differ from that of controls, and therefore altered myosin head distribution cannot be explained by a

Figure 3 Illustration of the cardiac sarcomere indicating the location of actin thin-filament and myosin thick-filament accessory proteins involved in the regulation of actin-myosin cross-bridge dynamics and kinetics. C0-C10: Immunoglobulin-like and fibronectin-like domains of myosin binding protein C; MD: M-domain of myosin binding protein C containing protein kinase phosphorylation sites.

difference in sarcomere length^[101]. Since alterations in thin filament complex cannot explain changes in myosin head extension (despite being a critical determinant of Ca^{2+} sensitivity and CB cycling rates), this implies that modifications to thick filament proteins that regulate myosin head extension are likely to be involved in the impaired CB dynamics and contractile dysfunction in early DCM.

The thick filament accessory proteins - regulators of myosin head extension

Two major proteins reside within the myosin thick filament complex that regulate myosin head extension, namely myosin light chain-2 (MLC2), otherwise known as regulatory light chain and cardiac myosin binding protein-C (cMyBP-C) (Figure 3). Detailed information on the complex molecular structure and broader physiological functions of both these proteins is beyond the scope of this paper but has been reviewed extensively by others (see reviews^[145-149]).

It is well accepted that MLC2 and cMyBP-C regulate myosin head extension by means of kinase phosphorylation. In the case of MLC2, phosphorylation is tightly regulated by MLC kinase and Ca^{2+} /calmodulin-dependent protein kinase (CaMK), and is dephosphorylated by MLC phosphatase (see review^[150]). X-ray diffraction experiments conducted by Colson *et al.*^[151] reveal that the negative charge created on the myosin neck when MLC2 is phosphorylated, repels the negative charge of the myosin backbone and thus, subsequently the myosin heads are displaced toward the actin filament.

cMyBP-C is a multifunctional protein within the sarcomere that is primarily involved in the regulation of contractility^[152-155] and the organization and structural maintenance of the sarcomere^[156-158]. cMyBP-C prevents myosin head projection toward actin by a "tethering"

mechanism^[159], however, upon phosphorylation, the molecular tether mechanism is released and myosin heads are freed to be displaced towards actin^[160,161]. As protein kinase A (PKA) is the primary kinase that phosphorylates cMyBP-C, it is thought that under β -adrenergic stimulation, cMyBP-C works in cooperation with the troponin complex to maintain force development and adequate relaxation and LV filling at higher heart rates^[151]. In support of this proposed role, cMyBP-C phosphorylation by PKA evokes radial displacement of myosin heads toward actin in isolated cardiac muscle^[162]. To date, seventeen phosphorylation sites have been identified on cMyBP-C^[163], however three (Ser273, Ser282, Ser302)^[164] have been identified as crucial regulators of contractility, which are all located within the M-domain of cMyBP-C (Figure 3). CaMK is also able to phosphorylate cMyBP-C at these sites in a Ca^{2+} dependent manner and thereby play a potentially important role in regulating contractile function independent of changes in intracellular Ca^{2+} transients^[165,166].

Several studies have demonstrated diminished phosphorylation of cMyBP-C in experimental^[167,168] and human^[163,168,169] non-diabetic cardiac disease. Although there is paucity of information in the literature, some evidence suggests that MLC2 and cMyBP-C phosphorylation are also reduced in DCM. In the hearts of diabetic rats, a significant depression of MLC2 phosphorylation is reported, accompanied by prolonged LV pressure development and decay rates^[170]. Diabetic swine also exhibit significantly reduced cMyBP-C phosphorylation^[171]. Most recently, in a rat model of early DCM, MLC2 phosphorylation was significantly reduced in comparison to normoglycemic controls while cMyBP-C phosphorylation remained unchanged^[123].

It should also be appreciated that other kinases including $\text{PKC}\beta_2$ and ROCK can directly phosphorylate cMyBP-C, and thus, potentially impact on contractile

function, without appreciably altering pan phosphorylation state. In isolated rat cardiomyocytes, increased PKC β_2 expression did not change pan phosphorylation of cMyBP-C despite prolonging rates of shortening and relaxation, but phosphorylation of Ser302 in particular was significantly increased^[172]. Taken together with the finding that phosphorylation Ser302 on cMyBP-C modulates CB kinetics^[173], this suggests that the contractile dysfunction observed in the isolated cardiomyocytes may, in part, be a result of altered CB dynamics. Others have also demonstrated active ROCK directly phosphorylates cMyBP-C in cardiomyocytes^[174]. Therefore, it is possible that cMyBP-C phosphorylation by PKC β_2 and ROCK may not alter pan phosphorylation, but may indeed impair CB dynamics by displacing myosin heads from the thin filaments and slowing rates of CB attachment and detachment. At the very least, thick filament accessory proteins probably play a role in contractile dysfunction in early DCM, although this requires further investigation.

The actin thin filament troponin complex could changes in calcium sensitivity contribute to early DCM?

Much of our previous discussion has focused on diabetes impact on the myosin thick filament, however we cannot overlook the importance of the actin thin filament in modulating cardiac contractile properties. The heterotrimeric cardiac troponin (cTn) complex is comprised of cTnC (Ca²⁺ reception site), cTnT and cTnI, the latter two are involved in the transduction of the Ca²⁺-binding signal (Figure 3). The multiple interactions of cTnI and cTnT with actin and tropomyosin regulate CB kinetics and the number of recruited CBs (reviewed in^[175]) (Figure 3).

cTnI is widely recognized to be the principle regulator of CB kinetics and myofilament sensitivity of the thin filament. Under physiological conditions, increased cTnI phosphorylation at Ser23/24 by PKA (which usually occurs under β -adrenergic stimulation) leads to decreased myofilament Ca²⁺ sensitivity and accelerated CB dissociation, and thus hastened relaxation^[176]. However, under pathophysiological conditions when expression and activity of PKC isoforms are elevated, PKC rather than PKA predominantly phosphorylates cTnI^[177]. Ca²⁺ sensitivity is decreased by PKC phosphorylation at Ser23/24 of cTnI in a manner similar to physiological phosphorylation by PKA, but in contrast, phosphorylation of other sites (Ser44/45 and Thr144) slow CB cycling and sliding velocity and impair relaxation^[176]. Thus, PKC-mediated phosphorylation of cTnI may partly explain contractile dysfunction in advanced DCM. Many studies have demonstrated that depressed myofilament Ca²⁺ sensitivity and PKC-induced increases in cTnI phosphorylation are observed in the hearts of rats after eight to twelve weeks of T1DM^[178-180].

In early DCM however, there are some conflicting findings regarding the contribution of cTnI. One study found that cellular PKC ϵ translocation paralleled a 5-fold increase in cTnI phosphorylation^[181]. Importantly, neither

cardiomyocyte function nor myofilament Ca²⁺ sensitivity was examined in this study. Conversely, others reported no changes in cTnI phosphorylation or myofilament calcium sensitivity four weeks post T1DM induction^[123]. Therefore, there are some uncertainties as to the role of cTnI changes in early DCM. Given the strong evidence implicating cTnI in chronic diabetes models, this may only be a prominent driver of contractile dysfunction in the advanced stages of DCM.

Interestingly, ROCK is able to phosphorylate multiple sarcomeric proteins. Vahebi *et al.*^[174] revealed a direct role for ROCK activation in depressing myofilament tension development and ATPase activity *via* phosphorylation of cTnT of the thin filament complex, independent of MLC2 phosphorylation. A possible limitation of these findings is that the authors used constitutively active ROCK2, and whilst many other studies have demonstrated functional changes in diabetes with selective ROCK inhibition, not all have found an increase in ROCK phosphorylation^[102,182]. Nonetheless, there is evidence to suggest an increase in ROCK activation in diabetes could contribute to reduced CB cycling through modulation of the thin filament, as well as the thick filament.

OTHER EXACERBATING RISK FACTORS OF DCM

In the clinical setting, DCM is rarely diagnosed independent of any additional risk factors, however, the cumulative effects of multiple risk factors in insulin resistance and diabetes has been rarely considered in preclinical studies. Risk factors that have been shown to exacerbate these disease states include hypertension and obesity, both commonly present with T2DM in patients (reviewed by reference^[183]). Hypertension alone is a serious risk factor for the development of diastolic heart failure. Raised systolic blood pressure associated with hypertension evokes an increase in cardiac afterload and accordingly, vascular remodeling and LV hypertrophy ensue as pathophysiological adaptations to maintain cardiac output. Several decades earlier, Factor *et al.*^[184] showed that diabetes combined with hypertension increased microvessel tortuosity, microaneurysms and focal constrictions more than either disease state alone, which would increase the risk of myocardial ischemia. Activation of the RAAS and sympathetic nervous system (SNS) in the hypertensive state leads to fibrosis and cardiomyocyte hypertrophy, ultimately leading to diastolic dysfunction (see review^[185]). In the context of early DCM where LV structural remodeling is normally absent, the additive effect of hypertension may accelerate cardiomyocyte subcellular dysfunction. Jeong *et al.*^[186] have demonstrated that diastolic dysfunction in deoxycorticosterone acetate treated hypertensive mice is driven by oxidative stress modifications to cMyBP-C, which subsequently suppresses CB kinetics^[186]. Further, chronic activation of ROCK plays a central role in most forms of hypertension and diabetic coronary

dysfunction^[87,102]. Thus, hypertension may exacerbate the development of cardiac dysfunction in early DCM by redox modifications of various sarcomeric proteins, disturbed CB dynamics and increased oxidative stress.

Obesity (in particular abdominal obesity) is a risk factor for the development cardiac dysfunction and heart failure, independent of diabetes^[187]. Several metabolic and neurohormonal mechanisms have been postulated to contribute to obesity-induced cardiomyopathy (see review^[188]). Of particular interest, is the interplay of the SNS and the RAAS, which occurs during obesity^[189,190]. Classically, obesity leads to activation of the SNS, which in turn rapidly activates the production of renin from the renal juxtaglomerular apparatus as well as angiotensinogen from adipocytes and thus, promotes the excessive production of ANG II. Consequently, systemic hypertension ensues (reviewed in^[189]). Given our previous discussion on hypertension-induced modulation of sarcomeric proteins leading to diastolic dysfunction^[186], it is plausible that obesity may exacerbate DCM in patients *via* the promotion of systemic hypertension. On the other hand, obesity may also exacerbate DCM by directly increasing SNS outflow to the heart. In normotensive obese patients, increased LV mass correlates with elevated cardiac SNS activity^[191]. Considering the hypertrophic and fibrotic actions of ANG II, elevated local RAAS activity driven by activation of the cardiac SNS could, in part, explain increased LV mass in obese patients. In addition, one study has shown that a high fat diet induced mitochondrial lesions and depressed mitochondrial density in the hearts of GK rats^[192]. Therefore, obesity induced activation of the SNS in combination with diabetes may indeed exacerbate DCM.

Lastly, gender must also be considered as an additional risk factor for the development, progression and severity of DCM (reviewed in detail by^[193]). Indeed, the Framingham Heart study revealed that diabetic women had twice the frequency of heart failure in comparison to diabetic men^[22]. More recent clinical evidence suggests that although non-diabetic women appear to have more pronounced endothelium-mediated dilation (due to higher rates of nitric oxide production), T2DM abrogates these sex differences in vascular function^[194]. Female mice also lose this vascular protection with T2DM^[182]. Although, similar vascular dysfunction is observed in both sexes, the molecular mechanisms underlying this dysfunction in males appears to be elevated ROCK activity, however this does not appear to be the case in female mice^[182]. The impact of sex on myocardial function in diabetes is less clear. Early in the time course of experimental T1DM, it appears that male rats are more vulnerable to cardiac dysfunction. Five to six weeks of STZ induced diabetes in rats caused greater prolongation of the rates of pressure development and decay in diabetic male rats in comparison to their female counterparts^[195-197]. However, others have demonstrated that female rats after four weeks from STZ induction exhibit significantly

lower MLC2 phosphorylation compared to diabetic males despite equivalent impairment in cardiac muscle tension development in both male and female diabetic rats^[123]. Sex differences in the loss of cardiomyocytes may contribute to differential changes in contractile function in diabetes. Females respond to metabolic stresses with greater myocardial glycogen accumulation and elevated glycogen-induced autophagy than males^[198,199]. Thus, the underlying mechanisms of sex differences in DCM require a great deal of research to appreciate which of the factors we have identified in this review differ between sexes and how the pathophysiology of diabetes might be compounded by other risk factors in females.

CONCLUSION

In summary, DCM is a progressive disease beginning with contractile dysfunction ahead of LV remodeling. A number of subcellular alterations to the cardiomyocyte contribute to contractile dysfunction in early DCM. While changes in Ca²⁺ handling protein expressions are evident and likely contribute to the prolongation of systole and relaxation, diminished intracellular Ca²⁺ transients appear to be associated only with advanced DCM. Diastolic LV dysfunction has its origins in changes in sarcomeric and other cytoskeletal proteins, both due to transcription and posttranslation changes. Upregulation of PKC β 2 activity is proposed as a central factor in the development of DCM, promoting the activity of both oxidative stress dependent and independent pathways to drive contractile dysfunction in early DCM. Independent of oxidative stress we suggest that hyperglycemia alters modulation of the sarcomeric thick-thin filaments through PKC β 2/ROCK activation. It is not known if any of these pathological changes in sarcomere function are exacerbated by other risk factors such as hypertension and obesity.

Abstract

Peripheral artery disease (PAD) is the atherosclerosis of lower extremity arteries and is also associated with atherothrombosis of other vascular beds, including the cardiovascular and cerebrovascular systems. The presence of diabetes mellitus greatly increases the

risk of PAD, as well as accelerates its course, making these patients more susceptible to ischemic events and impaired functional status compared to patients without diabetes. To minimize these cardiovascular risks it is critical to understand the pathophysiology of atherosclerosis in diabetic patients. This, in turn, can offer insights into the therapeutic avenues available for these patients. This article provides an overview of the epidemiology of PAD in diabetic patients, followed by an analysis of the mechanisms by which altered metabolism in diabetes promotes atherosclerosis and plaque instability. Outcomes of PAD in diabetic patients are also discussed, with a focus on diabetic ulcers and critical limb ischemia.

Core tip: Diabetes mellitus (DM) is a major risk factor of peripheral artery disease (PAD), leading to increased morbidity and mortality as well as an accelerated disease course. As such, a more thorough understanding of the multi-factorial mechanisms underlying disease etiology for both DM and PAD is justified. This review provides clinical insight into the current state of research in the pathophysiology of PAD in diabetic patients, as well as highlights the progress of endovascular interventions for PAD, with a focus on techniques that have shown promise for treatment of critical lower limb ischemia.

INTRODUCTION

Over 170 million people worldwide have diabetes mellitus (DM) and the worldwide burden is projected to increase to 366 million people by 2030^[1,2]. The major causes of DM include impaired insulin secretion or inadequate response to secreted insulin^[3]. DM is a major risk factor for atherosclerotic disease as well as cardiovascular mortality and morbidity^[3,4]. Atherosclerotic disease is not only increased in incidence in diabetic patients, but its course is also accelerated^[4], thereby accounting for as much as 44% of all-cause mortality^[5]. DM-associated atherosclerosis can lead to complications in all major of vascular beds, including the coronary arteries, carotid vessels, and lower extremity arteries^[5,6]. For example, a study by Haffner *et al.*^[7], estimated the 7-year incidence of a first-time myocardial infarction (MI) in diabetic patients at 20.2%, compared to 3.5% in nondiabetic patients.

Peripheral artery disease (PAD) is defined as atherosclerotic occlusive disease of lower extremities. PAD is associated with increased risk of lower extremity amputation and is also a marker for atherothrombosis in cardiovascular, cerebrovascular and renovascular beds. Patients with PAD therefore have an increased risk of MI, stroke and death^[8]. Additionally, PAD causes significant long-term disability in diabetic patients^[5,9]. The treatment of patients with PAD can therefore be expensive, owing to need for a variety of diagnostic tests, therapeutic procedures, and hospitalizations^[10].

The purpose of this article is to review the epidemiology and mechanisms that contribute to development of PAD in diabetic patients. The outcomes of PAD in diabetic patients are also compared to nondiabetics, with an emphasis on the prevention of major amputations among patients with DM who have severe PAD.

EPIDEMIOLOGY OF PAD IN PATIENTS WITH DIABETES

PAD affects 12 million people in United States. The most common symptom in PAD is claudication, characterized as a cramping, pain or aching in the calves, thighs or buttocks with exertion and relief with rest^[8]. However, many patients have atypical symptoms that may require formal testing with an ankle brachial index test to diagnose PAD^[11].

The strongest risk factors for PAD are DM and smoking, with an odds-ratio of 2.72 and 1.88, respectively^[12]. With decreased rates of smoking in Western countries, DM is projected to become an increasingly important contributor to the development and progression of PAD. Previous studies have shown that glucose intolerance is associated with a greater than 20% prevalence of an abnormal ankle-brachial index (ABI) relative to 7% in those with normal glucose tolerance^[4]. Moreover, 20%-30% of patients with PAD have DM, although this is likely underestimated by the asymptomatic nature of less severe PAD and the altered

pain perception in diabetic patients due to peripheral neuropathy^[5].

Age, duration of diabetes, and peripheral neuropathy are associated with an increased risk of PAD in patients with pre-existing DM^[8,12]. Using ABI to identify PAD, the prevalence of PAD in people with DM over 40 years of age has been estimated to be 20%^[13]. This prevalence increases to 29% in patients with DM over 50 years of age^[5,14]. The severity and duration of DM are important predictors of both the incidence and the extent of PAD, as observed in United Kingdom Prospective Diabetes Study, where each 1% increase in glycosylated hemoglobin was correlated with a 28% increase in incidence of PAD, and higher rates of death, microvascular complications and major amputation^[15,16]. This correlation is particularly strong in men with hypertension or active tobacco use^[5]. Patients with PAD who have DM also tend to stay longer in hospital, incur greater costs, and account for greater use of hospital resources compared to patients with PAD alone^[10,17].

DM is also associated with more severe below-the-knee PAD (e.g., popliteal, anterior tibial, peroneal and posterior tibial arteries), whereas risk factors such as smoking are associated with more proximal PAD in the aorto-ilio-femoral vessels^[8,16]. The prevalence of concomitant PAD and DM is especially high in those patients who have critical lower limb ischemia, with more than 50% of patients with critical limb ischemia (CLI) also having DM^[18].

In patients with PAD, the cardiovascular event rate over a 5-year period, including MI and stroke, is 20%, and the overall mortality rate is 30%^[19]. Among those with CLI, 30% undergo major amputation, and the 6-mo mortality rate is 20%^[20]. Diabetic patients comprise 25%-30% of patients undergoing coronary artery revascularization and up to 60% of patients presenting with acute MI^[21-23]. Cardiovascular and cerebrovascular event rates, both fatal and non-fatal, are increased in patients with PAD and DM relative to nondiabetic patients with PAD^[8].

Similar to the greater likelihood of diffuse and complex coronary artery disease in diabetic patients, patients with DM also tend to have more diffuse PAD, compared to the more focal disease observed in those without DM^[1,5,24]. Although patients with DM tend to present later in the course of disease progression, the incidence of intermittent claudication is also higher than in nondiabetics, as seen in Framingham study^[5,25]. In that cohort, the risk of claudication associated with DM was increased by 3.5 fold in men and 8.6 fold in women^[25]. Concomitant peripheral neuropathy, which diminishes sensory feedback and leads to a lack of symptoms from minimized pain perception, may predispose patients with DM and PAD to present with more advanced disease, such as an ischemic ulcer or gangrene, compared to patients without DM^[8]. The prevalence of major amputation in patients with DM is also higher than in nondiabetics, with rates ranging from 5 to 15 times greater in some studies^[8,16]. In a Medicare population, relative

to nondiabetic patients, the relative risk (RR) for lower extremity amputation was 12.7 in diabetic patients. The RR rose to 23.5 in a cohort aged 65–74 years^[4].

The risk relationship between PAD and DM is noted to be reciprocal: while DM is a risk factor for PAD, higher rates of PAD, up to 30%, have been found in diabetic patients^[26]. The Hoorn study further clarified the discrepancy in prevalence of PAD between diabetic and nondiabetic patients: glucose intolerance was associated with 20.9% prevalence of an ABI less than 0.9, relative to 7% in those with normal glucose tolerance^[27]. Moreover, the prevalence of PAD in diabetic patients is likely underestimated by the asymptomatic nature of the condition, lack of reporting by the patients, and the altered pain perception in diabetic patients due to peripheral neuropathy^[11,26].

MECHANISMS OF PAD IN PATIENTS WITH DIABETES

DM is characterized by hyperglycemia, dyslipidemia, and insulin resistance^[4,28–30]. These pathologic states foster development and progression of PAD through mechanisms similar to that in coronary or carotid artery disease^[31,32]. These mechanisms include derangements in the vessel wall through promotion of vascular inflammation and endothelial cell dysfunction; abnormalities in blood cells, including smooth muscle cells and platelets; and factors affecting hemostasis (Table 1). Such vascular abnormalities that cause atherosclerosis in DM patients are often prevalent prior to the diagnosis of DM, and their severity increases with worsening blood glucose control and duration of DM^[8,33]. Taken together, these mechanisms likely contribute to increased plaque burden, plaque instability, and greater complexity of vascular disease^[3,34–36].

Inflammation

Inflammation is a risk marker for atherothrombosis. Among biomarkers of inflammation, C-reactive protein (CRP) is associated with both the development of PAD and impaired glucose regulation^[37]. CRP may also play a direct pathophysiologic role by promoting production of procoagulant tissue factor, leukocyte adhesion molecules, and chemotactic substances. CRP causes derangement in vascular tone by inhibiting endothelial nitric oxide synthase (eNOS), which produces nitric oxide (NO) *via* phosphoinositol-3-kinase dependent pathway^[3,8,38]. Moreover, CRP impairs fibrinolysis *via* the production of substances such as plasminogen activator inhibitor (PAI)-1, which blocks the breakdown of plasminogen into plasmin, a fibrinolytic^[39]. All of these factors in diabetic patients increase the susceptibility of vascular walls to the development of atherosclerosis^[40].

DM is also associated with increased circulating levels of pro-inflammatory cytokines such as tumor necrosis factor (TNF)- α and interleukin-6^[41,42]. These cytokines bind to endothelial cell surface receptors and activate nuclear

factor (NF)- κ B. This process promotes transcription of endothelial cell adhesion molecules, leading to increased binding of leukocytes and platelets to the endothelial surface, thereby fostering thrombogenesis. Plaque inflammation and instability may also be enhanced due to the increased leukocyte migration, which is associated with an increased risk of rupture and subsequent thrombus formation^[3,40,43].

Endothelial dysfunction

Endothelial cells mediate the interaction between blood cell elements and the vascular wall, thereby affecting blood flow, nutrient delivery, coagulation, and the balance between thrombosis and fibrinolysis^[8,44]. Endothelial cells also release substances that are critical for blood vessel function and structure, including NO, reactive oxygen species, and endothelin^[4,44]. Insulin is critical for the induction of phosphoinositol-3 kinase signaling, leading to production of NO and subsequent smooth muscle cell relaxation^[38,45]. NO also inhibits platelet activation and limits vascular smooth muscle cell (VSMC) migration and proliferation^[46–48]. By mediating the interaction between leukocytes and the vascular wall, NO also plays an important role in vasodilation and inflammation^[8,44].

Hyperglycemia, insulin resistance, and free fatty acid (FFA) production all reduce NO bioavailability in diabetic patients. Hyperglycemia impairs eNOS function, promoting oxidative stress by producing reactive oxygen species in endothelial and VSMCs^[38,49]. In turn, these factors inhibit endothelial vasodilation^[4,38,44]. Insulin resistance induces excess production of FFAs, which activate protein kinase C (PKC), inhibit phosphatidylinositol (PI)-3 kinase (an important agonist of eNOS), and produce reactive oxygen species^[24,28,50,51]. These mediators inhibit NO production and decrease its bioavailability, thereby causing endothelial dysfunction and leading to greater susceptibility of the vascular bed to atherosclerosis^[8,24,38,44,49–51].

DM is also associated with the enhanced production of advanced glycation end products (AGEs), which are formed by binding of reducing sugars to free amino groups *via* the Maillard reaction^[3,52–54]. The interaction of AGEs with their receptors can upregulate the synthesis of pro-inflammatory transcription factors such as NF- κ B and activator protein 1^[54]. In addition to decreased endothelial function and impaired NO formation, these factors also lead to increased leukocyte chemotaxis, adhesion, transmigration, and transformation into foam cells. The latter process is the first step in the formation of atheromatous plaque^[8].

VSMC

VSMC migration from the medial layer into the intimal layer is associated with deposition of complex extracellular matrix, thereby stabilizing the atheroma. This decreases the risk of plaque rupture associated with thrombosis^[4,48,55,56]. In diabetic patients, plaques have fewer VSMC, increasing the chance of rupture and

Table 1 Mechanisms of peripheral arterial disease in diabetes mellitus patients

Disease characteristics		Mechanisms of pathology	Disease characteristics	
DM	Hyperglycemia Dyslipidemia Insulin resistance ↑ FFA production	<p>→ Vascular inflammation</p> <p>CRP: promotes leukocyte adhesion, coagulation, and chemotaxis; inhibits eNOS; impairs fibrinolysis</p> <p>TNF-α and IL-6: activate NF-κB, leading to thrombogenesis; promote leukocyte migration and adhesion, increasing plaque instability/rupture</p> <p>Endothelial cell dysfunction</p> <p>Decreased NO production: inhibits vasodilation</p> <p>Increased reactive oxygen species: inhibits vasodilation</p> <p>Increased AGE production: is proinflammatory; induces leukocyte chemotaxis, adhesion, and transformation into foam cells</p> <p>Vascular smooth muscle cell derangement</p> <p>Tissue factor production: proatherogenic; procoagulation</p> <p>FGF and TGF-α: Extracellular matrix production</p> <p>Impaired synthesis of collagen: destabilizes plaque</p> <p>Apoptosis of VSMC: increases risk of plaque rupture and thrombosis</p> <p>Increased production of endothelin-1, angiotensin II, and prostanoids: leads to vasoconstriction</p> <p>Platelet dysfunction</p> <p>Enhanced uptake of glucose: increases oxidative stress; decreased NO production</p> <p>Upregulation of P-selectin, GP I b, and GP II b/IIIa receptors: promotes platelet adhesion and aggregation</p> <p>Calcium dysregulation: increases platelet aggregation</p> <p>Hypercoagulability</p> <p>Increased tissue factor and FVII production: enhances coagulability</p> <p>Decreased antithrombin and protein C synthesis: enhances coagulability</p> <p>Rheology</p> <p>Elevated blood viscosity</p> <p>Increased fibrinogen production</p> <p>Impaired arteriogenesis</p> <p>Inhibited sensing of shear stress</p> <p>Decreased monocyte and growth factor signaling</p>	<p>→ Atherosclerosis (Increased plaque burden)</p> <p>Atherothrombosis (Increased plaque instability/rupture)</p> <p>Restenosis (Increased complexity)</p>	PAD

Note that there is significant interplay between the different mechanisms: for example, impaired NO production can affect inflammation, endothelial cell function and arteriogenesis, while increased reactive oxygen species causes platelet and endothelial cell dysfunction. FFA: Free fatty acids; CRP: C-reactive protein; eNOS: Endothelial nitric oxide synthetase; TNF- α : Tumor necrosis factor- α ; IL-6: Interleukin-6; NF- κ B: Nuclear factor- κ B; NO: Nitric oxide; AGE: Advanced glycation end products; FGF: Fibroblast growth factor; TGF- α : Transforming growth factor- α ; VSMC: Vascular smooth muscle cell; GP I b: Glycoprotein I b; GP II b/IIIa: Glycoprotein II b/IIIa; FVII: Factor 7; DM: Diabetes mellitus; PAD: Peripheral artery disease.

thrombosis^[57]. Moreover, the lipid modifications noted in diabetic patients, such as glycated oxidized low-density lipoprotein, can promote apoptosis of VSMC^[4,46]. The metabolic syndrome that defines DM results in enhanced production of reactive oxygen species, inhibition of PI-3 kinase and upregulation of PKC, AGE receptors and NF- κ B, which in turn further promotes an atherogenic phenotype in VSMCs^[4,58]. These factors further contribute to the increased apoptosis of VSMC and upregulation of proatherogenic tissue factor in diabetic patients, while impairing synthesis of collagen, an important plaque-stabilizing compound^[8,59]. DM is also associated with increased matrix metalloproteinases, which further break down collagen, leading to plaque instability^[60]. Therefore, DM not only promotes atherosclerosis but also destabilizes plaques, triggering thrombus formation and impacting clinical outcomes^[8].

DM has also been found to promote upregulation and enhanced activity of endothelin-1, a protein that activates the endothelin-A receptor on VSMCs, leading to enhanced vascular tone^[61]. Such dysregulated hyperactivation

of endothelin-A receptor can cause pathological vasoconstriction^[62]. Endothelin-1 is also responsible for increasing salt and water retention, inducing the renin-angiotensin system, and causing vascular smooth muscle hypertrophy. Other vasoactive substances, such as vasoconstrictor prostanoids and angiotensin II, are also increased in production, further inducing vasoconstriction^[63].

Platelet function

Platelets mediate the interaction between vascular function and thrombosis. Hence, platelet dysfunction can accelerate atherosclerosis, as well as impact the destabilization of plaque and promote atherothrombosis^[8,64]. Platelets take up glucose independent of insulin, which in turn activates protein kinase-C and decreases NO production^[39]. Oxidative stress is also increased when platelets take up glucose, thus promoting platelet aggregation. Platelet adhesion is enhanced in diabetic patients due to upregulated expression of P-selectin on platelet surfaces^[3].

Diabetic patients also have upregulated expression of platelet receptors, such as glycoprotein I b (which binds to von Willebrand Factor) and II b/III a receptors (integral to platelet-fibrin interaction); these receptors mediate platelet adhesion and aggregation, thus inducing thrombosis^[39]. Intra-platelet calcium regulation, important for regulation of platelet shape change and aggregation, as well as for thromboxane production, is also deranged in diabetic patients, further contributing to atherosclerosis in this patient population^[4,39,65,66].

Coagulation

DM and hyperglycemic states promote hypercoagulability *via* upregulation of tissue factor by endothelial cells and VSMCs^[67,68]. These conditions also increase coagulation factor VIIA production and decrease anticoagulants, such as antithrombin and protein C production^[67,68]. DM also impairs fibrinolytic function and induces PAI-1 production^[69]. Taken together, these factors increase the risk of atherosclerotic plaque rupture and subsequent thrombus formation^[8,68,70].

Rheology

Elevated blood viscosity and fibrinogen production also occur in patients with DM. This is manifested *via* abnormal ABI in patients with PAD as well as development and complications of PAD^[8,71].

Restenosis after angioplasty

Acutely elevated glucose levels may induce inflammation, smooth muscle proliferation, abnormal matrix production, and inactivation of endothelium-derived relaxing factor^[72]. Additionally, hyperglycemia may impact expression of fibroblast growth factor and transforming growth factor- α , which in turn promotes proliferation of smooth muscle cells and extracellular matrix production. Increased TNF- α and CRP, as well as oxidative stress and endothelial dysfunction, may also play roles in explaining the restenosis rates in patients with higher blood glucose values at time of angioplasty^[73]. Acute hyperglycemia also induces production of monocyte chemoattractant-protein-1, which has been linked with a higher risk of restenosis^[73]. Restenosis among patients with DM can therefore be explained by the abnormal inflammatory state, oxidative stress, endothelial and platelet function in patients with acute hyperglycemia^[1].

Arteriogenesis

Outward remodeling of pre-existing arteries in response to obstruction of blood flow to restore blood flow distal to the occlusion is termed arteriogenesis^[74]. Endothelial shear stress, detected by the vessel wall through integrins, adhesion molecules, tyrosine kinases, and ion channels, is hypothesized to be the main trigger for arteriogenesis^[45,75,76]. DM limits the adaptive arteriogenesis response and collateral blood flow development by attenuating the remodeling process^[77,78]. Specifically, diabetes attenuates the sensing of shear

stress and increases the response to vasodilatory stimuli, which reduces the recruitment and dilation of collateral arteries. Additionally, DM impairs various other factors critical to remodeling, such as the downstream signaling of monocytes, growth factor signaling, and endothelial NO synthetase, thus inhibiting arteriogenesis and contributing to the severity of occlusive disease in these patients^[74].

OUTCOMES OF PATIENTS WITH PAD AND DM

The outcomes of patients with coexistent diabetes and PAD depend on the interplay between factors such as patient comorbidities, presence of infection, neuropathy, and immunologic factors^[79]. Poor glycemic control has been associated with a higher prevalence of PAD and risk of adverse outcomes, including need for lower extremity bypass surgery, amputation or death^[80]. Poor glycemic control is also associated with worse outcomes following vascular surgery or endovascular intervention^[80].

It is therefore important to identify therapies that can affect the multifactorial pathophysiologic mechanisms of DM in order to provide effective long-term treatments^[3]. Lifestyle interventions, such as weight loss, physical activity, and reduced cholesterol and fat intake, all help reduce the risk of progression from glucose intolerance to diabetes, as well as improve cardiovascular risk factors^[81]. Tobacco cessation is also critical and has been associated with improved outcomes after surgical and endovascular interventions. Such secondary risk factor reduction can help reduce the prevalence and severity of PAD in diabetic patients and also minimize adverse events post revascularization^[3].

Revascularization in patients with PAD and diabetes

Revascularization, either *via* a surgical or endovascular approach, is an important therapeutic option for treatment of symptomatic PAD in diabetic patients^[5]. Due to the greater prevalence of below-the knee disease in patients with DM, some studies have shown that endovascular interventions are associated with worse outcomes in diabetics, especially as distal runoff diminishes^[4]. Endovascular interventions were initially therefore considered more appropriate in patients with focal disease above the knee. Diabetic patients were also noted to have greater durability with surgical approach to revascularization, especially in the setting of tibial disease managed *via* bypass with autologous saphenous vein^[5]. However, recent studies have suggested that diabetic patients with adequate distal runoff appear to have patency rates comparable to that of nondiabetics^[4].

This association of glucose control and vessel patency has been investigated in a single-center retrospective study of outcomes after infrapopliteal balloon angioplasty among diabetic patients. Patients were divided based on median pre-procedure fasting blood glucose (FBG) values into two groups. At one-year follow-up, primary patency,

defined as freedom from restenosis or reintervention based on duplex ultrasound, was 16% for those with FBG values above the median and 46% for patients with below the median FBG values. Amputation rates also trended higher among patients with high pre-procedure FBG compared to low FBG. One-year major adverse limb event rates were significantly higher for patients with FBG values above the median, even after adjusting for insulin use and lesion-specific characteristics. No association between FBG values and overall mortality, amputation-free survival or rates of major adverse cardiovascular events was noted^[80]. When the FBG levels were divided into quartiles, a fivefold increase was noted in primary patency in the lowest quartile of FBG relative to those in the highest quartile of FBG. These results remained significant even after adjusting for baseline insulin use. These outcomes failed to show an association between HbA1C and restenosis, therefore implying that glycemic control at the time of intervention may be a better predictor of primary patency than overall glycemic control^[80]. Furthermore, these results suggest that the acute metabolic milieu at the time of intervention plays an important role in restenosis.

Treatment of critical limb ischemia

In patients with CLI, revascularization is usually required for successful limb preservation^[5]. The prevalence of DM in patients with CLI is extremely high, with some studies suggesting a prevalence of up to 76%^[18]. Disease severity at the time of presentation and progression of CLI in diabetics has also been noted to be worse^[82]. Current recommendations suggest arterial reconstruction in patients with CLI who have a predicted 1-year amputation-free survival of at least 75%^[18].

While patients with CLI may require multiple procedures and close follow-up, the choice of initial revascularization does not appear to influence success in diabetic patients with CLI^[18]. Whether chosen initially or subsequently, surgical and endovascular approaches both are associated with similar outcomes in terms of survival without major amputation or repeated target extremity revascularization (TER)^[18]. However, that study did confirm that repeat TER is more frequently required in diabetic patients. Despite the increased need for repeat revascularization, repeated procedures were associated with overall success rates comparable to that in nondiabetic patients^[18]. Immediate revascularization was also associated with improved outcomes relative to delayed revascularization in patients with CLI, regardless of diabetic status^[13]. Additional studies have also shown that an aggressive multidisciplinary approach in diabetic patients who present with CLI had similar limb salvage, 30-d mortality, cumulative survival, amputation-free survival, and major amputation rates, relative to nondiabetic patients^[83]. Revascularization rates do appear to be better in this patient population when both endovascular and bypass grafting procedures are available relative to one of the two approaches only^[84].

While most patients with CLI can be revascularized,

the presence of irreversible gangrene, the absence of a target vessel, and the lack of availability of an autologous vein can limit successful limb preservation. In these patients, amputation may be the best option^[5]. In general, however, medical management and use of multidisciplinary approach that includes revascularization can lead to reduced amputation rates in patients with DM^[79].

Diabetic foot ulcer is another complication in these patients that is associated with an increased risk of all-cause mortality^[79]. In those patients with PAD whose course is complicated by diabetic foot ulcer, similar outcomes in terms of limb salvage rates were seen with endovascular and open surgical approaches^[85]. It is important to note, however, that concomitant PAD in patients with diabetic foot ulcers is linked to greater failure rates of wound healing and need for amputation. This association is complex, and different studies have shown that successful revascularization and ulcer healing are not always correlated^[79].

CONCLUSION

DM is associated with greater severity and more diffuse PAD relative to nondiabetics. It also correlates to greater risk of mortality and impaired quality of life. The mechanisms by which diabetes induces atherosclerosis are multifactorial and include inflammatory processes, derangements of various cell types within the vascular wall, promotion of coagulation, and inhibition of fibrinolysis. These factors both increase the susceptibility of the vasculature to atherosclerosis, as well as the instability that makes plaque prone to rupture and thrombosis. Thus, it is important for different specialists, from cardiology and internal medicine to vascular surgery, to collaborate and use a multidisciplinary approach to improve the clinical outcomes in this patient population.

Although diabetics have a higher risk of adverse outcomes when compared to nondiabetics, the rates are improving thanks to recent advances in pharmacology and procedural techniques. Nonetheless, further work remains necessary. For instance, while trials such as TRITON-TIMI 38 and PLATO show better clinical outcomes with prasugrel or ticagrelor compared to clopidogrel after percutaneous coronary intervention, it is unclear if similar benefit is seen in DM patients with PAD^[3]. Further studies should also include the impact of biochemical factors found in central obesity, which are known to promote atherothrombosis^[86]. Better understanding of the mechanisms responsible for restenosis among diabetic patients will also ultimately improve the outcomes of surgical and endovascular procedures in these patients.

Abstract

Atherosclerosis is the major complication of diabetes and has become a major issue in the provision of medical care. In particular the economic burden is growing at an alarming rate in parallel with the increasing world-wide prevalence of diabetes. The major disturbance of lipid metabolism in diabetes relates to the effect of insulin on fat metabolism. Raised triglycerides being the hallmark of uncontrolled diabetes, *i.e.*, in the presence of hyperglycaemia. The explosion of type 2 diabetes has generated increasing interest on the aetiology of

atherosclerosis in diabetic patients. The importance of the atherogenic properties of triglyceride rich lipoproteins has only recently been recognised by the majority of diabetologists and cardiologists even though experimental evidence has been strong for many years. In the post-prandial phase 50% of triglyceride rich lipoproteins come from chylomicrons produced in the intestine. Recent evidence has secured the chylomicron as a major player in the atherogenic process. In diabetes chylomicron production is increased through disturbance in cholesterol absorption, in particular Niemann Pick C1-like1 activity is increased as is intestinal synthesis of cholesterol through 3-hydroxy-3-methyl glutaryl co enzyme A reductase. ATP binding cassette proteins G5 and G8 which regulate cholesterol in the intestine is reduced leading to chylomicronaemia. The chylomicron particle itself is atherogenic but the increase in the triglyceride-rich lipoproteins lead to an atherogenic low density lipoprotein and low high density lipoprotein. The various steps in the absorption process and the disturbance in chylomicron synthesis are discussed.

Key words: Triglyceride; Cholesterol chylomicrons; Microsomal triglyceride transfer protein; Niemann Pick C1-like1; Lipoproteins; Diabetes; ATP binding cassette proteins G5/G8

Core tip: The explosion of type 2 diabetes has generated increasing interest on the aetiology of atherosclerosis in diabetic patients. Evidence is mounting on the importance of the atherogenic properties of triglyceride rich lipoproteins. In the post-prandial phase 50% of triglyceride rich lipoproteins come from chylomicrons produced in the intestine. Recent evidence has secured the chylomicron as a major player in the atherogenic process. In diabetes chylomicron production is increased through disturbance in cholesterol absorption. This paper reviews recent literature in relation to diabetes, the intestine and dyslipidaemia with a view to understanding new targets for treatment.

INTRODUCTION

The increasing incidence and prevalence of diabetes is of concern to patients their relatives and the medical profession. Politicians who do not fit into the above groups are also concerned because of the health budget considerations. Management of chronic conditions is expensive! A major cost of diabetes care goes on the management of cardiovascular atherosclerotic complications which are so much more common in both diabetes and pre-diabetes. Although statins remain at the centre of dyslipidaemia treatment for diabetes, there is generally an unawareness of the importance of the chylomicron and triglyceride-rich proteins being atherogenic in their own right but also in forming atherogenic low density lipoprotein (LDL). This lack of appreciation of the importance of hypertriglyceridaemia has for example encouraged Tenenbaum *et al*^[1] to write an article entitled "Hypertriglyceridaemia: too long an unfairly neglected major cardiovascular risk factor". Another important milestone in bringing the intestine to the notice of diabetologists and cardiologists has been the validation of ezetimibe, a drug that inhibits the absorption of intestinal cholesterol, which has been shown beyond doubt in the IMPROVE-IT study, demonstrating significantly lower primary combined endpoints in moderate to high risk patients who stabilise following acute coronary syndrome^[2]. This article reviews dyslipidaemia in diabetes with a focus on the intestine as a dysfunctional regulator of cholesterol metabolism.

Insulin deficiency is associated with disturbance in both carbohydrate and fat metabolism. In fact even before diabetes becomes manifest, in the pre diabetes phase of the condition free fatty acids fail to be suppressed after a glucose load leading to the suggestion that diabetes should be defined as lipidus rather than mellitus^[3]. Indeed, had the serum rather than the urine been easily available many centuries ago, post prandial chylomicronaemia, as demonstrated by the milky serum, would have been preferred to the sweet taste of the urine as the diagnostic tool of choice!

The chylomicron is a particle containing protein fat and cholesterol. The protein, which is mostly apolipoprotein (apo) B48, is the solubilising protein which facilitates the transport of fatty acids, triglycerides and cholesterol. The chylomicron is assembled in the intestinal mucosa under the influence of microsomal triglyceride transfer protein (MTP) which is the rate limiting enzyme. Very LDL (VLDL) is the major triglyceride-containing particle assembled in the liver and, in the postprandial state, about 50% of triglyceride is carried on the VLDL particle and 50% on the chylomicron. Although the chylomicron

by definition is the triglyceride rich particle containing apo B48 and VLDL by definition is the triglyceride-rich particle containing apo B100, the term chylomicron is also used based on density following separation in the ultracentrifuge and thus is a mixture of both chylomicrons and large VLDL particles. Hence there is often confusion about what is meant by the term chylomicron.

CHYLOMICRON AS AN ATHEROGENIC PARTICLE

For many years triglycerides have taken a back seat in the perception and understanding of the aetiology of atherosclerosis. Part of the problem might have been that triglycerides have usually been taken fasting whereas the chylomicron is a post-prandial particle and the hepatic VLDL, the other major triglyceride containing particle, is also mostly produced in the postprandial state. Evidence that Apo B48 is found in the atherosclerotic plaque^[4-7] has been around for years confirming the atherogenicity of the chylomicron particle. Trials such as the FIELD Study^[8], failed to show cardiovascular benefit for reduction of triglycerides and had an adverse effect on the understanding of the atherosclerotic effect of the chylomicron. This has been rectified particularly by the Danish group who have shown that postprandial triglycerides are indeed associated with an increased in cardiovascular events^[9]. Further analysis of the FIELD Study, and in particular understanding that too many people with normal triglycerides were included in the study, has resulted in a number of post hoc analysis of that study showing that reduction in triglycerides did have cardiovascular benefit. An evaluation of the effect of fenofibrate by sex in the FIELD Study was recently reported^[10]. In that study the authors found that fenofibrate reduced LDL, non-high density lipoprotein (HDL) cholesterol and apo B more in women than in men irrespective of menopausal status. The prevention of total cardiovascular events was more in women (30% *viz* 13%). In Patients with high triglycerides and low HDL the cardiovascular reduction was less different between the sexes (30% *viz* 24%). In a recent review Varbo *et al*^[11] conclude that post hoc subgroup analysis of randomised trials using fibrates in individuals with raised triglycerides show a benefit in lowering triglycerides. Conversely low non fasting triglycerides have been shown to be associated with reduced all cause mortality^[12]. The authors examined individuals from the Copenhagen Heart study. Genetically derived low triglycerides were associated with a reduction in all cause mortality and the authors suggest probably due to a reduction in cholesterol in remnant particles. Apo C111 interferes with the uptake of triglyceride-rich apo E containing lipoproteins (both chylomicron and VLDL). Loss of function mutations are associated with lower triglycerides. The effect of these loss of function mutations on the risk of coronary heart disease (CHD) was examined^[13]. An aggregate of rare mutations in the gene encoding apo C111 was associated with lower plasma triglycerides.

Levels were 39% lower in carriers when compared to non-carriers and circulating levels of apo C111 were 46% lower than in non-carriers. The study found that the risk of CHD among carriers of any apo C111 mutation was 40% lower than the risk among the non carriers. An other important boost to the importance of triglycerides in CHD. Fasting blood sugar is of course a recognised cause of increased cardiovascular risk^[14] and it is very interesting to see that patients with polymorphisms of the various genes known to be associated with raised glucose such as the glucokinase gene (*GCK*) rs4607517 have been shown to be associated with an increased risk of ischaemic heart disease and myocardial infarction as compared to genotypes associated with lower levels^[15]. It is likely that the raised glucose is associated with the failure to suppress triglyceride.

Inflammation is a key factor in atherosclerosis progression and obesity is associated with an increase in inflammatory proteins such as tumour necrosis factor alpha and interleucine 6 (IL6). A study genotyping for variants affecting levels of non fasting remnant cholesterol, LDL cholesterol and C-reactive protein (CRP) by both CRP alleles and IL6 receptor alleles found that increasing non-fasting remnant cholesterol was associated with significantly higher CRP. This was not the case for LDL, suggesting that remnant cholesterol may in part cause acceleration of atherosclerosis through an inflammatory process^[16-18]. Endothelial dysfunction is a precursor of atherosclerosis. Post prandially, when triglycerides rise neutrophils increase with concomitant production of pro-inflammatory cytokines and oxidative stress suggesting a contributory cause of endothelial dysfunction^[19,20]. Further triglycerides have also been shown to increase leucocyte activation markers^[21,22].

The mechanisms whereby the postprandial lipoproteins might be pro-inflammatory and stimulate the progression of atherosclerosis has been investigated^[23]. One mechanism is through the activation of neutrophils and Klop *et al*^[24] have shown in healthy volunteers that post prandially changes occur in the white cell population which are similar to that shown in infection. A good review of post-prandial inflammation and the role of glucose and lipids has recently been published^[25].

MTP

Since chylomicronaemia is such an important finding in diabetes it is of interest to examine MTP function in diabetes.

Biosynthesis of lipoproteins requires apo B and MTP. MTP binds and chaperones lipoproteins to the nascent apo B. MTP is an endoplasmic reticulum resident heterodimeric complex. The liver and intestine are the major organs that express apo B and secrete apoB containing lipoproteins. There is good agreement between apoB levels and activity and in various animal models of diabetes in rats, rabbits and fructose fed hamsters diabetes MTP is up regulated^[26-29].

In human studies in type 2 diabetes we demonstrated

an increase in MTP mRNA in intestinal biopsies^[30,31]. Diabetic patients who were on statin therapy had lower MTP mRNA compared to those not on statins^[31]. We found positive correlations between MTP mRNA and chylomicron fraction cholesterol and apo B48^[31]. A novel intestinal specific inhibitor of MTP has been shown to ameliorate impaired glucose and lipid metabolism in Zucker diabetic fatty rats but whether this effect was due to impairment of food intake or to inhibition of fat absorption is not clear^[32]. The signals that upregulate chylomicron formation to cope with excess fat in the diet are slowly being elucidated. Another non-specific inhibitor of MTP, which reduced serum levels of triglycerides by more than 70%, was also associated with significant improvements in glucose tolerance and insulin sensitivity in Zucker fatty rats^[33]. Hepatic MTP mRNA expression is negatively regulated by insulin and it is suggested that insulin might also directly inhibit apo B48 secretion independently of MTP even though it is probable that up-regulation of MTP stimulates apo B secretion^[34]. The membrane glycoprotein CD36 binds long chain fatty acids. CD 36 deficiency reduces chylomicron production^[35]. It has recently been shown that binding of lipid by CD36 upregulates apo B48 and MTP through CD 36 signalling *via* the ERK 1/2 pathway^[36]. Interestingly polymorphisms of MTP which have been associated with differences in serum lipids appear to alter cholesterol absorption but not synthesis in women^[37].

ATP BINDING CASSETTE PROTEINS G5/ G8

Once cholesterol has been transported across the brush border membrane it faces another regulatory process and may be excreted back into the intestinal lumen rather than being further processed for absorption into the lymphatic circulation. ATP binding cassette proteins G5/G8 (ABC G5/G8) are heterodimers which are mostly confined to the human small intestine and liver^[38]. These two proteins act in tandem to re-excrete both cholesterol, and in particular non-cholesterol sterols from the body. Much of the understanding of ABC G5/G8 comes from the rare mutations that cause a defect in ABC G5 and G8 and result in high levels of sitosterol in the blood. Sitosterolemia, is a condition which manifests itself in children as tendon xanthomas or in young adults as severe CHD with massive accumulation of sterols and stanols in monocyte derived macrophages^[39]. Ma *et al*^[40] found in an animal model, that dietary calcium had a beneficial effect on lipoprotein profile by up-regulating the mRNA levels of intestinal ABC G5/8 and cholesterol-7 α -hydroxylase (CYP7A1), whereas it down-regulated the intestinal NPC1L1 and MTP due to enhanced biliary cholesterol excretion. Méndez-González *et al*^[41] investigated the effect of ABC G5 and G8 deficiency on lipoproteins in mice. They found that postprandial triglycerides were 5 fold higher in the ABCG5/G8^{-/-} mice due to a lower fractional catabolic rate with lower post heparin lipoprotein lipase activities. They also showed

that liver triglyceride secretion and intestinal triglyceride secretion were higher and there was a relationship between this and the HOMA index as a measure of insulin resistance. Rats with induced diabetes (streptozotocin) had impaired expression of ABC G5/8. Treatment with insulin partially reversed this effect^[42]. This trend in impairment was found in Zucker diabetic rats^[43,44] and the Psamonas Obesus (sand rat) was found to have the same intestinal impairment^[45,46]. Intestinal G5/G8 mRNA in type 2 diabetic subjects produced similar findings^[30].

ABC 5/8 genetic variants have been associated with susceptibility to CHD. One polymorphism in particular was shown to be associated with increased triglycerides with a significant gene - tobacco smoking interaction^[47]. Another study has shown that ABC G5/8 regulate cholesterol available for chylomicron production. It is interesting to read that ABC G5/8 genotypes that are associated with low LDL cholesterol are protective against myocardial infarction but increase risk of symptomatic gall stone disease^[48].

NIEMANN PICK C1-LIKE 1

The first step in cholesterol absorption in the intestine appears to be through the multi transmembrane protein Niemann Pick C1-like1 (NPC1L1) which is highly expressed in the jejunum^[49]. In humans it is localised to the brush borders of the enterocytes and acts as a unidirectional transporter of cholesterol and non-cholesterol sterols^[50]. Zhang *et al.*^[51] discovered that it is the N-terminal domain of NPC1L1 that binds cholesterol. Twenty rare NPC1L1 alleles have been found in the low cholesterol absorbers and appear to impair NPC1L1 cholesterol uptake through various mechanism^[52,53], for review see Calandera^[54]. It has been shown that the effectiveness of ezetimibe, which blocks NPC1L1 and inhibits cholesterol absorption, depends on the NPC1L1 genotype.

Cholesterol absorption has been shown to be increased in both animal and human diabetes^[55] due to an increase in NPC1-L1^[43,44,55]. In an animal model of type 2 diabetes, Sammons Obesus, the opposite was found even though these animals have an increase in apo B48^[45,46]. Ezetimibe inhibits cholesterol absorption through inhibition of NPC1L1 (for review see^[56]). NPC1L1 activity appears to be governed by dietary cholesterol^[57]. The mechanism of this control is through the nuclear receptor, peroxisome proliferator-activated receptor (PPAR) δ/β ^[58]. Fenofibrate, a PPAR α agonist has been shown to inhibit cholesterol absorption, the mechanism has been shown to be through NPC1L1 transcription by binding to a PPAR α response element upstream of the human *NPC1L1* gene^[59]. In a human construct Iwayanagi *et al.*^[60] showed that PPAR α positively regulated human NPC1L1 transcription and Valasek *et al.*^[59] showed that Fenofibrate reduced intestinal cholesterol absorption by PPAR α modulation of NPC1L1. HMGCoA reductase inhibition (Atorvastatin) has been shown to increase cholesterol absorption in the intestine and downregulation

of NPC1L1^[61] in the intestine. Ezetimibe has been shown to improve biomarkers of inflammation and platelet activity^[62] as stated above the IMPROVE-IT trial has been presented at the American Heart 2014 but not yet published. Ciriacks *et al.*^[63] have examined the addition of Ezetimibe to simvastatin in type 1 and type 2 diabetes. The study demonstrated that ezetimibe was at least as effective in lowering cholesterol as simvastatin among type 1 diabetics. Some studies have suggested that there may be a difference in cholesterol absorption rates between type 1 and type 2 diabetic patients^[64].

OTHER TRANSPORTERS OF CHOLESTEROL

There are other transporters of cholesterol for example scavenger receptor class B type 1 (SR-B1) which is located both in the apical and basolateral membranes of the enterocyte^[65]. SR are cell surface proteins that can bind and internalise modified lipoproteins. SR-B1, which is involved in cholesterol uptake in the intestine, may play an important part in intestinal chylomicron production^[66]. The fatty acid transporter CD36 which is also involved in the uptake of oxidised LDL, is another member of the class B scavenger receptor family^[66]. Hayashi *et al.*^[67] investigated gene expression of key proteins involved in the active absorption of dietary fat and cholesterol in response to the development of insulin resistance. They used 2 models of diet induced insulin resistance, the fructose fed hamster and the high fat fed mouse. Expression of SR-B1 was increased in both the fructose fed hamster and the high fat fed mouse models of insulin resistance. In CaCo2 cells SR-B1 over expression increased apo B100 and apo B48 secretion. The authors conclude that apical or basolateral SR-B1 may have an important role in cholesterol absorption and may play a part in cholesterol over absorption in insulin resistant states. SR-B1 in the intestine may play an important role in chylomicron production. CdC42, a member of the Rho family of small Guanine triphosphatases with numerous functions, has been shown by Xie *et al.*^[68] to interact with NPC1L1 and to control its movement from endocytic recycling compartment to plasma membrane in a cholesterol dependent manner. Glucose stimulated CDc42 signalling appears to be essential for second stage insulin secretion^[69]. It is probable that in insulin resistance the signalling of NPC1L1 is disturbed through this pathway but we have been unable to find any studies in the intestine that have explored the pathway in diabetes/insulin resistance.

THE EFFECT OF HIGH GLUCOSE ON CHOLESTEROL ABSORPTION

Ravid *et al.*^[70] have shown that high glucose increases intestinal absorption of cholesterol through an increase in the protein expression of NPC1L1. The same group later showed that the effect was through the basolateral

domain suggesting glucose in the circulation rather than in the lumen to be the stimulus^[71]. The reason for the up-regulation of cholesterol through NPC1L1 in diabetes has been explored by Malhotra *et al*^[72]. Using CaCo2 cells they showed that removal of glucose from the culture medium significantly decreased NPC1L1 mRNA protein expression as well as pro-motor activity. Glucose replenishment significantly increased the promoter activity of NPC1L1 in a dose dependant manner. The authors concluded their experiments by examining mouse jejunum after 24 h fasting which confirmed the CaCo2 cell results.

The role of cholecystokinin on intestinal absorption has been reported by Zhou *et al*^[73]. They found that in mice cholecystokinin (CCK) increased cholesterol absorption and increased cell surface associated NPC1L1. Previously Irwin *et al*^[74] have shown that an CCK-8 analogue improves insulin sensitivity and triglyceride deposition in liver and muscle but with reduction in weight gain and food intake. The effect therefore on lipid metabolism might be very dependant on dietary intake and the inhibition of apatite and improvement in insulin sensitivity with improvement in glucose tolerance with CCK makes analogues of CCK of interest as a possible treatment in diabetes and the metabolic syndrome.

Interest in bile salt binding drugs for treatment of dyslipidaemia, such as cholestyramine, went out of fashion because of their poor cholesterol lowering effects and their unacceptable side effects. A new formulation colsevelam, is interesting in that not only that it lowers cholesterol and apo B but also lowers blood sugar. A recent study in type 2 diabetic patients demonstrated a 0.32 drop in HbA1c vs placebo at 24 wk and a reduction of cholesterol of 6.5%^[75,76]. The majority of adverse effects were mild or moderate, the authors concluding that the drug was well tolerated. Thus another option for patients who are near to but not on target with current medication.

CHOLESTEROL SYNTHESIS AND 3-HYDROXY-3-METHYLGLUTARYL CO-ENZYME A REDUCTASE

Cholesterol synthesis in the intestine makes up 25% of *de novo* cholesterol synthesis. Cholesterol synthesis is regulated by 3-hydroxy-3-methylglutaryl co-enzyme A (HMGCo A) reductase the rate limiting enzyme in the synthetic pathway. HMGCo A reductase activity has been shown to be reduced by insulin in the rat hepatocyte^[77]. It has been suggested that in type 1 diabetes improved glycaemic control will increase cholesterol synthesis. HMGCoA reductase inhibition has been shown to increase cholesterol absorption through a lowering of ABC G5/G8 and an increase in NPC1L1^[78].

HEPATIC STEATOSIS

Hepatic steatosis is common in diabetes, insulin resis-

tance and obesity. Inflammatory stress is present in these conditions and is also associated with obesity insulin resistance and diabetes. It is therefore of interest to read that Zhao *et al*^[79] demonstrated that IL1b and IL6 stimulation in Hep G2 cells increased SREBP2 and HMGCoA mRNA. Further high fat loading in mice or LDL loading in HepG2 cells suppressed the above genes but this suppression could be over ridden by the above inflammatory proteins. Severe calorie restriction in patients with steatosis results in rapid reduction of liver fat, insulin resistance and improvement in diabetes control^[80]. On the other side of the coin insulin resistance and the accompanying hyperinsulinaemia are associated with an upregulation of SREPB-2 through extracellular signal regulated pathways involving the kinases ERK-1 and 2 another example of the interaction between fat and carbohydrate metabolism, for review see Van Rooyen *et al*^[81].

In conclusion, vascular disease in diabetes is complex as would be expected with a condition that impacts on so many metabolic pathways. Examination of the intestine in the search for abnormalities in cholesterol absorption and chylomicron formation has been rewarding. Statins have been very effective in reducing the burden of atherosclerosis in patients with diabetes but even so a large proportion of patients still succumb to events. Reduction in triglycerides is now accepted as being important in those patients who have raised triglycerides and in particular the importance of postprandial disturbance in triglyceride metabolism and its impact on atherosclerosis is now accepted as being an important issue in management of diabetes and in the prevention of macrovascular complications.

Abstract

Hepcidin is a peptide hormone with both paracrine and endocrine functions that help in maintaining body iron stores. Type 2 diabetes (T2D) is one of the sequelae of excess body iron stores; thus, iron regulatory hormone hepcidin may have a direct or at least an indirect role in the aetiopathogenesis of T2D. Both human and animal studies at molecular and genetic levels have attempted

to establish a role for hepcidin in the development of T2D, and a few epidemiologic studies have also showed a link between hepcidin and T2D at population level, but the findings are still inconclusive. Recent data have suggested different pathways in which hepcidin could be associated with T2D with much emphasis on its primary or secondary role in insulin resistance. Some of the suggested pathways are *via* transcription modulator of hepcidin (STAT3); ferroportin 1 expression on the cells involved in iron transport; transmembrane protease 6 enzyme; and pro-inflammatory cytokines, interleukin (IL)-1, IL-6, tumor necrosis factor- α and IL-10. This review briefly reports the existing evidence on the possible links between hepcidin and T2D and concludes that more data are needed to confirm or refute hepcidin's role in the development of T2D. Examining this role could provide a further evidence base for iron in the aetiopathogenesis of T2D.

Core tip: Excess body iron has been demonstrated as an independent risk factor of type 2 diabetes (T2D). Lately, manipulation of serum hepcidin concentrations through the use of hepcidin agonist is being suggested in the management of iron overload diseases, of which T2D is one. However, little is known about the role of hepcidin in the development of T2D; hence, the need for a review of the existing evidence linking hepcidin and T2D. We discuss some of the main mechanisms through which hepcidin could be associated with T2D.

INTRODUCTION

Recently, attention has been shifting towards the iron-regulatory hormone hepcidin and its possible role in the aetiopathogenesis of type 2 diabetes (T2D). Hepcidin is primarily a hepatic peptide synthesized as a preprohepcidin, which is a 84-amino acid peptide. It undergoes enzymatic cleavage into a 60- to 64-residue prohepcidin peptide and finally into a biologically active 25-amino acid peptide hormone, hepcidin^[1-3]. Tissues of the kidney^[4], pancreatic beta cell^[5], macrophages^[6] and adipocytes^[7] have also been reported to produce hepcidin, but the role of this extra hepatic contribution to serum hepcidin is still unclear.

Hepcidin's role is to maintain iron homeostasis^[8,9]. It performs this action by regulating the expression and function of cell membrane-embedded ferroportin (FPN)^[10], the cellular iron exporter in iron-transporting cells^[8,9]. In response to the level of body iron stores, hepcidin regulates dietary iron absorption from the intestine and iron release from macrophages, by decreasing the cell surface expression of FPN.

Among the known diseases associated with the iron overload syndrome is T2D^[11,12]. Even mildly elevated body iron has been demonstrated as a risk factor of T2D^[13]. Some recent epidemiologic studies have tried to explore the association between serum hepcidin and T2D, with inconsistent findings^[14-16]. Also, serum glucose concentration has been shown to regulate serum hepcidin^[17]. As the underlying mechanisms between body iron stores and T2D still need further clarifications, hepcidin could provide some answers. Therefore, we reviewed the emerging links between hepcidin and T2D.

ROLE OF HEPCIDIN IN IRON METABOLISM

Iron is a transition metal that is predominantly absorbed in the duodenum and upper jejunum^[18]. The intestinal absorption of iron is in two waves of uptake of iron from intestinal lumen into the intestinal mucosa and from mucosa into the blood^[19]. The two known forms of dietary iron are heme and non-heme iron. The heme iron is well absorbed by the body while the non heme iron predominantly in ferric form Fe^{3+} is reduced to ferrous Fe^{2+} form by the duodenal cytochrome b reductase^[20]. This is transported by the divalent-cation transporter 1, a member of the natural-resistance-associated macrophage protein family, across the intestinal apical membrane^[21], and later stored in the cytosol of ferritin or exported from the basolateral membrane of the enterocytes *via* FPN1. Because of its numerous health effects due to excess or deficiency, there is a need to strictly regulate iron within the physiological range.

Following a feedback mechanism, hepcidin is either up- or down-regulated by hepatocytes, depending on the level of body iron. Genetically, the mRNA of the gene (*HEPC*) coding for hepcidin increases with increase in

body iron stores. At molecular level, hepcidin regulates iron transport from iron-exporting tissue into plasma by inhibiting intestinal iron absorption^[9], release of iron from macrophages^[22] and the placental passage of iron^[23]. It performs these functions by binding to FPN1, which is expressed on the duodenal enterocytes, hepatocytes, placental syncytiotrophoblasts and the reticuloendothelia macrophages. It later internalizes and degrades FPN1 leading to a reduction in the ability of these cells to export iron into the plasma^[8]. Conversely, there is re-expression of FPN1 on these iron-exporting cells in iron deficiency. However, it must be noted that body iron is not the only stimulus for hepcidin release. Hepcidin also responds to inflammation, infection, or both; as such, hepcidin appears to be a link between iron and inflammation. The antimicrobial properties of hepcidin would require conditions inconsistent with those observed in the serum, further emphasizing its iron-regulatory role rather than its broad-spectrum antibiotic activity^[24].

MECHANISMS LINKING HEPCIDIN AND T2D

Insulin resistance is a feature of T2D, and the relationship between iron metabolism and insulin resistance has been suggested to be bidirectional^[25]. However, the association between hepcidin and insulin resistance remains vague. Molecular studies have showed that insulin stimulates hepcidin *via* STAT3, which is a novel transcription modulator of hepcidin^[26]. A study by Wang *et al.*^[26], in which they induced diabetes in rats using streptozotocin with or without high-fat diet, showed a significant reduction in hepcidin expression in the liver, mediated by STAT3, causing abnormal elevation of FPN in the intestine, leading to serum iron elevation. Le Guenno *et al.*^[27] showed a 3.5-fold reduction in hepcidin mRNA in the group with higher insulin resistance when compared to the control group. Some previous studies^[15,28,29] also have shown reduced hepcidin and prohepcidin concentrations in T2D subjects, suggesting insulin signal loss among T2D subjects with elevated iron stores.

Another mechanistic link between hepcidin and insulin is through glucose stimulation. One of the extrahepatic sources of serum hepcidin is the beta cell of the pancreas^[5]. Insulin and hepcidin release have also been localized to beta cell granules where hepcidin may evoke its paracrine function. Thus, as glucose stimulates insulin release, there is a concomitant production of hepcidin. In the trial arm of a study by Aigner *et al.*^[17] in which they assessed the effect of glucose on serum iron and hepcidin, they found an increase in serum hepcidin in glucose-treated subjects compared to the control group treated with only water.

To further strengthen the association between hepcidin and T2D, a genome-wide association study (GWAS) by Gan *et al.*^[30] evaluated the association of transmembrane protease serine 6 (TMPRSS6) variants

Table 1 Studies linking hepcidin/prohepcidin and type 2 diabetes (n = 6)

Ref.	Subject/study design	Measurement of hepcidin/prohepcidin	Assessment of T2D	Results
Sam <i>et al</i> ^[15]	British men and women/case-control	Active serum hepcidin-25 and serum hepcidin-ferritin ratio measured using RIA	HbA1c = 73.17 ± 4.12, mean ± SEM	Student's <i>t</i> -test/Mann-Whitney <i>U</i> -test to compare hepcidin (ng/mL) and hepcidin-ferritin ratio in T2D <i>vs</i> control showed: 20.00 (10.00-41.00) <i>vs</i> 33.00 (18.05-54.00), <i>P</i> < 0.05 and 0.22 (0.15-0.32) <i>vs</i> 0.45 (0.26-0.58), <i>P</i> < 0.01
Guo <i>et al</i> ^[16]	Chinese men and women/case-control	Serum hepcidin measured using ELISA	Fasting plasma glucose > 7 mmol/L	Wilcoxon rank test to compare hepcidin (ng/mL) in T2D <i>vs</i> control showed: 34.44 ± 26.98 <i>vs</i> 32.34 ± 22.75, <i>P</i> = 0.72. Logistic regression analysis showed no significant association between serum hepcidin concentrations and onset of T2D: OR = 1.03, 95% CI: 0.87-1.22, <i>P</i> = 0.75
Gan <i>et al</i> ^[30]	Chinese men and women/prospective cohort	Two TMPRSS6 SNPs [rs855791 (V736A) and rs4820268 (D521D)] of hepcidin by DNA genotyping	WHO 1999 criteria or previous history of T2D. Fasting plasma glucose < 5.6 mmol/L = normoglycemia	Logistic regression analysis showed both 2 TMPRSS6 SNPs to be significantly associated with decreased risk of T2D:OR _{rs855791 (V736A)} = 0.801, 95% CI: 0.654-0.98, <i>P</i> = 0.0314 and OR _{rs4820268 (D521D)} = 0.802, 95% CI: 0.656-0.98, <i>P</i> = 0.0311
Jiang <i>et al</i> ^[14]	Chinese men and women/case-control	Serum hepcidin measured using ELISA	Fasting glucose ≥ 7.0 mmol/L, non-fasting glucose ≥ 11.1 mmol/L, use of diabetes medication, or a self-reported physician diagnosis	Kruskal-Wallis test/student's <i>t</i> -test to compare hepcidin (μg/L) in T2D <i>vs</i> control showed: 778.91 ± 175.22 <i>vs</i> 513.44 ± 281.73, <i>P</i> < 0.001
Aso <i>et al</i> ^[29]	Japanese men and women/case-control	Serum prohepcidin measured using ELISA	Not reported	Mann-Whitney <i>U</i> test to compare prohepcidin (ng/mL) in T2D <i>vs</i> control showed: 141 ± 42.6 <i>vs</i> 198.1 ± 36.7, <i>P</i> < 0.0001
Fernández-Real <i>et al</i> ^[28]	Spanish men/ cross-sectional and intervention	Serum prohepcidin measured using ELISA	Oral glucose tolerance test	Pearson's test showed significant correlation between circulating prohepcidin and fasting glucose (<i>r</i> = 0.27; <i>P</i> = 0.002) and HbA1c (<i>r</i> = 0.31; <i>P</i> < 0.0001). After phlebotomy, prohepcidin decreased significantly in T2D (<i>P</i> = 0.04) and in <i>HFE</i> gene mutation carrier (0.03) with a negative correlation between serum prohepcidin and insulin sensitivity (<i>r</i> = -0.50, <i>P</i> = 0.04)

HbA1c: Glycated hemoglobin; T2D: Type 2 diabetes; RIA: Radioimmunoassay; ELISA: Enzyme linked immunosorbent assay; TMPRSS6: Transmembrane protease serine 6; SNPs: Single nucleotide polymorphisms; WHO: World Health Organization.

with risk of T2D. TMPRSS6 is an enzyme that inhibits the expression of hepcidin and its iron-lowering variants were used in their study. They found a reduced risk between the two TMPRSS6 variants and T2D (*P* = 0.0277). It is at least plausible to report that lower hepcidin concentration exacerbates insulin resistance seen in T2D, if causal relationship is yet to be fully established.

T2D is a dysmetabolic state characterized by low-grade chronic inflammation, and some authors have suggested a role for pro-inflammatory cytokines such as interleukins (IL)-1, IL-6 and tumor necrosis factor- α , in the development of insulin resistance^[31], and in addition, IL-10 in T2D^[32]. Increased circulating concentrations of these pro-inflammatory cytokines have also been observed in T2D subjects^[33]. IL-6 is the most important inflammatory cytokine regulating hepcidin, and it performs this function during STAT3 phosphorylation, thus activating STAT3 for hepcidin gene expression^[24]. STAT3 has been reported as necessary and sufficient for IL-6 responsiveness of the hepcidin promoter^[34]. Thus, a low hepcidin concentration could stimulate IL-6, thereby enhancing its role in the development of T2D. A population-based study by Spranger *et al*^[35] showed that IL-1 β and IL-6 concentrations predict the risk of T2D. It is therefore enticing to speculate from the available evidence that hepcidin has a role in insulin resistance, the hallmark of T2D, through iron regulation from interrelated signals of STAT3, pro-inflammatory cytokines and the TMPRSS6 enzyme.

STUDIES LINKING HEPCIDIN AND T2D

Existing data across different populations suggest a link between hepcidin and T2D (Table 1). There are four case-control studies^[14-16,29]. In Sam *et al*^[15] study, the authors measured serum hepcidin and serum hepcidin:ferritin ratio, which has been suggested as a marker of adequate hepcidin production for a particular iron dosage^[36]. Aso *et al*^[29] also measured serum ferritin, prohepcidin and adiponectin, and both studies showed decrease in serum hepcidin/prohepcidin in T2D subjects when compared with the healthy control^[15,29]. Because of the confounding effect of obesity and renal status in serum hepcidin measurement, Sam *et al*^[15] matched their control subjects for body mass index (BMI) and serum creatinine. Aso *et al*^[29] assessed the correlation between adiponectin and prohepcidin in T2D subjects on the basis that adiponectin has a beneficial role in

glucose homeostasis^[37]; hence, in glucose dysregulation observed in T2D, adiponectin and prohepcidin were expected to be low. In keeping with their hypothesis, Aso *et al.*^[29] found low concentrations of adiponectin and prohepcidin and a positive correlation between them in T2D subjects. The other two case-control studies^[14,16] showed increased hepcidin/prohepcidin in T2D subjects when compared with the control group. In Jiang *et al.*^[14] study, T2D subjects had higher BMI and creatinine than the controls, thus suggesting obesity and renal impairment as possible reasons for the elevated serum hepcidin. Further, inflammatory markers, *i.e.*, IL-6, C-reactive protein and white cell counts, were elevated in T2D subjects compared to the controls, speculating inflammatory signals as the cause of the elevated hepcidin. One factor that could be responsible for the contradictory findings in the hepcidin-T2D association study is the wide range of assays with varying degrees of limitation that were used in evaluating serum hepcidin and serum prohepcidin. The lack of an accurate assay to evaluate serum hepcidin in the past may have influenced some investigators to choose prohepcidin, which is thought to be easier to measure due to its higher immunogenicity. Although some studies have shown that prohepcidin does not accurately reflect iron status and iron absorption^[38], others have claimed that it is an indicator of endogenous hepcidin levels^[39] in healthy subjects. This could be the reason why some studies used hepcidin while others used prohepcidin in examining the association between hepcidin and T2D. This is of particular interest in chronic renal disease patients in end-stage renal failure, where there is cross-reactivity in serum hepcidin-25 measurement with that of other hepcidins, *i.e.*, hepcidin-20 and hepcidin-22^[40]. The question then arises whether the concentration of hepcidin in T2D subjects is primary or secondary to elevated body iron stores. The GWAS with a prospective design by Gan *et al.*^[30] at least provided further insight into the role of hepcidin as they showed a decreased risk in developing T2D with the iron-lowering variants of TMPRSS6. Also, in the trial arm of the three-in-one study by Fernández-Real *et al.*^[28], a negative correlation was observed between prohepcidin and insulin sensitivity after phlebotomy to reduce body iron stores, suggesting an association between prohepcidin and body iron in insulin sensitivity.

CONCLUSION

In conclusion, we have briefly reviewed the emerging evidence pertaining to the role of hepcidin in T2D. Although the causative role of body iron in insulin resistance and T2D has been documented in both observational^[41] and interventional studies^[42], the role of hepcidin in this process is still uncertain. However, in addition to the regulatory role in body iron stores, serum hepcidin concentrations have been linked to pro-inflammatory cytokines, STAT3, and TMPRSS6, all of which have been associated with T2D. Data gathered

in this review showed that hepcidin concentrations vary in different populations with T2D. Further, hepcidin has either a primary or secondary role in insulin resistance which characterizes T2D. However, it is still inconclusive from these accumulated data that serum hepcidin is an independent risk factor in the aetiopathogenesis of T2D. Thus, more experimental and clinical studies are needed to confirm or refute the claim that hepcidin has a role in T2D.

Abstract

AIM: To investigate lipid metabolism and the relationship with monocyte expression of the fatty acid translocase CD36 in South Asians.

METHODS: An observational study of South Asians whom as an ethnic group have - a higher risk of developing diabetes. The susceptibility to diabetes is coupled with an earlier and more rapid progression of micro-, and macro-vascular complications. Twenty-nine healthy South Asian participants [mean age 34.6 (8.9) years, 76.2% male, mean body-mass index 25.0 (5.2) kg/m²] were recruited from an urban residential area of central Birmingham (United Kingdom). The main outcomes measured were post prandial (30 min) and post absorptive (120 min) changes from fasting (0 min) in circulating lipoproteins, lipids and hormones, and

monocyte expression of CD36 post injection of a 75 g oral glucose challenge. The inducements of variations of monocyte CD36 expression were analysed.

RESULTS: Our results showed evident changes in monocyte CD36 expression following the glucose challenge ($P < 0.001$). Non-esterified fatty acids (NEFA) levels decreased progressively during the challenge ($P < 0.001$), in contrast to increased cholesterol (but not triglyceride) concentrations within very low density lipoprotein (VLDL) and low density lipoprotein subfractions ($P < 0.01$). Levels of, glucose, serum triglycerides and high density lipoprotein cholesterol remained largely unchanged. Variations of monocyte CD36 were negatively ($r = -0.47$, $P = 0.04$) associated to fat from the diet and positively to carbohydrate from the diet ($r = 0.65$, $P < 0.001$).

CONCLUSION: These data suggest that the initiation of VLDL genesis follows the consumption of glucose within this population, inferring that the sequestration of NEFA from these particles happens due to the increased availability of CD36 receptors. While these are preliminary results, it would appear that lifestyle exposures have a role in moderating the expression of CD36.

Core tip: This study investigated the relationship between the expression of fatty acid translocase CD36 on monocytes and lipid and lipoprotein metabolism in South Asians. Post prandial and post absorptive changes from fasting in circulating lipids, lipoproteins, hormones and monocyte expression of CD36 were recorded subsequent to an oral glucose challenge. Our results showed discernible changes in monocyte CD36 expression post glucose administration. These data suggest that the production of very low density lipoprotein occurs subsequent to the ingestion of glucose within this population. It is presumed that the sequestration of non-esterified fatty acids from these particles happens due to an increase in availability of CD36 receptors.

INTRODUCTION

The prevalence of diabetes is increased on the Indian

subcontinent^[1]. Globally dispersed migrant populations of "South Asians" also have high rates of diabetes, which is evident when compared to the various indigenous populations of where they migrated^[2-6]. Nephropathy and retinopathy develop earlier and are more progressive in South Asian diabetics compared to White diabetics^[7-11]. The incidence of vascular disease is also higher in South Asians compared to the general White population^[12].

Established risk factors such as obesity and urbanised lifestyle "operate" amongst South Asians but it remains unclear as to how far they explain an increased susceptibility to diabetes for this group. Rates of glucose intolerance amongst Indians living in rural village settings appear to be no different to their migrant contemporaries living overseas in Western countries^[5,6]. We and others have observed that high glucose excursions in South Asians are underpinned by unregulated non-esterified fatty acids (NEFA) metabolism^[13,14]. This phenomenon is likely to be complex and multifactorial, and we were interested to investigate the role of the fatty acid translocase CD36^[15], which is the major facilitator of NEFA sequestration from the blood^[16]. Specifically, CD36 allows the transport of NEFA that are generated from the lipolysis of triglyceride-rich lipoproteins such as very low density lipoprotein (VLDL) across plasma membranes, and into cells (*e.g.*, monocytes, cardiomyocytes and adipocytes) for fatty acid oxidation and lipid deposition^[17]. Cardiomyocytes use glucose in addition to fatty acids for cellular respiration, and the expression of glucose transporter 4 (GLUT4) and the fatty acid transporter CD36 is stimulated by raised insulin concentrations and an increase in cardiac work^[18].

Given that abnormalities of increased CD36 expression and NEFA uptake may represent a common cause for diabetes and the progression of its complications^[19-21], we measured changes in the expression of CD36 on circulating monocytes and its association with direct indices of NEFA metabolism amongst South Asians during an oral glucose challenge.

MATERIALS AND METHODS

Participants

Healthy South Asian volunteers were recruited between Jan and July 2011 for diabetes research Diabetes Health, Residence and Metabolism in Asians (DHRMA): the DHRMA study - a blinded, randomised, placebo controlled trial at Sandwell and West Birmingham Hospitals NHS Trust (Birmingham United Kingdom) (described in detail elsewhere^[22]). All the participants were aged 18 years and over and were of self reported South Asian ethnicity with no known cardiovascular disease or associated medications, body-mass index (BMI) less than 30 kg/m², and normal glucose tolerance. The study design was approved by the Local Research Ethics Committee. Written informed consent was collected from all participants.

Table 1 Characteristics of South Asian volunteers

Characteristics of 29 South Asian volunteers	Mean (SD)
Age (yr)	34.6 (8.9)
Weight (kg)	69.6 (18.4)
Body-mass index (kg/m ²)	25 (5.2)
Waist circumference (cm)	86.8 (16.3)
Hip circumference (cm)	101 (10)
Hip to waist ratio	0.892 (0.144)
Systolic BP (mmHg)	119 (13)
Diastolic BP (mmHg)	75.8 (8.8)
Energy from carbohydrates (%)	45 (6.3)
Energy from fats (%)	40.8 (5.8)
Energy from protein (%)	9.4 (6.8)
Energy from sugars (%)	12.6 (7.5)
Energy from starch (%)	32 (8.5)
Energy from saturated fat (%)	9.7 (5.8)
Energy from monounsaturated fat (%)	10.7 (5.2)
Energy from polyunsaturated fat (%)	6.8 (2.9)
Energy from alcohol (%)	0.5 (2.2)

BP: Blood pressure.

Variables

All patients and controls attended a baseline assessment for the DHRMA study at Sandwell and West Birmingham Hospitals. The assessment incorporated an interview-administered medical history questionnaire, and a dietary assessment (24-h food recall) scrutinised using the WISP (Weighed Intake Software Program) nutritional package (version 3, Tinuviel Software, Llanfechell, United Kingdom)^[6], and anthropometric measurements, which were measured using Seca scales and stadiometer (Seca Ltd, Birmingham). Waist measurements were recorded from the narrowest circumference above the umbilicus and below the rib, and the hip was recorded as the widest circumference at the buttocks. Both girths were measured in duplicate, and repeated where there were differences more than 2%. Blood pressure (BP) measurement was repeated three times, 1 min apart (analysing the mean) using a semi automated BP monitor, the OMRON 705CP (Omron Healthcare Europe, Mannheim, Germany) in combination with suitable cuff sizes for each participant, after at least five minutes in the sitting position. During this assessment venepuncture was performed to collect blood (as serum, fluoride oxalate plasma and EDTA plasma) at fasting, 30 min post administration of a 75 g oral glucose load (Maxijul; SHS Supplies, Liverpool, United Kingdom). Blood collected with fluoride oxalate was analysed for glucose (glucose oxidase method) within 2 h of venepuncture using the Cobas Integra 400 auto analyser (Roche Diagnostics, United Kingdom). EDTA plasma was stored at 4°C was analysed by: (1) Flow cytometry was recorded using the becton dickinson (BD) FACSCalibur flow cytometer (BD, Oxford, United Kingdom) (described elsewhere^[23]). Absolute counts of monocytes analysed for human CD36 antibodies (Miltenyi Biotec GmbH, Germany). Monocyte CD36 was also assessed in subsets of monocytes by order of their co-expression of CD14, CD16 and CCR2, defined as Mon1: CD14(+)-CD16(-)-CCR2(+),

Mon2: CD14(+)-CD16(+)-CCR2(+), and Mon3: CD14(low)-CD16(+)-CCR2(-) (as described previously^[23]); and (2) Density gradient ultracentrifugation (described elsewhere^[24]) was used to separate VLDL, low density lipoprotein (LDL), high density lipoprotein (HDL)₂ and HDL₃ subfractions using the Optima TLX Ultracentrifuge (Beckman Coulter, High Wycombe UK). Briefly, VLDL subfractions were extracted at a density 1.006 kg/L, LDL at 1.063 kg/L, HDL₂ at 1.123 kg/L and HDL₃ at 1.21 kg/L. Concentrations of cholesterol and triglyceride were measured on these separated lipoprotein subfractions on the Cobas Integra 400.

Blood collected as serum was separated and stored at -70°C for batch analysis using commercially available (1) colourimetric assays for NEFA (Acyl CoA synthase/oxidase method, Randox Laboratories, Co Antrim, United Kingdom); (2) ELISA for Insulin (Abcam, Cambridge, United Kingdom), adiponectin (R and D systems, Abingdon, United Kingdom), soluble CD36 (Adipo Bioscience Inc., Santa Clara, United States); and (3) automated biochemistry assays for total cholesterol, HDL cholesterol, LDL cholesterol, apolipoprotein AI, apolipoprotein B on the Cobas Integra 400.

Statistical analysis

Statistical review of the study was performed by a biomedical statistician. Data were analysed and validated using SPSS version 16.0 (SPSS Inc., Chicago, IL, United States). The parametric distribution of variables was scrutinised against Kolmogorov-Smirnov plots. Normally distributed data was analysed using ANOVA. The central tendencies of the data were presented as mean and variation by SD. Non-parametrically distributed data were analysed using the Friedman test for related measures, and data were presented as both median and interquartile ranges. A two-tailed bivariate correlation analysis was performed using Spearman's correlation coefficient. Categorical data were analysed using χ^2 tests. A *P* value < 0.05 was accepted as statistically significant.

Statistical review was performed by Dr. Andrew Blann, a biomedical statistician.

RESULTS

A total of 29 volunteers were consecutively recruited for this study. The characteristics of the cohort are shown in Table 1. South Asians were typically of Indian origin (72.4%) and subscribed to diets where the fat intake was 40% of the total energy intake. Their mean age was 34.6 (8.9) years, 16 were male (76.2%) and mean levels of BMI, fasting blood glucose, fasting serum lipids, and BP were reflective of a healthy cohort (Table 2). Soluble levels of CD36 were unrelated to monocyte expression of CD36. Analysing variables reported in Tables 1 and 2, variations in the percentage expression of monocyte CD36 was associated with anthropometry and dietary intake (Table 3). These correlations were specific to monocyte subsets, where Mon1 was positively

Table 2 Fasting metabolic indices and monocyte CD36 expression amongst South Asian volunteers

Characteristics of 29 South Asian volunteers Median (interquartile range)	
Plasma glucose (mmol/L)	5.09 (4.50, 5.47)
Serum NEFA (mmol/L)	0.416 (0.264, 0.514)
Serum cholesterol (mmol/L)	3.41 (2.95, 3.96)
Serum triglycerides (mmol/L)	0.9 (0.67, 1.44)
HDL cholesterol (mmol/L)	1.27 (0.98, 1.48)
LDL cholesterol (mmol/L)	2.03 (1.56, 2.44)
Apolipoprotein AI (g/L)	1.21 (1.10, 1.43)
Apolipoprotein B (g/L)	0.58 (0.46, 0.77)
VLDL subfraction cholesterol (mmol/L)	1.26 (0.97, 1.44)
LDL subfraction cholesterol (mmol/L)	1.3 (0.80, 1.65)
HDL ₂ subfraction cholesterol (mmol/L)	0.58 (0.41, 0.76)
HDL ₃ subfraction cholesterol (mmol/L)	0.37 (0.25, 0.51)
VLDL subfraction triglyceride (mmol/L)	0.34 (0.24, 0.43)
LDL subfraction triglyceride (mmol/L)	0.27 (0.17, 0.55)
HDL ₂ subfraction triglyceride (mmol/L)	0.08 (0.06, 0.15)
HDL ₃ subfraction triglyceride (mmol/L)	0.06 (0.04, 0.08)
Insulin (mU/L)	4.64 (2.60, 8.23)
Adiponectin (ng/mL)	1.79 (0.65, 2.65)
Plasma soluble CD36 (mmol/L)	108 (0, 249)
Total monocyte CD36 (Mon CD36 ⁺ per μ L)	361 (301, 432)
Monocyte CD36 on Mon1 (%)	81.8 (75.1, 85.8)
Monocyte CD36 on Mon2 (%)	7.2 (5.0, 10.3)
Monocyte CD36 on Mon3 (%)	10.5 (8.7, 16.6)

Monocyte subset. Mon1: CD14(+)CD16(-)CCR2(+); Mon2: CD14(+)-CD16(+)-CCR2(+); Mon3: CD14(low)CD16(+)-CCR2(-); NEFA: Non-esterified fatty acids; VLDL: Very low density lipoprotein; LDL: Low density lipoprotein; HDL: High density lipoprotein.

Table 3 Correlation between characteristics and fasting metabolic indices against percentage monocyte CD36 expression

Characteristics and fasting metabolic indices	Spearman correlation coefficient (P)		
	Mon1	Mon2	Mon3
Body-mass index	-0.438 (0.02)	0.156 (0.43)	0.418 (0.027)
Hip circumference	-0.633 (0.002)	0.419 (0.06)	0.483 (0.027)
Serum NEFA	-0.349 (0.06)	0.151 (0.43)	0.478 (0.009)
Apolipoprotein AI	-0.282 (0.14)	0.475 (0.009)	0.149 (0.44)
Energy from total fat (%)	-0.472 (0.036)	0.399 (0.08)	0.458 (0.04)
Energy from monounsaturated fat (%)	-0.691 (< 0.001)	0.724 (< 0.001)	0.230 (0.33)
Energy from carbohydrates (%)	0.645 (0.002)	-0.496 (0.026)	-0.533 (0.016)

Monocyte subset. Mon1: CD14(+)CD16(-)CCR2(+); Mon2: CD14(+)-CD16(+)-CCR2(+); Mon3: CD14(low)CD16(+)-CCR2(-); NEFA: Non-esterified fatty acids.

associated with carbohydrate intake, and negatively with fat intake and BMI, while such trends appeared reversed in Mon2 and Mon3 subsets, which were additionally associated with apolipoprotein AI and NEFA (Table 3).

On analysis of serial measures of monocyte CD36 expression, there were evident changes in receptor concentrations for all monocytes ($P < 0.001$), as well as across subsets Mon1 ($P < 0.001$), Mon2 ($P = 0.011$) and Mon3 ($P = 0.03$) (Table 4). The profile of monocyte subset changes reflected a decrease post-prandially (30 min after the glucose challenge) and higher levels post-absorptively (after 120 min) in Mon1 and Mon2

Figure 1 Changes in monocyte subset CD36 expression (Mon CD36⁺ per μ L) pre and post administration of oral glucose. Monocyte subsets. Mon1: CD14(+)CD16(-)CCR2(+); Mon2: CD14(+)-CD16(+)-CCR2(+); Mon3: CD14(low)CD16(+)-CCR2(-).

(Figure 1). NEFA levels progressively decreased during the glucose challenge ($P < 0.001$), whereas cholesterol concentrations within VLDL and LDL subfractions increased ($P < 0.001$). The levels of triglyceride within VLDL particles and HDL particles appeared to decrease during the glucose challenge, but these changes were not significant. Levels of serum triglycerides, glucose, HDL subfraction lipids were largely unchanged following the glucose load. Similarly, there were no significant changes in percentage expression of monocyte CD36 on Mon1, Mon2 or Mon3.

DISCUSSION

Greater CD36 expression following a glucose challenge in healthy South Asians, could reflect a physiological

Table 4 Changes in metabolic factors absolute monocyte CD36 expression pre and post administration of oral glucose

	Circulating concentrations following the administration of glucose			P
	0 min	30 min	120 min

response to counteract the toxicity of excessive plasma glucose. Monocytes have been shown to present an intracellular CD36 pool^[25], and the transient expression of CD36 in monocytes during glucose challenge, may serve as a critical process in dictating the functional activity of CD36 during diabetic conditions and perhaps, atherogenesis. These increases in absolute monocyte CD36 concentrations occurred in parallel to an exponential decrease in NEFA, a rise in levels of VLDL and LDL cholesterol, and no changes in plasma glucose, serum triglycerides or HDL cholesterol. It is possible that the oral glucose challenge in South Asians results in the generation of VLDL particles, and the increased availability and action of CD36 results in the liberation of triglyceride from these particles. The expression of CD36 on monocytes is associated with factors such as dietary fat and carbohydrate, and we are tempted to speculate that lifestyle exposures have a role in moderating the expression of CD36.

An increase in the expression of CD36 is seen as a dysfunctional event, and in diabetics it is associated with a down regulation of the GLUT4 receptor and a reduction in glycogen synthesis^[18]. In South Asians, this response to increase CD36 expression following a glucose load may reflect a homeostatic process to up-regulate those mechanisms that preferentially store energy as fat. In animal models and cellular models, CD36 is shown to lower circulating NEFA concentrations and to promote the efflux of triglyceride from VLDL^[16].

The reasons this "ethnic" preference to process energy in this way are complex. One interesting aspect of CD36 measurement in South Asians is in its dual role in the clearance of red blood cells infected with *Plasmodium falciparum*. The interaction between malaria and CD36 receptors is complex and the subject of debate^[26]. South Asians have evolved from a part of the world where malaria was endemic^[27], and this may have

conferred a survival benefit^[28,29].

Hepcidin is upregulated in malarial infected individuals by interleukin-6^[29], a protein that supports hepatic gluconeogenesis, by a process that is dysregulated in diabetics. Further research is required to fully understand the link between exposure to malaria and a subsequent susceptibility to diabetes.

Monocytes and macrophages play a fundamental role in the pathogenesis of atherosclerosis, and various subtypes of monocytes are associated with cardiovascular diseases^[30]. Functional differences of three Mon1, Mon2 and Mon3 monocyte subsets have been described^[23]. Each monocyte subset responds differently to distinctive immunological stimuli. For example, Mon2 and 3 monocytes predominate during inflammatory states and Mon1 in response to *Candida albicans*^[29]. The production of cytokines such as tumor necrosis factor- α , associated with diabetes, also varies with stimulus^[31]. However, responses in CD36 expression following the glucose challenge were largely similar across these subsets, and as such the metabolic significance of these subclassifications are unclear. The increased surface expression of CD36 on Mon1 was associated with lower BMI and a higher intake of carbohydrate, where as the converse appeared true for Mon1 and Mon2, which were positively associated with dietary fat. Such findings suggest that the expression of CD36 on monocytes can be moderated by diet.

Due to the low numbers of subjects in this study, we only had sufficient statistical power to detect significant associations (α at 0.02) where the correlation coefficient was ≥ 0.55 . We found levels of soluble CD36 to be unrelated to monocytes and metabolic measures. However, elsewhere, soluble CD36 has been shown to reflect several aspects of insulin resistance in humans^[32]. The isolation of lipoprotein subfractions by ultracentrifugation is prone to losses during the

extraction process. Further work would need to be undertaken to analyse the generalisability of the data generated here. There is considerable diversity within the South Asian ethnic category, it encompasses over 22 different languages and more than 6 different religions. The dietary intake of fat in this cohort was similar to that we have measured in a larger cohort of South Asians Living in the United Kingdom^[33]. Nonetheless, the dietary intake of fat in these groups is much greater than that seen amongst South Asians living in rural India^[28].

In summary, these data describe changes in lipid metabolism following the oral ingestion of glucose in South Asians which includes the generation of VLDL, and an increase in monocytes expressing CD36. We presume that triglycerides from these particles are cleared by an increase in the availability of CD36 receptors, and it would appear that lifestyle exposures may influence this process.

COMMENTS

Background

The incidence of diabetes in South Asian populations, including those living in the Indian Subcontinent, and those who have migrated away, is significant. Indeed it is higher than in comparable Caucasian populations and the resulting complications of diabetes such as nephropathy and retinopathy occur both earlier and more severely. Despite extensive investigation, the underlying pathophysiological processes explaining this phenomenon remain elusive. For its part, this study investigated lipid and lipoprotein metabolism and its relationship with the expression of the fatty acid translocase CD36 on monocytes in South Asians.

Research frontiers

Gene variants in CD36, a macrophage scavenger receptor, have been implicated in the pathogenesis of type 2 diabetes and its complications.

Innovations and breakthroughs

This study found that following the administration of a glucose load to South Asian individuals, an upregulation of CD36 positive monocytes was demonstrated which has not been previously seen. In keeping with animal models, it is presumed this increased CD36 expression facilitates the sequestration of triglycerides from very low density lipoprotein particles.

Terminology

This finding suggests that CD36 may represent an as yet unexploited target for therapeutic interventions addressing both diabetes and dyslipidaemia.

Peer-review

This is a very interesting study and all the sections of the manuscript are complete; results have been well described in the text and in the Tables and Figure.

World Journal of Diabetes
Volume 6 Number 8 July 25, 2015

ABOUT COVER

Editorial Board Member of *World Journal of Diabetes*, Dr. Xi-Lin Yang, PhD, Research Assistant Professor, Department of Medicine and Therapeutics, Prince of Wales Hospital, LiHS, Shatin, Hong Kong, China

AIM AND SCOPE

World Journal of Diabetes (*World J Diabetes*, *WJD*, online ISSN 1948-9358, DOI: 10.4239), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJD covers topics concerning α , β , δ and PP cells of the pancreatic islet, the effect of insulin and insulinresistance, pancreatic islet transplantation, adipose cells and obesity.

We encourage authors to submit their manuscripts to *WJD*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ ABSTRACTING

World Journal of Diabetes is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Obesity and type 2 diabetes mellitus (T2DM) are major public health issues globally over the past few decades. Despite dietary interventions, lifestyle modifications and the availability of several pharmaceutical agents, management of T2DM with obesity is a major challenge to clinicians. Metabolic surgery is emerging as a promising treatment option for the management of T2DM in the obese population in recent years. Several observational studies and a few randomised controlled trials have shown clear benefits of various bariatric procedures in obese individuals in terms of improvement or remission of T2DM and multiple other health benefits such as improvement of hypertension, obstructive sleep apnoea, osteoarthritis and non-alcoholic fatty liver disease. Uncertainties about the long-term implications of metabolic surgery such as relapse of T2DM after initial remission, nutritional and psychosocial complications and the optimal body mass index for different ethnic groups exist. The article discusses the major paradigm shift in recent years in the management of T2DM after the introduction of metabolic surgery.

Key words: Metabolic surgery; Bariatric procedures; Type 2 diabetes mellitus; Body mass index; Diabetes remission

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Metabolic surgery or bariatric surgery has revolutionised the 21st century management of type 2 diabetes mellitus (T2DM) in obese patients. Marked reduction of body weight following the bariatric procedures results in improvement or remission of T2DM in a significant number of patients along with improvement of other diseases associated with obesity

such as hypertension, obstructive sleep apnoea, osteoarthritis and non-alcoholic fatty liver disease. Uncertainty exists about the long-term outcomes in terms of diabetes relapse, nutritional and psychosocial complications. However, the marked benefits of metabolic surgery outweigh the risks related to the procedure that has resulted in a major paradigm shift in the management of obese population with T2DM in recent years which is the topic of discussion of this paper.

Pappachan JM, Viswanath AK. Metabolic surgery: A paradigm shift in type 2 diabetes management. *World J Diabetes* 2015; 6(8): 990-998 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i8/990.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i8.990>

METABOLIC SURGERY: A PARADIGM SHIFT IN TYPE 2 DIABETES MANAGEMENT

Obesity has become a global pandemic in recent years that affects more than 600 million adults worldwide^[1]. World Health Organization estimated that 39% of adults aged 18 years and over were overweight [body mass index (BMI) ≥ 25 kg/m²; more than 1.8 billion persons], and 13% were obese (BMI ≥ 30 kg/m²) in the year 2014. A majority of these individuals reside in the developed countries although obesity and overweight are major public health issues even in developing nations. The National Health and Nutrition Examination Survey 2011-2012 regarding population prevalence in obesity revealed that 34.9% of the adults were obese and 33.6% were overweight in the United States^[2]. Although data on the prevalence of obesity is scant from most other countries, comparable figures probably exist in many developed countries.

Obesity is a major risk factor for type 2 diabetes mellitus (T2DM). By 2014 diabetes affected 387 million people worldwide and 4.9 million deaths in 2014 alone were directly related to diabetes^[3]. The global diabetes disease burden is mainly from T2DM and a majority of these cases are related to obesity. Despite diet and lifestyle interventions and the availability of pharmaceutical agents with weight losing properties the long-term management of obesity with these measures are disappointing. Different gastric bypass procedures collectively termed as bariatric surgery/metabolic surgery have emerged as very promising methods to treat obesity in the past 3 decades that can improve and potentially cure diabetes and many other diseases related to obesity. Through this paper we discuss the major paradigm shift in the management of T2DM in recent years after the introduction of metabolic surgery. We also discuss the long-term health benefits, adverse complications and emerging research questions related

to metabolic surgery.

TYPES AND EFFICACY OF DIFFERENT BARIATRIC PROCEDURES

Although there are a multitude of bariatric procedures developed over the past 50 years the common techniques used in present day clinical practice are adjustable gastric banding (AGB), sleeve gastrectomy (SG), Roux-en-Y gastric bypass (RYGB) and bilio-pancreatic diversion (BPD). The different surgical procedures are depicted in the Figure 1.

AGB and SG are predominantly restrictive procedures whereas RYGB and BPD are mainly mal-absorptive procedures that reduce effective area of nutrient absorption in the intestinal mucosa. Food passes through the alimentary limb in RYGB and BPD with gastrointestinal secretions in the bilio-pancreatic limb mixing with the nutrients where both limbs form the common channel.

In various randomised controlled trials (RCTs), the reported mean percentage (%) excess body weight loss (with 95%CI in parenthesis) achieved at one year after AGB, SG and RYGB were 33.39 (22.57-44.21), 69.70 (41.09-98.32) and 72.32 (64.60-80.04) respectively^[4]. The % excess weight loss (%EWL) reported with BPD was 76.89 ± 1.53 that is significantly higher than RYGB (67.17 ± 1.43 ; $P = 0.0004$)^[5]. AGB procedures are losing popularity in the recent years because of inferior efficacy and the necessity for repeated surgery in a higher proportion of cases years after the initial surgery^[6]. Although BPD is associated with a significantly higher %EWL and T2DM remission compared to other bariatric procedures the post-operative complication rates are higher^[7] making this a less preferred operation.

BARIATRIC SURGERY IN T2DM

The major RCTs reporting the effects of metabolic surgery on T2DM are summarised in Table 1. The total number of patients in these RCTs is relatively small for a common condition like T2DM and the duration of follow-up is limited to 12-24 mo. However there are cohort studies and non-randomized trials reporting benefits of metabolic surgery from different regions of the world. There are also a few systematic reviews and meta-analyses reporting the beneficial effects of bariatric procedures in T2DM.

In a meta-analysis of weight loss and remission of T2DM evaluated in RCTs and observational studies (OBS) of bariatric surgery vs conventional medical therapy over a 17 mo period the mean excess weight loss (EWL) for the bariatric surgery and the conventional treatment groups were 75.3% and 11.3% respectively; the corresponding T2DM remission rates were 63.5% and 15.6%^[12]. The limitation of the meta-analysis was that many short-term OBS were included and surgery was not always compared directly to more vigorous medical weight loss interventions. There was lack of

Figure 1 The diagrammatic representation of different bariatric surgical procedures. A: Adjustable gastric band; B: Sleeve gastrectomy; C: Roux-en-Y gastric bypass; D: Bilio-pancreatic diversion. Figure reproduced with permission from John Wiley and Sons. *Obesity* (Silver Spring) 2013 Mar; 21 Suppl 1: S1-27.

standardization in the definition of diabetes remission and it was unclear how specific bariatric procedures were chosen or what criteria were used for performing bariatric surgery.

A comparison of the mean changes in BMI and haemoglobin A1c (HbA1c) achieved with individual procedures^[12] are shown in the Table 2.

A few long-term cohort studies give us insight on the beneficial effects of metabolic surgery in T2DM^[16]. For example, the Swedish Obese Subjects (SOS) study, started in 1987 is a prospective case-control study with 2010 obese subjects who underwent bariatric procedures (predominantly vertical banded gastrostomy which is considered to be less effective and no longer undertaken)^[16,17]. A 72% remission of T2DM after two years and 36% durable remission after 10 years were observed in obese subjects in the SOS study^[16,18]. Compared to control the risk of developing T2DM was reduced by 96%, 84%, and 78% after 2, 10, and 15 years in obese subjects without T2DM at baseline^[19].

Utah obesity study retrospectively compared 7925 obese subjects who underwent RYGB with the same number of age, sex and weight matched controls and after an average follow up period of 7.1 years, found a 40% reduction in all cause mortality, 49% reduction of mortality from cardiovascular diseases and 92% reduction of death related to T2DM^[20]. The Longitudinal

Assessment of Bariatric Surgery (LABS-2) study is an ongoing multi-center cohort study that showed T2DM remission in 67% and 28% of those who underwent RYGB and AGB respectively after 3 years of follow up^[21].

MECHANISMS OF DIABETES IMPROVEMENT/REMISSION FOLLOWING METABOLIC SURGERY

Reduction in calorie intake

Typically, patients are put on a calorie-restricted diet after bariatric procedures. The average caloric intake ranges from 400-800 kcal/d in the first month^[22]. Calorie restriction has a significant impact on hyperglycemia with reduction of blood glucose levels. In fact, in a recent case-control study^[23], post-bariatric diet implemented before metabolic surgery resulted in more profound glucose reduction in T2DM patients than in the post-surgical period, indicating the role of calorie restriction in glycemic control after bariatric procedures. Very low calorie diet alone resulted in improvement of insulin sensitivity and β -cell function in obese T2DM cases (comparable to those who had bariatric surgery) in the short-term^[24]. Generally, a calorie-restricted diet should be maintained in patients following metabolic surgery on a long-term basis.

Table 1 Major randomised controlled trials reporting effects of metabolic surgical procedure on type 2 diabetes mellitus

RCT	Study details	Outcome	Diabetes remission
Dixon <i>et al</i> ^[8]	Un-blinded RCT. N = 60 Obese patients with recent onset T2DM Conventional therapy <i>vs</i> LAGB Follow-up: 2 yr	Weight loss $-1.7\% \pm 5.2\%$ in conventional group and $-20.7\% \pm 8.6\%$ in the surgical group	73% in surgical group 13% in conventional group (Remission of T2DM defined as FBS < 7.0 mmol/L and HbA1c < 6.2%)
Mingrone <i>et al</i> ^[7]	Single centre non-blinded RCT. N = 60. Severely obese patients. T2DM of at least 5 yr duration and HbA1c > 7.0%. Conventional medical therapy <i>vs</i> RYGB or BPD Follow-up: 2 yr	Weight loss $-4.7\% \pm 6.3\%$ with medical therapy, $-33.3\% \pm 7.8\%$ with RYGB and $-33.8\% \pm 10.1\%$ with BPD	75% in RYGB group; 95% in BPD group. None in the conventional group (Remission defined as FBS < 5.6 mmol/L and HbA1c < 6.5%)
Schauer <i>et al</i> ^[9]	Single centre non-blinded RCT in obese uncontrolled T2DM. N = 150 Intensive medical therapy <i>vs</i> RYGB or SG Follow-up: 12 mo	Weight loss -5.4 ± 8.0 kg in medical therapy group, -29.4 ± 9.0 kg in RYGB group and -25.1 ± 8.5 kg in SG group	12% medical therapy group 42% in RYGB group 37% SG group (Remission/primary outcome defined as HbA1c of 6% or less)
Ikramuddin <i>et al</i> ^[10]	Un-blinded RCT in obese T2DM with HbA1c over 8% with average duration of 9 yr. N = 120 Intensive medical therapy <i>vs</i> RYGB Follow-up: 12 mo	Difference in weight loss between surgical and medical group -17.1 ± 5.6 kg. % weight change in medical <i>vs</i> Surgical group -7.9 ± 2 <i>vs</i> -26 ± 2	75% RYGB group 32% in medical group (Remission defined as HbA1c < 7%)
Liang <i>et al</i> ^[11]	RCT in obese T2DM. N = 108. RYGB compared with standard care with or without Exenatide therapy Follow-up: 12 mo	Reduction in BMI (kg/m^2) in standard <i>vs</i> Exenatide <i>vs</i> RYGB: -0.56 ± 1.66 <i>vs</i> -3.44 ± 1.21 <i>vs</i> -5.97 ± 0.91	90% in RYGB group None in patients receiving standard care with or without Exenatide (Remission defined as HbA1c < 6.5%)

RCTs: Randomised controlled trials; T2DM: Type 2 diabetes mellitus; N: Number of subjects; LAGB: Laparoscopic gastric banding; FBS: Fasting blood sugar; RYGB: Roux-en-Y gastric bypass; SG: Sleeve gastrectomy; BPD: Bilio-pancreatic diversion.

Table 2 The mean changes in body mass index and haemoglobin A1c achieved with different gastric bypass procedures

Bariatric procedure	Body mass index (kg/m^2)			HbA1c (%)		
	Pre-surgery	Post-surgery	Mean reduction (95%CI)	Pre-surgery	Post-surgery	Mean reduction (95%CI)
AGB	37	29.5	7.5 (5.9-9.1)	7.8	6	1.8 (1.3-2.3)
SG	41.3	28.3	13.0 (10.1-15.9)	7.9	6	1.9 (1.0-2.8)
RYGB	34.6	25.8	8.8 (5.2-12.4)	8.2	6.1	2.1 (1.3-2.9)
BPD	50.5	34.6	15.9 (11.8-20.0)	8	5.2	2.8 (2.1-3.5)

AGB: Adjustable gastric banding; SG: Sleeve gastrectomy; RYGB: Roux-en-Y gastric bypass; BPD: Bilio-pancreatic diversion; HbA1c: Haemoglobin A1c.

Alterations in gut hormones

The acceleration of gastrointestinal transit time after bariatric procedures results in augmented secretion of gut hormones such as glucagon-like peptide-1 (GLP-1), Glucose-dependent insulintropic peptide (GIP) peptide-YY (PYY) and oxyntomodulin (OXM) that alter energy and glucose metabolism^[25]. The anorexiant and weight losing properties of GLP-1 is well established in experimental and clinical models. Several studies showed significant elevation of GLP-1 levels during oral glucose challenge and with meals after bariatric procedures such as SG^[26], RYGB^[27] and BPD^[28]. Elevated GLP-1 levels following metabolic surgery was also shown to reverse the obesity-induced endothelial dysfunction conferring cardiovascular protection in the obese^[29].

Increased PYY levels following bariatric procedures result in weight loss in obese subjects. PYY administration resulted in a 30% reduction in the caloric value of a meal consumed 2 h after PYY infusion and a 33% reduction in food consumption over 24 h period in human beings^[30]. Similarly, OXM administration has been shown

to reduce appetite, amount of food ingested and body weight^[31]. Ghrelin (a gut-derived peptide hormone that stimulates hunger) level was found to be low after RYGB, whereas the level was high in diet-induced weight loss, indicating the impact of suppression of hunger signals in subjects following bariatric surgery^[32]. Hypergastrinemia following SG has been recently reported in rat models of T2DM, although its impact on metabolic pathways and body weight changes have been unclear^[33]. The alteration in these gastrointestinal hormonal factors together contributes to significant improvement in T2DM and the body weight of the individual.

Pancreatic β -cell function

Improvement in insulin sensitivity and pancreatic β -cell function are important factors that contribute to improvement/remission of T2DM in obese subjects. Increase in secretion of incretin hormones (GLP-1 and GIP) and proliferation of the β -cell mass have been demonstrated following bariatric procedures in human beings and experimental animals^[34]. Although these

factors clearly contribute to T2DM control, there may be other mechanisms which are not yet clear.

Hepatic and peripheral insulin sensitivity

Significant improvement of hepatic insulin sensitivity is observed within few days of bariatric procedures much earlier and before significant weight loss occurs. Reduction of energy intake from the post-bariatric diet may contribute significantly to the improvement in hepatic insulin sensitivity. Although peripheral insulin sensitivity is not altered in the immediate post-operative period, delayed improvement is observed in patients^[25,35]. Reduced hepatic fat content and body weight loss account for the sustained improvements in hepatic and peripheral insulin sensitivity during long-term follow up of patients who had metabolic surgery^[25].

Role of bile acids

Bariatric procedures were shown to increase the plasma levels of bile acids that improved glucose and lipid metabolism^[25,36]. However, the exact mechanisms by which bile acids improve glycemic control and body weight remain elusive.

Gut microbiota

Major changes in the gut microbiota have been demonstrated following bariatric procedures in animal models and human beings^[37]. Increase in numbers of some of these intestinal microbial flora, and the related changes in the gut biochemical environment, may affect glucose and lipid metabolism that contribute to weight loss and diabetes improvement^[25,37]. More research is necessary on the role of gut flora in glucose and fat metabolism following bariatric procedures.

Body weight loss and diabetes remission

The major mechanism by which improvement and/or remission of T2DM occurs in obese subjects following metabolic surgery is the significant weight loss after the procedure. Analysis of participants in the Look AHEAD (Action For Health in Diabetes) study clearly showed a progressive increase in odds ratios for HbA1c reduction with higher proportions of weight loss^[38]. The odds ratios for % weight reduction (in parenthesis) were: 1.80 (≥ 2 to < 5), 3.52 (≥ 5 to < 10), 5.44 (≥ 10 to < 15) and 10.02 ($\geq 15\%$) respectively for HbA1c reduction of 0.05% in the study subjects. Substantial loss of body weight post-bariatric surgery therefore would explain the remarkable improvements in glycemic control and even remission of T2DM in the majority of patients.

Overall, a multitude of physiological, behavioural and anatomical alterations following the bariatric procedure result in significant improvements in metabolic and glycemic parameters that may even result in potential cure of T2DM in a good number of patients after the metabolic surgery.

COST BENEFITS AND OTHER HEALTH-RELATED OUTCOMES

Data from the National Bariatric Surgery Registry (NBSR) of the United Kingdom that included 18283 cases from 2010 to 2013 clearly showed compelling evidence of the cost effectiveness of bariatric surgery as a treatment option for severely obese T2DM patients^[39]. NBSR data showed that 61% of patients with obstructive sleep apnoea could come off their treatment after surgery 65% of patients with T2DM could stop their diabetic medications. A recent systematic review and meta-analysis revealed important cardioprotective effects of metabolic surgery in terms of regression of left ventricular hypertrophy, improvement of diastolic function and reduction of left atrial size^[40]. Improvement of hypertension, hypercholesterolemia, gastro-esophageal reflux disease, and arthritis are some of the other reported major beneficial effects of bariatric surgery^[41].

IMMEDIATE AND LONG-TERM COMPLICATIONS

The main complications in the immediate post-operative period are pulmonary complications, vomiting, wound infections, bleeding and anastomotic leak^[16,17]. In a recent systematic review and meta-analysis the peri-operative and post-operative mortality rates were 0.08% and 0.31% respectively in RCTs and 0.22% and 0.35% respectively in OBS^[4]. The overall complication rates were 17% in RCTs and 10% in OBS, and the reoperation rates were 7% and 6% respectively.

The most common long-term complications were iron deficiency anaemia in up to 15% of cases and re-operations in up to 8%^[14,16]. Psychological issues are emerging as an important complication on follow up of the cases, and alcohol overconsumption and substance misuse are increasingly being reported in patients on long-term follow up^[16,42]. For unknown reasons, the suicidal rates were found to be higher in patients who underwent bariatric surgery^[16,20]. Nutritional deficiencies including deficiencies of calcium, vitamin D, iron, zinc, and copper, are common after bariatric surgery^[16,43]. Periodic checking for deficiencies and nutritional supplements are indicated in patients.

Massive weight loss after the surgery may result in abnormal body contour because of extensive skin folds that may affect the psychological well being of many patients. Body contouring surgery improves this problem and may help improvement of physical and mental well being in these patients although financial cost may become an issue in many healthcare systems^[44]. Post-prandial hypoglycaemia is a common problem in many patients after metabolic surgery. Rapid transit of contents from stomach with smaller capacity could be a reason in many cases that can be treated with small frequent

meals and complex carbohydrates. However, severe hypoglycaemic episodes caused by hyperinsulinemia from pancreatic islet cell hyperplasia (nesidioblastosis) can sometimes be crippling necessitating pancreas resection, reversal of gastric bypass and restriction of gastric pouch in extreme cases^[45].

Diabetic microvascular complications such as retinopathy, neuropathy and nephropathy can sometimes get worse if there is rapid (abrupt) improvement of longstanding severe dysglycemia in patients with poorly controlled diabetes. A similar situation could be expected following metabolic surgery with acute improvement in glycaemic control. There is some evidence of worsening of pre-existing diabetic retinopathy in a proportion of cases following bariatric procedures, although improvement of the disease is also noted in some others^[46,47]. Therefore, counselling about this potential complication before surgery and close monitoring after the procedure are advisable. Though the data is insufficient, there is some evidence for improvement of diabetic neuropathy^[48] and nephropathy^[49] after bariatric surgery. There are no reports of worsening of these conditions after improvement of T2DM following bariatric procedures.

Pregnancies after bariatric surgery were found to be associated with significantly lower risk of gestational diabetes [odds ratio (OR): 0.25; 95%CI: 0.13–0.47], large-for-gestational-age infants (OR: 0.33; 95%CI: 0.24–0.44) and shorter gestation (mean difference: –4.5 d; 95%CI: –2.9 to –6 d; $P < 0.001$)^[50]. However, there were significantly higher risk of small-for gestational-age infants (OR: 2.20; 95%CI: 1.64–2.95; $P < 0.001$). The risk of stillbirth or neonatal death post-bariatric pregnancies appeared to be higher [1.7% vs 0.7% (OR: 2.39; 95%CI: 0.98–5.85; $P = 0.06$)] although this risk did not reach statistical significance.

APPROPRIATE PATIENT CATEGORY FOR METABOLIC SURGERY

There is no clear and uniform consensus from different international bodies about the minimum BMI cut off for consideration of the bariatric procedure in obese individuals. The National Institute for Health and Clinical Care Excellence (NICE) of the United Kingdom recently recommended bariatric surgery for people with a BMI of $> 40 \text{ kg/m}^2$ and $> 35 \text{ kg/m}^2$ in the presence of co-morbidities such as T2DM or hypertension^[51]. For people of Asian family origin a lower BMI threshold should be considered. NICE also recommends expedited assessment for Bariatric surgery to people with BMI of 30–34.9 kg/m^2 who have recent onset T2DM. This is based on the evidence that earlier intervention can improve the chances of remission following bariatric surgery^[39].

The Canadian Diabetes Association Clinical Practice Guidelines (2013) recommend bariatric surgery for people with class III obesity (BMI $\geq 40.0 \text{ kg/m}^2$) or class II obesity (BMI = 35.0 to 39.9 kg/m^2) in the presence of co-morbidities, with an inability to maintain

weight loss following adequate trial of health behaviour intervention^[52].

The American Association of Clinical Endocrinologists, the Obesity Society and the American Society for Metabolic and Bariatric Surgery (2013) recommend metabolic surgery in obese individuals with a BMI of $\geq 40 \text{ kg/m}^2$ without coexisting medical problems and surgical risk^[53]. For patients with BMI $\geq 35 \text{ kg/m}^2$, surgery may be offered if one or more severe obesity-related co-morbidities exist including T2D, hypertension, hyperlipidemia, obstructive sleep apnea (OSA), obesity-hypoventilation syndrome (OHS), Pickwickian syndrome (a combination of OSA and OHS), nonalcoholic fatty liver disease or nonalcoholic steatohepatitis, pseudotumor cerebri, gastroesophageal reflux disease, asthma, venous stasis disease, severe urinary incontinence, debilitating arthritis, or considerably impaired quality of life. Patients with BMI of 30–34.9 kg/m^2 and T2DM or metabolic syndrome may also be offered a bariatric procedure, although evidence for this recommendation is inadequate with the unavailability of long-term data^[53].

With robust clinical and epidemiological data emerging from all continents of the world, a global consensus on the appropriate patient categories that get definite benefits from metabolic surgery is expected to emerge in the near future.

AREAS OF UNCERTAINTY

Although there is accumulated experience from different regions of the world on the excellent outcomes of bariatric procedures, there is not enough data from resource poor nations of Asia, Arabian Peninsula, Africa and South America to generalise the recommendations of metabolic surgery, even though obesity epidemic is becoming a public health issue in these regions. Moreover, the BMI cut off for obesity in Asians is different from that of the western populations. For example BMI of $\geq 25 \text{ kg/m}^2$ is considered as obesity in India^[54] and $\geq 27 \text{ kg/m}^2$ in Taiwan^[55]. Diabesity (diabetes caused by overweight or obesity) is different for populations of Asian and Afro-Caribbean ethnic background owing to the difference in abdominal adiposity in these groups compared to other races, making generalisation of BMI cut offs metabolic surgery inappropriate.

For a common condition like diabetes there are only a handful of RCT's of short duration comparing bariatric surgery to medical therapy which ranged from standard care to intensive medical intervention. There are a few prospective studies available on long term outcomes of bariatric surgery. However, T2DM being a lifelong multisystem disease with almost all organs of the body involved, more data based on lifelong follow up of cases is necessary to understand the true impact of bariatric procedures. This requires maintenance of nationwide bariatric registries globally along the lines of NBSR in the UK which can provide valuable information.

Though there are some studies on the impact of bariatric surgery on the psychosocial, nutritional and

mineral metabolic status of patients, long-term data on these areas are still inadequate. Similarly the optimal management of post-bariatric nesidioblastosis that emerged as a challenging clinical problem is not yet clear.

Different multicentre on-going prospective clinical trials would be expected to answer these unresolved questions.

CONCLUSION

Metabolic surgery is emerging as a major paradigm shift in the 21st Century management of T2DM, and has revolutionised the care of diabetes. Massive weight loss with remission of T2DM in a significant proportion of cases along with improvement of most other obesity-related ailments makes the treatment a very attractive option for clinicians and patients. A recent analysis of the NBSR data clearly showed its cost effectiveness. Appropriate patient selection and long-term follow up of cases are necessary to optimise the outcomes and reduce the complications.

Abstract

Technologies for diabetes management, such as continuous subcutaneous insulin infusion (CSII) and continuous glucose monitoring (CGM) systems, have improved remarkably over the last decades. These developments are impacting the capacity to achieve recommended hemoglobin A1c levels and assisting in preventing the development and progression of micro- and macro vascular complications. While improvements in metabolic control and decreases in risk of severe and moderate hypoglycemia have been described with use of these technologies, large epidemiological international studies show that many patients are still unable to meet their glycemic goals, even when these technologies are used. This editorial will review the impact of technology on glycemic control, hypoglycemia and quality of life in children and youth with type 1 diabetes. Technologies reviewed include CSII, CGM systems and sensor-augmented insulin pumps. In addition, the usefulness of advanced functions such as bolus profiles, bolus calculators and threshold-suspend features will be also discussed. Moreover, the current editorial will explore the challenges of using these technologies. Indeed, despite the evidence currently available of the potential benefits of using advanced technologies in diabetes management, many patients still report barriers to using them. Finally this article will highlight the importance of future studies tailored toward overcome these barriers to optimizing glycemic control and avoiding severe hypoglycemia.

Key words: Diabetes; Technology; Glycemic control; Quality of life; Outcomes; Management

Core tip: There have been many advances in the technologies associated with diabetes care in the last few years, which have resulted in new opportunities

in the treatment of diabetes. Despite the encouraging results and the prospect of a fully automated closed loop system in the near future, metabolic control remains suboptimal in most patients with type 1 diabetes. Data from registries has recently shown that a large proportion of children with type 1 diabetes does not meet the age associated A1c targets across all countries, especially in the youth age. This editorial discusses the impact of these technologies on glycemic control and quality of life and attempts to address how to overcome barriers using these technologies to achieve improved metabolic control.

Giani E, Scaramuzza AE, Zuccotti GV. Impact of new technologies on diabetes care. *World J Diabetes* 2015; 6(8): 999-1004 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i8/999.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i8.999>

Recently, data related to the safety and effectiveness of a bionic pancreas under unrestricted outpatient conditions were published by Russel *et al.*^[11], reporting that “as compared with an insulin pump, a wearable, automated, bi-hormonal, bionic pancreas improved mean glycemic levels, with less frequent hypoglycemic episodes” in both adults and adolescents with type 1 diabetes, in outpatient settings. While the device is still imperfect, (difficulty with wireless connectivity, poor stability of glucagon, need for faster insulin analogues, risk of hypoglycemia and need for restrictions in food and alcohol intake) these results marked an important step toward a fully automated closed-loop system.

Currently, at least 20 research groups are working worldwide on glucose-sensor-controlled automated insulin delivery systems (closed loop pumps), and during the last years, great progress was reported in closed-loop system in outpatients settings, with a particular focus on overnight glycemic control, whereas postprandial and post-exercise glucose control remains a challenge^[2-5].

These promising studies bring the artificial pancreas closer to public use, which is possible due to the recent improvements in technology for diabetes care. Nonetheless, many patients spend the majority of their day outside the recommended glycemic ranges. As a result glycemic control remains suboptimal for many patients with type 1 diabetes^[6].

It has now been 10 years since the Epidemiology of Diabetes Interventions and Complications study confirmed the need to optimize glycemic control as early as possible to sustain risk reduction for micro- and macro vascular complications^[7,8]. Since then, many national and international diabetes associations [e.g., the American Diabetes Association and the International Society for Pediatric and Adolescent Diabetes (ISPAD)] revised their guidelines for type 1 diabetes management and now recommend a target glycated hemoglobin (A1c) of 6.5%-7.5% (48-59 mmol/mol) for most people with type 1 diabetes (T1D)^[9,10]. However, recently published

data by McKnight *et al.*^[11], reported that only 30% of males and 29% of females aged < 15 years, 24% of males and 20% of females aged 15-24 years, and 30% of males and 28% of females aged > 25 years achieved these recommended A1c levels (< 7.5% or < 59 mmol/mol). These data confirmed that this target is not easily achieved in many people with type 1 diabetes and also that A1c levels are higher in those aged 15-24 years than among other age groups across many countries^[11]. It is clear that there is still a gap between patients' glycemic control outcomes and what can be achieved with newer therapeutic improvements, even if technological key advances as the continuous subcutaneous insulin infusion (CSII) and the continuous glucose monitoring (CGM) have been shown to greatly improve diabetes care.

Focusing on the effectiveness of new technologies and the limitations of the use of such technologies in the real world may help find a way to achieve the A1c goals for many patients. In addition, it could give us greater insight into barriers to sustain the use of these therapeutic advances and how to overcome them. Several recently published review studies and meta-analyses addressed these topics^[12-14]. Deeb *et al.*^[15] assessed the association between how insulin pumps were used and blood glucose control to determine if the use of advanced pump features improved glycemic control. Indeed, over the last 15 years, it has been shown that the increasing use of insulin pump can result in many health benefits and an improvement of overall treatment satisfaction^[16,17]. Thus, it would be expected to improve long-time metabolic outcome in patients using this treatment. Although randomized controlled studies and systematic reviews of pediatric cohorts using CSII showed only modest benefits (in the range of 0%-0.9%^[18]) in terms of mean A1c compared to multiple daily injections (MDI), many prospective and retrospective case-control studies, clinic-based series and registries, reported that pediatric insulin pump users have a lower A1c when compared to patients using MDI, and that they are more likely to achieve A1c targets than those on injections. Recently, Olsen *et al.*^[19] showed a significantly lower mean A1c ($P < 0.0001$) in 1493 children and youth using CSII vs 1846 using MDI therapy over a 5 year period in all age groups. In the T1D Exchange clinic registry, A1c was shown to be lower in CSII users vs MDI users (7.9% vs 8.5%, $P < 0.001$); in the longitudinal analysis, one year after initiation of CSII therapy, A1c decreased by 0.2% on average ($P < 0.001$), with no difference in frequency of severe hypoglycemic events ($P = 0.2$)^[20]. Similar data have been reported in the national pediatric diabetes audit of England and Wales and in the DPV initiative of Germany and Austria at the last ISPAD meeting^[21]. What is more, in their meta-analysis, Pickup and Sutton reported patients on CSII had less hyperglycemia and less severe hypoglycemia^[22]. Other meta-analyses showed that the frequency of severe hypoglycemia was significantly higher with multiple daily insulin injections

than with insulin-pump therapy [odds ratio (OR), OR: 4.19; 95%CI: 2.86-6.13]. The greatest reduction was seen among patients who had had the greatest number of episodes of severe hypoglycemia while they were receiving injection therapy. Among these patients, the rate of severe hypoglycemia was higher by a factor of about 30 with multiple daily insulin injections than with insulin-pump therapy^[16].

Finally, CSII has been associated with an improved quality of life^[23,24]: CSII use is related to reduced frequency and intensity of parent stress, decreased fear of hypoglycemia, increased flexibility in quantity and timing of meals and sleep schedule, improvement in diabetes self-efficacy and independence^[23,25].

However, not all children benefit from CSII. This discrepancy allows us to determine predictors for improvement of glycemic control on pump. For example, Olsen *et al*^[19] showed that achievement of target A1c was significantly associated with lower A1c before insulin pump therapy initiation, younger age (< 12 years), shorter diabetes duration, higher number of daily boluses and more frequent daily self-blood glucose monitoring. Thus, patient characteristics are critical factors in deciding whether or not it is appropriate to prescribe an insulin pump to an individual.

Similar results are seen with continuous glucose monitors (CGM) use, and data from the T1D Exchange Clinic Registry showed that only a small proportion of patients with type 1 diabetes are using CGM daily in clinical practice, especially in the pediatric age range^[26]. The accuracy and usability of CGM has gradually improved over the past decade so that the overall accuracy of the latest sensor generations measured as the mean relative absolute difference vs a given laboratory standard is in the 8%-15% range^[27]. Despite this, CGM is still far from perfect. For example, more accurate evaluation of interstitial glucose levels during hypoglycemic events are necessary as CGM performs poorly in the hypoglycemic range, and the lag time between interstitial glucose and blood glucose, increased sensor sensitivity and inappropriate calibration require improvement^[28].

Several studies have showed that CGM is associated with a significant reduction in A1c^[29]. In two recent meta-analyses of randomized controlled trials, CGM was shown to be superior to self-monitoring of blood glucose alone in reducing A1c by almost 0.4% in both children and adults^[30,31]. In a JDRF-sponsored multicenter trial, there was a larger percentage of subjects 8-14 years old using CGM who achieved at least a 10% decrease in A1c and a target A1c < 7% (59 mmol/mol), compared with children using capillary blood monitoring (SMBG)^[32]. In a Cochrane meta-analysis, the largest improvement in glycemic control was observed in poorly controlled diabetes patients using CGM and CSII (sensor-augmented pump - SAP). There was no increase in risk of severe hypoglycemia or ketoacidosis in this evaluation.

Although the impact of CGM use on hypoglycemia is less clear, Floyd *et al*^[31] found a significant decrease in the duration of time in both mild and severe hypoglycemia

ranges and an increase in the time "in range" (70-180 mg/dL) in patient using CGM^[31].

In the last few years, several studies evaluated the impact of SAP on metabolic control compared to either MDI or SMBG^[33] or CSII and SMBG^[34-36]. SAP therapy was demonstrated to be effective at lowering mean A1c in both adult and pediatric patients^[33-36]. Switching to SAP therapy helped patients using MDI to lower their A1c levels to the same extent as the patients originally allocated to the SAP arm of the study. Benefits persisted through the entire 12-mo study phase (STAR 3 Study)^[33], as well as its follow up phase^[34]. Patients using SAP therapy were more likely to meet age-appropriate A1c target^[33].

However, studies investigating the effectiveness of SAP in patients already using the insulin pump showed conflicting results, ranging from no significant benefit to significantly improved glycemic control^[35-37].

SAP therapy was also associated with decreased time spent in hypoglycemia compared to MDI or CSII, but few significant results were found in the rate of severe hypoglycemic events.

Although current standards for diabetes management reflect the need to avoid diabetes complications, in the pediatric clinical setting, the fear of hypoglycemic events is a common barrier to achieving optimal metabolic control.

It has been reported that the most severe hypoglycemic events in children occur at night, and account for 75% of all hypoglycemic seizures^[38]. Thus, children may represent a group of patients that can benefit greatly from SAP therapy, especially when a low-glucose suspend (LGS) feature is implemented (*i.e.*, the feature that automatically suspends insulin delivery when the blood glucose is less than a pre-selected value, typically 70 mg/dL). LGS and predictive low-glucose suspend (PLGS) are the first steps toward the artificial pancreas, and can help reduce family stress related to glucose management, especially overnight. LGS systems have been demonstrated to be effective in reducing the rate, severity and duration of hypoglycemia, without an increase in A1c^[39]. In particular, this feature was shown to be most effective in patients with more frequent and severe hypoglycemia and in those with hypoglycemia unawareness^[39].

In a study from Ly *et al*^[40] the incidence of hypoglycemia after 6 mo decreased from 34.2/100 patient-months in the insulin pump group to 9.5/100 patient-months in the SAP plus LGS group, with the rate of severe hypoglycemia reduced to zero (0) in the SAP plus LGS group^[39,40].

In the PLGS system, a predictive algorithm stops insulin delivery prior to reaching a predetermined threshold. Only a few outpatient studies using PLGS have been published to date, but it was shown that a further reduction of the severity of hypoglycemia as compared with SAP plus LGS alone is possible^[41,42].

Despite all these encouraging results, CGM use is still difficult in youth with type 1 diabetes of all ages^[43]. It is

now clear that CGM can greatly help to improve glycemic control only in patients with type 1 diabetes who use the sensor for the majority of time (more than 70%)^[29,31,32], and works best when used on a near-daily basis. For this reason, physical, socioeconomic and educational factors that could impact the use of this technology are an area of current research, as are predictors of pump and sensor use^[44].

There are a number of barriers that may inhibit youth from wearing CGM. CGM use requires significant patient input (sensor insertion, calibration, response to sensor alarms and glucose trends) and ongoing SMBG for insulin dosing. The Juvenile Diabetes Research Foundation CGM trial on CGM satisfaction reported pain in sensor insertion, frustration with sensor alarms, skin reaction, and issues related to discomfort with wearing the device or technical problems as barriers to CGM wear^[44]. In the T1D Exchange registry, CGM use was more likely in subjects with higher educational level, higher income, private insurance, longer diabetes duration and those on insulin pump^[26]. In addition, recent data showed that most patients using CGM may not receive the full benefits of this technology, either because they do not use it enough or because they do not regularly download it and retrospectively review the data from the device^[45].

Lack of a proper education, diminished motivation, deliberate insulin omission, and behavioral attitude can affect patients' compliance. Ensuring long-term follow-up with intensifying education and involving behavioral therapy in training might improve adherence and enhance treatment satisfaction, leading to a better glycemic control^[26].

Beside technology by itself, great improvement has been observed also in immune-suppressor drugs or other drugs, useful to improve type 1 diabetes management^[46].

In conclusion, since most of the recently reported epidemiological data demonstrates that a large proportion of type 1 diabetes patients do not achieve A1c targets, we consider increased education on diabetes care as a good option to improve glycemic control. New technologies may have positive outcomes, but can underperform if the technology is not used as expected^[16,42-45].

While the hope for a fully automated artificial pancreas available in the near future remains, it is crucial to develop approaches for implementing and sustaining the use of technological advances that are currently available (*e.g.*, beside CSII and CGM). In addition, we need to continue our patient/family education efforts.

Abstract

Diabetic retinopathy (DR) is the worldwide leading cause of legal blindness. In 2010, 1.9% of diabetes mellitus (DM) patients were legally blind and 10.2% had visual impairment. The control of DM parameters (glycemia, arterial tension and lipids) is the gold standard for preventing DR complications, although, unfortunately, DR still appeared in a 25% to 35% of patients. The stages of severe vision threatening DR, include proliferative DR (6.96%) and diabetic macular edema (6.81%). This review aims to update our knowledge on DR screening using telemedicine, the different techniques, the problems, and the inclusion of different professionals such as family physicians in care programs.

Core tip: If telemedicine is especially suited for a particular medical specialisation, that specialisation is undoubtedly ophthalmology. The enormous healthcare pressure derived from the general population's high demand for vision control and the prevalence of certain diseases which affect the eyes, such as diabetes mellitus, combined with the tremendous progress in diagnostic imaging systems in this speciality make it especially possible to send images over telemedicine networks for the diagnosis or even prevention of eye diseases, thus making the demand for the use of these types of methods extremely important.

Romero-Aroca P, Sagarra-Alamo R, Pareja-Rios A, López M. Importance of telemedicine in diabetes care: Relationships between family physicians and ophthalmologists. *World J Diabetes* 2015; 6(8): 1005-1008 Available from: URL: <http://www.wjgnet.com/1948-9358/full/v6/i8/1005.htm> DOI: <http://dx.doi.org/10.4239/wjd.v6.i8.1005>

INTRODUCTION

If telemedicine is especially suited for a particular medical specialization it would undoubtedly be ophthalmology. There is enormous pressure on healthcare systems by the general population's high demand for vision control and the prevalence of certain diseases which affect the eyes, such as diabetes mellitus (DM). The tremendous progress in diagnostic imaging systems make it possible to send images over telemedicine networks for the diagnosis or even prevention of eye diseases.

We should not forget that eye-care centers are often a considerable distance away from the population that require healthcare, so being able to send information over a telemedicine network is a great advantage. Good liaison among specialists, such as the ophthalmologist and the family doctor, means that it is possible to avoid patients traveling and enabling them to be diagnosed and controlled closer to home.

In spite of ophthalmology perhaps being the best example of the use of telemedicine, the reality is that its use is still far from extensive. There are many problems that ophthalmologists and other specialists who could use this communication system may face, including incompatibility among data-processing systems used by different specialists, not only among specialists and general practitioners, but even among hospital centers themselves. This is heightened by the existence of personal data-protection laws that cover the sending of images along with other personal details of patients. All this can make the regular use of telemedicine quite difficult^[1].

Even within the field of ophthalmology, not all eye diseases can benefit from the use of telemedicine, the most common being to send images of diseases that affect the retina, many of them highly prevalent.

TELEMEDICINE IN DIABETIC RETINOPATHY

DM is recognized by the World Health Organization as an genuine pandemic^[2] that affects more than 10% of the population over 14 years of age^[3], with type diabetes mellitus 2 (DM2) being the most common presentation and associated with lifestyle habits such as sedentarism or obesity. Considered a chronic disease, its morbidity is brought about by the complications it causes throughout a patient's lifetime, these being mainly derived from damage to large vessels, or macroangiopathy (complicated by cerebrovascular accidents and myocardial infarction),

or damage to small vessels, or microangiopathy, leading to nephropathy, neuropathy or retinopathy.

Eye diseases caused by microangiopathy or diabetic retinopathy (DR) are the main cause of blindness among young adults in the western world (aged between 45 and 60) and are closely related to poor metabolic control of the DM and aggravated by other comorbidities that are present in DM, such as high blood pressure, dyslipidemia or nephropathy. Early diagnosis of DR is very important because it has been shown that strict control over glycemia and high blood pressure slows the progress of the retinopathy and, if it is not present, extends the time until its appearance^[4]. Screening diabetics is therefore fundamental for detecting the existence of DR as soon as possible. This should be carried out by taking retinal photographs with non-mydratic cameras, an accepted cost-effective method that makes it feasible to cover a large number of patients with DM^[5,6].

In spite of the fact that a system such as the one presented here would enable the screening of a large number of patients, with the benefit for the diabetic population this represents, the truth is that, to date, the screening of diabetic patients does not take place on a general basis and many patients with DM do not undergo regular eye examinations. So much so that in developed countries such as those in the European Union area, there are considerable deficiencies in compliance with eye examinations for diabetic patients.

With this in mind, the European "Screening for DR in Europe" group revised the 1990 St Vincent Declaration^[7]. A large group of ophthalmologists and endocrinologists from 29 European countries attended a number of meetings between 2005 and 2011, which revealed a series of difficulties in applying screening recommendations. Such difficulties were identified as a paucity of information supplied to the public regarding screening visits, a shortage of teams and training programs, and insufficient collaboration among general practitioners, endocrinologists and ophthalmologists. In view of this data, it was decided to implement systematic screening programs designed to reach at least 80% of diabetics by using staff and professionals specially trained for this purpose.

When deciding to implement a system of DR screening, we need to consider what type of healthcare professional should be responsible for controlling patients with DM. In the majority of countries this is the family doctor, with control by endocrinologists being restricted to patients with very poor metabolic control of the DM.

The family doctor was, therefore, the professional who it was thought should be able to ensure collaboration with DR screening, even though there was some reticence among some sectors, especially ophthalmologists and optometrists. The insufficient number of ophthalmologists for such large populations such as diabetics, combined with different studies on the effectiveness of screening by general practitioners^[8-10], led the different working groups to decide that the family doctor needs to be involved in the DR screening programs provided they are

experts in the analysis of retinal photographs and have the support of an ophthalmologist who can supervise them, without this implying non-performance of complete eye examinations^[11]. In the United Kingdom, a country where screening has been more widely developed, general practitioners are included in the programs and different professionals are involved in assessment (general practitioners or optometrists)^[2,12]. Furthermore, in the authors' healthcare areas, the general practitioner plays an important role in DR screening^[13,14]. It is therefore essential to impart the necessary training to these professionals so that they can detect the presence of an incipient retinopathy and establish contact with reference ophthalmologists^[14,15] so that the latter can then provide the required support. If more advanced forms of retinopathy are detected, they would be able to refer the patient for treatment as quickly as possible.

Telemedicine is clearly of great use to this system of DR screening making it possible to send images and information for a correct diagnosis, and disturbing diabetic patients as little as possible.

In the authors' experience, including general practitioners and ensuring they are appropriately supervised by ophthalmologists who are experts in DR, has enabled the screening of a large number of diabetics^[16,17]. Since 2007, from an estimated population of 17792 diabetics, it has been possible to screen 15396 patients (86.53%), with 3.18 ± 1 visits during these 7 years. The scheme involves firstly training general practitioners, who would then be responsible for analyzing the retinal photographs of diabetics in their area. In the event of any suspicion of the presence of signs suggesting DR, the reference ophthalmologist would be consulted, and he/she then makes the final diagnosis and decides how to manage the patient. This procedure has led to the detection of an annual incidence of between 8.06% and 8.92% of patients with DR, with the incidence of patients with diabetic macular edema being between 2% and 2.8% per year. It is also important to note that between 9.2% and 10.3% of other pathologies have been detected each year, including macular degeneration associated with age, pathological myopia and the presence of pigmented lesions such as nevi. In spite of the efforts we have made in our area, only between 32.40% and 41.16% of diabetic patients undergo screening for DR every year. Part of the problem is that screening is opportunistic rather than systematic, and poor awareness among the population.

With the current world economic crisis and the explosion of the prevalence of DM we are witnessing, we should strive to ensure that screening programs are more sustainable. Measures that should be considered include: (1) Extending screening intervals for patients who do not apparently have DR and have good metabolic control (biannual is sufficient). This has been studied by some groups and proven to be feasible; (2) Developing a diagnosis aid system by implementing the design of clinical decisions support system software to enable risk

factors to be considered when scheduling successive screening tests; and (3) Automatic reading of retinal photographs. Considerable advances have been made in this field, although these systems are currently very sensitive but not specific.

CONCLUSION

Telemedicine is a field that is extremely useful in ophthalmology and which has enormous potential, even though it is currently under-used and often limited to merely transmitting images and information about very specific pathologies such as DR or retinopathy in premature babies but has potential for many more eye diseases. Problems in data-processing systems can be solved and do not need to be an obstacle, but the lack of government regulation in many countries makes it difficult to apply in the vast majority of cases. Guidelines for government regulation are essential if communication among professionals is to increase, which can only lead to improving public health.

Abstract

Respiratory failure complicating the course of diabetic ketoacidosis (DKA) is a source of increased morbidity and mortality. Detection of respiratory failure in DKA requires focused clinical monitoring, careful interpretation of arterial blood gases, and investigation for conditions that can affect adversely the respiration. Conditions that compromise respiratory function caused by DKA can be detected at presentation but are usually more prevalent during treatment. These conditions include deficits of potassium, magnesium and phosphate and hydrostatic or non-hydrostatic pulmonary edema. Conditions not caused by DKA that can worsen respiratory function under the added stress of DKA include infections of the respiratory system, pre-existing respiratory or neuromuscular disease and miscellaneous other conditions. Prompt recognition and management of the conditions that can lead to respiratory failure in DKA may prevent respiratory failure and improve mortality from DKA.

Key words: Diabetic ketoacidosis; Respiratory failure; Hypokalemia; Hypomagnesemia; Hypophosphatemia; Pulmonary edema; Adult respiratory distress syndrome; Pneumonia; Neuromuscular disease

Core tip: Despite progress in its management, diabetic ketoacidosis (DKA) continues to cause significant morbidity and mortality. One of the conditions aggravating the course of DKA and causing several deaths is respiratory failure, which can be detected at presentation or, more frequently during the course of treatment of DKA. Several risk factors for respiratory failure in DKA are preventable. Early recognition and management of these risk factors, as well as early recognition of respiratory failure have the potential to improve both morbidity and mortality resulting from DKA.

INTRODUCTION

Ketoacidosis in subjects with type 1, or less frequently, type 2 diabetes mellitus remains a potentially life-threatening diabetic manifestation. The subject has justifiably attracted attention in the literature. Sequential reviews^[1-9] have documented important changes in the clinical concepts that are related to diabetic ketoacidosis (DKA) and its management. A large number of case series of DKA have addressed various aspects of its clinical presentation and management. For this review, we selected representative studies focused on management, outcome, age differences, gender differences, associated morbid conditions, ethnicity and prominent clinical and laboratory features^[10-35].

In recognition of the complexity of treatment, the recommendation to provide this care in intensive care units was made more than 50 years ago^[36]. Severe DKA is treated in intensive care units today^[31]. Evidence-based guidelines for the diagnosis and management of DKA have been published and frequently revised in North America^[37,38] and Europe^[39]. Losses of fluids and electrolytes, which are important causes of morbidity and mortality in DKA, vary greatly between patients. Quantitative methods estimating individual losses and guiding their replacement have also been reported^[40,41].

The outcomes of DKA have improved with new methods of insulin administration^[42] and adherence to guidelines^[43-46]. The aim of treatment is to minimize mortality and prevent sequelae. One study documented that the target of zero mortality is feasible^[42]. However, mortality from DKA, although reduced progressively in the early decades after the employment of insulin treatment^[1], remains high. Up to fifty plus years ago, mortality from DKA was between 3% and 10%^[1,16]. A recent review reported a death rate from hyperglycemic

crises of 7.5% in the United States, with greater mortality from hyperglycemic hyperosmolar state (HHS) than from DKA^[9]. Reported mortality from DKA varies among age groups and countries. In various academic medical centers, death rate from DKA was < 1%^[26,27] and < 2% among adult patients younger than 65 years^[24] in the United States, 0.4% in Japanese children without and 4.7% with coma^[23], 6.5% in adult Mexican patients^[25], 4.1% in adult Israeli patients^[34] without differences between men and women^[29], 5.8% in adult Thai patients^[30], 3.6% in adult Nigerian patients^[32], around 13% in Indian children^[33,47], and 22% in American patients older than 65 years^[24]. In an autopsy study, DKA was identified as a major cause of death in diabetic patients^[48].

One general observation impacting the outcome of DKA is that its management is not always optimal. Several reports documented varying degrees of non-adherence to guidelines^[49-51], despite their proven effectiveness. The last of these reports also documented an increasing prevalence of DKA^[51]. In addition to adherence to guidelines, efforts to reduce mortality from DKA should focus on individual causes of death. Causes of death in DKA were analyzed in several studies^[23,25,27,30-34,52-55]. Cerebral edema and sepsis were the two most common causes. In a study from Greece reporting a 12.9% death rate, multivariate analysis identified the following as predictors of mortality from DKA: co-morbidities, severe acidemia at presentation (arterial blood pH < 7.0), high dose of insulin and persistence of hyperglycemia, and the development of coma or fever during treatment^[54]. Another study from Indonesia reporting 40% death rate identified coma plus high serum lactate levels (> 4 mmol/L) as poor prognostic factors^[55].

In this review, we analyzed the causes, mechanisms, management and prevention of respiratory failure which is one of the causes of death in DKA. Respiratory or cardiorespiratory deaths were reported in several series of DKA^[25,27,31,34,47]. Respiratory failure may either be recognized at presentation or, more frequently, develop during the course of treatment of DKA. The main purpose of the review is to underline the diagnosis, pathogenesis, management and, in particular, prevention of respiratory failure in DKA through proper management.

DIAGNOSIS OF RESPIRATORY FAILURE IN DKA

The key features establishing the diagnosis of DKA are the presence of metabolic acidosis and large amounts of ketones (acetone, acetoacetic acid, beta-hydroxybutyric acid) in serum and urine. Hyperglycemia may be absent in some patients complicating the diagnosis of DKA^[56]. DKA should be differentiated from other conditions producing increased ketone formation including alcoholic ketoacidosis and starvation ketosis. Lactic acidosis from sepsis or hypovolemia is another type of metabolic acidosis which occurs frequently during the course of

Figure 1 Arterial PCO₂ response to serum bicarbonate concentration in diabetic ketoacidosis. The draft, which was drawn using Fulop's regression equation^[60], shows the mean and 95%CI of this response.

both DKA and HHS that should be differentiated from DKA. Serum lactate level should be measured in all patients with hyperglycemia and metabolic acidosis.

Assessment of the severity of DKA is primarily based on the degree of the acid-base disturbance. The most recent version of the United States guidelines for hyperglycemic crises in adults^[38] set three levels of DKA severity: mild, moderate and severe. Criteria common to all three categories included plasma glucose > 250 mg/dL, positive serum and urine ketone test, and variable levels of effective serum osmolality, calculated as $[2 \times (\text{serum sodium}) + (\text{serum glucose.mg/dL})/18]$. The criteria that differed between the three categories were arterial blood pH (mild: 7.25-7.30, moderate: 7.00 to < 7.25, severe: < 7.00), plasma bicarbonate ($[\text{HCO}_3^-]_p$, mild: 15-18 mEq/L, moderate: 10 to < 15 mEq/L, severe: < 10 mEq/L), serum anion gap calculated as $[\text{serum sodium} - (\text{serum chloride} + \text{serum bicarbonate})]$ (mild: > 10 mEq/L, moderate: > 12 mEq/L, severe: > 12 mEq/L) and mental status (mild: alert, moderate: alert/drowsy, severe: stupor/coma). The European guidelines for DKA in children^[39] classify the severity of DKA only by the magnitude of metabolic acidosis (mild: venous pH < 7.30, $[\text{HCO}_3^-]_p$: < 15 mEq/L. Moderate: pH < 7.20, $[\text{HCO}_3^-]_p$: 10 mEq/L. Severe: pH < 7.10, $[\text{HCO}_3^-]_p$: < 5 mEq/L).

In addition to its use in the diagnosis of DKA and establishing its severity, blood gas analysis provides two objective criteria for assessing the presence and severity of respiratory failure complicating DKA. The universal feature of respiratory failure is hypoxemia. Arterial blood PO₂ (PaO₂) at room air should be evaluated in all patients presenting with DKA. The second parameter of arterial blood gases that allows detection of respiratory failure in DKA is the arterial PCO₂ (PaCO₂). The application of PaCO₂ in the detection of respiratory failure complicating DKA merits some discussion.

It has been known for a long time that there is a predictable alveolar ventilatory compensation, within

narrow limits, to a given degree of metabolic acidosis^[57-59]. In its simplest form, this compensation is expressed as PaCO₂ as a function of $[\text{HCO}_3^-]_p$. The ventilatory response to metabolic acidosis was analyzed by Fulop^[60] in a series of 27 episodes of DKA uncomplicated by lactic acidosis or other acid-base disturbances. Fulop derived the following regression equation, which is almost identical to the original Winters equation^[57] that was derived from several types of metabolic acidosis: $\text{PaCO}_2, \text{ mmHg} = 7.27 + 1.57 \times ([\text{HCO}_3^-]_p, \text{ mEq/L})$

Figure 1 shows the 95% confidence area defined by Fulop's study. Fulop's diagram should be used to evaluate every case of DKA. This diagram may assist in the detection of associated other primary acid-base disorders, for example metabolic alkalosis from vomiting^[61]. In addition, its use is critical for the detection of respiratory abnormalities accompanying the DKA. Fulop's diagram allows detection of an associated primary respiratory alkalosis. In this instance, the measured PaCO₂ is below the corresponding low 95% confidence limit in the Fulop diagram. Primary respiratory alkalosis is not rare in DKA^[62,63]. Detection of primary respiratory alkalosis in a patient with DKA has great importance because it often provides a clue for the presence of sepsis^[62] which is the underlying cause of DKA in many instances^[37-39], respiratory distress secondary to cerebral edema, and other causes of respiratory alkalosis.

The second critical use of Fulop's diagram is in the detection of respiratory failure complicating DKA. In this case the PaCO₂ value is higher than the corresponding upper limit for PaCO₂ in the Fulop diagram. Such a finding should lead to a systematic search for potential causes of respiratory failure and frequent monitoring of the respiratory status of the patient including arterial blood gases.

Detection of respiratory failure in DKA is not based only on PaO₂ and PaCO₂ values. A diligent search for coexisting conditions adversely affecting the respiratory function has also great importance. Respiratory failure is

more often encountered during treatment of DKA than at its presentation, as will be shown later. Consequently, vigilance for any clinical or laboratory clue suggesting development of respiratory failure should be maintained throughout the treatment of DKA.

One potential pitfall of Fulop's equation is that it may not compute the respiratory response to profound degrees of DKA with accuracy. Soubani *et al.*^[64] suggested that there are limits for hyperventilation resulting from metabolic acidosis or sepsis. Subsequently, Guh *et al.*^[65] derived different regression equations of PaCO_2 on $[\text{HCO}_3^-]_p$ in DKA patients with arterial pH > 7.10 ($\text{PaCO}_2 = 6.6 + 1.65 \times [\text{HCO}_3^-]_p$) and those with arterial pH \leq 7.10 ($\text{PaCO}_2 = 2.88 + 3.18 \times [\text{HCO}_3^-]_p$). The regression equation for DKA with moderate acidemia was similar to Fulop's equation. The Guh equation for severe acidemia appears to differ from Fulop's equation. Indeed, there are substantial differences between the two equations for $[\text{HCO}_3^-]_p$ values that are not extremely low. For example, for $[\text{HCO}_3^-]_p$ equal to 10 mEq/L, Fulop's equation calculates an appropriate PaCO_2 of 23 mmHg (95%CI: 23-27 mmHg). From the Henderson-Hasselbach equation, the resulting arterial pH value is 7.24 (95%CI: 7.19-7.34). The corresponding values obtained from the Guh equation for severe acidemia are PaCO_2 34.0 (95%CI: 30.6-37.4) mmHg, and arterial pH 7.09 (95%CI: 7.05-7.14). However, the differences between the two equations are trivial in cases of profound acidosis. For example, we used the same equations to calculate the ventilatory responses and arterial pH values for $[\text{HCO}_3^-]_p$ equal to 3 mEq/L: from Fulop's equation, the values were PaCO_2 12.0 (95%CI: 8-16) mmHg; arterial pH 7.02 (95%CI: 6.89-7.19); from Guh's equation, the values were PaCO_2 12.4 (96%CI: 9.0-15.8) mmHg; arterial pH 7.01 (95%CI: 6.90-7.14). We suggest that Fulop's diagram is appropriate for evaluating the alveolar ventilation in profound DKA. In addition, vigilance for other clues of potential respiratory failure (hypoxemia, history of pulmonary or neuromuscular disease, clinical monitoring of the respiratory system) should be enhanced in this instance.

Metabolic acid-base parameters (pH, plasma bicar-

bonate concentration) were found to be comparable between venous and arterial blood samples in uncomplicated cases of DKA^[66-68]. However, venous blood gas determination is not appropriate for the detection of respiratory failure in the course of DKA^[66] for two reasons: The first reason is that venous blood measurements cannot detect abnormalities in the partial pressure of oxygen caused by ventilatory failure, especially in states of hypotension and tissue hypoperfusion. The second reason is that the regression equations used for detection of inadequate ventilatory response to DKA were developed in arterial blood. Transcutaneous monitoring of carbon dioxide has been proposed as a means of monitoring the treatment of DKA^[69]. Determining the accuracy of this technique in identifying respiratory failure in DKA will require further research.

The diagnosis of respiratory failure during the course of DKA can be greatly facilitated by a systematic search for risk factors that have been identified to specifically complicate the course of DKA. Clinicians should also be alert for pre-existing respiratory insufficiency and for conditions that can cause respiratory failure independently of DKA (e.g., severe hypothyroidism). The next section addresses risk factors for respiratory insufficiency associated with DKA. Detailed discussion of all causes of respiratory failure is beyond the scope of this review.

RISK FACTORS FOR RESPIRATORY FAILURE IN DKA

Table 1 shows these factors. The first two categories listed in this table (depletion of primarily intracellular ions and development of pulmonary edema) are direct consequences of hyperglycemia and DKA. The last two categories (infections of the respiratory tract and miscellaneous risk factors) include conditions that may lead to DKA but are not caused by it.

Deficits of ions with primary intracellular distribution in DKA

Potassium, magnesium and phosphate are ions with primary intracellular distribution that are depleted as a consequence of DKA. Depletion of these ions has severe, but preventable, clinical consequences. Clinical manifestations relevant to this report are muscle weakness that can culminate in respiratory failure and cardiac dysrhythmias that may affect myocardial function. If appropriate replacement is not done, the depletion of these ions is more frequent and profound during treatment than at presentation with DKA^[70]. A major aim of the treatment of DKA is to address the deficits of these ions. The mechanisms of deficit and their clinical consequences are discussed below. The mechanisms of potassium deficiency and of changes in serum potassium concentration in DKA will be discussed in some detail. Similar mechanisms create the abnormalities in the other two ions.

Potassium: There are disturbances in internal and external potassium balance in DKA. During development of DKA, the internal imbalance is caused by movement of potassium from the intracellular into the extracellular compartment causing hyperkalemia. The external imbalance is attributed to the fact that DKA causes losses of body potassium causing hypokalemia. The losses can be profound and are usually accentuated during treatment. In Martin's report^[70], hyperkalemia was present in 39% of the DKA cases at presentation and in 4% of the cases after 12 h of treatment, while hypokalemia was present in 18% of the DKA cases at presentation and 63% of the cases after 12 h of treatment. The incidence of hypokalemia at presentation of DKA may be affected by factors independent of DKA, such as previous gastrointestinal loss of potassium or diuretic use^[71]. In published reports of DKA, the frequency of hypokalemia at presentation varied between 0^[17] and 36.7%^[13]. A recent study found hypokalemia at presentation in 5% of patients with DKA^[72].

Balance studies during development or treatment of DKA documented the abnormalities in external and internal potassium balance caused by DKA^[73-79]. Potassium is lost in the urine during development of DKA because of osmotic diuresis caused by glycosuria. Urinary excretion of ketoacids obviates the loss in the urine of equivalent amounts of cations, particularly sodium and potassium. The contribution of ketonuria to the urinary potassium loss has not been studied in DKA, to our knowledge. Nevertheless, the loss of potassium in DKA is often large. Patients with previously undiagnosed type 1 diabetes who present with DKA after protracted polyuria may have life threatening potassium deficits^[41].

Despite the urine losses, large numbers of patients exhibit hyperkalemia at presentation with DKA^[70,80,81], because of transfer of potassium from the intracellular into the extracellular compartment. The mechanisms of this transfer have been studied extensively. The most important underlying mechanism is absence of insulin action, which has direct and indirect effects on internal potassium balance. Directly, inhibition of basal insulin secretion causes loss of intracellular potassium^[82] and hyperkalemia. Insulin causes hyperpolarization of the cell membranes and potassium entry into the cytoplasm^[83] through an increase in the sites of the alpha-2 subunit of the sodium-potassium ATPase of the cell membranes^[84]. The effect of insulin on cellular potassium uptake is dissociated from that on cellular glucose uptake^[85].

Indirectly, absence of insulin action causes hypertonicity (elevated serum effective osmolality) through both extracellular accumulation of solute (glucose) and osmotic diuresis, which causes loss of water in excess of monovalent cations^[41]. Hypertonicity leads to transfer of water and intracellular solutes, particularly potassium, into the extracellular compartment^[86]. Hyperkalemia will result in this case even if the state of hypertonicity has no effect on the transport mechanisms of cell membranes for potassium or on the electrical potential difference across the cell membrane^[87]. Contraction of the

extracellular volume as a result of osmotic diuresis tends to concentrate extracellular solutes including potassium and constitutes another source of hyperkalemia in DKA^[41].

The hyperkalemic effects of the disrupted internal potassium balance described so far are encountered in DKA and all other hyperglycemic syndromes. The question whether metabolic acidosis has additional hyperkalemic effects in DKA has been a matter of controversy^[88-90]. Two lines of research provide support for an added hyperkalemic effect of acidosis in DKA: Multivariate analysis in clinical studies identified arterial pH as a predictor of serum potassium level, in addition to serum glucose^[91,92]. The other line of evidence is the recent discovery that acidosis affects potassium distribution across cell membranes though alterations in cellular membrane transporters^[93].

For patients on maintenance dialysis, the hyperglycemic effects on internal potassium balance are almost completely unopposed because of absent or minimal osmotic diuresis. Studies of hyperglycemic syndromes in this group have provided support for an additional hyperkalemic effect of DKA when serum glucose concentration and effective osmolality are comparable between DKA and HHS^[94-99]. Finally, we are unaware of studies showing that the catabolic state induced by acidosis causes the release of cellular potassium into the extracellular compartment and contributes to the hyperkalemia. Nevertheless, there is sufficient evidence to support the concept of an independent hyperkalemic effect of DKA that is added to the other hyperkalemic effects of hyperglycemia. This further complicates the evaluation of potassium deficits in DKA.

Treatment of DKA leads to substantial declines in serum potassium concentration, even when large amounts of potassium are infused^[100-107]. Multiple mechanisms contribute to the hypokalemic effect of treatment. These include a direct effect of insulin on cellular potassium uptake^[83], correction of the hyperglycemic hypertonicity^[96], dilution of extracellular potassium due to infusion of large volumes of fluids and continuing losses of potassium through the urine or the gastrointestinal tract.

Urinary potassium losses during treatment of DKA merit attention because they often do not constitute a treatment focus as they should. Urinary losses of potassium in DKA are accentuated by coexistent states of hyperaldosteronism^[108]. Insulin has an effect similar to aldosterone on renal transport mechanisms of sodium and potassium and its administration to patients with DKA causes excessive renal potassium losses^[109]. The other mechanism of excessive potassium losses during treatment of DKA is ongoing osmotic diuresis while serum glucose remains elevated^[41]. Improvement of the renal circulation as fluid deficits are corrected has the potential of worsening potassium losses through osmotic diuresis.

Clinical consequences of hypokalemia associated with DKA were reported first in 1946 in a seminal paper

by Holler^[110] who observed a patient who developed hypokalemia and respiratory failure during treatment of DKA and whose respiratory failure resolved after infusion of potassium salts. The significance of Holler's report was stressed in a more recent report^[111]. Subsequently, a series of articles reported severe clinical manifestations secondary to hypokalemia developing or worsening during treatment of DKA^[112-135]. The majority of the reported cases exhibited varying degree of respiratory failure. In several patients, respiratory failure was associated with severe cardiac manifestations and/or profound and generalized muscle weakness. Death occurred in some cases^[122,129].

The management of DKA should adhere to guidelines that recommend the administration of intravenous potassium salts to patients presenting with DKA and hypokalemia and initiation of insulin infusion only after serum potassium has reached values > 3.3 mEq/L^[38]. Serum potassium concentration should be monitored during treatment in all patients with DKA. In DKA patients presenting with hypotension, extreme hyperglycemia and hypokalemia, urine volume and urine potassium concentration should also be monitored during treatment in order to guide, along with serum potassium, changes in the rate of infusion of potassium salts^[41]. Measuring potassium levels with the apparatus used for blood gas determination is not appropriate because these levels may vary substantially from simultaneous serum potassium determinations^[136]. Finally, electrocardiographic changes may indicate changes in serum potassium during the course of DKA^[137,138]. Monitoring of electrocardiogram to prevent inappropriate administration of potassium salts to patients with DKA has been proposed^[137]. However, dissociation of plasma potassium concentration and electrocardiographic abnormalities in a patient on DKA has been reported^[139]. Monitoring of serum potassium during the course of treatment of DKA should be primarily based on frequent determinations of serum potassium concentration. Electrocardiographic monitoring should be used as a guide for management of life-threatening hyperkalemia and for timely detection of dysrhythmias complicating the treatment of DKA.

Magnesium: In DKA body magnesium deficits through urinary losses are routinely encountered and are the consequence of absence of insulin^[140]. However, magnesium exit from the cells may cause hypermagnesemia, which is frequent at presentation with DKA. The magnesium defect is unmasked during treatment. In Martin's study^[70], hypomagnesemia was recorded in 7% of the cases at presentation with DKA and 55% of the cases after 12 h of treatment, while hypermagnesemia was found in 68% of the cases at presentation and 21% of the cases after 12 h of treatment.

In one reported case, profound hypomagnesemia caused respiratory failure and asystole, and cardiac function recovered after cardiopulmonary resuscitation and infusion of a large bolus of magnesium salts^[141]. A small number of patients with DKA and severe hypoma-

gnesemia were subsequently reported^[142-144]. The development of hypomagnesemia during treatment of DKA was linked to infusion of potassium phosphate^[142,144]. Aldosterone promotes urinary magnesium losses^[145]. Magnesium loss in the urine during treatment of DKA may be increased because of the state of secondary hyperaldosteronism discussed in the subsection on potassium.

An important consequence of magnesium deficiency is that it causes excessive urinary losses of potassium and phosphate^[146]. It is difficult to replete potassium stores when there are large magnesium deficits^[147]. In addition to its direct and indirect effects on respiration, magnesium deficits have major effects on both cardiac contractility and rhythm. Insulin, along with its effects on cellular uptake of potassium and nutrients, increases intracellular free magnesium concentration in myocardial cells^[148].

Magnesium deficit should be anticipated in patients with DKA. Serum magnesium concentration should be measured at presentation with DKA and should be monitored during treatment. Magnesium replacement should be guided by serum magnesium levels in this state.

Phosphate: Changes induced by DKA on both external and internal phosphate balances are similar to those of the balances of potassium and magnesium. Hyperglycemic osmotic diuresis causes urinary losses of phosphate, while metabolic acidosis causes shifts of phosphate from the intracellular into the extracellular compartment^[149]. Insulin causes cellular phosphate uptake and a decrease in serum phosphate concentration^[150,151]. The insulin-mediated decrease in serum phosphate concentration may be accentuated by dilution through intravenous replacement fluids and by continuing urinary losses. In Martin's study^[70], hypophosphatemia was found in 11% of the cases at presentation with DKA and 71% of the cases after 12 h of treatment, while hyperphosphatemia was detected in 90% of the cases at presentation and was not detected after 12 h of treatment.

Severe hypophosphatemia has multiple adverse consequences^[149]. Oxygen delivery to peripheral tissues is impaired by the depletion of red cell 2, 3 diphosphoglycerate (2,3-DPG), which causes a shift of the oxygen dissociation curve to the left thus impeding oxygen release. Depletion of high-energy phosphate compounds in muscles secondary to phosphate deficits causes muscle weakness and rhabdomyolysis, dysrhythmias, myocardial dysfunction and seizures^[149,152,153].

A number of cases of development of severe hypophosphatemia with varying degrees of respiratory failure during the treatment of DKA have been reported^[154-161]. Rhabdomyolysis was present in one patient^[161]. A recent report found that the severity of metabolic acidosis at presentation affects the degree of hypophosphatemia during treatment of DKA^[162]. Monitoring of serum phosphate should guide the replacement of phosphate deficit. Phosphate replacement was shown to be

effective in preventing the development of severe hypophosphatemia in this instance^[163,164]. However, phosphate infusion has not been shown to improve the outcome of DKA in prospective studies^[38] and may have adverse consequences including hypocalcemia and hypomagnesemia^[142,143]. Phosphate should be replaced during treatment of DKA only if serum phosphate levels are low. The guidelines suggest rates of infusion of potassium phosphate and other ions^[38]. The critical measure during treatment of DKA consists of close monitoring of the patient's clinical status and all serum components that are replaced^[41].

Pulmonary edema secondary to DKA or its treatment

The second category of direct consequences of DKA is the development of pulmonary edema. Arterial blood gases are necessary for evaluation of its severity and to guide its treatment. Oxygen administration is guided by the degree of hypoxemia, which is universal in patients with pulmonary edema^[165]. Abnormalities of PaCO₂ accompany the hypoxemia in the majority of the cases^[166]. Respiratory alkalosis, triggered by the hypoxemia, is frequent in pulmonary edema. Eucapnia and respiratory acidosis are also present in substantial numbers of patients with acute pulmonary edema^[165]. "Normal" or elevated values of PaCO₂ in patients with pulmonary edema indicate inadequate respiratory response to hypoxemia and should be considered as indicators of the severity of this condition. Elevated PaCO₂ levels have been reported in a small number of patients with end-stage renal disease and extreme hyperglycemia without DKA^[63]. Two varieties of pulmonary edema in DKA have been recognized, a hydrostatic form attributed to elevated pulmonary venous pressure and a form that develops because of increased pulmonary capillary permeability.

Hydrostatic pulmonary edema in DKA: Hydrostatic pulmonary edema is usually diagnosed at presentation with DKA or severe hyperglycemia without DKA and is corrected during the treatment of these syndromes. The sequence of pulmonary edema at presentation with severe hyperglycemia with or without DKA and its correction with insulin administration has been reported in patients with advanced renal failure^[166-170]. Development of circulatory overload and hydrostatic pulmonary edema in these patients was initially attributed to the acute shift of a substantial volume of fluid from the intracellular into the extracellular compartment. This volume shift is an osmotic consequence of solute accumulation in the extracellular compartment during development of hyperglycemia. Correction of hyperglycemia with insulin administration shifts fluid back into cells^[166].

The magnitude of osmotic translocation of fluid between the two major body fluid compartments that is secondary to hyperglycemia should affect the severity of the ensuing circulatory overload. This magnitude is affected by two main factors: The first and most obvious factor is degree of hyperglycemia. The volume of the

osmotic fluid transfer increases as the serum glucose level increases in the same episode of hyperglycemia. The second factor affecting the volume of fluid transferred from the intracellular into the extracellular compartment during development of hyperglycemia is the baseline status of the extracellular volume. For the same degree of hyperglycemia, patients with preexisting peripheral edema develop larger osmotic fluid transfers than those without edema and the same baseline intracellular volume^[171,172]. Insulin administration without any other therapeutic measures has led to correction of the pulmonary edema in the reported cases^[166-170]. However, other measures, including mechanical ventilation and emergency ultrafiltration may be required in some patients.

The development of extracellular volume expansion may not be the only cause of hydrostatic pulmonary edema in DKA. This syndrome has been reported in DKA patients without advanced renal failure, who usually have volume deficits at presentation^[173,174]. This suggests that the development of DKA may be due to factors other than extracellular volume expansion in some cases. In one instance, DKA was diagnosed during treatment of high altitude pulmonary edema^[173]. Recovery required treatment of both conditions. It is not clear which condition appeared first.

In another case, hydrostatic pulmonary edema developed during treatment of DKA in a 9-year-old child^[175]. Serum troponin levels were elevated and echocardiography showed segmental myocardial dysfunction when pulmonary edema was diagnosed. Repeated cardiac echocardiography was normal 6 d later. This case report illustrates the potential of DKA to cause acutely myocardial dysfunction. This dysfunction could be secondary to excessive fluid replacement. Another cause of myocardial dysfunction in DKA is absence of insulin. Insulin has inotropic effects in subjects with type 1 diabetes^[175], subjects with type 2 diabetes^[176] and normal controls^[176]. It is unclear whether the resolution of pulmonary edema at presentation results from a correction of the extracellular volume excess or a direct action of insulin on myocardial contractility.

Non-hydrostatic pulmonary edema in DKA:

Diabetes mellitus may affect the structure and function of the lungs, in addition to other target organs. Histological changes in the lungs of diabetic patients involve the wall of the alveoli and the pulmonary capillaries, while the most consistent functional changes include reduced lung volumes, reduced pulmonary elastic recoil, and reduced capillary lung volume leading to impaired diffusion capacity^[177]. Respiratory function in these patients is apparently preserved under normal conditions, but their lung reserves are reduced and can cause clinical lung dysfunction under stressful conditions including volume overload^[178]. The development of non-hydrostatic pulmonary edema [adult respiratory distress syndrome (ARDS)] in DKA may be related to the effects of stress on diabetic lungs.

Characteristically, ARDS is not present initially, but develops during the course of treatment of DKA. ARDS appears to be a more frequent and severe complication of DKA than hydrostatic pulmonary edema. A number of publications reported patients who developed ARDS during treatment of DKA^[179-192]. ARDS developing during treatment of DKA may lead to death^[192]. The severity of ARDS complicating the treatment of DKA is underlined by its association with cerebral edema.

DKA is one of the major causes of cerebral edema^[193]. Cerebral edema usually develops during treatment of DKA^[194] and is a major cause of mortality and long-term neurological sequelae^[195]. Simultaneous development of cerebral edema and ARDS has been reported in several publications^[28,196-203]. Research efforts have addressed factors that affect fluid transfers across blood capillary membranes of the brain and lungs during treatment of DKA. Early studies focused on Starling forces controlling fluid exchanges across capillary membranes. Infusion of large volumes of crystalloid solutions leads to increase in the capillary hydrostatic pressure and to dilution of serum proteins and decrease in the colloid osmotic pressure of the serum. Decreased serum colloid osmotic pressure was identified as a risk factor for ARDS during treatment of DKA^[204-208].

Decreased serum colloid osmotic pressure may lead to increased fluid transfer from the intravascular into the interstitial space of various tissues including the lungs where it will cause respiratory distress. However, serum colloid osmotic pressure is not a key determinant of fluid transfers between interstitial fluid and intracellular compartment. Efforts to identify risk factors for the development of both ARDS and cerebral edema in DKA have been focused on altered capillary membrane permeability and changes in the serum effective osmolarity (tonicity). Increased pulmonary capillary permeability during treatment of ARDS was found in early reports^[209,210]. The potential explanations include activation of lymphocytes^[211] and release of cytokines, particularly interleukin-1 (IL-1)^[212-215], the serum levels of which are much higher during treatment of DKA than at its presentation. These findings have linked the development of cerebral edema and ARDS in patients with DKA.

A potent driver of fluid exchanges between the extracellular and intracellular compartments is the tonicity of the extracellular compartment, which changes during treatment of DKA. Current strategy for preventing cerebral edema and ARDS consists of careful infusion of crystalloid solutions. Care should be exercised when selecting their volume and tonicity^[41]. Replacement of volume deficits should be guided by the clinical picture: Deficits causing severe clinical manifestations should be replaced promptly with isotonic solutions. Monitoring of the clinical signs of hypovolemia (hypotension, tachycardia, low urine output) should guide the rate of infusion, which should be slowed down when these signs are corrected. Clinical monitoring is critical for adequate volume replacement and prevention of overshooting.

Hypertonicity is common in hyperglycemic syndromes and can be severe. Tonicity changes may play a role in the development of cerebral edema during treatment of DKA^[203]. Tonicity changes have, in general, a substantially larger effect on intracellular volume than extracellular volume changes. Unlike volume deficits hypertonicity should be corrected slowly during treatment of DKA. The guidelines for management of hyperglycemic crises recommend an hourly decline in serum glucose concentration between 50 and 65 mg/dL^[37], which corresponds to a decrease in serum effective osmolarity of between 1.2 and 2.8 mOsm/L^[41]. An hourly rate of decrease in effective osmolarity ≤ 3 mOsm/L during treatment of DKA is desirable. Whether measures addressing lymphocyte function and cytokine production can be effective in preventing cerebral edema and ARDS during treatment of DKA are topics for future research.

Respiratory tract infections in DKA

Infections are known to be a major category of conditions precipitating DKA. A systematic search for infections is warranted in all patients presenting with DKA. This search is complicated by the similarity between symptoms of infection and those of DKA (malaise, abdominal distress, dyspnea, etc.) and by finding elevated white blood cell counts in both conditions. In addition, infections in the respiratory tract have the potential of causing respiratory failure in patients with DKA. Examples of respiratory tract infections reported to cause respiratory failure include pneumonia secondary to *Streptococcus pneumoniae*^[134,216], *Legionella pneumoniae*^[217], *Klebsiella pneumoniae*^[218], community-acquired pneumonia^[219], influenza^[220], pulmonary zygomycosis^[221], mucormycosis^[222-225], candidiasis^[224] and coccidiomycosis^[226]. The list of respiratory tract infections that can cause respiratory failure during the course of DKA is, in all probability, much larger.

A complicating feature of DKA associated with lung infections is that severe volume deficits may mask the clinical and radiographic manifestations of pneumonia, which blossom after hydration^[134]. This scenario represents one condition in which evaluation of the respiratory compensation to DKA in the arterial blood gases can offer an early sign of the presence of a condition complicating the DKA with the potential of respiratory failure^[134].

Pneumonia associated with hyperglycemic symptoms is an independent predictor of short-term (28 d) mortality in both DKA and HHS^[227]. Early diagnosis and management of pulmonary infections associated with DKA offers the promise of reducing this mortality.

Miscellaneous conditions associated with DKA

DKA may develop in patients with other serious medical conditions. Regardless of whether these conditions had an etiologic relationship with DKA or not, DKA aggravates their course. For example, development of respiratory stress from DKA during the course of conditions potentially causing respiratory failure, such as pre-

existing neuromuscular or pulmonary disease, should intensify the monitoring of the respiratory function.

Preexisting neuromuscular disease: DKA with respiratory failure has been reported in patients with Guillain-Barré syndrome^[228,229] and one of the mitochondrial myopathies, the Kearns-Sayre syndrome^[230]. Mitochondrial myopathies are associated with a high incidence of diabetes mellitus. Kearns-Sayre syndrome is characterized by progressive external ophthalmoplegia and cardiac conduction defects as its primary clinical manifestations. Patients with this syndrome exhibit multiple endocrine disorders including diabetes mellitus requiring insulin in about 15% of the cases^[231]. This condition exemplifies the potential severity of DKA in the course of a neuromuscular disease. It is probable that patients with other types of mitochondrial syndromes causing myopathy develop DKA with respiratory failure. The reported case of DKA with respiratory failure in a patient with Kearns-Sayre syndrome had a fatal outcome^[230].

Preexisting conditions of the respiratory system:

We found reports of respiratory failure during the course of DKA in a patient with tracheal stenosis^[232] and another patient with central venous catheter thrombosis^[233]. DKA creates a severe stress on the respiratory function that has the potential to aggravate chronic lung disease. There is a paucity of studies addressing the effects of DKA on respiratory function in patients with chronic lung disease and on the outcomes of DKA in this setting.

Other associated conditions: The development of acute kidney injury during the course of DKA may place greater demands on respiratory function. Two reports addressed respiratory distress in patients with DKA and acute renal failure^[234,235]. As previously noted, there is a great need for studies of DKA in patients with conditions potentially affecting the respiratory function (*e.g.*, drugs, severe hypothyroidism, *etc.*).

CONCLUSION

Respiratory failure developing during the course of DKA worsens its prognosis and is preventable in most instances. Prevention of respiratory failure has the potential to reduce mortality from DKA. Prevention and early detection of respiratory failure, by close monitoring of the clinical status and timely use and appropriate interpretation of arterial blood gases, have the potential of both decreasing mortality from DKA and preventing the debilitating somatic and psychiatric sequelae of prolonged mechanical ventilation^[134].

Abstract

Ethnicity is defined as "belonging to a social group

that has a common national or cultural tradition". Membership of certain ethnic groups has long been associated with increased risk of gestational diabetes mellitus (GDM). Studies that examined ethnic differences amongst women with GDM were often conducted in western countries where women from various ethnic backgrounds were represented. The prevalence of GDM appears to be particularly high among women from South Asia and South East Asia, compared to Caucasian, African-American and Hispanic communities. For some, but not all ethnic groups, the body mass index is a risk factor for the development of GDM. Even within a particular ethnic group, those who were born in their native countries have a different risk profile for GDM compared to those born in western countries. In terms of treatment, medical nutrition therapy (MNT) plays a key role in the management of GDM and the prescription of MNT should be culturally sensitive. Limited studies have shown that women who live in an English-speaking country but predominantly speak a language other than English, have lower rates of dietary understanding compared with their English speaking counterparts, and this may affect compliance to therapy. Insulin therapy also plays an important role and there appears to be variation as to the progression of women who progress to requiring insulin among different ethnicities. As for peri-natal outcomes, women from Pacific Islander countries have higher rates of macrosomia, while women from Chinese backgrounds had lower adverse pregnancy outcomes. From a maternal outcome point of view, pregnant women from Asia with GDM have a higher incidence of abnormal glucose tolerance test results post-partum and hence a higher risk of future development of type 2 diabetes mellitus. On the other hand, women from Hispanic or African-American backgrounds with GDM are more likely to develop hypertension post-partum. This review highlights the fact that management needs to be individualised and the clinician should be mindful of the impact that differences in ethnicity may have on the clinical characteristics and pregnancy outcomes in

women affected by GDM, particularly those living in Western countries. Understanding these differences is critical in the delivery of optimal antenatal care for women from diverse ethnic backgrounds.

Key words: Gestational diabetes mellitus; Ethnicity; Perinatal outcomes; Medical nutrition therapy; Prevalence

Core tip: The prevalence of gestational diabetes mellitus (GDM) is increasing world-wide, and studies have shown that optimal management of GDM improves pregnancy outcomes. This review summarises the differences in prevalence, clinical profile, management and pregnancy outcomes among women from various ethnic backgrounds who have GDM. Ethnicity is an important consideration in women affected by GDM, particularly in an antenatal service based in a Western society. There are particular challenges in individualising and tailoring medical nutritional therapy and insulin therapy. Also women from certain ethnic groups are at a higher risk of increased foetal and maternal morbidity and mortality. Understanding these challenges is important in providing optimal antenatal care for women of diverse ethnic backgrounds.

INTRODUCTION

Gestational diabetes mellitus (GDM) is defined as glucose intolerance first recognized during pregnancy^[1]. GDM has been reported to affect between 1.4% to 12.3% of pregnancies^[2], and its prevalence is increasing and parallels the rising incidence of type 2 diabetes mellitus worldwide^[3,4]. Risk factors for developing GDM in pregnancy include obesity, previously GDM, glycosuria, family history, ethnicity and hypertension^[5,6]. Arguably, one of the strongest non-modifiable risk factor for GDM relates to the woman's ethnicity.

The Oxford Dictionary defines ethnicity as "belonging to a social group that has a common national or cultural tradition"^[7]. In particular, ethnic groups that are considered high-risk include Hispanic, African-Americans, Native American, South or South East Asian, Pacific Islander or Indigenous Australian^[8]. It is also recognised that women with GDM from these and other ethnic groups may differ with regards to peri-natal and maternal outcomes^[9-12].

In this review we discuss the differences amongst women from various ethnic groups in terms of prev-

alence, diagnosis, treatment of GDM and pregnancy outcomes. Because of the variance in the diagnosis and management of GDM around the world, it is difficult to compare women with GDM between countries. In order to delineate ethnic differences in terms of GDM prevalence, metabolic profiles of the women and pregnancy and long-term outcomes, studies were often conducted in the same country (or under the same health care system) where the diagnostic criteria, screening process, treatment regimen and delivery of health care are uniform for all women^[13-16] (refer A Table 1).

DIAGNOSTIC CRITERIA

There are numerous diagnostic criteria for GDM currently being utilized in various parts of the world, as shown in Table 2. Many countries have based their GDM diagnostic criteria on the 1999 World Health Organisation (WHO) Criteria^[17], while in Australasia and the United States, they have adopted different glucose cut-offs to diagnose GDM based on the oral glucose tolerance test (OGTT)^[18,19]. Findings from the Hyperglycaemia and Adverse Pregnancy Outcomes study has put impetus on revising the diagnostic criteria for GDM, and the International Association of Diabetes in Pregnancy Study Group (IADPSG) had subsequently recommended new threshold glucose levels on the 75 g OGTT for diagnosing GDM^[20,21]. In 2013, the WHO adopted the IADPSG guidelines and revised the cut-offs for fasting plasma levels to ≥ 5.1 mmol/L (92 mg/dL), 1-h glucose level to ≥ 10.0 mmol/L (180 mg/dL) and 2-h glucose level to ≥ 8.5 mmol/L (153 mg/dL) following 75 g OGTT^[22]. It is expected that the 2013 WHO diagnostic criteria may standardise the diagnosis of GDM worldwide, but to date the implementation of this new criteria has been slow internationally.

There is preliminary data reflecting on the impact the new diagnostic criteria may have on the prevalence of GDM amongst different ethnic groups. A Singaporean study demonstrated that the proportion of women diagnosed with GDM in the Asian population using the 2013 WHO Criteria would be lower^[23]. The prevalence could drop from 30.9% to 18.9% in women of Chinese ethnicity, and from 33.5% to 28.1% among the South Asian population^[23]. On the other hand, in a predominantly Anglo-European population in Australia, the prevalence of GDM will increase from 9.6% to 13.0%^[24]. The reason for this divergence is that there are differences between ethnic groups in the glycaemic profiles on the OGTT from which GDM is diagnosed. In a cohort of over 850 women diagnosed with GDM from a multi-cultural community in south western Sydney, Australia, from the 75 g OGTT, those from South-East Asia had the lowest fasting glucose levels (4.95 ± 0.65 mmol/L) but the highest 2-h glucose level (8.75 ± 1.17 mmol/L). In contrast, Pacific Islanders had the highest fasting levels (5.71 ± 1.19 mmol/L) but the lowest 2-h levels (7.73 ± 1.27 mmol/L)^[25].

GDM: Gestational diabetes mellitus.

ETHNICITY AND THE PREVALENCE OF GDM

Specific ethnicities of women have long been considered as a risk factor for developing GDM. At-risk ethnic groups identified in the literature, are Aboriginal women in Australia, Middle Eastern (Lebanese, Syrian, Iranian, Iraqi or Afghanistan) women and Pacific Islanders^[2,8,26,27]. Table 1 outlines some large population studies describing the prevalence of GDM among different ethnic groups who resided in western societies.

Among Asian women, the prevalence for GDM varies greatly. For instance, a study conducted in New York showed the prevalence of South-Asian (Indian, Sri Lankan, Pakistani, Fijian Indian) women having

GDM are generally higher than the risk of South-East Asian (Cambodian, Vietnamese, Laotian, Thai, Filipino, Malaysian) women and the East-Asian (Chinese, South Korean, Taiwanese and Japanese) women. The prevalence of GDM in women who were born in Asian countries varied from 3.0% to 21.2%^[28]. Many studies have shown Asian women had a much higher risk of GDM than women of United States Caucasian or Australian descent (Table 1). The highest risk appears to belong to women from South Asia and their adjusted relative risk is quoted by Savitz *et al*^[28] to be as high as 7.1 (95%CI: 6.8 to 7.3).

Interestingly, studies have demonstrated that women who migrated from their native countries to a western society had a higher rate of GDM compared

to women of a foreign ethnicity but who were born in western countries^[28]. However this trend did not apply to Japanese and South Korean women^[29]. Table 3 summarises two large studies showing the prevalence of GDM amongst women of various ethnic groups who were born in western countries compared with those born in their native countries. Again the data seems to suggest women born in South Asian and Pacific Islander countries who have migrated to the United States had the highest rate of GDM than United States born women from the same ethnicity^[29].

The demographic profiles of migrant mothers also varied among different ethnic groups. Studies had shown that Vietnam-born pregnant women with GDM who moved to Australia were more likely to be older, underweight and pregnant for the first time^[30]. Similarly, Shah *et al*^[31] found that United States Caucasian and Asian women with GDM were more likely to be over the age of 35 and have a higher education level. Compared with other Asian groups, Japanese and South Korean women have the lowest risk of GDM^[12,29,32].

BODY MASS INDEX

Body mass index (BMI) has long been considered as a risk factor associated with the development of GDM^[33]. Ethnic origin also appears to be a factor with a twofold higher rate in obese Hispanic women compared to African-American and Caucasian women^[34]. Women with GDM from Pacific Islands had the highest pre-pregnant BMI ($34.5 \pm 8.0 \text{ kg/m}^2$), while those from South East Asia had the lowest ($23.7 \pm 4.8 \text{ kg/m}^2$)^[25]. As BMI increases, the sensitivity of BMI to identify GDM in each racial/ethnic group decreases while the specificity increases. In a retrospective study of 24325 patients presenting at the University of San Francisco using a BMI of ≥ 25 as a screening tool classified 76.8% of African-Americans with GDM in this category but only 24.9% of Asian women. Using a BMI cut-off of > 21.0 identified 91.5% of African-American women with GDM, 90.1% of Hispanic, and 79.8% of United States Caucasian, but only 68.4% of Asian women. African-Americans were shown to have the highest increased risk (OR: 5.1) of GDM when BMI > 25.0 was used as a screening tool, compared with US

Caucasians (OR: 3.6), Hispanics (OR: 2.7) and Asians (OR: 2.3)^[31].

Women from Asia were shown to have GDM during pregnancy despite having a BMI that is within or below normal range^[30,32,35]. Therefore the role of BMI as a screening tool or risk factor for GDM in women from Asia is certainly questionable^[31]. Hunsberger *et al*^[15] found that Asian women had the greatest risk of having GDM compared to other ethnicities regardless of whether their BMI was greater or less than 26 kg/m^2 . This population tend to have more visceral or central fat, which is a known risk factor for insulin resistance and cardiovascular disease^[36]. Hence we would recommend screening pregnant Asian women for GDM regardless of their BMI.

A recent study on the interaction between maternal age and BMI showed the odds ratios for GDM development were significantly higher in women older than 30 years if they were Caucasian, older than 25 years if they were African and older than 20 years if they were South-Asians. This study also found that Africans and South-Indians were at higher risk of developing GDM irrespective of BMI^[37].

MANAGEMENT OF GDM

Medical nutritional therapy (MNT) is the cornerstone in the management of GDM. The goal of MNT is to provide adequate calories and nutrients to meet the needs of pregnancy and consistent with maintaining normoglycaemia^[5]. Yet there is very little consensus on a specific recommended dietary approach in the treatment of GDM^[6,38,39]. A recent review of 6 randomised controlled trials in 250 women with GDM suggested that a diet higher in complex carbohydrate and fibre, low in simple sugar and saturated fat may be effective in preventing postprandial hyperglycaemia and avoid worsening insulin resistance and excess foetal growth^[40]. Yet studies comparing low-glycaemic index (GI) with a high-GI or conventional high-fibre diet showed no difference in birth weight or adverse pregnancy outcomes^[41,42]. Similarly a 2013 Cochrane Review assessing 11 different types of dietary advice for women with GDM was unable to conclude on which was the most suitable dietary advice. The specific diets analysed were low-and high-

Table 3 Studies comparing the prevalence of gestational diabetes mellitus among different ethnicities in women born in Western countries with women born in foreign countries

Ref.	Year	City/Region	Rate of GDM in ethnic groups born in Western country	Rate of GDM in ethnic groups who migrated from their native country to a western country
Savitz, Janevic, Engel, Kaufman and Herring ^[28]	1995-2003	New York City, United States	1.7% North African	7.5% North African

			4.39% Other Asian	6.21% Other Asian
			5.82% Pacific Islander	8.38% Pacific Islander

GDM: Gestational diabetes mellitus.

carbohydrate, high-monounsaturated fat, fibre-enriched diet, low-, moderate-, and high-GI, and energy-restricted and unrestricted. Overall there were no significant differences seen in the rates of macrosomia, large-for-gestational age deliveries or caesarean section^[39].

To achieve treatment goals, dietary plans should be prescribed by an accredited dietitian and should be culturally appropriate and tailored to the individual^[5]. The ability to adjust the amount and type of carbohydrate by training patients in "carbohydrate counting" is important to achieve target blood postprandial glucose levels^[38]. However, the amount of carbohydrate intake varies greatly between different ethnic and cultural groups. For instance, in South East Asia, rice is the staple food and this may pose major challenges for women from this background to curtail their rice intake. The diet for South-Asians is similarly heavily reliant on carbohydrate, and multiple sources of carbohydrate are often included at any one meal (e.g., lentil, dhal, rice in combination)^[43].

On the other hand, some women from the Middle East typically have a large meal in the afternoon with relatively smaller meals consumed at breakfast and dinner. They also have a tendency to delay breakfast till mid-morning and have dinner very late in the evening. Ramadan, an annual month of fasting observed by people of the Muslim faith, has significant impact on the timing of carbohydrate intake and meal portions. Ironically, it is the month where food consumption increases dramatically for Muslim communities as the daytime fasting is broken each evening with large banquets among family and friends which can last until dawn^[44]. Although pregnant women are exempted from observing Ramadan, many pregnant women with GDM still choose to observe the important religious ritual with their family.

For Pacific Islanders, they also tend to have large

servings of carbohydrate at main meals and multiple sources of carbohydrate at the one meal (taro, yam, cassava, green bananas, bread and rice)^[45]. All these factors should be taken into consideration when prescribing MNT. An overly regimental dietary recommendation will therefore result in poor compliance to therapy and suboptimal glycaemic control.

Health literacy among women from different ethnic groups may be highly variable, and this could have a significant impact on management of GDM. A study of women with GDM in the United Arab Emirates showed they had little understanding of carbohydrate knowledge, but not significantly different to women who did not have GDM. Moreover 22% of women with GDM were not reviewed by a dietitian for nutrition counselling and 65% attended a dietitian only once or twice^[46]. Furthermore, migrants in a Western society may also face huge challenges in managing their GDM. This could be related to language difficulty or their inability to adapt to an unfamiliar health system. A cross-sectional study conducted in Melbourne Australia showed that women coming from Vietnam had the poorest English skills and lowest education levels, with the greatest risk of misunderstanding GDM^[47]. Women with a history of GDM were shown to have poor diet quality as determined by the Australian Recommended Food Score, and in particular women who spoke a language other than English had significantly poorer knowledge than those who spoke English only^[48].

There were few studies that examined compliance to therapy for women with GDM. In an Australian study looking at failure-to-attend (FTA) rates of women with GDM, women who FTA more than once during their pregnancy had higher BMI, greater incidence of previous GDM and were more likely to be from non-Caucasian backgrounds^[49]. Apart from language barriers,

women from non-Caucasian backgrounds may need greater resources and time from clinicians to help them understand their condition better in order to improve their adherence to treatment recommendations.

INSULIN THERAPY

The glycaemic targets set for the management of GDM may also differ between countries, and hence it would be difficult to compare the proportion of women requiring insulin therapy across different regions. From a database in south western Sydney, women from South-East Asia had the lowest prevalence for insulin therapy (37.2%), compared with Anglo-Europeans (56.7%)^[25]. Despite having the highest 2-h glucose level on OGTT, women from South-East Asia also had the lowest need for rapid-acting insulin for the management of post-prandial hyperglycaemia. In that cohort, Pacific Islanders had the greatest need for insulin therapy, with 65% failing MNT. These women also had higher glycosylated haemoglobin ($5.9\% \pm 0.9\%$, 41 ± 10 mmol/mol) at the time of diagnosis of GDM compared to women from South East Asia ($5.4\% \pm 0.4\%$, 36 ± 4 mmol/mol)^[25]. In a similar study conducted in Hawaii, women from Pacific Islands had the highest rate of commencement of insulin therapy (27.5%), while women from Chinese heritage had the lowest (11.1%)^[11]. The higher percentage Pacific-Islanders requiring insulin before 20 wk of gestation in that study suggested that there could be a larger subset of Pacific-Islander women with previously undiagnosed type 2 diabetes.

FOETAL AND PERINATAL OUTCOMES

There is good evidence that treatment of women with GDM leads to better obstetrics and peri-natal outcomes^[50]. GDM increases risks of adverse perinatal outcomes including large for gestational age, shoulder dystocia, surgically assisted delivery and hypertensive disorders in pregnancy^[20]. In a 2013 systematic review commissioned by the United States Preventative Services Task Force and the National Institute of Health Office of Medical Applications of Research showed that treating GDM will result in a reduction in rates of preeclampsia, shoulder dystocia and macrosomia, but the benefits on preventing neonatal hypoglycaemia and averting long-term adverse metabolic outcomes of offspring are yet to be established^[51].

Among Asian subgroups, Cambodian and Laotian women with GDM had increased odds of macrosomia when compared with Japanese women with GDM. However, South East Asian women had lower rates of foetal macrosomia when compared with United States Caucasian women but preterm delivery with preeclampsia occurred more often when compared with Japanese and United States Caucasian women^[52]. Pacific Islanders have a higher rate of macrosomia than Asian or Caucasian women, but Asian neonates born with macrosomia had comparatively higher levels of NICU admission, need for

intravenous dextrose treatment for hypoglycaemia and respiratory distress, although the overall numbers were small^[10].

However another study from Ontario Canada showed that mothers of Chinese heritage had a significantly lower risk of adverse outcome at delivery compared to South Asian mothers. Chinese women also had a lower risk of adverse maternal outcomes compared with the general population^[53]. Several recent studies suggest infants born to mothers of non-Caucasian nationalities have lower adverse outcomes. A retrospective cohort study of 1865 adolescent women of different ethnicities born in a Californian University found that African-American, Hispanics and Asians had significantly lower rates of Caesarian delivery and low Apgar scores, while Asians and African-Americans had decreased rates of preterm delivery^[54]. There is no evidence to suggest any increase in peri-natal mortality for a particular ethnic group within a health care system. In a study of neonates admitted to intensive care unit, the mortality of 9813 infants of Australian-born mothers was not different to the 2166 infants born from migrant mothers^[55].

MATERNAL OUTCOMES

GDM represents relative beta-cell dysfunction which is caused by insulin resistance, revealed in response to the metabolic stress experienced during pregnancy^[56,57]. Women from particular ethnic groups who have GDM may be more susceptible to developing diabetes in the future^[2]. In particular, it appears that women with GDM from an Asian background who live in western societies are more likely than Anglo-European women to subsequently develop diabetes^[30,58]. Moreover a recent meta-analysis showed that women from ethnic groups other than "non-Hispanic white" had a higher rate of GDM recurrence of 56% compared with 39% in "non-Hispanic white" women who experienced GDM^[59].

A study of three ethnic groups of European, South Asian and Afro-Caribbean found that women who had a history of GDM had a range of metabolic abnormalities including beta-cell dysfunction with variable insulin resistance despite normal fasting blood glucose levels postpartum^[60]. Similarly a study in the United Kingdom of 221 women with GDM or impaired glucose tolerance (IGT) showed Asian women were shown to have significantly higher rates of persisting glucose intolerance compared with Afro-Caribbean or Anglo-European women post-partum. Use of insulin in Asian women during pregnancy was also associated with postpartum IGT^[14]. Development of type 2 diabetes mellitus in all ethnic groups was 3.5 times greater in women using insulin^[58].

An Australian study found that all ethnic groups living in a multicultural region with a high percentage of foreign-born residents all had a high rate of post-GDM diabetes or IGT^[2]. After a mean follow-up of 5.5 years, the study found that South Asians had the highest rate of either diabetes or IGT at 69%, more than the other

ethnic groups combined. South Asians and South-East Asians with either diabetes or IGT were also shown to have significantly lower BMI than Middle-Eastern or South European counterparts^[2].

A recent large retrospective analysis of women who delivered at Massachusetts General Hospital between 1998 and 2007 showed that women with GDM were 2.45 times more likely to develop hypertension compared to women without GDM. Furthermore, African-American and Hispanic women with GDM had a higher risk of developing hypertension and Asian women had a lower risk compared to United States Caucasian women subsequent to pregnancy^[61].

CONCLUSION

The increased risk of pregnant women developing GDM who belong to specific ethnic groups is widely acknowledged in the literature. This review highlights the major challenges in the provision of diabetes education and delivering MNT for GDM in an antenatal service where women may come from diverse ethnic and cultural backgrounds. Treatment involving MNT needs to be individually tailored and culturally sensitive, and insulin use may be more prevalent among some ethnic groups. Clinicians should appreciate that a "one size fits all" approach may not be appropriate in managing these women with GDM.

Abstract

The prevalence of gestational diabetes mellitus (GDM)

is increasing worldwide. This disease has many detrimental consequences for the woman, the unborn foetus and child. The management of GDM aims to mediate the effects of hyperglycaemia by controlling blood glucose levels. Along with pharmacology and dietary interventions, exercise has a powerful potential to assist with blood glucose control. Due to the uncertainty of risks and benefits of exercise during pregnancy, women tend to avoid exercise. However, under adequate supervision exercise is both safe and beneficial in the treatment of GDM. Therefore it is vital that exercise is incorporated into the continuum of care for women with GDM. Medical doctors should be able to refer to competently informed exercise professionals to aid in GDM treatment. It is important that exercise treatment is informed by research. Hence, the development of evidence-based guidelines is important to inform practice. Currently there are no guidelines for exercise in GDM. This review aims to assess the efficacy of exercise for the management of GDM in order to establish an exercise prescription guideline specific to the condition. It is recommended that women with GDM should do both aerobic and resistance exercise at a moderate intensity, a minimum of three times a week for 30-60 min each time.

Core tip: Exercise has been proven to be beneficial in improving pregnancy outcomes in women with gestational diabetes mellitus (GDM). However, there is currently no exercise guidelines published for this population. A review into research outcomes of exercise in pregnant women with and without gestation diabetes as well as guidelines pertaining to type 2 diabetes mellitus has been conducted. This review has shaped the first guidelines pertaining to exercise for GDM management.

INTRODUCTION

The use of exercise as part of the continuum of treatment in patients with diabetic related disorders is accepted and widely encouraged^[1]. One increasingly prevalent metabolic disorder is gestational diabetes mellitus (GDM). Although exercise prescription as treatment in this population group may be encouraged, a general exercise prescription guideline is lacking. Therefore the purpose of this review is to assess the efficacy of exercises currently being prescribed for the management of GDM in order to establish an exercise prescription guideline specific to GDM.

DEFINITION AND DIAGNOSIS OF GDM

GDM is defined as a "carbohydrate intolerance of varying degrees of severity with onset or first recognition during pregnancy"^[2]. Other variants of this definition further refer to the period of onset of hyperglycaemia, specifically within 24-28 wk of gestation^[3] and a natural dispelling of the hyperglycaemic condition after child birth^[4].

The earliest record of hyperglycaemia during pregnancy is from the 1960's, when a research group led by O' Sullivan (and endocrinologist/gynaecologist) noted that hyperglycaemia in pregnant women was associated with poorer pregnancy outcomes and a higher occurrence of type 2 diabetes in the years ensuing pregnancy^[4]. In 2013, the World Health Organisation (WHO) released a classification and diagnostic criteria for GDM (Table 1)^[5]. The new criteria was developed to take into account a quantifiable relationship between hyperglycaemia and adverse short-term pregnancy outcomes for both mother and newborn, in light of findings from the study of Hyperglycaemia and Adverse Pregnancy Outcomes (HAPO)^[6]. This diagnostic guideline can be used throughout pregnancy and can distinguish GDM from diabetes mellitus in pregnancy (Table 1)^[5]. However, as the new criterion recommends lower fasting plasma glucose levels than what has been previously used, the WHO anticipated an increase in the number of pregnant women diagnosed with GDM^[5]. The effects of these criteria changes are yet to be evaluated, especially in the area of pregnancy outcomes.

RISK FACTORS FOR GDM

There is a range of risk factors that increase the chance of developing GDM. Ethnicity may play a role in GDM development as elevated incidences have been reported in certain ethnic subgroups. In the United States epidemiological studies have reported a higher incidence

of GDM in African Americans, Native Americans, Hispanics and Orientals than in non-white Hispanic women^[7-9]. In Australia, the prevalence of GDM was found to be higher in Aboriginal Australians as well as women who were born in Asia and India^[10-12].

In Europe, a large scale epidemiological study ($n = 11205$) in London found that women of ethnic minority groups had higher prevalence of GDM^[13]. When compared to White women, relative risks ranged from 3.1 for Black, 5.9 for miscellaneous, 7.6 for South Asian and 11.3 for Indian women^[13]. Asian women living in Asia have less proportional incidence than Asian born women living in other continents^[14]. Indian women living in urban areas have greater observed incidence than those living in rural areas of India^[15].

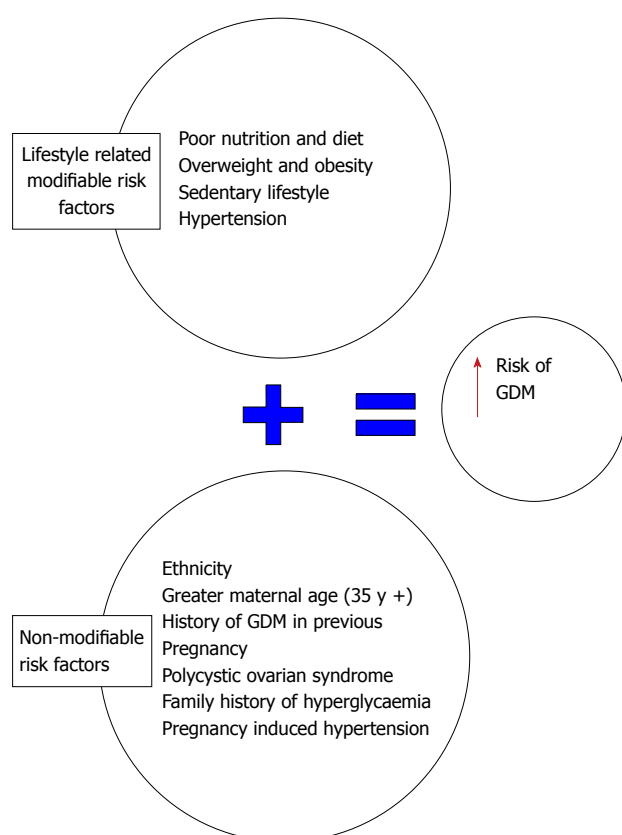

Furthermore, non-modifiable risk factors include greater maternal age (defined as 35 year of age plus)^[16,17], polycystic ovarian syndrome, family history of diabetes mellitus and pregnancy induced hypertension^[17]. Incidence of GDM has also been 30%-60% greater in women who have experienced the disease in a previous pregnancy^[18-22]. In a 16 year longitudinal retrospective study of 651 Canadian women who had GDM during their first pregnancy, 35% developed GDM in their second pregnancy^[23]. Greater pre-maternal weight was a strong predicting factor of GDM re-occurrence in ensuing pregnancies^[23].

This finding leads into a discussion of lifestyle related factors that are largely modifiable. Factors such as overweight and obesity can be modified. Weight gain during pregnancy was investigated using a nested-case control study of 1145 women^[24]. Findings suggested that subjects with greater weight gain during pregnancy (0.27-0.41 kg/wk or more) had an increased risk of developing GDM by 43%-74%. This effect was further exacerbated in overweight and obese women^[24]. Furthermore poor diet and nutrition are reported as mediators of increasing maternal weight and risk of GDM^[25-27]. Diets particularly high in refined sugars, with a high glycaemic index and fat content have been thought to increase the risk of GDM and hypertension during pregnancy^[25,28]. However, the majority of studies reporting these findings are small and have not been able to provide conclusive evidence on the role of diet in increasing the risk of GDM^[25,28]. Even so, one large prospective study ($n = 13475$), investigated the consumption of sugar sweetened beverages and incidence of GDM. After a 10 year follow up and 860 cases of GDM, excessive consumption (≥ 5 servings a week) of sugar sweetened cola was found to increase the risk of GDM by 22%^[29].

In a population based longitudinal study of 824 women, hypertension was found to increase relative risk of developing GDM up to twice as much (relative risk 2.03) as women without hypertension^[30]. The relationship between hypertension and GDM was confirmed in a Danish study of 215 women, in which higher rates of GDM was found in those with hypertension^[31]. Literature surrounding the pathophysiology of hypertension and gestational diabetes does not clearly underpin the

Table 1 Diagnostic criterion for gestational diabetes mellitus (WHO 2013) and diabetes mellitus in pregnancy (WHO 2006)^[5]

	Gestational diabetes mellitus	Diabetes mellitus in pregnancy
Fasting plasma glucose level	≥ 5.1-6.9 mmol/L	≥ 7.0 mmol/L
	OR	OR
75 g oral glucose tolerance test levels	1 h: ≥ 10.0 mmol/L 2 h: ≥ 8.5-11.0 mmol/L	1: Not required 2 h: ≥ 11.1 mmol/L
Random plasma glucose level	Not required	≥ 11.0 mmol/L

**Figure 1** Risk factors for gestational diabetes mellitus. GDM: Gestational diabetes mellitus.

mechanisms that cause such complications. However, it has been suggested that hypertension during pregnancy may heighten insulin resistance, alter immune responses and inflammatory pathways^[32]. These responses further encourage hypertension and hyperglycaemia, reminiscent of pathways in the metabolic syndrome^[32,33].

Sedentary behaviour and lifestyles characterised by low levels of physical activity have also been shown to increase the risk of GDM. In the largest reported study documenting physical activity and sedentary behaviour in relation to risk of GDM, Zhang *et al.*^[34] reviewed cases of 21765 women's pregnancies, 1428 of whom had GDM. They controlled for dietary factors and other covariates and found inverse relationships between vigorous activity, higher weekly physical activity levels and risk of GDM^[34].

Vigorous activity and brisk walking both had protective effects against developing GDM (RR = 0.77 and RR = 0.66 for each respectively). Women who were sedentary had a greater than two fold increase in developing GDM (RR = 2.30)^[34]. A more recent randomised control trial involving pregnant women had an exercise group ($n = 40$) which engaged in moderate land based resistance activity combined with aquatic aerobic activity^[35]. The control group ($n = 43$) was not given physical activity advice or exercise supervision. During 24-28 wk of gestation the women underwent a 50g maternal glucose screening test of which the exercise group had significantly better glucose levels (5.76 ± 1.13) than the control group (7.05 ± 1.73 mmol/L)^[35]. A case-control study by Dempsey *et al.*^[36] found a large reduction in GDM diagnosis in non-diabetic women who participated in recreational physical activity in the first 20 wk of pregnancy by 48%-78%. Further prospective studies of 909 non-diabetic American women, found that recreational exercise leading up to pregnancy, when performed for at least one year can induce a 56%-76% reduction in the risk of developing GDM^[37]. A large meta-analysis investigating seven pre-pregnancy and five early pregnancy studies found that pre-pregnancy exercise gave a pooled odds ratio of 0.45, a high protective effect against GDM^[38]. Furthermore, exercise in early pregnancy was also significantly protective of developing GDM with an odds ratio of 0.76^[38]. For a summary of risk factors see Figure 1.

EFFECTS OF GDM IN MOTHER AND CHILD
