Patient generally responds to the verbal command. Cardiorespiratory functions are unchanged. Minimal sedation does not invoke the monitoring requirements define in this policy. Although minimal sedation does not technically characterize the procedural sedation, the physicians should be aware that sedation can readily develop to the deeper level of sedation depth. The physicians and the registered nurses should be prepared to appropriately care for the patient in the event the level of sedation deepens.

Moderate (conscious) sedation

Patient responds persistently to the verbal command or light tactile stimulation. Additionally, the interventions are not needed to maintain the patent airway and the cardiorespiratory functions are sufficient and also usually preserved.

Deep sedation

Patient responds persistently to repeated or painful stimulation. The capacity to preserve respiratory function may be diminished. In addition, the patient may necessitate support in maintaining the airway and spontaneous respiration may be insufficient. However, the cardiovascular function is generally preserved.

General anesthesia

Patient does not response to the painful stimulus. The cardiorespiratory functions are usually reduced and the patients commonly demand the support in maintaining the airway. In addition, the positive pressure ventilations may be needed.

INDICATIONS

The two primary goals of suitable sedation for GIE procedures are to assist the procedures, and to reduce the anxiety and discomfort[6]. The optimal depth of sedation levels that registered nurses should be aiming for is minimal or moderate sedation depth[7].

LOCATIONS

Currently, endoscopic sedation can be performed in many units. The majority of practical locations of GIE procedures are endoscopy unit and operating room. Physicians who can facilitate the use of GIE sedation include the registered nurses, gastroenterologists, surgeon and anesthesiologists[8].

REQUIREMENTS

Personnel

A physician who continues current advanced life support qualification and who is familiar with endoscopic sedation, must be immediately available during the sedation and after the procedure. Resident and trainee may contribute in the GIE procedures by the supervision of staff physician. The physician is responsible for prescribing the medications including dose and type as well as also understanding pharmacology and the complications related with the sedative drugs. The physician will be in attendance throughout the procedure and will be responsible for managing the patient and must be able to manage the complications that may occur. In addition, the physicians performing the GIE procedure will maintain the responsibility and the competency for providing GIE sedation.

Consequently, an extra person is needed to establish an airway management. The registered nurses with appropriate competency can administer sedative medications with a written physician's order[9]. In addition, the registered nurse must be continuously monitored the patient and must be skilled to recognize clinical signs of hypoventilation and respiratory depression as well as abnormal vital signs and pulse oximetry readings. Importantly, the physician performing a GIE procedure can not be the person monitoring the patient.

Procedure room

The endoscopic room must be large sufficient to contain the operative personnel and monitoring equipments as well as permit an emergency cart to be brought into the room for emergency patient resuscitation. Additionally, the endoscopic room has adequate power outlets and adequate lighting to observe the patient and the monitoring equipments. The cart system with adequate space for the monitors, placed in a position where it is easily visible at all times for the personnel performing the procedural sedation.

Resuscitation equipment

The oxygen source, face mask and bag as well as suction equipments will be available in the endoscopic room. These equipments should be functional and checked before the start of GIE procedure. Moreover, the airway equipments including laryngoscope, endotracheal tubes and airways as well as an emergency cart will be available for the urgent use. This emergency cart must include the equipments for administering the resuscitate drugs and intravenous fluids including blood and blood components, as needed[1].

Monitoring

The patient undergoing sedation will be continuously monitored by the registered nurse with appropriate competency and knowledge. Consequently, vital signs, oxygen saturation and the responsiveness to a verbal stimulus will be documented before administration of sedative medications, 5 min during the endoscopic procedure and at least every 15 min in the recovery room. Electrocardiogram should be established in the high risk patients including elderly patients, patients with cardiac problems and ASA physical status $\geqslant$ Ⅲ[1].

PRE-SEDATION ASSESSMENT

Pre-procedural assessment and preparation part is very important. All patients scheduled for GIE sedation will have a pre-procedural assessment by a physician or registered nurse that includes the patient's medical condition, allergies, previous experience with sedation, drug use, alcohol and tobacco use, past medical history and current medications. A goal of physical exam including airway assessment and the major organ systems will be carried out. ASA physical classes of the patients should be documented before the procedure. A high ASA physical class is at increased risk for developing complications during sedation. Appropriate pre-procedure consultation with the proper specialists including an anesthesiologist is strongly recommended for the patients with severe underlying diseases.

The physician and the registered nurses are responsible for determining and documenting the patient's ASA physical class. If the provider determines that the patient is in an unstable condition or the GIE procedure is more invasive or complicated, sedation should not be considered by the registered nurses and an anesthesiologist consultation is recommended. Furthermore, the patients with ASA physical status IV or V are not the suitable cases in the absence of an anesthesiologist. Routine laboratory testing should not be carried out. However, the laboratory testing ought to depend on patients' physical status and underlying diseases.

Moreover, the informed consent must be completed before sedation is administered or the procedure is performed. All patients will be counseled on the risks, benefits, limitations and methods of sedation and also documented in the medical record before giving sedative drugs. Importantly, the patients can not drive home after sedation. A responsible adult person who will transport the patient should be confirmed before starting the GIE procedure. Fasting should be adhered to the guidelines except for necessary medications. All adult patients should be fasting for at least six hours before the procedural sedation. However, patients with normal gastric emptying time may have clear liquids in moderate amounts three hours prior to sedation. In addition, a time-out will be accomplished before the endoscopic procedure.

AMERICAN SOCIETY OF ASA CLASSIFICATION

The patient physical status is assessed from the ASA classification system. The ASA class should be determined by a person who will be performed GIE sedation: (1) ASA Ⅰ: Healthy patients; (2) ASA Ⅱ: Minimal systemic diseases, controlled on medications such as controlled hypertension, diabetes; (3) ASA Ⅲ: Severe systemic diseases with some limitations such as asthma, heavy smoking, obesity or multiple severe systemic illnesses all well controlled on medications, the patient with history of myocardial infarction or cerebrovascular accident; (4) ASA Ⅳ: Severe systemic diseases with severe limitations and life threatening such as poorly controlled hypertension, diabetes and coronary arterial disease; and (5) ASA Ⅴ: Not predicted to live 24 h regardless of any intervention.

PREPARATION OF SEDATION

The registered nurse who administered the sedative drugs should be considered monitoring equipments and availability of emergency medications and equipments during preparation of the procedure. The registered nurse may take the responsibility to monitor the patient during and after GIE sedation. In addition, the intravenous line must be continued all through the GIE sedation.

SUPPLEMENTAL OXYGEN

Several guidelines advise that oxygen supplementation should be performed during moderate and deep sedation[4]. However, oxygen supplementation will delay the finding of apnea by the pulse oximetry. The capnography can be a role for monitoring ventilation. Clinically, the incidence of desaturation will be reduced during the oxygen supplementation[10].

INTRAPROCEDURAL MANAGEMENT

Monitoring equipments during intraprocedural period should be included pulse oximetry, blood pressure monitor and ECG monitor. Resuscitation equipments and the reversal agents could be immediately accessed. Consequently, patients should receive supplemental

oxygen during the procedure when oxygen saturation reduces a 3% below their baseline saturation. An airway evaluation of the patient is continuously assessed. All evaluation and documentations are also noted. Accordingly, the consciousness should be reviewed frequently whenever sedative drugs are being titrated as well as also documented during sedation. Importantly, the patient is still remained responsive to a verbal stimulus and continued sufficient spontaneous ventilation. Ventilation should be continuously observed by clinical assessment. In patients where verbal response is not possible, search for other indications of consciousness.

A registered nurse experienced in moderate sedation can monitor and sedate the ASA physical status Ⅰ-Ⅱ patients. Generally, anesthesiologist should be consulted for the ASA physical status Ⅳ-Ⅴ patients and the deeply sedated patients as well as the high-risk patients. These patients need special care to make certain adequacy of pulmonary ventilation and to maintain hemodynamic parameters. In addition, the patient's airway must be supported and maintained.

SEDATIVES AND ANALGESIAS

Benzodiazepines

Benzodiazepines are widely used in procedural sedation even in GIE sedation because of their anxiolytic effects and dose-dependent anterograde amnesia[11]. Diazepam is not an ideal agent for short GIE procedures and in the outpatient cases because of its very long elimination half-life. In contrast, midazolam is the commonest premedication and sedative agent because of its pharmacokinetic properties[11]. Midazolam has a synergistic effect with anesthetic drugs. In that way, it can reduce the sedative medications[12]. Respiratory depression is the most important side effect of benzodiazepines when used in combination with opioids and/or sedative drugs. The standard dose is 0.03-0.1 mg/kg intravenously. The registered nurse can be safely used these dugs for GIE sedation.

Opioids

Opioids are usually used for the reduction of procedural pain and positional discomfort. Opioids are often used and carefully titrated with the combination of other sedative drugs[11]. The choice of which opioid should be used significantly depends on patients' physical status, the type and the duration of endoscopic procedure. Fentanyl and pethidine are widely used for GIE procedures. Similar to benzodiazepines, the registered nurses can be safely used the opiods for GIE sedation.

Pethidine

Pethidine (meperidine) is a synthetic opioid. Its onset and duration of action is longer than fentanyl. The standard dose of pethidine is 0.5-2 mg/kg intravenously. Its use in the renal insufficiency patients increases the potential for neurotoxicity. The patients taking monoamine oxidase inhibitors are contraindicated with pethidine[13]. Pethidine is commonly combined with midazolam for GIE procedure in the adult patients[14,15]. Pethidine and fentanyl are equally effective in providing analgesia for pediatric GIE procedures[16,17].

Fentanyl

Fentanyl has a rapid and short duration of action. It is also a synthetic opioid, and is the commonest opioid used for GIE sedation[11]. Normally, the dose of fentanyl is 0.5-2 mcg/kg intravenously. A previous study demonstrated that there were no significant differences in the recovery period, patient satisfaction, time to awake and sedation-related cardiorespiratory complications between the fentanyl-based sedation and the alfentanil-based sedation for esophagogastroduodenoscopy and colonoscopy. However, fentanyl is cheaper than alfentanil in each case[18].

Sufentanil

Sufentanil is also a synthetic opioid and is more potent than fentanyl. The standard dose of sufentanil is 0.1 mcg/kg intravenously[19]. Few studies have been evaluated the clinical efficacy of sufentanil in GIE procedure. In a previous study, the authors compared analgesia and sedation provided by one of four different opioids in combination with midazolam during GIE procedure. Patients were given 1-3 mg midazolam and sufentanil 5-10 mcg, meperidine 50-100 mg, fentanyl 50-100 mcg or alfentanil 150-300 mcg plus additional opioid and/or midazolam if needed. The study was concluded that sedation and analgesia were comparable in the upper gastrointestinal groups. Recovery time was shorter with sufentanil and alfentanil. However, analgesic properties of meperidine were significantly greater than sufentanil[20].

Alfentanil

Alfentanil also has a rapid and short duration of action. However, it is less potent than fentanyl. Donnelly and colleague studied the efficacy and cost of substituting sedation by using alfentanil and midazolam for the existing regimen of diazepam and meperidine in patients underwent upper GIE procedure. Their study demonstrated that the use of alfentanil for sedation in upper GIE procedure was safe and effective, and did not increase the total sedation cost[21]. Moreover, Liu *et al*[22] colleague demonstrated that the patient controlled analgesia with propofol and alfentanil offered greater sedation and patient satisfaction as well as a low complication rate compared with the combination of opioid and benzodiazepine.

Remifentanil

Remifentanil has an ultra-short action. It is a synthetic opioid. Importantly, the clearance of remifentanil is unchanged in the patients with hepatic and renal impairment[11,23]. Generally, remifentanil is given only by a continuous infusion technique. An analgesic dose of

remifentanil is 0.025-0.15 mcg/kg per min[24]. However, remifentanil is not extensively used for GIE procedure. Further studies should to be investigated.

REVERSAL AGENTS

Naloxone

Naloxone is an opioid antagonist. A dose ranges from 1-4 mcg/kg intravenously, and it may be repeated if required. The duration of action of naloxone is about 30-45 min[11]. Because of its short duration of action, an infusion dose of 3-5 mcg/kg per hour could be used after a bolus dose.

Flumazenil

Flumazenil is a benzodiazepine antagonist. It selectively binds to the GABAA receptor complex. The duration of action is approximately 1 h. The standard dose of flumazenil is 0.2 mg intravenously. It can be repeated if necessary. The maximum dose of flumazenil is 1 mg/dose and 3 mg/h[11]. Similar to naloxone, flumazenil can cause acute withdrawal syndrome in the patients who receive benzodiazepines chronically[11].

SAFETY OF NURSE-ADMINISTERED BENZODIAZEPINES AND OPIOIDS

Generally, the registered nurses can administer the benzodiazepines and opioids for moderate sedation in GIE procedures. Additionally, the registered nurse also can be administered the reversal agents by the order of a physician[25]. Consequently, the study of Yang *et al*[26] also investigated the nurse-administered moderate sedation by using the clinical criteria (Ramsay sedation scale, RSS) compared with using Bispectral Index values. They used midazolam and fentanyl or hydromorphone. The authors confirmed that the registered nurses could be safely and effectively performed moderate sedation by using benzodiazepine and opioid for GIE procedures.

However, the registered nurses should not to be sedated in the advanced GIE procedures such as ERCP and EUS procedures[27]. Guimaraes and colleagues assessed a cohort study of 9598 patients underwent ERCP and EUS procedures. The incidence of sedation and endoscopy-related complications as well as serious morbidity and mortality rates were compared. The study demonstrated that the anesthetic management for ERCP and EUS procedures in high-risk patients significantly decreased the incidence of sedation-related complications when compared with the registered-nurse care. However, endoscopy-related complications were unchanged[27].

PROPOFOL

Propofol is a phenol derivative with rapid and short duration of action. It has anxiolytic, hypnotic, anesthetic and antiemetic properties. The onset of action is about 30-60 s. The plasma half-life ranges from 1 to 4 min[28]. However, it does not have an analgesic effect. Propofol is commonly used for sedation in therapeutic GIE procedures[15]. It also potentiates the effects of other sedative drugs. The disadvantages of propofol are related with airway obstruction, apnea and hypotension as well as pain at the injection site.

NURSE-ADMINISTERED PROPOFOL

To date, propofol administration by nonanesthesiologists is controversial. Advocates of nurse-administered propofol sedation are due to the patient safety and the low cost[3,29,30]. American Society of Anesthesiologists guideline on sedation by nonanesthesiologists describes propofol as an anesthetic agent that is commonly related with deep sedation[4]. The use of propofol for routine GIE procedures also is not recommended by American Society of Gastrointestinal Endoscopy[31]. Generally, the registered nurses administered propofol sedation is cost-effective.

Several studies have been demonstrated the safety and efficacy of the registered nurses administered propofol sedation. For example, the study of Rex *et al*[32] demonstrated that the registered nurses and endoscopists could safely administer the propofol for GIE endoscopy[32]. Additionally, several data were also confirmed these in the invasive GIE procedures including ERCP, EUS and balloon endoscopy[33,34].

Moreover, the safety of nurse-administered propofol sedation in an ambulatory center also confirmed by the report of Walker and colleagues[35]. This report described the authors' experience in 9152 GIE procedures. The sedation-related adverse events were observed in seven patients including laryngospasm, apnea and pulmonary aspiration and all related with upper GIE procedures. However, tracheal intubation was not needed in all these cases.

To date, no clinical studies are directly compared between the registered nurse and gastroenterologist or endoscopist-administered sedation for GIE procedures. The administration of propofol by registered nurse is usually performed under direct supervision of the physician. The safety profiles of this sedation technique by the registered nurse for GIE procedures were evaluated in 27500 patients. Among these patients, 6.7% developed hypoxemia (SpO_2 < 90%) and 6.2% required oxygen supplementation. Severe hypoxemia (SpO_2 < 85%) was observed in 0.62% and 0.25% during upper GIE and colonoscopy, respectively. Bag mask ventilation or tracheal intubation was not required. Hypotension was observed in 1.2% and 3.5% during upper GIE and colonoscopy, respectively, and was immediately treated by using intravenous fluid administration. The mean recovery time was 14.6 min. This study demonstrated that propofol administration by the registered nurse was safe and effective[36].

Several studies have been confirmed that gastro-

enterologist or endoscopist can be safely and effectively performed GIE sedation in mild or moderate depth of sedation level. Redondo-Cerezo and colleagues assessed the efficacy and safety of endoscopist-administered propofol for GIE procedures[37]. They studied the propofol administration by gastroenterologist for sedation in EUS procedure. The induction time, duration of procedure, recovery time, patients' comfort and safety, hemodynamic profiles and complications as well as patient and endoscopist satisfaction were analyzed. Their study confirmed that propofol administration by gastroenterologist for EUS procedure in the elderly or the high-risk populations was safe and effective[38].

Recently, a tool for evaluation of the competency of the registered nurse-administered propofol has been developed by Jensen *et al*[39]. The study explored the reliability and validity of the nurse-administered propofol assessment tool. This study demonstrated that the assessment of sedation proficiencies could be performed by using a simulator. However, the video assessment required experienced physicians. Overall, this assessment tool demonstrated a good validity. Further investigations and controlled studies need to be confirmed.

POST-SEDATION CARE

Following the procedure, the registered nurse must continually monitor the patient until the patient ready to discharge. The patient also remains the responsibility of the registered nurse during the recovery period. Generally, the institutions would establish the recovery and discharge criteria for their patients. The recovery unit must have proper monitoring and resuscitation equipments.

The patients' vital parameters and the level of consciousness should be continuously observed in the post-sedation unit. The registered nurse is also required to manage the complications in this unit. The intravenous line and monitors should be utilized until the patient meets specific discharge criteria. If the reversal agents are used, the patients ought to be observed for $\geqslant$ 90 min after the administration of these drugs to assure they do not become re-sedated.

DISCHARGE CRITERIA

The registered nurses working in the post-procedural care use the discharge scoring system to assess the patient before discharge home or move to the ward. The discharge scoring systems such as the Aldrete score and the Post-Anesthesia Discharge Scoring System (PADSS) are commonly used for GIE procedures. The Aldrete and the PADSS scoring systems need continuous re-assessment of the patient. However, all discharge scoring systems have some disadvantages[40]. Importantly, the high-risk patients should be individually assessed. Currently, the reliability of these discharge scoring systems is clearly demonstrated. In the ambulatory setting, patients now accept the idea of going home only a few hours after diagnostic and/or therapeutic GIE procedures. The content and delivery of discharge instructions that outpatients receive from the registered nurse is very important. So far, the role of the registered nurse in providing patient education at the discharge process is becoming increasingly[41].

Importantly, the discharge criteria must be present before a patient can be discharged following GIE sedation. The following criteria suitable for the discharge are patient oriented to time, place and person or at pre-procedure status, vital signs within 20%-30% of pre-procedure values, unobstructed airway and sufficient ventilation, adequate oxygenation, easily and appropriately responsive to verbal commands, no severe pain and nausea/vomiting as well as the Aldrete score should be 9 or 10 in a total of 10. In the author's previous study, the periodic assessment of the home-readiness showed that most patients would complete an acceptable score on or before 1 h after GIE procedure. The time to complete an acceptable score associated with the type of GIE procedures. Consequently, most delayed recovery times after acceptable recovery scores were owing to the non-medical causes[42].

ANESTHESIOLOGIST CONSULTATION

The majority of sedation-related complications during and after GIE procedures are respiratory-related events such as pulmonary aspiration, hypoventilation, airway obstruction and apnea as well as the cardiovascular-related events such as hypotension and bradycardia[43]. Sedation-related adverse events are a risk to the success of the GIE procedure itself. Endoscopic sedation training is a very important issue. The registered nurses can learn about GIE sedation when to call for help and when to join the services of anesthesiologists. To date, the registered nurse should consult anesthesiologists for the patients with ASA physical status IV and V and the patients with known or suspected difficult airway management. In addition, anesthesiologists should be required for emergency or complicated GIE procedures such as ERCP, EUS and small bowel enteroscopy[44]. Moreover, anesthesiologist consultation is advocated for the patients with extremes of age or with significant renal or liver impairment, severe cardiorespiratory diseases, history of difficulty with moderate sedation, patients with previous inadequate response or adverse effect to moderate sedation, alcohol and drug abuse as well as patient or procedure needed at least deep sedation depth.

CONCLUSION

The use of registered nurse-administered sedation for GIE procedures has clinical significances. Most endoscopic patients require some forms of sedation and/or anesthesia. Generally, mild and moderate sedation for GIE procedures has been offered by the

nonanesthesiologist by using benzodiazepines and/or opioids. In contrast, the propofol sedation by the registered nurse is depended on the knowledge, skills and experience of individual nurse as well as the policy and the country guidelines. Importantly, the sedation training courses including clinical skills and knowledge as well as anesthesiologist consultation in high risk cases and procedures are necessary for the registered nurses to facilitate the patient safety and the successful GIE procedure. Additionally, appropriate patient selection and preparation, adequate monitoring and regular training will ensure that the use of registered nurse-administered sedation is also a practicable and safe technique for GIE procedures.

Abstract

Endoscopic suturing had previously been considered an experimental procedure only performed in a few centers and often by surgeons. Now, however, endoscopic suturing has evolved sufficiently to be easily implemented during procedures and is more commonly used by gastroenterologists. We have employed the Apollo OverStitch suturing device in a variety of ways including closure of perforations, closure of full thickness defects in the gastrointestinal wall created during endoscopic full thickness resection, closure of mucosotomies during peroral endoscopic myotomy, stent fixation, fistula closure, post endoscopic submucosal dissection, endoscopic mucosal resection and Natural Orifice Transluminal Endoscopic Surgery defect closures, post-bariatric surgery gastrojejunal anastomosis revision and primary sleeve gastroplasty.

Key words: Endoscopic suturing; Peroral endoscopic myotomy; Endoscopic full thickness resection; Natural Orifice Transluminal Endoscopic surgery; Endoscopic bariatric surgery; Endoscopic sleeve; Transoral outlet reduction

Core tip: The recent development of an endoscopic suturing platform, the only such device that is currently available in the United States, has led to a rapid expansion of endoscopic suturing applications ranging from simple procedures such as stent fixation to more complex ones such as closure of large full thickness defects and primary and revisional bariatric endoscopic surgery.

INTRODUCTION

Endoscopic suturing devices have been used in a limited fashion for about a decade. Some of the known devices

Table 1 Advantages and disadvantages of different suturing patterns

Suturing Pattern	Pros	Cons
Interrupted/ simple	Less tissue drag during tightening of the suture compared to a running suture No risk of suture crossing and entanglement as described for running suture Any failure during suturing would only involve the most recently placed interrupted suture rather than the entire suturing work up to that point as is the case with running sutures Suture failure after termination of the procedure would only involve a small segment of the closure without the risk of dehiscence of the entire closure that exists with running sutures	Approximation of the defect edges occurs as soon as the first interrupted suture is tightened and may limit good visualization and grasping of the edges of the nearly closed defect thus making placement of the subsequent interrupted sutures difficult or inaccurate Substantial increase in cost proportionate to the number of sutures used as discussed under running sutures
Figure of 8	Specialized suture used to close small circular defect in a circular fashion with equal circumferential anisotropic compression towards the center of the defect. Thus, it may be the optimal suturing pattern for fistula closure or oversewing an ulcer containing large vessel(s) at risk for bleeding	Technically more challenging than interrupted sutures Risk of suture entanglement Any suture failure (*e.g.*, erosion through tissue, breakage) would result in slack along the entire suture and result in dehiscence of the entire closure
Running	Allows clear visibilty of the defect edges until the suturing is completed Less expensive as it uses only one suture and cinch (in the United States, for the OverStitch platform, each additional suture+cinch adds approximately $100)	Tissue drag caused by the suture going through multiple bites of tissue requires gentle slow careful technique during tightening of the suture prior to cinching Avoiding entanglement of the long suture leading to the start of the suture line during placement of the transverse sutures across the defect requires careful technique and experience Any error such as accidental drop of the needle, fraying and breakage of the suture or device failure results in loss of the entire work up to that point with the need to start the closure from the beginning Similarly, any suture failure after termination of the procedure (*e.g.*, suture eroding through tissue prematurely or breaking) would result in failure of the entire closure

include the Bard Endocinch (MA-US), T-bars (Wilson Cook-NC-US), NDO Plicator (MA-US-no longer available) and GERDX TM (G Surg Seeon, Germany)[1-3]. There are reports on limited preliminary data from experimental or limited-release devices[4-7]. The OverStitch endoscopic suturing system (Apollo Endosurgery, Austin, Texas) evolved from the previously developed Eagle Claw device[8] and is currently the only widely available suturing device, and only Food and Drug Administration approved commercially available device in the United States[9]. Since the other devices briefly mentioned are not available either because they have been withdrawn or because they are at early experimental stages of development, this review will focus on the rapidly emerging widespread applications of suturing enabled by the Overstitch platform. Figure 1 illustrates the use of the endoscopic suturing device. It is a disposable, single-use device that is mounted onto a double-channel gastroscope and it can enable interrupted or continuous suture application[10]. Table 1 and Figure 2 demonstrates the advantages and disadvantages of different suturing patterns. Full thickness suturing is possible for tissue approximation or plication in the gastrointestinal tract *via* use of a tissue anchor, curved suturing arm and a cinch. The current version was approved in 2011 and early use included oversewing a recurrent marginal ulceration, a fundic ulcer, stoma reduction after gastric bypass surgery, and closure of a post-operative rectovaginal fistula[11,12].

PERFORATION CLOSURE

Closure of iatrogenic inadvertent endoscopic perforations not associated with endoscopic submucosal dissection (ESD)/endoscopic mucosal resection (EMR) is largely confined to the animal model. Recently, three patients with iatrogenic esophageal perforation had apparent successful repair with the OverStitch device[13]. The OverStitch device was used to successfully close a full thickness gastric defect in the pig in a two week survival study[14]. An interesting study in humans assessed the depth of endoscopic suture placement in the colon. Test sutures were placed intraoperatively in patients undergoing partial colectomy in the portion of the colon to be resected. Examination of the resected colon demonstrated successful placement of full thickness transmural sutures[15]. Figure 3 demonstrates a case in which we performed successful closure of a very large perforation that occurred during a colonoscopy performed to evaluate Crohn's disease in a 35-year-old patient. The patient had a second perforation at the cecum that was not appreciated by the referring endoscopist and was discovered during surgical exploration performed due to persistent abdominal pain, fever and leukocytosis 24 h after the index colonoscopy. The surgeon discovered a second perforation in the cecum, which he successfully repaired surgically and confirmed successful endoscopic closure of the splenic perforation not requiring surgical intervention. He noted that the endoscopic sutures placed using the OverStitch

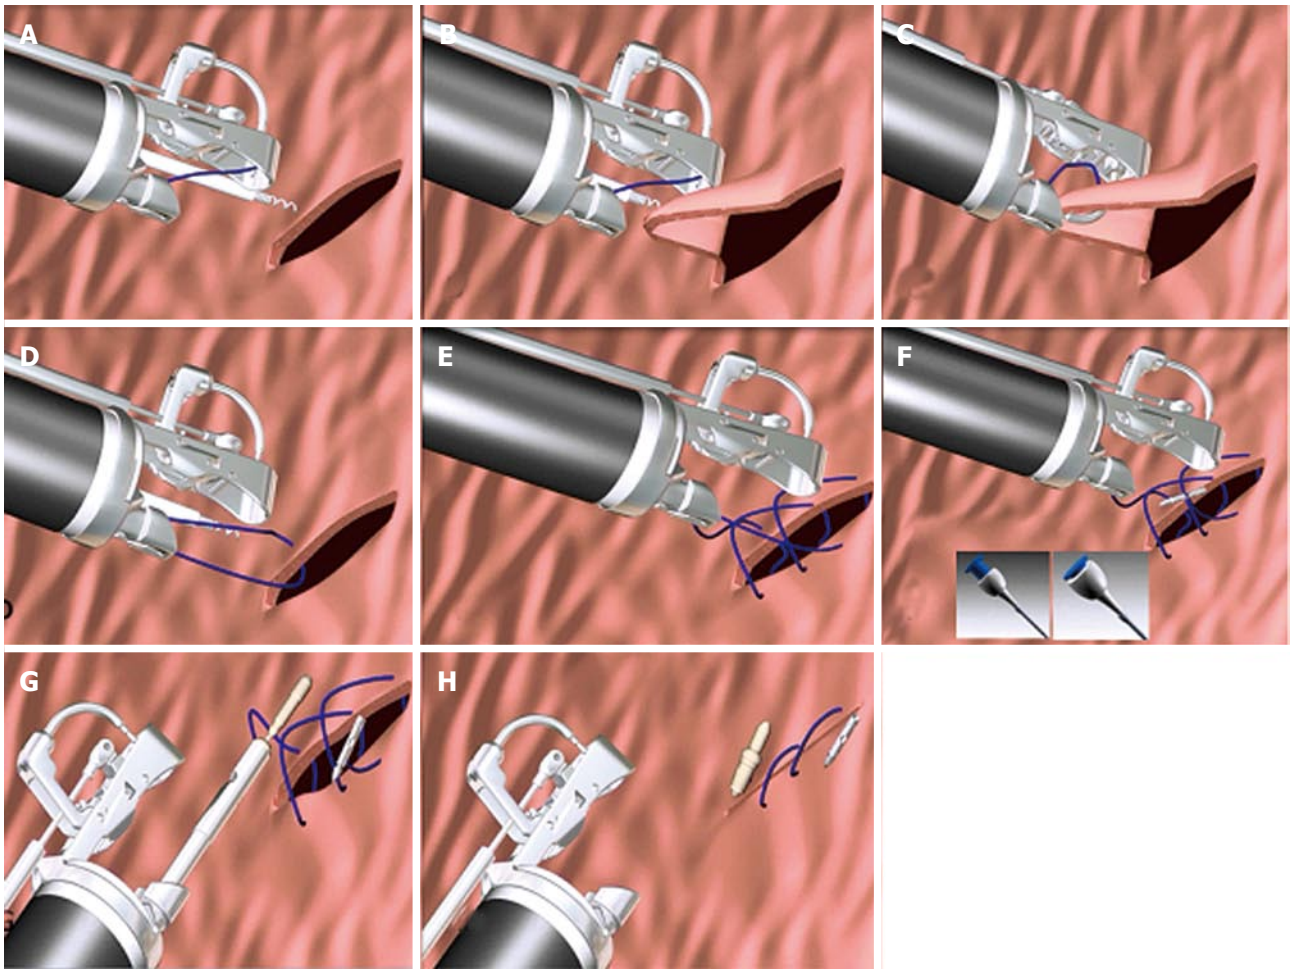

Figure 1 Steps involved in placing endoscopic sutures (Courtesy Apollo endosurgery Austin Texas). A: Grasp the tissue using the tissue helix; B: Retract the tissue into the needle path; C: Drive the needle through the tissue; D: Open the arm and release the tissue; E: Repeat stitched as desired; F: Press the blue button to release the needle (T-fastener); G: Tighten and cinch; H: Repeat as desired.

device had traversed the entire colonic wall, which is in accordance with the results of the colectomy study described above.

STENT FIXATION

Covered self-expanding metal stents have been employed in the treatment of perforations, strictures and fistulae/leaks. The covered feature allows subsequent removal but also predisposes to stent migration. Previously, endoscopic clips have been deployed to prevent stent migration with doubtful efficacy, but there is now an increasing experience with endoscopic suturing for this purpose. A porcine model study comparing clip *vs* suture fixation of esophageal stents favored suturing in terms of migration tendency and force needed to disrupt the stent fixation[16]. A study of esophageal fully covered self-expanding metal stents (FCSEMs) for leaks and strictures compared stenting with and without suturing, and the sutured stents migrated much less.(55% *vs* 35%)[17]. A case series featuring a variety of upper gastrointestinal issues (perforation, leaks, fistulae) necessitating stents had a similar migration of sutured stents (7 of 21 sutured SEM's)[18]. FCSEMs may have a role in treating post-bariatric leak/fistulae and our center and others have employed suturing for stent fixation and occasionally for primary defect closure[19].

FISTULA/LEAK CLOSURE

There is accruing experience with endoscopic suturing use in the treatment of gastrointestinal fistula/leak closure. These can be acute or chronic in nature and often result as complications from surgical anastomoses and stapled tissue divisions such as those of bariatric surgery (especially sleeve gastroplasty). As mentioned, suturing is often used in conjunction with other therapies including stents and glue[20]. The StomaphyX suturing system was used to treat gastric leaks in two bariatric patients[17]. The OverStitch device achieved closure in 3 of 7 patients with gastrogastric fistulae after gastric bypass[8]. This device has been used for a variety of fistulae[21,22]. One study demonstrated the superiority of the full-thickness OverStitch device compared to a superficial suction-based suturing system in the closure of gastrogastric fistulae[23]. The OverStitch device was used to close a persistent esophagopleural fistula[24].

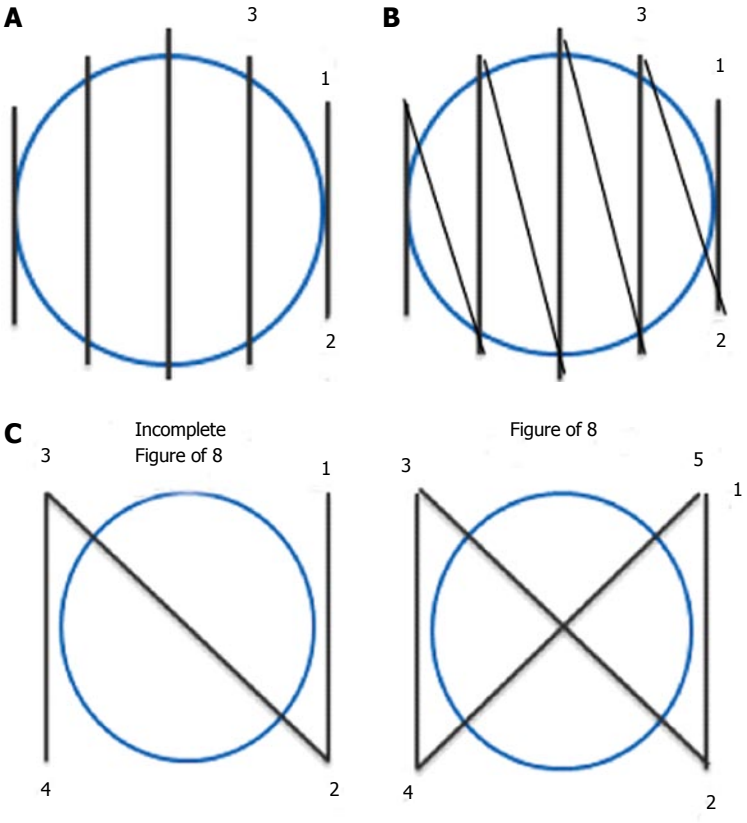

Figure 2 Types of suture pattern. A: Interrupted suture; B: Running suture; C: Figure of 8 suture.

Patients who are fortunate enough to have removal of their feeding tube after gastrostomy usually have wound closure, but occasionally there is a persistent gastrocutaneous fistula. There are a variety of closure techniques and endoscopic suturing may be employed as the sole intervention or in combination with other therapies (glue, clips, percutaneous suturing, *etc.*) Successful closure with the OverStitch device has been described[25,26].

ESD-EMR CLOSURE

There has been a veritable explosion of publications regarding endosurgical resection; predominantly ESD and related offshoots such as submucosal tunnel endoscopic resection (STER) and endoscopic full-thickness resection (EFTR). Endoscopic suturing has ensconced itself as an important if not indispensable component of advanced endoscopic resection. A porcine model study suggested quicker and more complete closure of ESD defects with sutures *vs* clips[27]. However, the efficacy of closure was somewhat subjective (visualization) and this comparison will need to be made in humans. The same group noted in another porcine study that effective suture closure after ESD can be done in a variety of ways and combined with clips[28]. In one study of 12 patients having ESD (4 gastric 8 colon), closure was made successfully with the OverStitch device and the patients were discharged home on the day of the procedure[29].

ESD has evolved such that large submucosal lesions and those with significant extraluminal extension can be resected with the technique known as EFTR. EFTR requires closure of potentially large defects (essentially intentional perforations) and endoscopic suturing is invaluable for this purpose. A porcine two-week survival study demonstrated the feasibility of suturing to close a full-thickness gastric defect (average size of gastric specimen 11 mm) without site ulceration[30]. Three patients with endoscopic perforation avoided surgery *via* OverStitch closure of the defect (all > 2 cm) in conjunction with catheter decompression of pneumoperitoneum, NGT insertion and Ⅳ antibiotics[31]. We employ the device after EFTR for gastric stromal tumors[32]. Without availability of the robust closure achievable with endoscopic suturing, closure of EFTR defects with endoscopic clips often requires specialized adjunctive techniques to achieve secure closure of these large perforations. We have demonstrated use of an omental patch to achieve secure closure with endoscopic clips of a large gastric EFTR one of our early cases prior to OverStitch availability[33]. In Asia, where OverStitch is not yet available, EFTR operators have largely converted to closures of EFTR defects with the endoloop and clips technique further emphasizing the inadequacy of clips for secure closure of these relatively large perforations[33-36]. Figure 4 demonstrates a few cases of EFTR defect closure with OverStitch. Kantsevoy

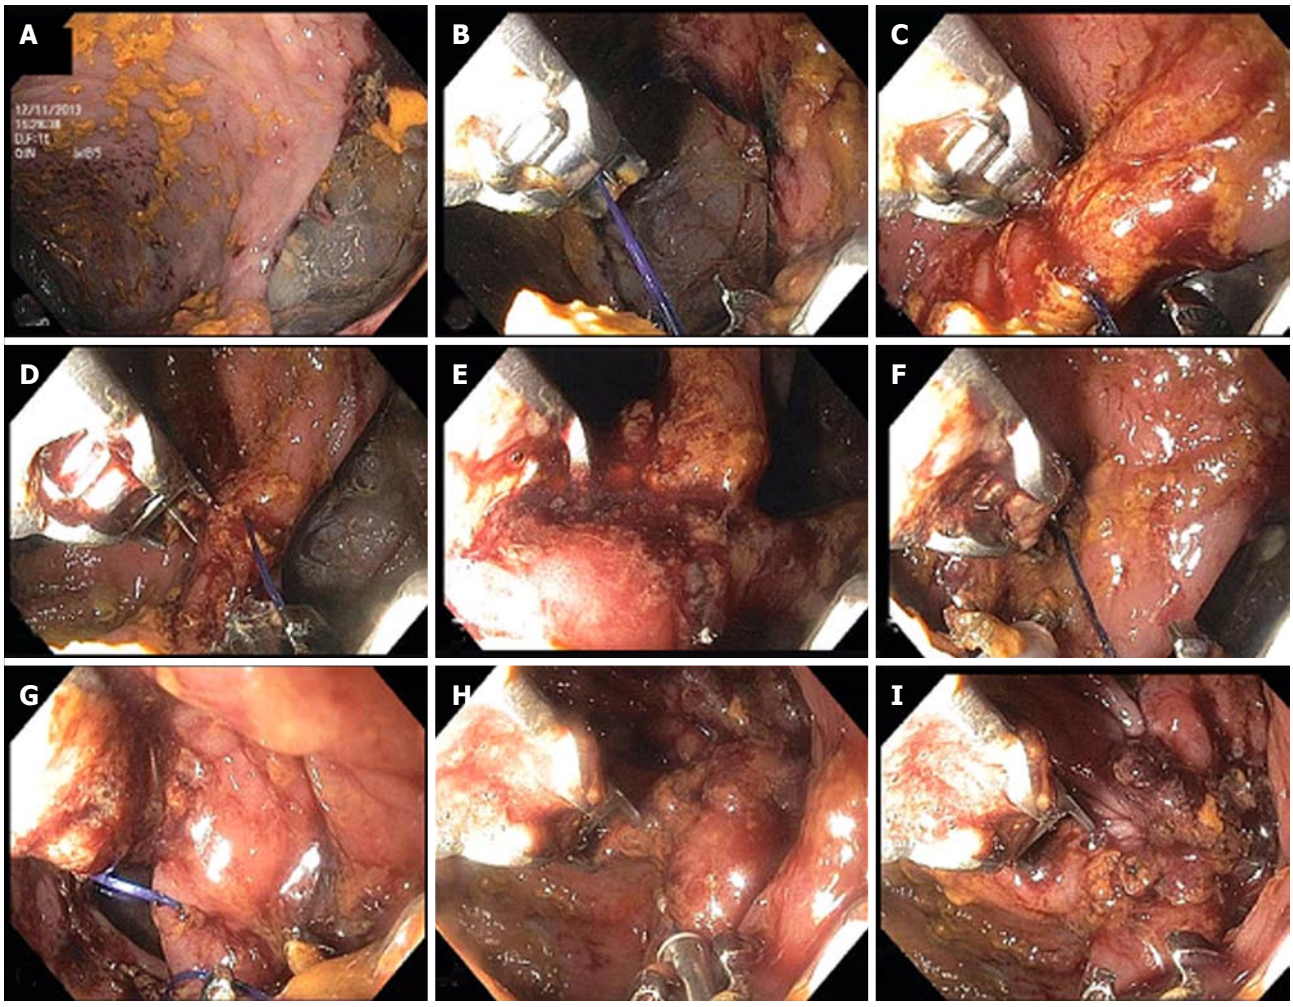

Figure 3 Closure of colonic perforation with endoscopic suturing device. A: Initial tissue bites forming a running suture (B-E) starting at the inferior edge of the perforation and progressing towards the center; F: Tissue helix retractor is used to ensure deep tissue bite along the distal, superior edge of the perforation; G: Suturing has reached the superior edge of the perforation the edges of which are now being pulled together by the sutures; H: After tightening of the sutures closure of the perforation has been achieved and the cinch device is seen being deployed at the 6 o' clock position of the image; I: Immediately after cinch deployment, the complete closure of the perforation is seen. Gastrografin was injected through the scope that confirmed absence of leak (not shown).

had successful OverStitch closure of two patients with one cm colon perforations after more extensive experience with closing two centimeter colon defects in pigs[36].

ESD is challenging for lesions in difficult locations where the endoscope cannot achieve a path tangential to the lesion such as the gastric lesser curvature. For such lesions, ESD can be facilitated by countertraction accomplished *via* use of the OverStitch device to create a "suture-pulley"[37].

A natural extension of EFTR is Natural Orifice Transluminal endoscopic surgery (NOTES) where the endoscopic intervention is done within the peritoneum and the trans-gastric entry site reliably closed. A suturing device was demonstrated to attain durable closure of gastric defects ranging to 18 mm in an animal model[38]. Closure success is similar for both continuous and interrupted suture application[39]. The OverStitch device was used in conjunction with a robotic device to remove a five cm diameter area of the gastric wall in two pigs, solely *via* endoscopic means[40].

PERORAL ENDOSCOPIC MYOTOMY MUCOSOTOMY CLOSURE

Per-oral endoscopic myotomy is a successful clinical application of NOTES. Endoscopic suturing has been utilized for closure of inadvertent mucosotomies and perforations during peroral endoscopic myotomy (POEM)[38-40]. Endoscopic suturing has also been shown to be useful in closing the mucosal entry point after the myotomy is performed (Figure 5)[41-43]. This is now our customary practice in POEM. During the first three years of our POEM experience (2009-2012), prior to the availability of endoscopic suturing, we performed closure of the tunnel entry site with clips. However, when endoscopic suturing with the OverStitch device became available, we converted to closure using suturing hoping for a more predictable and secure closure. We performed a retrospective comparison of clip closure *vs* OverStitch closure in our series of POEM procedures. We compared our initial 62 POEMs closed with a variety of endoscopic clips commonly available

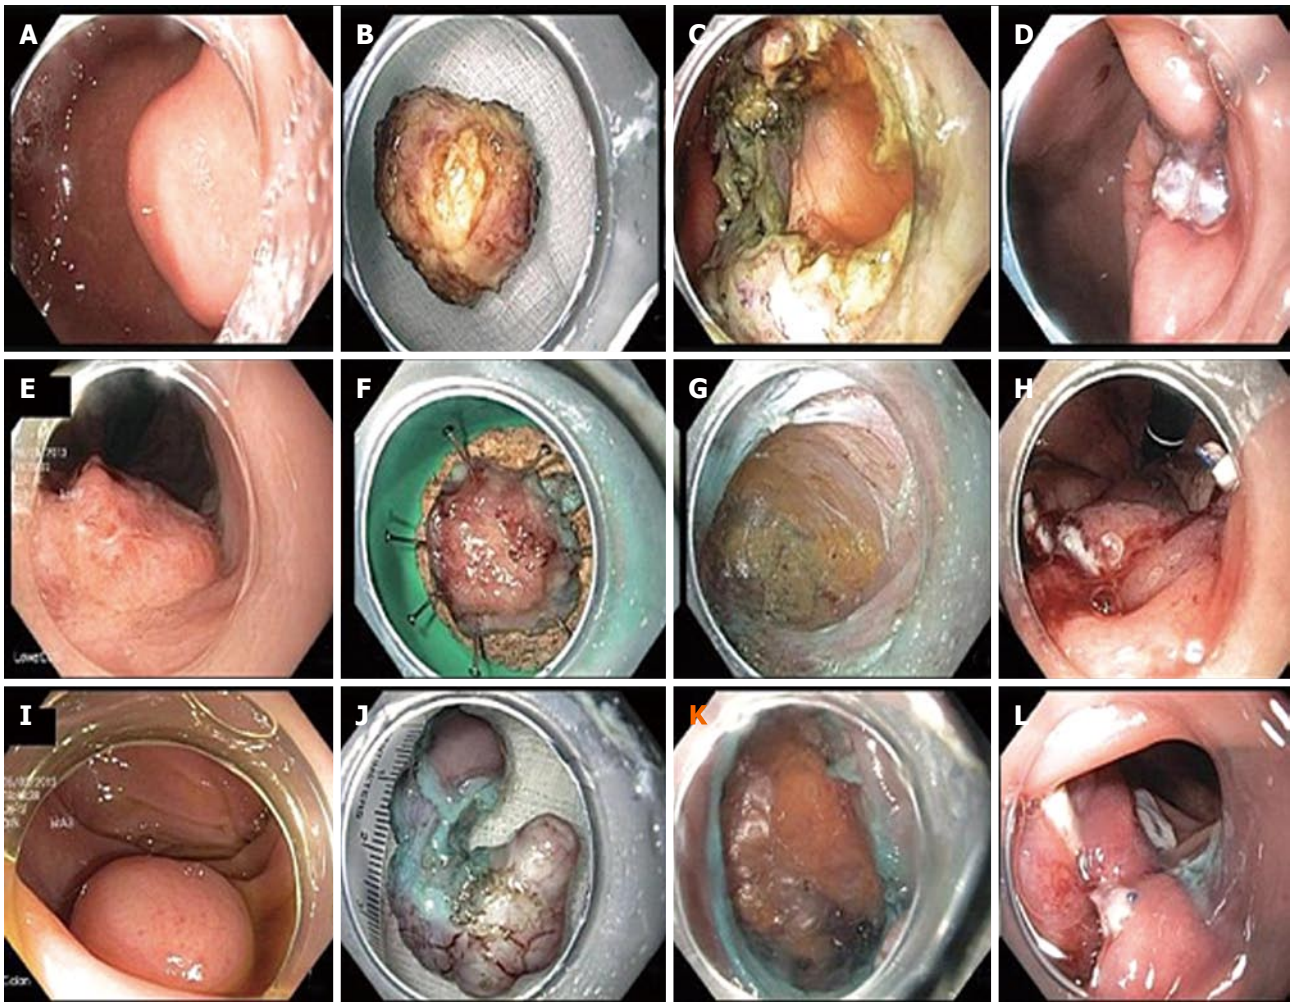

Figure 4 Closure of intentional full thickness perforations after subepithelial tumor removals with endoscopic suturing device. A: Endoscopic image of gastric muscularis propria based subepithelial tumor; B: 2.5 cm schwannoma; C: Resection crater revealing transmural fat; D: Endoscopic sutured closure of defect; E: Endoscopic image of rectal carcinoma superficially extending to muscularis propria; F: 1.3 cm rectal low-grade adenocarcinoma; G: Resection crater demonstrating perirectal fat, circular muscle layer and longitudinal muscle layers; H: Endoscopic sutured closure of defect; I: Endoscopic image of sigmoid muscularis propria based subepithelial tumor; J: 3cm leiomyosarcoma; K: Resection crater demonstrating peritoneal fat; L: Endoscopic sutured closure of defect.

in the United States with the subsequent 61 POEMS closed with endoscopic suturing (Table 2). We did not detect a significant difference in length of stay (1.9 *vs* 1.7 d) or complications (no significant complications in either group). There was one conversion to clips in the suturing group due to a superficial hypopharyngeal mucosal tear caused while attempting to insert the endoscopic suturing device in a patient with very narrow hypopharynx. Closure time and cost per closure was assessed for the most recent 25 cases where clips were used and the most recent 25 cases where suturing was used (after a plateau in the learning curve had been achieved by both techniques) and were found to be similar: mean closure time 8.8 (6-15) *vs* 10.1 (5-16) min and mean cost per closure $916 ($454-$2160) and $818 respectively, (cost based on the cost of these devices to our institution). We should note here, however, that endoscopic suturing device cost varies geographically with relatively small differences within the United States but significantly higher prices in Europe due to distribution costs there.

POST-BARIATRIC SURGERY ENDOSCOPIC STOMA REDUCTION

It is commonplace for patients with Roux-en-Y gastric biopsy to have dilation of both the gastric pouch and the gastrojejunal stoma. Endoscopic suturing lends itself well in reducing the gastric pouch and the stomal diameter, though most work to date centers on the latter. Endoscopic treatment of this condition avoids the need for revisional surgery which is technically challenging and carries significant morbidity. Twenty-five patients with dilated GJ anastomosis (mean 26 mm) had 100% technical success using the OverStitch device with marked reduction of the stoma diameter (mean 6 mm) and mean weight loss of 11 kg[44]. These results are concordant with the results of a multicenter randomized trial[45]. Weight loss was shown to be

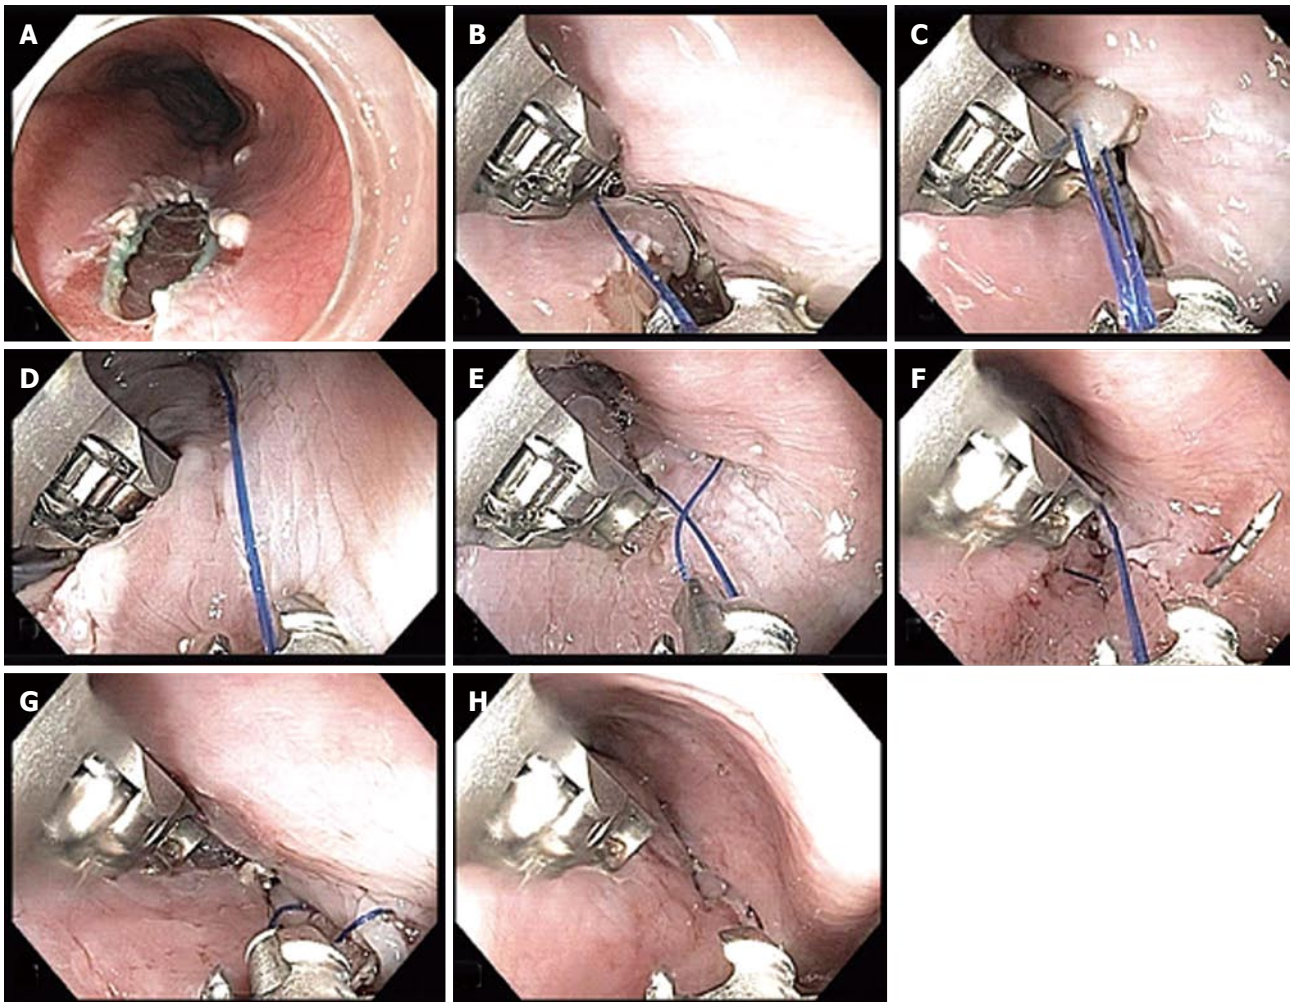

Figure 5 Closure of per oral endoscopic myotomy tunnel orifice with endoscopic suturing device. A: Closure of peroral endoscopic myotomy (POEM) tunnel orifice in a posterior POEM with the tunnel opening at the 5 o' clock position; B, C: We use a single running suture for closure starting at the distal, left margin of the defect as shown here. We attempt to penetrate mucosa and submucosa but not muscularis propria to avoid ischemia and pain or even possible injury to mediastinal structures; D: We proceed with suture placement through the right margin of the defect which is accomplished by torquing the endoscope as shown here; E: It is important to avoid having the running suture (here held by the needle onto the needle transfer catheter prior to loading it onto the needle driver) cross over the long suture leading to the start of the suture line which would then result in inability to properly deploy the cinch to the start or the suture line; F: The single running suture has been completed and has approximated the edges of the defect and the needle has been dropped in order to serve as a T-tag securing the suture at the proximal end of the defect; G, H: The cinch catheter is inserted over the long suture leading to the start of the running suture in the distal end of the defect, the suture is tightened and the cinch is deployed securing the suture at the start of the suture line in the distal end of the defect.

Table 2 Peroral endoscopic myotomy mucosal tunnel closure comparing endoclips and overstitch

	Endoclip	Overstitch
Total number of patients	62 patients	61 patients
Comparison of 25 consecutive closures		
Closure technique (mean number)	8 clips (5-14)	1 suture, 1 cinch, 1 device
Closure duration (mean minutes, $P = 0.1$)	8.8 min (6-15)	10.1 min (5-16)
Cost analysis (mean dollars, $P = 0.2$)	$915.84 ($453.81-$2160)	$818
Hospital Stay (mean days, $P = 0.1$)	1.9 d	1.7 d
Complications	No leaks Increased length of stay (4 d) in one patient with thick mucosal edges approximated with clips and endoloop	No leaks One aborted overstitch closure due to a mucosal tear in the hypopharynx during Overstitch insertion. Had mild sore throat for 4 d

inversely proportionate to stoma diameter[46]. Transoral outlet reduction (TORe) is most effective with a full thickness suturing device as compared to a superficial suturing device, even with similar stoma apertures[47].

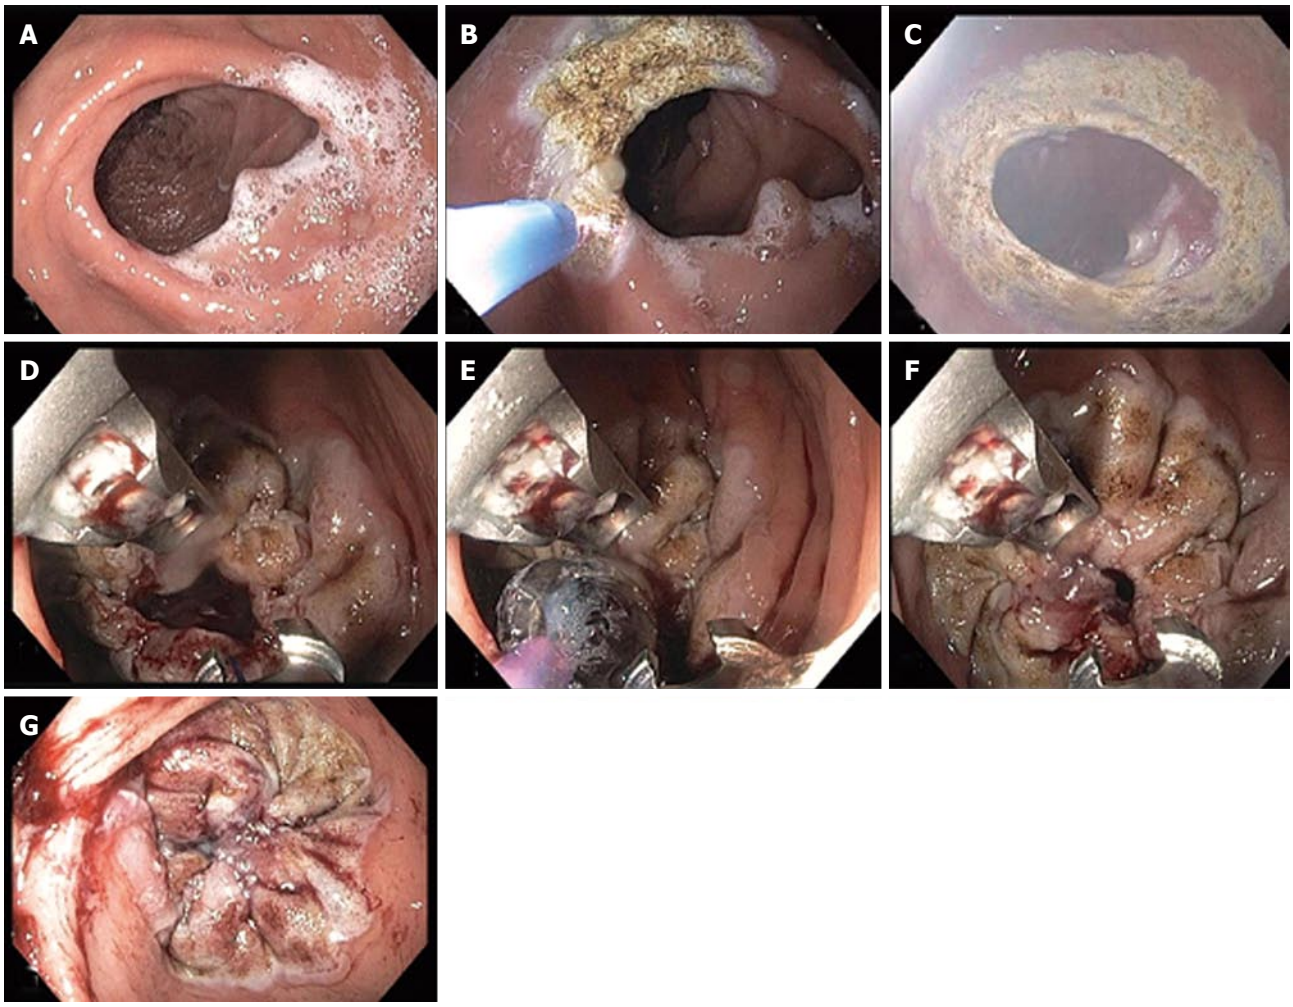

Figure 6 Endoscopic revision of gastrojejunal anastomosis in gastric bypass patient. A: An enlarged gastrojejunal anastomosis is noted; B and C: Argon plasma coagulation was used around the stoma to ablate the mucosa and facilitate tissue fusion during the healing process; D: Two sutures were used obtaining circumferential tissue bites to achieve a purse-like closure of the stoma; E: A 10 mm controlled radial expansion balloon was dilated and placed through the stoma opening via the second channel of the double-channel therapeutic endoscope and then the sutures were tightened so that the final stoma diameter was approximately 10 mm in size; F and G: The balloon was then deflated and removed. A markedly diminished stoma orifice is seen at the end of the procedure.

Preliminary TORe experience at our center in 10 patients is also favorable with mean weight loss of 19 lbs at mean follow-up of 34 wk. Figure 6 demonstrates TORe *via* endoscopic suturing in a 39-year-old woman who had roux en y gastric bypass 14 years ago. Longer term data concerning TORe is being accumulated.

PRIMARY ENDOSCOPIC OBESITY SURGERY

It appears that the restrictive anatomy after surgical sleeve gastroplasty can be duplicated by endoscopic plication of the gastric wall *via* endoscopic suturing. Two groups utilizing an older endoscopic suturing platform (Endocinch) performed gastric restriction in humans with excellent technical success rates and encouraging short term efficacy. Fogel utilized an early generation device of the Endocinch platform to reduce the gastric volume in 64 obese subjects from South America with no reported complications and an impressive 58% excess weight loss at 12 mo that has not been replicated however by other groups[48]. More recently another group used a second generation of the same device used by Fogel to reduce the gastric volume in 18 obese patients from the United States with no complications and a 27% (SD 22%) excess weight loss at 12 mo[49]. Preliminary encouraging data are emerging on endoscopic sleeve gastroplasty performed with the OverStitch device[50]. Under the current protocol followed at the Mayo Clinic, Brigham and Women's, our center and other centers investigating this technique in the United States, sutures are placed approximating the anterior wall, greater curvature and posterior wall of the stomach extending from the antrum to the fundus to achieve restriction similar to that of a surgical sleeve gastroplasty (Figures 7 and 8). The impressive restriction can be seen on the endoscopic images from a patient that underwent the procedure at our institution (Figure 9). Preliminary data indicate no significant morbidity with short-term weight loss similar

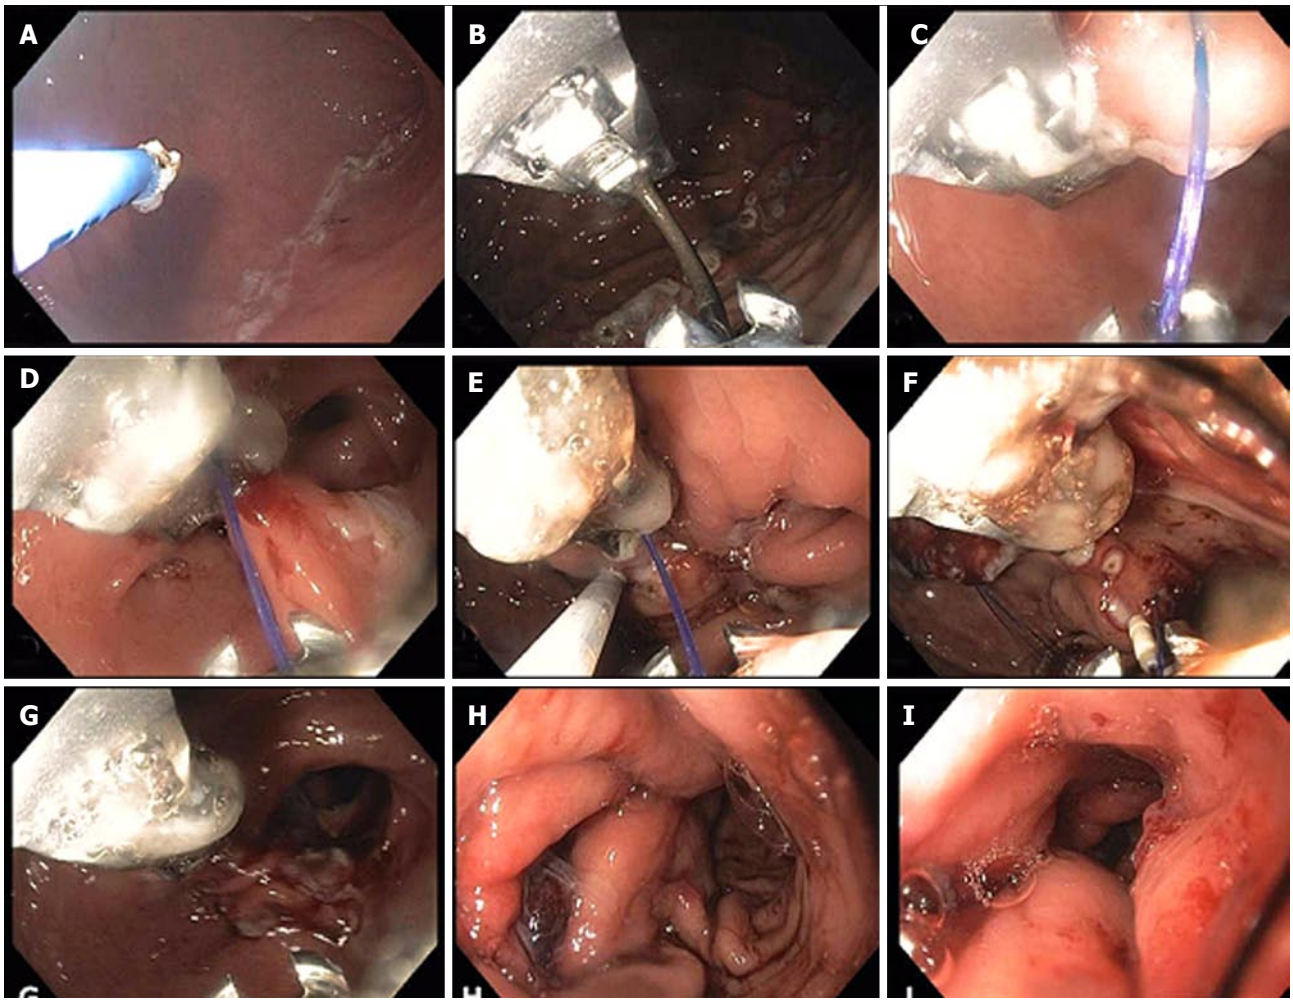

Figure 7 Endoscopic sleeve gastroplasty. A: Initially argon plasma coagulation is used at a setting of 0.8 L 30 W, forced coagulation to mark the anterior and posterior extents of a corridor that will contain the outer sutures to be placed (as shown in the attached schematic (bites along the anterior wall, greater curvature and posterior wall); B: The suturing device is inserted and placement of the first running outer suture is begun as shown in figures C and D reducing the lumen along the greater curvature of the antrum; E: The helical tissue retractor is used through the second channel of the endoscope as seen in figure E to achieve deep, transmural if possible placement of the sutures and to facilitate suture placement in difficult locations; F: Insertion of the cinch device shown at the 6 o'clock position. The running suture can be seen at 7 o' clock prior to tightening; G: After tightening and cinching of the suture the lumen reduction forming the beginning of the endoscopic sleeve can be seen; H: Completion of the outer sutures showing marked lumen reduction; I: Completion of the inner row of sutures with final appearance of the endoscopic sleeve gastroplasty at the end of the procedure. A tight 3-4 cm tunnel is seen which extends from just distal to the fundus to approximately 3 cm proximal to the pylorus.

to that reported for laparoscopic band (Christopher Gostout personal communication). Thus this procedure may find a niche along with other minimally invasive interventions, such as intragastric balloons, in the treatment of patients with moderate obesity (BMI 30-35) for whom traditional bariatric surgery may represent overtreatment. We have entered an era of endoscopic management of obesity, and the huge economic burden associated with this entity will drive further studies and technological development.

WINTHROP ENDOSCOPIC SUTURING EXPERIENCE

At our institution, we employed the Overstitch endoscopic suturing device extensively and in a variety of ways[51] (Table 3). One hundred and seventy-seven procedures incorporated endoscopic suturing. Since this represents one of the 2 or 3 largest volume series worldwide and includes novel applications such as a large number of POEM tunnel closures, we briefly review these data that illustrate the broad range of applications of endoscopic suturing. We typically do not require an overtube for device insertion. The closure success was remarkable with all patients having suturing for POEM, STER, EFTR, ESD, accidental perforations and leak closures having complete closure. Of these 149 closure procedures, there were no episodes of leakage or wound dehiscence; only 2 minor adverse events including one patient with dysphagia due to stricture at site of tunnel closure requiring a single balloon dilation with total resolution of dysphagia and one superficial mucosal tear in the hypopharynx during OverStitch insertion, which was clinically insignificant except for transient sore throat. Table 2 presents comparative data on POEM closure with clips *vs* suturing. We used clips in the

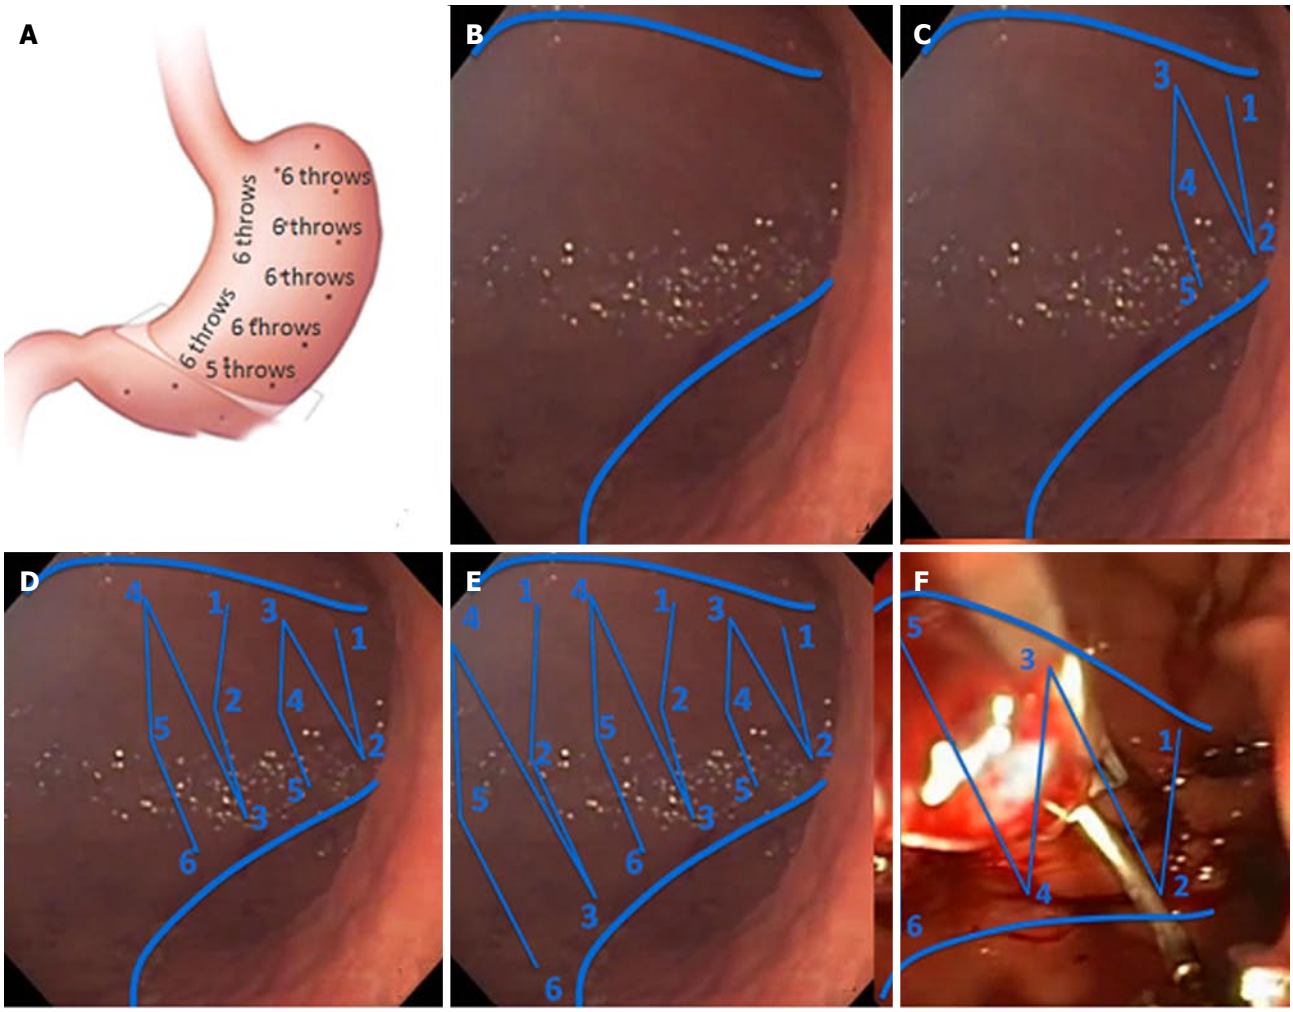

Figure 8 Suture placement needed to achieve endoscopic sleeve gastroplasty. A: Schematic of the configuration of sutures used to achieve endoscopic sleeve gastroplasty. Initially 5 to 8 plication sutures are placed along the greater curvature in a distal to proximal direction, followed by placement of an inner row of 2 to 3 short anterior/posterior "retention sutures" that take some of the tension off the plication sutures; B: Using APC ablation two lines are made along the anterior and posterior wall that mark the outer borders of the plication sutures; C: The first plication suture is placed within 3 cm of the pylorus where due to the narrowing of the lumen results in a modified 5-point suture with the first bites placed on the anterior and posterior wall of the antrum while the 3rd, 4th and 5th bites are placed on the anterior wall, greater curvature and posterior wall; D, E: Subsequent plication sutures all have the same 6 point configuration (anterior wall, greater curvature, posterior wall, anterior wall, greater curvature, posterior wall); F: The inner row of retention sutures consists of sutures of sutures between the anterior and posterior wall a shown (Courtesy Apollo Endosurgery Austin Texas).

Table 3 Winthrop University Hospital endoscopic suturing registry

Indication	Number of Cases	Comment
POEM submucosal tunnel entry closures	100	100% successful closure
EFTR of subepithelial tumor intentional defect closures	24	Mean closure time: POEM/STER -10 min for a mean 2 cm defect
STER submucosal tunnel entry closures	6	EFTR/ESD -13 min for mean 3 cm defect
ESD	22	Perforations/leaks-18 min for mean 1.8 cm defect
Accidental perforation	16	Complications: No episodes of leakage or wound dehiscence 2 minor adverse events
Transoral outlet reduction	7	At mean 34 wk follow-up, mean 19.1 lb weight loss (2-34 lbs)
Primary sleeve gastroplasty	1	At 32 wk follow-up pt lost 40 lbs
Ulcer oversew	1	Required surgical intervention 2 wk post procedure due to lack of response
Leak/fistulae closure	14	2 leaks and 12 fistulas (9 gastric sleeves, 2 roux en y gastric bypass, 1 post- PEG tube removal. 2/2 (100%) leaks and 10/12 (83%) fistulas were successfully closed
Stent anchoring	10	Mean time was 8 min. No episodes of stent migration at mean 8 wk

POEM: Per oral endoscopic myotomy; EFTR: Endoscopic full thickness resection; STER: Submucosal tunnel endoscopic resection; ESD: Endoscopic submucosal dissection.

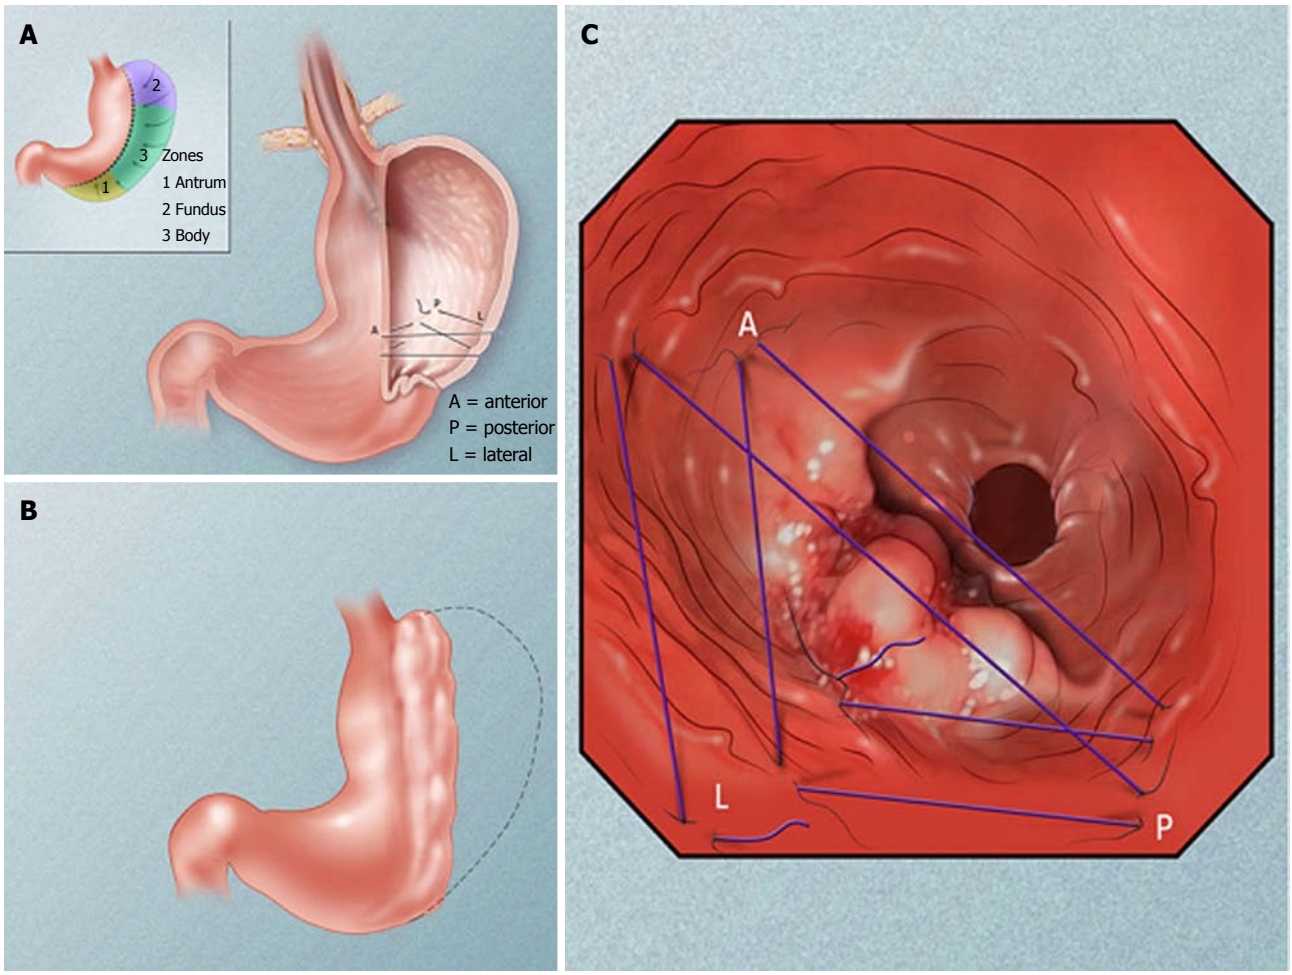

Figure 9 Illustration of the overall sleeve gastroplasty configuration achieved by placement of sutures as to achieve plication of the greater curvature of the stomach. A: Endoscopic gastroplication pattern; B: Plicated stomach; C: Schematic of suture pattern (Courtesy Apollo Endosurgery Austin Texas).

first half of our experience but switched to endoscopic suturing over the past two years. We selected the most recent 25 consecutive cases in each group (to eliminate any learning curve effects) to compare cost, closure time, length of stay and complications. There was no statistically significant difference between clips and suturing for POEM closure (however, regarding cost, it should be noted that this reflects costs of clips and the suturing device in the United States). All 10 sutured stents were in the same place at 8 wk. There was significant weight loss with both gastric outlet stomal reduction and the one primary sleeve gastroplasty. There were two fistula patients that required surgery and the single ulcer oversew patient required surgery for no evident healing at 2 wk.

FUTURE CONSIDERATIONS

The current version of the OverStitch, the dominant endoscopic suturing device requires a double channel gastroscope which limits flexibility and length of insertion thus making suturing in difficult locations such the gastric fundus or duodenum or in deep locations such as the right colon and small bowel difficult or impossible. Newer versions of the device are expected to address these issues. Looking further into the future, it is unclear what the impact of the development of flexible endoscopic staplers might have on endoscopic suturing. One would expect that selection of stapler *vs* suturing device would be guided by similar considerations as guide selection of hand-sewn *vs* stapled closures or anastomoses in surgery. However, unfortunately, this dilemma may not be a consideration for the near future given the expense and technical hurdles involved in developing flexible endoscopic staplers which likely resulted in two prior stapler devices having failed to become commercially viable[52,53]. Another device is in early trials but in its current version is restricted to a single indication, endoscopic fundoplication to treat GERD.

CONCLUSION

There has been a true revolution in gastrointestinal endoscopy with the evolution of endoscopic suturing to now be practically incorporated into clinical practice. As noted, there is a wide gamut of potential applications. There are issues including training and best imple-

mentation, but these should be clarified with time. The current instruments may be replaced or refined with technological developments and experience. Endoscopic suturing is here to stay!

Abstract

Gastroparesis (GP) is a common disease seen in gastroenterology practice particularly in western countries, and it may be underdiagnosed. The available drug therapies for this condition are quite disappointing. Botulinum toxin type A (BT) has been found to be effective therapy in various spastic disorders of smooth muscle of gastrointestinal tract. However, the benefits of BT injections in GP have been unclear. Several retrospective and open label studies have shown clinical advantages of intrapyloric Botulinum toxin type A injections, while two small randomized trials did not show positive results. Therefore, the available published studies yielded conflicting results leading to fading out of botox therapy for GP. We recognize possible clinical benefit of BT injections without any disadvantages of this treatment. We are calling for revisiting the endoscopy guided botox therapy in refractory GP. In this review we discuss important features of these studies pointing out differences in results among them. Differences in patient selection, doses and method of administration of botox toxin in the prior studies may be the cause of conflicting results. The mechanism of action, indications, efficacy and side-effects of BT are reviewed. Finally, we recognize limited evidence to recommend BT in GP and calling attention for future research in this field since no advances in drug management had been made in the last two decades.

Key words: Gastroparesis; Delayed gastric emptying; Botox; Botulinum toxin; Refractory gastroparesis

Core tip: Refractory gastroparesis (GP) has been identified as a chronic debilitating disease. After failure of diet and prokinetic drugs for treatment of refractory GP only surgical options are left. Because of the limited available treatment options and frequent failure of medical therapy, botulinum toxin (BT) injection in the pylorus might offer clinical value in GP. Currently available evidence is not strong enough to support the recommendation of this procedure in all patients with

refractory GP; but promising results have been seen as most patients have noticed symptomatic improvement. Although BT injections were successful in some GP patients, the role of BT remains undetermined. We addressed the position of botulinum toxin in the spectrum of available treatments for refractory GP. Continuing other treatment modalities after BT may improve the results.

INTRODUCTION

Refractory gastroparesis (GP) constitutes a major therapeutic challenge. Drug therapies are often found to be ineffective for a long term treatment. We found in our practice that some GP patients noticed significant improvement in symptoms and quality of life after botulinum toxin (BT) injections. Therefore, we question if there is a role for intrapyloric BT-A injections for treatment of GP. In this review article, the latest available literature (using Medline) and our own data on this topic will be summarized.

Epidemiology and types of GP

GP has been defined as a chronic disorder of impaired gastric motility in the absence of any mechanical obstruction of the upper gastrointestinal tract. Characteristic symptoms include early satiety, nausea, vomiting, bloating, postprandial fullness and upper abdominal pain[1]. The age adjusted prevalence of GP has been estimated to be 9.6 for men and 37.8 for women per 100000 by a community based study[2]. Most cases of GP have been found to be idiopathic or secondary to autonomic neuropathy associated with diabetes mellitus, surgery, Parkinson disease and collagen vascular diseases[3,4].

Idiopathic GP (IGP), the most common type of GP, is a result of viral or bacterial infection[5]. The underlying etiology of IGP is degeneration of myenteric plexus combined with loss of interstitial cells of Cajal[6]. In diabetic GP (DGP), many mechanisms are responsible for delayed gastric emptying (GE) including neuropathy which affects vagal nerve, reduction in the numbers of intrinsic inhibitory neurons responsible for motor coordination, and reduction in number of pacemaker cells. Acute hyperglycemia with serum glucose levels > 288 mg/dL significantly delays GE in diabetic patients when compared to euglycemia[7]. Post-surgical GP is less common type seen after surgery for peptic ulcer, fundoplication and bariatric surgery, pylorus-sparing pancreatoduodenectomy and heart and lung transplantation[8-10].

Pathophysiology and diagnosis of GP

Delayed GE as the major pathophysiological mechanism of GP is multifactorial, which includes impaired fundal tone, antral hypomotility, antroduodenal discoordination, gastric pacemaker dysrhythmias and excessive inhibitory feedback from the small bowel to the stomach[11]. It has been suggested that increased tone of the pylorus (pylorospasm) may contribute to delayed gastric emptying[12]. Therefore, reduction of pyloric pressure may facilitate improved GE and this can be achieved by botulinum toxin-A (BT-A) injection.

Diagnosis of GP is established based on the presence of clinical symptoms of GP, absence of gastric outlet obstruction or ulceration, and delay in gastric emptying. It is also recommended to document delayed gastric emptying before starting drug therapy of gastroparesis[13].

Treatment of GP

Treatment options for GP include dietary changes, prokinetic drugs, antiemetics, correction of malnutrition and electrolyte disturbances, jejunal feeding, parenteral nutrition, gastric neurostimulation therapy and surgery. In refractory cases of GP, a total gastrectomy has been suggested[14]. Prokinetic agents are the mainstay of treatment in GP after diet failure. However, the side effects and lack of effectiveness limits the long-term use of prokinetics in GP. Because of limited medical options, botulinum toxin-A intrapyloric injections have been offered as a salvage therapy in cases of refractory GP.

Botulinum toxin: Mechanism of action and clinical uses

Botulinum toxin, a bacterial neurotoxin, is one of the most potent paralytic agents of skeletal muscle. In two (2) *in-vivo* studies on piglets evaluating effects of BT-A on smooth muscle, the basal sphincter of Oddi pressure decreased by 50%, and lower esophageal sphincter pressure decreased by 60% with BT-A injection when compared to saline injection[15,16]. An *in vitro* study done on pyloric muscle strips showed that BT-A injection was able to decrease contractions induced by acetylcholine (Ach), substance P and electric field stimulation[17]. Two underlying mechanisms have been proposed for the action of BT-A. At low doses, BT-A inhibits the calcium dependent release of acetylcholine from cholinergic nerve terminals, and at higher doses direct inhibition of smooth muscle contraction has been observed[17]. The effects of BT-A are time and concentration dependent as axonal sprouting and accumulation of extrajunctional Ach lead to slow reversal of denervation[18,19].

BT-A has been found to be effective in the treatment of spastic disorders of smooth muscle in the upper and lower gastrointestinal tract. Case reports and prospective trials have shown positive results with BT-A administration in treatment of diffuse esophageal spasm[20], achalasia[21], oropharyngeal dysphagia[22], anismus[23], anal fissures[24] and anterior rectocele[25]. Administration of BT-A has a very low rate of adverse reactions and complications. Several case reports and

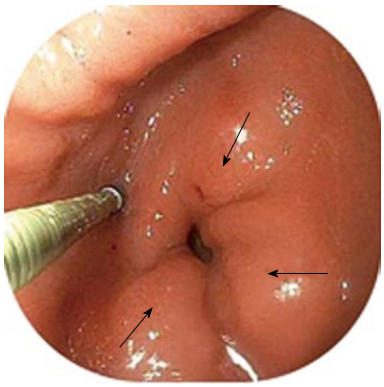

Figure 1 Endoscopic technique for botox injection in the pylorus (4 quadrants - see arrows).

trials of the effects of intrapyloric BT-A injection in GP have been published. Two small prospective studies suggested a limited value of endoscopic intrapyloric BT-A injections in GP[26,27].

There is conflicting data whether BT-A can effectively relieve the symptoms, improve quality of life and improve the rate of gastric emptying in GP patients.

Suggested technique of BT-A injection

The commercial preparation of BT-A in the United States is supplied in vials containing a 50 or 100 U of the lyophilized powder. The powder is diluted in 5 mL of normal saline to yield a solution containing 20-25 U/mL. After diagnostic upper endoscopy, the pyloric sphincter area is identified, and a sclerotherapy needle (23 or 25 gauge) is introduced through the biopsy channel. Aliquots of 1-1.5 mL (20-25 U botulinum toxin/mL) are injected into each of four quadrants of the pylorus, for a total of 100 U (See Figure 1). A total dose between 100 to 200 U can be injected. Patients go home after routine post-sedation criteria are met and they are allowed to eat light meal later on the same day.

CLINICAL STUDIES OF BT-A FOR TREATMENT OF GP

The first data on the intrapyloric application of botulinum toxin in patients with GP was published by Ezzeddine *et al*[28] in 2002. An open label trial included 6 males with diabetic GP, documented by solid phase gastric emptying study, and a mean age of 62 years. All patients had 100 U of botulinum toxin injected in the pyloric sphincter. A solid phase gastric emptying study was done before the BT-A injection, and then repeated at 48 h and 6 wk after the procedure. The mean solid phase gastric emptying at 90 min improved from 27.8% before BT-A injection to 44.4% at 2 wk, and 49% at 6 wk. Baseline clinical symptoms were recorded and the symptoms were reassessed at 2 wk and 6 wk interval after the BT-A injection to document improvement. A mean improvement of 55% was noticed at both 2 and 6 wk. No complications were seen after BT-A therapy. This study was very limited in terms of population and control group but it certainly demonstrated some clinical efficacy and immediate improvement in gastric emptying rate.

In an open label trial[29], eight patients (including 6 women) with type 1 diabetes and GP were studied. Mean age was 41 years. A control group consisted of asymptomatic non-diabetic patients matched for age and gender. A higher dose of BT-A 200 U was used. Clinical symptoms, antro-pyloric manometry, gastric emptying, weight and insulin use were measured at baseline and at 12 wk with follow up completed in 7 patients. Prokinetic drugs were not discontinued during the trial. Significant improvement in symptoms after the BT-A injection was reported in all the patients with the average symptom score reduction to 12 from 27.4 patients had improvement in the solid phase gastric emptying post therapy including 1 case of normal GE study. Three patients had no improvement in GE, and 1 patient had a worse gastric emptying rate when compared to the pre-procedural values. Radiologists reading the gastric emptying study were blinded to the trial protocol. Pylorospasm was demonstrated on antro-pyloric manometry in all patients with GP, but it was not seen in any of the controls. Significant reduction in pylorospasm was found after BT-A when compared to baseline. Insulin requirement was increased in 4 patients at 8 wk and remained increased in 3 of them at 12 wk follow up. Weight gain was noticed in all patients except one. Prokinetic drug use was reduced in 50% of the patients.

A retrospective study by Bromer *et al*[30] included 63 patients (53 women; 10 men) with average age 42 years. Most of the patients (44) received a dose of BT-A 200 U and 13 patients received 100 U. No dose was recorded for 6 cases. The outcomes in this study were assessed on the basis of improvement in major GP symptoms. Forty-three percent patients reported improvement in symptoms, and men had better response to BT-A therapy than women. The mean duration of response to BT-A therapy was 5.1 mo. Treatment with BT-A was repeated based on recurrence of symptoms. Apart from the small study population, the absence of any quantitative measure of improvement and no standardized scale of symptomatic relief limited the quality of this study.

A small retrospective analysis of 21 patients (15 females) with refractory GP was recently published from the United Kingdom[31]. The mean age of patients was 47.8 years and 81% of cases were secondary to DGP. A dose of 200 U of BT-A was used in all the patients. The mean follow up was 2 years. Sixty-two percent patients reported response to treatment compared to 19% non-responders. The mean response duration was 4.2 mo. Weight gain and increased insulin requirement was observed in the diabetic group. Greater effectiveness of BT-A therapy was found in the diabetic population compared to idiopathic GP cases.

In an open label trial[32] of 10 female patients with

IGP, a mean duration of symptoms of 4 years and prokinetics failure, BT-A in doses 80-100 U was used. Response was assessed on the basis of upper GI symptom improvement and 4-h solid phase gastric emptying study at 4 wk after the treatment compared to the baseline. Nine out of 10 patients reported improvement in symptom scores. An improvement in the gastric emptying rate was found in 7 of the 10 patients (70%), while 2 patients had no change and 1 case had worsening of gastric emptying rate. The patients were followed up for at least 6 mo. In 5 out of 10 patients repeat BT-A injections were required due to recurrent symptoms. All the patients reported improvement after the second BT-A injection. This study showed effectiveness of repeat BT-A injection but at the same time raised a question regarding long term outcomes of the procedure.

In another open label study[33], 20 patients with GP (17 women; 17 IGP) received 100 U of BT-A injections in the pylorus. An assessment of solid and liquid gastric emptying, and improvement in intensity of cardinal GP symptoms was performed at 4 wk. Significant improvement was found in solid phase gastric emptying and the symptom score compared to pre procedural numbers, but no improvement in liquid phase emptying was seen. No correlation was found between symptomatic improvement and the change in gastric emptying rate. This study had only a short follow up. The study raised an important question pertaining to the methods of measurement of improvement in GP patients. If we should assess the objective improvement based on the diagnostic test (GE study), a measurable standard, or the subjective improvement should be determined on the basis of their symptom scores as outcome measures.

Those promising results from the open label trials and observational studies prompted researchers to conduct randomized control trials. Two randomized, placebo controlled double blinded studies were published. In a trial by Friedenberg *et al*[26], a total of 32 patients were divided into two groups of 16, and randomized to receive either 200 U of botulinum toxin or saline injection in the pylorus. Each group contained 9 patients with diabetic GP. All patients had a symptom score $\geqslant$ 27. A decrease of 9 points or more in the symptom score at 1-mo follow up was considered as the primary endpoint. Only 6 patients in the botox group showed improvement compared to 9 patients in the saline injection group. Gastric emptying rate improved markedly in the BT-A group, but did not reach statistical significance when compared to the placebo group. Out of the 32 patients, 17 had no symptom improvement including 10 from the BT-A group. The study was based on an assumption of an efficacy of 80% for the BT-A injection which was relatively high and had a small population size and low statistical power. The second randomized controlled study by Arts *et al*[27] included 23 patients with GP (18 women, and 19 IGP). The mean age of the patients was 45 years. The study was double-blinded and patients received either BT-A injection at a dose of 100 U or saline injection in a cross-over pattern. Baseline gastric emptying and GP cardinal symptom index (GCSI) were recorded. In the first session, 12 patients received BT-A injections and 11 had saline injections. Both groups showed considerable improvement in the solid phase gastric emptying after the first injection. But no subsequent improvement was seen in either group after the second injection (cross-over). No statistically significant difference was seen when pooled data was compared from both groups after the two procedures. Both groups showed similar improvement in GCSI. Even though the pooled data analysis showed considerable improvement of post-prandial fullness and bloating in the BT-A group, it was not statistically different from the placebo group.

The largest study published up to date was a retrospective trial of 179 patients including 81 with DGP and 76 IGP cases[4]. The response was measured in terms of symptom improvement and change in body weight within 1 to 4 mo after BT-A injection. Almost 51% patients reported benefit and 32% of them had no benefit from the BT-A therapy. No record was available for the rest of the patients. BT-A was injected in doses ranging between 100-200 U. Patients who received higher doses reported better symptom control. Many patients (87) underwent repeat BT-A injections and received doses of 150 U or 200 U. Similar results were observed on repeat injections among first time responders and non-responders. This study results suggested a better response in women, younger patients (< 50 years old) and those with idiopathic GP.

Recently a case series[34] of 3 patients with diabetic GP and islet cell transplant between ages 42-55 years was published. They were treated with intrapyloric BT-A injections (2 patients received 200 U and one received 150 U). Symptomatic improvement was noticed in all the patients. The response lasted 6-8 wk in 2 patients who had BT-A 200 U injections and 8 mo in the patient who received lower dose 150 U. This result raised a question of the most effective dose to use for intrapyloric BT-A injections in GP.

The data on the use of BT-A in pediatric population with GP is even more scant. Only 1 study[35] has been published on BT-A in refractory GP. A retrospective review of 47 children including 23 girls was conducted with follow up available for 45 of them. The mean age of the patients was 9.8 years and mean follow up was 18 mo. The majority of the patients (66%) had idiopathic GP. Botulinum toxin was injected at a dose of 6 U/kg up to a maximum total dose of 100 U. The outcome was measured based on symptoms index as no response, mild, moderate or complete resolution of symptoms. At least mild improvement in symptoms was seen in 66.7% patients, with only 1 patient reporting worsening of symptoms. Repeat BT-A injections were required in 18 patients, out of which 8 showed response and 7 did not benefit from repeat treatment. Median duration of response to BT-A was 3 mo. The children older than 12

Table 1 Summary of the literature on use of botulinum toxin injection for gastroparesis in adults

Ref.	Number of patients	Study design	Botox dose (units)	Results (% of patients with symptomatic improvement)
Ezzeddine *et al*[28]	6	Prospective non-controlled	100	55
Lacy *et al*[29]	8	Prospective non-controlled	200	100

[1]100% improvement was seen on botulinum toxin as well as normal saline so botox was not proved to be better than placebo. RCT: Randomized-controlled trial; n: Number of patients.

years showed better response when compared to those of < 12 years old. This study was important by showing that efficacy rates, duration of response and safety of botox in children were comparable to the results seen in adult population.

In a recent meta-analysis[36] of 15 studies, including single case reports of GP, almost all open label and retrospective studies showed a beneficial effect of BT-A treatment for GP, while 2 randomized control trials have shown no superiority of BT-A in comparison to placebo. Based on the meta-analysis, it has been suggested that the current evidence did not justify the use of BT-A in GP patients, but the analysis consisted of only a small population (186 patients). Across these studies, the 2 randomized control trials included in the meta-analysis were found to be significantly heterogeneous. Because of these limitations, the meta-analysis failed to add any useful knowledge for practical purposes in therapy of GP (Table 1).

DISCUSSION

Botulinum toxin has been widely used in the past as a treatment option for patients with refractory GP with clinically beneficial effects, mainly symptomatic improvement. All the open label trials have reported the intrapyloric BT-A injection to be useful therapy in GP[28-35]. However, two small prospective randomized control trials (RCT)[26,27] did not show positive response to botox injection in regards to symptomatic improvement and rate of gastric emptying. Both studies in different subgroups (DGP *vs* IGP) of patients have not proven BT-A to be superior to normal saline injection, and cast some doubts over its effectiveness. Based on results of those RCTs some GI societies do not recommend routine use of botox injections as a treatment option in GP.

Limitations of therapy for gastorparesis

It has been a major concern that currently available drug therapy for severe GP is very limited. Traditionally prokinetics, metoclopramide, domperidone and cisapride, have been widely used in the treatment of functional dyspepsia and GP[37]. These prokinetic agents work by increasing antral contractility and accelerating gastric emptying[38]. In a systematic analysis, prokinetics have been shown to be more effective than placebo in GP by improving the symptoms of postprandial fullness, nausea and vomiting[39-42]. However, available prokinetic drugs only modestly enhance gastric emptying and the evidence that their symptomatic improvement in GP is related to enhancement of gastric emptying is actually lacking. Serious side effects such as cardiac arrhythmias (QT prolongation) seen with cisapride (Propulsid; Janssen Pharmaceutica, Titusville, NJ) led to withdrawal of the drug from United States market in 2000[43]. Cisapride was also banned in India and Philippines in 2011, and its use in Europe has also been quite limited. Metoclopramide (Reglan; A. H. Robins, Richmond, Va) is the most commonly used drug for the treatment of GP. However, extrapyramidal symptoms and sedative effects of metoclopramide limited its usage in GP. Metoclopramide significantly increases the risk of tardive dyskinesia, drug-induced Parkinsonism, and subjective akathisia[44]. The severity of tardive dyskinesia was greater in diabetics when compared to non-diabetics[44]. A dramatic reduction in prescribing of metoclopramide by clinicians for GP has been seen after a black box warning was placed for the risk of tardive dyskinesia when used for prolonged period[45]. Side effects are a common reason for discontinuation of metoclopramide therapy. Erythromycin is the only other Food and Drug Administration (FDA) approved drug for use in GP. Studies have shown symptom improvement in only 43% of the patients taking

erythromycin[46]. The use of erythromycin is often limited by development of tachyphylaxis as a result of down regulation of motilin receptors, which develops days after initiating the treatment[47]. Other side effects of erythromycin such as nausea, vomiting, and abdominal pain seen more often with higher doses can result in discontinuation of therapy[48,49]. Domperidone (Motilium; Janssen) appears to be effective for treating symptoms of GP. However, it is not available for sale in the United States. Domperidone has not been approved by the FDA because of concerns regarding its cardiotoxicity, mainly QT prolongation seen especially in hypokalemic patients[50]. The hurdles in obtaining the drug have discouraged the physicians in United States regarding its applications in GP. Currently, domperidone can be prescribed in United States for GP patients 12 years of age and older through an expanded access investigational new drug application and local institutional review board (IRB) approval[51].

Hence, there is a clear need for new therapeutic approaches for the treatment of GP. Gastric electric stimulator (GES) has been shown in clinical studies to be effective to control nausea and vomiting in GP patients. Even though patients with refractory symptoms have embraced the availability of this device, the special status and certain requirements used by some third party insurance carriers may deny coverage. The GES device has a humanitarian device status. Therefore, the gastric electrical stimulator cannot be implanted at any center unless its placement has been approved by the local IRB. Candidates for this therapy are patients with diabetes and IGP with relentless nausea and vomiting, who have failed medical therapy. Conversely, patients without nausea and vomiting but with other manifestations such as fullness, early satiety, anorexia, and abdominal pain have not been shown to predictably respond to gastric stimulation[52].

General concerns regarding studies on botox in GP

Most published studies looked only at a total symptom score (GCSI) rather than selected symptoms of nausea and vomiting. From clinical standpoint improvement in symptoms appears to be the most important outcome when treating patients with GP. The most troublesome symptoms for patients are nausea and vomiting, which tremendously limit oral intake and may lead to progressive weight loss and malnutrition. Abdominal pain associated with GP is the most challenging symptom to treat since patients often request pain medications, especially narcotics, and those drugs can lead to further delay in gastric emptying and diffuse GI tract dysmotility. Chronic dependence on narcotics has to be recognized in patients with both IGP and DGP. Those patients are taking opioids for different reasons including abdominal pain, but often not related to GP. Narcotics use makes this condition more difficult to treat. For some patients discontinuation of pain medications is not a viable option because of their quality of life.

In patients with refractory GP, even a partial clinical response may provide significant improvement in quality of life and possibly reduce number of hospitalizations. On the other hand, improvement in GE has not been shown to correlate with symptom improvement in this patient population. Therefore assessing response to BT-A based on GE study only has its own limitations.

Patients with severe refractory GP often require frequent visits to emergency center (ER) and hospitalizations, which is also associated with higher cost of medical care. Because of above limitations and high prevalence of GP, other therapeutic options are needed to improve symptoms and quality of life in GP patients. With the limited availability of medical treatment options, side effects and drug failure, we believe that physicians may need to reconsider botox as a trial therapy before directing patient with refractory GP for more aggressive treatment such as surgical interventions including placement of jejunostomy tube or GES and gastrectomy.

Our limited experience with Botox therapy in GP

In our small retrospective unpublished study of patients with GP (confirmed by solid phase gastric emptying study) treated with intrapyloric BT-A injection, a survey was performed to assess symptoms, the overall improvement after procedure, and the number of visits to ER and hospitalizations[53]. Twenty-five patients (19 females; 6 males) were included in the analysis. The causes of GP were idiopathic 17, diabetes 6, and postsurgical 2. Mean follow up was 31 mo. Seventy-two percent of our patients noticed significant (> 50%) symptom improvement. The patients who benefited the most from BT-A injection were males and those with IGP. Twenty-eight percent of patients (7/25), non-responders to botox therapy underwent laparoscopic GES placement. Reduction in number of ER visits and hospitalizations was reported by 24% of patients.

Role of botox in treatment of GP

The results of available literature are quite controversial to determine the clinical effects of botox therapy in GP. Some patients clearly reported symptomatic improvement with botox therapy. In refractory GP cases it is quite difficult to reject this therapeutic option especially as it is very safe.

For example, there is also controversy on effectiveness of botox in patients with anismus, but it has been often used since no other therapies offer benefits in this condition. We have solid data available on use of botox in achalasia, including safety and need for repeat injections. Despite more effective and permanent solutions available including Heller myotomy and peroral endoscopic myotomy, BT-A injections are still in the armamentarium for achalasia[54,55].

Several questions need to be further addressed regarding botox application in refractory GP. First, it is unclear, which patients with GP benefit the most from botox therapy. Some studies have suggested better results in patients with IGP including our own data[4,53].

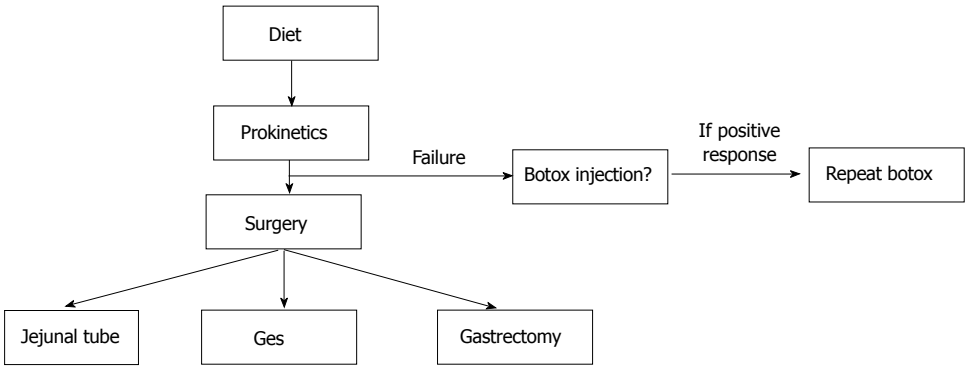

Figure 2 Summary of therapeutic options for gastroparesis. GES: Gastric electric stimulation.

There may be also a sex difference in response to BT-A injections. In a one retrospective study men had superior response[30], while the other large study showed the opposite results[4]. The effects of patient age on outcomes also need to be evaluated further. In pediatric population, older children appeared to have better results to BT-A injection[35]. There is a concern regarding safety of multiple BT-A injections into pylorus which could lead to local scarring as documented for comparison in achalasia patients[56,57].

Another issue that requires further study is to evaluate if the effect of botox injection may be dose dependent? Is a higher dose of botox more beneficial in GP? There is no clear answer to this question. In the RCTs botox was mainly used in two different dosages of 100 U or 200 U, and both showed negative outcomes[26,27]. Question has been raised about the effectiveness of higher dose of botox and the length of the response[34]. For example, in achalasia, no data exist to support that higher dose of botox is more effective and has longer lasting beneficial effect. One of the concerns is rather a short lasting effect of BT-A injections in GP. Based on the available studies the beneficial effects of Botox lasted between 3-8 mo[32,34]. Therefore, patients may require additional BT-A injections. The results on the duration of response to BT-A injection appear to be similar to published data in patients with achalasia. Often retreatment may be needed.

When to repeat BT-A injection? Should botox be used if there is no prior response or only if previously there was a good response to it? Should a higher dose of botox be injected next time if no response is found to the first treatment? Should the dose of botox be selected based on the severity of delayed gastric emptying?

Based on the prior studies, patients who had a positive response to the first dose continued to respond to repeat BT-A injections[4,32]. The studies do not provide an answer in which setting to use repeat botox. In our practice we use a standard dose of 100 U in each case. From personal experience we repeat BT-A injection only if there is an initial symptomatic improvement after first injection. The BT-A injections are repeated based on duration of response typically every 6 mo if needed. In patients with IGP spontaneous improvement in symptoms over time can be expected. Therefore botox injection may be used as a bridging therapy during a period of severe symptoms before the condition can be managed by diet and prokinetic drugs only.

To our knowledge no studies evaluated quality of life in patients with GP after BT-A injections. This issue may also be evaluated in further studies. If lower number of ER visits or hospitalizations can be documented with Botox therapy this could have an impact on cost of care in GP patients. Finally, we recognize that patients after BT-A injection need to continue to follow the diet and drug therapy. Diet and prokinetics adjustments should be done gradually as patients report symptomatic improvement. In only one study a reduction in prokinetic medication use has been addressed as an outcome measure[29].

There may still be a role for Botox use when patients fail diet modification, prokinetics or when the promotility drugs are not available. (See our proposed algorithm (Figure 2). At present there is no clear answer which patients benefit the most from botox injection. In general, patients have no contraindications for BT-A injection unless they face major cardiopulmonary issues not allowing for a safe endoscopy. Studies suggest that GP patients with pylorospasm have the best response to BT-A injections. However, in clinical practice, no easy access to gastroduodenal motility testing is available. Therefore, a decision to use botox has to be individualized in GP. Botox injections should not be used routinely in all GP cases.

CONCLUSION

Pyloric injection with botulinum toxin is an easy to perform procedure with minimal risk and negligible side effects compared to other available treatments for refractory GP. Although, the lack of convincing evidence has limited the use of botox in clinical practice, most uncontrolled studies have shown symptomatic improvement in the GP patients. Other concern regarding botox use is that, the dose and most effective site of BT-A injection for optimal response has not been standardized. Misplaced injections and skills of the endoscopist should also be taken into account

when determining the effectiveness of treatment with botox injection. If botox therapy is effective, the results of this treatment have not been long lasting and repeat procedures may be necessary. The long-term effects with repeat procedures have not been well studied. Further large population randomized studies are required to justify the use of botox for refractory GP. There may be a role for BT-A therapy in properly selected GP patients. With limited treatment options, we believe that botox injections can still be considered as treatment option for refractory GP when drug therapy failed.

Abstract

In recent years, the description of isolated bile duct dilatation has been increasingly observed in subjects with normal liver function tests and nonspecific abdominal symptoms, probably due to the widespread use of high-resolution imaging techniques. However, there is scant literature about the evolution of this condition and the impact of endoscopic ultrasound (EUS) in the diagnostic work up. When noninvasive imaging tests (transabdominal ultrasound, computed tomography or magnetic resonance cholangiopancreatography) fail to identify the cause of dilatation and clinical or biochemical alarm signs are absent, the probability of having biliary disease is considered low. In this setting, using EUS, the presence of pathologic findings (choledocholithiasis, strictures, chronic pancreatitis, ampullary or pancreatic tumors, cholangiocarcinoma), not always with a benign course, has been observed. The aim of this review has been to evaluate the prevalence of disease among non-jaundiced patients without signs of cytolysis and/or cholestasis and the assessment of EUS yield. Data point out to a promising role of EUS in the identification of a potential biliary pathology. EUS is a low invasive technique, with high accuracy, that could play a double cost-effective role: identifying pathologic conditions with dismal prognosis, in asymptomatic patients with negative prior imaging tests, and excluding pathologic conditions and further follow-up in healthy subjects.

Key words: Unexplained common bile duct dilatation; Endoscopic ultrasound; Normal liver enzymes

Core tip: Common bile duct dilatation, often without identified causes, in subjects with normal liver function tests and nonspecific abdominal symptoms, and absence of lesions on prior noninvasive imaging tests, is increasingly found in the clinical practice. Since the clinical suspicion for biliary pathology in that setting is usually low, and there are limited literature data, this condition is ignored. However, recent evidences show the existence of pathologies among these patients, often with a non-benign course. In this scenario, endoscopic

ultrasound may have a role in the identification of the etiology of dilatation.

Endoscopic ultrasound in common bile duct dilatation with normal liver enzymes. *World J Gastrointest Endosc* 2015; 7(8): 799-805 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i8/799.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i8.799

INTRODUCTION

The biliary system plays a central role in digestive pathophysiology, since it allows bile sterile flow from hepatocytes, through intra- and extra-hepatic ducts, Oddi's sphincter and Vater's ampulla, to the duodenum determining lipids absorption and excretion of metabolites and toxins in the small bowel[1]. In case of obstruction of these structures (as observed in choledocholithiasis, Mirizzi's syndrome, neoplastic or flogistic papillary strictures, parasitic infection, cholangiocellular or pancreatic adenocarcinoma), liver biochemical abnormalities and jaundice, sometimes in association with fever or abdominal pain, usually appear[1].

In recent years, due to the widespread use of high-resolution imaging techniques in order to investigate the causes of nonspecific abdominal symptoms, isolated bile duct dilatation in non-jaundiced patients with normal liver function tests has been increasingly reported. There is scant literature about the diagnostic impact of endoscopic ultrasound (EUS) in this setting and not much is known about the natural evolution of this condition. The aim of this review has been to analyze EUS accuracy in this scenario.

CAUSES OF BILIARY DILATATION

There are controversies regarding the upper normal diameter of the common bile duct (CBD) but it is conventionally accepted to be 7 mm[2-6]. A variety of factors can influence bile duct size, prominently imaging modality, age[7-10] and prior cholecystectomy. In transabdominal ultrasound (TUS), distal CBD may be difficult to visualize because of bowel gas, thus resulting in underestimation of duct size compared to other imaging techniques as computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC)[11]. On CT and MRCP imaging, bile duct wall is included in the measurement and, because of its oblique course and the difficulty to separate a possible low cystic duct insertion, result on the axial source may be inaccurate[8]. Finally, magnification and duct distension by contrast, used in ERCP and transhepatic cholangiography, may overestimate duct size[8].

Several studies in the last 20 years reported an increase in the CBD diameter in older patients, even if with consistent variability[6,7,9,10,12]. Based on autoptic observations, some authors identified loss of elastic fibers and proximal compensatory dilatation due to distal sclerosis as potential causes of the phenomenon[13]. Moreover, the fragmentation of the longitudinal smooth myocyte bands in elderly subjects and use of drugs such as calcium antagonists and nitroglycerine, may reduce contractility and cause hypotonus of the duct[12,14]. Finally, prior cholecystectomy seems to influence CBD diameter since gallbladder physiologically plays a role in accommodation of pressure fluctuation in biliary system which, after surgery, could be transferred to bile duct causing dilatation[11,15-17].

Among non-obstructive etiologies of CBD dilatation, opioids consumption has been described. Opiates may cause an increase in the basic pressure and in frequency of phasic contractions of the Oddi's sphincter leading to biliary dilatation[18,19]. In a study performed by Farahmand *et al*[20], the authors showed an association between increased biliary diameter, evaluated on TUS, and addiction to opioids in asymptomatic patients, with normal levels of serum bilirubin and alkaline phosphatase tests and absence of obstructive factors on TUS. In a recent study, opium addicts, symptomatic for abdominal pain were subjected to EUS. The authors observed CBD dilatation, especially in the extra hepatic tract, in all 15 patients included and increased surface area of Vater's papilla in 12 of them, after a mean of 20 years of opium addiction[21].

Pathologic conditions are also able to induce isolated bile duct dilatations with non-specific symptoms or biochemical abnormalities. Choledocholithiasis, which develops in about 10%-20% of patients with gallbladder stones, may be asymptomatic in half of cases and CBD stones cannot always be identified by traditional non invasive imaging techniques[22]. Reported sensitivity in detection of CBD stones is 18%-74% for TUS and 50%-90% for CT[23-25]. Recently developed imaging modalities, such as MRCP and helical computed tomographic cholangiography (HCT-C) have shown higher sensitivity than TUS and conventional CT, and remain less invasive than ERCP[26]. However, EUS is considered more accurate in detecting CBD stones, especially if smaller than 5 mm in diameter, which are sometimes not identified by MRCP and HCT-C[26]. When choledocholithiasis is suspected, sensitivity of EUS reaches 90% for the detection of CBD stones[27-29]. In a prospective study, performed by Fernández-Esparrach *et al*[30] on patients with dilatated biliary tree, EUS increased the pretest probability of accurately diagnosing choledocholithiasis as the cause of obstruction from 49% to 84%. On the contrary, this probability decreased from 49% to 0% if EUS ruled out lithiasis as the cause of obstruction[30].

In a meta-analysis published in 2008, on EUS perfor-

mance in detecting choledocholithiasis, the authors proposed EUS as a less low invasive technique to be incorporated into the diagnostic algorithm of patients with suspected CBD stones, in order to confirm the pathological condition before proceeding with therapeutic ERCP, when indicated[31]. Scheiman *et al*[32], in a prospective study and cost analysis performed on a cohort of patients referred to ERCP, defined EUS the preferred initial diagnostic test, compared with MRCP, for the evaluation of biliary system and identification of extrahepatic disease.

After excluding tumors, stones, flogistic strictures, a rare cause of CBD dilatation may be identified in choledochal cysts, a heterogeneous group of congenital focal or multiple anomalous dilatations of the biliary tree, usually diagnosed in childhood but remaining undetected until adulthood in 25% of cases[33,34]. Although abdominal pain is the most frequent symptom in adult patients, non-specific symptoms are also reported and the cyst may be incidentally identified in patients undergoing radiologic evaluation for other clinical suspicions[35,36].

IMPACT OF EUS IN THE DIAGNOSTIC WORK UP OF CBD DILATATION

In the presence of CBD dilatation without symptoms or clinical and laboratory alarm signs, when non-invasive imaging test (TUS, CT or MRCP) fail to indentify the etiology, clinical suspicion for biliary pathology is low, thus making further investigations unwarranted[2,8]. In this setting, despite negative results of previous imaging tests, diagnostic EUS could have a role in the identification of the etiology of dilatation (Figure 1) with a very low complication rate[37]. EUS combines endoscopy with real-time and high-resolution ultrasound providing excellent sonographic visualization of the extrahepatic biliary tree without interference of bowel gas, due to its ability to place the transducer in close proximity to the extrahepatic bile duct. Additionally, EUS permits the accurate and systematic visualization of the wall of the duodenum, including the papillary region[38].

Several authors compared MRCP and EUS in detecting choledocholithiasis showing cost-effectiveness and higher accuracy of EUS in detecting distal small stones in non-dilated ducts[26,32,39]. De Lédinghen *et al*[39] reported a 100% negative predictive value of EUS in the diagnosis of lithiasis, thus excluding the needing for further investigation and limiting unnecessary surgery. In the previously mentioned study by Scheiman *et al*[32], EUS was the most useful test for confirming a normal biliary tree, and the initial EUS strategy had the greatest cost-utility by avoiding unnecessary ERCPs and preventing ERCP-related complications[40].

In 2001, a prospective study performed by Kim *et al*[41] showed the existence of pathological conditions in subjects with dilatated CBD, despite the lack of symptoms, jaundice or causative lesions in TUS. Among the 49 patients who underwent ERCP, a significant prevalence of abnormal findings likely causative of dilatation (periampullary duodenal diverticula, benign strictures, choledochal cysts, anomalous pancreaticobiliary ductal anatomy and distal CBD masses), associated with both normal or altered liver chemistry tests, was found.

In 2007, Malik *et al*[3] retrospectively evaluated a cohort of patients with CBD dilatation and non-diagnostic imaging (TUS, CT or MRCP), previously performed for abdominal pain, weight loss or elevated liver enzymes in serum. These patients underwent EUS, being divided into two groups based on the level of clinical suspicion for biliary pathology (32 patients with normal liver chemistry tests and 15 patients with elevated enzymes)[3]. In the first group, the authors identified two findings on EUS (6%) potentially causative of biliary dilatation, a 7-mm stone of the CBD and a periampullary diverticulum. In the second group, 8 significant findings (53%) were observed: 4 periampullary diverticula, 3 choledocholithiasis and 1 ampullary tumor, not previously detected by TUS and CT.

As expected, the prevalence of biliary pathology is significantly higher in the case of elevated liver chemistry tests; however, despite the lack of pathological findings with non-invasive imaging techniques and normal liver biochemistry, biliary abnormalities may still be present and EUS is recommended for further evaluation.

A study by Carriere *et al*[42] showed a EUS yield of 28.7% in a cohort of 94 patients with unexplained isolated CBD dilatation, although an undetermined number of subjects of the group underwent endoscopy because of abdominal pain and/or abnormal liver function tests, thus suggesting a higher pre-test probability of pathological findings.

In an abstract published in 2009, based on a retrospective study, 30 patients with biliary dilatation and no evident causes on prior imaging underwent EUS[43]. Four patients had normal biliary system on EUS, 15 patients presented a dilatation of unknown etiology while pathology accounting for CBD dilatation was demonstrated in 11 of them (choledocholithiasis, ampullary adenoma, chronic pancreatitis or cholangiocarcinoma). Similarly to other studies, prevalence of abnormal findings during EUS examination was different between the patients with abnormal and those with normal liver chemistry tests (55% and 33% respectively). Conversely, the number of pathological findings in the latter group differed from percentages reported by other authors[2,3], probably because no details were specified in this study, about clinical presentation and previously used imaging techniques. Notably, none of the patients with unexplained CBD dilatation on EUS was found to have causative lesions after a mean follow-up of 16 mo.

Similarly, Bruno *et al*[2] studied 57 patients with normal liver enzymes (aminotransferases, gamma glutamyltranspeptidase and bilirubin) referred to EUS at our centre after prior negative imaging studies, excluding previous

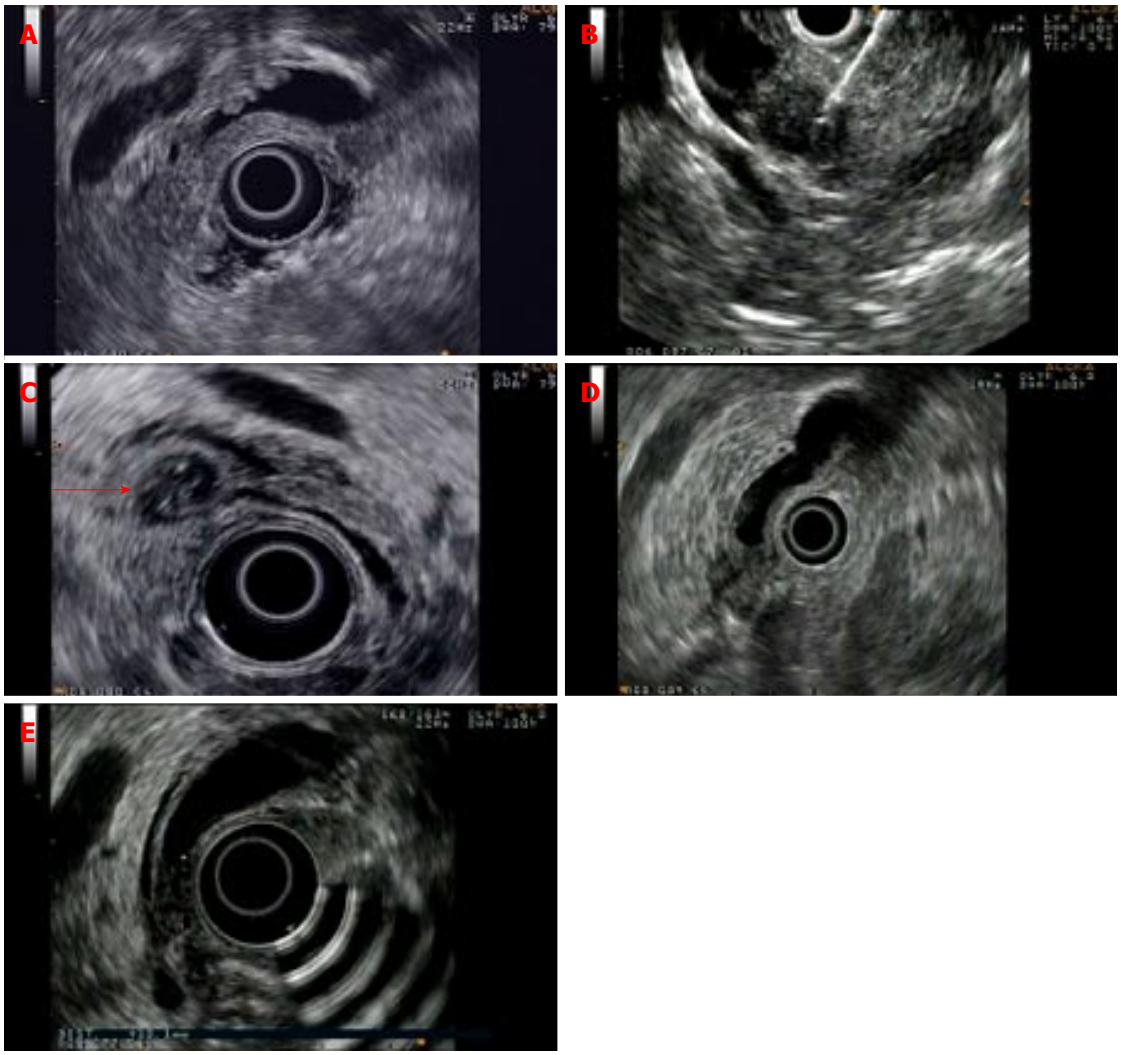

Figure 1 Examples of pathologic findings identified on endoscopic ultrasound in patients with negative prior imaging tests. A: Choledocholithiasis: Small stones in the common bile duct; B: Small pancreatic cancer; C: Small duodenal diverticulum with bile duct indentation (see arrow); D: Ampullary carcinoma with pancreas invasion; E: Inflammatory thickening of the distal common bile duct.

ERCP or history of biliary obstruction, pancreatitis or jaundice. Reasons for initial investigations were unspecific abdominal pain, dyspepsia, weight loss or pancreatic enzymes elevation in 49.2% of patients but in the majority of them biliary dilatation was an incidental finding. Employed imaging techniques, some of which performed in other centers, were TUS (7%), TUS and MRCP (63.1%), TUS and CT (10.5%) or TUS, MRCP and CT (19.3%). Abnormal EUS findings were observed in 12 patients (21%). As already described by other authors, causative identified lesions were periampullary diverticula, although a true compression on the CBD was rare (2/6), 2 ampullary adenoma, chronic pancreatitis according to predefined criteria[44] in 2 cases, a 7-mm biliary stone and one pancreatic cancer; 66.7% of patients were completely asymptomatic while unspecific abdominal pain or dyspepsia had been reported by the others. As suggested by the authors, a 21% prevalence of pathologic findings among patients with the aforementioned features, is probably overestimated since chronic pancreatitis and periampullary diverticula without bile duct indentation are not sure causes of biliary dilatation. Excluding these cases, the percentage is lower (10.5%) and comparable with Malik's findings[3].

Recently, a retrospective study was performed by Rana *et al*[45] about EUS diagnostic accuracy in patients with unexplained dilatation of CBD on MRCP, in order to establish EUS yield in the clinical practice. Among the 40 selected patients, 10 subjects had elevated serum alkaline phosphatase while the others presented normal liver function tests: in the former group, EUS detected a pathological condition causing dilatation of CBD (stones, cholangiocarcinoma, benign strictures) compared to a minority of significant findings identified in patients with normal liver tests (33.3% received diagnosis for stones or chronic pancreatitis). The remnant 20 patients with dilatated biliary system and normal liver function had regular EUS findings. There was no difference in the mean duct diameter in subjects presenting elevated serum alkaline phosphatase compared to patients with normal liver function tests nor between groups with identified pathology or not. The authors concluded, as

reported by previous scientific literature, that abnormal liver function tests are useful to identify patients with high pre-test probability of pathological findings underlying however that normal biochemistry does not exclude the existence of biliary ducts abnormalities.

Finally, Oppong *et al*[46] presented data retrospectively collected from a cohort of patients referred for EUS evaluation to a tertiary center. By excluding subjects with jaundice, liver function tests abnormalities, evidence of mass, stricture or ductal filling defect on pre-EUS imaging or symptoms suggestive of sphincter of Oddi dysfunction or chronic pancreatitis, they selected 40 patients with isolated dilatation of CBD. New findings on EUS were identified in 8 patients (20%). In 7 the following was considered as cause of dilatation: 3 had biliary polyps (not confirmed in 2 patients who later underwent ERCP), 3 had biliary stones and 1 had portal vein compression on the CBD. Microlithiasis, identified in the eighth subject, was assessed as a secondary event. Prior cholecystectomy was significantly more frequent in patients with no new findings on EUS, although CBD diameter did not differ among patients with prior surgery or not.

CONCLUSION

Changes in bile duct anatomy and adaptation of biliary system to normal or pathological processes, impose an accurate analysis of the patient anamnesis, liver biochemical parameters, clinical context in order to differentiate subjects with higher probability of biliary pathology from those with low index of suspicion. In recent years, the availability of a low-invasive modality, without post-procedural risk of pancreatitis, led to an increasing use of EUS in the investigation of biliary dilatation, even when symptoms or signs typically suggestive of obstruction were absent. On the other hand, the use of high-resolution cross-sectional imaging to investigate abdominal symptoms commonly results in increasing findings of dilatated biliary ducts in patients with normal liver tests. Currently, EUS program presents an increasing number of referrals in this setting and evidences in literature suggest a promising role for this technique in the identification of a potential biliary pathology, despite a low pre-test clinical suspicion. Firstly, in a small subset of patients, although asymptomatic or with vague symptoms, it can underlie pathologic conditions with dismal prognosis even with negative prior imaging tests. Secondly, according to the known high negative predictive value of EUS[47,48], if EUS evaluation does not identify the cause of biliary dilatation, the patient should be reassured and no further follow-up is recommended, since no pathologic conditions emerged during follow-up period in the aforementioned studies.

Abstract

Hilar biliary strictures are caused by various benign and malignant conditions. It is difficult to differentiate benign and malignant strictures. Postcholecystectomy benign biliary strictures are frequently encountered. Endoscopic management of these strictures is challenging. An endoscopic method has been advocated that involves placement of increasing number of stents at regular intervals to resolve the stricture. Malignant hilar strictures are mostly unresectable at the time of diagnosis and only palliation is possible.Endoscopic palliation is preferred over surgery or radiological intervention. Magnetic resonance cholangiopancreaticography is quite important in the management of these strictures. Metal stents are superior to plastic stents. The opinion is divided over the issue of unilateral or bilateral stenting.Minimal contrast or no contrast technique has been advocated during endoscopic retrograde cholangiopancreatography of these patients. The role of intraluminal brachytherapy, intraductal ablation devices, photodynamic therapy, and endoscopic ultrasound still remains to be defined.

Key words: Biliary strictures; Malignant; Benign; Endoscopy; Endoscopic retrograde cholangiopancreatography

Core tip: Management of benign or malignant hilar biliary strictures is difficult. Surgery is technically demanding for benign hilar biliary strictures and results of endoscopic management are not very satisfactory. Endoscopic palliation is preferred modality of managing malignant hilar strictures. However, it is still controversial to drain unilaterally or bilaterally. Use of contrast during endoscopic retrograde cholangiopancreatography and leaving some ducts undrained is a major problem in these patients. We have reviewed the literature on all these aspects of hilar biliary strictures.

INTRODUCTION

Biliary strictures at hepatic hilum are not uncommon and present a difficult diagnostic and therapeutic

Table 1 Etiology of benign and malignant hilar strictures[1]

Malignant hilar strictures
Primary tumors (cholangiocarcinoma)
Local extension (gallbladder cancer, hepatocellular carcinoma, and pancreatic cancer)
Lymph node metastases (Breast, colon, stomach, ovaries, lymphoma, and melanoma)
Benign hilar strictures
Postoperative injuries (cholecystectomy, liver transplantation, liver resection, and biliodigestive anastomosis)
Primary sclerosing cholangitis
Others (stone disease, follicular cholangitis, parasite infection, granular cell tumor, chronic fibroinflammatory process, compression from portal cavernomatosis, granulomatous process, and lymphoplasmacyticscleros ingpancreatitis/cholangitis)

problem. Hilar strictures can be benign or malignant which are often difficult to differentiate. Various modalities as surgery, endoscopy and radiology have been used in the management of these strictures with variable results. The role of some newer modalities, *e.g.*, intraluminal brachytherapy, intraductal ablation devices, photodynamic therapy (PDT), still remain investigational.

Etiology

Etiologically, these strictures can be divided into benign or malignant causes[1] (Table 1). The differentiation of benign from malignant hilar strictures is difficult.

Diagnosis

The alkaline phosphatase isoenzyme and CA19-9 have been used to discriminate benign from malignant strictures with variable sensitivity and specificity[2-4]. Radiologic evaluation of patients with hilar strictures can be done with ultrasonography, contrast-enhanced computed tomography (CT) scan, magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreaticography (MRCP). These modalities can help to delineate the level of bilary obstruction along with the extent of biliary dilatation. Any mass lesion or distant metastasis can also be detected with these methods[5-9]. Increased alkaline phosphatase and CA19-9 levels, increased thickness of bile duct wall to ⩾ 5 mm and regional lymphadenopathy (> 1 cm) on CT scan, and cholangiographic appearance of abrupt cutoff and separation of biliary ductal system suggest a malignant etiology of hilar obstruction[10]. Another study showed an association of raised bilirubin levels of > 8.4 mg% and CA19-9 level > 100 U/L with malignant etiologies of biliary obstruction[11]. MRI/MRCP performed better than CT to differentiate benign and malignant causes of biliary obstruction[11]. However, in a study of 49 patients with mass lesion at hilum on abdominal ultrasonography or CT scan, raised CEA and CA 19-9 levels, and presence of irregular, eccentric strictures with abrupt cutoff suggesting malignancy on cholangiography, benign diseases was documented in 24% of cases on surgical histopathology[12]. Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC) provide a better assessment of the biliary tree. It also enables brush biopsy and cytology studies providing a histological diagnosis in these patients. However, these procedures carry a significant risk of complications[13,14]. Various studies have shown a variable sensitivity (37%-70%) and high specificity (> 95%) for biopsies or brush cytology (Table 2)[15-18].

Table 2 Brush cytology in malignant biliary obstuction

No.	Ref.	No. of patients	Sensitivity (%)	Specificity (%)
1	Venu *et al*[15]	53	70	100
2	Foutch *et al*[16]	24	60	100
3	Ferrari Júnior *et al*[17]	70	56	100
5	Singh *et al*[18]	30	37	100

Table 3 Bismuth-lazorthes Classification of postsurgical benign biliary strictures

Type I: Common hepatic or main bile duct stump ⩾ 2 cm
Type II: Common hepatic duct stump < 2 cm
Type III: Hilar stricture- ceiling of the biliary confluence is intact, right and left ductal system communicate
Type IV: Ceiling of the confluence is destroyed, bile ducts are separated
Type V: Type I, II or III plus stricture of an isolated right duct

Endoscopic ultrasound (EUS) has shown promising results for the diagnosis of hilar strictures. In a study of 24 patients with negative or unsuccessful brush cytology results in cases of proximal bile duct obstruction, EUS revealed a mass lesion in 23 patients (96%)[19]. EUS-FNA in these patients provided a sensitivity of 77% and accuracy of 79%. However, the negative predictive value was quite low (29%). In another study of 44 patients with negative brush cytology in cases of suspected hilarcholangiocarcinoma, EUS-FNA had an accuracy of 91% with 89% sensitivity and 100% specificity[20]. Intraductal ultrasonography enhances the diagnostic accuracy of ERC (88%) as compared to MRC (58%) or ERC alone (76%)[21].

MANAGEMENT

Benign biliary strictures

Benign biliary strictures at the hepatic hilum most commonly result from surgical injuries, most often after cholecystectomy. Post-cholecystectomy strictures develop in 0.2%-0.5% of patients undergoing surgery and account for 80% of benign hilar strictures[22]. Post-liver transplant strictures develop in 5.9% of patients[23].

The management and outcome of postsurgical strictures depends on the type of stricture. Bismuth and Lazorthes classified postsurgical biliary strictures based on the level of healthy biliary mucosa suitable for anastomosis (Table 3)[24,25].

Surgical management of postsurgical benign biliary strictures carries a morbidity of 18%-51%, mortality

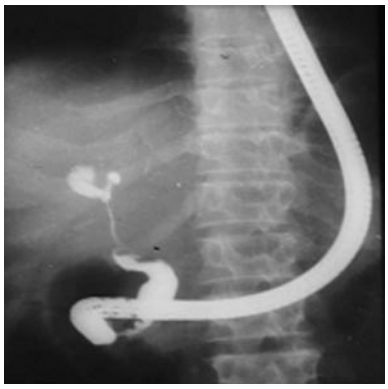

Figure 1 Postoperative type 3 hilarstricture with patent confluence.

Figure 2 Postoperative type 5 hilarstricture involving right hepatic duct.

Table 4 Bismuth classification of malignant hilar block[31]

Type I: Obstruction within 1 cm of bifurcation but confluence patent
Type II: Obstruction limited to confluence
Type III: Obstruction at confluence with proximal extension to right or left side
Type IV: Obstruction involving bilateral secondary or tertiary branches or multifocal strictures

of 4%-13%, and recurrence rate of 10%-30%[22]. It, therefore, requires specific skills and expertise. The management of hilar postsurgical strictures (types III, IV, and V) is more challenging and results in worse outcomes (Figures 1 and 2)[1]. A retrospective study of 57 patients surgically treated for cicatricial biliary strictures showed a higher rate (14%) of stricture recurrence and cholangitis in patients with hilar obstruction compared to none in patient with lesions below the hilum[26]. A recent study reported the safety and efficacy of right hemihepatectomy with cholangiojejunostomy in patients with strictures involving secondary bile duct branches associated with vascular injuries. The study showed 100% survival without stricture recurrence after a mean follow up of 80 mo. No major postoperative complications were documented[27].

Endoscopic management of postsurgical strictures is more safe and efficacious. Two 10F plastic stents are placed in for a maximum duration of 12 mo. Stent exchange is done at 3 mo interval to reduce the risk of stent blockage and cholangitis (classical approach)[28,29]. Endoscopic management is feasible in 80% of cases. Stricture recurrence occurs in 20% of patients after stent removal over a period of 9.1 years. All the instances of restenosis were noted within 2 years of stent removal. Mean time from stent removal to symptom onset was 2.6 mo (range 1 wk–2 year)[29].

An aggressive approach involves insertion of an increasing number of plastic stents until resolution of stricture, with stent exchange performed at 3-5 mo interval[30]. In a study of 40 patients with 18 hilar strictures, overall success rate with this approach was 89%. Recurrence occurred in only one patient after a mean follow up of 48.8 mo (range 2-11.3 years). Mean number of stents used was 3.2 ± 1.3 (range 1-6) over a period of 12.1 ± 5.3 mo (range 2-24 mo)[30].

Malignant biliary strictures

Cholangiocarcinoma, carcinoma gall bladder (GB) and secondaries account for majority of malignant hilar biliary strictures. Malignant hilar biliary strictures are classified as per the Bismuth Classification (Table 4)[31]. It carries a poor prognosis with 5 year survival of < 10%. Curative resection is feasible in < 10%. Palliation remains the mainstay of therapy. However, surgical palliation is associated with an unacceptable 33% mortality[31,32].

Current options for palliation include surgical bypass, percutaneous drainage and endoscopic stenting.Endoscopic drainage is safer and more successful with a lower propensity to bile leak, infection and haemorrhage. However, a recent randomized controlled study of 54 patients with unresectable carcinoma GB with Bismuth type 2 (Figure 3) or 3 hilar block showed better drainage (89% *vs* 41%) and lower complication rate (cholangitis 48% *vs* 11%) with percutaneous approach[33]. Both the groups had similar procedure-related mortality (4% *vs* 8%), 30-d mortality (4% *vs* 8%) and median survival (60 d in both; P = 0.71). Percutaneous drainage resulted in a significantly better quality of life, as assessed at 3 mo after the procedure[33]. This study used plastic stents instead of metal stents in unresectable carcinoma GB with Bismuth type 2 or 3 hilar block and biliary ducts were left opacified and undrained after contrast injection which could be responsible for higher rates of complication with endoscopic approach. Hence, the results need to be interpreted with caution.

Endoscopic stenting in hilar obstructions can be done with plastic or metal stents (Figures 4-7). Plastic stents are less expensive, have technically easy insertion with relatively easy removal and exchange. But, they have limited stent patency. Metal stents have prolonged stent patency, do not occlude side branches and have easier passage across biliary strictures due to relatively smaller delivery system. But, greater cost and difficulty

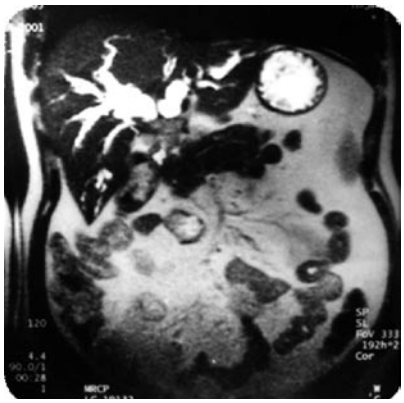

Figure 3 Magnetic resonance cholangiopancreaticography showing type 2 malignant hilarstricture.

Figure 4 Type 1 malignant hilar stricture.

Figure 5 Type 2 malignant hilarstricture.

Figure 6 Type 2 malignant hilarstricture with bilateral guide wires.

in removal once blocked are the limitations[34].

Metal stents have been shown to perform better than even large bore plastic endoprostheses. A prospective randomized trial of 20 patients with Bismuth type Ⅱ-Ⅳ hilar obstruction compared 14 French plastic stents with 24 French metal endoprostheses in the management of malignant hilar obstructions with obstructive jaundice[35]. Metal stents insertion was associated with greater success as well as patency rates compared to placement of plastic stent. It was also cost-effective due to lower number of re-interventions required in these patients. Another randomized controlled trial of 108 patients with Bismuth type Ⅱ-Ⅳ unresectable hilarcholangiocarcinoma demonstrated better drainage and more prolonged survival with self-expandable metal stents compared to plastic stents[36]. A meta-analysis of 10 trials showed a significantly higher successful drainage rate [odds ratio (OR) = 0.26; 95%CI: 0.16-0.42; I^2 = 40.3%], lower early complication rate (OR = 2.92; 95%CI: 1.65-5.17; I^2 = 0%), longer stent patency [hazard ratio (HR) 0.43; 95%CI: 0.30-0.61; I^2 = 57.6%], and longer patient survival (HR = 0.73; 95%CI: 0.56-0.96; I^2 = 56.9%) with metal stents in comparison with plastic stents[37].

There is much controversy regarding the placement of unilateral or bilateral stents for hilar strictures. In a study of 190 patients with Bismuth type Ⅰ-Ⅲ hilar strictures, successful drainage after single stent was achieved in 80% of patients[38]. The placement of a second stent was considered only in patients with new onset cholangitis or incomplete resolution of cholestatic symptoms. Early complications were observed in 7%, 14% and 31% patients with type Ⅰ, Ⅱ and Ⅲ strictures, respectively. De Palma *et al*[39,40] showed that unilateral stenting is feasible, safe and effective. In a prospective study of 61 patients with hilar malignancy, the placement of a single metal stent across the stricture into duct easier to access achieved successful stent insertion in 96.7% and successful drainage in 96.7% patients. Median survival of these patients was 140 d with median stent patency of 169 d. Stent malfunction was seen in 4.9%[40]. A recent meta-analysis also revealed that unilateral and bilateral biliary drainage may have equivalent efficacy in hilar biliary obstruction with a higher success rate for unilateral stent placement[37]. A case series of 151 patients with unresectable Bismuth type Ⅱ and Ⅲ hilar biliary obstruction revealed similar successful drainage rate, complications, 30-d mortality, number of re-interventions and survival based on whether right or left biliary ductal system was drained[41]. However, in patients with bilobar opacification of biliary ductal system, bilateral drainage should be obtained to reduce the risk of cholangitis[42].

Figure 7 Bilateral metal stents in type 2 malignant hilar stricture.

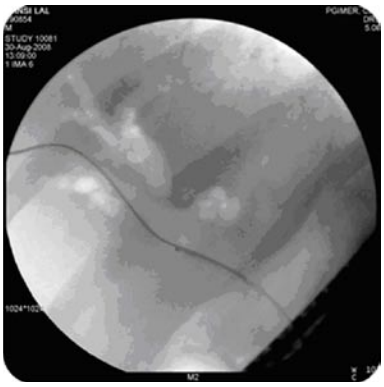

Figure 8 Air cholangiogram showing type 2 malignant hilar stricture.

It was widely held that draining 25% of liver volume provides adequate palliation of obstructive jaundice with biochemical improvement in these patients[43]. However, a recent study of 107 patients with Bismuth type Ⅱ-Ⅳ hilar strictures concluded that drainage of more than 50% of liver volume predicts efficacy of drainage and translates into longer survival (119 d *vs* 59 d, P = 0.005),especially in Bismuth type Ⅲ hilar strictures[44]. Bilateral stent insertion is often required to achieve more than 50% drainage. The study, however, has several drawbacks. The study had a retrospective design, most of the patients underwent plastic instead of metal stenting in hilar biliary obstruction and majority of the patients had cholangiocarcinoma which has relatively prolonged survival and can confound the results.

Failure to drain the hepatic lobes or segments after contrast injection is responsible for most of the cases of post procedure early cholangitis and mortality[42]. It brought to the fore the concept of contrast free stenting[45,46]. To avoid bilateral contrast injection and stent placement in Bismuth-type III and IV Klatskin tumors, Hintze *et al*[47] used MRCP in 35 patients for ERC and unilateral stent insertion. The placement of stents under MRCP guidance reduced incidence of post-ERC bacterial cholangitis. A prospective study of 18 patients with Bismuth type Ⅱ malignant hilar biliary obstruction demonstrated successful endoscopic drainage in all the patients and no cholangitis or 30-d mortality with MRCP guided contrast-free unilateral metal stenting[45]. Another study of 15 patients with Bismuth type Ⅱ malignant hilar strictures used contrast-free balloon-assisted unilateral plastic stenting with 100% successful drainage and no cholangitis or 30-d mortality[48]. Comparison of air and iodine contrast cholangiography in hilar strictures in a retrospective study showed less cholangitis with air contrast in Bismuth type Ⅱ-Ⅳ strictures[49]. Subsequently, two studies showed 100% successful stent placement and drainage with no cholangitis and 30 d mortality with contrast-free air cholangiography-assisted (Figure 8) unilateral stent deployment[50,51]. A recent randomized controlled study compared CO_2 cholangiography with iodine contrast cholangiography in 36 patients with Bismuth type Ⅱ-Ⅳ malignant hilar obstruction and revealed lower incidence of cholangitis in CO_2 group (5.6% *vs* 33.3%, P = 0.04)[52].

NEWER APPROACHES

Novel approaches including drug eluting stents, EUS guided biliary drainage, intraluminal brachytherapy, intraductal ablation devices and PDT have recently been used with variable results.

External beam irradiation therapy in malignant biliary strictures is limited by radiation tolerance of liver, bowel and kidneys. Intraluminal brachytherapy allows greater radiation dose locally administered to predefined volume of tissue. It can be administered *via* endoscopic or percutaneous route. A few recent studies have documented the safety and efficacy of intraluminal brachytherapy in association with stent placement in unresectable, malignant hilar strictures. This new method resulted in prolonged survival in these patients[53-56].

PDT is a promising mode of therapy for unresectable cholangiocarcinoma. It uses a combination of photosensitising chemical and light of appropriate wavelength to generate cytotoxic reactive oxygen species culminating in tumour cell death by necrosis or apoptosis. Continuous biliary drainage is achieved by stent implantation after the procedure. A randomized controlled study of 39 patients with histologically confirmed unresectable cholangiocarcinoma was terminated prematurely due to prolongation of survival (median 493 d *vs* 98 d; P < 0.0001), more effective biliary drainage and improved quality of life with stenting and PDT in comparison with stenting alone[57]. In a recent retrospective study of 184 patients with hilar cholangiocarcinoma managed with either surgery (60), stenting (56) or stenting with PDT (68); PDT had a longer survival compared to stenting (12.0 mo *vs* 6.4 mo, P < 0.01) and comparable survival to R1/R2 resection (12.2 mo)[58]. In conclusion,management of hilar biliary strictures is a difficult problem. Surgical, endoscopic and percutaneous approaches have been

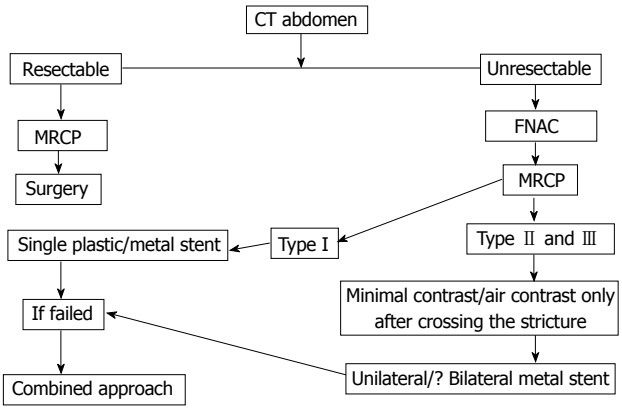

Figure 9 Approach to malignant hilar biliary strictures. CT: Computed tomography; MRCP: Magnetic resonance cholangiopancreaticography; FNAC: Fine needle aspiration cytology.

used in the management of these strictures with variable results. However, the appropriate management also depends on expertise available at that centre. Endoscopic management with increasing number of plastic stents and surgery for failed cases in benign biliary strictures is a reasonable approach. Appropriate management algorithm for malignant hilar strictures is given in Figure 9.

Abstract

The work of Muhe and Mouret in the late 1980s, paved the way for mainstream laparoscopic procedures and it rapidly became the mainstream method for many intra-abdominal procedures. Natural orifice transluminal surgery (NOTES) and Laparo-endoscopic single-site surgery (LESS) are very exciting new modalities in the field of minimally invasive surgery which work for further reducing the scars of standard laparoscopy and towards scarless surgery. However, according to objective assessment of the literatures, there is no clearly demonstrated benefit of NOTES (LESS), even cosmesis is poorly supported and had mixed results in the available data. NOTES (LESS) is far from the truly scarless surgery. Towards the Holy Grail, we have developed several techniques of creating nonvisible scar and named them as "Scar-hidden Endoscopic Surgery". With the rapid development of science and technology, we believe that minimally invasive surgery over the next 2 decades will continue to bring remarkable change and realize truly scarless surgery even we may not be able to imagine what lies ahead.

Key words: Minimally invasive surgery; Scarless surgery; Laparo-endoscopic single-site surgery; Natural orifice transluminal endoscopic surgery; Scar-hidden endoscopic surgery

Core tip: Natural orifice transluminal surgery (NOTES) and Laparo-endoscopic single-site surgery (LESS) are very exciting new modalities in the field of minimally invasive surgery which towards scarless surgery. However, according to objective assessment, NOTES (LESS) is far from the truly scarless surgery. Towards the Holy Grail, we have developed several techniques of creating nonvisible scar and named them as "Scar-hidden endoscopic surgery". With the rapid development of science and technology, we believe that minimally invasive surgery over the next 2 decades will continue to bring remarkable change and realize truly scarless surgery.

INTRODUCTION

The past thirty years has witnessed the infancy and rapid development of minimally invasive surgery (MIS). From the early multiple small incisions laparoscopic surgery to the single incision laparoscopic surgery nowadays, minimally invasive surgery has come a long way from its initial stage and scarless surgery has been the Holy Grail.

EVOLUTION OF SCARLESS SURGERY

Phillipe Mouret performed the first laparoscopic cholecystectomy in 1987[1]. Since then, laparoscopic approach has been used to many disease processes and gradually become the mainstream procedure for many intra-abdominal surgeries. Compared with open procedures, laparoscopic surgery has shown to decrease postoperative morbidity, shorten hospitalization and convalescence, and improve cosmesis for many applications[2,3]. Therefore laparoscopic surgery has been a well-established and commonplace technique worldwide in the past century. However, there were still 3-6 small incisions post-operation, which not only cosmetically unappealing, but also increase the wound pain and potential wound morbidity, such as abdominal wall bleeding and hernia, and intra-abdominal organ damage[4].

The quest for scar reduction and the increasing recognition of patient's satisfaction has led to the innovation of conventional laparoscopic surgery. In the last decade, natural orifice transluminal surgery (NOTES) and Laparo-endoscopic single-site surgery (LESS) have been considered as the most advanced representative "evolution" of minimally invasive surgery. NOTES was first descripted by Kalloo *et al*[5] in 2004 and developed towards the scarless surgery, but did not gain popularity due to a variety of reasons including difficulty in accessing anatomical sites, lack of appropriate devices and sterility. The lack of success of NOTES has prompted the interest in LESS which also aimed to "scarless" effect. Compared with NOTES, LESS offers an advantage to surgeons with its similar performance used in traditional laparoscopy. However, LESS is also more technically difficult than traditional laparoscopic surgery, due to the challenges included loss of triangulation, external an internal conflict[6]. What's more is that while laparoscopic literature sought to demonstrate superiority of the technique over that of open surgery, the publications on LESS generally seem to seek to demonstrate equivalence with laparoscopy, with the major focus being on cosmesis[7]. LESS still has far a long way to go before becomes the mainstream approach for truly scarless surgery as it remains an evolving technique.

WHAT'S TRULY SCARLESS SURGERY?

With the rapid development of science and technology, scarless surgery has been the Holy Grail of MIS. However, what's MIS? Indeed, the term "minimally invasive surgery" has often been bastardized to imply a specific access strategy such as laparoscopy, robotic surgery or endoscopy, but the true definition of minimally invasive surgery may have been created by Sir William Osler over a century ago when he said that, "Diseases that harm call for treatments that harm less". More specifically, minimally invasive surgery should meet the following factors. The first and foremost factor is curing the pathology[8]. When approach and technique are considered, the most important question that mandates answer is will the pathology be appropriately treated with the absolute best safety profile possible. Secondary to surgical efficacy is decrease blood loss, postoperative pain, postoperative complications, surgical time (not by itself an absolute goal), convalescence and length of hospital stay. Thirdly, and the least important are surgical cosmesis and cost-effectiveness ratios. Based on the above, when define the truly scarless surgery, not only do these procedures should provide equivalent outcomes to traditional laparoscopic surgery, but also offer significant benefits as quicker recovery, shorter hospital stays, less scarring, less pain, lower morbidity and less surgical time (not an absolute goal).

Towards to the scarless surgery, NOTES and LESS have been developed and aimed to reducing the incisions of conventional laparoscopy. Surgeon's interest was focused on reducing or eliminating the incisions caused by the procedure. The hope is that reduced access points will ultimately decrease pain, morbidity, convalescence, and improve cosmesis. However, according to objective assessment of the literature which compared current standard laparoscopic techniques with NOTES (LESS), there is no clearly demonstrated benefit of NOTES (LESS), even cosmesis is poorly supported and had mixed results in the available data[9,10]. In patient polls, surgical success, risk, pain, convalescence and cost all ranked higher than cosmesis. NOTES and LESS were far from the truly scarless surgery.

WHAT WE HAVE DONE FOR SCARLESS SURGERY?

As already mentioned, scarless surgery has been the Holy Grail of minimally invasive surgery. However, as it is difficult, if not impossible, to achieve truly scarless in current days, several techniques of creating nonvisible scar have been developed, which we named as "Scar-hidden endoscopic surgery (SHES)". SHES include 2 broad categories of those techniques performed by obtaining new access to peritoneal cavity and those by hiding scar in the anterior abdominal wall.

Figure 1 Ports position of approach 1.

Figure 2 Scars are hidden in the tattoo.

Obtain new access to peritoneal cavity

The use of first category was represented by NOTES. In its purest form, NOTES does not use any transabdominal ports therefore decreased pain and eliminated the abdominal wound morbidity. However, NOTES was hampered by difficulty in accessing anatomical sites, lack of appropriate devices and sterility, thus far been successfully performed in patients and not a truly scarless surgery.

Hide the scar in the anterior abdominal wall

The limitations of NOTES led to the concept of LESS which also produced nonvisible scar as it hidden easily in umbilical plica. However, LESS is also more technically difficult than traditional laparoscopic surgery, due to the inherent challenges. As techniques mentioned above were fraught with problems, we attempted other approaches.

Approach 1: Transfer the incision to the superior margin of suprapubic hair

Surgical technique: A10-mm trocar was placed through an umbilical incision. After establishment of a pneumo-peritoneum, a 5-mm 30° laparoscope was introduced through the trocar. Two 5-mm suprapubic trocars were placed near the right and left ends of the superior margin of suprapubic hair under the guidance of the laparoscope. The laparoscope was then moved to the left side trocar. The instruments were introduced through the umbilical and the right side ports (Figure 1).

Advantages: Our research indicated that, compared with LESS, this approach characterized by no visible scar, a shorter operation time, minimal bleeding, *etc.*, but longer instruments should be used[11].

Approach 2: Transfer the incision to the tattoo (Figure 2) or previous operation scar (Figure 3)

The surgical technique and advantages of this approach were the same as described in approach above. What' s different is that the two 5-mm trocars were placed near the right and left ends of the tattoo or previous operation scar.

Approach 3: Transfer the incision to the linea alba (the transxiphoid-umbilical laparoscopic approach)

Surgical technique: A 15-mm incision was made at the right side of the umbilicus; a 10-mm trocar for the optic unit and another 5-mm trocar for the grasper were inserted side by side into the incision; a 5-mm trocar for instruments (ultrasonic scalpel, grasper, electrosurgical hook knife and hem-o-lok clips) was placed 20 mm inferior to the xiphoid (Figure 4).

Advantages: In our opinion, the transxiphoid-umbilical laparoscopic approach for laparoscopic cholecystectomy is as comfortable as the conventional techniques for laparoscopic cholecystectomy and allows the use of normal laparoscopic instruments. It has an advantage over conventional three-port laparoscopic cholecystectomy in both postoperative pain and, more importantly, cosmetic outcome, without a significant learning curve or increase in operative time. It offers a realistic better approach to conventional LC for chronic benign gallbladder disease.

Approach 4: Reduce the size of incision.

According to a previous study of us, the Optimized two-trocar LESS technique (a 2-mm trocar inserted for a grasper in the right upper abdomen) was found to be faster and less painful than the LESS approach and the 2-mm incision was almost nonvisible post-operation[12]. Under the guidance of this technique, we proposed another novel SHES as described below.

Surgical technique: A 15-mm incision was made at the right side of the umbilicus; a 10-mm trocar for the optic unit and another 5-mm trocar for an ultrasonic scalpel or clips were inserted side by side into the incision. Under laparoscopy, a 2-mm needle-shape grasper was placed direct through the abdominal wall in the midclavicular line 20 mm inferior to the costal margin, and electrocautery placed 20 mm inferior toxiphoid (Figure 5).

Advantages: Using the 2-mm needle-shape instruments, the new technique has following advantages: (1)

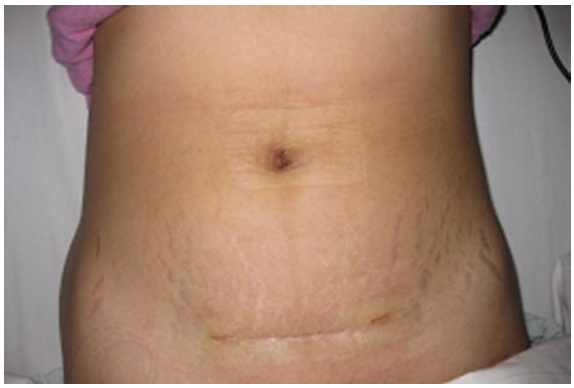

Figure 3 Scars are hidden in previous operation scar.

Figure 4 Ports position of the transxiphoid-umbilical laparoscopic approach.

The 2-mm grasper and electrocautery are at the normal location as the same as the traditional laparoscopic surgery. It helps to regain manipulate triangulation which not only enable performing sufficient traction of the gallbladder but also allow good mobilization of the gallbladder in order to dissect the calot's triangle safely; (2) compared with LESS, the novel SHES was performed more feasibly and safely, with significantly shorter operation time and higher satisfactory score. Cosmesis, safety, and economy were balanced better in this new technique; and (3) the scars of the new technique were hidden in the natural folds of the skin around the navel and were too small to affect cosmesis when the 2-mm puncture hole on the upper abdomen healing. Compared with conventional laparoscopic surgery, it produced better cosmetic results while the operative time was almost equal according to our data[13].

WAY TO TRULY SCARLESS SURGERY

According to the above analysis, NOTES or LESS is far from the truly scarless surgery as there were no longer follow-up, controlled and randomized studies which supported the touted benefits. There is no doubt that NOTES or LESS will be spurred on by rapid advances in technology and better instrumentation. However,

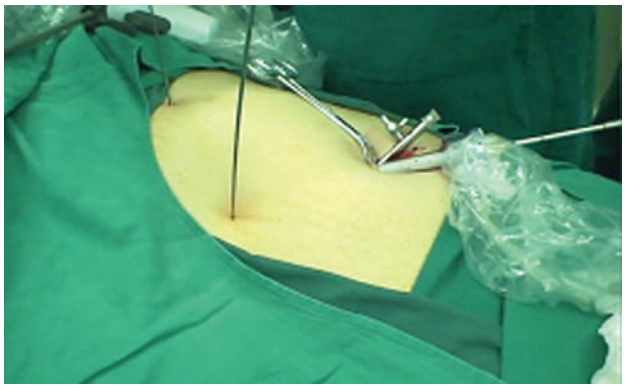

Figure 5 Laparoscopic cholecystectomy by using 2-mm needle-shape instruments without trocar.

when offering conventional *vs* investigational treatment options for patients, surgeons should be honest and balanced the safety and efficacy in their decision making.

In a word, what we believe is that, with the rapid development of science and technology, such as the use of da Vinci Surgical System, minimally invasive surgery in the nearly future will continue to bring remarkable changes and realize the truly scarless surgery.

Abstract

Iatrogenic colon perforation is one the most pernicious complications for patients undergoing endoscopic screening or therapy. It is a serious but rare complication of colonoscopy. However, with the expansion of the indications for endoscopic therapies for gastrointestinal diseases, the frequency of colorectal perforation has increased. The management of iatrogenic colorectal perforation is still a challenge for many endoscopists. The methods for treating this complication vary, including conservative treatment, surgical treatment, laparoscopy and endoscopy. In this review, we highlight the etiology, recognition and treatment of colorectal iatrogenic perforation. Specifically, we shed light on the endoscopic management of this rare complication.

Key words: Iatrogenic perforation; Colorectum; Surgery; Laparoscopy; Endoscopy

Core tip: Iatrogenic colorectal perforation is one of the most pernicious complications for patients who undergo endoscopic screening or therapy. In this review, we highlight the etiology, recognition and treatment of colorectal iatrogenic perforation, including conservative treatment, surgical treatment and laparoscopy. The flying development of the endoscope and its surgical assistant accessories have improved the endoscopic clip closure procedure. It can remarkably decrease the rate of surgical reparation following iatrogenic perforation of the colon.

INTRODUCTION

Iatrogenic perforation of the colon and rectum is an avoidable complication of diagnostic tests or an unavoidable procedure of endoscopic treatment. In the past, the causes of iatrogenic perforation were

barium enema and diagnostic endoscopy. Recently, due to the expanded indications for endoscopic resection lesions, more colon perforation occurs after colonoscopy therapy. As a major cause, it is estimated that the frequency of iatrogenic perforation is 0.019%-0.8% and 0.10%-3% for diagnostic and therapeutic colonoscopy, respectively[1-4]. Perforation located at the colon can rapidly cause peritonitis and even sepsis. These complications imply high morbidity and mortality. Therefore, all endoscopists should pay more attention to prevent this kind of perforation and immediate treatment is needed once colon perforations occur. In this review, we highlight the etiology, recognition and treatment of colorectal iatrogenic perforation. Specifically, we shed light on the endoscopic management of this rare complication.

ETIOLOGY

Colonoscopy is widely used during diagnosis and therapy in endoscopy. There has been an increasing number of patients undergoing this procedure. Consequently, the number of associated complications has also risen. In addition, older and less appropriate patients are receiving colonoscopies who are more vulnerable to iatrogenic colonoscopic injury. In the Iqbal *et al*[5] study, the perforation rates were higher at the rectosigmoid junction and the sigmoid colon (52%). The perforation rates in other sites of the colon were 17% (cecum), 14% (ascending colon), 7% (transverse colon), 8% (descending colon) and 1% (rectum), respectively. The perforation size was between 0.1 and 6.0 cm (average, 1.7 cm). Mechanical injury leads to the largest perforations, while electrocautery injury causes the smallest perforations. The patient risk factors were state of anticoagulation, extensive contamination, active malignancy, prior hospitalization history, delayed diagnosis and steroid usage. Electrocautery, polypectomy and mechanical injury caused the postoperative morbidity. Other factors which pose difficulty in colonoscopy and likely cause perforations include the existence of dense or wide-mouthed diverticula, incomplete bowel preparation, active hemorrhage and, the most important, the experience of endoscopists.

DIAGNOSIS

With the different causes, sizes and sites of perforation, there are various complaints from patients, including non-pain, only localized instantaneous pain which happens suddenly, severe cramp-like pain and distension of the abdomen[5,6]. If there was a tiny perforation caused by snaring or the endoscopic knife application, the patient would not have symptoms or only local pain. In general, the frequency of these kinds of abdominal pain is remarkably higher in perforation caused by diagnostic endoscopy than surgical endoscopy. Abdominal roentgenogram provides a quick sign. Cho *et al*[3] reported a lot of subdiaphragmatic free air in all cases of perforation caused by diagnostic endoscopy and in almost 45% of therapeutic perforation cases. Thus, abdominal roentgenogram is a cost-effective and useful method to detect the presence of subdiaphragmatic free air, with a positive predictive value of 92%[5]. However, sometimes subdiaphragmatic free air cannot be detected by abdominal roentgenogram. In this setting, computed tomography can offer great help in diagnosing the free air, micro-perforations and/or abscess. Patients who are clinically unstable or who exhibit peritonitis on physical examination warrant immediate exploration.

MANAGEMENT

Conservative management

If a patient presents as subdiaphragmatic free air alone, it is not an indication for surgical reparation. Most patients who do not show signs of peritoneal irritation or abdominal sepsis have an ideal prognosis after being given intravenous antibiotic therapy, bowel rest and serial abdominal examinations[7]. Conservative management in appropriate patients results in a shorter length of hospitalization and lower morbidity. Iqbal *et al*[5] reported only one death among patients undergoing conservative treatment, a patient in the intensive care unit whose family refused surgery.

Surgical management

Prompt abdominal surgery is usually recommended once perforation has occurred[8,9]. Immediate surgical intervention is not compulsory. Intraoperative findings determine the surgical management. Surgery may be primary closure or resection with primary anastomosis in cases of intra-abdominal contamination accompanied by normal tissues in order to limit the comorbidity. Due to the extensive contamination, poor tissue situation and a higher complication rate, stoma or fecal diversion after reparation is chosen. Iqbal *et al*[5] indicated that only two preoperative factors determined the type of procedure, the time after the perforation and mechanical injuries. Comparing patients who were diagnosed with perforation after 24 h, those within 24 h were more suitable for a primary closure because the latter was more likely to have extensive fecal contamination. Moreover, mechanical injury always induced larger perforations (average, 1.9 cm) which needs fecal diversion after resection. However, this type of injury cannot always be ascertained before surgery.

Laparoscopic management

With the emergence and development of minimally invasive surgery over the last few decades, laparoscopic colonic repair has been increasingly adopted for colorectal perforation repair[10-12]. In the past, laparotomy was usually selected as the treatment approach for iatrogenic colon perforation and most patients under-

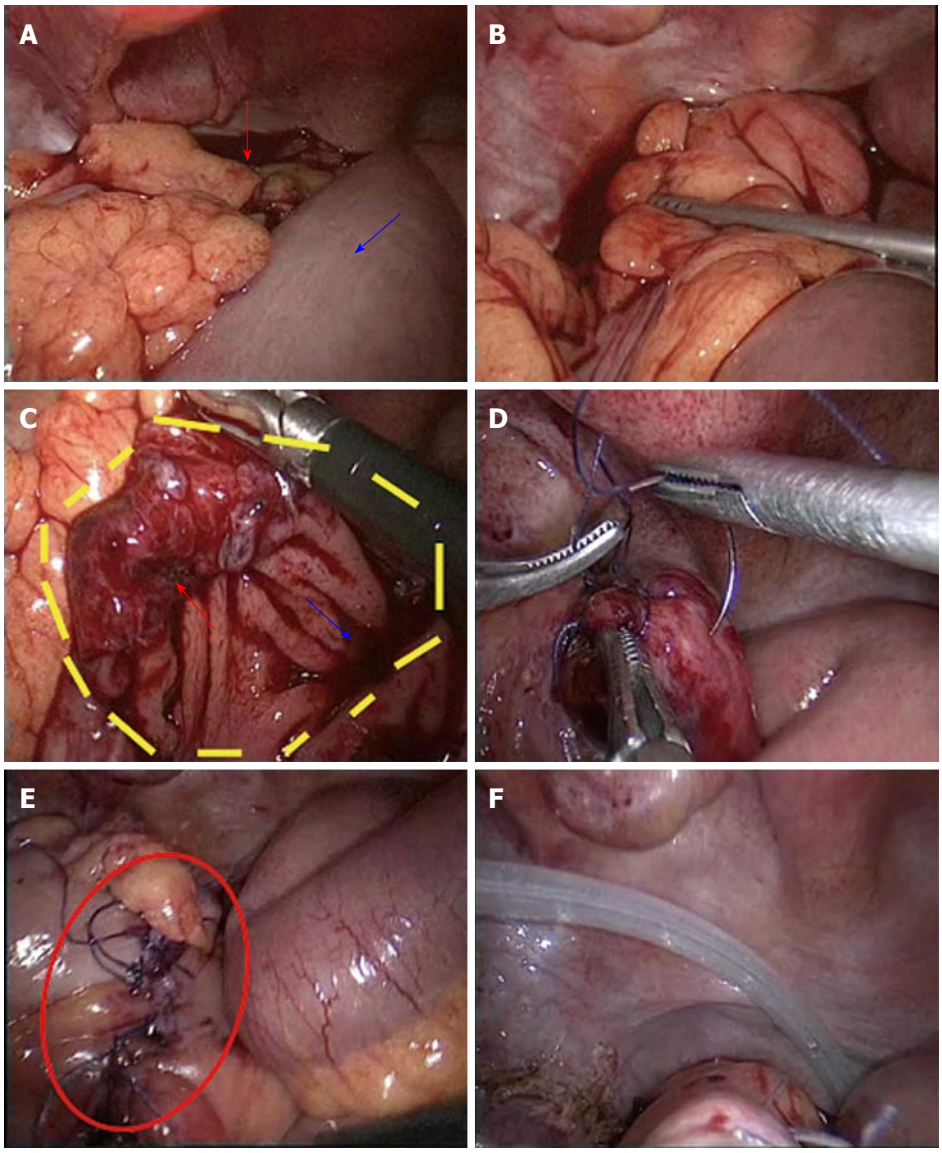

Figure 1 Laparoscopic management of iatrogenic colorectal perforation with endoscopic assistance. went colostomy[13,14]. Unfortunately, ileostomy and colostomy are associated with a significant decrease in patient quality of life and require another operation to restore intestinal continuity[15]. Several doctors have therefore proposed either a primary repair of the colorectal perforation or a segmental colectomy with primary anastomosis. The improvement of laparoscopic techniques boosts the practice of laparoscopic repair for colon perforations more widely[16]. In the Zhang *et al*[4] study, their experience in laparoscopic direct suturing of colon perforations indicated that laparoscopic primary perforation repair was a safe and feasible repair method. Compared to an open method, patients who underwent laparoscopic repair had a significantly shorter total incision length (16 ± 15 mm *vs* 163 ± 54 mm), shorter overall length of stay (5.1 ± 1.7 d *vs* 9.2 ± 3.1 d) and fewer perioperative complications (two *vs* five)[17]. Thus, their data suggest it is rational to regard laparoscopic therapy as the initial approach for repairing iatrogenic colorectal perforation.

Endoscopic management

Despite the fact that laparoscopy is effective in resolving colorectal iatrogenic perforation, recent advances of endoscopic techniques have made it possible to handle iatrogenic perforations by applying mini-invasive procedures. Endoscopy can assist laparoscopy to close the perforation (Figure 1). Repairing the perforation alone with endoclips has been well described in related studies since 1997[18]. In addition, large or difficult intestinal perforations can be treated with a combined application of endoclips and endoloops[19]. In the recent study by Kim *et al*[20], 115285 diagnostic colonoscopies were performed with a total of 27 iatrogenic colon

perforations (incidence of 0.02%). Endoscopic closure of the perforation site was attempted in 16 patients, with success in 13 patients. This suggests that immediate endoscopic closure with clips can be performed for diagnostic perforations as well as therapeutic colonoscopy-associated perforations.

Jovanovic *et al*[21] reported that endoscopic closure of colonic perforations could be performed when the perforation is < 1 cm. Few authors[22,23] have used the endoclips to treat perforations > 1 cm. Trecca *et al*[22] reported 2 perforations > 3 cm that were managed by using endoclips successfully. In the Velchuru *et al*[24] case report, the perforation was 3 cm in size and 7 clips were used to close the defect. The patient was discharged on the second day. The number of clips used depends on the size of the perforation. Endoscopic closure of an iatrogenic colonic perforation at colonoscopy is feasible as the prepped colon contains minimal contamination. Considering the technical challenge of endoclip application, an experienced endoscopist is the most important factor, as well as the site and size of the perforation. Clip closure was reported to be successful in 69.2% to 92.6% of cases[25,26].

However, there have also been some limitations in the treatment of colorectal perforation by endoscopic clips. It is hard to evaluate the degree of closure after an endoscopic clip reparation. If the endoscopic clip closure is incomplete, it would develop to limited leakage, which may result in the abdominal symptoms again. In these cases, minor symptoms make it difficult to decide whether or not to operate. The proper management may be delayed until the optimal period. Moreover, delayed complications can develop due to extra-luminal contaminants or intermittent minor leakage. The Cho *et al*[3] study indicates that peritoneal abscess formation developed in 50% of cases after a large perforation repaired by endoscopic clips. After colorectal perforation, the decision to perform surgery or endoscopic closure should be made promptly, within 24 h. The high risk clinical factors within 24 h after a colon perforation include a large perforation, leukocytosis, fever, severe abdominal pain and large peritoneal free gas and these should also be identified within 24 h.

CONCLUSION

In conclusion, iatrogenic colorectal perforation is one of the most pernicious complications for patients undergoing endoscopic screening or therapy. Its management is still a challenge for many endoscopists. The methods of treating this complication are varied and include conservative treatment, surgical treatment and laparoscopy. With the development of endoscopy and its assistant accessories, using endoscopic clips to repair the iatrogenic perforation could remarkably decrease the possibility of undergoing additional surgery. For patients with a high risk of complications after endoscopic clip reparation, an early decision regarding additional surgery such as laparoscopy is also significant.

Abstract

AIM: To examine the discrepancy, if any, between the endoscopist's estimate and pathologist's measurement of colonic polyp size.

METHODS: We retrospectively studied 88 patients who underwent colonoscopy with a clear unequivocal documentation of polyp size by both endoscopist and pathologist. Endoscopist measurements were based on the visual estimate of polyp size seen on high definition screens. The measurement was done by our pathologists after formalin fixation. We compared the endoscopist estimate of the polyp size to the pathologist measurement in order to explore the discordance between the two readings. Data regarding demographics and method of polypectomy (snare polypectomy *vs* excisional biopsy) was collected, as well. Statistical analysis software (SAS) was used to analyze the data.

RESULTS: Our cohort included 88 patients from which 111 polyps were removed. Fifty-two (46.8%) of the 111 polyps were excised using biopsy forceps and fifty-nine (53.2%) were removed by snare. In the biopsy forceps group, the mean polyp size documented by the pathologist was 0.38 ± 0.19 cm and the mean polyp size documented by the endoscopist was 0.54 ± 0.16

cm. The mean difference was 0.16 cm (P < 0.001). In the snare group, the mean polyp size documented by the pathologist was 0.54 ± 0.24 cm and the mean polyp size documented by the endoscopist 0.97 ± 0.34 cm. The mean difference was 0.43 cm (P < 0.001). Combining both groups, the mean size documented by pathologist was 0.46 ± 0.23 cm compared to 0.76 ± 0.35 cm documented by the endoscopist. The mean difference was 0.3 cm (95%CI: 0.23-0.36).

CONCLUSION: Post polypectomy measurement by the pathologist are generally smaller than the endoscopist's estimate.

Key words: Polyp size estimate; Colonic polyps; Endoscopist estimate

Core tip: Our results suggest wide variance in polyp size documentation. Neither endoscopist estimate nor pathologist measurement accurately reflects colonic polyp size. Inaccurate determination of polyp size can negatively impact advanced adenoma detection. Using a screen cursor like that used in ultrasound and computed tomography scanners may serve as a standardized, accurate technique to solve this issue.

INTRODUCTION

The incidence of colorectal cancer continues to rise to make it the fourth most common cancer in men and third most common cancer in women[1]. The concept of adenoma-carcinoma sequence has been already established by several studies[2-4]. The various characteristics that need to be considered upon evaluating the malignant potential of an adenomatous polyp are size, villous components and dysplasia[2,5]. These factors significantly impact the decision regarding follow up surveillance studies. While an experienced pathologist can precisely recognize the villous component or dysplastic changes in the polyp, achieving an accurate estimate of the polyp actual size remains challenging for the endoscopist as well as the pathologist.

With the growing importance of early detection of premalignant colonic polyps, accurate determination of polyp size becomes critical to recognize patients with potential to develop colon cancer. National and international guidelines consider polyp size as a key factor in determining follow up intervals with 10 mm cutoff as an important threshold for closer monitoring and surveillance[6,7]. Polyps less than 5 mm rarely show pre malignant histological features while a size over 10 mm has a 33% potential of pre malignant characteristics[8-10]. Polyp size is visually estimated during endoscopy. This is an approximate determination with variability between observers. Pathological measurements are made after excision using the untreated sample or after treatment with formaldehyde[11]. There is a possibility of incomplete estimation because some polyps are submitted piecemeal or fragmented. In addition, visual estimation is 2 dimensional while pathologic measurement is 3 dimensional[12]. Accurate estimation of polyp size also appears to be critical based on its location. Gupta *et al*[13] have reported advanced adenomas are more likely with a smaller size estimate on the right side of the colon. In this study, we aim to investigate the inconsistency, if any, between the endoscopist's estimate and pathologist's measurement of polyp size hoping to find a way to standardize the polyp size measurement.

MATERIALS AND METHODS

Eighty-eight subjects who underwent endoscopic polypectomy over a two-year period were studied retrospectively. Data was collected on 111 excised polyps. Visual estimation by the endoscopist was rounded to the nearest millimeter. Pathological estimation after fixation with formaldehyde was obtained from biopsy pathology reports. Data regarding the method of polypectomy being biopsy forceps *vs* snare was collected from each procedure report and analyzed accordingly. Demographic data was collected, as well. We only included patients with clear numerical documentation of the polyp size by the pathologist and the endoscopist and clear documentation of method of polypectomy in the endoscopy report. Subjects with incomplete data or missing parameters were not included. Only cases that were cared for by the teaching consult service were included. From the entire cohort, a random selection of 88 cases that fulfill these criteria was made by our GI pathologist. In order to get a wide representation of all endoscopists and fellows rotating through our service, an average of 3-4 cases from each month over the course of 2 years was maintained.

Visual estimates were obtained using Olympus Evis Exera 111 (CF-HQ190L/I and PCF-HQ190L/I) colonovideoscopes with dual focus optical system and Narrow Band Imaging. Visual estimation was done by the endoscopists for snared polyps and in reference to open forceps for excisional biopsies. The method of polypectomy was determined based on the size of the polyp and type of its attachment, *i.e.*, sessile or pedunculated. All study colonoscopies were performed by our 9 gastroenterology fellows under the supervision of 4 experienced faculty members. The documented

Table 1 Discrepancy in reporting polyp size between endoscopists and pathologists based on the method of excision

Method of excision	Number of polyps	Mean endoscopist's estimate	Mean pathologist's measurement	Mean difference	Overestimate	*P* value
Biopsy excision	52	0.54 (± 0.16) cm	0.38 (± 0.19) cm	0.16 cm	39%	< 0.001
Snare polypectomy	59	0.97 (± 0.34) cm	0.54 (± 0.24) cm	0.43 cm	77%	< 0.001
Total	111	0.76 (± 0.35) cm	0.46 (± 0.23) cm	0.3 cm	65%	< 0.001

size was agreed upon by the performing fellow and supervising faculty.

The pathologist was blinded to the visual estimate. The macroscopic measurement was done at the cut-up bench.

Statistical analysis

Retrospective analysis was performed comparing endoscopist visual estimate of polyp size and pathologist measurement. Continuous and categorical data were presented using means (± SD) and frequencies, respectively. Student *t* test was used to measure the difference of the means between different polypectomy techniques (snare *vs* excisional biopsy). Paired *t* test was used to estimate the difference of the means between the endoscopist and pathologist size determinations. Linear regression model was used to determine the predictors of the difference of the means between the two determinations (endoscopist *vs* pathologist). All statistical analysis was done using statistical analysis software (9.2, South Carolina).

RESULTS

In our cohort, 37% were men and 63% were women with 75% African American, 21% Hispanic, 3% Caucasian and 1% Asian American. Fifty-two (46.8%) of the polyps were excised using biopsy forceps and 59 (53.2%) of the polyps were removed by snare polypectomy. In the biopsy excision group the mean visual size reported by the endoscopist was 0.54 ± 0.16 cm *vs* a mean polyp size of 0.38 ± 0.19 reported during pathological exam. The mean difference was 0.16 (95%CI: 0.09-0.215) (Figure 1). The location of the polyp did not have any impact on the reported measurements. In the snare polypectomy group the mean visual size reported by the endoscopist was 0.97 ± 0.34 cm *vs* a mean polyp size of 0.54 ± 0.24 reported during pathologist exam. The mean difference was 0.43 cm (95%CI: 0.33-0.52) (Figure 2). Visual overestimation in the biopsy excision group was 39% in comparison 77% in the snare polypectomy group (Table 1).

Combining both groups, the mean visual size was 0.76 ± 0.35 cm compared to 0.46 ± 0.23 cm by the pathologist. The mean difference was 0.3 cm (95%CI: 0.23-0.36). Visual estimates during endoscopy were within 1 mm of the pathologist measurement in 28 polyps (25%) and were within 2 mm in 52 polyps (46%) (Figure 3).

DISCUSSION

To date, our study is the largest in the field with special emphasis on the method of polypectomy as a factor affecting the endoscopist visual estimate. It also clearly shows that endoscopists tend to overestimate the polyp size; a fact that was previously considered a controversial concept. This study showed that endoscopists tend to overestimate the polyp size by 65% in comparison to the measurements reported

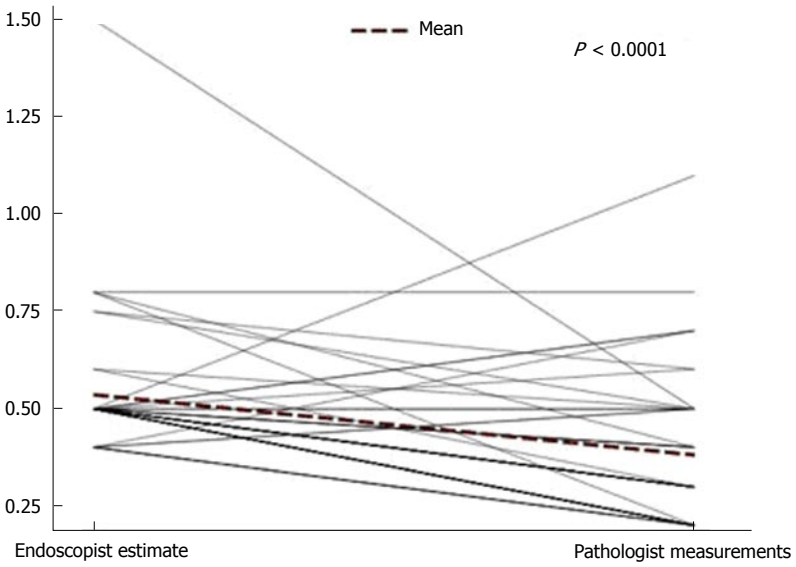

Figure 2 Forceps-excised polyp overestimate by the endoscopist. Dotted line is the mean difference (Measurements in centimeters).

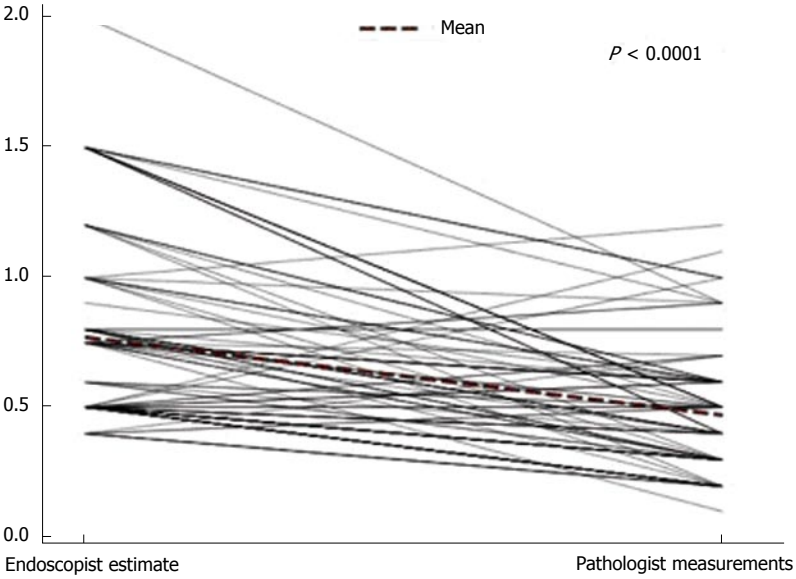

Figure 3 All polyps overestimate by endoscopist. Dotted line is the mean difference (Measurements in centimeters).

by pathologists. This difference between polyp size measurement that was noted between the endoscopists and pathologists may be attributed to the physical damage of the specimen. The polyp may be damaged in situ during excision or the endoscopist may not remove the polyp in its entirety. This will result in a specimen being sent to the pathologist that is actually smaller than it was *in situ*. Another factor that could be considered is the formalin fixation effect on size shrinkage. However, previous studies have shown that there was no significant difference between post excision polyp size and post fixation measurement, which strongly argues against formalin impact on polyp size[14,15]. Piecemeal submission of polyp tissue for pathological exam can be a factor that results in discrepancies in size too. Furthermore, a study by Schoen *et al*[14] determined that the type of polyp had an impact on the estimated size. In their measurement of 61 polyps, of which, 44 were pedunculated, the size was overestimated by the endoscopist 55% of the time. The stalk on pedunculated polyps may cause the polyp to sit on an angle which makes it more difficult for the endoscopist to accurately estimate its size. In our study, no such observation was noted.

In the current study, only 46% of the endoscopists estimations were within 2 mm of the pathologic measurements. There appears to be a wide variance in the remaining 54% of the measurements. Several published studies support our conclusion that endoscopists overestimate polyp size. A study of 61 polyps concluded that endoscopists overestimated polyp size by greater than 3 mm in 20% of the cases[14]. Morales *et al*[15] determined that in a sample of 31 polyps the endoscopists' estimates were on average 1.6 mm

greater than the postpolypectomy measurement. Other studies contradict our findings by asserting that endoscopists underestimate polyp size. A study of 107 polyps conducted by Turner *et al*[16] concluded that on average both colonoscopists and pathologists significantly underestimate polyp size in comparison to the prefixation measurement. Another recent study on 35 polyps also concluded that colonoscopists underestimate polyp size in 74% of the cases[11]. However, this study of 35 polyps presents a potential bias due to its small sample size.

It is noteworthy that, in our study, endoscopists showed greater overestimation of size in the polyps that were removed by snare biopsy *vs* removal using biopsy forceps (77% *vs* 39%). This can suggest that larger polyps are likely to be overestimated than smaller ones.

One possible limitation of this study is the retrospective model rather than a prospective one. This makes the study rely on the merit of record keeping by the endoscopists and pathologists. Moreover, we also looked only at post fixation size and did not have adequate data on prefixation measurements. However, the latter factor is unlikely to impact our findings in view of previously published studies about the effect of formalin fixation.

In conclusion, this study determined that endoscopists tend to overestimate the size of colonic polyps. This was more pronounced in case of snared polyps in comparison to polyps excised by forceps. Considering the major importance of accurate polyp size estimation on detecting advanced adenoma, visual estimates provided in a non-standardized manner can result in significant inter-observer (endoscopist) variations. Pathology reports for the size are not reliable either considering that most polyps get some degree of physical damage upon removal, which directly affects the size. Use of measurement cursors is a standard practice during imaging studies such as sonography. We suggest that the addition of a measurement cursor to video endoscopes can standardize the visual estimates and provide accurate information to determine appropriate surveillance intervals allowing for better management and ultimately a decreased mortality rate from colon cancer.

COMMENTS

Background

Colonic polyp size is critical in determining the significance of the polyp and thus the colonoscopy surveillance interval. The inaccuracy in determining the size can have remarkable consequences represented by repeating colonoscopy earlier than needed in case of overestimating the actual polyp size or delaying a necessary procedure which might result in development of colorectal cancer in case of underestimating the polyp size.

Research frontiers

There have been only few small studies that attempted to address the issue of estimating polyp size by the endoscopists. Those studies have shown inconsistent results in terms of endoscopists' tendency to overestimate *vs* underestimate polyp size.

Innovations and breakthroughs

This study is, to date, the largest of its kind and it clearly shows that endoscopists tend to generally overestimate polyp size with wide variance in the overestimate. On the other hand, the pathologist's measurement cannot be considered reliable given the possibility of physical damage or shrinkage of the polyp.

Applications

This study highlights the desperate need for an accurate standardized method of measuring colonic polyp size. To solve this issue, the authors suggest using cursors for colonoscopy screens like those used in ultrasound and computed tomography scanners.

Peer-review

This is a well-written manuscript. The retrospective nature of the study may actually be a plus as it gives a true representation of the endoscopists estimation of size as they would normally do in their routine practice.

Abstract

Indigocarmine chromoendoscopy has been proven to improve the detection of colonic lesions during screening colonoscopy, and is associated with increased adenoma detection rates. Furthermore, it is commonly used to help in the delineation and characterization of colorectal neoplasms. However, it usually requires the use of a spraying catheter that decreases the suction capacity of the endoscope, and is time- consuming. Herein, we report on the feasibility of indigo carmine chromoendoscopy during colonoscopy without using a spraying catheter, with the dye being administered through the air/water channel of the endoscope. Since the suction channel remains free, the air can be exsufflated and the staining then applies uniformly onto the colonic walls with the excess indigocarmine dye being immediately eliminated. In our experience with various types of colonoscopes and cap-assisted colonoscopy, this procedure makes indigocarmine chromoendoscopy much easier and quicker to perform, and might save the use of a spray catheter.

Key words: Indigocarmine; Chromoendoscopy; Colonoscopy; Adenoma detection rate; Colorectal cancer screening

Core tip: We report on the feasibility of indigocarmine chromoendoscopy during colonoscopy without using a spraying catheter, with the dye being administered through the air/water channel of the endoscope.

TO THE EDITOR

Indigocarmine chromoendoscopy has proven useful in increasing the overall diagnostic yield of colonoscopy and the adenoma detection rate[1]. This technique is currently recommended in routine colorectal cancer

Figure 1 0.2% indigocarmine solution prepared in the water bottle.

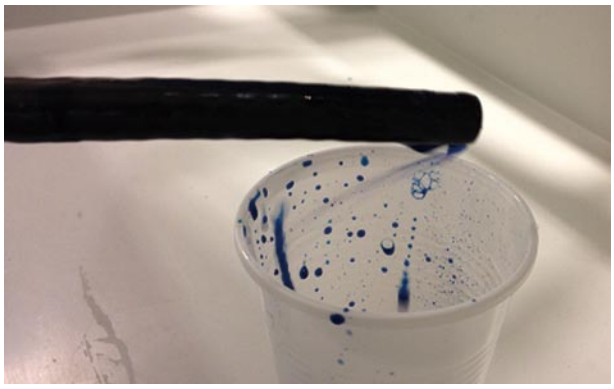

Figure 2 Indigocarmine dye application through the air/water channel of the endoscope.

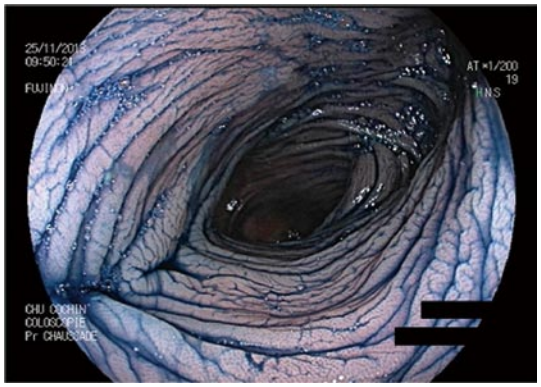

Figure 3 Endoscopic view of the colonic mucosa after indigocarmine staining using a Fujifilm® colonoscope.

screening in patients with long-standing inflammatory colitis or hereditary nonpolyposis colorectal cancer[2]. The standard technique implies pancolonic spraying with 0.2% indigocarmine delivered through a spraying catheter inserted in the accessory channel of the colonoscope. Spraying is performed segmentally during withdrawal of the endoscope and excess dye is suctioned before mucosal examination.

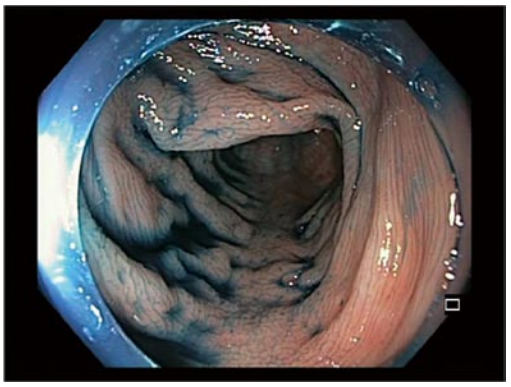

Figure 4 Endoscopic view of the colonic mucosa after indigocarmine staining using an Olympus® colonoscope and a cap.

Figure 5 Endoscopic view of a sessile serrated adenoma after indigocarmine staining.

However, the use of a spray catheter has a certain cost, limits the suction capacity of the endoscope and often requires several passages with the endoscope, which can sometimes be difficult in some patients. We report on the feasibility of the indigocarmine dye application directly through the colonoscope air/water channel. Upon cecal intubation, the indigo carmine solution is prepared in the water bottle, using two 10 mL vials of 1% indigocarmine diluted in 80 mL of water, in order to obtain the 0.2% concentration (Figure 1). The indigo carmine dye is delivered by pressing on the air/water valve while orienting the head of the endoscope against the colonic walls and withdrawing the colonoscope. The indigocamine dye application is shown on Figure 2. It should be noted that the indigocarmine stained water does not remain on the objective lens of the endoscope rendering clear water unnecessary for the cleaning of the tip of the endoscope during the chromoendoscopy procedure. Once the end of a colonic segment has been reached, suction of the air allows uniform application of the dye on the mucosa and elimination of excess fluid. New air insufflation is then needed for the colonic mucosal examination.

Immediately after the procedure, the air/water channel of the endoscope is flushed with water from another water bottle until the outflow is clear, to make sure that no indigocarmine dye remains inside the channel. After standard washing, we did not observe any residual staining in the water bottles. Our preliminary experience with 15 patients suggests that this simplified indigocarmine chromoendoscopic technique is feasible with Olympus® or Fujifilm® colonoscopes, with or without a cap (Figures 3-5) and with a median withdrawal time of 21 ± 12 min.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is a lethal neoplasia, for which secondary prevention (*i.e.*, screening) is advisable for high-risk individuals with "familiar pancreatic cancer" and with other specific genetic syndromes (Peutz-Jeghers, p16, BRCA2, PALB and mismatch repair gene mutation carriers). There is limited evidence regarding the accuracy of screening tests, their acceptability, costs and availability, and agreement on whom to treat. Successful target of screening are small resectable PDAC, intraductal papillary mucinous neoplasms with high-grade dysplasia and advanced pancreatic intraepithelial neoplasia. Both magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) are employed for screening, and the overall yield for pre-malignant or malignant pancreatic lesions is of about 20% with EUS and 14% with MRI/magnetic resonance colangiopancreatography. EUS performs better for solid and MRI for cystic lesions. However, only 2% of these detected lesions can be considered a successful target, and there are insufficient data demonstrating that resection of benign or low grade lesions improves survival. Many patients in the published studies therefore seemed to have received an overtreatment by undergoing surgery. It is crucial to better stratify the risk of malignancy individually, and to better define optimal screening intervals and methods either with computerized tools or molecular biomarkers, possibly in large multicentre studies. At the moment, screening should be carefully performed within research protocols at experienced centres, offering involved individuals medical and psychological advice.

Key words: Endoscopic ultrasound; Pancreatic cancer; Screening; High-risk individuals; Magnetic resonance

Core tip: Screening for pancreatic cancer is advisable for high-risk individuals. There is limited evidence regarding the accuracy of screening tests, their acceptability, costs and availability, and agreement on whom to treat. Successful target of screening are small resectable pancreatic ductal adenocarcinoma, intraductal papillary mucinous neoplasms with high-grade dysplasia and advanced pancreatic intraepithelial neoplasia. Both magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) are employed for screening, and the overall yield for pre-malignant or malignant pancreatic lesions is of about 20% with EUS and 14% with MRI/magnetic resonance colangiopancreatography. However, only 2% of these detected lesions can be considered a successful target. It is crucial to better stratify the risk of malignancy individually, and to better define optimal screening intervals and methods.

INDICATION FOR SCREENING FOR PANCREATIC ADENOCARCINOMA: WHICH PATIENTS SHOULD RECEIVE SCREENING AND WHICH LESIONS ARE WE LOOKING FOR?

Pancreatic ductal adenocarcinoma (PDAC) is the most common and lethal type of neoplasia occurring in the pancreas. Its incidence has progressively increased in Western countries, possibly due to changes in lifestyle[1]. The prognosis of PDAC is dismal, due to delayed diagnosis, biological aggressiveness and poor response to medical treatment[1,2]. PDAC is going to become the second cause of cancer-related death in the United States by 2030[2].

Prevention, therefore, seems one of the few reasonable approaches to tackle this deadly disease. Primary prevention, consisting of policies aimed at reducing the risk related with modifiable factors, such as cigarette smoking or overweight, is of paramount importance and might reduce substantially the incidence of PDAC[3].

On the other hand, secondary prevention (*i.e.*, screening) is not advisable for the general population, as the overall lifetime risk of developing PDAC is relatively low, being close to 1%. PDAC, indeed, does not meet some of the criteria set by the World Health Organization for considering a population screening worthwhile[4], such as being the target disease a common form of cancer, although it does have a high associated morbidity or mortality. Moreover, screening for cancer is justified if a there is an acceptable, safe and relatively inexpensive test procedure and if an effective treatment, capable of reducing morbidity and mortality, is available.

With regards to PDAC, there is limited evidence regarding the accuracy of screening tests, their acceptability, costs and availability, and agreement on whom to treat on the basis of screening results. Furthermore, as the accuracy of a given test also relies on the prevalence of the disease (pre-test probability), it is clear that screening is only advisable for specific population groups with a significantly increased risk of developing PDAC.

With regards to which individuals should undergo screening for early diagnosis of PDAC there is good general agreement among experts. The members of the International Cancer of the Pancreas Screening Consortium (CAPS)[5] have recently stated that screening is indicated for: (1) Individuals with "Familiar pancreatic cancer" (FPC), without a defined genetic syndrome, but with two or more blood relatives affected by PDAC, of whom at least one first degree relative (FDR); and (2) As far as regards known genetic syndromes, screening is indicated for all patients with Peutz–Jeghers syndrome regardless of family history of PDAC, while for p16 [familial atypical multiple mole melanoma syndrome (FAMMM syndrome)], BRCA2, PALB and hereditary non-polyposis colorectal cancer mutation carriers, screening is indicated only if one FDR or two family members are affected by PDAC.

It is more difficult to agree on which lesions should be considered the target of screening examinations. Ideally small cancerous lesions (T1) amenable for surgery should be diagnosed in due time and receive appropriate treatment, and individuals with clear macroscopic preneoplastic lesions, such as intraductal papillary mucinous neoplasms (IPMNs), might also be considered for surgery depending on size and other cyst features. However, there is no evidence suggesting that cystic lesions should be treated differently than in sporadic cases[6-8]. The possibility to recognize and the need to treat microscopic preneoplastic lesions such as pancreatic intraepithelial neoplasia (PanIN), whose presence might be indirectly suspected at screening examinations by signs of chronic pancreatitis, is less clear. Advanced PanINs (grade 3) might be considered an appropriate target for screening, while PanIN1 and 2 are extremely common findings in healthy subjects, with their prevalence increasing with age. The yield of "successful" screening examinations should therefore be considered in terms of detection and indication for surgery of lesions such as small, resectable PDAC, PanIN3 and IPMN with high grade dysplasia[5].

Finally, no imaging modalities gained a univocal evidence-based consensus for screening high-risk indivi-

duals (HRI) for pancreatic cancer, and both magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) have been proposed to be the first line modalities in terms of accuracy.

The present review article will discuss critically the rationale for the use, and the yield of EUS and MRI for detecting solid malignant and premalignant (solid or cystic) pancreatic lesions, and the outcome of surgery in this setting, in order to try to highlight the clinical impact of the screening policies.

EUS

EUS has emerged as an accurate imaging modality for the study of the pancreatic diseases providing high-resolution images of the pancreas without the risk of radiation exposure.

The CAPS Consortium suggests that initial screening of the HRIs should include EUS examination, with an agreement exceeding 83%[5].

EUS is, indeed, an extremely powerful diagnostic method, and is considered the most sensitive technique for the detection and diagnosis of PDAC. The sensitivity of EUS for solid lesions smaller than 2 cm is 93% compared to 53% and 67% of computed tomography (CT) scan and MRI respectively[9]. Moreover, the high negative predictive value (100%) of EUS for tumor detection suggests that the absence of a focal mass reliably excludes pancreatic cancer[10].

In the setting of cystic lesions, EUS obtains a good definition of their morphological characteristics, useful for the differential diagnosis and to identify features (mural nodules, wall thickness) associated with an increased risk of malignancy[11]. It has also been demonstrated that EUS performs better than MRI regarding the early detection of malignancy in patients with IPMN[12].

Finally, the possibility to perform guided fine needle aspiration (FNA) permits to obtain tissue samples for histopathological characterization of the lesion with low risk of complication[13]. However, although the sensitivity, specificity and accuracy of EUS-FNA in solid pancreatic masses was found to be high (84.3%, 97%, 84% respectively) the relatively low negative predictive value (64%) does not allow to exclude the diagnosis of PDAC if it is suspected[14]. The routine use of EUS – FNA in a screening program is therefore questionable.

On the other hand, microscopic precursor lesions of PDAC, such as PanINs cannot be reliably detected with current imaging methods. Some data, however, suggest that EUS might be able to detect parenchymal changes caused by these lesions. In HRIs PanINs are multifocal and might be associated with lobular atrophy of the surrounding parenchyma, but these features are not associated with the grade of dysplasia. The parenchymal changes caused by multifocal PanINs might be visualized at the EUS as chronic pancreatitis-like features (ectasia, irregularity of the duct and/or parenchyma heterogeneity and lobularity) that cannot be differentiated from non-neoplastic alterations[15].

For all these reasons, EUS has been used in several studies as the baseline screening test for PDAC in HRIs, alone or in combination with other abdominal imaging techniques. The diagnostic yield of this procedure in detecting any lesions - morphologically suspicious or histologically proven to be malignant or pre-malignant - ranged from 2.6% to 46% at baseline evaluation or during the follow-up. However, the actual rate of detected and resected lesions, for which screening might be considered successful, is much lower, as many patients undergoing surgery in these studies had PanIN 1 or 2, or IPMNs without dysplasia or even benign lesions such as serous cystoadenomas, and few others were diagnosed with unresectable PDAC (Table 1).

A screening programme based on EUS was first proposed by Brentnall *et al*[16] in 1999. A small prospective cohort of 14 patients (kindreds that had two or more members in the last two generations with pancreatic cancer) were evaluated with both EUS and endoscopic retrograde cholangiopancreatography (ERCP) and compared to CT results. The EUS findings were available for 13 of 14 patients and resulted abnormal in 10 (ranging from minimal to marked signs of chronic pancreatitis) at the first examination. Seven patients were treated with total pancreatectomy, with findings of signs of widespread dysplasia, although the grade of such lesions was not clarified in the paper. The diagnostic yield of EUS in this study was very high (46%) but whether resecting such target lesions might be considered a success is unclear given the associated morbidity of total pancreatectomy. Kimmey *et al*[17] reported the experience of the same centre, with a similar protocol, a few years later on 46 patients with more than two first or second-degree relatives with PDAC. This second paper seems to include also the patients reported in their pivotal study. Cross-sectional imaging did not detect abnormalities in those patients, while EUS showed signs of chronic pancreatitis in 24 patients, most of them also reporting symptoms such as diarrhoea and diabetes. Twelve patients (including the seven subjects of their first paper) underwent surgery and the histological examination showed widespread dysplasia in all of them. The diagnostic yield of EUS was equal to 26%, yet it is not clear if the operated patients had PanIN3 or lower grades of dysplasia. Notably, these pivotal papers employed ERCP in all screened individuals, and this might have caused some false positive findings, with the addition of possible procedure-related risks.

The pilot study of Johns Hopkins Hospital[18] enrolled 38 patients with $\geqslant$ 2 FDR with PDAC or affected by PJS. EUS was performed as a baseline screening method and in case of abnormalities CT scan and ERCP were carried out. Twenty-nine patients had abnormalities at EUS (12 pancreatic lesions and 17 EUS changes of chronic pancreatitis). FNA was performed in 21 and 3 alterations were found at cytological examinations (1 atypical neoplastic and 2 atypical reactive pancreatic cells). Seven patients underwent surgery, but only one was diagnosed with a T2N1 PDAC and another with multiple PanINs

Table 1 Summary of diagnostic yields of endoscopic ultrasound based protocols for familiar pancreatic cancer screening in high risk individuals

[1]Endoscopic yield is defined as EUS detection of any lesions morphologically suspicious for BD-IPMN or histologically proven (pre) malignant lesion (PanIN $\geqslant$ 2, IPMN and pancreatic adenocarcinoma) at baseline evaluation and, when performed, during the follow up; [2]Treatment is considered a success if any of the following lesions is found at surgery: resectable PDAC, MD-IPMN or IPMN with dysplasia, PanIN3. EUS: Endoscopic ultrasonography; FNA: Fine-needle aspiration; FPC: Familial pancreatic cancer; BD: Branch duct; MD: Main duct; IPMN: Intraductal papillary mucinous neoplasm; PDAC: Pancreatic ductal adenocarcinoma; PJS: Peutz–Jeghers syndrome; PanIN: Pancreatic intraepithelial neoplasia; FAMMM: Familial atypical multiple mole melanoma; FBOC: Familial breast ovarian cancer; HP: Hereditary pancreatitis; LFS: Li fraumeni syndrome.

ranging 1-3. The other 5 resected patients had either a borderline IPMN, PanIN2 or benign lesions (serous cystoadenoma). The diagnostic yield of EUS was 10.5%, if one considers borderline IPMN and PanIN2 appropriate targets for screening. The subsequent prospective study conducted by Canto *et al*[19] screened 78 consecutive HRIs with EUS. In case of abnormal findings at EUS, further evaluations with EUS- FNA/ERCP were performed. In four patients pancreatic malignancy was suspected at baseline screening. The surgical findings were of IPMN with carcinoma in situ in one case, and of IPMN with numerous foci of PanIN3 in another, while the other two patients had IPMN with diffuse and multiple PAnIN1-2, or diffuse PanIN1-2. During the follow-up, within 1 year, further 4 patients were diagnosed having suspected pancreatic neoplasia, and while 1 had an advanced unresectable adenocarcinoma, the others underwent surgery with findings of PanIN3 in one case, and either IPMN with/without PanIN1-2 in the other cases. Therefore, although EUS diagnosed 7 of 8 pathologically confirmed pancreatic neoplasms (yield of 10.2%), one might discuss that a large part of the resected patients did not have significant lesions, and that, despite the screening process, one lesion was diagnosed at mestastatic stage.

Poley *et al*[20] reported their data of a first-time EUS screening on a prospective study of 44 patients (with a relatively large proportion of carriers of a clearly defined genetic syndrome associated with an increased risk to develop PDAC). In case of EUS abnormalities, CT or MRI were performed, as well as a multidisciplinary discussion of all the findings. A total of 7 cystic lesions were diagnosed. Their morphological features at EUS examination were typical of IPMN without signs of malignancy (diameter between 4 and 15 mm without solid component or intramural nodules). In this study this was not considered an indication for surgery. Three asymptomatic solid lesions were detected by EUS and, after resection, the histological examination indeed showed adenocarcinoma. The stage of the tumour was T3N1M0 in two patients and T1N0M0 in the other, but even in this case distant metastases were found 16 mo after surgery. The diagnostic yield of EUS in detecting neoplasms in HRIs in this study was 22.7%.

No malignant lesion was diagnosed in the German surveillance program[21]. This prospective screening study was carried out in 76 HRIs. The imaging procedures performed at baseline were MRI combined with magnetic resonance colangiopancreatography (MRCP) and EUS. A total of 7 suspected lesions were further evaluated with FNA, but none showed cytological alterations. Surgical exploration of the pancreas was performed in 7 individuals, but the histological diagnoses were 3 serous cystoadenomas, 1 PanIN1, 1 PanIN2 and 1 IPMN. The diagnostics yield of EUS in this study was 2.6%, considering as a "successful" target precancerous lesions also the histologically presence of PanIN2 in the pancreatic parenchyma. This low yield compared to the other previous studies could be correlated to a

selection bias of the patients (the study included a large number of patients at moderate risk). The subsequent German study[22] evaluated 5-year of prospective screening in the HRIs from this same series, showing a higher yield in detection of pre-malignant lesions using EUS and MRI/MRCP as follow-up methods. Further 9 patients underwent surgical resection, with diagnosis of 1 advanced PDAC and 1 PanIN3, with the other lesions being either serous cysts (n = 3) or lower grade PanIN or IPMN.

Verna *et al*[23] screened a total of 51 HRIs, 31 of them with EUS. The most common abnormal findings, as expected, were parenchymal changes seen in chronic pancreatitis: two patients had a mass lesion confirmed to be PDAC after FNA, one was resectable (2 cm moderately differentiated adenocarcinoma arising from main duct IPMN), and one metastatic to the liver. Five BD (branch-duct) IPMN were diagnosed and in 4 of them surgery was carried out (all of these had BD IPMN with moderate dysplasia and multifocal PanIN2 lesions on pathology). In this cohort study the diagnostic yield was 22.5%, although only one of these lesions might be considered a successfully detected target.

The multicentre prospective cohort CAPS 3 study[24] enrolled three groups of asymptomatic HRIs (FPC, BRCA and PJS). It is the first blinded study that compared standardized protocol CT, gadolinium and secretin-enhanced MRCP and EUS. Of 226 patients, EUS diagnosed parenchymal and ductal abnormalities (chronic pancreatitis features) in 25%. Surgery was performed in 5 HRIs, and three of 5 them had IPMN with main duct involvement, high-grade dysplasia and/or associated PanIN3. The diagnostic yield in detecting precursor lesions was considered equal to 37%, but the number of significant lesions was relatively low, with few cases with indication for surgery as compared with previous studies.

MRI

MRI is a widely available technique, and when compared to EUS, has the advantages of being non-invasive, less operator-dependent, easier to be compared and reviewed over time by different specialists taking care of the patients. MRI also offers the opportunity to image the entire abdomen and pelvis. This latter aspect is noteworthy, as it might help diagnosing extra-pancreatic neoplasms, which are fairly common in some specific groups of HRI[25]. Moreover, MRCP provides excellent visualization of the pancreatic and biliary tree and is particularly useful for characterizing cystic lesions such as IPMNs that are the most common precursor lesions diagnosed in HRI[6,20,26].

Seven papers investigated the use of MRI for the screening of individuals at high risk for developing a pancreatic cancer. The employed methods are extremely heterogeneous in terms of employed MR scanner, acquisition phases, use of contrast agents and use of secretin. The diagnostic yield for the detection of pancreatic lesions also varies among the different studies (Table 2), ranging from 3.3% to 57.4%[21,23-25,27-29].

Secretin-enhanced sequences have been used in three of these seven papers[21,24,29], but its use has not been univocally validated to improve the diagnostic yield of MRCP in this setting. Nevertheless, a recently published paper on patients with a strong family history of pancreatic cancer undergoing a multicenter Cancer of the Pancreas Screening-3 trial (CAPS 3), proved evidences that the use of secretin can improve the visualization of ductal communication of cystic pancreatic lesions[30].

Some authors decided to use non-contrast MRI protocol for screening, basing on the hypothesis that changes in pancreatic duct and/or focal drop in pancreatic signal would be detectable even without contrast and that these alterations would have triggered further investigations[28]. Other authors indeed used a contrast-enhanced MRI protocol. The former argued against this latter position because, even if using a contrast enhanced protocol, all pancreatic cancers individuated in screening programmes were advanced and/or metastatic and due to patient's death[27,28].

The diagnostic yield of MRI varies sensibly among the different studies with a wide range, between 3% and 50%, probably due to the heterogeneity both of investigated populations and screening protocols[23,25]. The rate of solid lesions found at MRI seems to be low, ranging between 0.4% and 9%[24,27]. Similar results have been reported for the detection of chronic pancreatitis-like changes, duct ectasia and PanIn lesions, while pancreatic cystic lesions are diagnosed in a higher percentages of patients (2.6%-35.3%)[21,24,29]. In two series, a percentage of about 3% of patients with non-reproducible alterations has been reported[21,28].

Recently a series of 40 high risk individuals undergoing a MRI based screening protocol has been published. Patients underwent a baseline secretin-enhanced MRCP and then a yearly MRI imaging in case of negative result or a EUS with FNA/additional CT scan imaging protocol in case of suspicious result. An overall 40% MRI yield was reported (35% IPMNs, 5% PDAC) at a median 1 year follow up. An additional, synchronous PDAC was found during the IPMN follow up. Five patients underwent a surgical resection, all of them with a successful surgical treatment (3 PDAC, 2 IPMNs with indeterminate grade dysplasia)[30].

COMPARISON OF EUS AND MRI

There are few studies comparing the diagnostic yield of MRI and EUS in screening HRIs, and it is therefore still unclear which is the best method in detecting early stage PDAC and premalignant lesions in these subjects. The CAPS 3[24] study evaluated, in a blinded fashion, the ability of these two screening methods in detecting pancreatic lesions in HRIs. This study showed a high concordance between the two diagnostic examinations for the detection of any pancreatic lesion (91%). In

Table 2 Summary of diagnostic yield of magnetic resonance imaging based protocols for familiar pancreatic cancer screening in high risk individuals

[1]MRI yield is defined as detection of any lesions morphologically suspicious for BD-IPMN or histologically proven (pre) malignant lesion (PanIN $\geqslant$ 2, IPMN and pancreatic adenocarcinoma) at baseline evaluation and, when performed, during the follow up; [2]Treatment is considered a success if any of the following lesions is found at surgery: resectable PDAC, MD-IPMN or IPMN with dysplasia, PanIN3. FPC: Familial pancreatic cancer; BD: Branch duct; MD: Main duct; IPMN: Intraductal papillary mucinous neoplasm; PDAC: Pancreatic ductal adenocarcinoma; PJS: Peutz–Jeghers syndrome; PanIN: Pancreatic intraepithelial neoplasia; FAMMM: Familial atypical multiple mole melanoma; FBOC: Familial breast ovarian cancer; HP: Hereditary pancreatitis.

particular, a strong positive correlation was found for the size of the lesions, and a moderate agreement for the number of pancreatic cystic lesion/solid mass was described. MRI better assessed communication of the cyst with the main pancreatic duct, being superior to EUS (53% *vs* 27%). EUS missed five patients with a cystic lesion seen by MRI (2 of which BD-IPMN) but diagnosed 12 patients with cystic lesions not reported by MRI (3 of which BD IPMN).

A prospective blinded comparison study was conducted by the Rotterdam group and has recently been submitted for publication. A total of 139 high-risk patients were enrolled and screened with both MRI and EUS. There was high agreement regarding location and size of all lesions. Instead, only a moderate agreement (55%) was reached for the detection of the 11 clinically relevant described lesions. MRI was very sensitive for the diagnosis of cystic lesions, while EUS detected two solid lesions that were not found by MRI (one of these was shown to be PDAC). The results of this study suggest that both techniques are useful, and that they might be complementary rather than interchangeable in screening HRIs, with MRI being able to detect cystic lesions better than EUS, but EUS being more accurate for the diagnosis of small solid lesions, which are the primary target of screening.

Thus, even taken for granted the major sensitivity of EUS in detecting small solid pancreatic lesions, one might argue that there are no solid data suggesting that such ability has a beneficial effect on the disease outcome in this setting. On the other hand, MRI with MRCP protocols have reasonably a good accuracy for the detection of IPMNs, which represent a precancerous lesion, that potentially progress towards pancreatic cancer. Future studies should compare the ability of these methods in a randomized designed study, and their impact on the long-term outcome of screened subjects.

USE OF SERUM CARBOHYDRATE ANTIGEN 19-9 AS A SCREENING TEST

Serum carbohydrate antigen (CA) 19.9 is the most widely used biomarker for pancreatic cancer, and its use is recommended to monitor the response to treatment[31] in patients who had elevated level before treatment (between 5% and 10% of the general population are unable to express CA-19-9).

However, the dosage of Ca 19.9 in screening asymptomatic population is not recommended. A number of 70940 asymptomatic patients were screened by Kim *et al*[32] using Ca 19.9 (cut off > 37 U/mL)[32]. Although it showed an high sensitivity (the CA 19-9 level was increased in all four patients diagnosed with pancreatic cancer), in screening pancreatic cancer in the general population it showed a very poor predictive positive value (0.9%). Similar results were obtained by Chang *et al*[33] that found high sensitivity and specificity of this biomarker in predicting pancreatic cancer (100% and 92% respectively) but a 0.5% of positive predictive value.

Slightly better results were obtained in screening symptomatic patients (with high prevalence of pancreatic cancer equal to 49%) where it was found an high positive predictive value (71%) using a cut off Ca 19.9

> 40 U/mL[34].

The diagnostic role of Ca 19.9 in screening HRIs patients was poorly investigated. The serum dosage of Ca 19.9 was carried out in 8 of 14 patient screened by Brentnall *et al*[16] and found to be normal in all these patients. Between the patients enrolled by Verna *et al*[23] only one had elevated Ca 19.9. This patient was found to have a pancreatic cyst without dysplasia, and Ca 19.9 remained elevated after surgery. In the german study by Langer *et al*[21] all but one patient showed a normal Ca 19.9. The imaging examinations did not show any abnormality of the pancreas at the first evaluation and during the subsequent 28 mo of follow up, and after further investigations the cause of elevation of this biomarker remained unclear. Therefore, although data are limited, the dosage of Ca 19.9 doesn't seem helpful during the screening of HRIs.

SURGICAL INDICATIONS AND OUCTOME

Although screening policies for the prevention or early detection of pancreatic cancer have been initiated about 15 years ago, there are still not enough data to generate evidence-based guidelines regarding the role of pancreatic surgery in this setting. In many of the initial studies screening HRIs, indication for surgery was possibly too wide, and many patients undergoing surgery were diagnosed with benign or borderline findings[16-19]. As discussed above, what makes the current picture more complicated is the definition of the targets for surgery, as reasonable goals of the screening programme are early invasive or resectable pancreatic cancer, high grade dysplasia IPMNs, and PanIN3 lesions, while the significance of other lesions is less clear. The different approaches to screening and treatment of HRIs is reflected in the results from different surveillance programmes. In this view, not surprisingly, the more recent studies, and personal viewpoints now point toward a less aggressive surgical approach, both in terms of timing for surgery and in extent of pancreatic resection[35].

PanIN lesions are considered detectable by EUS, by some Centers[19]. Those lesions may appear as parenchymal changes resulting from a lobulocentric atrophy (LCA) that is present in chronic pancreatitis. However, recent studies showed that this association between PanIN and LCA is not clear and for this reason the use of LCA as a target for early detection of pancreatic cancer should be considered with extreme caution. First, PanIN might not be the cause of LCA; second, LCA can be found in other conditions (as aged pancreas); third, the value of low grade dysplasia at FNA can't exclude another area of high grade dysplasia in a distinct area, sometimes distant from the biopsy site, but not associated with LCA, and not visible at EUS[36]. Furthemore, while the agreement among different operators for the interpretation of EUS findings when a frank solid or cystic lesion is diagnosed is generally good, this is not the case for the diagnosis of chronic pancreatitis features, where the agreement remains disappointing even after a consensus process[37].

For all these reasons there is no consensus on surgical treatment of PanIN lesions, and it is questionable whether finding of PanIN1-2 should be considered a success. However, one can assume that histological confirmed PanIN3 lesions should be resected. The extent of pancreatectomy for those patients is not defined, but a radical partial pancreatectomy seems to be the adequate option.

IPMNs are the most frequent finding detected during the screening of HRIs[35]. Even if the natural history of IPMNs in individuals with family history is not well defined, some data[38] suggest that the risk to progress to cancer is not higher than that of sporadic cases. However, the IAP guidelines for treatment and follow-up of cystic pancreatic lesions[8] suggest to shorten follow-up intervals in patients with BD-IPMN and FPC, and more recently the Italian guidelines[7] have suggested to consider surgery for all IPMNs in the setting of FPC in fit patients. Which surgical procedure should be performed in such cases is also unclear. Notably, it has been reported that in the setting of HRIs, BD-IPMNs are often associated with distant foci of PanIN3[36], and IPMNs are also frequently multifocal, thus a radical surgical treatment might be a total pancreatectomy. On the other hand, this may often result in an overtreatment. At any rate, such patients should be discussed in highly specialized centers and the indications should also take in consideration patient age and perception of the problem.

The surgical treatment of solid tumors of the pancreas (suspected pancreatic adenocarcinoma) in HRIs, should follow the rules of oncologic surgery[26]. The initial approach to these patients in Seattle was total pancreatectomy[16], but this is not supported by evidence and might only be considered in cases with diffuse multiple lesions in the pancreas (for example a solid tumor in the head and IPMN in the tail). Data on post-operative follow-up of HRIs are extremely scanty. It seems reasonable to follow-up HRIs diagnosed with cancer and resected as other sporadic cases. For patients operated for pre-malignant lesions, the pancreas remnant should be followed-up according to the surveillance program for HRIs[5].

AREAS FOR IMPROVEMENT

Screening for pancreatic cancer or its precursors has an indication in research settings only. As compared with other screening policies for cancers indeed, there are a number of issues that need to be clarified in order to consider screening worthwhile.

The overall yield of screening methods for pre-neoplastic or neoplastic pancreatic lesions in HRIs is of about 20% with EUS and 14% with MRI/MRCP. However, only 2% of the detected lesions might be considered a successful target of screening (Tables 1 and 2), and there are insufficient data demonstrating that resection

of benign or low grade lesions improves survival. Many patients in the published studies, indeed, seemed to have received an overtreatment by undergoing surgery.

In this view, it is crucial to better stratify the risk of malignancy individually, and to better define optimal screening intervals and methods. The use of a computerized risk assessment tool named PancPRO has been proposed and tested in incident cases of PDAC[39]; similar tools taking into account the role of family history and possibly other factors such as smoking, might help selecting patients at a substantially higher risk. In the future, application of novel methods of molecular analysis might help better select patients for screening, and provide the indication for surgical treatment. Eshleman *et al*[40] recently investigated the possible role of KRAS and GNAS mutations in the duodenal juice of PDAC patients and HRIs undergoing screening EUS. As expected, a high percentage of PDAC patients had KRAS mutations, but among screened individuals the presence of KRAS mutations did not discriminate between these with or without lesions. This is most likely due to the fact that KRAS mutations are an early event, already present in PanIN1, which is extremely common in HRIs and does not represent a target lesion for resection. Crnogorac-Jurcevic *et al*[41] analysed the gene expression profile of precursor lesions, PanIN2/3 obtained from prophylactic pancreatectomy specimens of FPC from the Seattle-Washington screening program. They found that transcriptomic changes occur during the progression of PanIN to PDAC, not only in the epithelium but also in the surrounding stroma. These findings support the view that early changes in familial cases are similar to those seen in sporadic cases, and might serve as a tool to predict the behaviour of pre-neoplastic changes in HRIs. The possible role of microRNAs, and other biomarkers, has been investigated by Slater *et al*[42]. They reported that serum levels of miR-196a and miR-196b were significantly higher in patients with PDAC as compared to controls, but notably, the serum levels of such miRs were also higher in HRIs screened for PDAC with PanIN2/3 lesions than in screened subjects without lesions or with PanIN1 lesions only. These results, if confirmed, might suggest that a panel of miRs might help selecting patients at higher risk of significant findings among screened individuals.

It is also uncertain whether EUS or MRI, or both, should be employed as screening tests, as few studies compared these two methods. It seems that the two techniques might be considered somehow complementary, with EUS being more accurate for solid lesions and MRI for cystic ones. Future studies should also take into account different subgroups of HRIs when establishing screening intervals and modalities. As an example, it has been reported that in individuals with FAMMM (p16 mutation carriers), cystic lesions are less frequent than in FPC, but solid lesions diagnosed as PDAC are far more frequent[43]. Thus, in p16 mutation carriers a screening with EUS and not with MRI, with closer intervals, might be preferred.

Another intriguing issue regards the diagnosis of other pancreatic lesions at screening. Pancreatic neuroendocrine tumours (PNETs) have been diagnosed in HRIs receiving screening for PDAC, with a prevalence apparently exceeding the expectations[24,25,27]. It is unclear whether these findings are just occasional, or if PNETs may represent a part of FPC phenotype, as possibly suggested by findings of similar risk factors for the occurrence of PNETs and exocrine neoplasms[44].

Finally, it also needs to be determined whether screening for pancreatic cancer in HRIs is really cost-effective. In a simulation considering a 20% prevalence of pancreatic "dysplasia" and 90% sensitivity of EUS and ERCP, endoscopic screening was calculated to be cost-effective, but this analysis most likely considered an excess of lesions now considered as successful targets of screening[45].

Future large collaborative studies are likely to give the answer to many of these open questions but, until then, screening for pancreatic neoplasms in HRI should be carefully performed within research protocols at experienced centres, offering involved individuals medical and psychological advice.

Abstract

Laparoscopic sleeve gastrectomy is a surgical procedure that is being increasingly performed on obese patients. Among its complications, leaks are the most serious and life threatening. The placement of esophageal, covered, self-expandable metal stents in these cases has been performed by many authors but reports on the outcome of this procedure are limited and the technical aspects are not well defined. Stent migration is the main complication of the procedure and poses a challenge to the surgeon, with a limited number of options. Here we evaluate the technical and clinical outcome of a new, dedicated, self-expanding metal stent, comparing the advantages of this stent to those traditionally used to treat staple-line leak after sleeve gastrectomy. While published data are limited, they seem support the use of this kind of new stent as the best option for the stenting treatment of a staple-line leak after sleeve gastrectomy, over other kinds of stents. Further studies based on larger series are needed to better evaluate patient outcome.

Key words: Bariatric surgery; Leak; Obesity; Sleeve gastrectomy; Endoscopic stent; Therapy

Core tip: Laparoscopic sleeve gastrectomy (LSG) is a surgical procedure increasingly performed on obese patients with convincing outcomes. Among its complications, leaks are the most serious. The use of esophageal self-expandable metal stents in these cases has been performed by many authors but reports are limited and stent migration is the main complication of the procedure. Megastent®, a new stent dedicated to the treatment of leaks after LSG, seems to resolve most of the problems of the esophageal stents. While published data are limited, they seem support the use of Megastent® as the best option for the stenting treatment

of a staple-line leak after sleeve gastrectomy. Further studies on larger series are needed to better evaluate definitive outcomes.

Galloro G, Ruggiero S, Russo T, Telesca DA, Musella M, Milone M, Manta R. Staple-line leak after sleve gastrectomy in obese patients: A hot topic in bariatric surgery. *World J Gastrointest Endosc* 2015; 7(9): 843-846 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/843.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.843

A HOT TOPIC IN BARIATRIC SURGERY: NEW DEDICATED STENTS TO IMPROVE TREATMENT

Laparoscopic sleeve gastrectomy (LSG), first described by Gagner[1] in 2003, has become a well standardized therapeutic option for the surgical treatment of different degrees of obesity[2-6]. Since its introduction, LSG has gained acceptance due to its technical simplicity and the convincing outcomes[7,8]. While specific complications have been reported, including staple-line bleeding and stricture, staple-line leaks are the most serious as they are associated with the greatest morbidity. The incidence of this type of leak after LSG varies in different series[9-11] and its management has been attempted using several different therapeutic approaches[7,10,12-21].

Staple-line leak after LSG reportedly develops in 2.5% of patients undergoing primary sleeve gastrectomies, with a range between 0.5% and 7% in the different series of dedicated bariatric surgeons[6,7,10,16,22,23]. Recently Gagner[24] reported that the incidence of staple-line leak after LSG is decreasing from a generally accepted rate of 2.5% initially to a now 1.1% leak rate in 2013 as reported in a large cohort of 46.133 sleeve gastrectomies, with more than 50% decreased incidence.

Nevertheless, in our opinion, the true rate is probably underestimated. A detailed review by the American Society for Bariatric and Metabolic Surgery reported an overall complication rate after LSG of 0%-24%, with the leakage occurring in 16%-20% of the cases in several series of different experienced surgeons[16] and in patients requiring re-operation after a previous gastric operation performed in no-dedicated to bariatric surgery centers[25].

The gastro-esophageal junction and the proximal stomach near the angle of His are, according to the literature, the most frequent origins of leaks[6,9,11,15], but the reason for this predominance is still unknown. Baker[26] suggested that staple-line leaks are secondary to an impaired healing process and may have multiple risk factors (impaired suture-line healing, poor blood flow, infection, poor oxygenation with subsequent ischemia), but these can be divided into two main categories: mechanical-tissue causes and ischemic causes.

A mechanical mechanism can be invoked when the intraluminal pressure, in association with a low compliance of the gastric tube, exceeds the strength of the staple line. This situation is more likely in patients with difficulties in gastric emptying due to a middle or a distal stenosis of the sleeve[27,28]. In order to reduce the possibility of mechanical failure, the use of buttress material associated with the stapler has been advised, but there is no statistical evidence to support this solution[29].

On the other hand, some Authors claim that most fistulas are not due to staple failure and dehiscence but to ischemia in the gastric wall next to the staple line, likely reflecting devascularization of the gastro-esophageal junction during liberation of the greater curvature or dissection of the greater curvature when electrocautery, Ultracision®, or the LigaSure® system is used[30,31].

Moreover, regardless of the mechanism (mechanical or ischemic) the physiology of the normal sleeve must be considered as well. Studies assessing volume and pressure after LSG[28,32] clearly demonstrated that the removed portion of the stomach (fundus and corpus) is indeed the most expandable, with an important reservoir function. The volume of the sleeve is less than 10% of the volume of the whole stomach and the mean pressure in the sleeve is higher (43 ± 8 mmHg *vs* 34 ± 6 mmHg, $P < 0.005$). Furthermore, the valve function of the cardia and pylorus persists in the gastric sleeve as does the pumping function of the antrum, both of which may further increase the intraluminal pressure.

For these reasons, in obese patients undergoing LSG, although the high intraluminal pressure resulting from the small volume and reduced distensibility of the sleeve confers early satiety, it is also a risk factor for dehiscence of the staple line.

The use of covered, esophageal, self-expandable metal stents (C-SEMS) in the treatment of staple-line leak after LSG has been supported by many authors in recent years[15,17,18,31] even if this is not a widely accepted treatment. C-SEMS permit the comfortable management of this complication, as the temporary fistula-bypass enables enteral nutrition (liquid hyperprotein diet progressing to a soft diet as tolerated) and, if the clinical situation is appropriate, allows the patient to return home temporarily[15]. Nevertheless, reports on the outcome of this procedure are limited and the technical aspects are not well defined.

To select candidates for this form of treatment, the following criteria should be observed: (1) Any abscess or intra-abdominal collection should be previously drained prior to stent placement[31]; (2) Leaks located at the proximal and mid part of the sleeve are the only ones amenable to stent treatment[10,11,17,18,21]; (3) The size of the leak should not exceed 2 cm[17]; (4) The stent should be chosen based on an evaluation of the gastric sleeve diameter, using a larger size in case of doubt, to prevent migration[17,18]; and (5) Late leaks (persisting for more than 4 wk) have the best outcome[15,33,34].

Most authors recommend leaving the stent in place

for a period of 6-8 wk.

In the literature, a highly variable success rate has been reported for this technique[21]. However, most of the published papers have been case reports or small surveys; statistically reliable data are, at this point, lacking.

Stent migration is the main complication of the procedure and it occurs in 30% of the cases in some series[14,17,18,33] and in as many as 42%-50% in others[15,20,35]. The highly variable stent migration rate can be explained by the following: (1) These stents are designed for use in esophageal stenosis and have therefore been adapted in a different site and to a different target; (2) The "abnormal" placement of the stent along the last portion of the esophagus and the gastric sleeve does not ensure proper containment of the stent; and (3) The coating of the stents prevents its integration into the stomach wall but reduces the grip on the wall and therefore allows migration along the gastric tube.

Regardless of the cause, failure of C-SEMS treatment poses a challenge to the surgeon, as successful management of the fistula is then very difficult, with a limited number of options.

Recently, Taewoong Medical Industries developed and marketed Megastent®, a new, fully covered stent dedicated to the treatment of leaks after LSG. Its features resolve some of the above-mentioned problems. The proximal and distal ends of the stent are slightly flared, with a high edge profile permitting good anchorage. The body of the stent is longer than that of other esophageal stents (15, 18 and 23 cm) thus allowing the distal end (with the same shape as the proximal one) to open into the duodenal bulb. The large diameter (24 or 28 mm) ensures optimal adherence of the stent to the sleeve wall, even in the antral segment, conferring adequate radial strength to dilate a possible stenosis. The entire stent is coated, which prevents its integration into the stomach wall due to a granulomatous reaction while the flexibility of the stent nets is sufficient to allow adaptation of the stent to the post-operative anatomy of the gastric sleeve.

In our experience[36], stents 230 cm long and 24 mm in diameter were chosen. The shape of the proximal end of the stent and its angle with respect to the stent body allowed complete coverage of the leak, thus promoting healing. Moreover, the total length of the stent facilitated delivery of the proximal end into the distal esophagus and the distal end into the duodenal bulb, such that the stent body extended through the entire sleeve. In our opinion, this is the main advantage of the Megastent®, as this feature eliminates the pressure gradient in the gastric sleeve. Thus, by establishing a communication with the esophagus and the duodenum, the Megastent® completely resolved the high-pressure condition that had developed in the gastric sleeve, thus promoting healing of the leak hole. The absence of stent migration was likely due to the fact that the length and diameter of the stent allow it to firmly grip the entire gastric sleeve, despite its full-length coating.

In our patients one week after the stent placement a liquid high protein diet was started, followed by a soft diet and discharge 3 d later. The stent was removed after 8 or 9 wk and an upper endoscopy documented complete healing of the leak.

While the procedure described herein was successful, two problems arose during and after stent placement. The first was biliary vomiting, which the patient experienced during the treatment. Pharmacologic therapy with domperidone was mandatory, to reduce the symptoms, which were due to esophageal biliary reflux. The second problem occurred after stent removal: a decubitus lesion in the duodenal bulb that arose, in our opinion, from the decubitus of the free edge of the distal end of the stent, strained by the radial strength of the net.

In conclusion, we recommend that the complicated multi-disciplinary management of patients with gastric leakage treated by stent graft should be confined to specialized centers. Stent placement, in appropriately selected patients, is a safe and effective treatment for staple-line leaks after LSG. This minimally invasive technique has an acceptable complication rate and causes little discomfort to the patient, who avoids the need for more invasive procedures or even total gastrectomy.

Published data about Megastent® are limited but very interesting and encouraging. I like to close this article citing the words by Gagner[24] on a his recent editorial: "I project that staple line leaks will continue to decrease. However, it may never be eliminated completely and nonoperative treatment with endoscopic fully covered metallic stent placement will continue to be the best method in leaks < 12 wk. If the long stents advoked by Galloro *et al*[36] will solve the migration problem seen in earlier series, as well as take care of the mid-body stricture often associated, then we might see less fistula-jejunostomies in the near future".

Obviously, further studies based on larger series are needed to better evaluate patients outcome.

Abstract

A new paradigm in the treatment of obesity and metabolic disease is developing. The global obesity epidemic continues to expand despite the availability of diet and lifestyle counseling, pharmacologic therapy, and weight loss surgery. Endoscopic procedures have the potential to bridge the gap between medical therapy and surgery. Current primary endoscopic bariatric therapies can be classified as restrictive, bypass, space-occupying, or aspiration therapy. Restrictive procedures include the USGI Primary Obesity Surgery Endolumenal procedure, endoscopic sleeve gastroplasty using Apollo OverStitch, TransOral GAstroplasty, gastric volume reduction using the ACE stapler, and insertion of the TERIS restrictive device. Intestinal bypass has been reported using the EndoBarrier duodenal-jejunal bypass liner. A number of space-occupying devices have been studied or are in use, including intragastric balloons (Orbera, Reshape Duo, Heliosphere BAG, Obalon), Transpyloric Shuttle, and SatiSphere. The AspireAssist aspiration system has demonstrated efficacy. Finally, endoscopic revision of gastric bypass to address weight regain has been studied using Apollo OverStitch, the USGI Incisionless Operating Platform Revision Obesity Surgery Endolumenal procedure, Stomaphyx, and endoscopic sclerotherapy. Endoscopic therapies for weight loss are potentially reversible, repeatable, less invasive, and lower cost than various medical and surgical alternatives. Given the variety of devices under development, in clinical trials, and currently in use, patients will have multiple endoscopic options with greater efficacy than medical therapy, and with lower invasiveness and greater accessibility than surgery.

Key words: Weight loss; OverStitch; Aspire; Transoral outlet reduction; Gastric balloon; Orbera; EndoBarrier; Apollo; Primary Obesity Surgery Endolumenal; Gastric bypass; Duodenal sleeve; Intragastric

Core tip: A broad array of endoscopic procedures and

devices will be approved to treat obesity and its metabolic comorbidities in the coming years. A robust body of safety, efficacy, and cost effectiveness data will continue to develop. Endoscopists should have familiarity with target population, benefits, contraindications, and adverse events for each device or procedure. Furthermore, the use of these devices and procedures in the context of a diet and lifestyle management program will be important to ensure success.

INTRODUCTION

A new paradigm is developing in the treatment of obesity and metabolic disease. Endoscopic procedures in development, in trials, and in use have the potential to bridge the gap between medical therapy and weight loss surgery. Obesity and its comorbidities - diabetes, hypertension, hyperlipidemia, and nonalcoholic fatty liver disease, have become a global epidemic[1]. Dietary modification, exercise, and pharmacologic therapy have been ineffective in arresting the spread of obesity at the population level. Bariatric surgery, which is effective and is utilized by hundreds of thousands of patients each year, can only be performed on a fraction of eligible patients given the current number of practicing surgeons[2]. Endoscopic therapies for weight loss are potentially less invasive, reversible, and lower cost; they may also be repeatable as necessary. These characteristics mean that various endoscopic procedures may play a role as primary therapy, as a bridge to bariatric surgery, or as a revisional procedure after bariatric surgery. Current primary endoscopic bariatric therapies can be classified as restrictive, bypass, space-occupying, or aspiration therapy. These procedures, as well as endoscopic revision of gastric bypass, are discussed herein.

RESTRICTIVE PROCEDURES AND DEVICES

Restrictive procedures remodel the stomach *via* suturing, stapling, or tissue anchor placement to reduce gastric volume.

Incisionless Operating Platform for Primary Obesity Surgery Endolumenal

The Incisionless Operating Platform (IOP) [USGI Medical, San Clemente, California (CA)] can perform full-thickness tissue plication. The platform of the IOP is the four-channel TransPort, which is steerable in four directions and has a 73 cm insertion length. A 4.9-mm endoscope is passed through one channel for endoscopic visualization. The g-Prox, which is capable of 360-degree rotation, has 33-mm stainless steel jaws at its tip to grasp tissue. A helix, called g-Lix, is passed through one channel to grasp tissue and pull it into the jaws of the g-Prox. The g-Cath is advanced through the g-Prox and used to deploy suture anchors. The g-Prox is able to cut suture. The device can be reloaded *in vivo*.

The device has been used to perform the Primary Obesity Surgery Endolumenal (POSE) procedure. To perform POSE, eight to ten plications are created in the gastric fundus (in retroflexion) in two parallel ridges until the fundic apex is brought down to the level of the gastroesophageal junction. The device is then straightened so that the distal gastric body is visualized. A tissue ridge is created with three or four plications in the distal gastric body across from the incisura. Care should be taken to avoid deep g-Lix insertion in this area, in order to avoid injury of adjacent viscera. After the procedure, patients advance from a clear liquid diet to soft pureed diet during the first month, and then to solid food by six weeks. A study of 45 patients with average body mass index (BMI) 36.7 ± 3.8 kg/m^2 reported six-month weight loss of 16.3 ± 7.1 kg or 15.5% ± 6.1%[3]. BMI decreased by 5.8 ± 2.5 kg/m^2 over six months. Adverse events associated with the procedure included one case of low-grade fever and one case of chest pain. POSE is currently being studied in the ongoing randomized sham-controlled ESSENTIAL trial.

OverStitch for endoscopic sleeve gastroplasty

The Apollo OverStitch (Apollo Endosurgery, Austin, TX) can place full-thickness stitches in a variety of interrupted or running patterns. Sutures can be reloaded without endoscope removal. The OverStitch includes a curved needle driver attached to the tip of the endoscope, a catheter-based suture anchor, and an actuating handle attached near the endoscope controls. A double-channel endoscope is necessary.

The OverStitch can be used to perform endoscopic sleeve gastroplasty (Figure 1). Initial human cases were performed in a three-center study: a pilot study of five patients to establish procedure technique, safety, and feasibility followed by 23 cases to study efficacy[4]. Gastroplasty was performed by placing running stitches in a triangular configuration starting in the antrum and working proximally. Each suture was used to create two conjoined triangles. Between 8 and 14 sutures were placed in this fashion. The procedure included fundic reduction in retroflexion. The sleeve was reinforced with interrupted stitches. BMI in the 23 patients studied for efficacy decreased from 34.2 ± 1.1 kg/m^2 to 29.4 kg/m^2. Gastroplasty using a different method was studied in a single-center pilot trial including four patients with average BMI of 35.9 ± 1.2 kg/m$^{2[5]}$. This technique employed two parallel rows of interrupted plications to create a gastric sleeve. The trial established technical feasibility. The multicenter Primary Obesity Multicenter

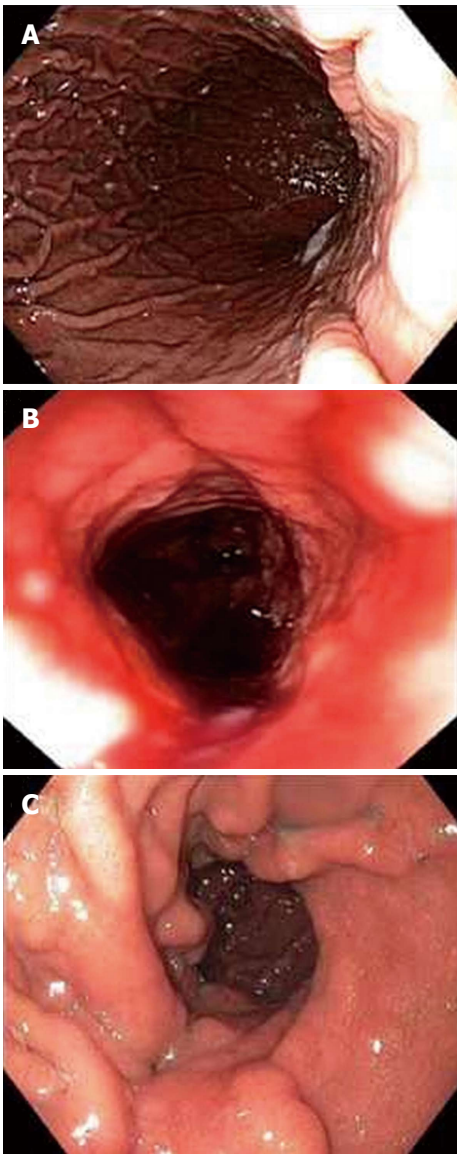

Figure 1 Endoscopic sleeve gastroplasty using Apollo OverStitch: before (A), after (B), and at three months (C)[5].

Incisionless Suturing Evaluation trial to study efficacy of endoscopic sleeve gastroplasty using OverStitch is ongoing in the United States.

EndoCinch for endoscopic gastroplasty

The EndoCinch [Davol, Murray Hill, New Jersey (NJ)] is a superficial-thickness endoscopic suturing system. EndoCinch uses suction to acquire tissue in a hollow capsule, and then passes a needle through the tissue. EndoCinch has been studied for endoscopic gastroplasty in adolescents and adults. A study of gastroplasty in 64 patients with average BMI of 39.9 kg/m^2 reported no serious adverse events[6]. Weight loss of 58.1% ± 19.9% Excess Weight Loss (EWL) was reported after one year. A study of the same procedure in 21 adolescents (age 13-17) with average BMI of 36.2 kg/m^2 reported 67.3% EWL after one year and 61.5% EWL after 18 mo[7]. The device was then modified and named the RESTORe (Davol, Murray Hill, NJ), and was capable of both full-thickness suturing and suture reloading *in vivo*. This device was studied in a two-site trial including 18 patients[8]. There were no significant adverse events. One-year mean weight loss was 11.0 ± 10 kg, or 27.7% ± 21.9% EWL. Half of the patients lost more than 30% of excess weight. Average waist circumference declined by 12.6 ± 9.5 cm. Blood pressure decreased significantly (systolic -15.2 mmHg, diastolic -9.7 mmHg). However, follow-up endoscopy revealed partial or complete release of plications in 13 of 18 patients.

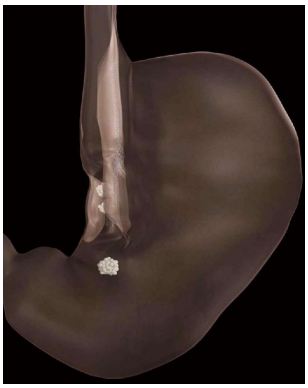

Figure 2 Creation of sleeve using TransOral GAstroplasty[9].

TransOral GAstroplasty

The TransOral GAstroplasty device (TOGA; Satiety Inc, Palo Alto, CA) is a flexible endoscopic stapler capable of full-thickness tissue apposition. The device comprises a stapler and a restrictor. The sleeve stapler comprises a handle and a long but flexible shaft. It also has a short rigid capsule with stapler assembly, two vacuum pods, and a septum at the end. An 8.6 mm endoscope can be passed through the device and retroflexed to visualize the procedure. The stapler creates a vertical sleeve approximately 8 cm long and 2 cm in diameter along the lesser curvature. The restrictor has a long flexible shaft and a short rigid capsule with stapler. It reduces the sleeve outlet to 10-15 mm in diameter. The procedure begins with dilation of the esophagus to 60F with a Savary dilator[9]. The device is inserted into the stomach over a guidewire. Once in position, vacuum apposes the gastric walls, acquiring tissue into the device. Firing the stapler creates a 4.5 cm sleeve around the stapler using titanium staples. The device has to be removed for reloading, and the firing process is repeated once more distally, overlapping the first sleeve. The restrictor is inserted over the guidewire, with the endoscope adjacent to the device. Vacuum acquires tissue into the device at the distal sleeve, and firing the restrictor creates a 2.5 cm long stapled narrowing at the outlet of the sleeve.

TOGA has been studied for endoscopic gastroplasty (Figure 2). A study of 21 patients (average BMI 43.3 kg/m^2) used the first-generation device[10]. There were no serious adverse events, although pain, nausea, vomiting, and temporary dysphagia were reported. Average 6-mo weight loss was 12 kg (24.4% EWL). Endoscopy at that

Figure 3 Transoral Endoscopic Restrictive Implant System restrictive diaphragm[14].

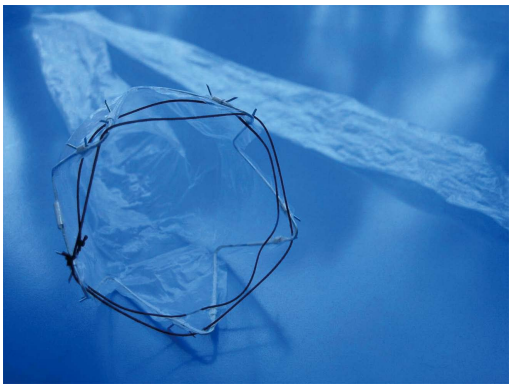

Figure 4 EndoBarrier duodenal-jejunal liner[16].

time found staple line gaps in 13 patients, although every patient had at least a partial sleeve. The second-generation device was studied in 11 patients[11]. In this study, additional distal restrictions were created during retreatment if necessary. No significant adverse events were reported. Six-month weight loss was an average 24.0 kg, and average BMI decreased from 41.6 to 33.1 kg/m^2. A multicenter study of 67 patients reported adverse events including respiratory insufficiency in one case and asymptomatic pneumoperitoneum in another[9]. At one year, patients with BMI $\geqslant$ 40 had 52.2% EWL and patients with BMI < 40 had 41.3% EWL. There were significant improvements in hemoglobin A1c (decline from 7.0% to 5.7%), HDL and triglycerides. A single-center study of 29 patients reported mean BMI decline from 41.7 kg/m^2 to 35.5 kg/m^2 over two years[12]. Average weight loss was 16.8 kg, or 14.9% total body weight loss.

ACE stapler

The ACE stapler (Boston Scientific Corporation, Natick, MA) is an endoscopic stapler with a head capable of both 360-degree rotation and complete retroflexion. A 5-mm endoscope enables visualization; the device is 16 mm in diameter. The stapler head acquires gastric tissue using vacuum suction; firing the stapler creates a full-thickness plication using a 10-mm plastic ring with 8 titanium staples. For gastric volume reduction, up to 8 plications are made in the fundus. Two plications are created in the antrum, which may delay gastric emptying. A prospective safety and feasibility study of gastric volume reduction in 17 patients (median BMI 40.2 kg/m^2) reported median procedure time of 123 min[13]. The most common adverse event was abdominal pain (7 patients); sore throat, diarrhea, nausea, constipation, and vomiting were also reported. All were self-limited. Median EWL was 34.9% (interquartile range 17.8-46.6). Endoscopy performed at 12 mo (in 11/17 patients) revealed 6-9 plications in all participants, as well as durability of gastric volume reduction.

Transoral Endoscopic Restrictive Implant System

Unlike the aforementioned devices, Transoral Endoscopic Restrictive Implant System (TERIS) (Barosense, Menlo Park, CA) is an implanted device. A gastric pouch is created by implanting a diaphragm with a 10-mm orifice. This is attached to the cardia (Figure 3). For implantation, a 22-mm endogastric tube is inserted. A gastroscope with a stapling device is retroflexed, and a full-thickness plication is created in the cardia. An anchor is attached to the plication. This is repeated until five anchors have been implanted. The restrictive diaphragm is then attached to the anchors. A study of TERIS in 13 patients reported three adverse events: One gastric perforation and two cases of pneumoperitoneum[14]. The procedure was modified after these events, and no further adverse events occurred. In total, 12 of 13 implantation procedures were successful. Procedure time was 142 min on average. Weight loss at three-month follow-up was 16.9 kg or 22.2% EWL; median BMI fell from 42.1 to 37.9 kg/m^2.

BYPASS DEVICES AND PROCEDURES

Bypass of the small intestine is thought to have a significant role in the weight loss and metabolic benefits experienced after certain bariatric surgeries. Animal models suggest that duodenal exclusion and accelerated arrival of partially-digested meals to mid-jejunum and ileum are partially responsible for the salutary effects of gastric bypass in diabetes and obesity. Endoscopically implanted devices have been developed to reproduce this effect.

EndoBarrier duodenal-jejunal bypass liner

The EndoBarrier duodenal-jejunal bypass device (GI Dynamics, Lexington, MA) comprises a nickel-titanium implant attached to a 60 cm polymer sleeve (Figure 4). The sleeve extends from the duodenal bulb into the jejunum. It prevents food from contacting the mucosa of the small intestine, but allows pancreaticobiliary secretions to move along the outside of the device to the jejunum. Additionally, it allows food to reach the mid-jejunum earlier. The device is placed endoscopically, with fluoroscopic guidance, under general anesthesia. A guidewire is advanced into the duodenum. The sleeve

and anchor are enclosed in a capsule, which is advanced over the guidewire. The sleeve is deployed in the intestine; once it is fully extended, the anchor is deployed in the duodenal bulb approximately 5 mm distal to the pylorus. Device removal is also performed under general anesthesia. A foreign body hood is placed at the tip of the endoscope, and the device is removed by securing the anchor with a procedure-specific grasping device.

A multicenter randomized trial compared 30 EndoBarrier patients (BMI 48.9 kg/m^2) with 11 controls (BMI 47.4 kg/m^2)[15]. No serious adverse events were reported. However, four of 30 EndoBarrier patients required removal due to migration, obstruction, pain, or anchor dislocation. The EndoBarrier group had significantly higher weight loss at three months, with BMI decrease of 5.5 kg/m^2 *vs* 1.9 kg/m^2 in control patients. Notably, 7 of 8 diabetics in the EndoBarrier group had improvement in diabetes.

A multicenter randomized trial including 25 patients reported successful EndoBarrier implantation in 21 patients, with implantation failure in patients with small duodenal bulb[16]. Adverse events resulted in device explantation in seven of 21 implanted patients, including three cases of bleeding that presented as hematemesis. There was significantly more weight loss in the EndoBarrier group: (8.2 ± 1.3 kg *vs* 2.0 ± 1.1 kg).

A randomized trial of 39 patients assigned 25 patients to EndoBarrier and 14 patients to the control group[17]. At 3 mo, the EndoBarrier group had 22% EWL *vs* 5% EWL in controls. The adverse event rate, including bleeding, migration, and obstruction, was 20%.

A multicenter randomized controlled trial including 77 patients with obesity and type Ⅱ diabetes included 31 patients who completed EndoBarrier therapy and 35 controls who completed dietary intervention[18]. The EndoBarrier group experienced 32.0% EWL *vs* 16.4% in the control group; the EndoBarrier group also had a significantly larger improvement in hemoglobin A1c (P < 0.05 for both). After the EndoBarrier had been removed for 6 mo, EWL was 19.8% *vs* 11.7% in controls (P < 0.05).

A one-year prospective open-label trial of 42 patients reported that 39 patients were successfully implanted[19]. Premature explantation was necessary in 15 patients due to anchor movement in 8 patients, device obstruction in 3 patients, abdominal pain in 2 patients, acute cholecystitis in 1 patient, and one patient request. Initial average BMI was 43.7 ± 5.9 kg/m^2. At 1 year, the 24 patients with EndoBarrier in place experienced weight loss of 22.1 ± 2.1 kg or 47.0% ± 4.4% EWL, and BMI decline of 9.1 ± 0.9 kg/m^2. Waist circumference decreased significantly, from 120.5 ± 6.8 cm to 96.0 ± 2.6 cm. Statistically significant improvements were also reported in blood pressure, hemoglobin A1c, cholesterol, low-density lipoprotein, triglycerides, and prevalence of metabolic syndrome.

A modified EndoBarrier with a 4-mm flow-restriction orifice was implanted in 10 patients with average BMI of 40.8 kg/m^2[20]. Eight of 10 patients in the trial developed abdominal pain, nausea, and vomiting; they required balloon dilation of the restrictive orifice. Weight loss at three months was 16.7 ± 1.4 kg.

SPACE-OCCUPYING DEVICES

Space-occupying devices displace volume and induce gastric distention, but may also alter gastrointestinal motility, nutrient transit, and hormone levels[21]. One space-occupying device, the intragastric balloon, was described in 1982 and approved for American use in 1985[22]. In the intervening decades, balloons have built a track record of safety and efficacy in Europe, and are likely to reappear in the United States. The intragastric balloon has found a role as a bridge to bariatric surgery in patients with high risk for anesthesia, temporary use in patients eligible for bariatric surgery but unwilling to undergo it, and temporary use in patients not eligible for bariatric surgery as part of an integrated medical weight loss program[23]. Space-occupying devices other than balloons are in clinical trials.

Orbera intragastric balloon

The Orbera (formerly BioEnterics) intragastric balloon (Apollo Endosurgery, Austin, TX) is an endoscopically implanted spherical silicone elastomer device. The balloon is placed in the stomach and then filled with saline (and where allowed, methylene blue dye, which alters urine color in case of balloon perforation). The balloon is resistant to gastric acid, and is indicated for insertion for up to six months. The device is inflated in the gastric fundus during endoscopic visualization using 500-750 mL saline and 10 mL methylene blue.

Orbera balloon placement was studied in a meta-analysis of 3698 patients[24]. Early device removal was required in 4.2% of patients; reported adverse events included nausea, vomiting, bowel obstruction (0.8%), and gastric perforation (0.1%). Average weight loss after six months was 14.7 kg or 32.1% EWL, with drop in BMI of 5.7 kg/m^2. The largest study in the meta-analysis, which included 2515 patients, reported average decrease in BMI of 9.0 kg/m^2 over six months[25]. Notably, statistically significant improvement was reported in blood pressure, fasting glucose, and lipid profile. Significant decrease in or normalization of hemoglobin A1c was reported in 87.2% of the 488 diabetic patients in the study. Two instances of mortality were reported, both in patients with prior gastric surgery.

The long-term weight loss trend after removal of the Orbera balloon was studied in 500 patients[26]. Average BMI before therapy was 43.7 kg/m^2. Success was defined as ⩾ 20% EWL. At the time of balloon removal, 83% of patients had reached this threshold, with average loss of 23.9 ± 9.1 kg and BMI loss of 8.3 kg/m^2. In the 41% of patients available five years after balloon removal, the successful group had average loss of 7.3 ± 5.4 kg and average BMI loss of 2.5 kg/m^2.

The effectiveness of a second Orbera balloon place-

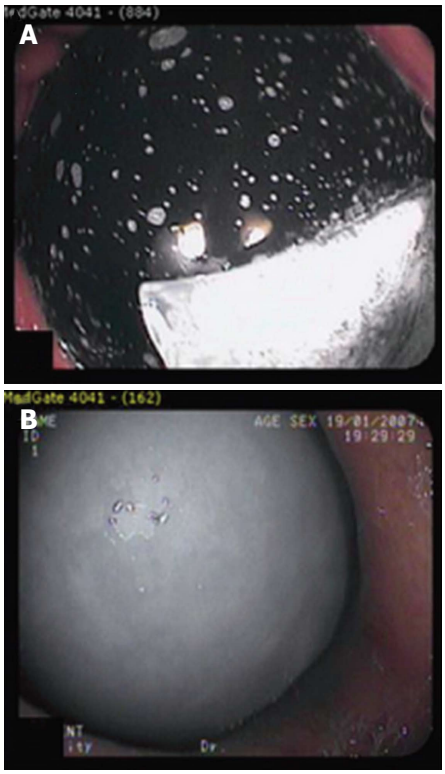

Figure 5 The Orbera intragastric balloon (A) and Heliosphere BAG (B)[34].

ment was studied in a prospective trial of 118 patients[27]. The balloon was replaced immediately in 8 patients, replaced after a balloon-free interval in 11 patients, and not replaced in 99 patients. Those patients undergoing a second balloon placement with a balloon-free interval regained 13.6 kg on average during that interval. The second balloon therapy did result in weight loss, although its magnitude was smaller than that of the initial therapy (9.0 kg *vs* 14.6 kg, or 18.2% EWL *vs* 49.3% EWL). The effect of second balloon placement dissipated by the third year of follow-up. A study of 112 patients undergoing a second Orbera balloon placement within one month of removing the first balloon found average BMI loss of 2.5 kg/m^2 with the second balloon in addition to BMI loss of 6.5 kg/m^2 with the first balloon[23].

The utility of the Orbera balloon as a bridge to gastric bypass was studied in 60 consecutive super-super obese subjects with average BMI of 66.5 ± 3.4 kg/m^2[28]. The balloon was placed in 23 patients, while 37 patients went to surgery without prior balloon therapy. In the Orbera group, the balloon was in place for 155 ± 62 d. The balloon group achieved BMI loss of 5.5 ± 1.3 kg/m^2 at the time of gastric bypass, as well as statistically significant decreases in systolic blood pressure and gamma-glutamyl transpeptidase. The operative time for performance of gastric bypass was shorter in the Orbera group (146 ± 47 *vs* 201 ± 81 min). The Orbera group also experienced significantly fewer major adverse events (defined as conversion to laparotomy, ICU stay longer than 2 d, and total hospital stay longer 2 wk): 2 events *vs* 13 in patients who did not have balloon placement. Weight loss was similar between groups one year after gastric bypass.

The metabolic effects of Orbera balloon placement were examined in a prospective trial including 130 patients (average BMI 43.1 kg/m^2)[29]. Premature balloon explantation was required in ten patients due to intolerance, abdominal pain, or vomiting. Patients were maintained on a 1000-1200 daily kilocalorie diet during the 6-mo balloon therapy period. Average weight loss was 13.1 kg, with decrease in prevalence of class Ⅳ obesity from 23% to 8%. Metabolic effects included decrease in the prevalence of hyperglycemia from 50% to 12%, and hypertriglyceridemia from 58% to 19%. Patients with decrease in BMI of greater than 3.5 kg/m^2 experienced a significant decrease in the prevalence of severe hepatic steatosis from 52% to 4%. Weight regain occurred in 50% of the patients in the follow-up period (median 22 mo) after balloon removal.

Dietary counseling during Orbera balloon therapy was been found to be beneficial in a study of 28 patients[30]. Patients saw a dietitian weekly for two weeks, every two weeks for one month, and then monthly while the balloon was in place. BMI declined from 32.4 ± 3.7 kg/m^2 to 28.5 ± 3.7 kg/m^2 with therapy. Of the patients who achieved at least 20% EWL, 85% had attended at least half of dietitian appointments. Of patients failing to reach 20% EWL, 75% had missed at least half of dietitian appointments.

Orbera balloon therapy is associated with mental health benefits in patients with depression[31]. In this study, 100 consecutive female patients were characterized as depressed (65 patients) or non-depressed (35 patients) using the Beck Depression Inventory score. Other characteristics were similar between groups. Weight loss was similar between groups (39.3% EWL in depressed patients *vs* 36.1% EWL in non-depressed patients). The Depression Inventory score improved from 20.3 ± 8.5 to 7.9 ± 5.6 during balloon therapy. Resolution of depression occurred in 70.8% of the depressed patients, with a decrease in the prevalence of severe depression (27.7% to 1.5%).

Heliosphere BAG

The Heliosphere BAG is filled with 950 mL of air rather than fluid. The Heliosphere BAG has been compared with the Orbera balloon (Figure 5)[32]. Sixty patients with average BMI of 46.3 kg/m^2 were randomly assigned. The Heliosphere group achieved BMI decrease of 4.2 kg/m^2, *vs* 5.7 kg/m^2 in the Orbera group. The Heliosphere group had significantly longer extraction procedure time and significantly more discomfort during extraction.

A prospective study of 91 patients compared the Orbera balloon (73 patients) with Heliosphere BAG (18 patients, mean BMI 45.2 kg/m^2)[33]. Balloons were implanted for six months, and 13.2% were removed early due to intolerance. Average weight reduction at six months was 13.3 kg, and BMI reduction was 5 kg/m^2; 88% of weight reduction occurred in the first three

months. Weight loss was similar between balloon types. The Heliosphere BAG deflated and passed spontaneously in 2 cases. Balloon extraction was difficult in 8 cases, and a rigid esophagoscope as required in 4 cases; laparoscopic surgery was required to remove BAG in 1 case. BAG was significantly more likely to result in retrieval complications.

A nonrandomized study compared Heliosphere BAG with the Orbera balloon in patients who failed six months of medical and dietary weight loss therapy[34]. The Orbera balloon was placed in 19 patients (BMI 45.6 ± 9 kg/m^2), and the Heliosphere BAG was placed in 13 patients (BMI 45.0 ± 8 kg/m^2). The Orbera balloon was more effective, with weight loss of 19.0 kg *vs* 13.0 kg for Heliosphere BAG. One patient with the Orbera balloon required removal for persistent nausea and vomiting at one month. There was one mortality in the Orbera group 13 d after placement.

Reshape Duo intragastric balloon

The Duo intragastric balloon (Reshape, San Clemente, CA) contains two silicone spheres filled with a total of 900 mL of saline, which prevents migration if one balloon deflates. A prospective trial of Duo included 30 patients at three centers (21 Duo *vs* 9 controls)[35]. Both groups received diet and exercise counseling. Four of the 21 Duo patients were readmitted for nausea, and two patients were found to have gastritis at the time of balloon removal. After 48 wk, 30% of the Duo patients achieved 25% EWL, *vs* 25% of the control patients.

Obalon intragastric balloon

The Obalon intragastric balloon (Obalon Therapeutics, Carlsbad, CA) is a 250-mL gas-filled balloon which is swallowed under fluoroscopic visualization rather than inserted endoscopically. The balloon is enclosed in a capsule. A catheter, which extends through the esophagus and outside the mouth, is used to fill the balloon with gas. The balloon is removed endoscopically; it is punctured and then grasped with forceps for extraction. If the balloon is tolerated and induces weight loss, a second balloon can be swallowed at 4 wk and a third balloon at 8 wk. A study including 17 patients with BMI ranging from 27 to 35 kg/m^2 reported that 98% of balloons were swallowed successfully[36]. Abdominal pain (in 76%) and nausea (in 41%) were the most frequent adverse events. All balloons were removed endoscopically, under conscious sedation, at 12 wk.

Transpyloric Shuttle

The Transpyloric Shuttle (BAROnova, Goleta, CA) is made of a large spherical bulb attached to a smaller cylindrical bulb by a flexible tether. The cylinder is small enough to enter the duodenal bulb with peristalsis, and pulls the spherical bulb to the pylorus. The spherical bulb is too large to traverse the pylorus, but occludes it intermittently to reduce gastric emptying. The device is delivered transorally *via* catheter and removed endoscopically. A single-center nonblinded prospective trial of 20 patients with average BMI of 36.0 kg/m^2 reported loss of 8.9 ± 5.2 kg, or 31.3% ± 15.7% EWL, at 3 mo[37]. Six-month weight loss was 14.6 ± 5.7 kg, or 50.0% ± 26.4% EWL. Two patients required early removal due to persistent ulcer.

SatiSphere

The SatiSphere (Endosphere, Columbus, OH) is made from a preformed memory wire with curled ends that conforms to the shape of the duodenum. The device anchors itself in the distal stomach and in the duodenum. Several mesh spheres are mounted along the wire. SatiSphere slows duodenal transit of food, which may alter satiety hormones levels and glucose metabolism. A trial of 31 patients with average BMI of 41.3 kg/m^2 compared 21 SatiSphere patients with 10 controls[38]. Device migration was reported in 10 of 21 implanted patients. Emergency surgery was necessary in two patients. Of patients completing the trial, three-month weight loss was 6.7 kg in the SatiSphere group *vs* 2.2 kg in controls. SatiSphere was associated with delayed glucose absorption, delayed insulin secretion, and altered glucagon-like peptide-1 kinetics.

ASPIRATION THERAPY

AspireAssist

The AspireAssist (Aspire Bariatrics, King of Prussia, PA) is a modified percutaneous endoscopic gastrostomy tube with an external accessory capable of aspirating a portion of ingested caloric intake. The device includes a large-bore gastrostomy tube with holes in the intragastric portion; this is attached to a skin port with a connector and valve placed at the skin (Figure 6). A 600-mL reservoir allows for flushing and aspiration of gastric contents after meals.

A randomized trial of 18 patients assigned 11 to AspireAssist and 7 to the control group; all patients underwent a 15-session diet and behavioral education program[39]. At one year, 10/11 Aspire patients and 4/7 control patients remained in the trial. Weight loss was 18.6% ± 2.3% of total body weight in Aspire patients *vs* 5.9% ± 5.0% in controls. Of the ten Aspire patients in the trial at one year, seven chose to continue for another year; this group reached 20.1% ± 3.5% total body weight loss. Notably, there was no evidence of increased food intake to compensate for the aspirated food. Reported adverse events included abdominal pain at the aspiration tube site, which improved after the device was redesigned; infection in three patients requiring topical medication or oral antibiotics; and persistent gastrocutaneous fistula (which eventually closed spontaneously) in one of the four patients who underwent aspiration tube removal. A prospective multicenter clinical trial, PATHWAY, is ongoing.

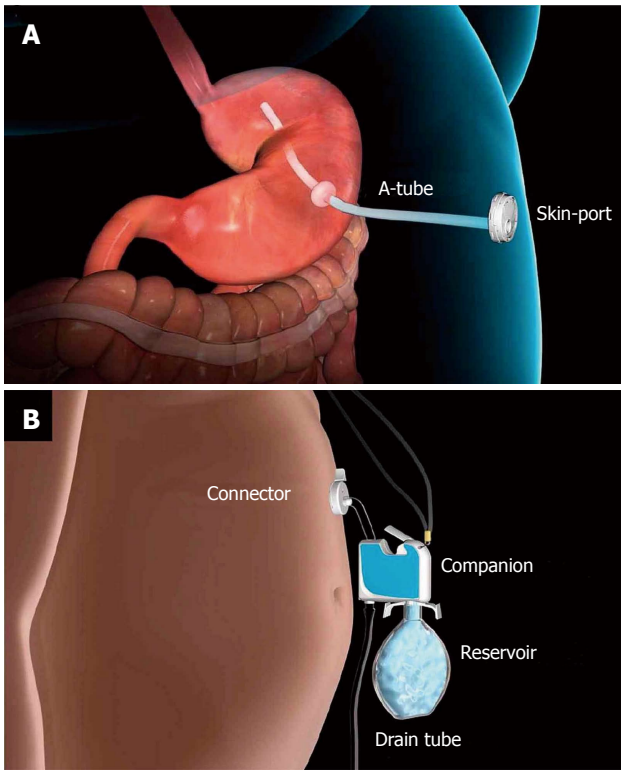

Figure 6 The Aspire aspiration tube (A) and AspireAssist (B)[39].

ENDOSCOPIC REVISION OF GASTRIC BYPASS

Roux-en-Y gastric bypass can induce 56.7%-66.5% EWL during the two years after surgery[40]. Comorbidities associated with obesity, including hypertension, diabetes, obstructive sleep apnea, and hyperlipidemia, often improve or resolve. It is postulated that small gastric pouch size and gastrojejunal anastomosis aperture create a restrictive effect. A weight plateau typically occurs as equilibrium in energy balance is reached 12 to 18 mo after gastric bypass[41]. However, approximately 20% of patients fail to achieve 50% EWL in the first year after gastric bypass. Additionally, 30% of patients regain weight by 18 to 24 mo after bypass; average regain of 18 kg has been reported at 2 years[42,43]. The long-term outcome of gastric bypass is affected by a number of factors, including preoperative BMI and postoperative diet and lifestyle[44]. Weight regain may be induced by neuroendocrine-metabolic dysregulation resulting in a starvation-like response[45,46]. Anatomic factors may also play a role: increased gastrojejunal anastomotic aperture may result in loss of restriction, and has been associated with weight regain in a linear fashion[5,47,48].

Surgical procedures, including reconstruction of the gastrojejunal anastomosis, placement of an adjustable gastric band over the gastric pouch, surgical revision of the pouch, and distal gastric bypass, are available to treat weight regain; however, few patients undergo surgical revision. Revision surgery is challenging in the context of older patients, altered anatomy, scarring, and adhesions; complication and mortality rates are higher than that of primary gastric bypass[49,50]. Endolumenal revision is an attractive option in this patient set. Endoscopic suturing, plication, and sclerotherapy are discussed here.

EndoCinch for transoral outlet reduction

The EndoCinch (Bard Davol, Murray Hill, NJ), as described above for endoscopic gastroplasty, is a superficial-thickness suturing device which uses suction to acquire tissue. The EndoCinch has been used to perform transoral outlet reduction (TORe), or endoscopic revision of gastric bypass. First, the entire gastric margin of the gastrojejunal anastomosis is ablated with argon plasma coagulation. The aperture of the gastrojejunal anastomosis is then reduced by placing interrupted stitches at the anastomotic margin, across the anastomotic opening. Cinching the sutures apposes the anastomotic margin, reducing the diameter of the anastomosis. The volume of the gastric pouch can be reduced by creating ridges and suturing them together.

Use of the EndoCinch for TORe was first reported in 2004[51]. The device was used in RESTORe, a randomized sham-controlled double-blinded multicenter trial which resulted in level 1 evidence for the effectiveness of endoscopic suturing in revision of gastric bypass[52]. Seventy-seven patients with gastrojejunal anastomosis aperture larger than 20 mm were randomized to TORe or to sham endoscopy. Average BMI was 47.6 kg/m^2. Anastomotic aperture of < 10 mm was achieved in 89% of TORe patients. There was no difference in the adverse event rate between groups, and no perforations occurred. In the intent-to-treat analysis, total body weight loss was 3.8% in TORe patients *vs* 0.3% in the sham group (P = 0.02). Weight stabilization or weight loss was achieved in 96% of TORe patients during the 6-mo follow-up period.

OverStitch for TORe

Apollo OverStitch, as described in detail above for endoscopic sleeve gastroplasty, is reloadable *in vivo* and is capable of placing full-thickness sutures in a variety of stitch patterns. After TORe is performed to reduce the aperture of the gastrojejunal anastomosis, gastric pouch size can be reduced and fistulas can be closed during the procedure. TORe should be performed using general anesthesia, endotracheal intubation, and carbon dioxide insufflation. An overtube should be placed. Upper endoscopy is performed to ablate the margin of the gastrojejunal anastomosis. This can be performed using end-firing argon plasma coagulation (at 30 watts) to create a ring 5-10 mm thick around the margin of the anastomosis, or performance of endoscopic mucosal resection around the anastomosis. Anastomotic reduction can be performed using an interrupted technique, in which stitches are placed across the anastomosis and then cinched to appose its margins. Alternatively, a pursestring suture technique can be used (Figure 7). The pursestring technique potentially confers a number of benefits compared with the interrupted technique. It

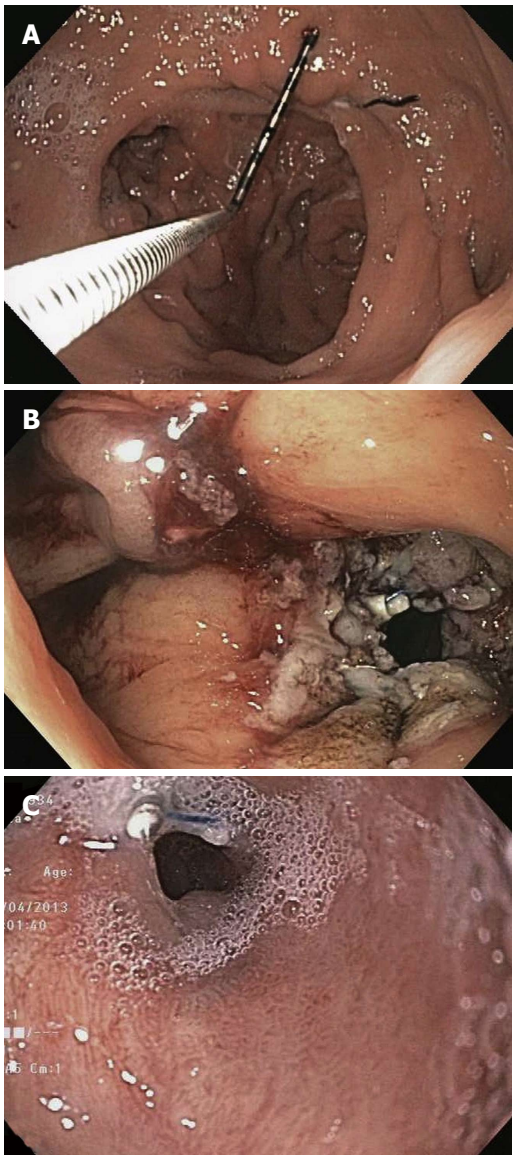

Figure 7 Gastrojejunal anastomosis before (A), immediately after (B), and six months after (C) TORe using Apollo OverStitch[54].

allows the use of a sizing balloon, which ensures precise control of final anastomosis aperture. It reinforces the entire circumference of the anastomosis against future dilation, and against transient compliant dilation during meals. In contrast, the interrupted technique closes part of the lumen entirely, but does not reinforce the remaining anastomotic margin, and the final anastomotic diameter cannot be precisely controlled. To perform anastomotic reduction using the pursestring technique, a running pursestring suture is placed around the anastomosis. A controlled radial expansion balloon is passed through the second channel of the endoscope and inflated to 8-10 mm. The pursestring is tightened around the balloon, and the suture is cinched. A second pursestring can be placed around the anastomosis for reinforcement.

Endoscopic revision of gastric bypass using OverStitch proved effective in a study of 25 patients[53]. Gastrojejunal anastomosis aperture was reduced from 26.4 mm to 6 mm on average. No significant adverse events were reported. Patients lost an average 11.7 kg during the 6-mo follow-up period, or 69.5% of regained weight. Endoscopic revision of gastric bypass using the superficial-thickness EndoCinch and full-thickness OverStitch were directly compared in a matched cohort study[54]. The interrupted stitch technique was used in both groups, and the technique used in the EndoCinch patients was the same technique used in the RESTORe trial. One hundred eighteen patients (59 in each group) were sequentially matched by gastrojejunal anastomosis aperture, then BMI, and then age. Average weight loss at six months was significantly higher in patients undergoing full-thickness suturing (4.4 ± 0.8 kg with EndoCinch *vs* 10.6 ± 1.8 kg with OverStitch, $P < 0.01$). One-year weight loss was also significantly higher in the OverStitch group (2.9 ± 1.0 kg with EndoCinch *vs* 8.6 ± 2.5 kg with OverStitch, $P < 0.01$).

IOP for Revision Obesity Surgery Endolumenal

The IOP (USGI Medical, San Clemente, CA), as described in detail above for the POSE procedure, is capable of performing full-thickness tissue plication by placement of tissue anchors. The platform has been optimized specifically for endoscopic revision of gastric bypass, called Revision Obesity Surgery Endolumenal (ROSE). ROSE entails reduction of dilated gastric pouch and gastrojejunal anastomosis aperture. A prospective study included 20 patients with weight regain[55]. The procedure was technically successful in 85%, with reduction of anastomotic aperture by an average of 65% and reduction of gastric pouch length by 36%. Anastomotic aperture was reduced to an average of 16 mm. Average weight loss was 8.8 kg after 3 mo. A subsequent iteration of the device was studied in five patients, with all five patients losing weight (average weight loss was 7.8 kg)[56]. A prospective multicenter trial of 116 patients with dilated gastrojejunal anastomosis and gastric pouch achieved technical success in 97%[57]. Gastrojejunal anastomosis aperture was reduced by an average of 50%, and the gastric pouch was shortened by an average of 44%. No significant procedural complications occurred; three patients had superficial esophageal tears, one of which required placement of an endoscopic clip. Pharyngitis was reported in 41% of patients, nausea and vomiting in 12%, and abdominal pain in 11%. During the 6-mo follow-up period, patients lost 32% of the weight regained after Roux-en-Y gastric bypass. Patients with anastomotic aperture of less than 10 mm at the end of the procedure experienced 24% EWL. The device has since been further optimized for revision of gastric bypass.

StomaphyX

StomaphyX (EndoGastric Solutions, Redmond, Washington) is a full-thickness tissue plication platform capable of endoscopic revision of gastric bypass. It uses vacuum to acquire a fold of the gastric pouch.

Polypropylene H-fasteners are passed through the tissue to create full-thickness plications. Without removal of the device, 3 to 4 rows with 4 to 6 plications each (a total of 12-24) are created circumferentially around the margin of the anastomosis.

A study of StomaphyX in 39 patients with average BMI of 39.8 kg/m^2 reported no adverse events[58]. EWL was 13.1% after 3 mo and 19.5% after 1 year. A subsequent study of 64 patients with average BMI of 39.5 kg/m^2 reported placement of an average 23 plications, resulting in reduction of anastomotic diameter from 22 mm to 9 mm[59]. One patient had bleeding that did not require transfusion; no other significant adverse events were reported. During follow up (average 5.8 mo), patients lost an average 7.6 kg. A retrospective study of 59 patients with mean BMI of 36.1 kg/m^2 reported mean weight loss of 3.8 kg and 11.5% EWL after 6 mo[60]. However, endoscopy in 12 patients at an average of 18 mo after revision showed no sustained reduction in pouch or anastomosis size. Mean follow-up duration was 41 mo, with average loss of 1.7 kg; 35.8% of patients had actually gained weight by this point. A randomized sham-controlled single-blind trial of StomaphyX revision with SerosFuse fasteners was terminated prematurely due to failure to reach preliminary efficacy targets. There was one adverse event in the StomaphyX group, and laparoscopic exploration and repair were necessary. A total of 45 StomaphyX patients and 29 sham patients completed 1-year follow-up. Of these, 22.2% of the StomaphyX patients and 3.4% of the sham patients achieved 15% excess BMI loss ($P < 0.01$). The StomaphyX group had significantly more weight loss at 6 and 12 mo ($P \leqslant 0.05$).

Endoscopic sclerotherapy

Endoscopic sclerotherapy entails injection of a sclerosant, such as sodium morrhuate, around the gastrojejunal anastomosis to reduce compliance and aperture. The procedure can be performed under conscious sedation in many patients. The anastomotic aperture should be measured prior to injection, as measurement afterwards will be inaccurate due to transient edema. A test dose of the sclerosing agent should be injected at the rim of the anastomosis, and the patient should be monitored for an adverse reaction before further injection. Approximately 2 mL should be injected into the submucosa at the margin of the gastrojejunal anastomosis until a bleb forms. Several such injections are performed around the anastomotic margin, for a total of 10-25 mL[61]. Overinjection is indicated by dark red or black discoloration and subsequent overt bleeding. Intravenous ciprofloxacin should be given as prophylaxis prior to the procedure, followed by a five-day course of liquid ciprofloxacin or trimethoprim-sulfamethoxazole. The patient should can start a liquid diet the day after the procedure and advance to a regular diet during the month after the procedure. Sclerotherapy can be repeated every 3-6 mo until the anastomosis aperture has reached a target of 12 mm; two or three sessions are often necessary[62]. The development of scar tissue after each sclerotherapy session can eventually make submucosal injection difficult.

Endoscopic sclerotherapy has proven effective in arresting weight regain after gastric bypass. One study including 28 patients reported that most patients (64%) lost more than 75% of regained weight[62]. An average of 2.3 sessions was required. Notably, patients with anastomotic aperture larger than 15 mm did not benefit. A study of 32 patients reported arrest or reversal of weight regain in 91.6% of patients at 1 year[61]. A study of 71 patients reported arrest or reversal of weight regain in 72% of patients after 1 year[63]. A recent study of 48 patients undergoing sclerotherapy reported average loss of 1.45 kg during a follow-up period averaging 22 mo[64]. Although weight regain was arrested, weight loss after sclerotherapy was not significant. The largest published series included 231 consecutive patients with mean anastomosis diameter of 19 mm undergoing 575 sclerotherapy sessions[65]. Weight regain was arrested in 78% of patients at one year after sclerotherapy. Average weight loss at six months was 4.5 kg. Bleeding occurred in 2.4%, with 57% of those requiring endoscopic clip placement. Transient elevation in blood pressure was observed in 15%, and was associated with higher injection volume. Small ulcerations were found on follow-up endoscopy in 1%.

CONCLUSION

The global obesity epidemic has continued to expand despite the availability of diet and lifestyle counseling, pharmacologic therapy, and bariatric surgery. Endoscopic therapies for weight loss have the potential to transform the treatment of obesity. Given the variety of devices under development, in clinical trials, and in use, patients will have multiple options with greater efficacy than medical therapy, and with lower invasiveness and greater accessibility than bariatric surgery. Endoscopic therapies have also proven safe and effective for revision of bariatric surgery. As data for safety, efficacy, and cost effectiveness of endoscopic therapies accumulates over the coming years, endoscopists will play a leading role in the management of obesity and metabolic disease.

Abstract

In this review, I outline the characteristic endoscopic findings of serrated lesions of the colorectum based on image enhanced endoscopy (IEE). Histopathologically, lesions with serrated structures are typically classified into the following three types based: hyperplastic polyps (HPs), traditional serrated adenomas (TSAs), and sessile serrated adenoma/polyps (SSA/Ps). Both HP and SSA/P often present as dark-green colors on auto fluorescence imaging (AFI) colonoscopy that are similar to the normal surrounding mucosa. In contrast, TSAs often have elevated shapes and present as magenta colors that are similar to the tubular adenomas. The superficial type of TSA also includes many lesions that present as magenta colors. When SSA/Ps are associated with cytological dysplasia, many lesions present with magenta colors, whereas lesions that are not associated with cytological dysplasia present with dark-green colors. When observed *via* narrow band imaging (NBI), many SSA/P include lesions with strong mucous adhesions. Because these lesions are observed with reddish mucous adhesions, we refer to them as "red cap sign" and place such signs among the typical findings of SSA/P. Because the dilatation of the pit in SSA/P is observed as a round/oval black dot on magnified observations, we refer to this finding as Ⅱ-dilatation pit (Ⅱ-D pit) and also positioned it as a characteristic finding of SSA/P. In contrast, dilatations of the capillary vessels surrounding the glands, such as those that occur in tubular adenoma, are not considered to be useful for differentiating HPs from SSA/Ps. However, in cases in which SSA/P is associated with cytological dysplasia, the dilatation of capillary vessels is observed in the same area. When submucosal layer invasion occurs in the same area, the blood flow presents with irregularities that are similar to those of common colorectal cancer at an early stage and disappears as the invasion proceeds deeply. The surface pattern of invasive cancer that is observed at the tumor surface is also likely to disappear. Based on the above results, we considered that the differentiations between HP and TSA, between TSA and SSA/P, and between HP and SSA/P might become easier due to the concomitant use of white light observation and IEE. We

also concluded that AFI and NBI can be useful modalities for SSA/P lesions associated with cytological dysplasia.

Key words: Image enhanced endoscopy; Hyperplastic polyp; Early colon cancer; Traditional serrated adenoma; Sessile serrated adenoma/polyp

Core tip: Histopathologically, "serrated lesions" are categorized by the World Health Organization into three groups: (1) hyperplastic polyp; (2) traditional serrated adenoma; and (3) sessile serrated adenoma/polyp (SSA/P). I have discussed the findings associated with each lesion type as observed on image enhanced endoscopy. Regarding HPs and SSA/Ps, it is easy to differentiate both lesions. Especially, dilatations of the gland orifices are frequently observed in SSA/P and appear as blackish dotted orifices. And a thick mucous adhesion referred to as a "mucous cap" can be confirmed as red mucus on narrow band imaging observation and can be recognized when it adheres to the surface of a "red cap" polyp in SSA/P.

INTRODUCTION

Among colon polyps, hyperplastic polyps (HPs) have previously been defined as non-neoplastic lesions and are not considered to be lesions that are indicated for endoscopic treatment[1]. However, since the mid-1980's, reports on HP lesions associated with neoplastic changes have become more common[2,3] and it has been suggested in 1990 that the serrated lesions that are associated with neoplastic changes be referred to as serrated adenomas[4] to differentiate them from HPs. Later, in 2003, there was a report of a lesion with a gland structure that was an extremely similar to that of HP, and this lesion invaded into the submucosal layer (SM) primarily in the right colon[5].

Therefore, several guidelines for colon polyps have been published regarding the indications for the endoscopic treatment of sessile serrated lesion in the past several years[6-9]. However, the details of the endoscopic characteristics of sessile serrated lesions (SSLs) have obviously never been described in terms of guidelines. Particularly, the macroscopic appearances of SSLs present as flat elevations in the proximal colon, and it has been suggested that proximal serrated lesions, which can be more difficult to find than lesions in the distal portion due to the fold, might have an important role in this limitation[10-13]. Thus, Butterly *et al*[14] recommended that more time should be taken to withdraw to enable the detection of SSLs in the proximal colon.

Here, we would like to illustrate the characteristic endoscopic findings from these serrated lesions of the colorectum, particularly as observed with image enhanced endoscopy (IEE). These endoscopic images are observed with a Lucera Elite system® (Olympus Medical Science, Tokyo Japan).

ENDOSCOPIC FEATURES WITH PATHOLOGICAL FINDINGS

Histopathologically, "serrated polyps" can be categorized into the following three types according to the World Health Organization (WHO) classification[15] (Table 1): (1) HPs; (2) traditional serrated adenomas (TSAs); and (3) sessile serrated adenoma/polyps (SSA/Ps). All of these lesions have serrated structures within the crypts from the histological perspective: however, the extent to which these tissue diagnostic standards have become widespread and commonly understood among gastroenterological pathologists across the world remain unclear[16]. Especially, the definition of all sessile serrated adenomas and sessile serrated polyps are not as neoplastic changed lesions despite of the usage of "adenoma". Therefore there is a strong possibility to confuse whether neoplastic or non-neoplastic lesions for SSA/Ps.

Here, the conventional endoscopic features, including those from magnified examinations, related to SSLs are reviewed based on previous reports[9,17-19].

HP (Figure 1)

HPs can be categorized into the following three subtypes based on histological findings: (1) microvesicular HPs: MVHPs (Figure 1A); (2) goblet-cell rich HPs: GCHPs (Figure 1B); and (3) mucin-poor HPs: MPHPs (Figure 1C). Of these, MVHPs are thought to often be found often in the right side of the colon, and GCHPs are often found in the left side of the colon. The incidence of MPHPs is low[20-23]. All of these lesions are small in diameter and treated as non-neoplastic lesions[24].

The characteristic endoscopic findings of these HPs are that they generally present with pale colors and the boundaries with the normal surrounding mucosa are occasionally obscure. Adhesions of the mucus are also commonly observed on the surface. Large tumors are often found in the right side of the colon and differentiation between the above-mentioned MVHPs and SSA/Ps can be necessary. HPs characteristically presents with primarily asteroid shaped pits (type Ⅱ pits) on magnifying endoscopy (ME).

SSA/P (Figures 2-4)

Prior to the proposal of a definition of SSA/Ps based on pathological criteria, SSA/Ps were termed "large HPs[25]", "giant HPs[26]", *etc.* Therefore, these sessile serrated lesions thought to be defined as a single entity.

SSA/Ps are primarily located in the right side of the colon and account for 3%-9% of all of the colorectal

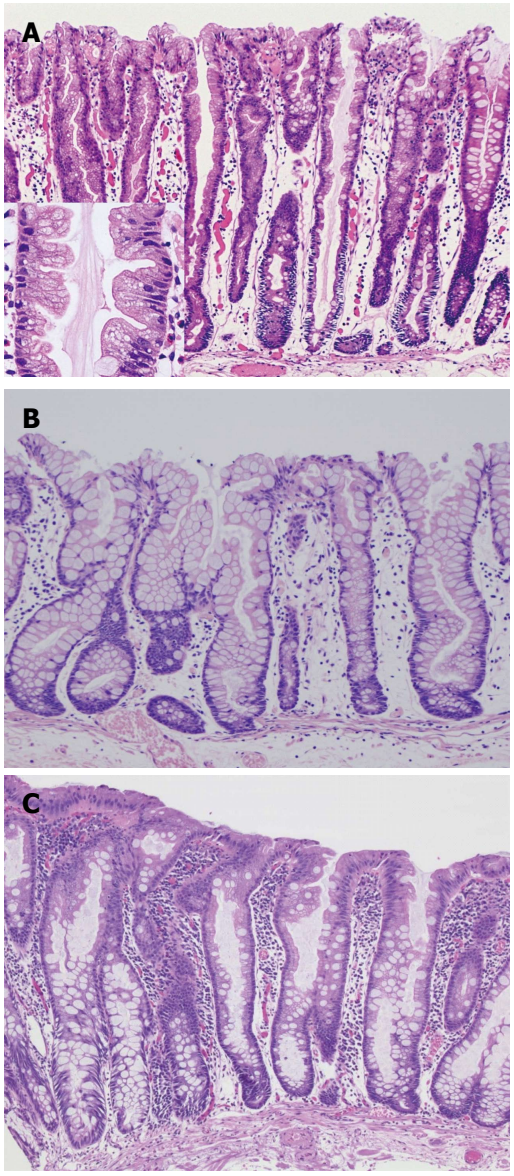

Figure 1 Histological findings of hyperplastic polyps. A: Microvesicular hyperplastic polyp (MVHP): The crypts and surface epithelium showing a serrated appearance with micro-goblet cells increased. High power view is shown at left side bottom. Many small droplet (microvesicular) mucin within the cytoplasm at the epithelial layer is specific findings as shown the picture; B: Goblet-cell rich HP: In contrast to MVHP, this type polyp is showing a much less serrated appearance inside the surface epithelium of crypts. And showing a preponderance of goblet cells without microvesicular mucin; C: Mucin-poor HP (MPHP): MPHP is rare, and little is known about their molecular features and natural history. The histological features are showing no cytoplasmic mucin with a luminal serration pattern. And also showing increased nuclear atypia without pseudostratification.

polyps[10,15,21,23,27]. The most important histological findings of SSA/Ps are characterized by the shapes of the growth pattern within the serrated glands as follows: (1) crypt dilatation; (2) irregularly branching crypts; and (3) horizontally arranged crypts in the basal portion that have boot-like shapes (*i.e.*, inverted T- and/or L-shaped crypts) (Figure 2H and I, 3H, 4J)[5,15,28-30].

The histological characteristics of SSA/Ps can be differentiated from those of HPs based on the histological criteria advocated by the WHO. SSA/Ps are also sub-

Traditional serrated adenoma

categorized into the following two types based on cellular dysplasia (Table 1); *i.e.*, those without and with cytological dysplasia (Figures 2-4). As shown in the Figure 3 and 4, SSA/Ps with cytological dysplasia comprise two types of lesion; the first is confined within the mucosa (Figure 3), and the second invades further into the SM layer (Figure 4).

Conventional SSA/P endoscopic findings have revealed superficial types of lesions with a pale color that is similar to that of HPs. Notably, the characteristic tumor sizes of such lesions are greater than 10 mm and these lesions adhered with a yellowish thick mucus. Some studies have termed this mucus a "mucous cap"[19,31,32]. When observed with crystal violet staining under magnification, the orifices can be seen to be widely opened and are referred to as Ⅱ-open pit[19,32,33]. However, these findings are often also found in associated with HPs and thus not suitable for differentiation at present.

Traditional serrated adenoma (Figure 5)

Traditional serrated adenoma (TSA) is an additional name for "serrated adenoma" that was previously advocated and is currently user to differentiate TSAs from SSA/Ps as further discussed below. Although this type of lesions is primarily observed on left side of the colon[17,18] and these lesions are primarily of the protruded type (Figure 5), there are also some superficial types of lesion. The characteristic pathological findings as a serrated adenoma are the following: (1) the presence of goblet cell; (2) upper zone mitoses; (3) prominent of nucleoli; and (4) the absence of a thickened collagen table[4]. Based on the above observations, the characteristic pathological findings of SSA/Ps are not observed among the above-mentioned four findings.

The characteristic endoscopic findings of TSAs reveal that the protruded type is composed of enhanced-reddish villous lesions that are often associated with a type Ⅱ pit pattern at the base[17]. The macroscopic gross type is characterized as "pine cone-shaped" or "coral-shaped" *via* conventional observation[34]. Magnifying endoscopic findings also reveal that the type Ⅳ pit pattern is often present and that differentiation from traditional adenomas is easy. In contrast, differentiation of superficial type lesions from SSA/Ps based on endoscopy is considered difficult due to the similar pit patterns. Some endoscopists have used the terms types ⅢH and ⅣH pits or type Ⅳ-serrated pit pattern to differentiate

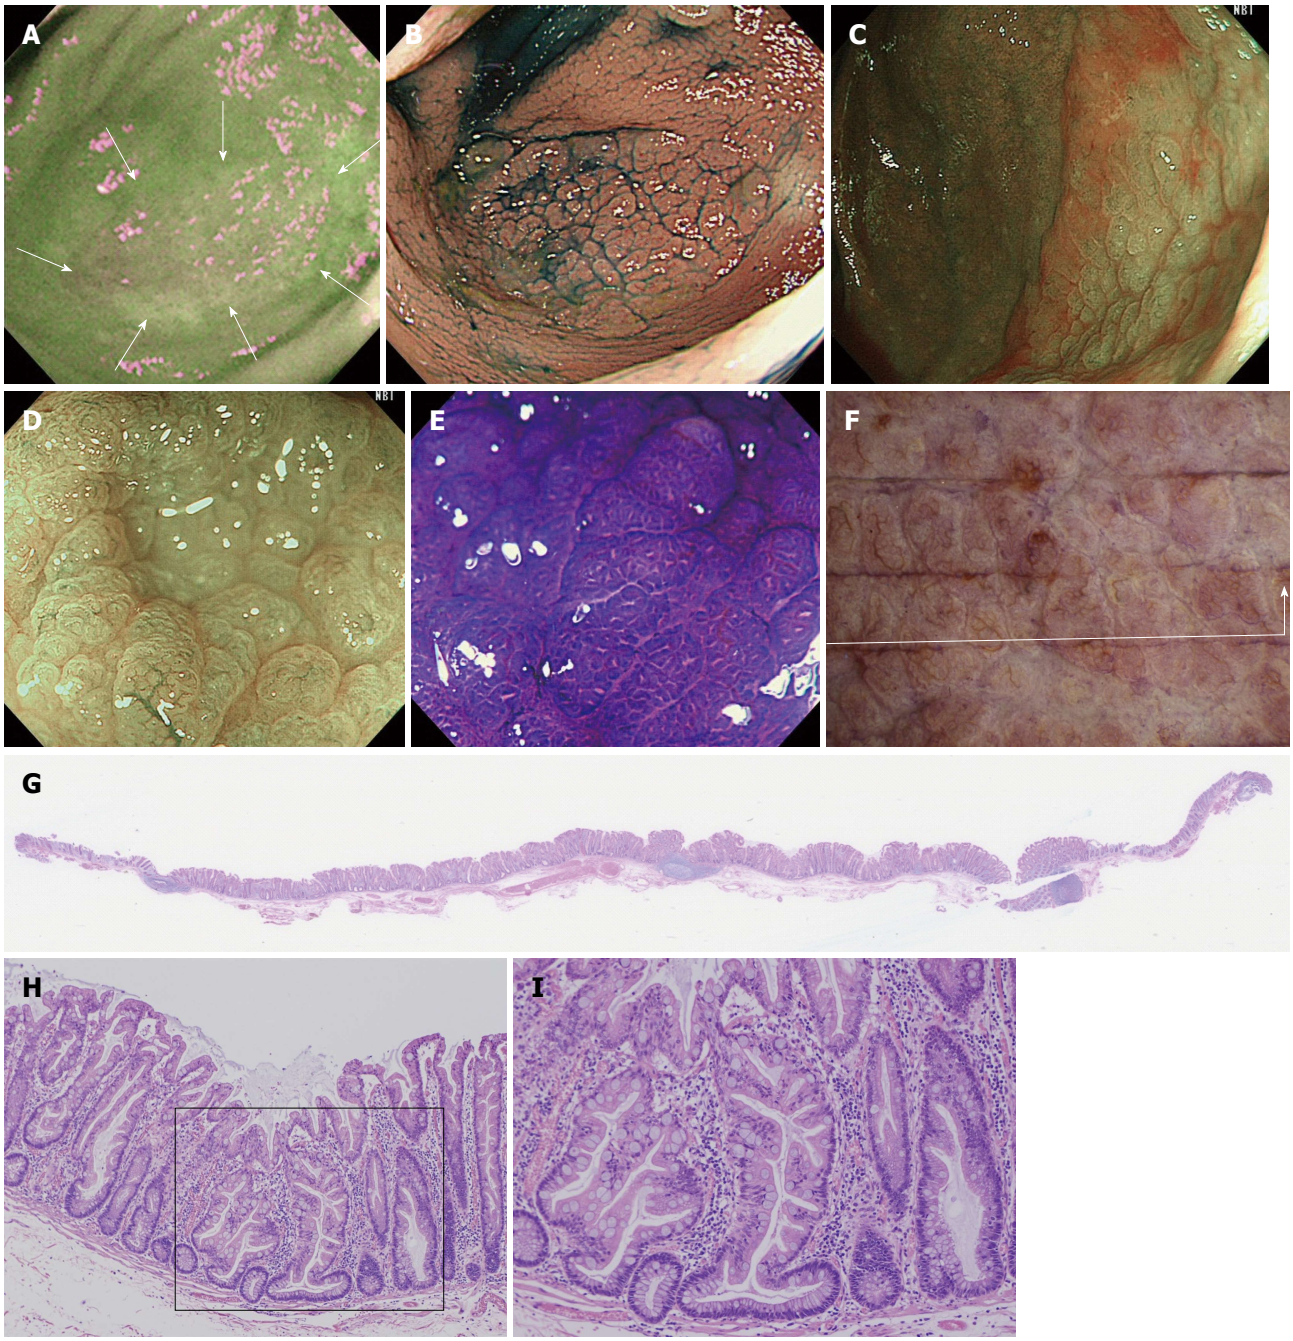

Figure 2 A case of sessile serrated adenoma/polyp without cytological dysplasia (scope: CF: FH260AZI). A: AFI imaging. The flat elevated polyp is approximately 37 mm in diameter as is located in cecum. No change to magenta of the tumor relative to the surrounding normal mucosa can be observed (inside white arrows); B: Indigocarmine spraying endoscopic finding. The structure of the granular surface is clearly revealed by chromoendoscopy; C: NBI observation, non-magnified. A red cap is covering the surface of the tumor; D: NBI observation, magnified. Small black dots can be observed in the tumor. This finding indicates that this tumor possesses the characteristic of SSA/P; E: Crystal violet staining under magnified observation. Type Ⅱ open pits (Ⅱ-O pits) containing T normal type Ⅱ pits are shown in the tumor; F: Stereoscopic finding. The tumor was excised by the ESD method. The tumor was cut into12 pieces; G: HE staining, whole specimen findings from section #4; H: Low power view of the HE staining findings. The tumor contains serrated glands in the mucosal layer; I: High power view of the HE staining findings. Typical histological findings for SSA/P. The crypt exhibits an "inverted T" type. NBI: Narrow band imaging; SSA/P: Sessile serrated adenoma/polyp; AFI: Auto fluorescence imaging.

conventional villous adenomas (Figure 4E and F)[18,19,33,34].

ENDOSCOPIC FEATURES ON IEE

According to the endoscopic imaging-object-oriented classification[35,36], IEE can be classified into three major categories: auto fluorescence imaging (AFI); narrow band imaging (NBI); and infra-red imaging. In this review, I will describe the characteristic endoscopic findings of AFI and NBI observations in details.

HP

Most of HPs are visualized as dark-green colors on AFI that are similar to the normal surrounding mucosa. We

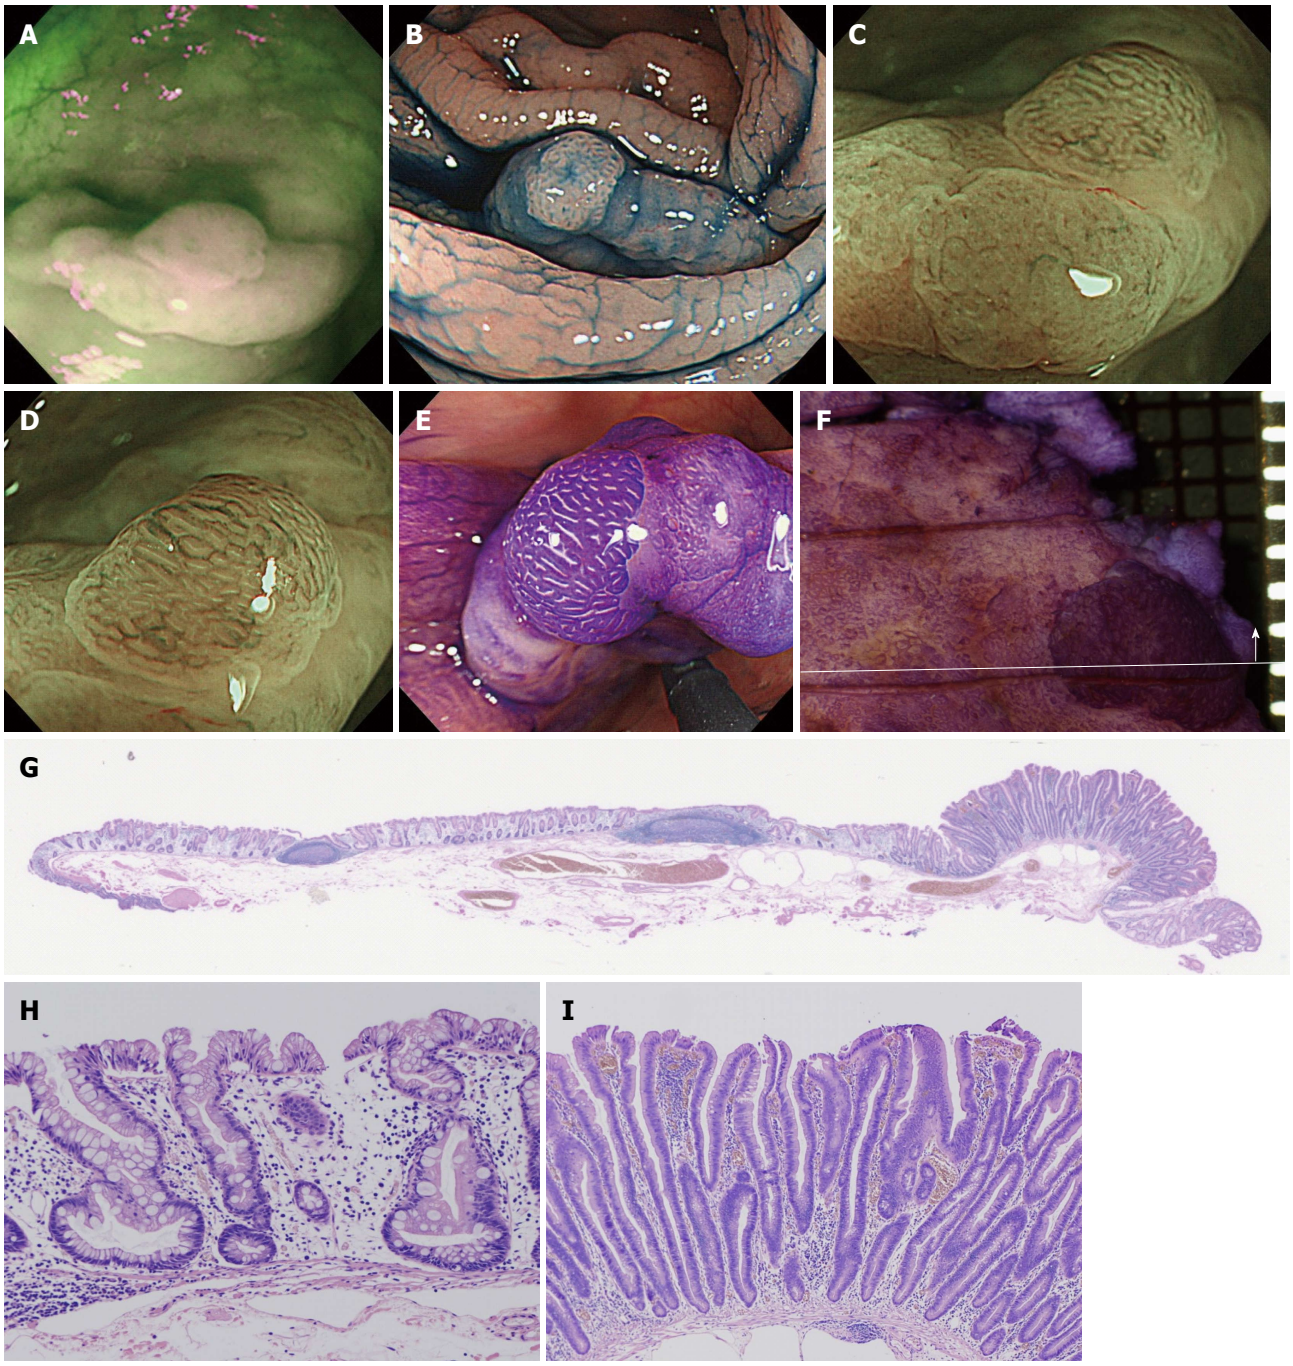

Figure 3 A case of sessile serrated adenoma/polyp with cytological dysplasia (scope: CF: FH260AZI). A: AFI imaging. The polyp is shown as a flat elevated lesion with a small nodule and is located in the ascending colon. A slightly change to a magenta color can be seen localized to a small elevated lesion in the tumor; B: Indigocarmine spraying endoscopic finding. The small elevated nodule in the tumor can be seen observed following dye spraying; C: Magnified NBI observation. In the tumor lesion, whitish mucosa with II-D pits can be observed. The microcapillary vessels are not dilated in the tumor; D: Magnified NBI observation. In contrast, the microcapillary vessels are dilated surrounding the tumor pits at the small elevated nodule. Moreover, a III$_L$ pit (white line) can be indirectly observed; E: Magnified crystal violet staining observation. Type II open pits (II-O pits) containing normal type II pits are shown in the tumor; F: Stereoscopic finding. The tumor was excised by the ESD method. The tumor was cut eight pieces; G: HE staining, whole specimen findings from section #4 including a small nodule; H: High power view of the HE staining finding. A part of an SSA/P is shown in the picture; I: High power view of the HE staining finding. The small elevated lesion is shown as a neoplastic change. Low grade cytologic dysplasia is present with nuclear hyperchromasia and pseudostratification. NBI: Narrow band imaging; SSA/P: Sessile serrated adenoma/polyp; AFI: Auto fluorescence imaging.

have previously reported that HPs can also be observed to exhibit dark-green colors[36,37]. Unlike neoplastic lesions, dilatation of the capillary vessels surrounding the glands cannot be observed *via* NBI magnifying endoscopy (NBI-ME)[38-42], and the type Ⅱ pit pattern can be indirectly observed. Basically, as visualized by IEE, HPs appear to be similar to the normal colon mucosa.

SSA/P (Figure 6)

Currently, satisfactory analysis based on AFI has not

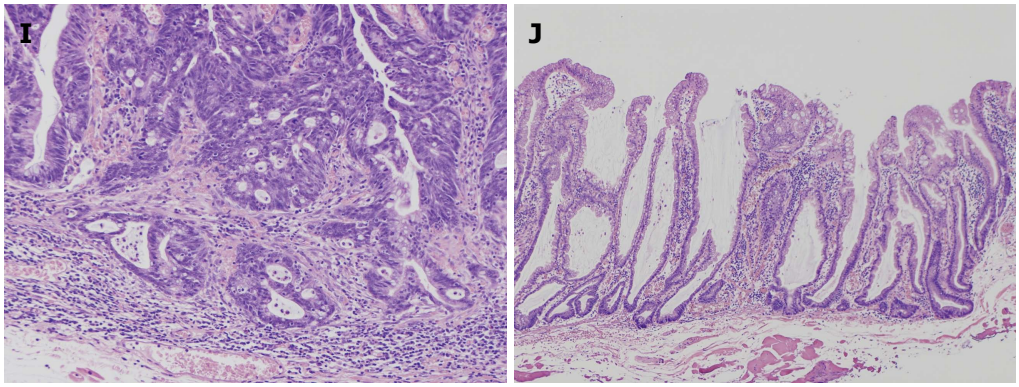

Figure 4 A case of an sessile serrated adenoma/polyp that has invaded the submucosal layer (scope: CF: HQ290I). A: Conventional white light observation. A flat elevated polyp of approximately 20 mm with a reddish depressed area can be observed in the ascending colon; B: Indigocarmine spraying endoscopic finding. Chromoendoscopy revealed this lesion, which is clearly composed of lesions. One edge area is covered with thick mucus; C: Magnified NBI observation. Firmly attached mucus can be observed on the tumor. A II-D pit that is indicative are markedly dilated crypts can be seen in this area; D: Magnified NBI observation. A granular surface pattern with dilated microcapillary vessels can be observed on this tumor in the absence of a thick mucous adhesion; E and F: Magnified crystal violet staining observation; G: Stereoscopic finding. The tumor was excised by the EMR method. The tumor was cut into seven pieces; H: HE staining, whole specimen finding from #4; I: High power view of the HE staining. The neoplastic glands have invaded into the SM layer to a depth of approximately 400 μm. The glands exhibit high grade dysplastic change; J: Low power view of the HE staining. This polyp is composed of SSA/P glands with markedly dilated crypts. NBI: Narrow band imaging; SSA/P: Sessile serrated adenoma/polyp.

been achieved[43,44]. However, in a single study from our group, we identified substantial difference between SSA/Ps with and without cytological dysplasia based on further prospective study prior to resection.

Specifically, the frequency with which the color changed to magenta color in SSA/Ps with dysplasia was higher than that of the SSA/Ps without dysplasia (Figures 2A and 3A). Moreover, the frequency of color changes among SSA/Ps is also higher than that among HPs[43]. Specifically, highly dysplastic lesions were strongly visualized. In contrast, 26 out of 46 SSA/P lesions (56.5%) presented with dark-green colors. Additionally, 17 out of 25 HP lesions (68.0%) presented with dark-green colors. Based on the above results, AFI observations can be considered useful for diagnoses in terms of whether SSA/Ps are associated with neoplastic changes.

When the above-mentioned "mucous cap" is observed on NBI, the bile is visualized in a red color tone; therefore, we reported this observation as the "red cap sign" (Figure 6A) and considered it to be useful in the differentiation of SSA/Ps. Additionally, because the orifices of the glands are frequently found to be wide open on magnified NBI observation, such orifices are referred to as type Ⅱ dilatation pits (Ⅱ-D pits) to differentiate them from Ⅱ-open pits[19,33] (Figure 6B).

Also in this study, Ⅱ-D pits were observed in 37 of 46 SSA/Ps without dysplasia lesions (80.4%), and HPs were found in approximately half of the lesions (7/25, 28.0%). Regarding SSA/Ps with dysplasia, only 4 of the 15 lesions presented type Ⅱ pits or Ⅱ-D pits, and 11 of these lesions presented with type Ⅲ to Ⅴ pits (Figure 4D). Based on the above results, differentiation can be considered to the possible based on observation of magenta color on AFI and the neoplastic pit pattern (with the exception of type Ⅱ pits) on magnified NBI observations when SSA/Ps are mixed with neoplastic changes.

Additionally, one, study has also reported that the presence of varicose microvascular vessels is useful for the differentiation of HPs based on magnified NBI observations of SSA/P lesions[45]. Unlike the blood vessels around the glands of the superficial mucosal layer, this finding is characterized by the observation of blood vessels running throughout the deep mucosal layer.

Dilatations and irregularities of the capillary vessels that are similar to those that develop from conventional adenomas are observed in polyp sites of SSA/Ps with dysplasia, but the disappearance of blood vessels and the superficial structures have been confirmed in invasive lesions that are deep into the SM layer (Figure 4D).

TSA (*Figure 5*)

Unlike HPs, TSAs can be visualized as magenta colors when observed on AFI, and this change is indicative of a neoplastic lesion. Protruded type TSAs primarily present with villous structures[17,18] and can be visualized as a color that is a mix of magenta and dark-green (Figure 5A). In contrast, superficial type TSAs can be identified although the intensity of the visualization of the magenta color varies depending on the degree of histological dysplasia.

In contrast, lesions that present with red color under white light observation can be observed to exhibit brownish color on NBI. Regarding the protruded type, the orifices of the glands and the interstitial capillaries can be observed in whitish and in blackish-brown color, respectively, on NBI magnifying observations; thus, their appearances are similar to those of normal villous tumors (Figure 5D). The superficial type of TSA can also be indirectly observed to exhibit a relatively villous

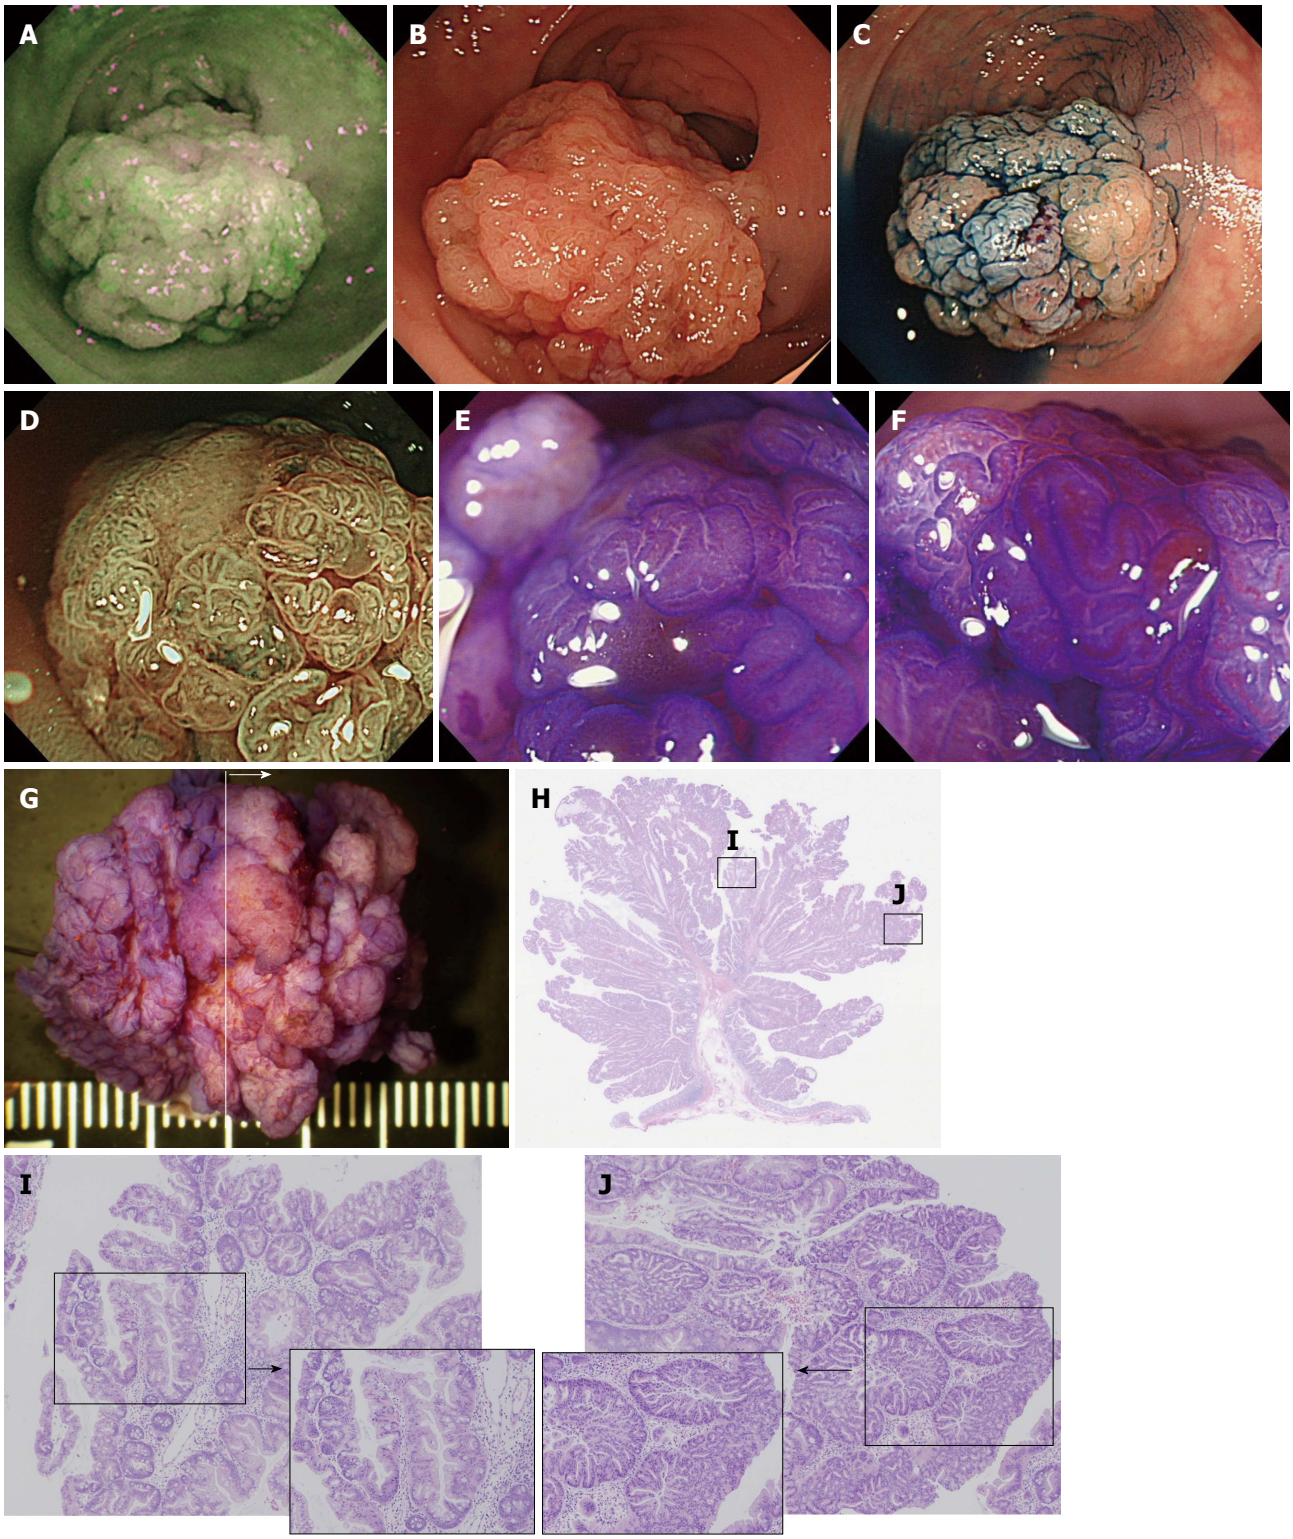

Figure 5 A case of a traditional serrated adenoma with conventional dysplasia (scope: CF: FH260AZI). A: AFI imaging. A dark green tone that is nearly the same as the surrounding normal colon mucosa can be observed in the tumor; B: Conventional white light observation. A large (approximately 30 mm) semipedunculated polyp exhibiting a slightly reddish change can be observed at the rect-sigmoid junction. There are no findings suggestive of submucosal invasion of the cancer; C: Indigocarmine spraying endoscopic findings. The structure of the nodular surface pattern is clearly revealed; D: NBI observation, magnified. A granular surface pattern with dilated microcapillary vessels can be observed in the tumor; E and F: Magnified crystal violet staining with observation. A type III_{H} or IV_{H} pit pattern is shown in the tumor; G: Stereoscopic finding. The tumor was excised by the EMR method. The tumor was cut into 4 pieces; H: HE staining, whole specimen finding from section #2; I: Histological findings from the HE staining. The tumor contains serrated glands in the mucosal layer. Dysplastic change is not observed; J: Histological findings of the HE staining. At several points, TSAs with conventional epithelial dysplasia exhibiting enlarged crowding and pseudostratification of the nuclei with crypt structure dysplastic changes can be observed. TSA: Traditional serrated adenoma; NBI: Narrow band imaging; AFI: Auto fluorescence imaging.

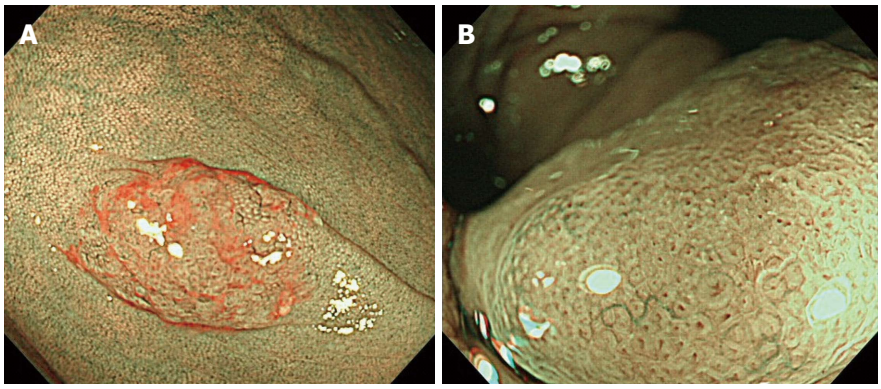

Figure 6 Endoscopic characteristics on narrow band imaging observation. A: Red cap sign – positive case; B: A finding of showing Ⅱ-D pit.

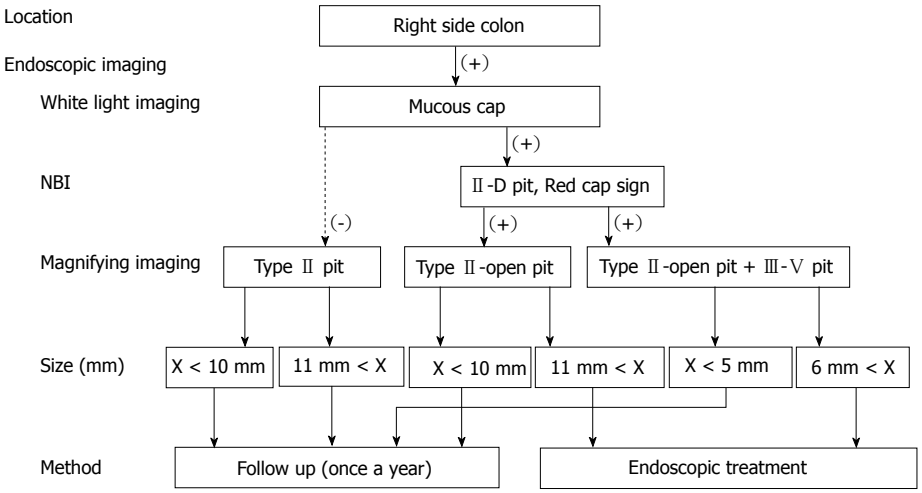

Figure 7 Flow chart for endoscopic treatment about sessile serrated adenoma/polyp. NBI: Narrow band imaging.

structure that is characteristic of a lack of associated with vasodilatation in contrast to the protruded type. However, within the lesion, a blackish dotted orifice of the crypt that is similar to that of SSA/Ps is often observed as discussed later (Figure 2B); this similarity makes, differentiation difficult.

INDICATIONS FOR ENDOSCOPIC TREATMENT

Currently, there is no established indication for endoscopic treatment about serrated polyps. However, according to the guidelines of management published by the ASGE[6,11,31] or ESGE[46], a five-year follow-up period is recommended for SSA/Ps without dysplasia that are 10 mm or less in size, and a follow-up with a three-year intervals is recommended for SSA/Ps with dysplasia of that are 10 mm or more in size. Notably, a biennial follow-up is recommended for serrated polyposis.

However, we summarized about the indication for endoscopic treatment of serrated polyps as a flow chart in Figure 7. Especially, the indication of endoscopic treatment for SSA/Ps is complicated. As we mentioned above, it is recommended to use the ME with NBI method and chromoendoscopy for diagnosis of characterized findings. At first, it is recommended to do the endoscopic treatment for greater than 6 mm sized polyps with Ⅱ-D pit and neoplastic changes (type Ⅲ-Ⅴ pit pattern) on right side colon. In contrast, small sized polyps smaller than 10 mm are should be follow up, even if shown to the mucous cap and Ⅱ-D pit. And also most of small sized HPs at sigmoid colon and/or rectum are not indication for endoscopic treatment. However TSAs, which are shown to type Ⅲ-Ⅳ pit pattern in left side colon are indication for endoscopic treatment.

In terms of numbers of lesions, once every-five-year follow-ups are recommended when SSA/Ps and TSAs greater than 10 mm are found at three or more sites, and once every-three-year follow-ups are similarly recommended for SSA/Ps and TSAs greater than 10 mm according to guideline. In contrast, once every-three-year follow-ups are recommended when SSA/Ps and TSAs of 10 mm or less are found at three or fewer sites, and one to three year follow-ups are recommended when lesions of 10 mm or more are found at two or more sites. The same follow-up schedule is recommended when associated cytological dysplasia is found.

Although the above mentioned guidelines recommend

a once every-three-year follow-ups for lesions that are associated with dysplasia and are 10 mm or more in size (regardless whether they are SSA/Ps or TSAs), we recommend endoscopic resection such conditions in our department. We made this recommendation because some lesions will develop SM invasion even if they are less than 10 mm sized polyp. Lesions with tumors that are 20 mm or greater are particularly recommended for endoscopic resection even when endoscopic findings of obvious dysplasia are absent.

CONCLUSION

Histopathologically, "serrated lesions" are categorized by the WHO into three groups[15]: (1) HPs; (2) TSAs; and (3) SSA/Ps. I have discussed the findings associated with each lesion type as observed on IEE and provided a particular focus on such associated findings on magnified, AFI and NBI[43]. The differentiation between HP and TSA or SSA/P based on AFI is possible to some extent based on changes in color tone. However, similarly to HPs, more than half of SSA/Ps exhibit no change in color. In contrast, 90% lesions of SSA/P with cytological dysplasia changed in magenta color tone; therefore, AFI might be a useful method for determining the presence of neoplastic characteristic of SSA/Ps.

Regarding HPs and SSA/Ps, differentiation is impossible based only on the presence or absence of dilated microcapillary vessels because such dilatation is not observed around the glands on magnified NBI observation. However, dilatations of the gland orifices are frequently observed in SSA/P and appear as blackish dotted orifices (Figure 6B). Additionally, a thick mucus adhesion referred to as a "mucous cap" can be confirmed as red mucus on NBI observation and can be recognized when it adheres to the surface of a "red cap" polyp (Figure 6A). According to our data, it is concluded to possible to differentiate between SSA/Ps and another serrated polyps. When AFI color changes were used to differentiate from HPs and SSA/Ps, the sensitivity, specificity, PPV, NPV, and diagnostic accuracy of SSA/P diagnosis were 43%, 68%, 71%, 40%, and 52%, respectively. In contrast, NBI method with using magnifying observation is also usefulness. When the red cap sign was used to differentiate between HPs and SSA/Ps, the sensitivity, specificity, PPV, NPV, and diagnostic accuracy of SSA/P diagnosis were 94%, 40%, 74%, 77%, and 75%, respectively. And the existence of Ⅱ-D pit in magnifying observation is also important. When the Ⅱ-D pit was used to differentiate between HPs and SSA/Ps, the sensitivity, specificity, PPV, NPV, and diagnostic accuracy of SSA/P diagnosis were 80%, 72%, 84%, 67%, and 78%, respectively.

Based on the above findings, the differentiation of HPs and SSA/Ps is likely possible. In contrast, the superficial type of TSA is considered to be difficult to differentiate from SSA/Ps. However, further studies should be conducted because the histopathological diagnoses of both HPs and SSA/Ps have ambiguities that have yet to be resolved.

Additionally, SSA/Ps with dysplasia are observed to be associated with dilatation of the microcapillary vessels at the tumor site, and the same finding as been observed to be associated with traditional neoplastic change (Figure 4D).

Abstract

Endoscopic diagnosis with histological evidence is necessary to decide the best strategy for treating esophageal squamous cell carcinoma and Barrett's-associated neoplasia, and the recent development of endoscopic technologies have made possible real-time information of malignant hallmarks. We focused on the development of optical coherence tomography (OCT), the only technology that can depict real-time cross-sectional images with high resolution. With the improvements in image resolution, acquisition rate and demonstrable area of three-dimensional devices with Doppler capability, OCT imaging was shown to enable visualization of structural/functional alterations in the mucosal/submucosal tissue of the esophagus, resulting in more accurate preoperative diagnosis of such malignancies. Moreover, it approved to be useful for targeting malignant areas for biopsy and treatment as well as for predicting the treatment effects. Therefore, further development of this technology is expected to overcome the current clinical issues in management strategies of esophageal malignancies.

Key words: Optical coherence tomography; Barrett's esophagus; Esophageal squamous cell carcinoma

Core tip: Optical coherence tomography (OCT) provides real-time cross-sectional images with extremely high resolution. We previously reported that OCT provided significantly more accurate preoperative staging of esophageal squamous carcinoma (ESCC) than endosonography. With remarkable improvements in this technology, such as three-dimensional devices with Doppler capability, for the detection of Barrett's-associated neoplasia, the diagnostic accuracy gradually became better through enhanced visualization of structural/functional alterations in mucosal/submucosal tissue. Recent reports suggested its usefulness for targeting malignant lesions for endoscopic intervention and for predicting treatment effects. Therefore, further development of OCT should promote improved management strategies for esophageal malignancies, including ESCC.

coherence tomography for preoperative diagnosis of esophageal malignancies. *World J Gastrointest Endosc* 2015; 7(9): 872-880 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/872.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.872

INTRODUCTION

Both endoscopic assessment and histological evidence of gastrointestinal malignancies are necessary to decide the best treatment strategy. Notably, image-enhanced endoscopic technologies have been developed to provide real-time information on malignant hallmarks. In this review, we focused on the development of optical coherence tomography (OCT), the only technology that can depict real-time cross-sectional images of biological tissue at a near-microscopic level without contrast agents[1].

OCT IMAGING

Mechanism of OCT imaging and its advantage

OCT images by near infrared light in the wavelength range of 700-1500 nm are similar to the B-mode images of ultrasonography. To construct an image, optical interferometry measures the delay between the emission of an invisible beam and the detection of its reflection to determine the distance from the emitter to the site. Its axial resolution is determined by coherence length of the light source. Most of the OCT devices reported in previous studies were first-generation probe-types [Light Lab Imaging (Boston, United States)] that used a super-luminescent diode light source with a center wavelength of 1300 nm, a bandwidth of 50 nm, and power output of 10 mW[2-7]. They had 10-20 μm of axial resolution, 5-25 times higher than that of high-frequency endosonography, which was another cross-sectional imaging device. Although its image acquisition rate was gradually improved from 1 frame/s to 9.8 frames/s with a lower signal-to-noise ratio, 4.0 frames/s could be used for the easy interpretation of images (Table 1)[8-10]. As a result, detailed OCT images can be constructed in gray-scale.

These mechanical characteristics provides several advantages to OCT in comparison with other advanced endoscopic technologies, as follows. First, it provides high-resolution cross-sectional images in real-time. OCT shows tissue structures in the mucosal/sub-mucosal layers at a microscopic scale, such as "pit and gland" morphology, revealing crypts/villi/vessels[4,6,7,11,12], as well as intracellular strictures, such as nuclei and other organelles, based on their different intensity of signal scattering[13]. Second, OCT does not always need tissue contact or coupling, although a biocompatible chemical agent was reported to possibly enhance its signal penetration depth[14]. Actually, we used a probe-type OCT [HOYA (Tokyo, Japan)] to depict detailed structures of the esophageal wall components, regardless of the location, while EUS-based imaging required acoustic coupling with a water preparation or a water-filled balloon, resulting in some difficulty in avoiding artifacts[2]. Third, a prototype OCT has a through-the-endoscope design, which may be easier to handle during endoscopic examination. In the next section, we will describe the technique for acquiring high-quality images using the OCT.

Best technique and indication for OCT imaging

Nowadays, two types of OCT probe-devices, such as a radial-probe/linear-probe, and one balloon-type device are available but only for research[10,11,13]. While linear scanning is able to sample only a small area, radial scanning creates an image similar to that of radial EUS with the potential for assessing larger areas, due to its easier identification of the scanning orientation compared with the linear scanning. Therefore, radial-type probes have been applied in most of the previous studies.

The OCT devices are inserted through the accessory channel of an endoscope and maneuvered under direct endoscopic observation so that the imaging plane is perpendicular to the gastrointestinal wall. Its position when scanning across the tissue surface is monitored using visible light. A series of tomograms are obtained, while its spot diameter is selected for maintaining the appropriate depth of focus, while the distance above the surface is controlled by endoscopic maneuvers. In fact, the distance between the device and the site may affect the penetration depth of its signal. While mucosal structures were well-focused when the probe was held about 1 mm above the surface, the structures in the deeper submucosa (SM) could be revealed when the wall was compressed or collapsed around the probe. Using such a technique, the penetration depth of the OCT signal and consequent image quality in the stomach, duodenum, and colon were reported to be inadequate compared with those in the esophagus, suggesting that the OCT device was most suitable for the esophagus[11].

Previous studies demonstrated close correspondences between the clear, five-layered morphologies in the OCT images and those of a normal esophageal wall in the histological findings[4,15]. It was shown that the first relatively less reflective layer corresponded to stratified squamous epithelium (EP); the second more reflective layer to the lamina propria mucosa (LPM); the third less reflective layer to the muscularis mucosa (MM); fourth more reflective layer to the SM; and fifth less reflective layer to the muscularis propria (MP) with deeper structures of the esophageal wall. Subsequent studies based on such findings promoted the development of OCT devices for the management of Barrett's-associated neoplasia and esophageal squamous cell carcinoma (ESCC). Originally, the studies aimed to improve the quality of "optical biopsies" of OCT devices for Barrett's-associated neoplasia and remarkable advances were achieved in the West from the first-generation conventional probe-type OCT to the second-generation OCT (Table 1). In the East, we demonstrated the usefulness of the first-

Table 1 Specification of optical coherence tomography devices

Manuscript	OCT device			Diameter (mm)	Image acquisition rate (frame/s)

generation OCT in the preoperative staging of superficial ESCCs (SESCCs) (Table 1). Therefore, we review these achievements, and propose future roles for OCT in the management of esophageal disease.

OCT-BASED DIAGNOSIS OF BARRETT'S-ASSOCIATED NEOPLASM

Significance of OCT in Barrett's esophagus

Barrett's esophagus (BE) is a precursor lesion with a 30-40-fold increased risk of cancer occurrence, *i.e.*, from specialized intestinal metaplasia (SIM) to low grade dysplasia (LGD) and high grade dysplasia (HGD) and, finally, to adenocarcinoma[16]. Based on knowledge of the multi-step transformation, a surveillance program with regular endoscopic examination is recommended, but the prognosis for adenocarcinoma remains poor, with an overall 5-year survival of less than 20%[17]. Previous studies suggested that some dysplasia and intramucosal adenocarcinoma might be overlooked until the advanced stage in the current clinical setting[18]. Most of them were shown to be minute with a patchy distribution in a wide-ranging BE, and subsquamous SIM (SSIM) was found in 71.4% of pre-treatment dysplastic BE when 0.4-6.8 mm of oral extension was observed, although the sampling area and depth by random biopsy were limited[18-22]. Therefore, there still remain controversies about sampling errors and costs/time of endoscopic biopsies in the current surveillance system[18,20,21]. Moreover, several studies have pointed out the low inter- or intra-observer agreement of their histological diagnoses[23-29]. Likewise, cutting-edge endoscopic technologies have difficulties in reaching a consensus on the recognition or interpretation of abnormal patterns, which can limit their clinical usefulness[30]. However, real-time visualization of high-resolution cross-sectional architectural information, even in the SM, analogous to the loupe image, is an important advantage of the OCT imaging. In this section, we list previous achievements by OCT devices employed for endoscopic "optical biopsies" of Barrett's-associated neoplasm.

First-generation of probe-type OCT

Previous studies demonstrated that *in vivo* or *ex vivo* use of probe-type OCT devices could provide characteristic images of normal human esophagus, gastric mucosa, BE, dysplastic BE and adenocarcinoma, although subsequent studies showed that the differences in OCT images between non-dysplastic BE and dysplastic BE were subtle. Bouma *et al*[13] first reported the ability of *in vivo* OCT to provide detailed images of structures in Barrett's-associated neoplasia by investigating biopsy-correlated OCT images, and proposed OCT-based grading criteria for characterizing dysplastic BE, as follows: (1) normal squamous epithelium: homogenous layered structures; (2) BE: absence of the layered-structure of normal esophagus in addition to abnormal/disorganized glandular structure of low reflectance within/under the mucosa; (3) dysplastic BE: highly reflective intensity of the background correlated with increased architectural disorder and heterogeneity; and (4) Barrett's adenocarcinoma: abnormal configuration of neoplastic epithelium containing large pockets and surrounded by cellular stroma.

In 2001, using 288 biopsy-correlated OCT images of 121 patients, Poneros *et al*[4] demonstrated that *in vivo* OCT had sensitivity of 97% and specificities of 92% for the diagnosis of BE. In 2005, Isenberg *et al*[5] conducted a prospective study to evaluate diagnostic accuracy of *in vivo* OCT for dysplastic/non-dysplastic BE in comparison with the histological diagnosis of jumbo biopsy specimens. They used a 2.4 mm-diameter probe under a two-channel endoscope fitted with a cap attachment, which might stabilize the OCT device on the mucosal surface during the procedure. Using a total of 314 biopsy-correlated OCT images of 33 patients, they reported sensitivity of 68%, specificity of 82%, and positive predictive value of 53%, negative predictive value of 89%, and diagnostic accuracy of 78% for the

diagnosis of BE. When the analysis was restricted to the diagnosis of HGD/ adenocarcinoma based on findings, such as: (1) lack of epithelial surface maturation; (2) gland architecture disarray; and (3) cytologic atypia[31,32], its sensitivity and specificity was 54% and 72%, respectively. Although such a negative predictive value may be advantageous for directing the examiners' attention to malignant areas for the biopsy target, there remained limitations, such as large variability in the endoscopists' accuracy rates, 56%-98%. Therefore, more refined criteria for differentiating dysplastic BE from non-dysplastic BE were required. In 2006, in a prospective study, Evans *et al*[6] investigated the relationship between a new scoring system, a "dysplasia index", based on both the OCT findings of surface maturation and gland architecture, and biopsy-proven histology of HGD/adenocarcinoma in BE subjects. Using a total of 177 biopsy-correlated OCT images, the threshold of > 2 in the scoring system had sensitivity of 83% and specificity of 75% for the diagnosis of HGD/adenocarcinoma. Accordingly, these studies demonstrated that discrimination between non-dysplastic BE and dysplastic BE using OCT devices with standard resolution still remained a challenging issue.

Then, Chen *et al*[33] developed an ultra-high resolution OCT (UHR-OCT) with 5-μm axial resolution and compared its image quality and diagnostic accuracy with those of a standard OCT with 12-μm axial resolution. Using a total of 233 biopsy-correlated OCT images of 50 patients, the accuracy of UHR-OCT for making a diagnosis of normal squamous epithelium, non-dysplastic BE, HGD and adenocarcinoma was 100%, 98.1%, 83.3% and 100%, respectively. Actually, UHR-OCT depicted smaller/finer structures and sharper layered structures, resulting in improved discrimination and more detailed features of dysplastic BE. In 2010, Cobb *et al*[34] reported that UHR-OCT detected clearly SSIM as well as abnormal structures of non-dysplastic BE/HGD/adenocarcinoma in 14 post-surgical specimens. Accordingly, these studies suggested that higher-resolution OCT with the developed criteria might be more useful for targeting biopsies to differentiate between BE and normal esophagus, or between dysplastic/cancerous BE and non-dysplastic BE. However, some studies pointed out that the point-sampling nature of a probe-type OCT, similar to those of biopsy, might miss dysplastic lesions in large surface areas of BE[10].

Second generation of OCT

These drawbacks of the probe-type OCT might have been mainly caused by the relatively slow image-acquisition rate, while recent improvements in OCT technology have enabled dramatic increases in imaging speed[35-38]. As a result, three-dimensional balloon-type OCT, referred to optical frequency-domain imaging (OFDI) and three-dimensional probe-type OCT (Light-Lab Imaging, Massachusetts, United States), could be developed with a combination of high-resolution at a near-microscopic level, large field of view, and rapid data acquisition[10].

Three-dimensional probe-type OCT: Volumetric data of a 10-mm circumference and 20-mm length could be acquired in 20 s by the helical scan of a prototype three-dimensional OCT, and each of data set provided comprehensive imaging of the glandular structure over a sampling area of 200 mm^2, which was 30-60 times as large as those of approximately 6 mm^2 by jumbo biopsy forceps and those of approximately 2.5 mm^2 by conventional biopsy forceps[39]. Additionally, the imaging depths of 3D-OCT and biopsy were 1.5-mm and < 1 mm, respectively. Using data of biopsy-correlated OCT images of 3 patients, Adler *et al*[39] demonstrated the usefulness of a three-dimensional OCT system for the detection of large areas of a normal esophagus, non-dysplastic BE and post-ablative BE. The increase in the data volume of three-dimensional OCT improved the clear detection of SSIM at 300-500 μm depth beneath neosquamous epithelium, and they therefore proposed its use to guide decisions concerning additional treatment sessions or biopsy points with a reduction of sampling error[39]. Subsequent studies demonstrated that the pre-treatment thickness of Barrett's mucosa and the presence of residual glandular structures immediately after focal radiofrequency ablation (RFA) in the three-dimensional OCT images were correlated with the treatment response determined by surveillance endoscopy with biopsy 6-8 wk after the latest session[40,41]. Accordingly, the three-dimensional OCT findings might be used as a promising real-time predictor of successful ablative therapy for BE.

Use of OFDI/volumetric laser endomicrography: OFDI can provide more than 100-fold faster imaging, compared with the conventional probe-type OCT[42]. The optical components in the inner sheath, positioned at the center of a 1.8 mm-diameter balloon catheter, are rotated helically, and cross-sectional images of the esophageal wall are revealed when the balloon is in contact with the mucosal surface, whose demonstrable area in the circumferential lumen might be affected by the degree of contact. All raw data are simultaneously stored and displayed in real-time. The OFDI/volumetric laser endomicrography (VLE) image with balloon-compression has four advantage, as follows: (1) the acquirement of microstructural data over large areas; (2) increased contrast of anatomical architecture; (3) increased signal penetration depth; and (4) reduced artifacts during imaging process.

Originally, volumetric OFDI images of the mucosa extended to the outer layer of the MP, with clear delineation of each layer, obtained for 4.5-cm-long segments in less than 6 min. In 2008, in a single-center study, complete acquisition of the OFDI data was successfully performed in 8 of 12 patients, and their images were consistent with the histological findings obtained by target/random biopsy specimens[10]. The loss of

an appropriate image due to inadequate contact of the balloon was observed in 0.37% ± 0.79% of the total tubular esophageal surface area/patient. More recently, the Nvision Volumetric laser endomicrography Imaging System (Nine Point Medical, Cambridge, MA) was developed as a commercially available device. It is derived from OFDI and provides real-time three-dimensional images of mucosa/SM over a 6-cm length of the esophagus in 90 s. Baron *et al*[43] demonstrated that *in vivo* use of VLE clearly depicted SSIM proven by random endoscopic biopsy in 3 post-RFA BE patients, and Leggett *et al*[44] revealed that *ex vivo* use of VLE clearly detected subsquamous adenocarcinoma of endoscopic mucosal resection specimens, which could not be seen by conventional endoscopy or confocal laser endomicroscopy (CLE). In a multicenter prospective feasibility study, 4 lesions of HGD/adenocarcinoma were detected by VLE in 74 BE patients[45].

However, there still remain two drawbacks. First, previous studies pointed out that inadequate contact of the balloon, due to the interference of blood/mucus, existing motion artifacts, or excessive compression of the balloon on the mucosal surface, might still reduce the image quality. Especially, in some parts of the esophagus, such as in large hiatal hernias, tissue contact with the balloon surface was not maintained throughout the imaging window. Second, it is impossible to make one-to-one correlations between OFDI/VLE images and the histological evidence, because the balloon-centering system is not suitable for the subsequent biopsy procedure, nor is the technology to localize the region of interest in the three-dimensional data. Unfortunately, unreliable correlations between them may make it difficult to determine whether the possible discrepancies are caused by either a sampling error or misdiagnosis of the images, so we cannot assess abnormal findings detected in only one session of OFDI/VLE. Actually, the true biological significance of SSIM has not been clarified by the current OFDI/VLE system without histological evidence. To overcome this issue, a biopsy guidance platform that provides endoscopically visible laser markings at VLE-determined sites was developed, and its feasibility was demonstrated in a pilot study[46]. During the examination of VLE, the marks were made in 2 s at 410 mW of electric current, with the thermal-damage predominantly limited to the mucosa[47]. The accuracies of endoscopy, VLE intent-to-biopsy, and corrected VLE post-marking images for diagnosing tissue between the marks were 67%, 93%, and 100%, respectively. The transverse and longitudinal targeting error was 1.2 ± 1.3 mm and 0.5 ± 0.9 mm, respectively, while there were no longitudinal targeting errors in 21 of 30 cases. Henceforth, larger trials by VLE-guided biopsy can be expected to evaluate its practical usefulness.

Doppler OCT: Doppler OCT can directly visualize the intensity of the blood-flow data derived from moving erythrocytes, and its velocity resolution was reported to be 10-100-times as high as that of Doppler EUS[48]. Previous studies demonstrated that it could depict dramatic alterations in the functional microvascular network, which might provide additional clues for improved identification of the layer structure, during the sequential development of Barrett's carcinogenesis[42,49]: (1) Normal esophagus: Distinct layers with small vessels in the LPM and medium vessels in the SM; (2) BE: Absence of the distinct layers with diffuse/small vessels and glandular structure; and (3) Esophageal Adenocarcinoma: Absence of distinct layers with diffuse/small vessels.

Recently, Tsai *et al*[50] developed OCT-angiography with an ultrahigh-speed (more than 10 times than that of conventional systems) and minimal motion artifacts, enabling imaging of the finer/denser microvascular architecture in BE. With an image acquisition of 400 frames/s, the total area of its image acquisition was improved to > 100 mm^2 in 8 s. Because of these technological advances, the OCT-angiography could reveal more detailed structural/functional changes in the subsurface vasculature/glandular structure for early identification of Barrett's carcinogenesis.

OCT-BASED TUMOR STAGING OF SUPERFICIAL ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Significance of OCT-based staging

In the East, ESCC is the most predominant type of esophageal carcinoma, and its mortality rate remains still high. With the development of endoscopic technologies, the indication for endoscopic treatment for SESCCs has been expanded, since it is a minimally invasive procedure with few complications and after-effects. According to the esophageal cancer treatment guidelines of the Japanese Society of Esophageal Diseases, the definitive indication for endoscopic resection (ER) is limited to carcinoma *in situ* and tumors invading the LPM, regardless of tumor size[51]. Although more precise preoperative staging has been required for curative treatment, the accuracy of EUS has not yet been satisfactory, due to its limited visualization[52,53].

Establishment of staging criteria of SESCCs

Second, we established the criteria of OCT-based staging for SESCCs in a phase I study. We used a probe-type OCT system under endoscopic observation in order to detect every part of a key finding for tumor staging[2]. After we investigated correlation the between OCT-based staging and histological staging of *en bloc* ESD specimens, the criteria of OCT-based staging for SESCCs were established. The criteria were classified into 3 categories based on the treatment guidelines: clinical EP/LPM, clinical MM, and clinical SM: (1) Clinical EP/LPM: the thick or normal layer Ⅰ with regular interfacial signal of layer Ⅱ or involvement of the tumor signal

into layer Ⅱ without involvement of layer Ⅲ; (2) Clinical MM: involvement of the tumor signal into layer Ⅲ with regular interfacial signal of layer Ⅳ; and (3) Clinical SM: Destruction of layers Ⅰ to Ⅲ and irregular interfacial signal of layer Ⅳ or loss of layer Ⅴ architecture by high backscattering.

Thereafter, in a prospective phase Ⅱ study, we investigated the accuracy based on the criteria in 62 consecutive patients[2]. The overall accuracy was 92.7%, and the accuracy of EP/LPM, MM, and SM cancer was 94.7%, 85.0%, and 90.9%, respectively. Although the staging accuracy was not significantly different among tumor locations (P = 0.79), the 0.46 (range 0.10-1.5) mm thickness of the lesion in the images without deep attenuation was significantly thinner than the 2.5 (1.2-5.0) mm images with deep attenuation. Conversely, this study uncovered the following limitations of this modality: (1) the limited depth of OCT signal penetration; (2) the inability to distinguish between cancer cell invasion and inflammatory cell infiltration; and (3) the inability to distinguish between intraepithelial cancer and normal tissue. Still, this phase-Ⅱ study suggested that the criteria might be applicable for clinical use with high accuracy of tumor staging for SESCCs.

Comparison of tumor staging accuracy between OCT and EUS

Finally, we investigated the clinical usefulness of OCT-based staging of SESCCs in a single-center prospective study by comparing the staging accuracy of OCT with that of 20-MHz probe-type EUS (UM-3R; Olympus, Tokyo) without a water-filled balloon for a total of 131 SESCCs in 123 consecutive patients[3]. The histological staging was confirmed by specimens obtained by *en bloc* ESD or surgical resection. As the primary endpoint, the accuracy for EP/LPM, a definitive indication for ER, by OCT was significantly higher than that by EUS (94.6% *vs* 80.6%, respectively, $P < 0.05$). The overall accuracy of OCT and EUS was 90.1% and 77.1%, respectively (P = 0.0046). Although there were no significant differences in the accuracy of OCT among tumor locations, the accuracy of EUS in the distal esophagus was significantly lower than that in the middle esophagus (P = 0.023). Further, due to the inferiority of EUS in image resolution, we found that the accuracy rate in 33.6% of the cases, which had less than 9-layer visualization in the EUS finding, was significantly lower than that in the remaining cases, which showed a clear discrimination of the 9-layer structure (P = 0.015). This study demonstrated that, because of mechanical advantage of OCT compared to EUS, the accuracy of OCT was significantly superior to that of EUS for the preoperative staging of EP/LPM in the clinical management of SESCCs. However, we noted 3 drawbacks of OCT: (1) a limitation in the penetration depth; (2) the limited width of the depiction area (limited to 4 mm); and (3) the inability to distinguish between cancer invasion and inflammatory cell infiltration. Accordingly, since the first-generation OCT-device still had limited usefulness in the management of SESCCs, further development of the OCT devices will be needed.

PERSPECTIVE

From the point of view that OCT may have advantages in the real-time visualization of the mucosal/submucosal architecture with/without functional alterations, we review promising research data on OCT-devices for providing "optical biopsies" for early detection of neoplastic changes during Barrett's carcinogenesis or for accurate staging of SESCCs to improve treatment curability. However, to apply this technology in the clinical setting, the following issues will needed to be addressed, *i.e.*: (1) easy interpretation with low inter-observer variability; (2) real-time image acquisition for large-areas; and (3) cost effectiveness.

As for the first issue, more refined criteria for easy interpretation with less variability are needed for effective and stable stratification during surveillance. Although accurate interpretation is necessary for both well-trained endoscopists and well-trained pathologists, Qi *et al*[54] demonstrated 82% sensitivity, and 74% specificity in a computer-aided algorithm for the diagnosis of dysplastic BE based on the current criteria. Hence, future computer-aided algorithms can be realized by easy-to-identify criteria.

For the next two issues, OFDI/VLE may provide great cues toward real-time imaging of structural/functional alterations in the 6 cm-length circumferential esophageal mucosa during cancer development and the after-effects of endotherapies. Although no study has demonstrated a close correspondence between the OFDI/VLE imaging and histological evidence, a monitoring system for occult lesions, such as SSIM and tiny dysplastic Barrett's mucosa, with a laser marking platform at VLE-determined sites for biopsy-guidance might unmask their true malignant potential during surveillance. Actually, there has been no study of them using conventional endoscopic imaging, CLE or the first-generation OCT, due to the limited sampling width/depth[55]. Instead, recent studies have proposed that OCT devices might be used to guide the biopsy target for enhanced detection of malignant Barrett's mucosa or to assist in predicting the treatment effect[39,40,49]. Future monitoring by biopsy-correlated OFDI/VLE imaging might yield more effective management strategy with a risk-stratification, which could have the greatest impact on cost-effectiveness and clinical risk-management.

Regarding this point, we also emphasize that the second-generation OCT-devices with marking equipment may have a great impact on the development of new management strategies for SESCCs. In fact, there remain two difficulties in the current strategy for SESCCs. First, accurate staging for large-sized SESCCs by the detection of tiny abnormalities of superficial microvascular structure in the magnifying endoscopic findings with point-sampling characteristics is more difficult than that for small-sized SESCCs[56]. Second, another well-known

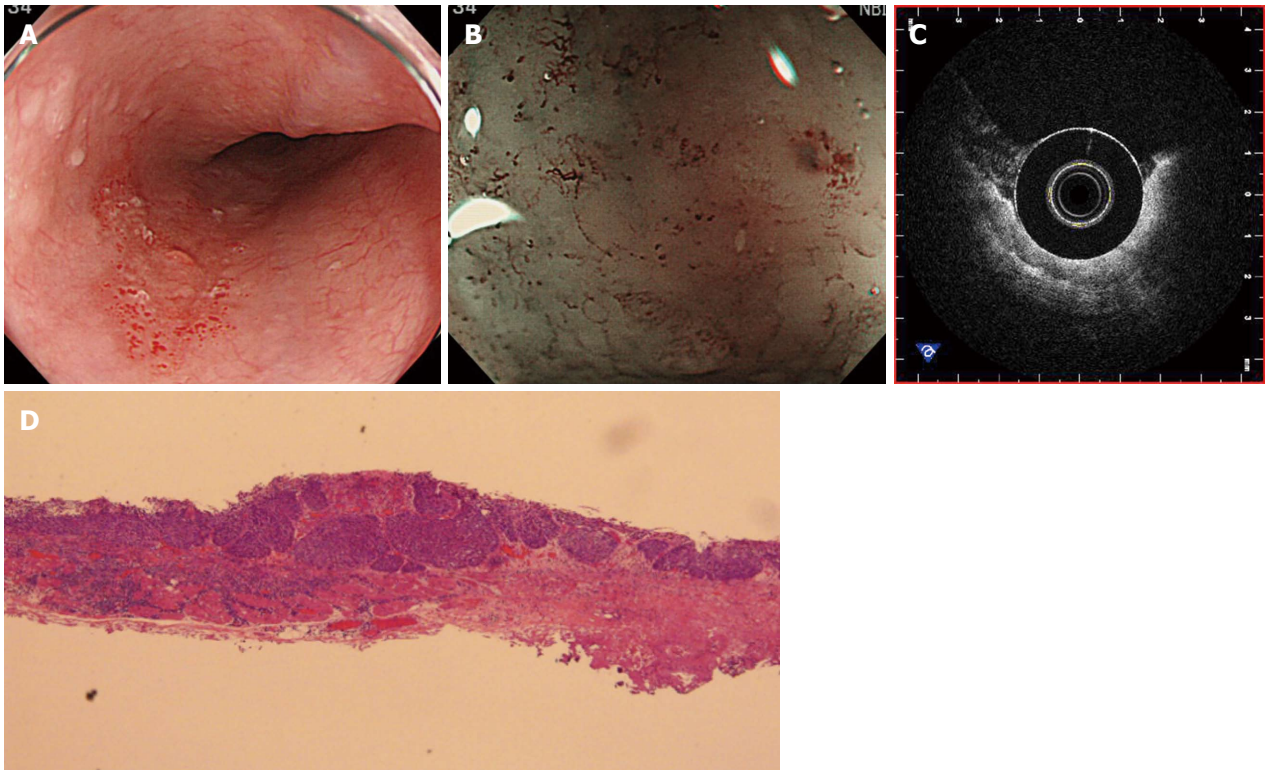

Figure 1 Representative images of superficial esophageal squamous cell carcinoma (0-IIc) with the recurrence after chemo-radiation therapy. A 71-year-old patient suffered from the recurrence of esophageal squamous cell carcinoma after chemo-radiation therapy. A: Irregular reddish lesion in the middle-esophagus in a non-magnifying white light endoscopic finding; B: Avascular area with irregular microvessels was observed in narrow-band imaging magnifying endoscopic finding; C: The involvement of the tumor signal into layer II without involvement of layer III in the OCT-imaging; D: A representative photo of *en bloc* ESD specimen demonstrated pT1a-LPM of histological diagnosis (× 10). OCT: Optical coherence tomography; LPM: Lamina propria mucosa.

difficulty is achieving early detection of the subepithelial recurrence of SESCCs after chemo-radiation therapy (Figure 1). However, the newly advanced OCT-devices can help with early detection by revealing tiny and invasive spots in large lesions and small subepithelial lesions[57]. Accordingly, real-time inspection with the OCT devices, after further technologic innovation, may play a central role in the histological diagnosis and choice of management strategies for esophageal malignancies.

CONCLUSION

In this review, we described previous achievements by which endoscopic OCT enhanced the visualization of structural/functional alterations in mucosal/submucosal tissue of the esophagus, and suggested that it might be useful for guiding/monitoring the area to be targeted for biopsy and treatment as well as to predict the treatment effect. Basically, it is important that the examiner/reviewer have familiarity and expertise in both histopathology and OCT imaging in order to achieve high accuracy in the diagnostic process. However, if reliable criteria of OCT imaging can be developed with computer-aid algorisms, the general use of OCT-related devices may provide "optical biopsies" or "optical staging" of Barrett's-associated neoplasia and SESCCs. Therefore, further development of OCT technology is required for the future progress of management strategies of the esophageal malignancies.

Abstract

AIM: To assess how many patients with benign "difficult" colorectal lesions (DCRLs) referred to surgical resection, may be treated with endoscopic resection (ER) rather than surgical resection.

METHODS: The prospectively collected colonoscopy database of our Endoscopic Unit was reviewed to identify all consecutive patients who, between July 2011 and August 2013, underwent an endoscopic re-evaluation before surgical resection due to the presence of DCRLs with a histological confirmation of benignancy on forceps biopsy. ER was attempted when the lesion

did not have definite features of deeply invasive cancer. The "nonlifting sign" excluded ER only in naive lesions without a prior attempted resection. Lesions were classified, using the Kyoto-Paris classification for mucosal neoplasia. For sessile and non-polypoid lesions the "inject and cut" resection technique was used. Pedunculated and semi-pedunculated lesions were transected at the stalk just below the polyps head and before or after resection, metal clips or a loop were applied on the stalk to prevent bleeding. The lesions were histologically classified according to the Vienna criteria and for the pedunculated lesions the Haggitt classification was used.

RESULTS: Eighty-two patients (42 females, mean age 62 years) with 82 lesions (mean size 37 mm) were included in the study. Sixty-nine (84%) lesions were endoscopically resected, while 13 underwent surgical resection since ER was deemed unsuitable. On histology, cancer was found in 21/69 lesions (14 intra-mucosal, 7 sub-mucosal) and was associated with the size ($P < 0.001$) and with type 0-Ⅱa + Ⅰs ($P = 0.011$) and 0-Ⅱa + Ⅱc ($P < 0.001$) lesions. All patients with sub-mucosal cancer, underwent surgical resection. Complications occurred in 11/69 patients (7 bleedings, 2 transmural burn syndromes, 2 perforations), all managed endoscopically or conservatively, and were associated with presence of invasive cancer ($P = 0.021$). During follow-up recurrence/residual tissue was found in 14/51 sessile or non-polypoid lesions (13 treated endoscopically, 1 underwent surgical resection) and was associated with type 0-Ⅱa + Ⅰs lesions ($P = 0.001$), piecemeal resections ($P = 0.01$) and with lesion size ($P = 0.004$). Overall, 74% of patients avoided surgery. Surgical resection was significantly associated with type 0-Ⅱa + Ⅰs ($P = 0.01$) and 0-Ⅱa + Ⅱc ($P = 0.001$) lesions, with sub-mucosal invasion on histology ($P < 0.001$), with presence of the "nonlifting sign" ($P < 0.001$), and related to the dimension of the lesions ($P = 0.001$). In the logistic regression analysis, the only independent predictor for surgical resection was the dimension of the lesions ($P = 0.002$).

CONCLUSION: Before submitting patients to surgical resection for a benign DCRL, a second opinion by an experienced endoscopist is mandatory to avoid unnecessary surgery.

Key words: Difficult colorectal lesion; Complications; Endoscopic resection; Non-polypoid lesions; Polypoid lesions; Recurrence

Core tip: A "difficult" colorectal lesion (DCRL) is defined as any lesion that due to its size, shape and location or due to fibrosis as a consequence of previous attempts of endoscopic resection (ER), makes it difficult to remove. Patients with DCRLs are often referred to surgeons for surgical colorectal resection. In our institution, for all patients referred for colorectal surgical resection for DCRLs, the surgeons request an endoscopic re-evaluation and if possible an ER of the lesions. The purpose of this study was to review our results with this approach.

INTRODUCTION

A "difficult" colorectal lesion (DCRL) is defined as any lesion who's endoscopic resection (ER) is technically challenging due to the size, the shape or the location, or due to the presence of fibrosis as a consequence of previous attempts of ER[1].

For these reasons, patients with DCRLs are often referred to surgeons for colorectal surgical resection[2,3].

However, surgery is associated with significant morbidity and mortality, especially in older patients with comorbid illnesses, as well as higher costs of the procedures[4-6].

In our institution, patients referred for surgical colorectal resection of DCRLs, with a histological confirmation of benignancy on forceps biopsy, are advised by surgeons to undergo an endoscopic re-evaluation and, if possible, an ER of the lesions.

The aims of this study were to estimate how many patients referred to our unit with DCRLs really needed surgical resection, and to evaluate the outcomes of ER of the lesions in whom it was possible.

MATERIALS AND METHODS

Patients

The prospectively collected colonoscopy database of our Endoscopic Unit was reviewed to identify all consecutive patients who, between July 2011 and August 2013, underwent an endoscopic re-evaluation before surgical resection due to the presence of DCRLs with a histological confirmation of benignancy on forceps biopsy.

All patients underwent a colonoscopy to confirm the presence and location of the lesions, to exclude synchronous lesions, and if possible to endoscopically resect the lesion.

ER was attempted when the lesion did not have definite features of deeply invasive cancer, such as surface ulceration, converging folds, firm consistency with a surface pit pattern suggestive of invasion.

The "nonlifting sign" excluded ER only in naive lesions without a prior attempted resection, whereas it was

not considered an exclusion criteria in case of recurrent lesions or that had undergone a previous partial resection.

Lesion classification

Lesions were classified, using the Kyoto-Paris classification for mucosal neoplasia[7,8]. Polypoid types rise > 2.5 mm above the surrounding mucosa, including lesions with a clear stalk, pedunculated (0-Ip) and semi-pedunculated (0-Isp) types, and lesions without clear stalk, defined as sessile (0-Is) type. Non-polypoid types rise < 2.5 mm above the surrounding mucosa and include elevated (0-Ⅱa), barely perceptible elevated or flat (0-Ⅱb) and slightly depressed (0–Ⅱc) types. Mixed types are lesions with mixed pattern of both a polypoid sessile and a non-polypoid morphology in distinct sectors and include 0-Ⅱa + Is and 0-Ⅱa + Ⅱc types.

ER procedure

All endoscopic procedures were performed by one expert interventional endoscopist (Carmelo Luigiano)[9-12].

For sessile and non-polypoid lesions the "inject and cut" resection technique was used; *en bloc* resection was attempted for lesions ⩽ 30 mm, while for lesions > 30 mm piecemeal resection was performed, taking care to include 1-3 mm of normal tissue in the lateral margins of the resection[9,10].

Pedunculated and semi-pedunculated lesions were transected at the stalk just below the polyps head, complete ensnarement of the head portion with a single application of the snare was first attempted; if this failed, the lesion was trimmed with piecemeal technique until the snare could be placed around the lesion. Before or after resection, metal clips or a loop were applied on the stalk to prevent bleeding[11,12].

Patients were prepared with a fiber- and residue-free diet within 72 h and 4000 mL of a polyethylene glycol electrolytic lavage solution 18 h before colonoscopy.

The procedures were performed with a high-definition colonoscope (Pentax EC-3490L: Pentax, Hamburg, Germany), with a paediatric colonoscope or with an operative or diagnostic video gastroscope (Pentax, Hamburg, Germany), with a high-definition processor (Pentax EPK-i HD).

Submucosal injections were performed with variceal injection needles (Olympus). The injection solution contained only saline, saline with epinephrine (1:10000) or saline and epinephrine with methylene blue mixture (1:10000). The snares used were standard, jumbo or stiff (US Endoscopy, Mentor, Ohio).

Electrosurgery was performed using a combination of cutting (120 W) and coagulation current (60 W), using an ERBE-ICC 200 (Erbe Elektromedizin GmbH, Tübingen, Germany). For sessile or non-polypoid lesions argon plasma coagulation (APC) at a power of 40-60 W and gas flow of 2 L/min using an ERBE APC 300 (Erbe Elektromedizin) was used to ablate any residual tissue at the edge of the resection area.

If localization of the ER site during colonoscopic follow-up was likely to be difficult, the site was marked with a submucosal injection of sterile carbon particle suspension (Spot, GI Supply, Camp Hill, Penn) in the adjacent normal mucosa.

ER procedures were performed on outpatients in the morning. After ER, patients remained in a second-stage recovery area for 4 to 6 h until medically cleared for discharge by the endoscopist. If the case of clinical concerns, the patient was admitted for observation. On discharge, dietary instructions, written contact information and instructions regarding symptoms and potential problems were provided to patients.

Assessment of lesions size and histopathology

The size of the lesions was estimated by comparison with open biopsy forceps and, when possible, also after retrieval. All removed tissue was retrieved using a basket or through the suction channel. All specimens were stained with hematoxylin and eosin for histopathological assessment, and two experienced pathologists examined the resected material. Based on the histological configuration of the crypts, adenomas were classified into tubular, villous, and tubulo-villous. The lesions were histologically classified according to the Vienna criteria and for the pedunculated lesions the Haggitt classification was used[13,14].

Complications

ER induced bleeding was defined as procedural (occurring during resection), early (within 24 h) or delayed (after 24 h). The diagnosis of early and delayed bleeding was based on the presence of rectorrhagia or melena. Transmural burn syndrome, caused by thermal injury, with resultant serosal inflammation, was characterized by localized abdominal pain, leucocytosis and, occasionally, fever. Perforation was diagnosed either by endoscopy during the resection or by the presence of free air on plain abdominal film or abdominal computed tomography scan.

Clinical and endoscopic follow-up

Clinical follow-up was performed after 3 wk from the ER, when the histological results were communicated to the referring specialists and patients.

In patients with pedunculated and semi-pedunculated lesions, surveillance colonoscopy was performed at 12 and 24 mo for lesions with high and low-grade dysplasia, respectively, while for lesions harbouring cancer at 6 and 12 mo, and annually thereafter.

In patients with sessile, non-polypoid and mixed type lesions surveillance colonoscopy was performed after 3, 6 and 12 mo, and then annually after the initial ER.

In patients with sessile, non-polypoid and mixed types lesions, recurrence was defined as the presence of tissue on a follow-up endoscopy. If visible tissue was seen on follow-up examinations, it was snare resected when

Table 1 Characteristics of patients and colorectal lesions recruited

mm: Millimeters; M: Male; F: Female; 0-Ip: Pedunculated lesions; 0-Isp: Semi-pedunculated lesions; 0-Is: Sessile lesions; 0-Ⅱa: Elevated non-polypoid lesions; 0-Ⅱb: Barely perceptible elevated non-polypoid lesions; 0-Ⅱc: Slightly depressed non-polypoid lesions.

feasible and submitted for histopathological examination. The edges of the resection site were typically cauterized with the argon plasma coagulator. Lesions that were too small for snare resection were removed with forceps and then fulgurated with an argon plasma coagulator. During the endoscopic follow-up, any alterations of the mucosa in the area of the previous resection (ulceration, scarring, retraction of mucosa, *etc.*) underwent biopsies.

Outcomes of the study

The parameters evaluated in the study were: age, sex, associated intestinal or extra-intestinal diseases, lesions size, shape and location, reason for surgical resection, successful of ER, reason of aborted ER, technique of ER, complications, technique of treatment of complications, histology, grade of dysplasia and cancer, and recurrence.

Statistical analysis

Continuous data are described by mean, standard deviation and range, according to distribution. Categorical data are presented as numbers and percentages. Relationships between numerical variables were examined by the Spearman correlation coefficient, between categorical and numerical variables by the Biserial correlation, and between categorical variables by the Log-likelihood Ratio test. Results were analyzed in relation to lesion size (divided in two groups: group A lesions < 35 mm and group B lesions ⩾ 35 mm) and were also compared for the technique of resection used (*en bloc vs* piecemeal; APC *vs* no APC). Logistic regression was used to assess the independent predictors of outcomes. A *P*-value of less than 0.05 was considered statistically significant. The software packages applied were SPSS for Windows 11.0. Data analysis of the study was performed by a biomedical statistician (Angela Alibrandi).

RESULTS

During the study period, 82 patients (42 female; mean age 62 years) underwent an endoscopic re-evaluation before surgical resection of a DCRLs with a histological confirmation of benignancy on forceps biopsy. Demographic and clinical data of the included patients are summarised in Table 1.

The reason for referral was the location of the lesion in 36 cases, the size in 32 cases, the type in 10 and recurrence in 4 cases.

The mean (± SD) lesion size was 37 ± 18 mm (range 20-100 mm). The most frequent type was the mixed types in 30 cases (18 type Ⅱa + Is and 12 type Ⅱa + Ⅱc) and the most frequent location was the sigmoid colon in 16 cases.

Among the included lesions, 44 (54%) were < 35 mm, while 38 (46%) were ⩾ 35 mm in diameter.

Of the 82 lesions, 69 (84%) were successfully resected endoscopically, while 13 cases were referred for surgical resection since ER was considered unsuitable due to the following reasons: presence of the "nonlifting sign" in 6 patients, endoscopic appearance of invasive cancer in 3 cases, very large size with difficult location in 2 cases (one patient with a sessile lesion occupying more than 60% of the lumen in the rectosigmoid junction and one patient with a type Ⅱa lesion involving more than half of the cecum and more than half of the circumference of the proximal ascending colon) and in 2 cases due to difficult location (1 with ileocecal valve and 1 with appendiceal orifice involvement).

mm: Millimeters; 0-Ip: Pedunculated lesions; 0-Isp: Semi-pedunculated lesions; 0-Is: Sessile lesions; 0-Ⅱa: Elevated non-polypoid lesions; 0-Ⅱb: Barely perceptible elevated non-polypoid lesions; 0-Ⅱc: Slightly depressed non-polypoid lesions.

The characteristics of the 69 resected lesions are presented in Table 2. All lesions were resected in a single session and the resection was evaluated as endoscopically complete in all procedures.

Of the resected lesions, 42 (61%) were < 35 mm, while 27 (39%) were ⩾ 35 mm in diameter. In 12 pedunculated and semi-pedunculated lesions, bleeding prophylaxis was performed with the application of clips to the stalk in 9 cases and with endoloop in the 3 remaining cases.

In the 57 sessile and non-polypoid lesions, *en-bloc* resection was performed in 23 cases while piecemeal resection was used in the other 34 cases. Argon plasma coagulation was applied to the margins of the lesions in 15 of the 57 lesions (all piecemeal resections).

Histological diagnosis of the resected lesions showed 47.5% tubulo-villous, 32% villous, 19% tubular and 1.5% serrated adenomas. Carcinoma was found in 30% of patients (21 cases), out of which 14 showed intra-mucosal and 7 sub-mucosal invasion. All patients with lesions showing sub-mucosal invasion on histology underwent surgery.

Of the 7 invasive lesions, one was located at the rectum, one at the rectosigmoid junction and the remaining 5 lesions in the colon.

The presence of cancer on histology was significantly associated with type 0-Ⅱa + Is (P = 0.011) and 0-Ⅱa + Ⅱc (P < 0.001), and was also related to the size (P < 0.001) of the lesions.

Procedural bleeding occurred in 5/69 (7%) resected lesions; one early (within 10 h) and one delayed (after 72 h) bleeding occurred, both requiring blood units transfusion. The procedural bleeding was always managed endoscopically by applying clips.

Transmural burn syndrome occurred in 2 patients (3%) and was successfully managed conservatively.

Two patients had a perforation that occurred during the final resection of a 40 mm 0-Ⅱa lesion of the ascending colon and during a resection of a 30 mm 0-Is recurred lesion of the rectum. In both patients, successful closure of the perforation with clips was achieved and no further intervention was required.

Endoscopic complications were significantly associated with the presence of invasive cancer on histology (P = 0.021), and in the logistic regression analysis, the only independent predictor of a complication was the dimension of the lesions (P = 0.002).

Among the 69 cases of successful ER, 62 (90%) patients have undergone colonoscopy follow-up for a mean (± SD) time of 16 ± 6 mo (range 6-24).

Among the sessile and non-polypoid lesions (51 cases), during the endoscopic follow-up residual/recurrence tissue was found in 14 (27%) cases; 13 were successfully treated endoscopically, while one patient underwent surgical resection due to 2 recurrence during the endoscopic follow-ups.

Recurrence of the lesion after ER was significantly associated to type 0-Ⅱa + Is (P = 0.001) lesions, to piecemeal resection (P = 0.01) and to the dimension (P = 0.004) of the lesions.

Overall, 74% of patients avoided surgery. Surgical resection was significantly associated with type 0-Ⅱa + Is (P = 0.01) and 0-Ⅱa + Ⅱc (P = 0.001) lesions, with sub-mucosal invasion on histology (P < 0.001), with presence of the "nonlifting sign" (P < 0.001), and related to the dimension (P = 0.001) of the lesions.

In the logistic regression analysis, the only independent predictor for surgical resection was the dimension of the lesions (P = 0.002).

DISCUSSION

This report describes a single-center experience in the endoscopic treatment of a cohort of patients with

DCRLs, showing that three quarters of the patients referred for surgical resection were successfully treated endoscopically.

Data of an European regional FOBT-based colorectal cancer screening program, suggest that up to 10% of patients with benign adenomas detected by screening colonoscopy after a positive fecal occult blood test will be treated surgically[15].

Indeed, a proportion of colorectal lesions, due to their location, size, or shape are considered technically more challenging to be removed endoscopically or are associated with an increased risk of complications (such as bleeding or perforation). Thus, these lesions are not routinely endoscopically resected and are often referred to surgeons for surgical resection[1-3].

Our study confirms these findings since, in our series, failure of ER was associated with the large size and the type of the lesions, as well as the lack of the lifting sign.

However, considering all the patients evaluated, 69 (84%) of them were successfully treated endoscopically, and 61 (74%) have so far avoided an unnecessary surgical procedure.

Our results are in agreement with other studies in whom, in referral centers surgical resection was avoided in the majority of patients with DCRLs (range 58%-90%)[2,16-18].

Therefore, it is possible that endoscopists who are inexperienced or are not used to treat technically challenging lesions, choose to refer patients for surgical resection.

Compared to the 20.1% morbidity and 1.3% mortality rates for surgery of colorectal tumors, general data on ER show much lower morbidity rates (0.7% to 3.7% for perforation and 0.4% to 3.8% for bleeding) and no mortality[19].

The Munich Polypectomy Study showed a correlation between large size, non-pedunculated shape and right-sided location of colorectal lesions and the occurrence of post-procedural complications[20].

Considering only the studies on DCRLs resection, these findings were evident, indeed the mean morbidity rate was 18% (the majority treated endoscopically), however without mortality[2,16-18,21,22].

In accordance with previous studies[2,16-18,21,22], also in our series, ER for DCRLs was performed without mortality and with an acceptable rate of morbidity (16%); moreover, all the complications that occurred were successfully managed endoscopically or conservatively. Procedural bleedings were controlled endoscopically in all cases and all the perforations were detected during the procedure and closed endoscopically with good clinical outcomes.

Furthermore, the complications of ER seem to depend on the lesions characteristics as well as on the experience and skills of the endoscopist.

The present study confirms that ER of DCRLs can be performed with satisfactory safety and that high-risk ERs should be performed by experts at a high-volume center.

Residual/recurrent disease can occur after ER of non-pedunculated colorectal lesions, with a mean rate of 15%[23].

For DCRLs, the mean rate of residual/recurrence is doubled, approximately 30%[2,16-18,21,22]. In our study the local residual/recurrence was detected in 27% of cases in accordance with the results of previous studies on the ER of DCRLs. Moreover, our results confirmed that the piecemeal technique is associated with a higher rate of residual/recurrent neoplasia, as stated by the Italian Colorectal ER Study Group in a recent published paper[24], and was similar despite the use or not of APC after resection.

Our results show also a correlation with the size of the lesions, in accordance with a recent systematic review[23]. The review also confirmed that the pooled estimate risk of recurrence was significantly higher for piecemeal (20%; 95%CI: 16%-25%) than for en bloc resections (3%; 95%CI: 2%-5%; Cochran's Q test $P < 0.0001$)[23].

To reduce residual/recurrence rates, endoscopic submucosal dissection (ESD) has been proposed as a superior technique compared to the "inject and cut" piecemeal ER, since it allows an *en bloc* excision of large colorectal neoplastic tissue, thus allowing a more accurate pathological diagnosis[19].

However, ESD in the colon is technically demanding, with a long learning curve and increased procedures duration; moreover, it requires the use of specialized accessories, increasing the costs of the procedures and has a high perforation rate, making it unlikely to be adopted into therapeutic colonoscopy practice in western countries[19].

Hypothetically, applying ESD to our series, at the best of the performance of the technique, we would have achieved an *en-bloc* resection rate of 80% (45 out of 57 patients). This could have allowed a better evaluation of the submucosal invasion in the 7 patients in which it was found to be present, virtually avoiding surgery to 2 or 3 more patients. The lower recurrence rate (about 1%-2%) could allow a reduction of the number of treatments needed to achieve complete clearance of the lesion, but the higher costs of the procedures counterbalance the reduction of the number of sessions. Moreover, ESD has higher complication rates, requiring the mandatory admission of the patient to be treated. About 1% to 2% of these complications need surgical intervention, reducing the beneficial effect of the better *en-bloc* resection rate.

Furthermore, if the piecemeal ER is performed acquiring as bigger and fewer pieces as possible, including at least 1-3 mm of normal tissue surrounding the lesions, and all fragments of the lesion are retrieved, the risk of missing neoplastic invasion seems negligible, and the recurrence rate is acceptable.

Our results also show that the endoscopic treatment of residual/recurrent tissue was easy and effective (successful in 93%), in accordance with the systematic review by Belderbos *et al*[23], in which after a mean of 1.2 endoscopic re-treatments, successful eradication was

achieved in 91.4% of recurrences.

The main limitations of our study are the relatively small number of reported lesions and the non-prospective, randomized design of the study. Thus, the superiority of ER over surgical treatment cannot be proven, however, such a trial would probably be unethical to perform.

In conclusion, before submitting patients to surgical resection of a benign colorectal lesion, a second opinion by an examiner who is experienced in ER of such lesions is worthwhile and mandatory to avoid unnecessary surgery.

COMMENTS

Background

A "difficult" colorectal lesion (DCRL) is defined as any lesion who's endoscopic resection (ER) is technically challenging. In less experienced endoscopic centres, benign DCRLs are often referred to surgical resection.

Research frontiers

This study aimed to assess how many patients with benign DCRLs referred to surgical resection, may be treated with ER rather than surgical resection.

Innovations and breakthroughs

In these research results, 74% of patients with DCRLs referred to surgeons for colorectal resection, after an endoscopic re-evaluation were successfully treated with ER and avoided surgery.

Applications

Before submitting patients to surgical resection for a benign DCRL, a second opinion by an experienced endoscopist is mandatory to avoid unnecessary surgery.

Terminology

A DCRL is defined as any lesion who's ER is technically challenging due to the size, the shape or the location, or due to the presence of fibrosis as a consequence of previous attempts of ER.

Abstract

AIM: To evaluate the efficacy and safety of single-step endoscopic placement of self-expandable metallic stents (SEMS) for treatment of obstructive jaundice.

METHODS: A retrospective study was performed among 90 patients who underwent transpapillary biliary metallic stent placement for malignant biliary obstruction (MBO) between April 2005 and October 2012. The diagnosis of primary disease and MBO was based on abdominal ultrasound, computed tomography, magnetic resonance imaging, endoscopic ultrasound, endoscopic retrograde cholangiopancreatography with brush cytology, biopsy, and/or a combination of these modalities. The type of SEMS (covered or non-covered, 8 mm or 10 mm in diameter) was determined by the endoscopist. Ninety patients were divided into two groups: group 1 (49 patients) who underwent a single-step SEMS placement and group 2 (41 patients) who underwent a two-step SEMS placement. The technical success rate, complication rate, stent patency, and patient survival rate were compared between the groups. In addition, to identify the clinical prognostic factors associated with patient survival, the following variables were evaluated in Cox-regression analysis: gender, age, etiology of MBO (pancreatic cancer or non-pancreatic cancer), clinical stage (Ⅳb; with distant

metastases or Ⅳa >; without distant metastases), chemotherapy (with or without), patency of the stent, and the use of single-step or two-step SEMS.

RESULTS: Immediate technical success was achieved in 93.9% (46/49) in group 1 and in 95.1% (39/41) in group 2, with no significant difference (P = 1.0). Similarly, there was no difference in the complication rates between the groups (group 1, 4.1% and group 2, 4.9%; P = 0.62). Stent failure was observed in 10 cases in group 1 (20.4%) and in 16 cases in group 2 (39.0%). The patency of stent and patient survival revealed no difference between the two groups with Kaplan-Meier analysis, with a mean patency of 111 ± 17 d in group 1 and 137 ± 19 d in group 2 (P = 0.91), and a mean survival of 178 ± 35 d in group 1 and 222 ± 23 d in group 2 (P = 0.57). On the contrary, the number of days of hospitalization associated with first-time SEMS placement in group 1 was shorter when compared with that number in group 2 (28 *vs* 39 d; P < 0.05). Multivariate analysis revealed that a clinical stage of Ⅳa > (P = 0.0055), chemotherapy (P = 0.0048), and no patency of the stent (P = 0.011) were independent prognostic factors associated with patient survival.

CONCLUSION: Our results showed that single-step endoscopic metal stent placement was safe and effective for treating obstructive jaundice secondary to various inoperable malignancies.

Key words: Endoscopic stenting; Single-step; Malignant biliary obstruction; Self-expandable metallic stents; Two-step

Core tip: Single-step placement of expandable metallic stents for treating malignant biliary obstruction is useful for shortening hospitalization. To maximize symptomatic relief and cost benefits, stent placement should not be delayed after deciding on metal stent palliation.

Yamamoto R, Takahashi M, Osafune Y, Chinen K, Kato S, Nagoshi S, Yakabi K. Comparison of endoscopic stenting for malignant biliary obstruction: A single-center study. *World J Gastrointest Endosc* 2015; 7(9): 889-894 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/889.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.889

INTRODUCTION

Because of improvements in operative procedures and diagnostic techniques, both the incidence of biliary pancreatic malignancies and resection rates have increased. Nevertheless, partly due to the high incidence obstructive jaundice in affected patients, some cases remain inoperable with a poor prognosis. Presently, the preferred treatment for jaundice due to malignant biliary pancreatic obstruction is biliary stent placement. Such stenting was initially performed using polyethylene plastic stents; however, expanding metal stents have been available for several years[1,2]. These expandable metallic stents have several advantages over plastic stents: (1) they can be introduced by a smaller delivery catheter; (2) they have a large inner diameter; and (3) they can remain fixed in position after release[3-6]. In this study, we assessed the safety and efficacy of single-step endoscopic placement for self-expandable metallic stents (SEMS) for treating obstructive jaundice secondary to various inoperable malignancies.

MATERIALS AND METHODS

This study included 90 patients who underwent transpapillary biliary metallic stent placement for malignant biliary obstruction (MBO) between April 2005 and October 2012 at the Saitama Medical Center of Saitama Medical University. For these 90 patients (72 men and 18 women), the diagnoses of primary disease and MBO were based on abdominal ultrasound, computed tomography, magnetic resonance imaging, endoscopic ultrasound, endoscopic retrograde cholangiopancreatography with brush cytology, biopsy, and/or a combination of these modalities. Before cholangiography, all patients were diagnosed with obstructive jaundice caused by an unresectable malignancy because of either very advanced carcinoma or old age. The type of SEMS (covered or noncovered, 8 mm or 10 mm in diameter) was determined by the endoscopist. Ninety patients were divided into two groups: group 1 (49 patients) who underwent a single-step SEMS placement and group 2 (41 patients) who underwent a two-step SEMS placement, depending on the severity of cholangitis. The flowchart for the single-step and two-step SEMS placements for distal MBO is shown in Figure 1.

The technical success rate, complication rate, length of hospital stay, stent patency, and patient survival rate were compared between the groups. Techinical success was defined as successful endoscopic deployment of the stent at the appropriate position resulting in a smooth drainage of the stented bile ducts. Complication rate was defined as the pancreatitis, bleeding and cholangitis arising from stent placement for malignant bile duct obstruction. And, length of hospital stay was defined as the period between hospital admission and discharge. In addition, to identify the clinical prognostic factors associated with patient survival, the following variables were evaluated with a Cox-regression analysis: gender, age, etiology of MBO (pancreatic cancer or nonpancreatic cancer), clinical stage (Ⅳb with distant metastasis or Ⅳa > without distant metastasis), chemotherapy (with or without), patency of the stent, and the use of single-step SEMS or two-step SEMS. This study was performed according to the principles of the Declaration of Helsinki, and informed consent was obtained from the patients and/or their families.

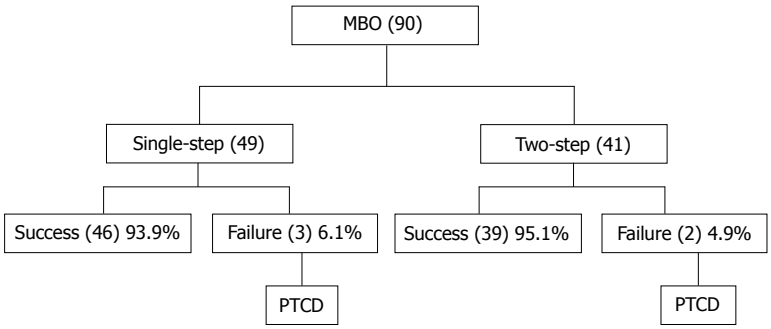

Figure 1 Flowchart showing one-step and two-step self-expandable metal stent placement for distal malignant biliary obstruction. MBO: Malignant biliary obstruction; PTCD: Percutaneous transhepatic cholangiodrainage.

Table 1 Patients characteristics in the two groups

Variable	Single-step (n = 49)	Two-step (n = 41)	P
Mean age (yr)	70.1 ± 12.6	74.3 ± 9.9	NS
Gender (n)			
Male	49	23	< 0.01
Female	0	18	
Etiology of MBO: pancratic cancer (%)	59.2	31.7	0.016
MPD tumor involvement present (%)	36.7	24.4	NS
Spincterotomy (%)	2.0	22.0	0.003
Hilar biliary obstruction (%)	22.4	46.3	0.03
Clinical stage			
Ⅳa > (%)	40.8	61	NS
Ⅳb (%)	59.2	39	NS
Bilateral drainage (%)	4.1	12.2	NS
Technical success rate (%)	93.9	95.1	NS
Complication rate (%)	4.1	4.8	NS
Chemotherapy (%)	55.1	51.2	NS
Length of hospital stay (d)	28.1 ± 28.6	39.6 ± 25.7	< 0.05

MBO: Malignant biliary obstruction; MPD: Main pancreatic duct.

Statistical analysis

We reviewed medical records and radiological images of all patients undergoing stent placement. We then assessed the following variables using univariate analyses (χ^2 test or Fisher's exact test) to identify patient survival: sex, age, etiology of MBO (pancreatic cancer or nonpancreatic cancer), clinical stage (Ⅳb with distant metastasis or > Ⅳa without distant metastasis), chemotherapy (with or without), stent patency, and the use of single-step SEMS or two-step SEMS. We estimated survival times with the Kaplan–Meier method and compared them using the log-rank test. We also calculated odds ratios with 95%CIs for all variables. These statistical tests were two-sided, and statistical significance was set at P value < 0.05 for all analyses. The statistical evaluation was performed using SPSS (IBM, JAPAN) 21.0 for Windows.

RESULTS

The clinical characteristics of the study participants are summarized in Table 1. The single-step group (group 1) included only 49 men (percentage of men = 100%) with a mean age of 70.1 years. The two-step group (group 2) included 23 men (56.1%, P < 0.01) and 18 women (43.9%) with a mean age of 74.3 years. The incidence of pancreatic cancer was higher in group 1 than in group 2 (59.2% *vs* 31.7%, P = 0.016) (Table 1). The information concerning stricture location and endoscopic sphincterotomy (EST) performance before stenting is shown in Table 1. The number of ESTs performed before stenting was statistically significantly higher in group 1 than in group 2 (2.0% *vs* 22%, P < 0.01). The patient characteristics in the two groups categorized by treatment are summarized in Table 1. Although hilar obstruction was significantly less frequent in group 1 than in group 2 (22.4% *vs* 46.3%, P = 0.03), there was no difference in bilateral drainage rate between the two groups (group 1, 4.1% and group 2, 12.2%; P = 0.24). Immediate technical success was achieved in 93.9% (46/49) patients in group 1 and 95.1% (39/41) patients in group 2; there was no significant difference (P = 1.0). Serum total bilirubin levels were within normal limits within two weeks after placement of the stent in all patients who underwent successful procedures. Likewise, there was no difference in the occurrence of complication between the groups (group 1, 4.1% and group 2, 4.9%; P = 0.62).

We observed stent failure in 10 cases in group 1 (20.4%) and 16 cases in group 2 (39.0%). The stent was patent in all 26 cases. There was no difference in the stent patency or patient survival between both groups using the Kaplan–Meier analysis, with a mean patency of 111 ± 17 d in group 1 and 137 ± 19 d in group 2 (P = 0.91, Figure 2), and a mean survival of 178 ± 35 d in group 1 and 222 ± 23 d in group 2 (P = 0.57, Figure 3). In contrast, the number of hospitalization days associated with first-time SEMS placement in group 1 was shorter than in group 2 (28 *vs* 39 d; P < 0.05). Multivariate analysis found that a clinical stage of Ⅳa > (P = 0.0055), chemotherapy (P = 0.0048), and no patency of the stent (P = 0.011) were independently associated prognostic factors for patient survival (Table 2).

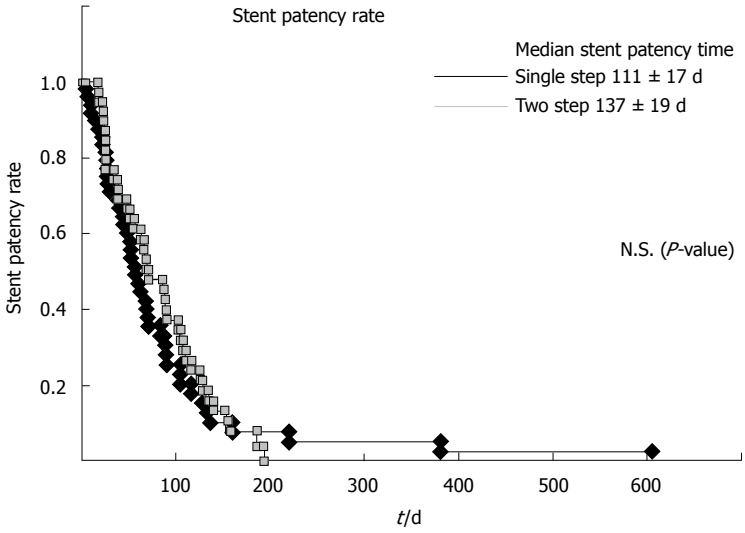

Figure 2 Kaplan-Meier curves showing the patency time of the stent in the single-step and two-step groups.

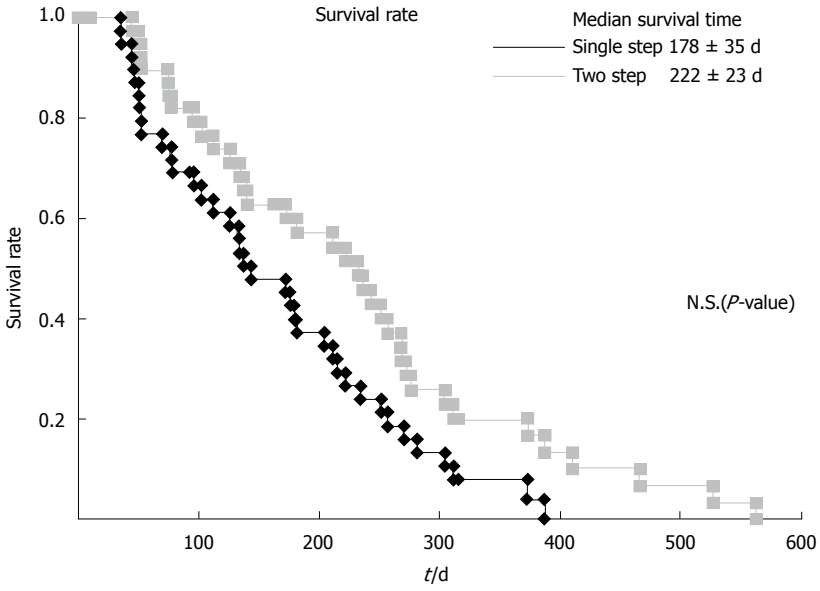

Figure 3 Kaplan-Meier curves showing the survival time of the patient in the single-step and two-step groups.

DISCUSSION

Patients with malignant bile duct obstruction have poor long-term survival and are not candidates for surgical resection. The goals of palliation using a biliary stent placement are symptomatic relief of obstructive jaundice, prevention of cholangitis, and prolongation of survival. Stenting has also been found to improve quality of life of these patients. To maximize the symptomatic relief and cost benefits, the stent should be placed as soon as the decision for metal stent palliation has been made. However, a recent study[7,8] that compared the single-step and two-step procedures found that procedure-related complication rate improved with single-step procedures with no increase in early complications. However, Hamada *et al*[8] reported that single-step SEMS placement for distal MBO was associated with a shorter time to dysfunction and a higher rate of stent migration than two-step SEMS placement. In addition, single-step procedure caused minimal patient discomfort, and avoided both the second intervention and drainage catheter dislocation risk before the deployment of the stent. The single-step placement procedure has two goals: (1) reducing the number of interventions and hence the procedural expenses; and (2) eliminating the need for bile-collecting bags or bottles, thus resulting in an improvement in quality of life as well as reduction in hospitalizations.

In this study, we evaluated the efficacy and safety of the single-step endoscopic placement of SEMS for treating obstructive jaundice that can be caused by various inoperable malignancies. There was no difference in stent patency and patient survival between the two groups in the Kaplan–Meier analysis. In contrast, the

Table 2 Multivariate analysis to identify the clinical prognostic factors for patient survival

Variables	OR	95%CI	*P*
Step (single *vs* two)	0.81	0.49-1.36	0.42
Gender (male *vs* female)	1.05	0.66-1.67	0.83
Age (69 ≥ *vs* 70 <)	1.02	0.59-1.76	0.96
Pancratic cancer (yes *vs* no)	1.01	0.21-1.61	0.98
Clinical stage (ⅣA ≥ *vs* ⅣB)	2.03	1.23-3.34	0.006
Chemotherapy (with *vs* without)	2.18	1.27-3.76	0.005
Patency of the stent (no *vs* yes)	2.21	1.20-4.07	0.011

number of hospitalization days associated with first-time SEMS placement in group 1 was lower than in group 2 (28 *vs* 39 d, $P < 0.05$). The multivariate analysis revealed that a clinical stage of ⅣA > ($P = 0.0055$), chemotherapy ($P = 0.0048$), and no patency of the stent ($P = 0.011$) were independently associated prognostic factors of patient survival. Patients with inoperable malignant strictures generally receive only palliative radiotherapy or chemotherapy and have a limited life expectancy. One possible reason for poor outcomes may be the delay between the diagnostic cholangiography and the placement of the metallic stent[9]. McDougall *et al*[9] determined that 25 (78%) patients had a plastic stent placed before placement of the metallic stent, leading to a mean delay of 123 d, and that 7 (22%) patients had > 1 metallic stent placed. This clearly suggests that if a metallic stent is placed earlier in the course of the disease, the stent patency can be prolonged.

The strategies for self-expandable metal stent placement can depend on the primary cancer types because of the differences in their biological behavior. However, the survival times were not significantly different between patients with pancreatic cancer and those with other primary cancers in our study population. Therefore, this factor may not have any effects on the results of the analyses.

The limitations of our study were as follows. Firstly, our study population was not large enough for a meaningful analysis regarding the efficacy of single-step endoscopic metal stent placement. Secondly, because this was not a prospective study, selection biases regarding the type of SEMS and the procedure adopted for cannulation of the ampulla were present. We propose the implementation of initial stenting for partial drainage of malignant hilar bile duct strictures, rendering contralateral drainage as a last resort for cases with severe cholangitis or insufficient reduction of jaundice.

To conclude, single-step placement of expandable metallic stents for MBO cases that are inoperable is a useful method to shorten hospitalization. Once the decision about metal stent palliation has been made, the stent should be placed as soon as possible to maximize symptomatic relief and cost benefits.

In conclusion, our results showed that single-step endoscopic metal stent placement was safe and effective for treating obstructive jaundice secondary to various inoperable malignancies.

COMMENTS

Background

Although self-expandable metal stent (SEMS) placement has been widely performed for treating malignant biliary obstruction (MBO), few studies have compared single-step SEMS (direct placement without a prior plastic stent) and two-step SEMS (stent placement at second session following temporary plastic stent placement).

Research frontiers

The objective of this study was the evaluation of the safety and efficacy of single-step endoscopic placement of SEMS for treating obstructive jaundice caused by various inoperable malignancies.

Innovations and breakthroughs

This was a retrospective single-center study of 90 consecutive patients who had undergone endoscopic retrograde cholangiopancreatography-guided transpapillary biliary metallic stent placement for MBO during a 7.5-year-period. The patients of this study were divided into two groups: a single-step SEMS placement group ($n = 49$) and a two-step SEMS placement group ($n = 41$). MBO etiologies were similar between both groups, with pancreatic cancer accounting for 46.7% cases. No significant differences in the patency rate of stents and patient survival were observed between the single-and two-step groups. In contrast, the number of hospitalization days associated with first-time SEMS placement in the single-step group was lower compared with that in the other group (28 *vs* 39 d). Multivariate analysis identified that ⅣA > clinical stage ($P = 0.0055$), chemotherapy ($P = 0.0048$), and no patency of the stent ($P = 0.011$) were independently associated prognostic factors for patient survival.

Applications

These findings will be particularly interesting to the readership of World Journal of Gastrointestinal Endoscopy as they demonstrate that single-step endoscopic metal stent placement is effective and safe for treating obstructive jaundice caused by various inoperable malignancies.

Peer-review

This is a manuscript about an interesting issue that has not been published extensively. It is written in fluent, simple English, easy to comprehend.

Abstract

AIM: To present evidence and formulate recommendations for sedation in pediatric gastrointestinal (GI) endoscopy by non-anesthesiologists.

METHODS: The databases MEDLINE, Cochrane and EMBASE were searched for the following keywords "endoscopy, GI", "endoscopy, digestive system" AND "sedation", "conscious sedation", "moderate sedation", "deep sedation" and "hypnotics and sedatives" for publications in English restricted to the pediatric age. We searched additional information published between

January 2011 and January 2014. Searches for (upper) GI endoscopy sedation in pediatrics and sedation guidelines by non-anesthesiologists for the adult population were performed.

RESULTS: From the available studies three sedation protocols are highlighted. Propofol, which seems to offer the best balance between efficacy and safety is rarely used by non-anesthesiologists mainly because of legal restrictions. Ketamine and a combination of a benzodiazepine and an opioid are more frequently used. Data regarding other sedatives, anesthetics and adjuvant medications used for pediatric GI endoscopy are also presented.

CONCLUSION: General anesthesia by a multidisciplinary team led by an anesthesiologist is preferred. The creation of sedation teams led by non-anesthesiologists and a careful selection of anesthetic drugs may offer an alternative, but should be in line with national legislation and institutional regulations.

Key words: Gastro-intestinal endoscopy; Gastroscopy; Colonoscopy; Sedatives; Pediatric ages; Anesthetics; Analgesics

Core tip: Sedation for pediatric gastro-intestinal endoscopy is preferably performed by pediatric anesthesiologists, as part of a multidisciplinary team. However, in many hospitals pediatric anesthesiology is insufficiently developed. The creation of sedation teams led by non-anesthesiologists and a careful selection of anesthetic drugs may offer an effective and safe alternative. These teams should be in line with national legislation and institutional regulations. This paper will help non-anesthesiologists to provide as good-as-possible sedation for children undergoing endoscopy. Practical protocols were developed providing up-to-date information on the most effective and most safe options.

Orel R, Brecelj J, Dias JA, Romano C, Barros F, Thomson M, Vandenplas Y. Review on sedation for gastrointestinal tract endoscopy in children by non-anesthesiologists. *World J Gastrointest Endosc* 2015; 7(9): 895-911 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/895.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.895

INTRODUCTION

Esophago-gastro-duodenoscopy in children needs almost always to be performed under anesthesia or deep sedation. Procedural analgesia and sedation for procedures performed in ambulatory care are changing. The authors reviewed the literature on sedation and for endoscopy by non-anesthesiologists and to propose practical algorithms.

In order to obtain the greatest yield from a pediatric gastrointestinal (GI) endoscopic procedure and to perform these with the highest quality and with the maximum level of safety, some prerequisites must be fulfilled. A pediatric gastroenterologist or dedicated pediatrician must have judged the necessity of the procedure to optimize patient management. The procedure must be performed by a skilled endoscopic team with appropriate equipment in a suitable environment. The patient and parents or guardians must be informed as much and good as possible.

General anesthesia is only possible in a limited number of centers because of shortness of anesthesiologists. The aim of this review is to present and discuss different sedation protocols for non-anesthesiologists for pediatric GI endoscopies. Several protocols for procedural sedation by non-anesthesiologists have been produced by different professional bodies and organizations. However, practical algorithms for these procedures have not been published[1].

MATERIALS AND METHODS

The search for studies on pediatric sedation for GI endoscopy was an update of van Beek and Leroy[2]'s search strategy for the period between January 2011 (when their search was finished) and January 2014 and utilized the following databases: MEDLINE, Cochrane, and EMBASE[2]. These were searched for the keywords "endoscopy, GI", "endoscopy, digestive system" and "sedation", "conscious sedation", "moderate sedation", "deep sedation", and "hypnotics and sedatives" for publications in English restricted to the pediatric age group, which was defined as 0 to 18 years. Subsequently a search for pediatric GI endoscopy sedation guidelines for the same keywords as above for the last 20 years with the same limits (publications in English, pediatric population) was undertaken. The search was expanded to include guidelines for GI endoscopy sedation by non-anesthesiologists for the adult population for the last 10 years. Furthermore a search for guidelines for pediatric procedural sedation published in the last 10 years was made.

RESULTS

The first search revealed 12 studies of which 8 are listed in Table 1[3-10]. Four of them were not relevant: Liu *et al*[11] analyzed anesthesia for outpatient gastroscopies and colonoscopies in adults only, Yen *et al*[12] studied sex differences in sedation with midazolam and alfentanil for gastroscopy only in adults, too[3,4]. The aim of the study of Vadlamudi *et al*[13] was evaluation of ileoscopy *via* stoma and not a sedation[13]. And finally, Siwiec *et al*[14] tested transnasal gastroscopy with ultrathin endoscope in non-sedated healthy volunteers or patients with the signs or symptoms of gastro-esophageal reflux disease.

We found one guideline for pediatric GI endoscopy in

Table 1 Publications from the first search ("endoscopy, gastrointestinal", "endoscopy, digestive system" AND "sedation", "conscious sedation", "moderate sedation", "deep sedation", and "hypnotics and sedatives"; limits: publications in English, paediatric population

Ref.	Methodology	Results	Limitations	Conclusions
Bedirli *et al*[3]	Study type: prospective, randomised, double-blinded Patients: *N* = 80; 1–16 yr; ASA Ⅰ, Ⅱ Procedure: upper GI endoscopy Drugs: baseline: propofol (1 mg/kg; additional 0.5–1 mg/kg as needed); intervention: fentanyl (2 μg/kg) *vs* tramadol (2 mg/kg) Intended sedation level: deep sedation Additional interventions: spray of lidocaine 10%; infusion of 10 lactated Ringer's solution (10 mL/kg per hour); supplemental oxygen 3–4 L/min) Administered by: anesthesiologist Outcome measures: Adverse events: HR (change for 20% from the baseline), BP (change for 20% from the baseline), SpO2 (< 90% for more than 15 s), respiratory rate, agitation score Effectiveness: Ramsey sedation score, duration of endoscopy, Steward recovery score, endoscopist's rating of ease of procedure, total propofol consumption	Adverse events: self-limited bradycardia and transient desaturation in age group 0–2 yr, more in the fentanyl group Effectiveness: lower sedation scores in tramadol group; no difference of gastroenterologist rating	Only one dosage of drugs instead of titrating them	Propofol with tramadol or propofol provided efficient sedation; significantly less adverse effects in the tramadol group
Brecelj *et al*[4]	Study type: randomized, controlled, single-blinded Patients: *N* = 201; 1–18 yr Procedure: gastroscopy, colonoscopy Drugs: ketamine (0.75 mg/kg with additions of 0.25 mg/kg up max. to 1.5 mg/kg; repeated after 10–15 min at 0.5 mg/kg as needed) Intervention: midazolam (0.1 mg/kg; max 2.5 mg; repeated after 30–60 min at 0.05 mg/kg as needed) *vs* no premedication Intended sedation level: deep sedation Additional interventions: none Administered by: dedicated nurse under supervision of endoscopist Outcome measures: Adverse events: respiration rate, HR, BP, SaO2 (any drop below 92%), adverse reactions Effectiveness: ease of procedure, total ketamine consumption	Adverse events: mild self-limited laryngospasm in 3%, high rate of desaturations (approx. in 40%), vomiting in 17%, regardless of study group; more emergence reactions in ketamine group during recovery (10 *vs* 2) Effectiveness: high rate of sedation adequacy	Study was not double-blinded	Ketamine starting dose should be at least 1 mg/kg; more emergence reactions without midazolam premedication; same frequency of other adverse reactions
Miqdady *et al*[5]	Study type: retrospective cohort study Patients: *N* = 301; 1 (more than 10 kg) –18 yr; ASA Ⅰ, Ⅱ Procedure: upper, lower or combined GI endoscopy Drugs: atropine (0.01–0.02 mg/kg per minute. 0.1 mg, max. 0.4 mg); midazolam (0.05–0.2 mg/kg); ketamine (0.5–1 mg/kg) Intended sedation level: deep sedation Additional interventions: none Administered by: endoscopist Outcome measures: Adverse events: respiration rate, HR, BP, SaO2 (any drop below 94%), side effects Effectiveness: the adequacy of sedation	Adverse events: desaturation in 12.3%, in 1.2% disruption of examination due to persistent desaturation; in 1.2% respiratory distress after examination Effectiveness: effective and uneventful sedation in 79.4%	Retrospective study	Midazolam and ketamine sedation is safe and effective for diagnostic GI endoscopies in children older than 1 yr weighting more than 10 kg without comorbidities

Motamed *et al*[6]	Study type: prospective, randomised, double-blinded Patients: *N* = 150; 1–18 yr; ASA Ⅰ, Ⅱ Procedure: upper GI endoscopy Drugs: main sedative: midazolam (0.1 mg/kg; if needed repeated doses up to 5 mg or 0.3 mg/kg); premedication 45 min before the procedure with oral placebo (normal saline), oral ketamin (5 mg/kg), or oral fentanyl (2 μg/kg) Additional interventions: spray of lidocaine 10%; additional oxygen trough nasal cannula at 2 L/min Administered by: registered nurse supervised by anaesthesiologist Outcome measures: Adverse events: respiration rate, HR (decrease by 30% from baseline), BP (decrease or increase by 20%), SaO2 (any drop below 90%) Effectiveness: total midazolam dose, modified Ramsey sedation score, procedure time, discharge time, ease of *iv* catheter placement, separation from parents agitation, the adequacy of sedation	Adverse events: in total in 26% of patients (hypoxia in 7.3%, hypotension in 6.7%, dizziness in 20%, nausea in 10%, vomiting in 17.6%); mild, easily managed Effectiveness: the total recovery and procedure duration time was shorter in the ketamine-midazolam group, inadequate sedation in 10.2% in placebo-midazolam and in 8% in fentanyl-midazolam *vs* in 3.9% in ketamine-midazolam group; the mean administered dose of midazolam was the lowest in ketamine-midazolam group; the *iv* line placement and separation from parents was easier in ketamine-midazolam group; only 27.4% of patients did not remember the procedure		Sedation with oral ketamine-iv midazolam is better than placebo-midazolam or oral fentanyl-iv midazolam
Chiaretti *et al*[7]	Study type: retrospective (12 yr), multicentric Patients: N = 36516; 1 to > 10 yr; ASA Ⅰ, Ⅱ, Ⅲ Procedure: different painful procedures Drugs: main sedative: propofol 2 mg/kg in children from 1 to 8 yr of age and 1 mg/kg in older children and in children younger than 1 yr; further doses of 0.5–1.0 mg/kg in the case of agitation or complain; premedication: atropine 0.010–0.015 mg/kg, ketamine (0.5 mg/kg) to avoid infusion pain in 2 centres (not in gastroscopy); additional oxygen trough nasal cannula at 6 L/min Intended sedation level: deep sedation Administered by: paediatrician (anaesthesiologist available in case of need) Outcome measures: mean arterial pressure, heart rate and SatO2, incidence, type and timing of adverse events (major and minor) and number of calls to the emergency team Effectiveness: total dosage of the sedative agents, level of sedation (Ramsay scale)	Adverse events: in 6 patients (0.02%) emergency team intervention (prolonged laryngospasm in 3 patients, bleeding in 1, intestinal perforation in 1, and 1 during lumbar puncture); milder adverse events: hypotension in 19 patients (0.05%), ventilation by face mask and additional oxygen in 128 patients (0.4%), laryngospasm in 78 patients (0.2%), bronchospasm in 15 patients (0.04%); minor complications more often in children who underwent gastroscopy; none of the children experienced severe side effects or prolonged hospitalisation.	Retrospective study	Propofol is safe and effective for paediatrician-administered procedural sedation in children; appropriate training for paediatricians is important
Gül *et al*[8]	Study type: randomized, controlled, double-blinded Patients: *N* = 64; 3-14 yr; ASA I Procedure: esophagogastroduodenoscopy Drugs: main sedative: propofol 2 mg/kg; analgesic: group R: remifentanil 0.25 μg/kg, group F: fentanyl 0.5 μg/kg; additional oxygen trough nasal cannula at 4 L/min Intended sedation level: deep sedation Administered by: anesthesiologist Outcome measures: MAP, HR, RR, and SpO_2 Effectiveness: ease of gastroscopy, patient's movements during procedure, additional doses of drugs; level of sedation (Ramsay scale); duration of PACU stay	Adverse events: prolonged apnoea in 14 (43.8%) children in group R and in 11 (33.3%) children in group F; none required endotracheal intubation; Effectiveness intraoperative respiratory rate, time to eye opening, opioid consumption, and duration of recovery were significantly shorter in group R duration of PACU stay were significantly shorter in group R than in group F		Remifentanil (combined with propofol) is an efficient and as safe as fentanyl propofol combination for esophagogastroduodenoscopy in children
Long *et al*[9]	Study type: retrospective analysis of prospectively collected data Patients: *N* = 4904; 15-90 yr; ASA Ⅰ-Ⅳ Procedure: esophagogastroduodenoscopy Drugs propofol 1-100 mg and/or midazolam 1-3 mg^2 mg/kg Administered by: endoscopist Outcome measures: influence of pre-existing disease and ASA score on oxygen desaturation (SpO_2) < 90%	Adverse events: hypoxemia in 245 patients (5%); risk factors: high BMI (30 kg/m^2), hypertension, diabetes, gastrointestinal disease, heart disease ASA score was not predictive for hypoxemia	Retrospective study	Independent risk factors for hypoxemia were high BMI, hypertension, diabetes, gastrointestinal and heart diseases and combined gastro and colonoscopy

Agostoni *et al*[10]	Study type: retrospective analysis of prospectively collected data Patients: *N* = 17999 (17524 in older than 12 yr, 457 in < 12 yr); 4-74 yr; ASA I-IV Procedure: esophagogastroduodenoscopy and in some cases different procedures (mucosectomy, hemostatic clip, percutaneous endoscopic gastrostomy, …) Drugs: propofol induction (in children 1-2 mg/kg BW) then in continous infusion Intended sedation level: deep sedation Administered by: anesthesiologist Outcome measures: adverse events (hypotension, desaturation, bradycardia, hypertension, arrhythmia, aspiration, respiratory depression, vomiting, cardiac arrest, respiratory arrest, angina, hypoglycemia, and/or allergic reaction)	Adverse events: rare in children (2.6%) and in adults (4.5%), in children were more often only bradycardia (2.1%) and hypotension (0.44%) 3 adult patients died; no death case in children	Retrospective analysis, single centre data	Deep sedation with intravenous propofol for endoscopic procedures is safe in children and adults

ASA: American Society for Anesthesiology; BP: Blood pressure; GI: Gastrointestinal; HR: Heart rate; SpO2: Oxygen saturation; BMI: Body mass index; RR: Respiratory rate.

English which addressed different aspects including sedation[15].

We expanded the search to guidelines for sedation for GI endoscopy performed by non-anesthesiologists in adult patients during the last 10 years. The search revealed 9 publications which are listed in Table 2[16-24].

The search for guidelines for pediatric procedural sedation published in English during the last 10 years revealed 10 publications. Two are general guidelines for sedation in children[25,26]. Another one, followed by an update published 7 years later, addresses specifically ketamine sedation for emergency departments[27,28]. Others are specifically developed for sedation for dental procedures in children. They are listed in Table 3[15,25,26,28-33].

Pre-requisites for safe and effective sedation by non-anesthesiologists

GI endoscopy must be discussed with the child if emotionally and intellectually competent enough and parent(s)/guardian(s). The pre-sedation assessment is listed in Table 4. Patients should be classified by physical status assessment as developed by the American Society for Anesthesiology (ASA) (Table 5). If the child's ASA classification conforms to class Ⅰ or Ⅱ, sedation can be performed safely. If the child fits in ASA class Ⅲ classification, the benefits of sedation must be carefully weighed against the risks and in the vast majority of cases anesthesiology will be preferable. Patients in ASA class Ⅳ and Ⅴ must be anesthetized by anesthesiologists[28,34].

The depth of sedation is influenced by the procedure. If analgesia is needed together with sedation, as in the case of endoscopic-therapeutic procedures, the patient has to be anesthetized. The same is valid for emergency GI endoscopies such as removal of a foreign body from the upper GI tract and GI bleeding. Sedation necessitates that a team member assigned for observing the vital signs of the patient, since monitoring of pulse oximetry, heart rate and preferably also capnography are insufficient[8,12].

Equipment for resuscitation must be present in the endoscopy room. The team has to be trained in pediatric advanced live support techniques and has to be familiar with measures needed in any scenario of complications[1].

Sedatives and their combinations

Legislation and regulation regarding limitations of administration of different medications, such as inhalation anesthetics, differ from country to country. Therefore, limitations caused by local legislation should be carefully checked. In most countries, the administration of inhalation anesthetics is only authorized by anesthesiologists.

Premedication

Premedication with midazolam (oral or intra-nasal) lessens the stress for an intravenous (*iv*) catheter placement and other preparations for GI endoscopy before sedation or anesthesia. This procedure is effective and safe although intranasal administration may cause local discomfort. In order to decrease the stress and pain caused by a venepuncture, an eutectic mixture of the topical anesthetics lidocaine and prilocaine provides local anesthesia when applied with an occlusive dressing 30-60 min before venipuncture[35].

An *iv* catheter provides the most effective way of delivering agents needed for sedation and analgesia. Inhalation, intramuscular or other sedation regimens are less well

Table 5 American Society of Anesthesiologists physical status classification[24]

Class	Description	Suitability for sedation
Class Ⅰ	A normally healthy patient	Excellent
Class Ⅱ	A patient with mild systemic disease (*e.g.*, controlled asthma)	Generally good
Class Ⅲ	A patient with severe systemic disease (*e.g.*, a child who is actively wheezing)	Intermediate to poor
Class Ⅳ	A patient with severe systemic disease that is a constant threat to life (*e.g.*, a child with status asthmaticus)	Poor
Class Ⅴ	A moribund patient who is not expected to survive without the operation (*e.g.*, a patient with severe cardiomyopathy requiring heart transplantation	Extremely poor

documented. An *iv* catheter is also important for emergency access in the case of adverse events occurring during sedation or the endoscopic procedure[25,36,37].

Mechanisms of action and the main undesirable effects of sedatives and adjuvant medicines are listed in Table 6[8,38-49]. Usual dosage regimens and the main contraindications are listed in Table 7.

Propofol

Propofol is a rapid onset and short acting anesthetic without analgesic properties and with a narrow therapeutic range. Its sedative properties result from agonistic action on gamma-aminobutyric acid (GABA) receptors. Propofol is contraindicated in infants younger than 1 mo bacasue of missing data on safety according to a Cochrane review[50]. The main undesirable effects include pain on injection, respiratory depression, bradycardia and hypotension[38,46].

van Beek and Leroy[2] reported failure to conduct a procedure due to incomplete sedation in only 0.0%–0.4% of cases, despite the fact that the sedation was performed in 88.1% by non-anesthesiologists[2]. The recovery time after propofol administration was shorter than after midazolam/meperidine[2]. Major respiratory complications occurred in 11/3883 propofol sedations (0.3%), but no I intubation and no sequelae were reported. The incidence of undesirable effects (*e.g.*, temporary desaturation due to hypoventilation, laryngospasm) was comparable to other protocols and was more frequent in younger children, especially infants[2].

A randomized study in 90 adults undergoing colonoscopy showed that the satisfaction of patients was greater

Table 6 Sedatives and adjuvant medicines for paediatric gastrointestinal endoscopy sedation

Generic name	Mechanism(s) of action	Main undesirable effects	Comments	Ref.
Sedatives				
Fentanyl	Opioid receptors agonist; analgesia and sedation	Respiratory depression, hypotension	Due to analgesic effect only it should be combined with benzodiazepine; antagonist naloxone	[38-40]
Ketamine	Binds to the Nmethyl-Daspartate (NMDA) receptors; anesthesia, analgesia, amnesia, sedation, immobilisation	Laryngospasm, hypertension, tachycardia, hypersalivation, vomiting, random movements, increase in intraocular pressure, emergence phenomena (floating sensations, vivid dreams, blurred vision, hallucinations, and delirium)	Beneficial respiratory properties and analgesic potency S(+) isomer has less adverse effects	[40-42]
Meperidine	Opioid receptors agonist; analgesia and sedation	Respiratory depression, pruritus, vomiting	Interaction with monoamine oxidase inhibitors	[38,43,44]
Midazolam	GABA receptor agonist; anterograde amnesia, anxiolysis, sedation, hypnosis	Respiratory depression, hypotension, paradoxical agitation	Without analgesic effect; should be combined with analgesic (usually opioids) Concomitant use with opioid increases the risk of respiratory depression antagonist flumazenil	[38-40]
Nitrous oxide	Inhalation anaesthetic	Vomiting, dizziness, voice change, euphoria, laughter	The need of scavenging system Use mostly limited to anaesthesiologists	[38,40,45]
Propofol	GABA receptor agonist; sedation, hypnosis, amnesia	Respiratory depression, apnoea, hypotension, painful injection		[38,40,46]
Sevoflurane	Inhalation anaesthetic	Recovery agitation, bradycardia, hypotension, cough, vomiting, seizures	The need of scavenging system Use limited to anaesthesiologists	[47-49]
Antagonists				
Flumazenil	Benzodiazepine antagonist	Nausea, vomiting	Contraindicated in benzodiazepine dependence, seizure disorder, cyclic antidepressant overdose, elevated intracranial pressure in patients, and in patients taking medicines known to lower the seizure threshold	[40]
Naloxone	Opioid antagonist	Nausea, vomiting, tachycardia		[40]

and there were less undesirable effects when they were sedated by an endoscopist than by an anesthesiologist[51]. A Scandinavian study tested a 6-wk educational program for registered nurses with excellent safety results[52].

The largest multicenter prospective study of propofol sedation for different pediatric procedures outside an operating theatre was published by the international (United States and Canada) Pediatric Sedation Research Consortium. They analysed the data of 49836 propofol sedation episodes and showed that propofol-based sedation is amongst the safest sedation practice for children[53]. Cardio-respiratory resuscitation was necessary in two cases. Pulmonary aspiration of gastric fluid secondary to vomiting during sedation occurred in four patients. Less serious respiratory adverse events were: desaturation in 154/10000 procedures; central apnea or upper airway obstruction in 124/10000; stridor in 10/10000; laryngospasm in 20/10000; excessive salivation in 73/10000; and vomiting in 10/10000 cases. The authors of this report estimate propofol sedation safe in children. Interestingly there were no differences in adverse effects between anesthesiologists and non-anesthesiologist. However, it should be pointed out that this report did not focus on upper GI endoscopy specifically, in which a shared airway is an important consideration, especially as attempting esophageal intubation may have the potential for induction of laryngospasm. However, it is stressed by the European Society of Paediatric Gastroenterology, Hepatology and Nutrition Endoscopy Working Group that the advice of the Pediatric Sedation Research Consortium, including institutions with highly motivated and well organized sedation/anesthesia teams, is only to be considered when anesthetic teams are not available, and that priority should go to actions to obtain these anesthetic teams.

Chiaretti *et al*[7] published a retrospective study on pediatric procedural sedation with propofol over a 12-year period in three Italian hospitals[7]. They analyzed 36516 procedural sedations for different painful procedures. Deep sedation was achieved in all patients. None of the children experienced severe side effects or needed a prolonged hospitalization. In six patients (0.02%) emergency team had to intervene (prolonged laryngospasm in three patients, bleeding in one, intestinal perforation in one, and one during lumbar puncture). But milder adverse events were more often: hypotension in 19 patients (0.05%), ventilation by face mask and additional oxygen in 128 patients (0.4%), laryngospasm in 78 patients (0.2%), bronchospasm in 15 patients (0.04%). Minor complications were more often in children who underwent gastroscopy.

The usual loading dose of propofol is 2 mg/kg in infants and young children (younger than 3 years) and 1 mg/kg in older children and teenagers. Subsequent

Table 7 The list of sedatives/analgesic, adjuvant medicines and antagonists with usual dosage regimens, and main contraindications

Medicine generic name	Route	Dose	Time to start sedation/ analgesia (after *iv* application)	Sedation/ analgesia duration	Repeating time and dose	Contraindications	Comments	Ref.
Sedative/ analgesic								
Fentanyl	*iv*	1–2 μg/kg (up to 50 μg)	0.5 s	20–40 min (30–60 min)	3 min 1–1.25 μg/kg		Due to higher clearance younger children need frequent dosing	[38,40]
Ketamine	*iv* slowly over 1 min; other routes have less predictive effects and different dosing – see the discussion	1–1.5 mg/kg	1–5 min	15 min	10 min 0.5 mg/kg	Severe cardiovascular disease, malignant hypertension, CSF obstructive states (controversial), intraocular pressure pathology; previous psychotic illness, hyperthyroidism or thyroid medicine use; porphyria	A single enantiomer S(+); the anesthetic management of seriously ill hypovolemic patients, it may be the agent of choice for managing children and burned patients; low cost	[8,40-42]
Meperidine	*iv* slowly over 1–2 min	0.3–2 mg/kg	3–6 min	60–180 min		Simultaneous treatment with monoamine oxidase inhibitors		[38,43,44]
Midazolam	*iv* slowly over 2–3 min; other routes have less predictive effects and different dosing	0.05–0.1 mg/kg in < 5 yr (max. 0.6 mg/kg); in 6–12 yr 0.025–0.05 mg/kg (max.0.4 mg/kg); in older than 12 yr 2–2.5 mg (in total not per kg BW)	2–3 min	45–60 min	Repeating doses every 2–5 min until desired effect; in children 6 mo–5 yr total dose up to 0.6 mg/kg or max. 6 mg; in 6–12 yr total dose up to 0.4 mg/kg or max. 10 mg; in older than 12 yr additional boluses of 1 mg until desired sedation	Respiratory depression, hypotension	Rarely used as a sole sedative; might be used to sedate the frightened child before iv catheter placement; mostly combined with opioids; paradoxical irritation in 1%–5% of patients	[38-40]
Nitrous oxide	Inhalation	Mostly the mixture of nitrous oxide (50%) and oxygen	0.5–1 min	5 min	Continuously or "on demand"	Pneumothorax, bowel obstruction, head injury, pregnancy	Its use limited to anaesthesiologists	[38,40,45]
Propofol	*iv*	2 mg/kg in infants and young children (younger than 3 yr); 1 mg/kg in children older than 3 yr	1–2 min	5–15 min	1 mg/kg (infants and children up to 3 yr); 0.5 mg/kg (children older than 3 yr) to reach the desired sedation; may be continuously infused at 100 μg/kg per min and increasing the speed of infusion by 50 μg/kg per min for prolonged procedures	Egg or soy allergy	For additional medication to alleviate infusion pain see text; alfentanil but not fentanyl increases propofol blood level; in many countries the use is limited to anaesthesiologists	[38,40,46]
Sevoflurane	Inhalation	Different concentrations according to the age				Duchenne's muscular dystrophy, moderate to severe liver disease of unknown aetiology, history of malignant hyperthermia	Its use limited to anaesthesiologists	[47-49]
Antagonists								
Flumazenil	*iv*	0.02 mg/kg (max. 1 mg)	1–3 min	30 min	1 min; same dose	Chronic benzodiazepine use; ingestion of drugs that increase the risk for seizures development (*e.g.*, cyclic antidepressants, cyclosporine, and others)	Due to its shorter duration of action than most of benzodiazepines (*e.g.*, midazolam) repeated doses may be needed	[38,40]
Naloxone	*iv* or *i.m.*	0.1 mg/kg (max. 2 mg)	2 min	20–40 min	2 min; same dose	Hypersensitivity only	Due to its shorter duration of action than most of opioids (*e.g.*, fentanyl) repeated doses may be needed	[38,40]

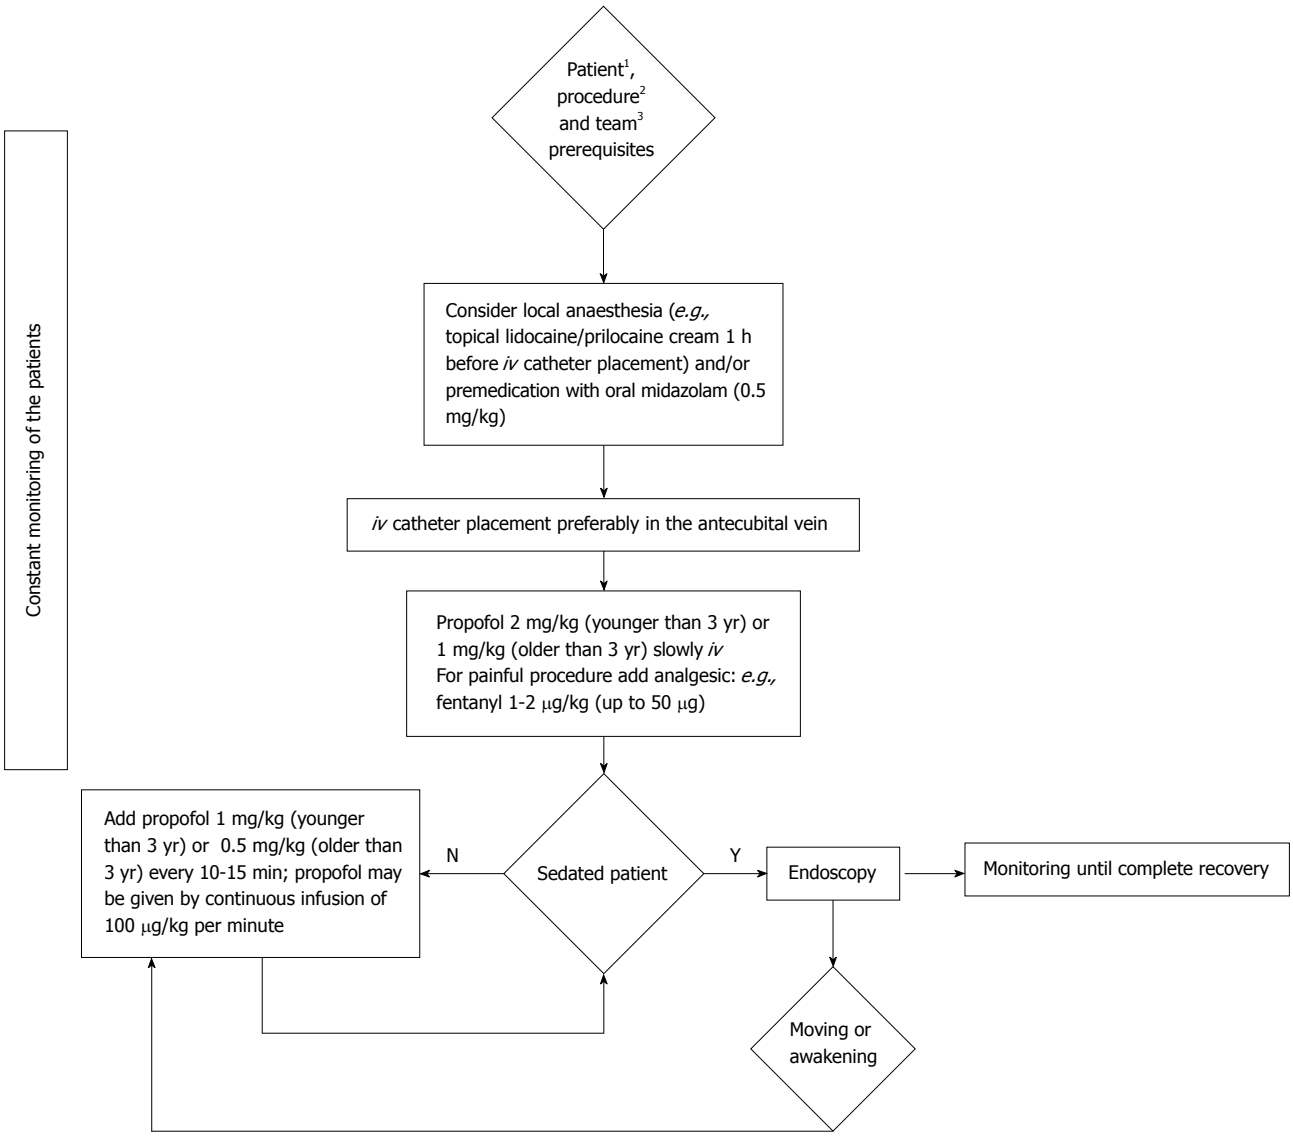

Figure 1 Flow chart of propofol sedation protocol for paediatric gastrointestinal endoscopy. [1]Older than 1 mo, without contraindications (egg or soy allergy); [2]Diagnostic endoscopy or procedure for which no endotracheal intubation is needed; [3]The team qualified for paediatric sedation for gastrointestinal endoscopy.

boluses of 1 mg/kg for younger, or 0.5 mg/kg for older children, may be added to ensure the appropriate level of sedation. For longer procedures propofol may be administered in a continuous infusion[38].

For painful procedures an analgesic must be added as propofol has no analgesic properties[38]. Bedirli *et al*[3] showed that the addition of tramadol or fentanyl to propofol provided efficient sedation, with less adverse events in the tramadol group (less desaturation, hypotension, and bradycardia; but more vomiting in fentanyl group)[3]. According to Gül *et al*[8] there was no difference in safety and efficacy between remifentanil and fentanyl co-administration with propofol.

The pain of propofol injection can be reduced by choosing a larger vein such as the antecubital site, or alternatively the injection of lidocaine[54]. A possible flow chart of propofol sedation for pediatric GI endoscopy is presented in Figure 1.

Generally, one cannot extrapolate data from adult practice to children. However, four different European Societies (of Gastrointestinal Endoscopy, of Gastroenterology, of Endoscopy Nurses and Associates, and of Anesthesiology) jointly issued guidelines for propofol sedation of adults for GI endoscopy by non-anaesthesiologists[16]. It is interesting that although the Board of Directors of the European Society of Anesthesiology (ESA) decided unanimously to endorse these guidelines, a majority of the national societies of the ESA did not support them. Consequently ESA retracted the endorsement[55]. The Danish training program for nurses includes training on how to administer propofol for GI endoscopic procedures in adults[52].

Ketamine

Ketamine is a dissociative anesthetic and analgesic. It is an N-methyl-D-aspartate channel antagonist and

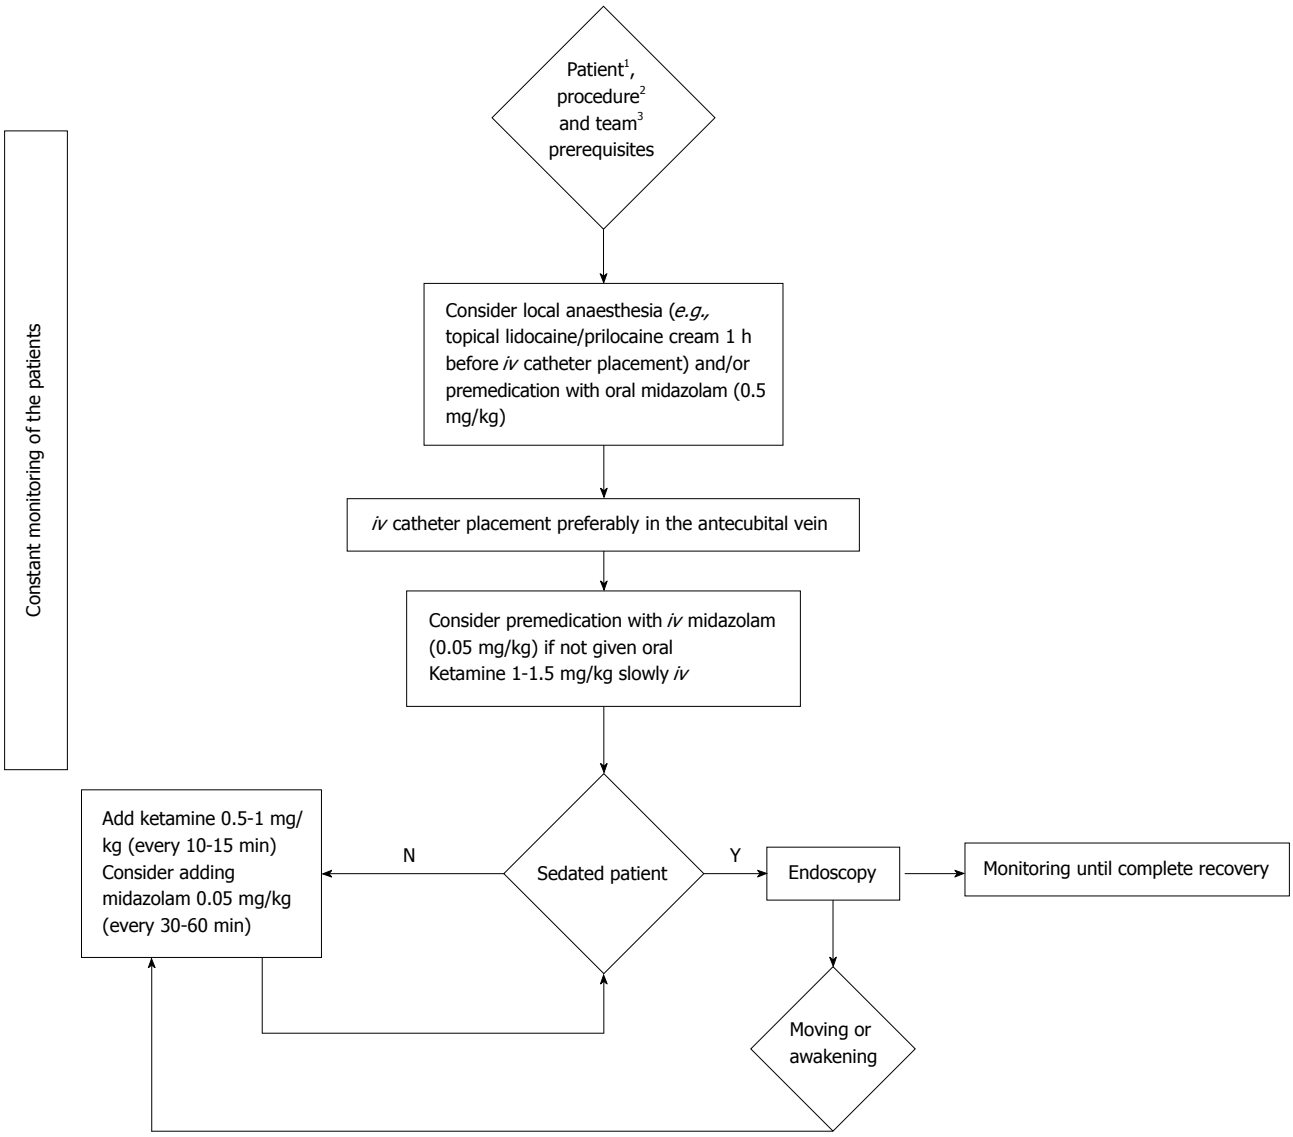

Figure 2 Flow chart of ketamine sedation protocol for paediatric gastrointestinal endoscopy. [1]Older than 3 mo, without contraindications (severe cardiovascular disease, malignant hypertension, CSF obstructive states, intraocular pressure pathology, psychotic illness, hyperthyroidism or thyroid medicines use, and porphyria); [2]Diagnostic endoscopy or procedure for which no endotracheal intubation is needed; [3]The team qualified for paediatric sedation for gastrointestinal endoscopy.

depresses sensory association areas of the cortex, limbic system and thalamus. It has been used for a long time for sedation and analgesia in emergency pediatrics due to its association with a preserve gag reflex and lack of respiration depression and hypotension[41]. Despite its good safety profile, the significant association with laryngospasm (especially with gastroscopy), emergence phenomena such as hallucinations, excitation, nightmares, delirium, recurrent illusions or "flashbacks", vomiting, and hypersalivation limit ketamine's broader use[27,38,41].

When used as a sedative, ketamine must be administered by slow *iv* injection at a dosage of 1-2 mg/kg initially. The sedative effect lasts 10-15 min. Repeated doses of 0.5 mg/kg prolong its action (Figure 2)[27,38].

The most frequent undesirable effects are vomiting, hypersalivation, nystagmus, hypertension, tachycardia, skin erythema, and emergence phenomena. Laryngospasm, which is potentially of greatest danger, is uncommon. The use of ketamine is contraindicated in infants younger than 3 mo, patients with psychosis, uncontrollable hypertension or hyperthyroidism, and as it increases intracranial and intraocular pressure. Ketamine should not be used after a head or eye trauma, or surgery, although some data advocate against these precautions[27,38].

The concomitant use of midazolam with ketamine decreases the frequency of emergence phenomena, although this remains controversial[56]. Two randomized double-blind studies performed in pediatric emergency departments did not find sufficient evidence to support the addition of midazolam for this purpose[57,58]. However, a randomized study using midazolam in co-administration with ketamine for pediatric sedation for GI endoscopy

suggests that midazolam does prevent emergence phenomena[4]. Other co-administered medicines might lessen some undesirable effects of ketamine but their use is not supported by sufficient evidence. Anticholinergics may prevent hypersalivation[59], but this has also been contradicted[60]. The anti-emetic ondansetron prevents vomiting in some patients[61].

Benzodiazepines and opioids

Midazolam is a short-acting benzodiazepine which is widely used for sedation but is generally considered to be insufficient as a monotherapy. It has anxiolytic, amnesic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties which result from GABA receptor activation[38,39]. The major undesirable effects are respiratory depression and hypotension, which are avoidable with appropriate dosing and are reversed by the antagonist flumazenil[38]. Other undesirable effects such as paradoxical agitation are reported in up to 15% of children[38].

Midazolam may be administered orally as an anxiolytic before the placement of an *iv* cannula but its effect is less predictive orally than when administered *iv* The usual starting dose is 0.1 mg/kg *iv* as a pre-medication but may be titrated to the desired effect by incremental doses of 0.05 mg/kg[39].

Opioids are potent analgesics which express their activity *via* different opioid receptors. The most suitable for sedation is fentanyl due to its rapid onset and short action. As it has no sedation properties it must be combined with benzodiazepines but the combination increases the risk of respiratory depression[38]. Other undesirable effects are itching, hypotension and vomiting but those are less pronounced than in histamine-releasing opioids such as morphine and meperidine[38]. Naloxone is an opioid receptor antagonist and is administered intravenously at 0.1 mg/kg[38].

Meperidine was the first synthetic opioid agent. It acts mainly as an antagonist of μ and κ receptors and has an analgesic potency ten times greater than that of morphine[62]. Like other opioid drugs, meperidine causes nausea, vomiting, urinary retention and respiratory depression. Its property of acting on nerve fibers, similar to those of local anesthetics, allows its use as an alternative for anesthetic blockade and differentiates it from other opioids. An *iv* route has been used for treating moderate to severe pain, for regional anaesthesia, for pre-medication and for analgesia during anesthesia. The combination of midazolam and meperidine can be used to achieve sedation and analgesia during colonoscopy[63]. There are few studies that have compared the efficacy of midazolam alone to midazolam and meperidine. According to Ozel *et al*[64], there were no significant differences in oxygen saturation/blood pressure but a better patient compliance was observed in the combined sedation group[64]. Cinar *et al*[65] showed that in respect of the recovery and procedure time there were no significant differences between the midazolam and the midazolam/meperidine group[65]. In a randomized trial comparing the efficacy and recovery time of two sedation regimens consisting of midazolam in combination with either meperidine or fentanyl, it was found that the fentanyl combination with midazolam resulted in a significantly faster recovery, without any apparent loss of analgesic effect[66]. Again, these are adult studies, and extrapolation to pediatrics is not necessarily appropriate.

Meperidine is administered intravenously at 1 mg/kg[64]. A possible flow chart of benzodiazepine and opioid sedation for pediatric GI endoscopy is presented in Figure 3.

Fentanyl is usually administered at 1–2 μg/kg. The analgesic effect lasts 20-40 min[38].

van Beek and Leroy[2]'s analysis found opioid and benzodiazepine sedation protocols suboptimal. These protocols were inferior in comparison to general anaesthesia. The comparison of midazolam/fentanyl with propofol sedation by Lightdale *et al*[67] addressed mainly procedure duration and discharge times which were similar for both groups, but the endpoint of this study was not to compare safety or efficacy.

Inhalation anesthetics

In most countries, legislation limits the administration of inhalation anesthetics to anesthesiologists.

Sevoflurane: Sevoflurane is an inhalational anesthetic with a very good safety profile (low incidence of airway hypersecretion, respiratory depression or cardiovascular events)[47]. When used for paediatric sedation for endoscopies it was characterized by a shorter recovery time and earlier discharge. Sevoflurane can only be administered by an anesthesiologist. The insertion of an *iv* catheter may not be needed. The use of inhaled anesthetics requires waste gas scavenging to prevent anesthetic gases being released into the ambient air[47].

There are no recently published studies on sevoflurane sedation for pediatric GI endoscopies.

Nitrous oxide: Nitrous oxide is an inert gas which has analgesic, sedative and amnesic properties of short duration. Michaud *et al*[68] reported a good experience with 50% nitrous oxide for gastroscopies and procto-sigmoidoscopies in children. They did not evaluate it for ileo-colonoscopy nor compare this type of sedation to other protocols[68]. There are no newer studies on nitrous oxide sedation for GI endoscopy in children.

In adults nitrous oxide has been used successfully for proctoscopies and colonoscopies. In a systematic review Welchman *et al*[45] analyzed in a systematic review 11 studies including 623 patients. Continuous nitrous oxide inhalation provided comparable analgesia to *iv* sedation for colonoscopies. There was no difference in procedural pain between on-demand nitrous oxide and no sedation for colonoscopies. The recovery time was shorter in the nitrous oxide groups[45].

Nitrous oxide is often more used as an anxiolytic before *iv* catheter placement if the face mask does not agitate the patient. However, most anesthesiologists

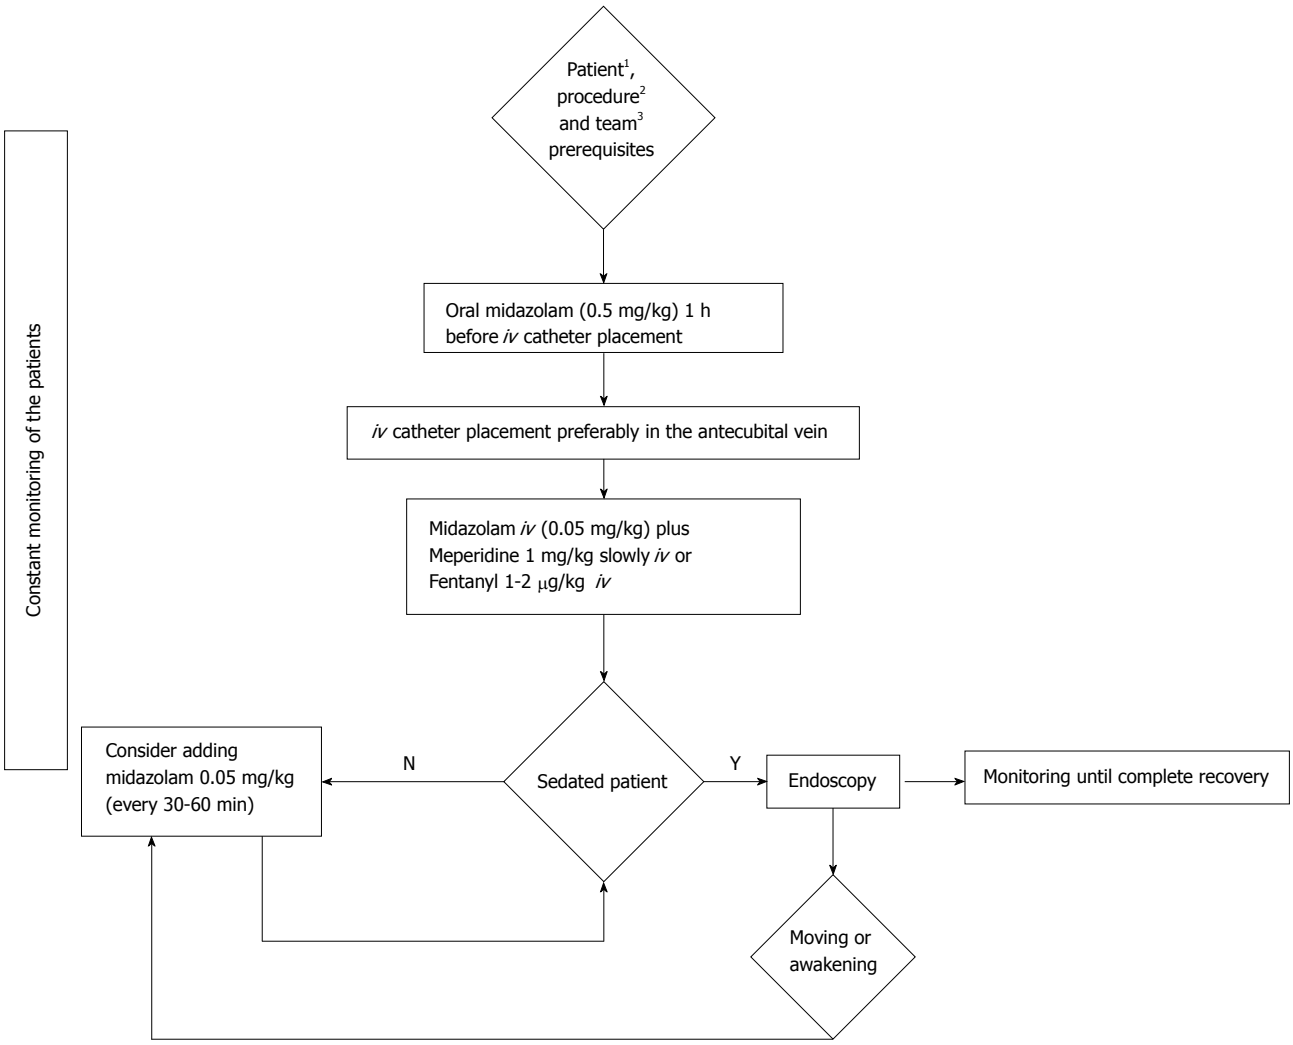

Figure 3 Flow chart of opioid and benzodiazepine sedation protocol for paediatric endoscopy. [1]Patient without contraindications (not being simultaneously treated with monoamine oxidase inhibitors); [2]Diagnostic endoscopy or procedure for which no endotracheal intubation is needed; [3]The team qualified for paediatric sedation for gastrointestinal endoscopy.

would suggest that age-appropriate calming of a patient by engagement would have a similar result. Vomiting occurs in up to 10%. It is contraindicated in bowel obstruction and should not be administered if any of the team members is pregnant[38]. Its routine use in pediatric GI endoscopy is not ratified.

Adjuvant medicines and antagonists

Anti-cholinergics: As discussed in the section on ketamine, anti-cholinergics (*e.g.*, atropine or glycopirolate) decrease the hypersalivatory effect which may influence airway patency[59]. However, importantly, it should be noted that available evidence does not support this practice and anti-cholinergics are no longer routinely recommended[26,60].

Anti-emetics: Many sedative/analgesic agents (*e.g.*, ketamin, fentanyl), with the exception of propofol, provoke vomiting[50]. Ondansetron reduced the incidence of vomiting in a double-blind, randomized, placebo-controlled study in 255 children in an emergency department sedated by ketamine[61].

Flumazenil: Flumazenil is an antagonist used to reverse the undesirable effects of benzodiazepines such as respiratory depression. It is delivered *iv* at 0.1 mg/kg up to a maximum of 2 mg and has a rapid onset of action in 1-3 min. The half-life of flumazenil is shorter than that of other benzodiazepines (*e.g.*, midazolam) making close monitoring essential and reapplication sometimes needed[38,40].

Naloxone: Naloxone reverses opioid effects and results in normal respiration within 1-2 min of application of 0.1 mg/kg (up to 2 mg) *iv* or intramuscular. Its duration of action is around 20-40 min hence repeated doses might be needed as the duration of action of most opioids (*e.g.*, fentanyl) is longer[38,40].

DISCUSSION

Effective and safe sedation for pediatric endoscopic proce-

dures is a non-negotiable pre-requisite and an important factor for lowering patient distress. In principle, total *iv* anesthesia should be performed by anesthesiologists. However, it has to be recognized that in many countries, including a majority of European countries and in parts of the United States, the limited availability of anesthesiology teams and limited organizational considerations represents a medical dilemma. In many European countries anesthesia departments cannot cope with the increasing demands[37]. Therefore, a shortage of anesthetic teams may force pediatric endoscopists to conduct sedation without anesthetic teams applying guidelines adapted according to national regulations and institutional practices[4]. However, this situation is not optimal and requires consequent actions to increase the number of anesthesiologists.

In this situation, the intention of the authors is not to encourage such practice. This paper summarizes the evidence for sedation schemes which could be safely and efficiently performed by non-anesthesiologists. Sedation protocols have to be adapted to international, national and local legislation and institutional practice. The national institutions must organize multidisciplinary teams for education, licensing and supervision of non-anesthesiologists and registered nurses involved in sedation practices as long as there is a shortness of anesthesiologists. An efficient system of quality control is a paramount.

The choice of medicines for procedural sedation is wide, but none has the properties of an ideal sedative, which are: predictable dose dependent level of sedation with rapid onset; broad therapeutic window; anxiolytic effect with anterograde amnesia for the duration of the procedure; absence of respiratory, cardiovascular and other undesirable effects; and a smooth post-procedural recovery without side effects[34]. Another important problem in pediatrics is the off-label use of many medicines, which was recently addressed for medicines prescribed for outpatients in pediatric gastroenterology[69]. The investigators found that in 33.2% of the prescriptions, medicines were used "off-label" and that 47.3% of the patients had at least 1 medicine described as an "off-label" medication. Sedatives and other *iv* medicines were not covered by this study. The legal risk of a prescribing doctor is greater when using "off-label" medicines or indications. Parents should be informed of the "off-label" use. A solution of this problem is to motivate the pharmaceutical companies to register medicines for pediatric use, as has happened in the majority of the EU Countries under the jurisdiction of the European Medical Agency for new medicines.

Propofol is probably the most promising and controversial sedative/anesthetic at present. It is stated that only those trained in anesthesia should use it, a position that anesthesiologists and their societies strongly defend[70]. On the other hand, there are studies of safe and efficient use of propofol for sedation for GI endoscopic investigations in pediatric and adult gastroenterology[2,3,7,8,51,71]. The administration of propofol by non-anesthesiologists is "off-label" in most cases and, therefore, every adverse event might have medico-legal consequences.

Therefore, these data could not be simply extrapolated to every sedation/analgesia practice. According to the review by Havidich *et al*[72] the evidence of the safety of sedation by non-anesthesiologists for procedures outside operating theatres is growing, especially for propofol. Despite the drawbacks listed above, published data justify propofol use in certain circumstances[2].

Ketamine-based sedation is safe and effective in otherwise healthy infants older than 3 mo[27]. Ketamine has dissociative anesthetic and analgesic properties with a wide safety margin and is frequently used in pediatric emergency departments[27,28]. Emergence reactions are observed in adults in up to 28%, but seem less prevalent in paediatric studies and not influenced by the addition of midazolam to ketamine[56-58]. Guidelines advised against routine benzodiazepine pre-medication[27,28]. Data from larger studies are needed as one recent study found less emergence reactions when midazolam was routinely administered as a pre-medication[4]. Another major limitation of ketamine-based sedation for endoscopy is laryngospasm. In general, the laryngospasm resolves without consequences rapidly after removal of the endoscope and administration of oxygen[73]. Another study reports transient laryngospasm manageable with simple measures in 3% of gastroscopies[4]. Therefore, the ketamine-based sedation regime for GI endoscopy is an acceptable option when sedation with propofol is not feasible.

Midazolam is most likely the most widely used drug for sedation in everyday endoscopic work. The duration of action of midazolam is dependent on the duration of its administration. The sedative and amnestic effects of benzodiazepines sometimes do not provide adequate patient comfort during colonoscopic procedures[74]. Opioids are often added and meperidine is commonly used[75]. The value of adding analgesics to sedatives has well evaluated in large number of prospective, randomized and placebo-controlled studies[76]. Sedation with midazolam/meperidine is safely and can be administrated under adequate monitoring[77].

These recommendations review and discuss sedation practices for pediatric GI endoscopy which can be safely and efficiently performed by non-anesthesiologists, but only when the necessary pre-requisites regarding patient assessment, team composition and experience, medicines and equipment are met.

ACKNOWLEDGMENTS

The authors reviewed the literature and made practical recommendations for effective and safe sedation for endoscopic procedures in children. However, the authors decline every legal responsibility for the proposed algorithms. Legislation and regulation regarding limitations of administration of different medications, such as inhalation anesthetics, differ from country to country.

Therefore, limitations caused by local legislation should be carefully checked.

COMMENTS

Background

Anesthesia is by preference performed by anesthesiologists.

Research frontiers

The creation of sedation teams led by non-anesthesiologists and a careful selection of anesthetic drugs may offer an alternative, but should be in line with national legislation and institutional regulations.

Innovations and breakthroughs

The intention of this review is to offer effective and safe alternatives for non-anesthesiologists.

Peer-review

The present paper was well organized and well investigated. This paper will give us important information about the anesthesia during endoscopy especially in children.

Abstract

Detection of polypoid lesions of the gallbladder is increasing in conjunction with better imaging modalities. Accepted management of these lesions depends on their size and symptomatology. Polyps that are symptomatic and/or greater than 10 mm are generally removed, while smaller, asymptomatic polyps simply monitored. Here, a case of carcinoma-*in-situ* is presented in a 7 mm gallbladder polyp. A 25-year-old woman, who had undergone a routine cholecystectomy, was found to have an incidental 7 mm polyp containing carcinoma *in situ*. She had few to no risk factors to alert to her condition. There are few reported cases of cancer transformation in gallbladder polyps smaller than 10 mm reported in the literature. The overwhelming consensus, barring significant risk factors for cancer being present, is that such lesions should be monitored until they become symptomatic or develop signs suspicious for malignancy. In our patient's case this could have led to the possibility of missing a neoplastic lesion, which could then have gone on to develop invasive cancer. As gallbladder carcinoma is an aggressive cancer, this may have led to a tragic outcome.

Key words: Gallbladder; Polyp; Cholecystectomy; Size; Carcinoma

Core tip: Current guidelines for management of gallbladder polyps recommend cholecystectomy for

polyps with size > 10 mm and/or presence of symptoms. Considering some cases of carcinoma in polyps with size less than 10 mm have been seen, consideration of a cholecystectomy for smaller size polyps is warranted.

Carcinoma *in situ* in a 7 mm gallbladder polyp: Time to change current practice? *World J Gastrointest Endosc* 2015; 7(9): 912-915 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/912.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.912

INTRODUCTION

Detection of polypoid lesions of the gallbladder (PLG) has become increasingly more frequent over the last thirty years primarily due to an increase in the use of ultrasound and other imaging modalities in evaluation of patients with abdominal complaints. In the adult population, 0.03%-9.5% of people are estimated to have PLG[1]. Due to the malignant potential of these lesions their management has been well documented[2,3].

In current practice, symptomatic lesions or polyps greater than 10 mm warrant cholecystectomies, while asymptomatic polyps less than 10 mm are followed with routine ultrasound every 3-6 mo for one to two years[3]. Here, we present a case of a 25-year-old woman who presented with a 7 mm PLG which was found, after cholecystectomy, to contain carcinoma-*in-situ*. Our goal is to add to existing literature of PLG and to caution physicians that delaying polyp removal simply due to lack of a lesion's symptoms or significant size may be harmful.

CASE REPORT

A 25-year-old female presented to the emergency room with right upper quadrant abdominal pain for duration of 2 d. On physical examination she had mild tenderness in right upper quadrant. Laboratory work up revealed: WBC 7500/mL, ALT 148, AST 254, ALP 119, Total Bilirubin 0.5 and direct bilirubin 0.3. Ultrasound examination showed multiple gallstones and a common bile duct (CBD) of 12 mm. She underwent an endoscopic retrograde cholangiopancreaticography at which time her CBD was cleared of stones, and subsequently a laparoscopic cholecystectomy was performed. The postoperative period was uneventful and the patient was discharged home.

The final pathology report revealed acute and chronic cholecystitis with multiple small gallstones. An incidental 7 mm pedunculated tubular adenoma was seen in the fundus of the gallbladder, with a segment of carcinoma *in situ*.

The patient was informed, and an appointment for oncology was arranged, but the patient chose not to go. Current guidelines do not recommend further treatment for T1a tumors, and certainly not for Tis disease[4,5]. Even aggressive surveillance is not recommended according to the National Comprehensive Cancer Network[6]. The patient next presented to our hospital system for an unrelated problem three years later, and was showing no signs of disease.

DISCUSSION

Approximately 4% of the adult population is estimated to have gallbladder polyps, the majority of which are benign cholesterol lesions[1,2]. Adenomas comprise the second most common PLG, 3% to 8% of which are reported to have malignant potential[1,2].There is no correlation between symptomatology and the probability of a malignant lesion. As such, there is no reliable way of differentiating a benign polyp from a malignant one outside of pathologic examination of the polyp[1,3].

The consensus regarding resecting a patient's gallbladder or leaving it in place has been widely documented. A search including PubMed, Embase, and Web of Science was done to locate relevant literature on the subject. Keywords included gallbladder, polyps, carcinoma or neoplasms, and gallbladder neoplasms were used.

Boulton *et al*[7] published the basic algorithm utilized today which differentiates lesions primarily based on size and symptoms but also included "complicating factors," or risks, in ultimately making a decision[8]. These risk factors include age greater than 50 and the presence of gallstones. Cha *et al*[9] include diabetes mellitus as a significant risk, while Myers *et al*[1] include polyp growth and a solitary lesion among these complicating factors, but state that no "consistent profile" exists among patients. Polyps > 10 mm (or some say > 9 mm) are resected regardless of a person's symptoms or risk factors, as are symptomatic PLG[7,10]. All asymptomatic lesions < 10 mm in patients with limited/no risk factors are monitored by ultrasound[7]. The duration of monitoring is inconclusive with some sources quoting every 3-6 mo for 1-2 years, while others state that lesions less than 6 mm do not need monitoring at all[3,7,10,11].

A number of studies have been done in an attempt to ascertain the appropriate size that gallbladder polyps should be removed due to their risk of malignant potential. Corwin *et al*[10] published a study in 2011 describing 346 patients with PLG. Following these patients with cholecystectomy and serial ultrasound, no neoplastic lesions were found in polyps < 6 mm, one neoplastic polyp was noted in polyps 7-9 mm, and two polyps greater than 10 mm were neoplastic[10]. Their conclusion was that PLG's < 6 mm require no follow up, but regarding lesions > 7 mm no conclusion could be made and further studies were recommended[10]. Another study published in 2010 by Matos *et al*[12] followed 93 patients, 91 of whom had benign polyps and two who had malignant ones. Of the two, which were found to be malignant, the average size in diameter was 18.8

mm and they concluded that polyp diameters greater than 10 mm were required to induce surgery, assuming no known risk factors existed[12]. Several other studies of asymptomatic patients with PLG have been reported in the literature, with case series ranging between 161 and 417 patients. These have all come to the conclusion that 10 mm or greater was the appropriate cutoff in asymptomatic patients with no risk factors to require surgery[13-15].

In our patient, a 7 mm polyp was incidentally identified after a cholecystectomy performed due to symptomatic gallstones. Upon pathological examination carcinoma *in situ* was discovered within the lesion. In a less fortunate person with a PLG and no symptomatic gallstones, current management would have resulted in missing a precancerous lesion. Considering that gallbladder carcinoma usually presents late, with a five-year survival from 5%-13%[16], this may have led to a detrimental outcome in our patient. This is a drastic difference in survival outcome compared to gallbladder cancers that are removed early, which has up to a 95% to 99% survival if extracted prior to muscularis and mucosal invasion, respectively[17].

Our patient demonstrates the care that must be taken regarding the management of polyps even smaller than 10 mm. This is especially true considering the significant benefit of avoiding a serious cancer relative to the small risk of surgical complications. Perhaps we should consider removing gallbladders with asymptomatic PLG that are between 5 mm-10 mm in size even in the absence of known risk factors. While this paper adds to the growing literature on these smaller size polyps, larger studies with more cases are necessary before formal recommendations can be made.

COMMENTS

Case characteristics

A 25-year-old woman presented with right upper quadrant abdominal pain for two days.

Clinical diagnosis

There was mild right upper quadrant tenderness on exam, with no jaundice.

Differential diagnosis

Differential diagnosis included acute cholecystitis or biliary colic, with choledocholithiasis less likely at this point.

Laboratory diagnosis

White blood cell count was normal, with elevation of transaminases, minimal elevation of alkaline phosphatase and normal bilirubin.

Imaging diagnosis

Ultrasound showed gallstones and a significantly dilated common bile duct of 12 mm.

Pathological diagnosis

Acute and chronic cholecystitis with gallstones, and an incidental finding of a 7 mm gallbladder polyp with carcinoma *in situ*.

Treatment

Patient underwent endoscopic retrograde cholangiopancreaticography and then laparoscopic cholecystectomy, which is sufficient for her carcinoma *in situ*.

Related reports

Other reports have suggested observation for polypoid lesions of gallbladder less than 10 mm.

Term explanation

Polypoid lesions of the gallbladder refer to lesions seen on imaging that look like a polyp, as opposed to stones which are mobile and layer in the dependent region of the gallbladder.

Experiences and lessons

The important lesson from this case is that malignant degeneration can develop in polyps less than 10 mm in size.

Peer-review

This adds to the literature of polyps less than 10 mm, and can suggest lowering the threshold for recommending cholecystectomy, but more research with larger numbers is necessary.

Abstract

Amebic liver abscess is a parasitic disease which is often encountered in tropical countries. A hepatogastric fistula secondary to an amebic liver abscess is a rare complication of this disease and there are only a handful of reported cases in literature. Here we present a case of an amebic liver abscess which was complicated with the development of a hepatogastric fistula. The patient presented with the Jaundice, pain and distension of abdomen. The Jaundice and pain improved partially after he had an episode of brownish black colored increase in frequency of stools for 5 to 6 d. Patient also had ascites and anemia. He was a chronic alcohol drinker. Esophagogastroduodenoscopy performed in view of the above findings. It showed a fistulous opening with bilious secretions along the lesser curvature of the stomach. On imaging multiple liver abscesses seen including one in sub capsular location. The patient was managed conservatively with antiamebic medications along with proton pump inhibitors. The pigtail drainage of the sub capsular abscess was done. The patient improved significantly. The repeat endoscopy performed after about two months showed reduction in fistula size. A review of the literature shows that hepatogastric fistulas can be managed conservatively with medications and drainage, endoscopically with biliary stenting or with surgical excision.

Key words: Amebic liver abscess; Hepatogastric fistula; Esophagogastroduodenoscopy; Entaameba histolytica; Ultrasonography; Computed tomography

Core tip: Hepatogastric fistula is a rare complication of the amebic liver abscess. High index of suspicion is required for its diagnosis. The presenting complaints may be brownish black vomitus or stool. It can be managed conservatively, endoscopically or surgically depending on case. Hence in cases of amebic liver abscess developing brownish black stools or vomiting we should always rule out hepatogastric fistula formation especially when it is associated with improvement of symptoms.

Pawar SV, Zanwar VG, Gambhire PA, Mohite AR, Choksey AS, Rathi PM, Asgaonkar DS. Unusual complication of amebic liver abscess: Hepatogastric fistula. *World J Gastrointest Endosc* 2015; 7(9): 916-919 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i9/916.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i9.916

INTRODUCTION

Amebic liver abscess is a parasitic disease which is commonly encountered in tropical countries[1]. A hepatogastric fistula secondary to an amebic liver abscess is a rare complication and only a handful of cases have been reported in literature[2,3]. A patient presenting with an anchovy sauce like vomitus or stool along with a simultaneous decrease in a preexisting pain in the abdomen should alert a clinician to the possibility of a hepatogastric fistula due to an abscess. There are a few other causes of this clinical entity. This condition can be managed conservatively with antibiotics and proton pump inhibitors, failing which surgery is the treatment of choice. Surgery involves excision of the fistulous tract with anastomosis. Here we report a case which presented with an anchovy sauce like stool and was successfully managed conservatively.

CASE REPORT

A 47-year-old male, with a history of regular alcohol intake presented with a history of pain and swelling in right upper abdomen which was mild to moderate in intensity, dull aching in character with occasional throbbing sensation with no radiation to any other site. The pain lasted a month and a half and was followed by generalized distension of the abdomen. This was accompanied with high color urine and jaundice. There was no fever. The patient then developed an increased frequency of stool which was liquid brownish-black and went on for 6 d. This was associated with a marked improvement in the abdominal pain and a decrease in the swelling over right upper abdomen. On examination there was tender hepatomegaly with ascites. The patient's hemoglobin was 9.3 g/dL and leucocyte count was 16700/mcl. There was reversal of albumin and globulin ratio, increase in aspartate transaminase was more than alanine transaminase and increased total and direct bilirubin. Ascitic routine microscopy revealed a high serum ascites albumin gradient. Patient's ultrasonography showed hepatomegaly with multiple heterogeneous solid cystic lesions with thickened walls, the largest measured 13.7 cm × 7.5 cm. In view of a history of daily alcohol intake with recent onset of black stool and a physical finding of ascites an esophagogastroduodenoscopy was performed. The study revealed a 2 cm × 2 cm deep ulcer with bilious discharge just above incisura on lesser curvature of the stomach (Figure 1). There were no varices. On further evaluation computed tomography (CT) suggested multiple large hepatic abscesses in both lobes of liver, the largest measuring 12.8 cm × 8.6 cm × 3.4 cm in the right lobe of liver. One of the abscesses in right lobe was sub capsular. The left lobe of liver had a hepatic abscess in segment 3 which had an exophytic extension and was indenting the lesser curvature of stomach. Air pockets were seen in the abscess cavity suggesting the probability of a fistulous opening within the stomach (Figure 2). His blood antibodies [enzyme linked immunosorbent assay (ELISA)] for entaamoeba histolytica came positive. An ultrasonography guided pigtail catheter was placed in right sub capsular abscess. The abscess content was anchovy sauce like. Pus culture was negative for bacteria. He was started on metronidazole and other supporting medications. He was also started on diloxanide furoate for luminal clearance of cysts. The patient improved clinically and at 4 wk a repeat endoscopy was performed. It showed a significant decrease in the size of the fistulous tract. A surgical option was explained to the patient and his relatives but they opted for medical line of management in view of risk associated Child Pugh C status. He was continued with close monitoring with proton pump inhibitors. The patient has been in regular follow up since the past 6 mo. The patient had American society of anesthesiologists' classification of physical status of 4 on presentation, 3 at the time of discharge and 2 at 6 mo follow up.

DISCUSSION

The prevalence of E. histolytica infections in India has been shown to range from 3.6% to 47.4% in different areas[1]. Amebic liver abscess occurs in less than 1% of entaameba histolytica infested patients[2]. Liver abscess rupturing into the pleural and peritoneal cavities is a relatively common phenomenon[3]. Only a handful of case reports of hepatogastric fistula have been published till now as it is a rare complication[3]. Hepatogastric fistulas have also been reported in cases of hepatocellular carcinoma intruding into stomach and presenting as an upper gastrointestinal bleed[4], post embolization for hepatocellular carcinoma leading to the formation of an abscess[5], as a complication of placing a pig tail in a liver abscess and also in cases of post hepatic surgeries. An iatrogenic hepatogastric fistula can be done for biliary drainage in infants with congenital obstructive jaundice.

The presentations of hepatogastric fistula secondary

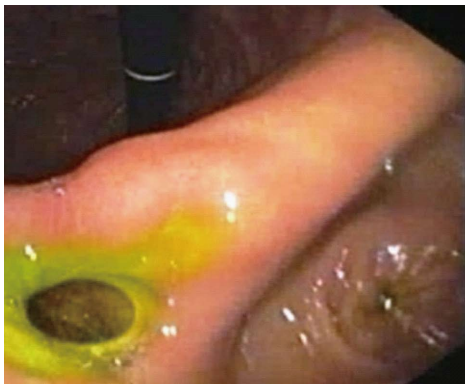

Figure 1 On retroflexon in stomach fistula with bile seen.

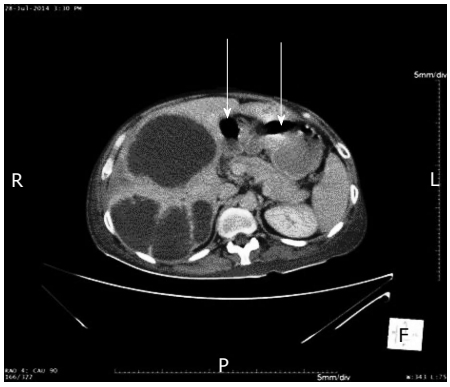

Figure 2 Multiple liver abscess with air pocket seen in the abscess in left lobe. (White arrows).

to amebic liver abscess can be as an anchovy sauce color vomitus or stool, hematemesis or malena[6]. In our patient decompression of the abscess into the stomach probably lead to the anchovy sauce color of stool and subsequent improvement of pain. Diagnosis was made based on the imaging and endoscopic findings. ELISA test for detecting antibodies was done for confirming entaameba histolytica as the causative agent. On the CT scan images the abscess seen with air pocket in continuation with the stomach was also a clue to the presence of the fistula (if it was performed before the endoscopy). On esophagogastroduodenoscopy the fistulous opening was seen as deep ulcer with (as in our case) or without bilious discharge[3]. In our case the diagnosis was confirmed taking into account the serology, CT finding and endoscopic findings. Rupture of an amebic liver abscess into an adjacent structure such as pleural and peritoneal cavity is a life threatening condition but rupture into stomach is not a dreaded complication.

Definitive management is surgical but if the patient's general condition does not permit surgery (as in our case) conservative management has also showed improvement[7]. Conservative treatment includes metronidazole for clearance in extraintestinal site and diloxanide furoate or paromomycin for luminal clearance. In certain cases of impending rupture of sub capsular abscess, pigtail drainage of the liver abscess has to be done to avoid complications. Biliary stenting has been found to hasten the recovery due to selective drainage of bile through common bile duct[8]. Nutrition can be given through per oral, nasojejunal tube, or feeding jejunostomy. Spontaneous closure of fistula can be seen within 5 wk of conservative management which was observed in our case[9]. If no improvement is observed on conservative management or if there is clinical worsening then surgical excision of the fistulous tract with gastric anastomosis is an option. Complications of hepatogastric fistulas include sepsis, debilitation and electrolyte imbalance[10].

In conclusion, hepatogastric fistula is a very unusual complication of liver abscess. One has to have a high index of suspicion for it to be diagnosed early. Management can either be conservative, endoscopic or surgical. We have managed this patient conservatively as patient was Child Pugh C status and high risk for surgery.

COMMENTS

Case characteristics

A 47-year-old male, chronic alcoholic presented with pain and distention of abdomen along with jaundice followed by brownish black diarrhea for 5 to 6 d.

Clinical diagnosis

Patient was having symptoms of chronic liver disease along with hepatomegaly and pain specifically in right upper quadrant.

Differential diagnosis

This is a case of chronic liver disease with either hepatocellular carcinoma or liver abscess or spontaneous bacterial peritonitis causing decompensation of liver disease.

Laboratory diagnosis

Patient had anemia and high leucocyte count along with inversion of albumin and globulin ratio and presence of antibodies to entaameba suggestive of chronic liver disease along with infection.

Imaging diagnosis

Ultrasonography and computed tomography suggestive of liver abscess with air in left lobe abscess probably fistulous opening which is confirmed on esophagogastroduodenoscopy.

Treatment

Patient was managed conservatively with metronidazole, diloxanide furoate.

Related reports

Very few case reports were published related to hepatogastric fistula due to hepatocellular carcinoma, iatrogenic and abscess.

Term explanation

Hepatogastric fistula is communication of liver with stomach due to various etiologies.

Experiences and lessons

High index of suspicion is required for diagnosis of hepatogastric fistula. Patient had marked improvement in pain and upper right quadrant swelling once he had brownish black stools for 5 to 6 d. Though rare, knowledge of this complication leads to early diagnosis and prompt treatment.

Peer-review

This is a well prepared and detailed case report referring to a rare complication of amebic liver abscess, a hepatogastric fistula. The manuscript is well organized with a comprehensive discussion section.

Abstract

Endoscopy has important roles in the management of primary sclerosing cholangitis (PSC), ranging from narrowing down the differential diagnoses, screening for complications, determining prognosis and therapy. While the need for a diagnostic endoscopic retrograde cholangiopancreatography (ERCP) may be obviated by a positive magnetic resonance cholangiopancreatography (MRCP), a negative MRCP does not exclude PSC and may therefore necessitate an ERCP, which is traditionally regarded as the gold standard. In this editorial we have not covered the endoscopic management of inflammatory bowel disease in the context of PSC nor of endoscopic surveillance and treatment of portal hypertension complicating PSC.

Key words: Sclerosing cholangitis; Endoscopic retrograde cholangiopancreatography; Endosonography; Cholangiocarcinoma; Stents; Fluorescence *in situ* hybridization technique; Biochemical markers

Core tip: Primary sclerosing cholangitis is a cholestatic disease of unclear etiopathogenesis, often seen in association with inflammatory bowel disease. It is characterized by fibrosis of the intra and extra hepatic bile ducts, resulting in stricturing disease, predisposing to cholangiocarcinoma. Diagnosis requires a high index of clinical suspicion and is often made by magnetic resonance cholangiopancreatography in the appropriate clinical context, although endoscopic retrograde cholangiopancreatography remains the gold standard. The latter being invasive is seldom used as a diagnostic modality and is reserved for management of complications including dilatation and stenting of dominant and anastomotic strictures, brush cytology and for SpyGlass Cholangioscopy.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disease characterized by inflammation and fibrosis that may involve the entire biliary tree. Inflammation and fibrosis results in diffuse narrowing of the intra and extra hepatic bile ducts causing persistent biliary stasis eventually leading to secondary biliary cirrhosis. It usually presents in the fourth decade of life with a variable disease progression[1].

Laboratory tests do not play a significant role as there is no definite test to confirm PSC. Non-invasive imaging modalities like trans abdominal ultrasound may pick up nonspecific abnormalities such as bile duct thickening, gall bladder enlargement or wall thickening. Contrast computed tomography (CT) scan and magnetic resonance cholangiopancreatography (MRCP) may detect inflammation, intrahepatic dilations as well as varices and splenomegaly indicative of portal hypertension. CT detects intraabdominal lymphadenopathy, suggestive of underlying cholangiocarcinoma. Even invasive tests like percutaneous transhepatic cholangiography have been used in the past. However none is confirmatory.

PSC recurs in about 10% of patients post orthotopic liver transplantation (OLT), with acute cellular rejection, need for maintenance steroids, HLA-DRB1*08 being positive predictors and pan colectomy being a negative predictor[2,3]. The diagnostic modalities for recurrent PSC (r-PSC) remain the same, with low threshold for biopsy to rule out rejection, which needs to be managed aggressively to prevent decompensation of the liver[2].

It is important to distinguish immunoglobulin (Ig) G4-associated cholangitis (IAC), also called IgG4-related sclerosing cholangitis, a recently described chronic cholangiopathy from PSC and other secondary sclerosing cholangitis, due to the excellent response of the former to steroid treatment. About 10% to 15% of patients with PSC also have elevated IgG4 levels. There is some evidence that the incorporation of IgG4/IgG1 ratio may be used in clinical practice to distinguish PSC from IAC[3,4]. Liver biopsy is rarely used these days, thought, might still be needed in the diagnosis of small duct PSC and when diagnosis is unclear.

Biliary IgG antineutrophilic cytoplasmic antibody and IgA against biliary epithelial cells correlates with the severity of bile duct strictures and may serve in the future as a diagnostic and prognostic marker of the disease progression and biliary complications[5,6]. Biliary protein biomarkers might help in distinguishing benign from malignant strictures, though further studies are warranted[7]. Novel biliary biomarkers like extracellular vesicles containing Micro-RNA's (miRs), U2 small nuclear RNA fragments (RNU2-1f) and oxidized phosphatidyl cholines (ON-PC and S-PC) have been proposed for the early diagnosis of cholangiocarcinoma in PSC, that is stable, reproducible, and has potential clinical utility[7-9].

ENDOSCOPIC DIAGNOSIS

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is the mainstay for accurate assessment of the hepatobiliary tree to establish a diagnosis of PSC. Typical cholangiographic findings include multifocal annular biliary strictures interspersed between dilated intra and extrahepatic bile ducts with alternating normal segments, creating the characteristic beaded pattern of PSC.

Even though MRCP is the preferred cholangiographic modality given the high sensitivity, non-invasive nature and lack of exposure to radiation, it has limited accuracy in early PSC, cirrhosis and in the differentiation of Caroli's disease, secondary sclerosing cholangitis and cholangiocarcinoma (CCA)[10]. A retrospective study by Moff *et al*[11] demonstrated that ERCP and MRCP were comparable for diagnosis of PSC. They recommended that MRCP be employed as the initial diagnostic modality given the safety profile as well as sensitivity and specificity of approximately 90% and 88% respectively, although ERCP with its higher specificity of nearly 96% would be necessary for confirmation[11].

Complications occur in about 4% to 16% of patients with PSC undergoing ERCP[12,13]. The complication risk was often dependent on the ease of cannulation, with post ERCP pancreatitis (PEP) reported in up to 7% of procedures[14]. Hence, we recommend routine sphincterotomy, especially in those who are likely to need further procedures, to minimise the risk of PEP[14]. PSC patients undergoing ERCP are routinely given antibiotic prophylaxis to reduce the risk of cholangitis, which is more so in the presence of strictures[12,14,15]. An extra attempt is made to clear the bile duct of all contrast by suctioning or irrigation. Overall, benefits of doing an ERCP outweighed the risks in PSC, when the indications were appropriate[14,15].

A confirmatory ERCP is warranted when clinical suspicion of PSC is moderately high, also in cases with inconclusive MRCP results and or cases being evaluated at centres where the technical expertise with MRCP is not well established[16]. A cost effectiveness analysis comparing ERCP with MRCP by Meagher *et al*[17] in the face of competing technologies revealed that initial MRCP, when negative, followed by subsequent ERCP was the most economic initial approach in the work-up of patients with suspected PSC.

It is crucial to distinguish dominant strictures (DS) in PSC from cholangiocarcinoma, which remains a challenge given that the former predisposes to CCA, which could be found in upto 25% of DS as per some studies[18]. The American Association for the Study of Liver Diseases (AASLD) guidelines recommend those with dominant strictures be assessed with CA 19-9, MRCP and ERCP for tissue acquisition. CCA is one of the major causes of mortality in PSC and

may be detected concurrently at the time of or within months of its diagnosis. However, cholangiocarcinoma related mortality does not diminish with early liver transplantation[19]. Due to the unpredictable natural history and lack of early predictors of cancer, there is no set guideline for surveillance of patients with PSC. Biliary tissue acquisition can be achieved by brush cytology and or intraductal biopsy (for histology using pediatric forceps) to distinguish benign from malignant strictures. Brush cytology being technically easy, safe and less time consuming is more commonly used[20]. The AASLD guidelines recommend performing the above to exclude superimposed malignancy prior to endoscopic therapy for dominant bile duct strictures[21]. A meta analysis by Navaneethan *et al*[7] demonstrated that biliary brush cytology has high specificity (97%) for the diagnosis of CCA, however the low sensitivity limited its role in detecting early CCA[22]. Most cases of malignant DS occur in the perihilar region and accessible to brush cytology[23]. Repeated brush cytology aids early detection of high grade dysplasia before manifest CCA, enabling pre-emptive liver transplantation[24]. A weighted scoring system, proposed by Witt *et al*[25], termed the Atypical Biliary Brushing Score (ABBS) helps to risk stratify the individuals with atypical brush cytology to identify those at high risk of CCA[25]. ABBS considers seven variables including age over 60, pancreatic mass as an indication, distal biliary stricture, CA 19-9 over 300 U/mL scoring one each, endoscopic impression of malignancy, common hepatic duct stricture and a definite diagnosis of PSC with the last three scoring two each. Patients with a score over 4 are considered to be at high risk of harboring malignancy despite atypical results on a biliary brush cytology[25].

There are now advanced techniques in cytology such as digital image analysis (DIA) and fluorescence in situ hybridization (FISH) that enhance the sensitivity and improves diagnostic yield of brush cytology, compared with routine cytology[26-28]. DIA is a method by which microscopic images of a cell are quantified by digital conversion and computer analysis of the image feature[29]. FISH allows fluorescent labeling of DNA probes to target chromosomal regions to detect numerical or structural chromosomal abnormalities, such as trisomy or polysomy which suggest malignant process. The ability of FISH to detect polysomic cells from pancreatobiliary brushings puts it ahead of other pathological or imaging modalities in detecting CCA[30]. FISH of the cytologic specimen has significantly greater sensitivity than conventional cytology for the identification of CCA in patients with PSC, however it has lower specificity compared to biliary brushings[26,31]. Combining FISH with routine cytology can markedly improve the odds of detecting CCA at an early stage[30,32]. By identifying chromosomal abnormalities, DIA and FISH highly improve sensitivity while maintaining specificity. A prospective study from Mayo clinic revealed that composite DIA and FISH yielded 100% specificity and improved sensitivity by fivefold in indeterminate biliary strictures[27]. Many of these techniques once widely available should be used routinely.

Cholangioscopy

In recent years, peroral cholangioscopy as an adjunct to ERCP has gained popularity as it helps overcome diagnostic inaccuracies in biliary diseases, initially described by Chen and Pleskow[33]. In the management of challenging indeterminate biliary strictures, cholangioscopy permits direct intra luminal view of the biliary tree, targeted tissue acquisition and allows endoscopic guidance for therapeutic interventions[34]. The dual operated cholangioscope, "mother-baby" system was the first to be introduced, however the "two scope system" was time consuming, expensive, had limited manoeuvrability, poor irrigation capacity, required two endoscopists, and was easily damaged[35,36] it is therefore seldom used in clinical practise. The single-operator peroral cholangioscopy using SpyGlass direct visualization system appears to have overcome some of the limitations of the conventional peroral cholangioscopy. In addition to having two independent irrigation channels, this provides a 70-degree field of view, though the single use SpyBite forceps has only a maximum jaw separation of 4.1 mm. Hence, negative findings on the mini-forceps biopsy cannot exclude CCA owing to small sample obtained[37]. SpyGlass system was shown to have a lower complication rate, with a potential to become a diagnostic standard for the assessment of indeterminate biliary lesions with further refinements[38]. In a single center prospective study of thirty six patients with indeterminate biliary stricture, Ramchandani *et al*[36] from the Hyderabad group, showed that SpyBite had an overall accuracy of 82% in differentiating malignant from benign ductal lesions on an intention-to-treat analysis. The sensitivity of SpyGlass to obtain adequate tissue from indeterminate strictures could be upto 88%, especially when atleast 3 bites are taken. Sensitivity of diagnosing CCA by visual impression is 78% and by biopsy alone is 49%[39].

Endoscopic ultrasound scan

Endoscopic ultrasound scan (EUS) is a safe, accurate and technically feasible approach for diagnosing extrahepatic PSC. Lutz *et al*[40] demonstrated it to be an efficient tool for confirming suspected PSC, which has eluded diagnosis by ERCP or other modalities. Sensitivity and specificity of EUS-FNA for evaluation of biliary strictures ranges from 43% to 86% and 95% to 100% respectively[40-42]. The specific sonographic features include duct wall thickening greater than 1.5 mm, irregular CBD wall/caliber (change of wall thickness by $\geqslant$ 1 mm over 5 mm and caliber $\geqslant$ 2 mm over 5 mm ductal length) and the presence of perihilar lymph nodes at least 1 cm diameter, with an EUS diagnosis of PSC when two or more of above

criteria positive[43]. EUS enables refinement in disease detection and diminishes need for high risk invasive procedures[40]. In patients with a high index of suspicion of PSC with an inconclusive MRCP and EUS, core biopsy of the liver could be done safely in the same sitting (less than 1% risk of major complication), to look for small duct PSC and also to rule out cirrhosis, which would have prognostic implications[44-47]. Tumour seeding has been rarely reported with the FNA and hence some authorities advocate FNA of only suspicious lymph nodes[48]. Hence, we do not advocate EUS-FNA of the bile duct in a patient with suspected cholangiocarcinoma, who is a possible OLT candidate, until discussion at the tumor meeting with transplant surgeons. Direct biopsy using a cholangioscope would certainly be the preferred modality of tissue acquisition. EUS guided FNA has a significant role in diagnosing CCA when standard modalities are inconclusive, as it allows assessment and aspiration of malignant appearing lymph nodes[49,50].

Intraductal ultrasound

Intraductal ultrasound (IDUS) utilises a standard duodenoscope to insert a high frequency ultrasound transducer over a wire into the biliary system under fluoroscopic guidance. IDUS allows visualisation of the wall layers of the biliary strictures thereby providing an estimate of the extend of potentially cancerous infiltration[51]. This information is valuable in deciding treatment options. IDUS as an adjunct to ERCP guided tissue sampling significantly enhances the ability to distinguish malignant from benign strictures, it however is not an efficient modality assessing lymph nodes associated with malignant strictures[52]. Biliary cannulation with IDUS can be performed with ease, thereby avoiding the need for sphincterotomy; it provides detailed images of ductal and peri ductal tissues with high resolution. Additionally, when CCA is identified, IDUS may be employed for local staging in candidates prior to surgical resection[53].

Confocal laser endomicroscopy

Probe-based confocal laser endomicroscopy (pCLE) is a novel diagnostic technique that provides a virtual biopsy to facilitate subepithelial evaluation of the pancreatobiliary mucosa. It delivers microscopic information in real time and also provides dynamic information such as blood flow, cellular architecture, contrast uptake and leakage[54].

In a small single centre study of pCLE, Heif *et al*[55], showed a high technical success rate in patients with PSC and DS. Sufficient visualization was achieved in 95%, with sensitivity, specificity, positive predictive value and negative predictive values of 100%, 61.1%, 22.2% and 100% respectively, in detecting neoplasia. If verified in larger prospective studies, this could be potentially utilized for risk stratification of dominant strictures in patients with PSC[55].

ENDOSCOPIC THERAPY

PSC is characterized by inflammation and fibrosis leading to bile duct strictures. DS is defined as stenosis with a diameter of 1.5 mm in the common bile duct or 1 mm in the hepatic duct[21,56]. They develop in about forty percent of patients with PSC leading to significant biliary obstruction[57]. These predispose to stone formation, recurrent cholangitis and secondary biliary cirrhosis; also it may be a marker for underlying malignancy.

Traditionally ERCP has been employed for the stone removal that is the main indication for biliary sphincterotomy in PSC; balloon dilation *via* ERCP reduces stenosis thereby improving biliary flow and potentially preventing recurrent cholangitis[58,59]. Current therapy for stricture in PSC including balloon dilation, biliary stent placement and often a combination of both have become the mainstay of treatment, at least as a first line intervention[43,60]. Studies have established that repeated endoscopic therapy in patients with PSC is safe, the prognosis however worse in the subgroup of patients with dominant strictures at increased risk for development of cholangiocarcinoma[56].

An average of 3.46 ERCP's were needed per patient over a 8 year follow up study, with an improved observed survival rate of 82.8% at 4 years compared to 71.3% predicted survival (as per the Mayo Clinic natural history model)[58]. Endoscopic dilatation with short-term stenting is effective in benign dominant strictures and does not have predilection for malignant transformation or complications after transplantation[23]. Gotthardt *et al*[61] in a 20 year follow up of 171 patients have shown that repeated endoscopic therapy helps preserve a functioning common bile duct for many years, improving transplant free survival to 81% at 5 years and 52% at 10 years after initial endoscopic therapy. In a small subset of patients with DS in the extra hepatic duct without signs of cirrhosis, resection or bypass surgery may be performed, especially when endoscopic treatment fails[62].

Biliary sphincterotomy done in PSC is often a limited one, to minimize the reflux of enteric contents and ascending cholangitis[63]. Sphincterotomy prior to stent placement minimizes the chance of post ERCP pancreatitis (PEP)[64]. Stricture dilation could also be done using tapered-tip dilators (Cotton graded dilator) over a guide wire as a stand-alone or in combination with balloon dilatation[65]. In difficult cases, where only the wire could be passed through, a screw-tip dilator (Soehendra screw) could be employed[66]. In high grade stenosis, a Terumo guide wire could be used, since it has the added advantage of a very flexible tip[63]. Following this, stiff dilatation upto 7F facilitates balloon dilatation upto a target of 24F in the common duct and 18F in the hepatic ducts. Stiehl *et al*[57,67] have shown that even long segment stenosis (over 2 cm) of the common bile duct and shorter-segment intrahepatic stenosis within 2 cm of the hilum could be successfully

treated endoscopically.

Although controversial, there are interventional endoscopists, who advocate routine placement of one or more stents with frequent stent exchanges (every 6 to 8 wk), after dilatation with any of the above modalities, to prevent the stricture from reforming immediately due to the underlying fibrosis and elasticity[43]. International bodies like AASLD however, do not endorse this above practice, since there is no strong evidence demonstrating additional benefit of stenting over endoscopic dilatation[68]. Though results have been conflicting, there is evidence from a recent study in favour of additional stenting when clinically appropriate[68]. In cases of hilar strictures, it is preferable to gain access into both ducts first, as dilatation of one system somehow makes access to the other side more challenging[69].

Stents used in PSC could be either plastic or self-expandable metallic stents (SEMS). Teflon (PTFE) stents are the most commonly used ones, with longer patency[70]. However, fully/partially covered SEMS (CSEMS) have also been used for management of dominant strictures, though there are no randomized trials to support this[71-73]. The possible reasons why SEMS has not become standard of care of dominant strictures in PSC, is the theoretical risk of ascending cholangitis in this high risk group due to the larger caliber of the metal stent, in addition to not being cost effective compared to plastic stents in this situation. This is in addition to the potential risk of cholecystitis from obstruction of the cystic duct (in individuals who have not undergone cholecystectomy) and of obstruction of bile flow from the other lobe of the liver in case of hilar lesions.

Uncovered SEMS has been successfully used for palliation of inoperable CCA[56,74,75]. SEMS is preferred over plastic stents for patients with life expectancy over 3 mo[76]. For hilar strictures, stenting of one or both lobes and use of plastic stent or metallic stents continues to be debated, with ongoing research into the design of specifically tailored stents including cross wired stents and new plastic inside stent with thread (IT) stent[77-79].

EUS-guided palliation of malignant obstructive jaundice, when ERCP access fails has been gaining grounds and when expertise available replacing percutaneous drainage, since the latter is less appealing cosmetically with the external bag and inconvenient. This is mostly used for drainage of the obstructed left system (though there have been initial attempts to drain the right duct) using EUS-guided hepaticogastrostomy and of the main duct by a choledochoduodenostomy. Although technically feasible, the challenge is in the controlled deployment of the fully CSEMS, preferably in a single step, to minimize the risk of perforation, biliary peritonitis and stent migration[80-85]. These risks are minimized by the availability of lumen apposing metal stents. Endoscopic placement of nasobiliary drains to decompress the non-atrophic lobe has been done in some centers especially in Japan, to bridge the gap to surgery[79].

Biliary complications can occur in as many as 10% to 35% of patients after orthotopic liver transplantation with PSC recurrence in around 10%[86-88]. The most common biliary complications after OLT include biliary strictures (anastomotic or ischemic), bile duct leaks, common bile duct stones, and biliary casts, sphincter of Oddi/ampullary muscle dysfunction/spasm and r-PSC. With the advances in biliary endoscopy, majority of the complications could be managed with ERCP using regular techniques and tools. ERCP directed brachytherapy for locoregional disease control in cholangiocarcinoma, using photodynamic therapy or radiofrequency ablation, is promising, though still in its early stages[89,90]. They have comparable efficacy for local disease control and safety profile.

APPROACH TO THE PATIENT WITH SUSPECTED PSC

We recommend MRCP to be done as the initial diagnostic modality in suspected patients with PSC. ERCP with brush cytology and or biopsy, to date, continues to be the gold standard for diagnosis especially if the former is inconclusive, due to the surveillance and prognostic implications of making a correct and early diagnosis. EUS, IDUS and cholangioscopy could be utilized in the evaluation of patients, especially those with indeterminate dominant strictures, to get better cytologic yields to exclude early biliary dysplasia and cholangiocarcinoma. With further evidence and validation of EUS criteria for PSC, it might be done before ERCP in the diagnostic algorithm, especially considering its safety profile. Advancements in cytology including DIA and FISH should be considered to improve the yield, when ever available. The role of molecular markers and proteomics in diagnosis is still evolving. ERCP with repeated biliary dilatation with or without stenting is our current practice in management of benign strictures, in addition to routine use of antibiotic prophylaxis, as per BSG and ASGE recommendations. EUS guided biliary drainage procedures could be attempted in cases of failed SEMS deployment by ERCP for palliation of CCA. There is some evidence that endoscopic therapy could delay the need for orthotopic liver transplantation in patients with PSC.

CONCLUSION

Endoscopy has a pivotal role in the diagnosis and management of the condition, both pre and post orthotopic liver transplantation. Advances in endoscopy (complimented by cross sectional imaging) and ancillary cytologic testing would enhance earlier diagnosis, facilitating a surveillance protocol that could be used, to improve survival rates by timely curative therapy.

Abstract

Gastrointestinal lymphomas represent up to 10% of gastrointestinal malignancies and about one third of non-Hodgkin lymphomas. The most prominent histologies are mucosa-associated lymphoid tissue lymphoma and diffuse large B-cell lymphoma. However, the gastrointestinal tract can be the site of rarer lymphoma subtypes as a primary or secondary localization. Due to their rarity and the multifaceted histology, an endoscopic classification has not been validated yet. This review aims to analyze the endoscopic presentation of rare gastrointestinal lymphomas from disease diagnosis to follow-up, according to the involved site and lymphoma subtype. Existing, new and emerging endoscopic technologies have been examined. In particular, we investigated the diagnostic, prognostic and follow-up endoscopic features of T-cell and natural killer lymphomas, lymphomatous polyposis and mantle cell lymphoma, follicular lymphoma, plasma cell related disease, gastrointestinal lymphomas in immunodeficiency and Hodgkin's lymphoma of the gastrointestinal tract. Contrarily to more frequent gastrointestinal lymphomas, data about rare lymphomas are mostly extracted from case series and case reports. Due to the data paucity, a synergism between gastroenterologists and hematologists is required in

order to better manage the disease. Indeed, clinical and prognostic features are different from nodal and extranodal or the bone marrow (in case of plasma cell disease) counterpart. Therefore, the approach should be based on the knowledge of the peculiar behavior and natural history of disease.

Key words: Endoscopy; Lymphoma; Endosonography; Stomach; Intestine

Core tip: The gastrointestinal tract can be the site of rare lymphomas as a primary or secondary localization. Their endoscopic behavior has been scantily evaluated but is emerging as a useful tool with prognostic and therapeutic implications. T-cell lymphomas present mainly with ulcerative lesions, while B-cell lymphomas (follicular or mantle cell lymphomas) present as a duodenal mass or multiple polyposis. Plasma cell-related disorders localize to the gastrointestinal tract, either as a neoplastic mass or as an amyloid deposition. Immunodeficits (primary or secondary) can lead to gastrointestinal localization of rare and seldom fatal high-grade lymphomas. More rarely, Hodgkin's lymphoma localizes to the gastrointestinal tract with an uncertain impact on prognosis.

Rare gastrointestinal lymphomas: The endoscopic investigation. *World J Gastrointest Endosc* 2015; 7(10): 928-949 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i10/928.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i10.928

INTRODUCTION AND MAIN SECTION OF THE WORK

Gastrointestinal (GI) lymphomas represent 5%-10% of primary GI malignancies and almost two third of extranodal non Hodgkin's lymphomas (NHL), that in turn account for 24%-49% of all NHL[1,2]. The most common lymphomas are mucosa-associated lymphoid tissue (MALT) and diffuse large B-cell lymphoma (DLBCL), accounting for 70%-95% of GI lymphomas[3,4]. Apart from MALT and DLBCL, the GI tract can be the site of other lymphomas, either as a primary or secondary localization[5], and these lymphomas will be the subject of this report. The knowledge of their clinical and echo-endoscopic features would help in addressing clinical questions[3,6-8], sparing inappropriate evaluations[9-13]. Nonetheless, histology, together with immunohistochemistry and molecular biology, are mandatory for diagnosis[14].

While the endoscopic classification for MALT and DLBCL has been already validated[15,16], such an analysis on rare GI lymphomas is still under debate. In 2001 and 2003, the Taiwanese[17] and the South Korean group[18] respectively published a 3/5 item classification of ileocolonic GI lymphomas. Table 1 shows patterns analyzed in both classifications. Basically, the endoscopic appearance is classified according to the presence and depth of ulcerations and of fungating lesions. To date, these were the only attempts to classify rare GI lymphomas. After that, Kim *et al*[19] investigated the endoscopic differences between B- and T-cell lymphomas of the colon and they observed that B-cell lymphomas occur more often as fungating or ulcerofungating lesions, while T-cell lymphomas more frequently have an ulcerative or ulceroinfiltrative pattern (Figure 1). Notwithstanding, a clear prognostic implication based on the endoscopic pattern has not been validated yet.

Table 1 Endoscopic features of rare gastrointestinal lymphomas according to two classification systems

Ref.	Wang *et al*[18]		Myung *et al*[17]	
No. of patients	13		32	
Endoscopic pattern	Mucosal - ulcerative	30.7%	Fungating	39%
	Mucosal - erosive	15.3%	Ulcerative	6%
	Polypoid	23%	Infiltrative	14%
	Massive	31%	Ulcerofungating	31%
			Ulceroinfiltrative	11%

Newer techniques, *i.e.,* capsule endoscopy (CE) and double-balloon enteroscopy (DBE), are emerging as useful tools in detecting small bowel tumors (15% of them represented by lymphomas)[3,20-22]. Surely both techniques can augment the endoscopic diagnostic field (especially for follicular lymphomas[21]). Moreover, spiral enteroscopy has been also evaluated as a tool for revealing GI lymphomas of the small intestine. Boudiaf *et al*[23] reported that 4 out of 14 patients affected by refractory celiac sprue developed a small bowel mass that was confirmed to be an enteropathy-associated T-cell lymphoma (EATL) by histological evaluation. Although less widespread, single-balloon enteroscopy has been used in the definition of small bowel lesions and recently it has been implemented with the water exchange method in order to improve the visualization of the lumen to better define and sample the lesion[24]. However, such deep diagnostic tools have not been validated for routine use in GI lymphoma staging and follow-up since they do not induce a treatment change. Thus, their application in gastric or colonic lymphomas has not been fully validated[25]. Differently, faced with T-cell lymphomas with a jejunal tropism, DBE can lead to a definitive diagnosis coupling the endoscopic investigation with the bioptic evaluation[26,27]. However, not many publications related to the usage of these techniques are available to date.

A particular consideration should be given to the role of endoscopic ultrasonography (EUS). Its role has gained more and more importance in MALT lymphomas since the locoregional staging of the disease has a great

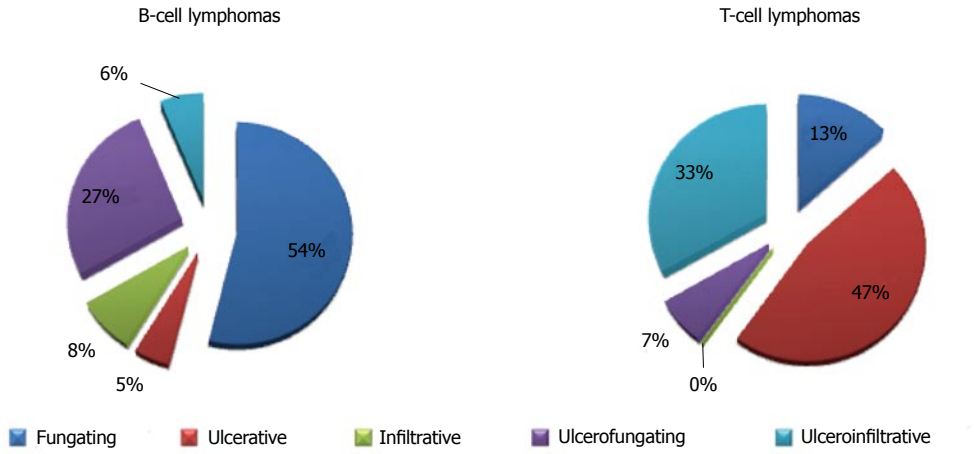

Figure 1 Differences in endoscopic pattern between B-cell and T-cell lymphomas of the gastrointestinal tract. Data extrapolated from Kim *et al*[19] 2005.

impact on the treatment approach[6]. Regarding DLBCL, the locoregional extension has significant prognostic implications, although its role in treatment definition is still under discussion[3]. In contrast, few data are available in rare GI lymphomas. In particular, they are more frequently regarded as general diseases so that the locoregional extension is not always evaluated, with some reports indicating just the EUS pattern without any clinical implication. Exceptional cases have indicated the role of EUS in defining the limited extension of the disease, thus leading to an endoscopic resection of the mass [see the paragraph "Extramedullary Plasmacytoma (EMP) and Plasma Cell-related Diseases"]. That notwithstanding, EUS information is gathered only for describing the behavior of these lesions in most cases without any significant clinical impact.

Definitively, a proper staging for GI lymphomas will include[28]: (1) physical examination: evaluation of superficial lymph nodes and Waldeyer ring inspection; abdomen palpation in order to detect liver enlargement, splenomegaly and abdominal masses; (2) endoscopic ultrasonography that is the golden standard in defining the locoregional GI involvement since it is able to distinguish the involvement of a specific layer and also of regional lymph nodes. However, as stated above, its role is under study and it is not strictly recommended in this setting; (3) computed tomography of the neck, chest and abdomen in order to detect involvement of nodes above and below the diaphragm and also other extranodal involvement not pertaining to the GI tract. In some cases, computed tomography can be of great help in defining the extension of a large bulky mass departing from the GI tract but exteriorizing outside the GI tract (see the paragraph "Plasma-cell related diseases"); (4) positron emission tomography is not generally indicated as a staging procedure, especially in MALT lymphomas, but it retains a role in defining the pre-treatment lymphomatous involvement and response to treatment; and (5) bone marrow biopsy: notwithstanding the low-grade, indolent diseases that tend to remain localized at the GI tract, bone marrow biopsy should be performed in order to exclude a marrow involvement that could influence treatment and follow-up management. However, the level of evidence on its utility is poor. A recent update of the staging recommendation in nodal lymphomas does not encourage the performance of bone marrow biopsy facing diffuse large B-cell lymphoma and Hodgkin's lymphoma, but this strategy has not been evaluated specifically for GI lymphomas[29].

However, these are general guidelines adopted from MALT lymphoma since in more rare GI lymphomas these guidelines have not been fully validated.

The aim of the present review is to highlight macroscopic features of rare GI lymphomas using endoscopy and related techniques. In particular, we will focus on T-cell lymphomas, lymphomatous polyposis (LP) and mantle cell lymphoma (MCL), follicular lymphoma (FL), plasma cell-related diseases, gastrointestinal lymphomas in immunodeficiency and Hodgkin's lymphoma (HL). An outline on the endoscopic presentation will be given for the diagnostic aspect and follow-up assessment. As a whole, Table 2 summarizes the clinical and molecular characteristics and prognostic features of these lymphomas.

T-cell and natural killer lymphomas

GI T-cell lymphomas are rare, representing about 5% of GI lymphomas[14,30,31]. However, the incidence varies according to the geographical zones. European studies reported that 1.3% of primary GI lymphomas are of T-cell origin[32], while groups from eastern countries reported 7%-15%[33,34], reaching 41% in other series of intestinal lymphomas[35].

Ulcerated lesions are the main endoscopic features[30,36-38]. The first definition of this disease was "ulcerative jejunitis" by Isaacson and Du, given the always present ulcerative pattern[14]. Usually, symptoms are related to malabsorption[14], although perforation[39] or intestinal bleeding[40] can occur. Incidentally, GI perforation or bleeding can occur in cases of nodal T-cell lymphomas independently from GI localization and are an infective etiology, reflecting the immune impairment that characterizes these lymphomas[41,42].

Table 2 Table listing gastro-intestinal lymphoma with main gastro-intestinal organ involvement, typical presenting characteristics, typical immunophenotype and genotype and prognosis

Lymphoma histotype		Presenting characteristics	Main GI involvement	Main endoscopic pattern	Typical immunophenotype	Typical genotype	Prognosis
T and NK lymphomas	EATL	Celiac patients with abdominal pain and small intestine obstruction/ perforation	Duodenum and jejunum	Multiple erosions and ulcers	$CD3^+$, $CD4^-$, $CD8^{+/-}$, $CD7^+$, $CD5^-$, $CD2^+$, TIA^+, $GrBPer^+$, $CD30^{-/+}$, $CD25^{-/+}$, $CD56^{-/+}$, $CD16^-$, $CD57^-$, $BCL6^-$, $CD10^-$, EBV^-, $EMA^{-/+}$	TRB and TRG clonally rearranged +9q31.3 -16q12.1 +1q32.2-q41 +5q34-q35.2 +8q24 (MYC)	Poor
	PTCL	Poor performance status	Stomach and duodenum	Ulcerative	$CD3^+$, $CD4^+$, $CD8^-$, $CD7^+$, $CD5^+$, $CD2^+$, TIA^-, $GrBPer^-$, $CD30^{-/+}$, $CD25^-$, $CD56^-$, $CD16^-$, $CD57^-$, $BCL6^-$, $CD10^-$, EBV^-, EMA^-	[1]TCR clonally rearranged +7q/+8q/+17q/ +22q/-4q -5q/-6q/-9p/-10q/-12q/-13q	54% survival at five year Poor in case of high IPI score and stage III-IV disease
	Extranodal NK/T-cell lymphoma	Gastrointestinal bleeding and B symptoms	Small intestine	Multiple erosions and ulcers	$cyCD3^+$, $CD4^-$, $CD8^{-/+}$, $CD7^-$, $CD5^-$, $CD2^+$, TIA^+, $GrBPer^+$, $CD30^-$, $CD25^-$, $CD56^+$, $CD16^-$, $CD57^-$, $BCL6^-$, $CD10^-$, EBV^+, EMA^-	TCR in germinal configuration No specific cytogenetic studies on this specific subtype	Poor especially if perforation occurs
	Adult T-cell leukemia/ lymphoma	Abdominal pain, diarrhea, general fatigue, weight loss	No site preferences	Ulcers	$CD3^+$, $CD4^+$, $CD8^-$, $CD7^-$, $CD5^+$, $CD2^+$, TIA^-, $GrBPer^-$, $CD30^{-/+}$, $CD25^{++}$, $CD56^-$, $CD16^-$, $CD57^-$, $BCL6^-$, $CD10^-$, EBV^-, EMA^-	TCR clonally rearranged Monoclonal integration of HTLV-1	Poor[2] Good[3]
	Indolent lympho-prolipherative diseases of GI tract: T-LPD	Dyspepsia and mild diarrhea	Small intestine and colon	Unremarkable/ friable or erythematous mucosa	$CD3^+$, $CD4^-$, $CD8^+$, $CD7^{+/-}$, $CD5^{+/-}$, $CD2^+$, $TIA^{+/-}$, $GrBPer^{-/+}$, $CD30^-$, $CD56^-$, EBV^-	TCR-γ monoclonal	Indolent course
	NK-cell enteropathy	Vague symptoms (dyspepsia)	Stomach and small intestine	Lesions exhibit superficial ulceration, flat elevations with central depression and are associated with edema and local hemorrhage	$cCD3^+$, $CD4^-$, $CD8^-$, $CD7^+$, $CD5^-$, TIA^+, $GrBPer^+$, $CD56^+$, EBV^-	TRC polyclonal or oligoclonal	Indolent course
Mantle cell lymphoma		Vague symptoms (dyspepsia)	Colon	Multiple polyposis, seldom with ulcerations	$CD19^+$, $CD20^+$, $CD5^+$, $CD10^-$, $CD43^+$, sIg^+, $BCL6^-$, $IRF4/MUM1^-$, $Cyclin\ D1^+$	BCR rearranged t(11;14)(q13;q32)	Negative impact on prognosis
Follicular lymphoma		Vague symptoms (dyspepsia)	Second part of duodenum	Whitish polyps	$CD19^+$, $CD20^+$, $CD5^-$, $CD10^+$, $CD43^-$, sIg^+, $BCL6^+$, $IRF4/MUM1^{-/+}$, $Cyclin\ D1^-$, $\alpha4\beta7^+$	BCR rearranged t(14:18)(q32:q2 1)	Good
Extramedullary plasmacytoma		Alarm symptoms and obstruction	Stomach	Infiltrating mass	Plasmacells expressing $CD79a^+$, $CD38^+$, $CD19^-$, $CD138^+$, $CD56^+$, usually $CD20^-$	BCR rearranged t(11;14)(q32;q13)	Poor
PTLD		Alarm symptoms	Colon	Rubbery erythematous or ulcerated	Similar to DLBCL and Burkitt's lymphoma $CD19^+$, $CD20^+$, $CD5^{-/+}$, $CD10^{-/+}$, $CD43^{-/+}$, $sIg^{+/-}$, $BCL6^{-/+}$, $IRF4/MUM1^{-/+}$, $Cyclin\ D1^-$	Monoclonal BCR	Poor median survival 6 mo
Plasmablastic lymphoma		Alarm symptoms	Stomach	Large masses and exophitic processes	$CD79a^+$, $CD138^+$, $CD38^+$, $IRF4/MUM1$, $CD45^-$, $CD20$, $PAX5^-$, $CD56^-$	Clonal IgH chain gene rearranqement	Poor
Hodgkin's lymphoma		Obstruction	Colon	Protruding mass	$CD30^+$, $CD15^+$, $CD45^-$, $CD20^-$, $CD79a^-$, $PAX5^+$, Ig^-, $OCT2^-$, $BOB1^-$, $CD3^-$, $CD2^-$, $CD5^-$, ALK^-	Clonal immunoglobulin gene rearrangements	Prognostic impact not known

Guidelines suggest that diagnostic work-up and follow-up should be done in synergism between hematologists and gastroenterologists in order to better define the staging and the treatment needed and to ensure the best nutritional guidance (evidence level Ⅲ grade B)[43].

In a study from the German group, the most frequent histotype of intestinal lymphoma was T-cell lymphomas[44]. The most commonly involved organs are the duodenum and jejunum, followed by the ileum and colon. Less frequent is the involvement of the stomach[45], also as part of composite lymphoma[46], *i.e.,* lymphoma with B- and T-cells origin. Regarding gastric involvement, in 30% of cases there is localization in the upper part of the stomach, in 20% the localization is in the middle part and diffuse in 40% of cases[47]. Due to the fact that the prognosis and treatment strategy depends on the lymphoma histotype, bioptic evaluation is a mandatory step. In addition, each subtype presents peculiar endoscopic behaviors that can drive diagnosis and treatment. GI T-cell lymphomas typically have a mature phenotype, while acute types of T-cell neoplasms do not classically involve the GI tract[48].

According to the 2008 WHO classification of hematological malignancies, the most prevalent histotypes are[48,49]: (1) enteropathy-associated T-cell lymphomas (EATL) (distinguished in type Ⅰ and Ⅱ); (2) peripheral T-cell lymphomas and extranodal natural killer (NK)/T-cell lymphoma; and (3) adult T-cell leukemia/lymphoma (ATLL).

In addition, very rare cases have been reported (mostly as singular events) of colorectal T-cell prolymphocytic leukemia/lymphoma[50] or anaplastic T-cell lymphoma (ALCL) ALK$^+$[51] or ALK$^-$[52]. Distinct entities not described in the WHO classification are indolent T-cell/NK diseases that will also be taken into account.

Although EUS findings are not usually reported except in peculiar cases, submucosal hypoechogenic lesions destroying the involved layer would be the main pattern[53]. Another proof of the sub-mucosal origin of the tumor is given by narrow band imaging that is able to show intact gastric pits elevated from the underlying mass[51]. Very rare and unusual is the GI involvement in Sezary syndrome where, despite unremarkable gastric mucosa, EUS can show the hyperechogenic submucosa layer at giant fold level[54].

Enteropathy-associated T-cell lymphoma

EATL can be divided into two forms[14]. The first variant is characterized by features of celiac disease with abdominal pain and small intestine obstruction/perforation. Usually there is a large mass with massive necrosis, while the neighboring mucosa shows villous atrophy and crypt hyperplasia as in typical enteropathy. Type II exhibits villous atrophy in the context of tumor mass with normal intestinal mucosa in uninvolved sites. Contrarily to type I EATL, type Ⅱ EATL does not progress from undiagnosed or refractory celiac disease[14,55]. Prognosis is poor with a median overall survival of 7-10 mo[56].

The exact incidence and lymphoma risk in celiac patients is still a debated issue[57]. Some studies indicate a 200-fold increased risk of developing EATL compared to the general population[58,59]. According to other studies, the risk of developing non-Hodgkin's lymphomas in celiac patients appears to be 6-fold higher than in the general population and this risk assumes a downward trend over years[60]. Nonetheless, it appears clear that the occurrence of complications in celiac patients, although infrequent, is an event that negatively impacts on patient survival[61]. In fact, the occurrence of intestinal perforation in a patient affected by celiac disease should lead to suspicion of lymphoma.

Usually, EATL patients tend to have a poorer performance status than B-cell lymphomas (even though tends to be localized), independent of the stage. Fever and diarrhea are the most frequent symptoms[44]. The duodenum and jejunum are the most involved sites, with secondary involvement of the gross intestine in 14% of cases[44]. The diagnosis of the disease in some cases is difficult since neoplastic lymphocytes can be present in a context of an inflammatory background.

Endoscopic features are aspecific, with multiple erosions and ulcers[31]. Nodularity and thickened folds can be seen at DBE[26,27]. Strictures and masses are less common[62]. In some cases, macroscopic findings together with the occurrence of an intense inflammatory reaction can lead to a mistaken diagnosis of Crohn's disease (CD)[31,63]. However, although it is not a general rule, CD ulcers are transversal, while, in the presence of T-cell lymphoma, ulcers are longitudinal[63].

Peripheral T-cell lymphomas and extranodal NK/T-cell lymphoma

Peripheral T-cell lymphomas (PTCL) and NK lymphomas are more frequent in South America and Asia. These entities are distinct from other GI T-cell lymphomas by morphological and immunohistochemistry criteria[62] and should be diagnosed when other more frequent T-cell lymphomas are excluded[48]. Korean and Japanese series indicated that these are the most frequent GI T-cell lymphoma subtype, accounting for 40% of primary T-cell GI lymphomas HTLV-1 negative[64]. PTCL arises frequently in extranodal sites, especially at the skin. However, the involvement of the gastrointestinal tract is a severe prognostic factor[65,66]. The stomach and duodenum accounts for 60% of GI localizations[52]. The most frequent findings are ulcerative (46% of cases), infiltrative (9%), ulceroinfiltrative (18%), ulcerofungating (18%) and erosive (9%)[52]. Multiple polyposis can also be detected[67]. In the literature, there are two reports indicating the involvement by T-cell lymphomas in the ileocolonic anastomosis for a previously resected right colon, presenting with polypoid lesions[68] or ulcerative lesions[69].

Extranodal NK/T-cell lymphoma usually arises in nasal cavities and rarely affects the GI tract. A strict relationship exists between ENKTCL and EBV infection,

with almost 70% of cases positive for Epstein–Barr virus-encoded small RNAs (EBER) detection[70]. The small intestine is the most involved organ, while the stomach is rarely involved[71]. The endoscopic pattern in the majority of cases is given by multifocal ulcers[72-75] and infiltrative lesions[52]. Sometimes the ulceration leads to intestine perforation and acute peritonitis (60% of the total complications)[52]. Additionally, perforation is more frequent in the infiltrative pattern compared to the non-infiltrative. Fungating lesions are not usually reported[76]. The most involved organ is the small intestine[77,78] and/or colon[72,76] (depending on the case series), followed by the small intestine, rectum and stomach[72]. However, the location at the GI tract does not seem to affect the prognosis[77]. Interestingly, since the perforation usually leads to the development of peritonitis, the Lugano staging system has been applied, resulting in the advanced stage of the disease being a prognostic factor at multivariate analysis[72]. Due to the high risk of perforation, many patients undergo surgery as a pre-emptive or curative strategy, rarely for diagnosis[79]. However, according to Kim *et al*[77], patients undergoing surgery followed by chemo/radiotherapy would show a better OS. However, as the authors themselves stated, this benefit would be ascribed to the fact that patients undergoing surgery had a better performance status and more limited disease which would have affected the outcome. Similarly, as Hong *et al*[78] reported in a multivariate analysis, surgery ensures a better survival compared to chemotherapy. Therefore, an appropriate locoregional staging is also useful to tailor treatment.

Adult T-cell leukemia/lymphoma

As for EATL, ATLL tends to present with ulcers with aggressive behavior. This is a specific variant of peripheral T-cell lymphoma that recognizes the HTLV-1 virus as an etiological agent[48]. This variant is mainly found in endemic areas of Japan[64]. In about one third of ATLL cases, GI involvement is secondary to a systemic disease[49]. According to the first data by Suzumiya, the stomach is involved in 40% of cases and the small and large intestine in 38% and 34% respectively[80]. Although four types of ATLL have been depicted (*i.e.,* smoldering, chronic, lymphoma, acute), no endoscopic pattern has been related to a peculiar histotype. HTLV-1 infection has no role in determining the macroscopic features[47]. Noteworthy, the detection of GI involvement has a prognostic impact[49], representing the aggressiveness of the disease[43]. In fact, smoldering or chronic ATLL subtypes do not typically show GI involvement[81]. However, primary GI smoldering ATLL have been described and show long term disease-free survival after chemotherapy[82]. Gastric involvement can be enhanced by *Helicobacter pylori* infection that creates an inflammatory state able to lead lymphocytes (also malignant) to migrate into gastric wall through the expression of specific adhesion molecules[83].

An ulcerative pattern is present in more than half of cases of gastric involvement[47]. Single or multiple yellow-whitish polyposis of the first or second loop are more frequent in the duodenum[49] and multiple polyposis is the recurrent lesion in cases of colon involvement[84]. Although a single or multiple polyps are the most frequent lesions, flat ulcerations/erosions can also be present[84]. Red flat or elevated lesions in the rectum have been also documented[85,86]. Rarely, there is the involvement of the ileum, where polyps are the main features[87]. It should be underlined that GI lesions are not always monotone but can be variegated. For examples, case reports indicate the occurrence of protruding masses with normal or eroded mucosa at the stomach and the occurrence of flat granular, friable lesions that bled on contact with mucosa at the colon[88] or reddish irregular flat lesions at the esophagus[89].

Narrow band imaging is able to document irregular microvascular architecture, dilated and destroyed gastric pits and dense aggregations between the pits with variegated irregular nuclei without interglandular infiltration (reflecting the absence of lymphoepithelial lesions)[90].

Indolent lymph-proliferative diseases of the GI tract

A new category of T-cell GI lymphoproliferative disease, namely T-cell lymphoproliferative disease (T-LPD), has been recently introduced[91]. The indolent course is the main clinical hallmark while this entity has been previously treated and managed as PTCL. Noteworthy, the etiology of the disease is unknown, although many patients present with a history of inflammatory bowel disease (IBD). Basically, the clinical picture is dyspepsia and mild diarrhea, while endoscopic features can vary from unremarkable mucosa to erythema. The small intestine and colon are the most frequently involved sites, followed by the oral cavity, stomach and esophagus. Usually, the gastric mucosa is normal despite a disease localization, while the duodenum can show thickened folds and an irregular pattern. In the colon, the occurrence of friable mucosa, erythematous mucosa and small polyps can be seen. Ulcerations are not described. At immunohistochemistry, lymphoid cells have a cytotoxic phenotype ($CD8^+$; $CD4^-$; TIA^+), clonal T-cell receptor (*TCR*) gene rearrangements, do not form masses, do not invade the intestinal crypts and do not cover the full thickness of the bowel[91]. Additionally, the lymphoid infiltrate is limited to the mucosa and sub-mucosa. The molecular study for TCR can show a monoclonal rearrangement of TCR-γ chain[91]. The recognition of this disease has many therapeutic implications since aggressive chemotherapy is excessive and an immunosuppressive treatment is virtually sufficient.

Indolent $CD4^+$ T-cell lymphoma has also been described and shows a good outcome and survival despite a persistence after immunomodulatory drug-based treatment[92]. Rarely, gastric mucosa can show multiple nodularities[93]. However, a clinical and endoscopic follow-up of these lesions is always

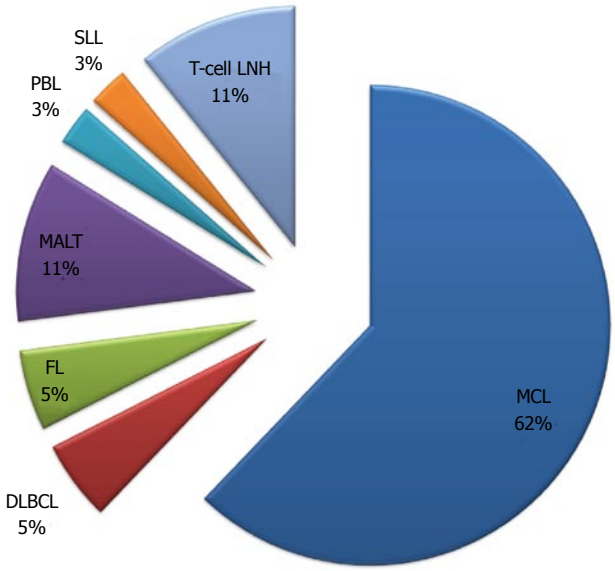

Figure 2 Pie chart describing the distribution of lymphomatous polyposis as a presenting gastrointestinal feature in gastrointestinal non-Hodgkin's lymphomas according to histotype. SLL: Small lymphocytic lymphoma; PBL: Plasmablastic B-cell lymphoma; DLBCL: Diffuse large B-cell lymphoma; MCL: Mantle cell lymphoma.

advisable[93], also for the risk of progression in the long term[92].

Similarly to T-LPD, NK cells can also give rise to an indolent form of lymphoid infiltrate in the context of the GI tract, *i.e.,* NK-cell enteropathy[94]. Usually the symptoms are vague and the GI lesions can be present in the stomach (more frequently), duodenum, small intestine and colon. At endoscopy, these lesions exhibit superficial ulceration, flat elevations with central depression and are associated with edema and local hemorrhage. Usually these ulcers are 1 cm in diameter and the surrounding mucosa is not abnormal. This disease is distinct from ENKTL since gastric involvement in the latter is really infrequent (and if present, the localization is not limited to the stomach) and EBER is positive. In addition, in the presence of NK-enteropathy, the epithelium can be invaded, showing a lymphoepithelial-like lesion[95]. Moreover, contrarily to T-LPD, the TCR rearrangement is polyclonal or oligoclonal[94].

Lymphomatous polyposis and mantle cell lymphoma

The pioneering study by Cornes *et al*[96] in 1961 first reported the term "lymphomatous polyposis (LP)". It is defined as the presence of diffuse proliferation of monotonous small-to-intermediate sized lymphocytes presenting as multiple polypoid tumors from 2 mm to several centimeters in different GI sites. Although the preferred site is the small intestine[14], other sites can be involved alone or at the same time[97-104]. Actually, LP is present in 4%-9% of all GI lymphomas[14], more frequently in western than eastern countries[105]. B-cell lymphomas are more frequent than T-cell lymphomas and this is due to the fact that histologically these polyps originate from the mantle zone of the lymphoid follicle of the mucosa-associated lymphoid tissue[106]. Additionally, this fact justifies the augmented frequency in the small intestine (rich in lymphatic tissue) compared to other GI tract sites. Additionally, multiple tumors or different kinds of lymphomas can be simultaneously present in a context of LP[107]. Therefore, the biopsy of more than one polyp and of different types of lesions is always advisable[108,109]. Additionally, it must be underlined that although the occurrence of multiple polyposis in a patient with nodal lymphoma is not a criterion to absolutely define the involvement of the GI tract, the histological evaluation is always mandatory[110].

Typical lymphoma presenting with LP is MCL[14,111], although other tumors can show this feature[98-100,112-114]. Among 37 case reports of LP since 2000[67,84,98-100,103,112-142], MCL was indeed the most frequent disease (more than 50% of cases) (Figure 2). The most involved site was the colon (Figure 3). In the case series by Saito *et al*[143], regarding patients affected by MALT lymphomas or MCL at the ileal site, it was underlined that LP was the most frequent presentation of MCL and the least common lesion in MALT lymphomas (Figure 4).

MCL can locate at the GI tract secondary to the generalized disease[102] and, although only 25% of patients with nodal mantle cell lymphoma suffer GI symptoms, 77%-88% have a localization at the gross intestine and 43%-77% in the upper GI tract, also in the absence of macroscopic lesions[14] (Figure 5). LP is the most frequent endoscopic pattern although other endoscopic features can be present[144], for example, a granular pattern associated with polyps (Figure 6) or ulcerated polyps[145] or masses[146]. In addition, the endoscopic pattern varies according to the part of the GI tract involved (Figure 7). EUS has been applied in this setting, giving the possibility of identifying submucosal lesions[115]. MCL appears echo-poor, usually departing from the second layer and remaining confined to the GI wall (Figure 8)[115,147,148]. In some cases, the diagnosis of MCL could be incidental during the endoscopic definition of gastric bleeding caused by gastric ulcers[149].

Contrarily to GI follicular lymphoma (discussed below), the GI tract involvement by MCL assumes a great prognostic implication and is useful to monitor patients after the treatment[14,101]. Indeed, the occurrence of LP designates a median survival of 3-4 years[14,101]. Due to the fact that the small intestine can be also involved by the tumor, the performance of CE or DBE would be advisable in order to correctly stage the patient and assess the follow-up evaluations[116,117].

Although the disease presentation has been well studied, there are no data about the management of LP during follow-up assessment. Our opinion is that endoscopic evaluation with mapping biopsies should be performed in these patients since in some cases the presence of aspecific abnormalities during follow-up can lead to the finding of lymphoma reappearance[146], sometimes many years after complete remission[103,119].

Follicular Lymphoma

GI FL is a rare entity, representing up to 3.6% of all GI NHL[150,151]. Primary GI FL was recognized as an histological variant of FL in the 2008 WHO classification of hematopoietic tumors[152]. Sites most frequently involved are the duodenum (55.6% of cases)[101], in particular the second part[152], and the terminal ileum (33.3% of cases)[151,153]. Since positron emission tomography and computed tomography have low sensitivity and specificity[154] in catching small intestine involvement, CE and DBE have acquired more and more importance[155,156]. Indeed, these techniques have shown that the small bowel can be involved in 70%-83% of cases[157,158], even in cases of duodenal lymphoma[152].

To date, a clear endoscopic classification of GI-FL has not been done, as for GI MALT lymphomas. However, Yamamoto *et al*[151], reviewing 249 GI-FL cases, reported a reliable endoscopic classification of the disease. Whitish polyps usually up to 2 mm[151,153] and/or white granules-nodular aggregates, with or without ulceration of the mucosa layer (Figure 9), are the typical endoscopic pattern[150,159,160]. This can be unifocal or multifocal and is mainly present in intestinal FL. A large mass with or without ulceration is less frequent and in half of cases can be associated with multifocal whitish polyps. The latter is the most frequent endoscopic pattern of primary gastric FL. Multiple lymphomatous polyposis can also be

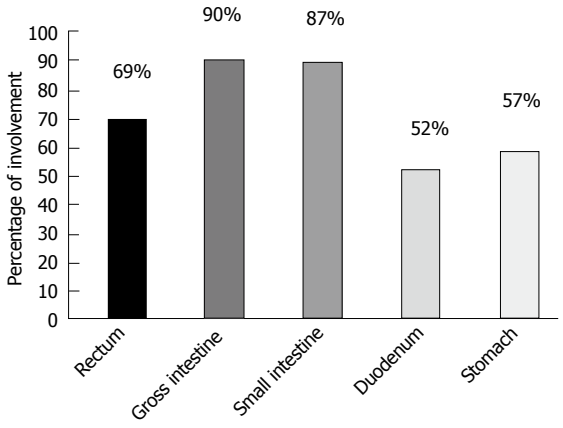

Figure 5 Frequency of the sites involved in mantle cell lymphoma. Adapted from Ruskoné-Fourmestraux *et al*[101], 2010.

found[30,101,150,158,161,162]. Interestingly, in the series of 48 patients with GI FL reported by Yanai *et al*[163], it was found that the LP was the most frequent endoscopic feature (more than 50% of cases), followed by polypoid or ulcerative lesions (Figure 10).

Recently, high-definition endoscopy, as well as magnifying endoscopy (ME), has been used to describe the surface microstructures of GI FL, such as enlarged whitish villi and tiny whitish depositions and an irregular microvascular pattern[164,165]. This fact indicates that the tumor is of non-epithelial origin and usually reflects the formation of lymphoid follicles[164,166-169]. EUS has not been widely applied. A few reports have indicated that the echoendoscopic pattern is given by second and third layer thickening, dotted by hypoechogenic nodules[170].

Capsule endoscopy and double-balloon enteroscopy are useful in the definition of small intestine involvement in a non-invasive way. The typical picture is a whitish submucosal elevation presenting as nodules or polyps[21], usually multifocal[171,172]. However, the limitation is the inability to perform a biopsy that is postponed until the enteroscopy and the risk of retention in cases of stenosis (unusual in cases of GI-FL).

Nodal spread is rare and GI FL tends to be localized in the gastrointestinal tract (stage IE according to Ann Arbor staging system)[173] and to have an indolent course[152,174]. However, transformation to aggressive lymphoma has been documented[175]. Different from other form of lymphomas, the GI involvement is not an adverse prognostic factor[176]. Lymphoma grading is low in the majority of cases, while in the nodal counterpart grade I-II FL is documented in 1 case out of 10[173]. Furthermore, in contrast to nodal FL, these cells do not acquire additional mutations and this justifies the absence of grade 3 GI FL and the very low rate of transformation[173,175].

Treatment strategies are not uniform, although GI FL are treated more frequently compared to the nodal counterpart[177]. Different case series have demonstrated that a watch and wait approach is as useful as the pharmacological approach, except for relieving clinical symptoms[163,178-180]. However, case series differ greatly

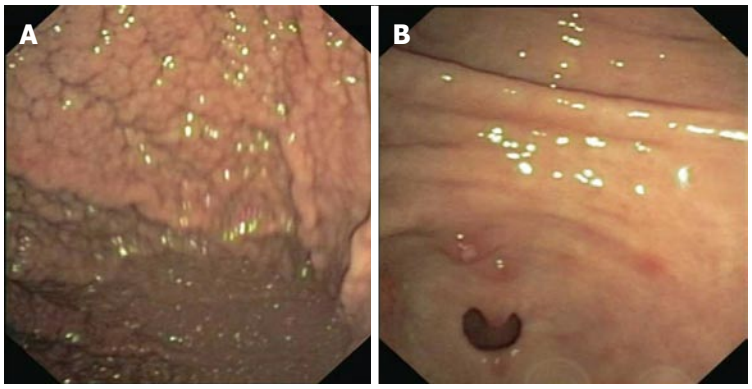

Figure 6 Endoscopy stomach: Granular pattern of the fundus and body of the stomach (A) and polyps in the antrum (B).

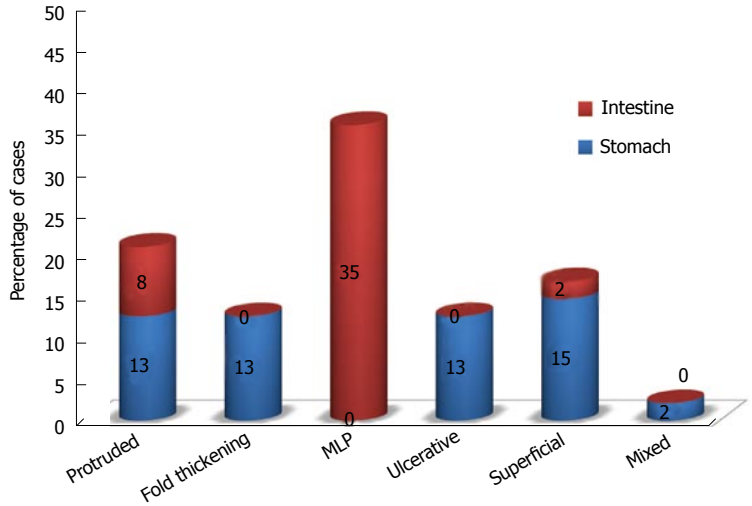

Figure 7 Endoscopic lesions in mantle cell lymphomas according to the gastric and intestinal localization. Adapted from Iwamuro *et al*[144], 2010.

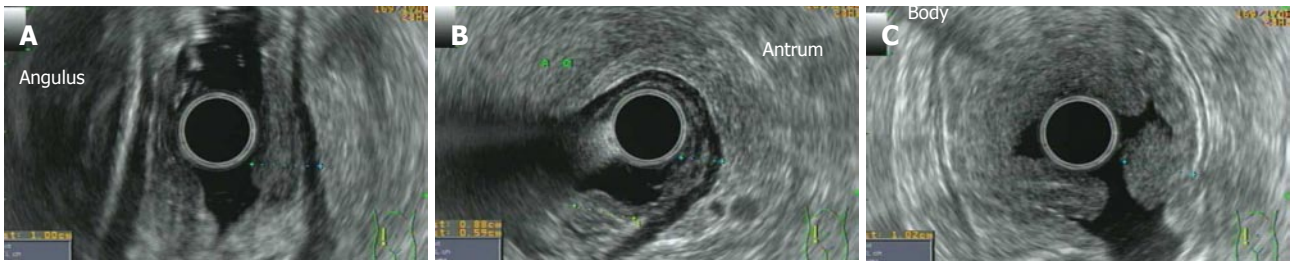

Figure 8 Endoscopic ultrasonography (radial scanning): Marked thickening of the muscularis propria and increased wall thickness (12 mm) in the angulus (A); antrum (B); body (C).

in identifying the correct treatment approach to be applied. Surgical resection is not recommended and chemoimmunotherapy is preferred[151,171]. It must also be considered that the introduction of anti CD20 antibodies has augmented the survival rate and in some series localized/low-grade GI FL have been treated with anti CD20 monoclonal antibody alone, without chemotherapy[151].

It is debatable whether CE and/or DBE are truly useful. Indeed, no studies have demonstrated that the detection of small bowel involvement (especially if duodenal lymphoma is present) would have changed the treatment needed. Surely, these procedures would change the treatment strategy in cases of radiation or surgical treatment and are needed in cases of obscure gastrointestinal bleeding[172,181]. Apart from these occurrences, the effectiveness of chemoimmunotherapy or immunotherapy alone would render these procedures less practical in patient management. However, since no clear data exists regarding survival and quality of life in dependence of small bowel involvement, clinician choice is the only way to proceed.

That notwithstanding, the diagnostic suspicion based on the endoscopic features, together with the patient history, is fundamental in addressing the pathological diagnosis. Indeed, in almost 20% of cases, FL can be misdiagnosed by endoscopic biopsy evaluation[182]. Therefore, multiple biopsies would be necessary. In particular, biopsies of the peripheral mucosa would be more informative than biopsies from the erosion/ulceration since the probability of catching necrotic tissue decreases significantly.

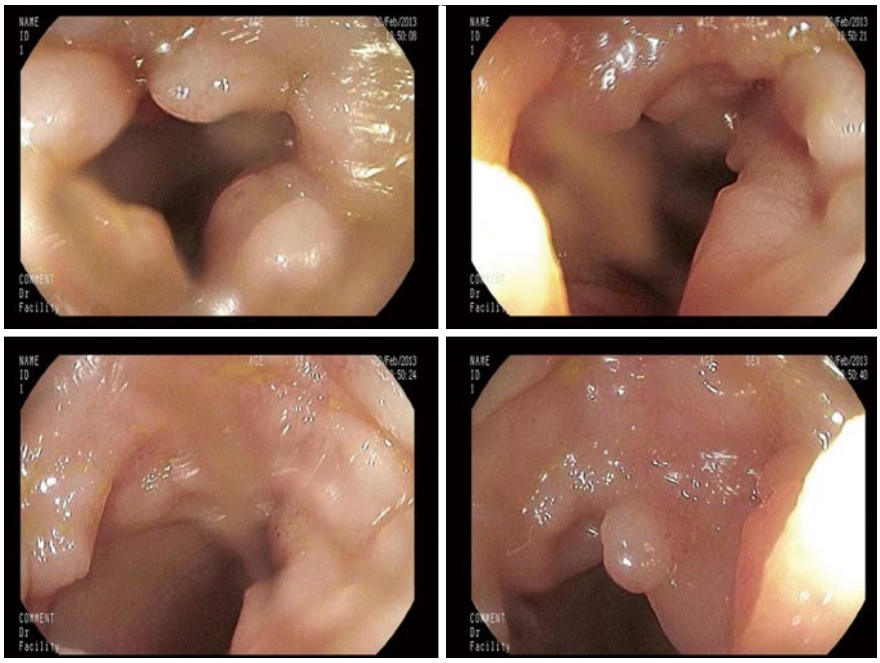

Figure 9 Ileoscopy revealing the presence of hyperemic mucosa with whitish polypoid nodularity. The subsequent diagnosis was a grade 2A follicular lymphoma.

EMP and plasma cell-related diseases

EMP belongs to a precise type of lymphoid malignancies, *i.e.,* plasma cell neoplasms, representing 3%-4% of cases[183]. It is important to distinguish this subtype from lymphomas with plasmacytic differentiation, particularly MALT lymphomas[48]. The upper respiratory tract is the most involved organ (almost 80% of cases), while GI localization is rare[48]. Among these cases, the stomach is the most involved site, followed by the liver, colon and the small intestine (duodenum, jejunum and ileum)[184].

Usually, gastric localization is secondary to a plasma cell myeloma (PCM) and often emerges through a clone selection process. Indeed, multiple myeloma treatment itself can select a particular chemoresistant PC clone able to migrate at extra-nodal organs. In these cases, an accurate endoscopic investigation is critical for the diagnostic assessment and disease monitoring[185]. Due to the strict relationship with plasma cell myeloma, the clinical course is poor. The most frequent endoscopic finding consists of an infiltrating mass or masses in the stomach and/or the duodenum[186,187] or well-demarcated, flat, yellow-whitish mucosal changes[188] or nodular lesion with central umbilication[189]. Endoscopic appearance as diffusely thickened mucosal folds simulating linitis plastica is rare[190]. Sometimes, large ulcerations can be seen[191,192]. However, the gastric mucosa can appear normal, while the extramural growth is incredibly vast (Figure 11). EUS could be of great help in defining the disease extension that appears as a large echo-poor mass infiltrating surrounding organs[186]. However, sometimes EUS can be useful to detect limited gastric wall involvement and in these cases, an endoscopic resection of the mass can be performed, resulting in safety for the patient and effective in the treatment of the disease[188,193,194]. Alternatively, patients with localized disease can be treated with radiation treatment[190,195].

Small intestine involvement is generally primary with a benign course. These lesions can be explored by enteroscopy and/or capsule endoscopy[196], paying attention to the cases in which obstructions or retention are expected. Differential diagnosis is other cases of

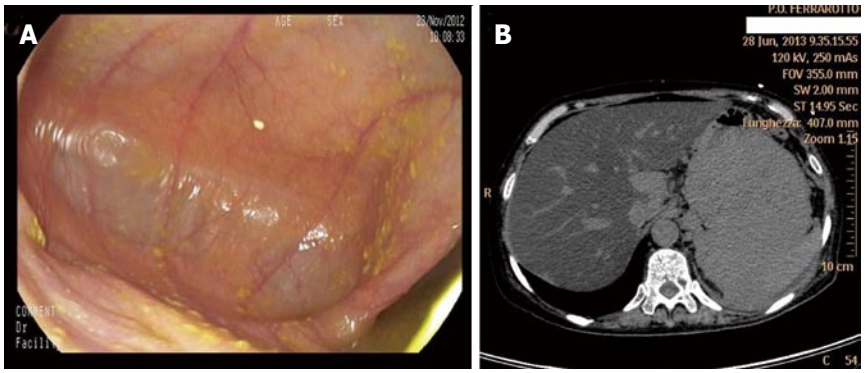

Figure 11 Extra-medullary plasmacytoma with gastric localization arising after treatment for multiple myeloma. A: Gastroscopy resulted negative for tumor detection; B: CT scan analysis of the upper abdomen showing a bulky mass departing from the stomach.

sub-mucosal masses in the small intestine, as reported by Lopes da Silva[196]. Colon involvement appears more frequently as stricture[197,198], in some cases difficult to differentiate from colon adenocarcinoma[199], returning to the differential diagnosis of sub-mucosal tumors[193]. Rarely it can determine rectal bleeding[200]. The localization at the rectum appears as a mild granularity as well as a reddish, protruded lesion[201]. Usually these lesions disappear after treatment and this is a confirmation of treatment efficacy[186], although mucosal atrophy and non-specific inflammation can be reinstated[195].

Apart from EMP, other plasma cell-related disorders can involve the GI tract. This is due to the production of amyloid protein in AL amyloidosis (light chain amyloidosis)[187]. The most involved organ is the small intestine. In some cases the amyloid deposition is synchronous with EMP[187,193,195] or other GI lymphomas[202]. Usually, the amyloid protein in AL amyloidosis involves the submucosa and the muscularis mucosae, resulting in thickened folds and valvulae conniventes and polypoid lesions in the GI tract. The typical deposition of AL amyloid proteins result in pseudo-obstruction, constipation and mechanical obstruction as the main symptoms[203]. Intestinal bleeding can also occur[204] and if this event occurs in a patient with multiple myeloma, the occurrence of aspecific elevated lesions at the endoscopic evaluations should lead to suspicion of systemic amyloidosis. More rarely, submucosal hematoma, ulcers and hemorrhagic bullous colitis can be seen[205]. On the other hand, nodularity, fine granular appearance and mucosal friability are more frequent in other types of amyloidosis, *i.e.,* AA amyloidosis (amyloidosis secondary to systemic disorders). This is due to the deposit of amyloid proteins into the lamina propria with impaired absorption and subsequent diarrhea[203].

Immunodeficiency and GI lymphomas

Immunodeficiency is defined as a state of impaired function of the immune system that can be congenital, acquired or iatrogenic. The reduced immune-surveillance can determine an augmented rate of lymphomas. Two conditions mainly determine the arising of lymphomas: human immunodeficiency virus (HIV) infection with the correlated acquired immunodeficiency syndrome (AIDS) and post-transplant immunosuppression. In both conditions, the GI tract is the most involved site[206]. Apart from HIV and PTLD, common variable immunodeficiency (CVID) has been associated with the development of gastrointestinal NHL, although this is a very rare finding[207,208].

In HIV patients, the rate of GI lymphomas was higher in the pre-HAART era before 1996[209] and the risk of gastric NHL was 353-fold compared with normal subjects, with aggressive lymphomas the most prevalent feature[59]. In cases of AIDS-related lymphoma, the GI tract is involved in 20% to 50% of cases[206,210]. However, the decrease of GI lymphoma incidence has not been as high as in central nervous system lymphomas[209]. A recent analysis of 243 HIV patients performed at the University of Sao Paolo revealed an incidence of gastric NHL of 2.5%[211]. Co-infection with EBV and/or CMV would complicate the prognosis[212], although the occurrence of viral infection is less pathogenetically important compared to PTLD[206]. The main histologies are B-cell lymphomas (67%) (DLBCL, Burkitt lymphoma, MALT lymphoma)[213], while T-cell lymphomas are less frequent (33%)[209] and other types of hematological malignancies are anecdotal[214,215]. In 5%-10% of cases, cMyc rearrangement is present and confers a poor prognosis[212]. Additionally, the prompt recognition of this lymphoma subtype has a great impact in patient management since the presenting symptoms are usually alarm symptoms in about half of patients. However, in the majority of patients, the lymphoma is diagnosed at Ann Arbor stage Ⅲ-Ⅳ[206]. The most frequent endoscopic features are multifocal ulcerations, followed by polypoid or a bulky mass together with bloody spots[206,212]. The most involved sites are the stomach and duodenum[216], followed by the small bowel and colon-rectum (Figure 12)[211]. However, unusual presentations can be seen more commonly than in immunocompetent patients[206]. At narrow-band, a honeycomb-like pattern is present without irregularity in the microvasculature[212]. The localization can also be perirectal and in these cases,

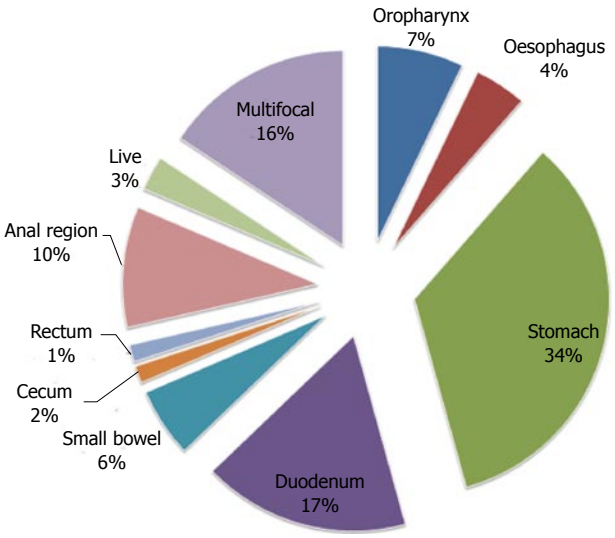

Figure 12 Frequency of the involved gastrointestinal tract in human immunodeficiency virus-related gastrointestinal lymphomas. Adapted from Heise[206], 2010.

EUS-guided fine needle biopsy would be a valid tool for diagnosis given the high grade nature of this kind of lymphomas[217]. Noteworthy, EUS appearance is of a hypoechoic poorly defined mass[217] and is important for the locoregional staging[206]. Prognosis is poor with a median survival of 6 mo and a rate of complete remission less than 40%[211]. Prognosis is also impaired by the occurrence of opportunistic infections[210]. Extremely suggestive is the development of EBV-related DLBCL in patients suffering other types of lymphomas that induce a state of immunosuppression, such as AITL[218]. In these peculiar cases, the outcome is really poor and alarm symptoms and perforation can occur with fatal implications[218].

GI lymphomas are also more frequent in solid organ transplant recipients, particularly after renal, heart and small bowel transplantation, encompassing the spectrum of PTLD (Table 3). The pathogenetic events seem to be different compared to HIV-related lymphomas since in this kind of lymphomas, Epstein-Barr virus reactivation due to immunosuppressants plays a pivotal role[219]. Apart from negative EBV serology prior to transplantation, length of immunosuppression is an overt risk factor[220,221]. EBV-positive lymphomas arise earlier than EBV-negative lymphomas[221]. In adults, the majority of cases arises over 12 mo from transplantation[222], at a median of 36 mo[223]. A second peak is after 5-10 years[206]. Median overall survival is 8 years and the principal histotype is B-cell lymphoma, although lymphomas of T-cell origin can also be present. Noteworthy, the GI tract is involved in one third of cases. Endoscopy is of great help in establishing the diagnosis. Especially in small bowel transplantation, endoscopic follow-up has gained a pivotal role in defining the transplant-related complications, including the onset of PTLD[224]. Typically, lesions are raised, rubbery, erythematous or ulcerated[222,225,226]. The most involved organ is the colon, followed by the small intestine and stomach[223]. However, the recognition of symptoms together with the patient history is of great help in driving the diagnosis. Additionally, endoscopic procedures are essential in order to follow the course of disease[225], also valid in the long-term[226]. Interestingly, early stage PTLD can be safely removed endoscopically and this would be a valid approach in the treatment of localized PTLD[224].

Table 3 Prevalence of gastrointestinal lymphomas among transplant recipients according to transplanted organ

Transplant	Prevalence
Bone marrow	0.50%
Liver	1%-2%
Kidney	0.7%-4%
Heart	2%-10%
Small bowel	up to 30%

The data extracted from Heise[206], 2010.

Plasmablastic lymphoma (PBL) is a rare and aggressive type of lymphoma characterized at histological evaluation by the presence of large immunoblasts with plasmacytic differentiation with an high replication index[227]. Usually, this lymphoma arises in the oral cavity in HIV-infected patients and in the literature there are few cases of GI localization (Table 4)[228-237]. The stomach is the most involved site (about 50% of cases), followed by the small intestine, anal region, cecum, colon and esophagus[237]. Large masses and exophytic processes are the main endoscopic appearance in the stomach and anal region. Intestinal localization is extremely rare and when present, the endoscopic appearance is of multiple nodularity[227]. Moreover, PBL can also arise in immunocompetent patients with ulcerated lesions at the stomach[236]. These patients are normally older than HIV^+ patients, tend to present with GI localizations more that HIV^+ patients and have a worse overall survival[236,237].

Additionally, CD has also been linked to the development of lymphomas of the gastrointestinal tract. Most of them are of B origin, comprising DLBCL and HL, although T-cell lymphomas can also arise. In the recent report by Kappelman *et al*[238], patients with CD showed a greater risk of developing hematological malignancies compared to the general population. This study confirmed the previous report by Askling *et al*[239], also showing an augmented rate of hematological malignancies compared to the general population and 10% of developed lymphomas were T-type. Probably, it would be related to the state of immunosuppression leading to infection of lymphotropic and oncogenic viruses, but the specific mechanism is still to be clarified. This predisposition seems to be unrelated to immunosuppressive treatment. In this setting, anti-TNFα treatment has been related to development of hepatosplenic T-cell lymphoma[240]. However, two years later, a meta-analysis by Siegel *et al*[241] indicated that

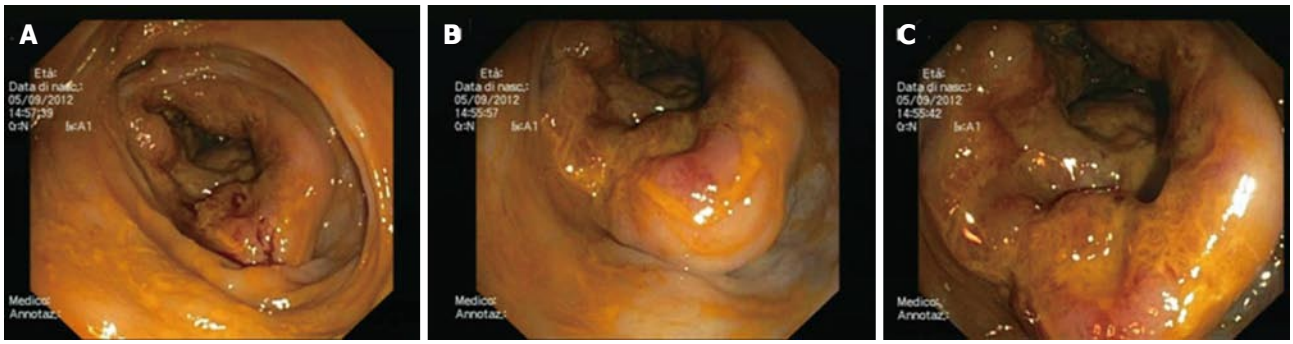

Figure 13 Exophytic erythematous circumferential non-ulcerated mass determining a stenosis of the ileocecal region. The mass arises from the deep layer and the mucosa presents reddish areas suggestive for lymphomatous infiltration of the cecum.

Table 4 Reports of gastrointestinal plasmablastic lymphoma from 1998

Manuscript	Year	localization	Endoscopic appearance	HIV
Pruneri *et al*[230]	1998	Stomach	Large polypoid mass	-

HIV: Human immunodeficiency virus; GI: Gastrointestinal.

immunosuppressive treatment is not a risk factor for the development of NHL in CD patients. However, it is still a matter of discussion since the augmented incidence of GI lymphomas in these patients is related to the more intensive examinations. Moreover, the histological evaluation is a crucial point since the inflammatory background can lead to a false positive result. That notwithstanding, anti-TNFα treatment seems to be safe regarding the incidence of NHL and should not be regarded as a risk factor. Therefore, more epidemiological studies will be needed in order to better define the link between CD and GI lymphomas.

Hodgkin's lymphoma

Lymphomatous GI involvement in HL appears as a stricture (Figure 13) or ulceration[242-245]. The abundant lymphoid tissue present at this site renders it one of the most involved regions[246]. HL rarely presents as a colonic localization (almost 1%-3% of extra-nodal HL cases[247] and less than 5% of gastrointestinal lymphomas[243]) and the prognostic impact is still obscure. Mixed-cellularity subtype is the most common feature[248]. As for the nodal counterpart, the inflammatory background is a key feature of HL[249]. In some cases, the endoscopic and histological presentation can resemble IBD, that in turn is seldom associated with colonic HL[244,250]. Additionally, immunodeficiency is a risk factor[251], although this type of lymphoma can also arise in immunocompetent patients[247].

Recently, a new entity has been proposed, *i.e.*, "EBV-associated mucocutaneous ulcer" (EBVMCU)[252]. This disease subtype resembles HL but there are peculiar clinical and histological differences. Indeed, the presence of "plasmacytoid" apoptotic cells and the confinement to mucosa and sub-mucosal layers are the histological hallmark that can lead to a differential diagnosis from cHL. However, EBV infection is always present, as in GI-HL.

CONCLUSION

Endoscopic features of GI lymphomas are variegated encompassing ulcers, erosions, polyps and so on. It is a fascinating matter of study for both hematologists and gastroenterologists. As stated in guidelines, a synergism between these two figures is fundamental. This is due to the lack of data and the fact that information regarding rare GI lymphomas are extrapolated from case series or

case reports. Actually, the scientific community is gaining more and more knowledge about the recognition and management of these lymphomas, with the creation of proper guidelines for specific lymphoma subtypes. In this setting, the collection of different case series and their analysis will assume a pivotal role in drawing general guidance on disease characterization. Certainly, as has emerged in the manuscript, the management of these lymphomas is different from the nodal or medullary counterparts and a proper understanding of the endoscopic features together with clinical and histological characteristics is crucial for better management of patients, with the ultimate goal of improving clinical outcome and quality of life for patients.

Duodenal adenoma surveillance in patients with familial adenomatous polyposis

Fábio Guilherme Campos, Marianny Sulbaran, Adriana Vaz Safatle-Ribeiro, Carlos Augusto Real Martinez

Fábio Guilherme Campos, Adriana Vaz Safatle-Ribeiro, Gastroenterology Department, Hospital das Clínicas, University of São Paulo Medical School, São Paulo, PC 01411-000, Brazil

Marianny Sulbaran, Gastroenterology Department, University of São Paulo Medical School, São Paulo, PC 01411-000, Brazil

Carlos Augusto Real Martinez, Colorectal Division, State University of Campinas (UNICAMP, São Paulo), Postgraduate Program in Health Sciences at San Francisco University, Bragança Paulista, PC 12916-350, Brazil

Author contributions: Campos FG performed research and wrote the paper; Martinez CAR also performed research and wrote the paper; Sulbaran M and Safatle-Ribeiro AV contributed with photo documentation and endoscopic examinations.

Conflict-of-interest statement: None.

Abstract

Familial adenomatous polyposis (FAP) is a hereditary disorder caused by Adenomatous Polyposis Gene mutations that lead to the development of colorectal polyps with great malignant risk throughout life. Moreover, numerous extracolonic manifestations incorporate different clinical features to produce varied individual phenotypes. Among them, the occurrence of duodenal adenomatous polyps is considered an almost inevitable event, and their incidence rates increase as a patient's age advances. Although the majority of patients exhibit different grades of duodenal adenomatosis as they age, only a small proportion (1%-5%) of patients will ultimately develop duodenal carcinoma. Within this context, the aim of the present study was to review the data regarding the epidemiology, classification, genetic features, endoscopic features, carcinogenesis, surveillance and management of duodenal polyps in patients with FAP.

Key words: Familial adenomatous polyposis; Adenoma; Duodenum; Surveillance; Endoscopy; Digestive system

Core tip: The development of duodenal adenomas is considered a very common and important extracolonic manifestation in patients with familial adenomatous polyposis. Results from recently published studies have indicated the need for life-long surveillance of patients presenting with this condition due to a risk of malignization, especially in patients with severe adenomatosis. The present study discusses the incidence, endoscopic features and management of duodenal adenomas and reviews the published data regarding cancer prevention and surveillance.

Duodenal adenoma surveillance in patients with familial adenomatous polyposis. *World J Gastrointest Endosc* 2015; 7(10): 950-959 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i10/950.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i10.950

INTRODUCTION

Familial adenomatous polyposis (FAP) is an inherited autosomal dominant syndrome that is caused by germline mutations in one copy of the adenomatous polyposis coli (*APC*) gene. These mutations lead to the development of a variable number of colorectal polyps during the second and third decade of life[1,2]. *APC* is a tumor suppressor gene that is located on the long arm of chromosome 5 (5q21-22) and is composed of 15 exons. Exons 1-14 are small compared to the large exon 15, which has 6571 base pairs and accounts for over 70% of the coding portion of the gene[3,4].

As the disease is associated with an almost 100% risk of developing colorectal cancer (CRC) in untreated patients, prophylactic colectomy is considered the cornerstone of FAP management[1,5]. Performing a proctocolectomy before a patient reaches adulthood is associated with a substantial reduction in the incidence of CRC and a better prognosis. Consequently, the extracolonic manifestations (ECM) of the disease have been reported to lead to a relative increase in death[6]. Survival effects associated with screening and prophylactic surgery, life expectancy remains lower than that observed in the general population[7,8].

The majority of ECM have little clinical significance, but some of them may cause serious complications and even lead to death[9-11]. The majority of FAP patients (over 70%) present with some level of ECM during the course of the disease, such as cutaneous lesions (lipomas, fibromas, sebaceous and epidermoid cysts), desmoids tumors, osteomas, dental abnormalities, congenital hypertrophy of retinal pigment epithelium lesions (CHRPE) or upper-gastrointestinal polyps[1]. Moreover, patients with PAF are also at an increased risk for several malignancies, including hepatoblastoma, pancreatic, thyroid, biliary-tree, brain and duodenal cancers[12].

Gastric fundic gland polyps, gastric adenomas, duodenal adenomas and carcinoma represent the most common upper digestive lesions that are diagnosed in FAP patients (Figure 1)[13,14]. As they are an important potential cause of morbidity in FAP patients, duodenal polyps require diagnosis, follow-up and preventive measures to avoid carcinogenesis. Thus, the aim of the present study was to review the data regarding the epidemiology, classification, genetic features, endoscopic features, carcinogenesis, surveillance and management of duodenal polyps in patients with FAP.

CHARACTERIZATION OF DUODENAL POLYPS IN FAP

Historical aspects

After the colon and rectum, the duodenum is the second most common site of polyp development in patients with FAP[12-14]. The existence of gastric and duodenal polyps in these patients was established more than a century ago, and Cabot described the first case of duodenal cancer in 1935[12-17]. In a different study, it was found that a considerable number of stomach and duodenum polyps develop at an early age in the majority of pediatric patients, which led to the recommendation of periodic screening of the upper gastrointestinal in the 1960s[18]. The malignant potential of duodenal lesions was gradually established over the next decade, primarily following the introduction of flexible endoscopes during the 1970s[18-21]. During the 1970s and 1980s, numerous additional studies described high numbers of gastroduodenal polyps being identified during endoscopic screenings, providing definitive support for the inclusion of upper digestive endoscopy during routine evaluation and surveillance of FAP patients[22,23].

Epidemiology

Duodenal adenomas tend to occur approximately 15 years after the appearance of colonic adenomas[20,21,24]. Duodenal adenomas have been found in 30%-92% of FAP patients, with a lifetime risk approaching 100%[7,14,22-24]. The frequency of detecting duodenal adenomas in FAP patients may vary depending on endoscopic technique and the method of tissue sampling[7,23-27]. Employing side-viewing endoscopes and random biopsies, exceptional detection rates of 70% and above may be achieved for duodenal and periampullary adenomas[22,26,28]. Biopsies of periampullary regions and duodenal papilla revealed numerous microadenomas that were not detected in normal duodenal mucosa[22,26,27].

Polyp distribution and histology

The macroscopic appearance of duodenal adenomas in patients with FAP varies widely[21,29-31]. These lesions are usually white, numerous and sessile flat. Due to their small size, they may easily be missed or even entirely overlooked during upper endoscopy. With the aid of chromoscopic techniques, such as sprinkling indigo-carmine or methylene blue over the mucosa, the number of detected polyps may increase considerably. In any given patient, using such techniques can identify anywhere from no visible microadenomas to the existence of over 100 microadenomas of varying diameters (1-10 mm)[7,21,22]. The use of side-viewing endoscopes may eventually enable the detection of a prominent papilla of Vater within a solitary adenoma (Figure 2).

The distribution pattern throughout the duodenum

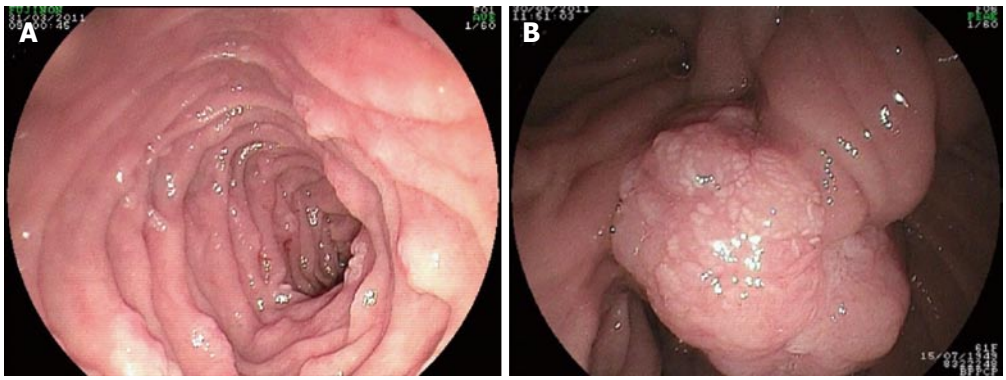

Figure 1 Endoscopic view showing a stage II disease (10-20 small duodenal adenomas with tubular histology) in A, and a large papilla lesion which biopsy revealed a well-moderated carcinoma in B.

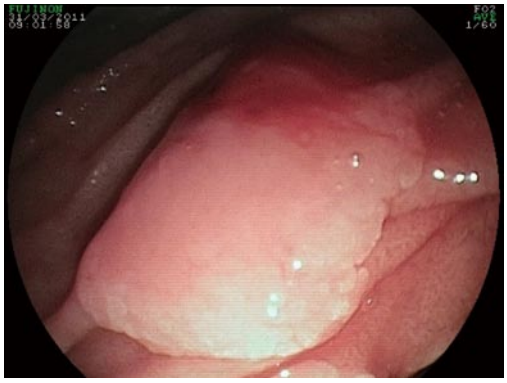

Figure 2 Detection of a prominent papilla of Vater with a solitary adenoma with the help of a side-viewing endoscope.

and the upper part of the small bowel reveals that the majority of polyps are found in clusters around and mainly distal to the ampulla of Vater (second and third part of the duodenum)[32,33].

In 1989, Spigelman *et al*[22] proposed a five-stage classification (0-IV) system to evaluate polyp severity that has become widely adopted. Classification is based on points that are accumulated according to the number, size, histology and dysplasia of polyps. Following this, disease stages are categorized as mild (I), moderate (II), or severe (III and IV) (Table 1).

Previous reports have indicated that approximately 70%-80% of FAP patients have stage II or III duodenal disease and 20%-30% have stage I or IV disease[22,33] (Figure 3). In a retrospective Swedish study that evaluated 180 patients with FAP, 134 (74%) of the patients exhibited duodenal adenomas, of which only 14 (7.8%) were classified as stage IV periampullary adenomas. The authors estimated a time course of 7.1 (range: 5.3-9.8) years for the development of stage IV periampullary adenomas from normal duodenum. Periampullary adenocarcinomas were diagnosed in 5 (2.7%) patients, of whom 3 had a previous diagnosis of stage IV disease based on endoscopic screening and 2 had less severe periampullary adenomatosis[34].

In an interesting, large multicentric study that analyzed 368 upper endoscopies, Bülow *et al*[14] detected duodenal polyps in 228 (61.9%) patients, with adenomas in 209 (91%) and normal mucosa in 19 (9%). Moreover, random duodenal biopsies revealed adenomatous tissue in 28 patients who did not have visible polyps at endoscopy. Based on Spigelman classification, 34%, 15%, 27%, 17% and 7% of patients had stage I, II, III, IV and V disease, respectively. Two of the patients in this series presented with duodenal carcinoma during screening. The estimated cumulative lifetime risks were 88% for duodenal adenomatosis and 35% for stage IV disease. The authors also measured a cumulative cancer incidence of 18% at 75 years of age. Groves *et al*[33] followed 99 patients over a course of 10 years and reported a progression in the incidence of stage IV disease from 9.6% to 14% in patients with a mean age of 42 years. These prospective studies showed that adenomas progress slowly in the duodenum and that adenomatosis is usually diagnosed at a premalignant stage.

In addition to the above, it must be emphasized that although Spigelman classification correlates well with duodenal cancer risk, it focuses primarily on non-ampullary duodenal disease. Therefore, a separate evaluation of ampullary disease is required to establish an accurate individual risk assessment[35].

Duodenal carcinogenesis and cancer risk

The distribution of adenomas within the duodenum probably reflects the exposure of duodenal mucosa to bile acids, suggesting a role for these compounds in duodenal carcinogenesis[22]. Duodenal cancer is one of the two leading causes of death (the other being desmoid tumors) in patients with FAP after they receive prophylactic colectomy[10,12]. When compared to the general population (in whom duodenal carcinoma is rare), the relative risks of developing duodenal adenocarcinoma and ampullary carcinoma were respectively 331 and 124 times higher in FAP patients[36]. Similarly, another study estimated these risks as being 100- to 330-fold higher[27]. The absolute lifetime risk was estimated to be approximately 3%-5%[32-35].

In contrast to colorectal polyps, duodenal polyps

Figure 3 Endoscopic aspect of a stage Ⅰ patient exhibiting 3 adenomatous-tubular polyps with low-grade dysplasia (left); on the right, one may observe a 6 mm tubulo-villous polyp with severe dysplasia, along with other smaller adenomas diagnosed in another patient (stage Ⅳ disease).

do not inevitably transform into cancer[14]. Dysplastic duodenal polyps in FAP patients generally occur 10-20 years after the development of colorectal polyps, and the risk of malignant transformation ranges from 1% to 5%[14,33,37,38].

Stage Ⅳ patients have the greatest risk of developing duodenal cancer, with rates of 7%-36% having been described in 7.6- to 10-year follow-up periods[14,33]. Alternatively, this risk is low (0.7%) among stage 0 to stage Ⅲ patients[12] . Mortality rates from duodenal cancer vary from 1.7% to 8.2%[10,39-43].

Genotype-phenotype correlation

Several genotype-phenotype correlations have been described for colonic polyposis and ECM in FAP patients, including those related to CHRPE and desmoids[44-46]. Aside from the identification of genetic hot spots that are associated with the severity of duodenal adenomatosis, a genotype-phenotype correlation for the disease has not been well defined[12,47].

In a study conducted by Friedl *et al*[48], no correlation was detected between the locations of mutations and the severity of duodenal polyposis. Conversely, Soravia *et al*[49] described severe duodenal polyposis in patients with 5′ mutations. Additional reports have suggested that mutations in the central part of the APC gene and in exon 15 (particularly distal to codon 1400) may predispose an individual to a severe duodenal phenotype[50].

SURVEILLANCE AND MANAGEMENT

Why is surveillance necessary?

In patients with FAP, small bowel polyps are predominantly found in the duodenum and ampulla, although they may also develop in ileostomies and ileal pouches[51]. Within the duodenum, the cumulative incidence of polyp development increases with age (65% at 38 years and 90%-95% by 70 years)[14].

Recognition of the problem is essential toward establishing recommendations for surveillance of the upper gastrointestinal tract. The risk of malignancy increases with size, location (ampullary) and adenomatosis severity[35,52]. Thus, between the existence of an almost 100% lifetime risk of developing duodenal adenomatosis and the cumulative incidence rates of Spigelman stage Ⅳ disease and carcinoma (4% to 10%), there is a clear need for careful follow-up and surveillance of this population[14,52-54].

Improving prognosis through early detection of neoplastic changes is the basis for endoscopic surveillance, and decision analysis has shown that surveillance increases life expectancy by seven months[40]. Moreover, a surveillance program that was based on endoscopic/histological findings and associated with early diagnosis and resection of cancer was shown to improve the prognosis of selected patients[55].

How much and how often?

Adequate evaluation of the duodenum can be obtained with the use of frontal and side viewing (lateral) endoscopes, which facilitate evaluation of the Vater Papilla. Additionally, indigo carmine chromoendoscopy and electronic imaging techniques may improve the efficacy of detecting lesions. As periampullary carcinomas represent a leading cause of death in FAP patients, biopsies of this region should be performed regardless of whether mucosa appears normal, as approximately 7.6% of patients with normal endoscopic results exhibit adenomatous tissue on random biopsy[10,14,33].

When to begin surveillance of FAP patients is a controversial issue, with some clinicians supporting that surveillance begin when FAP is diagnosed and others proposing that it should not begin until patients reach 25-30 years in age, as a diagnosis of duodenal cancer before age 30 is rare[12,33,56,57]. Post-baseline evaluations should be planned according to Spigelman disease stage. This classification is widely accepted as the best option for stratifying the risk of duodenal cancer[54]. Surveillance is the most advantageous in stage Ⅳ patients, as their risk of duodenal carcinoma ranges from 7%-36% compared to non-stage Ⅳ patients, who have an overall risk of 5%.

Although published recommendations differ, in

Table 1 Spigelman classification for duodenal polyposis in patients with familial adenomatous polyposis

Criterion	Points		
	1	2	3
Polyp number	1-4	5-20	> 20
Polyp size (mm)	1-4	5-10	> 10
Histology	Tubular	Tubulo-villous	Villous
Dysplasia	Mild	Moderate	Severe

Stage 0: 0 points; stage I: 1-4 points; stage II: 5-6 points; stage III: 7-8 points; stage IV: 9-12 points

Table 2 Recommendations for surveillance and management of duodenal polyposis in familial adenomatous polyposis patients[11,12,28]

Spigelman stage	Suggested interval (yr) to next duodenoscopy	Conservative therapy	Surgical treatment
0 (0 points)	4 (maximum 5 yr)	No	No
I (1-4 points)	3 (maximum 5 yr)	No	No
II (5-6 points)	2-3	Chemoprevention with or without endoscopic therapy	No
III (7-8 points)	6-12 (maximum 1-2 yr)	Chemoprevention with or without endoscopic therapy[1]	Acceptable
IV (9-12 ponits)	6-12 (maximum 1-2 yr)	Endoscopic therapy and endoscopic ultrasonography	Duodenectomy with pancreas/ pylorus preservation

[1]Consider endoscopy general anesthesia.

general, early stage patients are advised to undergo endoscopy either every 4-5 years (stages 0-I) or every 3-5 years (stage II)[33,57-60]. In stage II patients, Groves *et al*[33] have suggested that endoscopic therapy include endoscopic mucosal resection (EMR). However, the above intervals may be reduced to 1-3 years for patients with mild polyposis (stage III) or to 6-12 mo for patients with severe polyposis, large adenomas or dysplasia[12,14,58]. It has been suggested that stage III patients undergo EMR to reduce duodenal adenomatosis[33,57]. As one third of stage IV patients may experience malignant transformation if they are not treated, these patients should also undergo endoscopic ultrasonography and computed tomography for staging during initial evaluation[14,61].

For patients with periampullary lesions, a different protocol has been proposed due to the greater associated risks[35,62]. This protocol recommends that patients with ampullary polyposis should be examined annually, irrespective of disease severity in other regions of the duodenum. Progression of the disease may be evaluated with magnetic resonance imaging and/or endoscopic ultrasound.

The majority of large studies have shown that the risk of advanced duodenal adenomatosis (stage IV) increases with age. Bulow *et al*[63] found a 52% cumulative risk at 70 years, which was similar to the 50% risk reported by *Saurin* et al[14] and the 20%-30% risk found by studies conducted in Sweden and Finland[14,34,63,64].

Therefore, endoscopic surveillance programs should be performed according to the following published recommendations (Table 2).

Endoscopic treatment

Ideally, treatment should include complete removal or destruction of adenomas and minimal morbid risk. Endoscopic management may be performed with standard polipectomy and local ablation techniques (thermal ablation, argon plasma coagulation or photodynamic therapy)[12,35]. Endoscopic therapy with argon plasma coagulation and Nd-YAG lasers has been attempted with varying results.

The plaque-like morphology of the majority of duodenal adenomas may pose some technical difficulties in performing endoscopic polipectomy, and new techniques of mucosal elevation/resection and hemostasis using different tools may reduce the risks of bleeding, pancreatitis and perforation. Another possible advantage of endoscopic treatment is the postponement of major operations such as duodenopancreatectomy. Although polipectomy or polyp destruction in stage II and stage III patients may be useful, long-term results have demonstrated adenoma recurrence rates of 50%-100%, and complications are not rare[26,49,65]. Thus, endoscopy generally does not affect disease course and follow-up remains necessary.

In this context, low-risk lesions (small, tubular, low-grade adenomas) should be biopsied and observed. Conversely, high-risk lesions (adenomas greater than 1 cm and those with villous patterns or high-grade dysplasia) may be treated *via* transduodenal resection[61]. Endoscopic or surgical ampullectomy should be used on lesions that have developed in the ampulla of Vater (mainly those with severe dysplasia, Tis or T1), despite the associated morbidity[66].

Patients with large stage III polyps (or stage IV, for which surgical treatment is not appropriate) may be candidates for endoscopic polipectomy. The use of general anesthesia may optimize therapeutic maneuvers by allowing the introduction of front and lateral endoscopes to evaluate the papilla, and third and fourth portions of duodenum. Such a strategy aims to avoid progression to stage IV disease, as this results in a greater risk (1 in 3 patients) of duodenal cancer[33]. The management of stage IV patients with desmoids disease, unfavorable clinical conditions or diffuse involvement of duodenal mucosa remains a significant problem.

Surgical treatment

Surgical management includes local procedures (duodenotomy with polypectomy and/or ampullectomy),

pancreas- and pylorus-sparing duodenectomies, and pancreatico-duodenectomy (Whipple's operation). The specific choice of which procedure to use appears to be related to technical expertise, local features (size and site of polyp) and disease severity. In the final analysis, the morbidity and mortality of these procedures must be weighed against the risk of developing duodenal adenocarcinoma.

Whereas radical resection is the obvious option for patients with carcinomas, a prophylactic operation (pancreas and pylorus sparing duodenectomy) to avoid cancer is also justified in cases of severe adenomatosis (Spigelman Ⅳ) or after a failed attempt at local resection (endoscopic or surgical)[33,67]. Even patients with stage Ⅲ polyposis have been considered for surgery[49,68,69]. However, no randomized studies to help guide surgical selection have been published thus far.

Duodenotomy with local resection may be indicated in selected patients who present with one or two dominant duodenal lesions and in whom endoscopic resection would be considered dangerous. In a recent review on this subject, Brosens *et al*[12] indicated that this approach might be useful for delaying major procedures in young patients. Otherwise, high recurrence rates have been reported after local surgical resection, similarly to what occurs after endoscopic resection. Moreover, patients who have previously undergone prophylactic colectomy and present with desmoids tumors have a significant risk of developing complications from duodenectomy[37,57].

Pancreatico-duodenectomy remains a last resort for advanced duodenal and ampullary adenomatosis, despite the risks of this complex procedure and the possibility of inducing desmoid tumor formation[58].

Pharmacological treatment

Chemoprevention is defined as the use of pharmaceutical drugs, natural agents or dietary supplements to reduce the incidence or delay the onset of diseases, including cancer[70]. In FAP patients, the colorectum, ileal pouch and duodenum represent the most clinically relevant sites of carcinogenesis[71]. Consequently, FAP patients constitute an ideal group for assessing the efficacy of various chemopreventive strategies at delaying polyp progression, postponing prophylactic colectomy and preventing the recurrence of adenoma following colectomy with IRA. These effects have also been evaluated in the upper gastrointestinal tract, particularly in the duodenum[72].

As prophylactic surgical resection of an ampulla and/or duodenum may be accompanied by significant morbidity, duodenal resection is currently reserved for only severe cases of duodenal polyposis or duodenal carcinoma. In this context, chemoprevention should be the strategy employed to control premalignant lesions[72]. Secondary chemoprevention has been attempted with the use of agents such as non-steroidal anti-inflammatory drugs (NSAIDs)[73-75]. The use of the cyclooxygenase (COX) non-selective inhibitor sulindac and of the selective COX-2 inhibitors celecoxib and rofecoxib may be beneficial when duodenal polyposis develops by inducing polyposis regression or stabilization.

Studies using sulindac have revealed the drug to have a statistically significant effect on small (2 mm) duodenal polyps, whereas larger (> 3 mm) polyps were unaffected[76,77]. In a different study, the administration of 300 mg/d of sulindac for 10 mo resulted in a 30% discontinuation rate due to side effects and no regression of polyps; furthermore, three patients developed large polyps and one developed an infiltrating carcinoma while on this drug[78].

In a large randomized trial, the use of celecoxib resulted in a 14%-31% reduction in the regions of the duodenum that were affected by adenomatosis and therefore this drug may be recommended as a therapeutic alternative to patients with moderate adenomatosis[33,79]. However, the promising use of coxibs in chemoprevention must be weighed against their potential cardiovascular and renal side effects[80,81]. In addition to the fact that celecoxib may delay worsening of polyposis, there have not been sufficient long-term results or evidence from controlled studies on cancer protection to routinely recommend these agents during follow-up[14,51,58].

In conclusion, although they may reduce the progression and even lead to regression of small adenomas, the role of NSAIDs and other compounds in duodenal polyposis regression remains unclear, and thus far the results have primarily been ambiguous[12]. The evidence must prove to be reproducible, and potential cardiovascular and renal side effects, in addition to the risk of gastrointestinal bleeding, must be taken into account[24]. Moreover, duodenal adenomas are less likely to degenerate compared to colonic polyps, and they also appear to be less responsive to chemoprevention with NSAIDs[12,82].

To date, no medical therapy has demonstrated long-term effectiveness and safety in the management of duodenal adenomatosis. There has been a single report indicating an apparent disappearance of duodenal polyposis in a patient who was treated with FOLFOX chemotherapy for an ileal pouch adenocarcinoma[83].

As dietary chemoprevention has shown no effective results, a new line of interventions focus on the role of the estrogen receptor (ER) in reducing polyp numbers and sizes, based on the supposed preventive effects of CRC. In an interesting study, Calabrese *et al*[84] evaluated whether dietary supplementation with phytoestrogens, which are selective agonists of the estrogen receptor, was able to prevent the progression of duodenal polyps. They demonstrated that short-term (90 d) supplementation with Eviendep® in FAP patients with recurrent adenomas in the duodenal mucosa resulted in a 32% reduction of polyp numbers and 51% reduction in polyp size.

This study clearly demonstrates that researches with FAP patients will always have a lead role in the testing

of new agents, favoring their own interests and those of non-familial adenomas, a problem with even greater social impact. For the next future, the role of NSAIDs in chemoprevention has gained renewed interest in sporadic adenoma prevention, although the long-term risks associated with its use have always been a source of concern[85,86].

As chemoprevention may eventually avoid surgical resection of at-risk duodenal adenomas, it would desirable to identify patients important to select advanced adenomas that would be candidates. In an interesting research, it was reported that mRNA levels of glutathione S-transferase A1 (28.16% *vs* 38.24%, P = 0.008) and caspase-3 (3.30% *vs* 5.31%, P = 0.001) were significantly lower in patients with FAP *vs* non-FAP patient controls, respectively[87]. This finding points at a lower capacity to detoxify toxins and carcinogens, with subsequent increased susceptibility for malignant degeneration[88]. Previous studies have already found lower GDT enzyme activity in colonic mucosa but no differences in duodenal mucosa when compared to patient controls[89,90]. Other eventual risk factors include the development of small intestinal adenomas and location of APC mutation[91-93].

All of these findings indicate that routine gastroduodenal endoscopy in FAP patients is necessary[94-96]. In this setting of surveillance, both endoscopy and EUS are extremely important to select advanced adenomas that are candidates for endoscopic intervention instead of surgical resection[97,98]. Moreover, although these lesions progress in severity (size and degree of dysplasia), their progression rate to carcinoma is slow[96,99].

Abstract

There is an increasing role for endoscopic ultrasound (EUS)-guided interventions in the treatment of many conditions. Although it has been shown that these types of interventions are effective and safe, they continue to be considered only as alternative treatments in some situations. This is in part due to the occurrence of complications with these techniques, which can occur even when performed by experienced endosonographers. Although common complications have been described for many procedures, it is also crucial to be aware of uncommon complications. This review describes rare complications that have been reported with several EUS-guided interventions. EUS-guided biliary drainage is accepted as an alternative treatment for malignant biliary obstruction. Most of the uncommon complications related to this procedure involve stent malfunction, such as the migration or malposition of stents. Rare complications of EUS-guided pancreatic pseudocyst drainage can result from air embolism and infection. Finally, a range of uncommon complications has been reported for EUS-guided celiac plexus neurolysis, involving neural and vascular injuries that can be fatal. The goal of this review is to identify possible complications and promote an understanding of how they occur in order to increase general awareness of these adverse events with the hope that they can be avoided in the future.

Key words: Complications; Endoscopic ultrasonography; Rare; Therapeutic; Uncommon

Core tip: This article reviews the rare complications that occur with endoscopic ultrasound-guided interventions, including those for biliary and pancreatic pseudocyst drainage and celiac plexus neurolysis. Knowledge

of the types of rare complications will promote an understanding of their causes, and help to reduce their occurrence.

Uncommon complications of therapeutic endoscopic ultrasonography: What, why, and how to prevent. *World J Gastrointest Endosc* 2015; 7(10): 960-968 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i10/960.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i10.960

INTRODUCTION

Endoscopic ultrasound (EUS)-guided interventions have recently been accepted as an alternative to percutaneous or radiologic-guided treatments, as well as for more invasive treatments such as surgery, for many conditions. Accumulating evidence continues to demonstrate the feasibility, efficacy, and safety of these novel procedures. Although such methods are less invasive, there are reports of adverse events with EUS-guided transluminal therapies. It is important for endosonographers to have adequate knowledge of the indications, techniques, and potential risks before performing any given procedure. Indeed, many reviews have been published describing common complications related to EUS-guided procedures. However, only a limited number of studies report on rare complications. Thus, the purpose of this review was to identify the uncommon complications related to these interventions, evaluate how they occurred, and ascertain how to prevent them. To achieve this, a search was made of English-language human studies listed in the PubMed database that were published between1991 and December 2014. The following keywords were used alone or in combination with EUS: therapeutic complication, drainage, guidewire, celiac plexus neurolysis, tumor ablation, ethanol ablation, pancreatic fluid collection, pancreatic drainage, fiducial, cystogastrostomy, abscess drainage, antibiotics, endoscopy, vascular, glue injection, oncolytic virus, and cryotherapy. References of identified articles were also searched for potentially relevant studies.

EUS-GUIDED BILIARY DRAINAGE

EUS-guided procedures have recently gained popularity for performing biliary drainage in patients for whom endoscopic retrograde cholangiopancreatography (ERCP) has failed. The initial report of EUS-guided cholangiography in 1996 was followed by a description of EUS-guided choledochoduodenostomy in 2001[1]. Since then, additional techniques for EUS-guided transluminal biliary drainage have been described, including creating a bilo-enteric fistula, using an EUS-antegrade approach, and a rendezvous technique to assist transpapillary cannulation[2]. Fistula tracts can be created either between the intrahepatic bile duct and stomach, as in EUS-guided hepaticogastrostomy, or between the extrahepatic bile duct and duodenum, as in EUS-guided choledochoduodenostomy[3]. These procedures have become a rescue therapy[4]. Although small case series of no more than five patients describe successful procedures with no complications[5-7], larger series report complication rates ranging from 9.5% to 40%[3,8-14]. The most common complications were bile leakage, stent misplacement, bleeding, and pneumoperitoneum, which accounted for 5.2%, 3.1%, 2.1%, and 1.0% of cases, respectively[3,15].Other rare complications such as biloma, cholangitis and perforation were also reported, all of which were related to the use of needle knife cautery in the multivariate analysis[15].

Most complications can be treated conservatively[15,16]. For example, bilomaas a result of stent migration can be treated with a variety of methods[8,11], including percutaneous[3] or EUS-guided[17] drainage. Only one fatality was reported, which involved severe peritonitis[18]. A case of retrogastric fluid collection was successfully treated with antibiotics and percutaneous drainage[19]. Several series reported cholangitis as an early or late complication resulting from reflux of gastrointestinal (GI) contents or stent migration[11,14,15,20]. In other cases, shortening of the metallic stent after deployment caused misplacement into to the abdominal cavity or gastroduodenal perforation, which required surgical intervention[3,19,21]. Cases of bleeding from the puncture site[3,9,19] or from a hepatic artery aneurysm, which was treated by angiographic embolization[22], were also reported. One technical concern involving guidewire shearing by the EUS-needle bevel was reported, which was treated by radiologic intervention[23].

Preventative measures

When inserting stents into the bilo-enteric tract, the membrane from fully/partially covered or specially designed metal stents prevents leakage of bile from the newly created tract. As stent shortening was related to cases of biloma, perforation, and peritonitis, an appropriate-length stent should be carefully selected and placed in the optimal position. Stent dislocation can be prevented by placing clips at the endoluminal stent margins[9], or, as we have observed, by placing a double-pigtail plastic stent inside the fully covered self-expanding metal stent. In addition, the maneuver applied during stent deployment is critical, and it is recommended that the endoscopist perform the initial stent deployment under fluoroscopic monitoring, before switching to endoscopic monitoring.

Infectious complications were reported[3], including a case of cholecystitis due to previous ERCP contamination of the obstructed biliary system[20]. Although the role of antibiotic prophylaxis in such procedures has not been established[24], it has been used by several authors who found that 4-5 d (nil per mouth) of antibiotic treatment was essential for preventing minor leakage and perito-

neum contamination[4,10,20].

Although guidewire shearing during the procedure is not common during EUS-guided biliary drainage, the risk could be eliminated by avoiding acute angles during needle retraction and by retracting slowly with a lot of caution for any resistance. If any resistance is felt, the needle and the wire should be retracted concurrently[25]. Other authors recommend changing the EUS needle after puncture to a 4 Fr cannula for guidewire manipulation[26], or using a blunt-ended needle with a sharp needle-tip stylet (Access needle®; Wilson Cook Inc., Winston-Salem, NC, United States) for biliary access[23,27]. In one case, guidewire knotting occurred in an EUS-guided rendezvous procedure as a result of guidewire loop formation during endoscopic–catheter exchange[28]. In this report, the guidewire was untangled with rat-toothed forceps using a gastroscope, and the author suggested that, to prevent looping, constant tension on the wire should be maintained during exchanges. A summary of uncommon complications from EUS-guided biliary drainage is presented in Table 1.

EUS-GUIDED PANCREATIC DRAINAGE

EUS-guided pancreatic drainage can be performed to remove accumulated fluid due to acute pancreatitis or pancreatic duct obstruction. This procedure is typically performed *via* transpapillary, transluminal, or transanastomotic approaches with neotract formation or by the rendezvous technique in patients for whom ERCP has failed or who have surgically altered anatomy[25,29,30]. EUS-guided pancreatic drainage is effective with a lower morbidity compared to the other platforms[31]. The success rate depends on the type of fluid collection, and ranges from 50.0%-63.2% up to 100%[32,33]. The common complications of pancreatic duct drainage are pancreatitis, bleeding, perforation, and stent migration, with overall complication rates ranging from 0% to 52%[25,30,34]. In some case series, the complication rate was significantly higher in patients with necrosis compared to those with pseudocysts[34].

Less common complications that have been reported with EUS-guided pancreatic drainage include peri-pancreatic abscesses, fluid collection, and shearing of the guidewire during diagnostic pancreatography and therapeutic drainage[29,35-37]. In these reports, peri-pancreatic collection was the result of pancreatic fluid or pseudocyst leakage. To prevent bacterial peritonitis, some endoscopists recommend antibiotic prophylaxis[37]. Guidewire shearing occurred more frequently than was reported for EUS-guided biliary drainage, likely due to the greater angle between the EUS needle and the desired direction of the pancreatic duct[29,36], with similar remedies for prevention. A splenic artery aneurysm within the pancreatic pseudocyst was the cause of bleeding in one case, which was treated by selective angiographic embolization[38]. A summary of uncommon complications from EUS-guided pancreatic drainage is presented in Table 2.

The rare but fatal complication of air embolism was also reported, occurring in one patient who had previously undergone ERCP, and in one case of EUS with fine-needle aspiration of an accessory spleen[39]. A fatal case occurred in a patient who underwent EUS-guided pancreatic pseudocyst drainage[40]. Hikichi *et al*[41] reported a case of gallbladder puncture and drainage following misdiagnosis of a pancreatic pseudocyst, which was treated with nasocystic-tube drainage and antibiotic administration. The authors strongly recommended that every endosonographer should verify the location of the puncture site *via* EUS-scanning before initiating any drainage intervention.

EUS-GUIDED CELIAC PLEXUS NEUROLYSIS AND CELIAC PLEXUS BLOCK

Celiac plexus neurolysis (CPN) and celiac plexus block (CPB) have been performed for more than five decades in patients with upper abdominal pain of pancreatic origin and from stomach, intestinal, and intra-abdominal metastases. CPB has been performed under guidance of radiography, fluoroscopy, CT, and ultrasonography. Common complications with this procedure include local pain, diarrhea, and hypotension, whereas lower extremity weakness, paresthesia, lumbar puncture, pneumothorax, pleuritic pain, hiccups, and hematuria occur in only 1% of patients[42]. EUS-guided CPB has gained in popularity since the 1990sas it enables the endoscopist to easily and accurately determine the location for injection[43]. For EUS-guided CPN, the complications are similar, with hypotension, pain, and diarrhea occurring in 3.4%-20.0%, 6.8%-9.0%, and 10.3%-17.0% of cases, respectively[44-46].

Uncommon complications, which occurred less than 1%, from EUS-guided CPN have primarily been described within case reports. Despite the improved injection-site localization, there were reports of anterior spinal cord infarction due to alcohol-induced injury to the lumbar artery and prolonged hypotension[44-48]. Nevertheless, the occurrence is much more infrequent than is observed with other approaches[49-54]. It is possible that spinal arterial spasm or thrombosis due to the chemical agent or the direct injection into the cerebrospinal fluid in cases of percutaneous injection caused the infarctions[49,55]. Other reports describe celiac artery thrombosis resulting in gastric ulceration with hepatosplenic infarction[42,56,57] or fatal multiple organ ischemia[58]. In two of these cases[56,58], color Doppler was performed either before or after the procedure to ensure celiac artery patency. Aspiration tests were also conducted after needle puncture in two cases[56,57]. The cause of arterial thrombosis was attributed to a vasospasm of affected vessels from alcohol irritation, as the amount of alcohol was similar among the cases. There was one case of peri-pancreatic collection after absolute alcohol injection that was treated by EUS-

Table 1 Uncommon complications of endoscopic ultrasound-guided biliary drainage

Ref.	Procedure	Stent	Complications (*n*/total successful cases)	Postulated causes	Treatment	Prevention recommendation
Püspök *et al*[20]	EUS-CDS, EUS-HGS, rendezvous	Plastic stent, FCSEMS, UCSEMS	Cholangitis (1/6), cholecystitis from previous ERCP (1/6)	Cholangitis may result from previous ERCP attempt	Antibiotics, PTBD, surgery	Consider antibiotic prophylaxis
Bories *et al*[11]	EUS-HGS, rendezvous	FCSEMS	Biloma (1/11), cholangitis (1/11)	Stent shortening	Percutaneous drainage (biloma), second stent insertion (cholangitis)	Select a stent of appropriate length Observe stent position during deployment (both endoscopic and fluoroscopic views)
Attasaranya *et al*[19]	EUS-CDS, EUS-HGS, cholecystoduodenostomy, transduodenal FCSEMS insertion	Plastic stent, FCSEMS	Duodenal perforation (1/31), retrogastric collection (1/31), cholangitis (1/31)	Stent shortening	Surgery (duodenal perforation), percutaneous drainage (retrogastric collection)	Keep at least 2 cm length of stent at the mural site
Martin *et al*[18]	EUS-HGS	PCSEMS	Stent migration and biloma	Stent migration	(Dead)	
Siddiqui *et al*[21]	EUS-CDS	FCSEMS	Duodenal perforation (1/8)	Stent shortening	Surgery	
Khashab *et al*[23]	EUS-HGS	Not mentioned	Wire shearing (1/1)	Injury from EUS needle	Percutaneous intervention	Avoid acute angulation of guidewire and retract it gently Change needle to a small-size cannula during guidewire manipulation
Prachayakul *et al*[8]	EUS-CDS, EUS-HGS	FCSEMS	Biloma (1/21)	Malpositioned stent	Percutaneous drainage[17]	Observe stent position during deployment (both endoscopic and fluoroscopic views)
Prachayakul *et al*[22]	EUS-HGS	FCSEMS	Bleeding from hepatic artery aneurysm (1/1)	Iatrogenic trauma during EUS-HGS	Angiographic embolization	Puncture site should be away from major vascular structure
Kawakubo *et al*[3]	EUS-CDS, EUS-HGS	Plastic stents, FCSEMS	Cholangitis (1/61), biloma (1/61), perforation (1/61)	Stent misplacement	Percutaneous drainage (biloma), surgery (perforation)	Observe stent position during deployment (both endoscopic and fluoroscopic views)
Saxena *et al*[28]	Rendezvous	FCSEMS	Guidewire knot	Guidewire formed a knot during exchanges	Untangled using forceps	Maintain constant pressure on the guidewire during exchanges

ERCP: Endoscopic retrograde cholangiopancreatography; EUS-CDS: Endoscopic ultrasound-guided choledochoduodenostomy; EUS-HGS: Endoscopic ultrasound-guided hepaticogastrostomy; FCSEMS: Fully covered self-expandable metallic stent; PCSEMS: Partially covered self-expandable metallic stent; PTBD: Percutaneous transhepatic biliary drainage; UCSEMS: Uncovered self-expandable metallic stent.

guided drainage and intravenous antibiotics[59]. Another case involved a mixed fungal and bacterial brain abscess as a result of hematogenous spread[60]. As with the other EUS-guided procedures, the use of antibiotic prophylaxis has not been established for these rare infectious complications[24]. A summary of uncommon complications from EUS-guided CPN is presented in Table 3.

EUS-GUIDED INTRA-ABDOMINAL INTERVENTIONS

Intra-abdominalabscess drainage

Only a limited number of cases using EUS-guided intra-abdominal drainage for liver abscesses have been reported, which were performed without complications[61-65]. In addition, several reports involving 4-25 cases each of pelvic abscess drainage using a transrectal approach with or without an irrigation tube to prevent stent occlusion by fecal material have been described, also without complications[66-70]. One case series describes abscess drainage in nine patients through the esophagus, stomach, and colon[64]. Mediastinitis and pneumothorax developed in one patient who underwent transesophageal drainage of a pancreatic pseudocyst, and was treated conservatively. Stent migration occurred in another patient undergoing transcolonic drainage, which was treated endoscopically.

Vascular therapy

EUS-guided interventions have been used for creating portosystemic shunts to treat GI bleeding (both variceal and non-variceal bleeding)[71]. In addition, EUS-guided injection of cyanoacrylate or coil embolization has

Table 2 Uncommon complications of endoscopic ultrasound-guided pancreatic drainage

Ref.	Procedure	Stent	Complication (*n*/total successful cases)	Postulated causes	Treatment	Prevention recommendation
Hikishi *et al*[41]	EUS-cystogastrostomy drainage	Plastic stent, nasobiliary drainage	Gallbladder puncture and drainage	Marked distension of gallbladder with debris, overlapping location between pseudocyst and gallbladder in fluoroscopy	Conservative with antibiotics	EUS scanning prior to initiating drainage intervention
Barkay *et al*[29]	EUS-PD rendezvous, dye injection	Plastic stent	Peripancreatic abscess (1/10), wire shearing (1/10)	Failed to inject PD (peripancreatic abscess), repeated to-and-fro movements of wire	Percutaneous drainage (abscess), transluminal removal (wire)	Carefully manipulate the guidewire, avoid acute angles
Jows *et al*[40]	EUS-cystogastrostomy drainage	Not mentioned	Air emboli	Prolonged high pressure air sufflation, inflammation, mechanical injury	(Dead)	Use CO_2 inflation instead of air
Fujii *et al*[36]	EUS-PD stent (antegrade and retrograde)	Plastic stents	Peripancreatic abscess (1/32), wire shearing (1/32)	Balloon dilation? Multiple devices (peripancreatic abscess), injury from EUS needle (wire shearing)	EUS-guided transmural drainage (abscess)	Carefully manipulate the guidewire
Kurihara *et al*[38]	EUS-PD rendezvous, and PD stenting	Plastic stents, UCSEMS	Pancreatic pseudocyst with splenic artery aneurysm	Pancreatic juice leakage	Angiographic embolization	Avoid major vascular structures

EUS-PD: Endoscopic ultrasound-guided pancreatic duct drainage; PD: Pancreatic duct; UCSEMS: Uncovered self-expandable metallic stent.

Table 3 Uncommon complications of endoscopic ultrasound-guided celiac plexus neurolysis

Ref.	Composition of injection solution	Complication	Treatment and outcome	Prevention recommendation
Fujii *et al*[47]	0.25% bupivacaine in 99% alcohol (ganglia: 1 mL; plexus: 23 mL)	Paraplegia	Remained paraplegic until death	Use color Doppler to avoid intravascular injection
Mittal *et al*[48]	0.25% bupivacaine and epinephrine with alcohol (1:5) (ganglia: 5 mL; around the celiac artery: 19 mL)	Paraplegia	Lumbar drainage but no improvement	Minimize the volume of absolute alcohol
Jang *et al*[56]	0.25% bupivacaine (5 mL), 98% ethanol (10 mL), triamcinolone (1 mL)	Hepatosplenic, stomach, and small bowel infarctions, gastroduodenal ulcers	Supportive treatment, died 27 d later	
Ahmed *et al*[57]	0.25% bupivacaine (20 mL), 98% ethanol (20 mL)	Pancreaticosplenic infarction, gastric ischemia and stenosis	Subtotal gastrectomy with Roux-en-Y gastrojejunostomy	
Gimeno-García *et al*[58]	0.5% bupivacaine (5 mL), absolute alcohol (10 mL) on each side of the celiac takeoff	Thrombosis of celiac artery, pneumatosis of the stomach andsmall and large intestines, and liver, kidney, and spleen infarctions	Conservative treatment, died 8 d later	
Muscatiello *et al*[59]	Not mentioned	Peripancreatic abscess	EUS-guided aspiration of abscess and ceftazidime injection	Consider antibiotic prophylaxis
Lalueza *et al*[60]	Not mentioned	Brain abscess by *Cladosporium macrocarpum* and *Streptococcus constellatus*	Surgery, antibiotics, and antifungal	

EUS: Endoscopic ultrasound.

emerged for treatment of refractory variceal bleeding. Numerous studies have reported on the feasibility, efficacy, and safety of such methods with the aid of EUS Doppler for treatment of esophagogastric[72-75] and ectopic varices[76-78]. EUS-guidance allows for optimization of the obliteration rate as well as reduction of cyanoacrylate to lower the risk of embolization, which, though not completely eliminated, is not fatal[73]. Sclerotherapy and cyanoacrylate injections have also been used for non-variceal bleeding from duodenal

ulcers, aneurysms, and Dieulafoy's lesion[79,80]. EUS-guided injection of cyanoacrylate and polidocanol for treatment of upper GI bleeding had a success rate of 87.5%, with only one of these eight cases experiencing asymptomatic cyanoacrylate diffusion into the hepatic artery[79].

Tumor-ablative therapy

EUS-guided procedures have also shown promise for the treatment of intra-abdominal tumors and cystic lesions, such as pancreatic cystic neoplasms. Currently, there are only a few reports of ethanol ablation with or without paclitaxel lavage for pancreatic cystic lesions[81-86]. Common complications with these procedures included acute pancreatitis, abdominal pain, and hyperamylasemia. One case experienced asymptomatic splenic vein obliteration with collateral formations after 27 mo[86]. Ethanol ablation has also been described for solid tumors in the abdomen, including pancreatic neuroendocrine tumors[87-90], a GI stromal tumor[91], metastatic lymph nodes[92], and metastatic tumors in the liver[93,94] and adrenal glands[95]. The majority of these cases were treated successfully without complications, except for low-grade fever and hematomas following liver tumor ablation[94].

There are a few reports describing EUS-guided injection of biologic agents[96] and oncolytic virus therapy[97], and insertion of radioactive seed, cryotherapy, and fiducial placement for stereotactic body radiotherapy[98-103] to treat pancreatic adenocarcinoma, a deadly cancer for which only 15%-20% of patients are candidates for curative resection[96]. Adverse events were rare for these procedures, consisting of duodenal perforations due to the EUS tip, effects from the injected agents[97], mild pancreatitis, cholangitis, bleeding and fever[99-101]. Antibiotic prophylaxis was utilized in one study[100], in order to prevent cholangitis.

CONCLUSION

Therapeutic EUS is becoming more prominent in the treatment of many diseases due to the increased accuracy afforded by real-time high-resolution imaging. As a result, information regarding possible complications is greatly needed. The review presented here describes some of the less common complications that have been reported in various EUS-guided applications. By acknowledging the adverse events that occur, we can gain a better understanding of their causes and preventative actions to increase the safety of these techniques. EUS-guided interventions have been utilized for procedures of biliary and pancreatic drainage and CPN, as well as for various intra-abdominal conditions. Potential complications and preventive strategies will become clearer in the future as the number of patients treated and procedures reported increase. The authors recommended that endosonographers apply this knowledge in routine endoscopic practice for monitoring and early detection (including treatment) of these uncommon adverse events for the best clinical outcomes.

Abstract

Adenoma detection rate (ADR) is a key component of colonoscopy quality assessment, with a direct link between itself and future mortality from colorectal cancer. There are a number of potential factors, both modifiable and non-modifiable that can impact upon ADR. As methods, understanding and technologies advance, so should our ability to improve ADRs, and thus, reduce colorectal cancer mortality. This article will review new technologies and techniques that improve ADR, both in terms of the endoscopes themselves and adjuncts to current systems. In particular it focuses on effective techniques and behaviours, developments in image enhancement, advancement in endoscope design and developments in accessories that may improve ADR. It also highlights the key role that continued medical education plays in improving the quality of colonoscopy and thus ADR. The review aims to present a balanced summary of the evidence currently available and does not propose to serve as a guideline.

Key words: Colorectal cancer; Adenoma detection; New technology; Techniques; Colonoscopy

Core tip: The most important quality indicator in colonoscopy is Adenoma detection rate. It is associated with outcomes from colorectal cancer, with low detection rates being associated with increased mortality and poor outcomes. Whilst a number of technologies are emerging to improve adenoma detection rate (ADR), at present, it seems that education, team work and optimising current practice will provide the biggest gains in ADR whilst maintaining financial acceptability.

INTRODUCTION

Colorectal cancer is the third most common cancer in men and the second in women. Worldwide, an estimated 1.2 million cases of colorectal cancer occur annually[1]. The highest incidence rates have previously been in North America, Australia, New Zealand, Europe, and Japan. In recent years some of these incidences has stabilised and even began to reduce, *e.g.*, United States and this may, in some part, be related to the introduction of national screening programmes (Figure 1).

Worldwide, colonoscopy forms the basis of colorectal cancer screening programmes and has been shown to reduce the risk of death from colorectal cancer through detection of tumours at an earlier, more treatable stage and through removal of precancerous adenomas[2]. There are a number of quality assurance measures for colonoscopy in screening programmes include caecal intubation rate, bowel preparation quality, complications, cancer detection and adenoma detection rate (ADR, the proportion of colonoscopies performed by a physician that detect at least one histologically confirmed colorectal adenoma). However, ADR is now established as the most important quality indicator due to 2 landmark studies. The first demonstrated increased risk of interval cancer when the colonoscopy is performed by an endoscopist with a ADR below 20%[3]. As a result professional societies recommend a detection rate of > 25% in order to be deemed adequate[4]. The second demonstrated an inverse relationship between ADR and the risks of interval colorectal cancer, advanced-stage interval cancer, and fatal interval cancer. With each 1.0% increase in ADR was associated with a 3.0% decrease in the risk of cancer[2].

There are a number of techniques and technologies, both established and emerging that provide an exciting and promising potential to improve ADR. This article will discuss effective technique and behaviours, developments in image enhancement, advancement in endoscope design and developments in accessories that may improve ADR.

EFFECTIVE TECHNIQUE AND BEHAVIOURS

Bowel preparation

Good bowel preparation is vital for effective lesion recognition at colonoscopy. Consequently, guidance from the United States multi-society task force for colorectal cancer recently published strong recommendations for adequate bowel preparation with split-dose regimes in order to optimise ADR[5]. Poor bowel preparation has been associated with a adenoma miss rate of 43%[6]. Studies have demonstrated a clear improvement in ADR (35%) with split dose preparation ($P \leqslant 0.001$). They also showed a clear improvement in caecal intubation rate (95.5%) and preparation quality[7]. Attempts to implement further measures to improve bowel preparation have also been studied. One such scheme studied telephone education relating to the bowel preparation prior to colonoscopy. There was a improvement in compliance, preparation quality and ADR[8].

Insertion and withdrawal polypectomy

Colonic configuration during insertion phase and withdrawal phase is different and some polyps seen during insertion are difficult to find during withdrawal and vice versa[9]. It is typical practice to perform the formal mucosal examination and polypectomy on withdrawal, noting any pathology on insertion for subsequent intervention. One study suggested this may not be preferable, finding that polyp < 10 mm identified during insertion are frequently missed on withdrawal, suggesting polypectomy during insertion[10]. A more recent study compared 610 colonoscopies where patients were randomised to either polypectomy during insertion and withdrawal or just withdrawal. In both arms, mean number of adenomas detected per patient were similar. With the only significant difference being that of insertion time[9]. Overall, the evidence suggests neither technique is superior over the other.

Retroflexion in the caecum

Rectal retroflexion forms part of the required standards for colonoscopy completion. Retroflexion in the right colon is not routinely performed but has been reported to improve ADR. A prospective cohort study conducted in the United States examined the potential impact of caecal retroflexion on ADR. One thousand consecutive adults undergoing colonoscopy were studied. A standard forward viewing colonoscopy of the right colon was performed and polyps were removed. There was then repeated examination in retroflexion from the caecum to the hepatic flexure. Retroflexion was successful in 94.4% of the patients. The subsequent examination in retroflexion demonstrated a 9.3% miss rate for the forward viewing method[11]. However, safety concerns have been raised due to the risk of perforation of using this technique.

Dynamic position change

Randomised controlled trials examining dynamic position changes have produced conflicting results regarding ADR, but predominate positive findings. It is clear that position change aids caecal intubation rate and patient comfort. Such position changes result in better distension with less insufflation of air, shifting of fluids and residues, and opening tight angles at flexures[12]. Specifically during withdrawal, such position changes have repeatedly been shown to improve ADR[13,14].

Antispasmodics

Hyoscine butylbromide is a relatively safe antispasmodic anticholinergic agent that blunts the response of colonic neurons to muscarinic and nicotinic stimulation which leads to inhibition of smooth muscle contraction in the

Figure 1 Cumulative hazard rates for interval colorectal cancer, according to the endoscopists adenoma detection rate. The graph shows cumulative hazard rates for interval colorectal cancer among subjects who underwent screening colonoscopy that was performed by an endoscopist with an ADR in one of the following categories: less than 11.0%, 11.0% to 14.9%, 15.0% to 19.9%, and 20.0% or more. ADR: Adenoma detection rate.

colon[15]. A recent meta-analysis assessed the results of 8 Randomised control trials (RCTs) conducted in Europe, Asia and Australia concluded hyoscine use in patients undergoing colonoscopy does not appear to significantly increase the detection of adenomas[16]. However, a recent study has shown that within the bowel cancer screening programme (BCSP) in England, it does improve ADR when used[17]. Recently, another antispasmodic topically applied: L-menthol (an organic compound found in peppermint oil, has been shown to improve ADR when sprayed on to the colonic mucosa during colonoscopy[18]. Whilst promising further studies are need to corroborate these findings.

Procedural factors-withdrawal time, use of sedation, colonoscopist and time of day

Variable factors inherent to colonoscopy have been shown to affect ADR. Time spent during the withdrawal phase is one such factor. A recent study within the BCSP in England demonstrated a plateau effect after approximately ten minutes. The lowest ADR was demonstrated if the withdrawal was less than 7 min, with the maximum ADR, seen with a withdrawal time of 9-11 min[17]. A multi centred RCT assessed multiple factors that may affect ADR, namely, bowel cleansing, sedation, withdrawal time in normal colonoscopies, and caecal intubation rates. They concluded a mean withdrawal time of > 8 min was the only modifiable factor related to the ADR in colorectal cancer screening colonoscopies[19].

Sedation use in one study found that larger amounts of sedation improved many aspects of colonoscopy quality. ADR increased (25.9% to 35%), early complications rate decreased (3.4% to 0.3%) and completion rates increased (88.3% to 96.4%)[20]. The mode of sedation that is used also appears to influence the quality of colonoscopy and particularly ADR. Again the literature reports conflicting results. A study which compared 843 colonoscopies found that deep sedation was associated with improved caecal intubation rates, and increased ADR. There were more immediate complications reported in the deep sedation group[21]. Another study suggested the type of sedation used during colonoscopy does not affect the number of patients in whom adenomatous polyps are detected. This followed a retrospective study that examined 3252 colonoscopies across two centres. ADR was the comparable for those receiving propofol and conscious sedation (midazolam and fentanyl)[22].

A variety of different studies have questioned whether the individual colonoscopist, *i.e.*, the person performing the examination, influences ADR. A study that assessed factors that influence the quality of 12000 screening colonoscopy found that annual case volume and life experience did not affect ADR but continued medical education (CME) was found to be most influential, with those who attended most CME meetings having the highest ADR[23]. These findings were supported by a study from the Mayo clinic that formally assessed the impact of a colonoscopy education program. An additional training program, known as Endoscopic Quality Improvement Program (EQUIP) was used. ADRs were measured at baseline, then half of the 15 colonoscopist were randomly assigned to EQUIP. Baseline and post training ADRs were then compared, a total of 1200 procedures were completed in each of the two study phases. In the post-training phase, the group of endoscopists randomized to EQUIP training had an increase in ADR to 47%, whereas the ADR for the group of endoscopists who were not trained remained unchanged at 35%[24].

The procedural start time may also affect ADRs

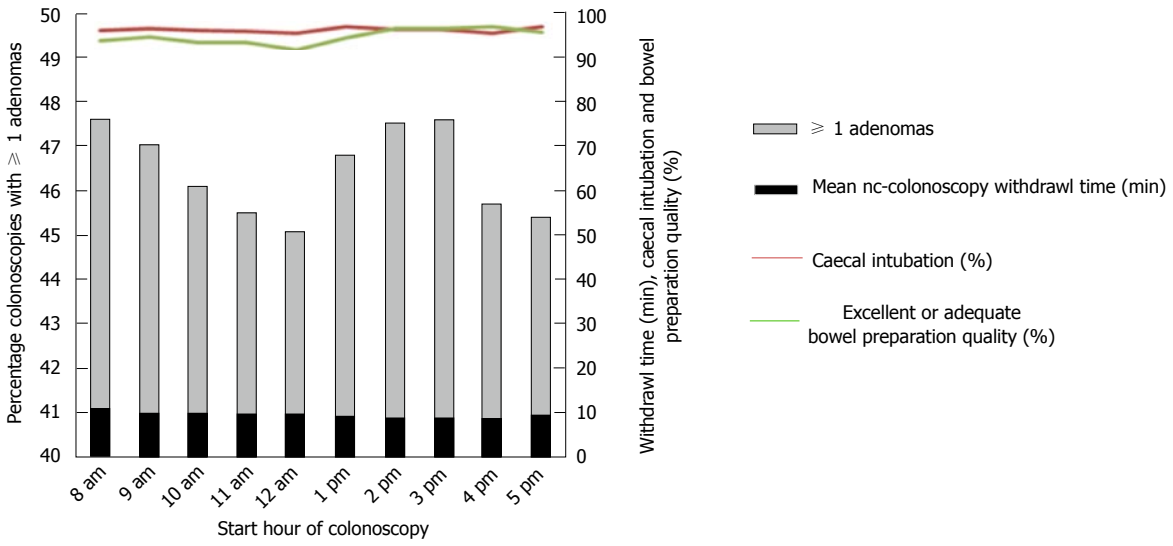

Figure 2 Relationship between start time of colonoscopy and adenoma detection, withdrawal time, caecal intubation, and bowel preparation quality.

as suggested by a study of > 31000 colonoscopies. Procedures starting in the second half of a session (11:00-14:00 or 16:00-18:00) were associated with a reduction in detection of adenomas and advanced adenomas compared with procedures starting between 08:00 and 11:00 or 14:00 and 16:00[17]. Having assistance from the entire technical team to spot abnormalities during the examination has also been shown to improve ADR. In one such study the process was termed "all eyes on screen", increasing ADR from 34% to 51% in 2 years[25]. A central visual gaze pattern on the colonoscopist has also been shown to improve ADR[26] (Figure 2).

Water infusion techniques

The original goal of this novel technique was to facilitate caecal intubation, reduce colonic spasms, lower patient discomfort and need for sedation, for which it performs well[27,28]. It works by combining or replacing air-insufflation with water infusion. Concerns have been raised about an impaired ability to detect lesions due to contaminated water impairing visibility[27]. A systematic review performed in 2012 reported no difference in ADR when comparing water infusion to conventional insufflations[29]. A similar technique is known as Water Exchange. The water-exchange method is a technique in which water containing residual faeces is removed and "exchanged" for clean water in lieu of air-insufflation. The exchange of large volumes of water during the insertion of the colonoscope results in additional cleansing of the mucosa[27]. A study in 2009 exploring this technique failed to reach statistical significance for an improved ADR[30]. Improved ADR was demonstrated in one study when they combined the water exchange technique with cap-assisted colonoscopy (P = 0.002)[31].

The prolonged insertion time, colonoscopist experience and general technicalities of these techniques including expense are likely to limit their introduction into routine practice.

IMAGE ENHANCEMENT TECHNIQUES AND TECHNOLOGY

Standard white light, high definition and zoom endoscopy

There is conflicting evidence when assessing the superiority of high definition colonoscopy *vs* standard white light. A meta-analysis involving 4422 patients provided data on ADR. There was no significant difference in detection of high risk ADR. The detection of small adenomas was slightly better in the high definition group, but overall the analysis concluded here were marginal differences between high definition colonoscopy and SVE for the detection of colonic polyps/adenomas[32]. A more recent study showed improved ADR with high definition colonoscopy, when used by endoscopists with a low ADR (< 20%). For those with an ADR already > 20% there was no improvement in detection of high risk polyps, flat polyps or proximal lesions[33]. In contrast, other studies that have directly compared high definition colonoscopy to standard video endoscopy have shown significant improvements in ADR. On such study did so without compromising procedure duration, caecal intubation or levels of sedation. The additional polyps detected were mainly flat and sessile[34]. A further study with similar design also showed a lower adenoma miss rate with high definition colonoscopy[35]. Interestingly, a study assessing the multiple factors that influence the quality of colonoscopy identified advancing generations of colonoscope technology as a positive effector over ADR[23].

In summary, it would appear there are gains to be made from the use of high definition colonoscopy, but these may be limited, but the use of new generation colonoscopes (compared to older ones) may be the important factor.

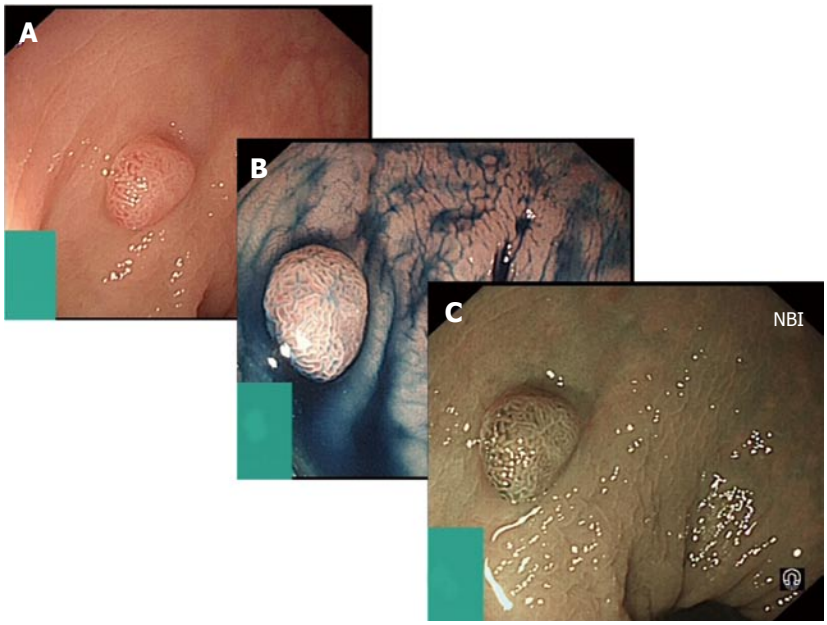

Figure 3 Digital chromoendoscopy. A: Represents sessile adenoma seen in standard white light; B: Shows the same adenoma after the use of indigo carmine applied for chromoendoscopy; C: Shows further assessment of the adenoma using narrow band imaging (NBI).

Chromoendoscopy

Chromoendoscopy refers to the topical application of stains or dyes at the time of endoscopy in an effort to enhance tissue characterization, differentiation, or diagnosis[36]. The stains that are used for chromoendoscopy are classified as absorptive, contrast, or reactive. Indigo carmine is an example of a contrast stain and is most commonly used to improve ADR. Indigo carmine staining combined with magnification endoscopy appears to be a useful technique for the detection of aberrant crypt foci in the rectum, a potential biomarker for proximal flat colonic neoplasia[36,37].

A number of studies have examined whether the use of chromoendoscopy can improve ADR when compared to conventional white light colonoscopy, many of which have demonstrated an increase in the yield of neoplasia detection[38-40]. Many of these studies examine its use in high risk groups[37], One study compared high-definition chromocolonoscopy with high-definition white light colonoscopy for the detection of colorectal adenomas in average-risk United States persons undergoing screening colonoscopy. They compared the colonoscopy results of 660 patients, finding no significant difference in the number of small adenomas, advanced adenoma or carcinoma. Concluding that their results do not support the routine use of high-definition chromocolonoscopy for colorectal screening in average-risk patients[41]. These conflicting results and the time consuming nature of dye spray may limit its adoption into routine screening of average risk patients.

New promising techniques are emerging, with stains incorporated into bowel preparation. One such formulation uses methylene blue (MB MMX, Cosmos Technolgies). This has been designed as a modified release device which ensures colonic release. The methylene blue is taken up by normal mucosa and poorly by neoplasia resulting in unstained areas where the lesions are present. A preliminary study has been promising on the efficacy of MB MMX 25 mg for the detection of polyps involved 96 patients undergoing routine colonoscopy. Polyps were detected in 61 patients, resulting in a 63.5% polyp detection rate[42].

Digital chromoendoscopy

Digital chromoendoscopy refers to advances in endoscope technology that manipulate wavelengths of the light source to create an effect similar to chromoendoscopy by accentuating lesion characteristics (Figure 3).

Narrow band imaging (NBI) is available on Olympus endoscopes. When used in colonoscopy, it allows potential improvement in ADR due to the enhanced appearance of certain mucosal and vascular features. A filter leads to the use of ambient light of wavelengths of 440 to 460 nm (blue) and 540 to 560 nm (green). Because the peak light absorption of haemoglobin occurs at these wavelengths, blood vessels will appear very dark, allowing for their improved visibility and the improved identification of other surface structures[43]. Compared with chromoendoscopy, classification of colorectal polyps by NBI appears to have a shorter learning curve. However, there is still substantial inter-observer variability, and classification of colorectal lesions based on vascular patterns is not objectively standardized yet[44]. A meta-analysis of 7 studies in 2936 patients showed no statistically significant difference in the overall adenoma detection rate with the use of NBI or white light (36% *vs* 34%, P = 0.4). They also showed no difference in the number of polyps detected between the two modalities (P = 0.2). A second met-analysis performed again failed

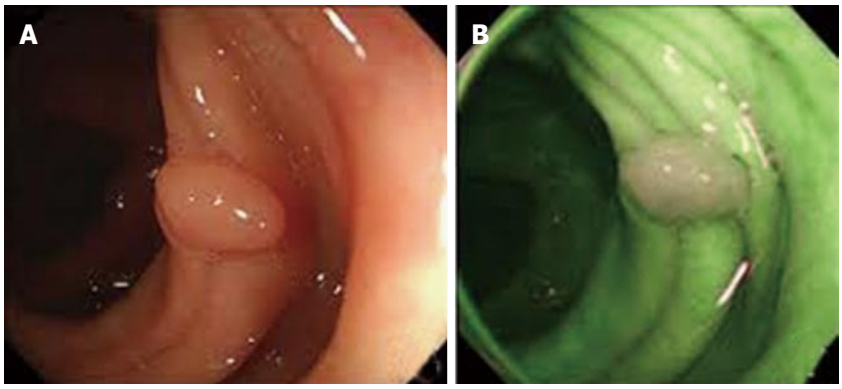

Figure 4 Digital-auto-fluorescence. A demonstrates polyp in white light, whilst B represents the same area in digital-auto-fluorescence. The normal mucosa appears green, with the adenoma appearing white.

show a significant difference in ADR between NBI and conventional white light. Concluding, NBI does not increase the yield of colon polyps, adenomas, or flat adenomas, nor does it decrease the miss rate of colon polyps or adenomas in patients undergoing screening/surveillance colonoscopy[45]. A further, larger, meta-analysis examined 11 RCTs evaluated NBI and ADR in a screening population of average- and higher-risk individuals and found limited benefit compared with white light colonoscopy[46]. These results were supported by a recent Cochrane review of 3673 patients in 8 randomized trials [relative risk (RR), 0.94; 95%CI: 0.87-1.02][47].

As with narrow-band imaging, the Fujinon intelligent colour enhancement (FICE) also narrows the bandwidth of conventional white-light colonoscopy to improve visualization, but it creates this effect electronically. Dedicated computer algorithms are used to generate the image. FICE enables the endoscopist to choose between different wavelengths for optimal examination of the colon mucosa[48]. It is reported to allow inspection of microvascular patterns as well as pit patterns and circumvents some limitations in conventional chromo-endoscopy[49]. Back to back studies have examined FICE and its impact upon ADR. Neither study demonstrated an improvement in ADR or adenoma miss rate when compared to NBI and white light[50,51].

The Pentax technology equivalent is i-Scan, for which there are limited RCT with most of the literature focusing on lesion characterisation. Some studies have compared high definition scopes coupled with i-Scan against standard resolution scopes. One such study demonstrated significantly more neoplastic lesions and more flat adenomas could be detected using high definition endoscopy with surface enhancement. Histology could be predicted with high accuracy (98.6%) within the HD+ group[52].

Digital-auto-fluorescence

Digital-auto-fluorescence (AFI) is technology available only in Olympus endoscopes where rotating filter wheel in front of the light source sequentially generates blue light (390-470 nm) and green light (540-560 nm)[53]. The exposure of tissue to this specific light leads to the excitation of some endogenous substances and subsequently the emission of fluorescent light. The reflected blue light is blocked by a second filter while the reflected red light and the emitted green autofluorescence from the tissue are used to obtain an image. AFI colonoscopy colours neoplastic lesions red-purple while non-neoplastic mucosa appears green[27] (Figure 4).

Three of the most widely reported studies comparing AFI and white light describe a lower adenoma miss rate with AFI, with up to a 20% difference[54-56]. One study reported that the detection rate of flat and depressed adenoma, but not elevated adenoma; by AFI is significantly higher than that by white light. In less experienced hands, AFI dramatically increased the detection rate (30.3%) and reduced miss rate (0%) of colorectal adenoma in comparison to white light (7.7%, 50.0%); this was not seen with more experienced endoscopists. They did describe a significantly longer duration time in the AFI group[54]. Another study explored the use of AFI in those undergoing colonoscopy for Lynch syndrome surveillance or those with a family history of colorectal cancer (one first-degree relative with colorectal cancer diagnosed at a young age (< 50 years) or two first-degree relatives regardless of age). This study reported a significantly higher sensitivity of AFI compared with white light (92% *vs* 68%; $P = 0.001$). The additionally detected adenomas with AFI were significantly smaller than the adenomas detected by white light (mean 3.0 mm *vs* 4.9 mm, $P < 0.01$)[55]. AFI also achieved better diagnostic accuracy (77%) than white light (57%) or NBI (63%) for polyp differentiation in the evaluation of still images by inexperienced endoscopists (accuracy compared with white light, $P = 0.001$; with NBI, $P = 0.016$)[57].

At present, whilst evidence exists that digital chromoendoscopic techniques (NBI, FICE and i-Scan) aide's lesion recognition, the evidence does not currently support that it improves ADR. There is some evidence to support of the positive effects of AFI, however, it is associated with added expense and poor image resolution, which are practical concerns for the

Figure 5 Example of the display module of the full spectrum endoscopy system and the 330° view (top). Bottom image is the full spectrum endoscopy scope demonstrating the side mounted camera and lights[27].

widespread introduction of this technology.

ADVANCEMENTS IN ENDOSCOPE DESIGN

Extra-wide angle view colonoscopes

This may represent one of the few recent developments in the design of the colonoscope that aide ADR. The full spectrum endoscopy (FUSE) system (EndoChoice) is currently on the market. It allows for full-spectrum views of the colon lumen, comprising 330 degrees. The colonoscope in the Fuse system has 2 additional cameras, on the left and right side of the scope's tip, to supplement the front camera. The video images transmitted from the cameras are displayed on 3 contiguous monitors corresponding to each camera. This array provides a comprehensive view of the total colonic lumen, including imaging of the traditionally encountered blind spots at the flexures or proximal edges of the mucosal folds (Figure 5).

During its initial development, trials revolved around anatomical models with simulated polyps, some of which were purposely placed in the tradition blind spot, *e.g.*, behind folds. In one such study 37 endoscopists performed colonoscopy by using the forward-viewing camera scope, followed by a colonoscopy with all 3 camera on; this increases the field of view to previously described 330 degrees. In total, 85.7% of the polyps were detected with the three cameras compared to 52.9% with only forward-viewing colonoscopy ($P \leqslant 0.001$). Particularly polyps that were "hidden" behind flexures and folds were more frequently detected with FUSE colonoscopy than with forward-viewing colonoscopy (81.9% *vs* 31.9%)[58]. An international, multicentre, randomised trial, the results of which were published in 2014 examined the use of FUSE further. Patients aged 18-70 years referred for colorectal cancer screening, polyp surveillance, or diagnostic assessment, were included. One hundred and eighty-five participants were assessed. The adenoma miss rate was significantly lower in patients in the FUSE group than in those in the standard forward-viewing procedure group: (7%) *vs* (41%) ($P = 0.0001$). In those who underwent standard colonoscopy first ($n = 88$), the FUSA system detected 39 additional polyps[59]. The authors reported a significantly longer withdrawal time ($P \leqslant 0.01$), however in real-time this was only a median time of 30 s. There certainly appears to be promise for ADR improvement with the FUSE system, more numerous and larger RCT's will be required to confirm this.

The findings from a study examining the effectiveness of a prototype wide angled colonoscopy were recently reported. The prototype colonoscope has a extra-wide angle of view has a 144°-232°-angle lateral-backward viewing lens in addition to a standard 140°-angle forward-viewing lens. Views from both lenses are simultaneously constructed and displayed on a video monitor as a single image. The ADR reported from this study was 57.1%, achieved whilst maintaining appropriate caecal intubation rate, completion times and no adverse event[60].

Balloon assisted colonoscopy

The NaviAid G-EYE colonoscope (SMART Medical Systems) is one such system. With this there is an integrated balloon on the flexible tip of the scope. The balloon can be reprocessed and reinflated by the endoscopist upon withdrawal of the scope. The mechanical flattening and straightening of haustral folds with the inflated balloon permit visualization of hidden anatomic areas, thus increasing the ADR[28]. Only simulated studies on anatomical models exist for this device. One such study showed a significantly greater ADR in the balloon assisted group ($P \leqslant 0.0001$)[61]. Clearly larger scale human studies are required to more about the utility of this device.

Real-time histology and confocal microscopy

Confocal laser endomicroscopy (CLE) is an emerging technology, which allows *in vivo* imaging of cellular and subcellular details of the gut mucosa and vessels during ongoing endoscopy. The most commonly used contrast agents are acriflavine hydrochloride and fluorescein sodium. For colon pathology assessment, the administration of fluorescein intravenously produces a strong staining of both surface epithelium and deeper layers of lamina propria[62,63]. Mounted into the end of a regular colonoscope is a miniature confocal microscope. When the tip of the scope is placed in direct contact with the mucosa and an argon ion laser excites the tissue a grayscale image can be produced, with a 7 μm thickness and a lateral resolution of 0.7 μm, the field of view being 475 μm × 475 μm[63] (Figure 6).

A number of studies have demonstrated the ability of confocal microendosocopy to perform real time

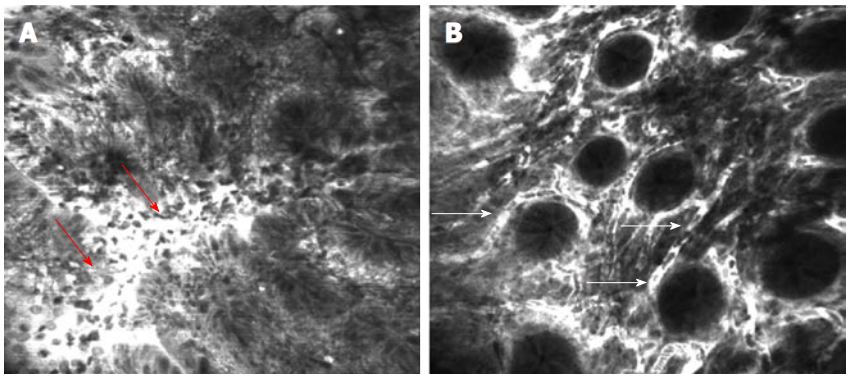

Figure 6 Confocal laser endomicroscopy of the colon using intravenous fluorescein. A: Colon carcinoma with total disorganization of cell architecture, invasion and destruction of the vessels with leakage of fluorescein (arrows); B: Severe inflammatory changes in ulcerative colitis with cellular infiltrate causing an increase in the distance between crypts and excessive vascularity (arrows)[63].

Figure 7 Third eye retroscope®. A: Image of the third eye retroscope® protruding from the working channel of the colonoscope; B: Forward view of third-eye retroscope®; C: View from lens of third-eye retroscope®[27].

histological analysis. Showing its ability to separate hyperplastic and adenomatous polyps, whilst identifying malignant features also[62-64]. The application of confocal is somewhat in its infancy, however as things develop real-time microendoscopy may become mainstream for endoscopist. There is little evidence to suggest that confocal can improve ADR, but it can improve decision making once the adenoma is detected.

DEVELOPMENTS IN ACCESSORIES

Third eye retroscope®

Third eye retroscope® (Avantis Medical Systems, Inc) consists of a video processor, a single-use polarizing filter cap for the colonoscope light source, and a 3.5 mm flexible single-use catheter with a camera and diode light source at the tip. The retroscope is retroflexed 180 degrees after being advanced through the working channel of the colonoscope and provides a 135 degrees retrograde view of the colon[27]. The system has been quoted to increase mucosal visualisation from 87% to 99%[65]. Like the FUSE system, initial studies of the third-eye system used anatomical models with simulated polyps. Standard colonoscopy detected 12% of the polyps located on the proximal aspects of folds, while 81% of these polyps were detected with the third eye retroscope[66]. A study demonstrated a 14.8% increase in polyp detection and a 16.0% increase in adenoma detection in their study that included 298 patients[67]. A further study reported similar result with a 13.2% increase in polyp detection and a 11.0% increase in adenoma detection[68]. The largest study for Third eye was the TERRACE study. TERRACE was a multi-centred study that included 349 patients. A net additional detection rate with the third eye retroscope of 29.8% for polyps and 23.2% for adenomas was reported. The study was criticised as the withdrawal time for the Third eye scopes were on average 2 min longer, however post-hoc analysis found withdrawal time to be independent of ADR[69] (Figure 7).

Despite the apparent improved ADR and reduced miss rate, third eye endoscopy has some significant flaws. It results in a 50% reduction in suction capacity; it needs to be removed from the working channel as another device is required and is very expensive[27].

Cap assistance

Transparent caps attached to the distal tip of the colonoscope were first designed to assist during endoscopic mucosal resection but they have also been suggested to be of help in depressing colonic folds to improve visualization of their proximal aspects[27]. Particularly in the hands of trainees and less-experienced colonoscopist they have been shown to improve

caecal intubation times and rates[70]. Most recently, a study, assessed ADR using cap-assisted colonoscopy *vs* normal colonoscopy. A total of 1380 patients were randomly allocated cap-assisted or normal, these consisted of asymptomatic participants (aged 50-75 years) in a primary colonoscopy screening programme. There was no significant difference in the type, location, size or number of polyps detected between the two groups. Caecal intubation time and Gloucester Comfort Scores were lower in the cap-assisted group[71]. A further study had similar finding, only demonstrated a superior ADR for polyps < 5 mm in the cap-assisted group[72]. Such finding have been persistent in other studies over the last decade with one of the original cap-assisted studies that examined 684 patients failing to demonstrate a significant difference in ADR[70]. This has been supported further by a meta-analysis performed in 2012 that concluded cap-assisted colonoscopy does not significantly improve ADR[73]. It would appear that cap-assisted colonoscopy may be of benefit in reducing caecal intubation time, but has limited or no benefit on polyp detection.

A similar device is Endocuff (Arc Medical, United States). Endocuff has been introduced as a means of enhancing visualization and scope stability during endoscopic mucosal resection of large or flat polyps of the sigmoid colon[74]. The Endocuff is a 2-cm long, flexible cuff with 2 rows of small flexible, hinged wings that help flatten large mucosal folds during withdrawal of the instrument. A prospective randomized trial in 498 patients undergoing screening colonoscopy showed Endocuff-assisted colonoscopy increased the absolute rate of polyp detection by 14% over unassisted colonoscopy from 42% to 56% (P = 0.001). The increase was particularly marked for polyps in the sigmoid colon 32% *vs* 15% (P = 0.0001) and caecum 4% *vs* 7% (P = 0.019)[75].

CONCLUSION

Novel and refinement of existing techniques, together with advancements in technologies can improve ADRs, and thus, potentially reduce cancer mortality. The use of chromoendoscopy in high risk groups such as colitis or HNPCC is becoming standard practice, but remains unsubstantiated for general use and is impractical. However, the development oral preparation given with the bowel preparation is a promising development. Increased ADR is yet to be proven with NBI, FICE and AFI beyond the use of high quality colonoscopes, and the marginal gains of using water exchange endoscopy are negated by time constraints, expense and further technical points for widespread application. Extra-wide angle colonoscopes such has FUSE has additional cost but its significant ADR may in the long-term make this economically viable, but more studies investigating the diagnostic before this device can be recommended for routine practice. The third-eye retroscope may be prohibited by cost, despite the apparent benefit, In contrast, cap-assistance is relatively inexpensive and further studies may show such devices as the Endo-cuff to be cost effective in improving ADR. However, at present, it seems that education, team work and optimising current practice will provide the biggest gains in ADR whilst maintaining financial acceptability.

Abstract

Complex and lengthy endoscopic examinations like endoscopic ultrasonography and/or endoscopic retrograde cholangiopancreatography benefit from deep sedation, due to an enhanced quality of examinations, reduced discomfort and anxiety of patients, as well as increased satisfaction for both the patients and medical personnel. Current guidelines support the use of propofol sedation, which has the same rate of adverse effects as traditional sedation with benzodiazepines and/or opioids, but decreases the procedural and recovery time. Non-anesthesiologist administered propofol sedation has become an option in most of the countries, due to limited anesthesiology resources and the increasing evidence from prospective studies and meta-analyses that the procedure is safe with a similar rate of adverse events with traditional sedation. The advantages include a high quality of endoscopic examination, improved satisfaction for patients and doctors, as well as decreased recovery and discharge time. Despite the advantages of non-anesthesiologist administered propofol, there is still a continuous debate related to the successful generalization of the procedures.

Key words: Non-anesthesiologist administered propofol sedation; Advanced interventional endoscopy; Endoscopic ultrasound; Endoscopic retrograde cholangiopancreatography

Core tip: A large amount of clinical research data demonstrated that propofol provides significant advantages over traditional sedation techniques during advanced endoscopic procedures like endoscopic retrograde cholangiopancreatography and/or endoscopic ultrasonography. Thus, propofol is more effective and safer than the combination of midazolam and meperidine to maintain an adequate level of sedation during advanced endoscopic procedures, with shorter recovery times and increased patient and endoscopist satisfaction. The trend of an increased usage of propofol and generalization of non-anesthesiologist administered propofol sedation in both hospital and private practice settings will certainly increase in the years to come.

Current role of non-anesthesiologist administered propofol sedation in advanced interventional endoscopy. *World J Gastrointest Endosc* 2015; 7(10): 981-986 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i10/981.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i10.981

INTRODUCTION

Most of the endoscopic procedures, either diagnostic or therapeutic, are nowadays performed under sedation, used as a standard practice in most of the centers[1]. Non-complex endoscopic examinations can be performed safely without any sedation, but with thorough psychological preparation and pre-procedural care, which might be good enough for patients to decrease procedure related anxiety[2]. However, the number and complexity of endoscopic procedures increased due to the generalized usage of sedation, which diminishes anxiety, discomfort and/or pain for the patients, thus improving patient acceptance and satisfaction[3-7]. Sedation is also important to medical practitioners as it improves the quality of endoscopic examinations and completion rate, but also treatment outcomes in therapeutic endoscopy, thus increasing endoscopist's satisfaction[3]. Sedation levels and medication types depend on a variety of factors, related to both patient characteristics (age, comorbidities, preference, *etc.*), as well as procedure types (simple diagnostic gastroscopy or colonoscopy, as opposed to prolonged complex therapeutic procedures)[4].

Sedation levels are variable and include a continuum of states ranging from minimal and moderate sedation to deep sedation and general anesthesia[4]. Conscious sedation assumes an *iv* administration of pharmacologic agents that lower the level of consciousness up to a state of drowsiness, relaxation, but the patient stays awake during the procedure retaining its ability to maintain an open airway and to breath spontaneously (patients do not require intubation and mechanical ventilation as with general anesthesia). Conscious sedation also helps to ensure adequate cardiac output, to communicate with the medical team and to respond to verbal commands[8,9]. Nevertheless, complex and lengthy procedures like endoscopic ultrasound (EUS) and endoscopic retrograde cholangiopancreatography (ERCP) usually require a deeper sedation level[10]. Consequently, deep sedation makes the pain more tolerable, minimizes patient anxiety and/or discomfort, and has no memory effect (the patient will never recall any negative emotions) and thereby facilitates the procedure performance by the endoscopist[4]. Current guidelines also support the use of propofol-based sedation as compared with traditional (conventional) sedation with benzodiazepines and/or opioids, thus offering higher patient and endoscopist satisfaction, decreasing procedure-related time, as well as recovery time, without increasing the rate of adverse events[11].

On the other hand, the use of intravenous sedation has increased the demand of qualified medical providers to assess and intervene on behalf of the patient, before serious adverse events occur[6].

Due to limited anesthesiology resources in most countries, non-anesthesiologist administered propofol (NAAP) sedation has started to be used extensively[6]. Registered nurses have responded to this demand through implementation of educational programs, definition of clinical competencies and promulgation of recommended practice guidelines by professional practice organizations and nursing position statements[12].

The aim of this article was to critically review the available evidence on deep sedation procedures necessary for complex therapeutic EUS and/or ERCP procedures, highlighting the controversies that still concern sedation by non-anesthesiologists (either endoscopists or nurses) based on structured multisociety sedation curriculum programs.

METHODS OF SEDATION

Sedation methods differ widely from one country to another, from one health system to another and, of course, they depend on local circumstances and both patient's and endoscopist's preferences that all increased the threshold on quality[2]. On the other hand, the differences between various hospitals/departments, university/community hospitals, as well as public/private endoscopy units, and other systematic differences of practice, might influence a particular endoscopy unit concerning its own sedation practices. Various types and degrees of sedation techniques are thus used during gastrointestinal (GI) endoscopic procedures, although the optimal sedation is tailored according to the individual patient, based on the balance between clinical risks and type of procedure performed[13]. Even nowadays, there is no standard system of sedation, while in the private institutions the choice of sedation depends on endoscopist and/or anesthesiologist preference, as well as the complexity of procedures to be performed.

Recent pharmacological researches and progresses have also contributed to the increased use of conscious sedation for specific patient populations. The introduction of "non-barbituric" intravenous anesthetics (propofol, remifentanil, ketamine, etomidate) with shorter half-lives and having minimum cumulative active metabolites, have increased the safety and efficacy associated with the administration of sedation. Nevertheless, both propofol (alone or in combination with other agents), but also conventional/traditional sedation techniques (using benzodiazepines and/or opioids) can induce deep sedation, even though only moderate sedation is desired[5].

Benzodiazepines

Benzodiazepines, such as midazolam, alprazolam, bromazepam, diazepam, *etc.*, are among the most commonly prescribed drugs[2]. These drugs act as anxiolytics, sedatives, hypnotics, anesthetics, antiepileptic and muscle relaxants. Moderate sedation using midazolam and an opioid is still considered the standard method of sedation, although propofol is increasingly used in many countries, mainly because both the endoscopists', as well as patients' satisfaction are higher than for conventional sedation. Midazolam is currently considered the benzodiazepine of choice because of its shorter duration of action and better pharmacokinetic profile compared with diazepam. The duration of action of midazolam is dependent on the duration of its administration. Mental function returns to normal after approximately 4 h after administration, the drug being very useful for short procedures. One published meta-analysis reported that midazolam provided better patient satisfaction as compared to diazepam, and less frequent memory of procedures[9]. The recovery time can be shortened after midazolam usage by using the benzodiazepine antagonist flumazenil[14].

Opioids

Among the opioids, fentanyl and meperidine/pethidine and are the most popular[2]. Fentanyl is a synthetic narcotic analgesic characterized by a rapid onset and short duration of action. At the level of respiratory system, higher doses can cause respiratory depression, immediately, as well as late. It can induce chest muscle rigidity followed by a difficult or even impossible intubation. Also, the combination of fentanyl and midazolam that is used quite often in some endoscopy departments can produce apnea and cardiac arrest[9]. Pethidine/meperidine is a weak opioid (7-10 times weaker than morphine) which relaxes smooth muscles, produces sedation and mild euphoria. The combination between midazolam and meperidine is safe and effective for GI endoscopy[15]. Ketamine is also a suitable sedative for GI endoscopy[16], although it might stimulate salivary and tracheobronchial secretion, while it sometimes gives a dissociative anesthesia that can produce hallucinations and delirium awakening[17].

Propofol

Propofol is an ultra-short-acting, sedative-hypnotic agent that has multiple potential advantages compared with "traditional sedation" based upon administration of an opioid and benzodiazepine agents for endoscopic procedures[18]. Propofol is a highly soluble phenol derivative, consisting of an *iv* emulsion for injection or infusion (1% concentration, 10 mg/mL) containing also 10% soybean oil, 2.25% glycerol and 1.2% purified egg phosphatide[2]. Propofol has become undoubtedly the induction agent of choice in GI endoscopy, as it is really easy to administer and provides prompt awakening, with fewer side effects[19]. Postprocedure, propofol reduces nausea and vomiting as well as the time required for the ability to walk, as compared with thiopental and methohexital. The pain on injection of propofol may be reduced by injecting it into large veins or by mixing with 20-40 mL of lidocaine anesthetic agents. Co-induction with midazolam reduces the dose of propofol, produce sedation and amnesia without prolonging hospitalization time[20]. Nevertheless, recovery is slower, which for outpatient endoscopy cabinets can be an impediment.

ADVANCED ENDOSCOPY

Compared to standard diagnostic upper or lower GI endoscopy, advanced therapeutic procedures (EUS and/or ERCP) are often longer and complicated, thus requiring higher doses of sedatives for corresponding patient compliance, without recall of the procedure[10].

ERCP

ERCP is a technically demanding, but highly important modality to diagnose and treat pancreaticobiliary disorders. ERCP has progressed from an initial diagnostic technique to an exclusively therapeutic procedure used for the management of common bile duct stones, as well as biliary strictures. Pancreatic stones, strictures or even pseudocysts can be also managed by ERCP in highly specialized tertiary centers[21]. Traditional conscious (moderate) sedation with the combination between a benzodiazepine and an opiate is challenged nowadays by the use of propofol sedation. A Cochrane review on individual studies concluded that patients have a better recovery profile after propofol sedation, as compared to the combination midazolam - meperidine, with no difference in complication rate[22]. The same conclusion has been reached by several meta-analyses that indicated clear advantages for propofol sedation, without increased risk of cardiopulmonary adverse events[18,23]. In order to obtain the desired deep sedation effects, balanced propofol sedation (propofol in combination with midazolam and fentanyl) has been used showing a longer recovery time without any other difference in term of complications[24]. The conclusion was that non-anesthesiologists propofol sedation can also be administered safely by trained, registered sedation nurses, with the same being

valid also in emergency ERCP[25]. Although propofol is nowadays preferred, in high doses it induces a risk of cardiopulmonary complications (bradycardia, hypotension, apnea, hypoxemia, *etc.*), consequently various methods of administration have been designed. Target propofol infusion (TPI) consists of an initial bolus, followed by a rate of constant infusion controlled by a computer, and has been compared to self-administration of propofol through patient controlled sedation (PCS)[26]. The later technique showed a reduced consumption of propofol and a faster recovery, but no significant benefits over TPI.

EUS

EUS is a state-of-the-art method for the assessment of GI pathology, especially for pancreaticobiliary lesions, but also GI tract or lung cancers. Moreover, the procedure allows the performance of EUS-guided fine needle aspiration (FNA) used to obtain a final diagnosis through cytology or histology exams of the obtained samples[27]. While routine diagnostic or staging EUS carries a relatively low risk, it is usually more time consuming and more uncomfortable than a simple diagnostic upper GI tract endoscopy. Likewise, EUS-FNA procedures are more difficult and lengthier, therefore a deeper sedation is necessary. The same thing is valid for therapeutic procedures which start with the initial placement of a needle through EUS-guidance, for, *e.g.,* celiac plexus neurolysis or pancreatic pseudocyst drainage. Other therapeutic procedures performed under EUS-guidance or assistance, like hepaticogastrostomies, choledocoduodenostomies or cholecystogastrostomies, are also performed under deep sedation or general anesthesia, even in high risk patients [American Society of Anesthesiologists (ASA) Ⅲ-Ⅳ][28]. A large prospective study including 500 patients showed that administration of propofol by qualified persons, other than endoscopist, is safe and effective for patients with ASA less than 2, during upper GI EUS[29]. Balanced propofol sedation techniques have been used also during EUS-FNA procedures without any major complications[30]. Likewise, TCI during monitored anesthesia has been proven useful for safe sedation during EUS, without major complications[31].

NAAP

NAAP propofol sedation caused major debates due to limited anesthesiology resources that determined administration of NAAP by trained nurses or endoscopists in selected endoscopy procedures[6]. A comprehensive guideline endorsed by the European Society of Gastrointestinal Endoscopy (ESGE) and European Society of Gastroenterology and Endoscopy Nurses and Associates established the role of NAAP in clinical endoscopy. Thus, trained registered nurses or endoscopists can safely administer propofol during ongoing endoscopy, with a very low rate of respiratory events requiring endotracheal intubation[32]. The recommendations from the ESGE guidelines are clear, indicating that propofol sedation has a similar rate of adverse events compared to conventional sedation (based on benzodiazepines ± opioids), with a high post-procedural satisfaction for both the patients, but also endoscopists. Moreover, the time for sedation decreases, with a higher quality of the endoscopic examination, while the recovery and discharge time will decrease[6]. Even psychomotor ability after the procedure seems to be improved leading to a possible continuation of daily routine (including driving after recovery in the medical suites)[33]. Because higher category of ASA physical status classification system leads to higher complication rate, an anesthesiologist is usually required on-site or for all patients with ASA category equal to or more than Ⅲ[34].

A dedicated person (usually a trained registered nurse) should be used for propofol administration, based on a clear protocol and adequate monitoring of the patient. An intravenous access should be maintained based on catheter with continuous supplemental oxygen, with careful continuous pulse oximetry and automated non-invasive blood pressure monitoring at 3-5 min intervals[6]. While simple endoscopic procedures can be performed with moderate sedation, complex procedures like EUS and/or ERCP are usually performed with deep sedation[10]. Currently, there is insufficient evidence that balanced propofol sedation with combination of drugs, beside propofol, has more beneficial effects[35,36]. The preferred mode of administration is with intermittent bolus administration or PCS in a minority of patients, if available[37]. Nevertheless, one large study from Germany showed that the combination of propofol and midazolam has a significantly lower sensation of pain, as well as reduced symptoms of dizziness, nausea and vomiting as compared to patients that received only propofol mono-sedation[38]. There is a lot of data to support the usage of patient-selected music during the procedures, which can decrease the dosage of propofol administered[39].

Both endoscopists and nurses should undergo a specific training program, which includes theoretical and practical parts on both basic life support and advanced cardiac life support[6]. A structured training program followed by an implementation phase documented a low incidence of adverse events, while the independent risk factors were: type of intervention and level of staff experience[40]. Thus, the patients had short duration hypoxia (4.7%), needed suction (2.4%) or bag-mask ventilation (0.9%), with only 0.3% of procedures that had to be discontinued[12]. Anesthetic assistance was necessary for only 0.4% of patients. A recent meta-analysis compared pooled results for NAAP and AAP studies, and showed the same rates of hypoxia (oxygen saturation less than 90%) and airway intervention in both arms[41]. Respiratory complications after endoscopist directed sedation were also shown to be important, with coughing or vomiting resulting in an increased risk of respiratory infections, thus requiring antibiotic treatment[42]. However, pooled patient satisfaction and

pooled endoscopist satisfaction rate, as well as the dose of propofol administered were lower in the NAAP group, as compared to the AAP group. In order to generalize this approach there are important legal issues that may arise if sedation complications occur during NAAP procedures, while these legal implications usually have country or even hospital specificities and particularities.

Nevertheless, cautious opinions on NAAP still exist, with more data required before transition of procedures from major hospitals to community practice[43,44]. Retraction of endorsement for the NAAP guideline by the European Society of Anesthesiology (ESA) came in line with the concerns of using NAAP by trained nurses or endoscopists, mainly in view with the possible complications and their proper management[45]. Our own approach for the patients with advanced interventional endoscopic procedures (EUS and/or ERCP) consists of exclusive use of propofol sedation in the presence of an anesthesiologist, as required by the current national and local legislation practices. Based on a total number of 192 patients examined during one year in the Research Center of Gastroenterology and Hepatology Craiova, Romania, we have encountered no severe adverse events, with drowsiness, nausea, vomiting, dizziness, headache, coughing or shivers being the most frequent, while less than 2% of patients had mild braycardia.

CONCLUSION

In conclusion, several large prospective studies and meta-analyses demonstrated that propofol provides significant advantages over benzodiazepine and opioid agents for deep patient sedation during advanced endoscopic procedures like ERCP and/or EUS: propofol was more effective and safer than the combination of midazolam and meperidine for achieving and maintaining an adequate level of sedation during endoscopic procedures, with better titration of the level of sedation and shorter recovery times. The trend of an increased usage of propofol and generalization of NAAP sedation in both hospital and private practice settings will certainly increase in the years to come.

Abstract

In the majority of cases, duodenal papillary tumors are adenomas or adenocarcinomas, but the endoscopy biopsy shows low accuracy to make the correct differentiation. Endoscopic ultrasonography and endoscopic retrograde cholangiopancreatography are important tools for the diagnosis, staging and management of ampullary lesions. Although the endoscopic papillectomy (EP) represent higher risk endoscopic interventions, it has successfully replaced surgical treatment for benign or malignant papillary tumors. The authors review the epidemiology and discuss the current evidence for the use of endoscopic procedures for resection, the selection of the patient and the preventive maneuvers that can minimize the probability of persistent or recurrent lesions and to avoid complications after the procedure. The accurate staging of ampullary tumors is important for selecting patients to EP or surgical treatment. Compared to surgery, EP is associated with lower morbidity and mortality, and seems to be a preferable modality of treatment for small benign ampullary tumors with no intraductal extension. The EP procedure, when performed by an experienced endoscopist, leads to successful eradication in up to 85% of patients with ampullary adenomas. EP is a safe and effective therapy and should be established as the first-line therapy for ampullary adenomas.

Key words: Epidemiology; Ampullary tumors; Endoscopic resection; Endoscopic ultrasound; Staging; Endoscopic papillectomy; Surgical ampullectomy

Core tip: Although the endoscopic papillectomy (EP) represent higher risk endoscopic interventions, it has successfully replaced surgical treatment for benign or malignant papillary tumors. The accurate staging of ampullary tumors is important for selecting patients to EP or surgical treatment. Compared to surgery, EP is associated with lower morbidity and mortality, and seems to be a preferable modality of treatment for small benign ampullary tumors with no intraductal extension.

The EP procedure, when performed by an experienced endoscopist, leads to successful eradication in up to 85% of patients with ampullary adenomas. EP is a safe and effective therapy and should be established as the first-line therapy for ampullary adenomas.

INTRODUCTION

Ampullomas represent an uncommon group of gastrointestinal malignancies. Advances in endoscopic ultrasound (EUS) and endoscopic retrograde cholangiopancreatography (ERCP) have significantly impacted the clinical approach to patients with suspected premalignant or malignant lesions of the duodenal papilla[1]. The present review leads us to the discussion of numerous current issues related to the epidemiology of ampullary tumors, the role of the endoscopy biopsy, EUS, and ERCP, as well as indications, optimal technique, complications and outcomes in patients with benign or malignant tumor.

The term "endoscopic papillectomy" refers to the duodenal mucosa and submucosa resection, including all the anatomic attachments of the ampulla of Vater, and the tissues around the bile and pancreatic ducts. In turn, the term ampullectomy should be used to define this surgical procedure, which consists in the resection of the ampulla of Vater, through a duodenotomy including the cephalic pancreatic tissue resection, followed by reinsertion of common bile duct (CBD) and main pancreatic duct (MPD) in the duodenal wall[2].

The endoscopic papillectomy (EP) was first reported as a route of access to the biliary tract[3]. Years later, it was used as a treatment modality for two cases of duodenal papilla cancer[4], and today it is accepted as a viable alternative therapy to surgery in patients with sporadic adenoma of the major or minor duodenal papilla due to its high success rate and low recurrence[2].

EPIDEMIOLOGY

Tumors of the duodenal papilla may be classified as benign, premalignant, and malignant[5]. The annual incidence of ampullary lesions in the United States is 3000, with reported prevalence rates of 0.04%-0.12% in autopsy series[6,7]. Ampullary adenomas may occur sporadically or in the setting of hereditary polyposis syndromes, including familial adenomatous polyposis (FAP) with adenomatous polyposis coli gene mutations. In patients with FAP, ampullary adenomas occur in up to 80% of individuals during their lifetime and progress to malignancy in 4%[8]. Ampullary adenomas are likely to follow an adenoma-to-carcinoma sequence similar to colorectal adenocarcinoma[9]. These lesions are considered premalignant, with an incidence of transformation to carcinoma ranging from 25%-85% for sporadic adenomas. As with all neoplasms, tumor stage dictates the appropriate therapy[10].

DETERMINANT FACTORS IN THE RESECTION OF NON-INVASIVE NEOPLASMS OF THE VATER´S AMPULLA

It seems that the knowledge of the histological and immunohistochemical characteristics is useful for precisely indicate an EP. In this context, the study of such characteristics is useful for selecting the appropriate surgical or endoscopic procedure. To corroborate this fact, japanese authors reported the results of this analysis in 56 noninvasive ampullary tumors. They demonstrated that the intestinal type cancer of intra-ampullary location shows lower CK20 expression than tumors of the periampullary location, and besides that, the intestinal type tumors without CDX2 expression, that included extended and intra-ampullary location types, tend to show a compromised vertical margin after EP. This suggests that periampullary tumors, intestinal histology and high CK20-positive rate can be regarded as good indications for the EP procedure. On the other hand, this study shows that tumors that are either pancreatobiliary or intestinal type without CDX2 expression have a higher chance of involvement of the common channel inside duodenal papilla, CBD and MPD[11].

INDICATIONS

The indications for EP are based on features that can predict a complete tumor removal, while minimizing complications related to the procedure[1]. Currently the indications are not fully established and are far from a consensus.

The main criteria for EP include the lesion size (up to 5 cm), no evidence of intraductal tumor growth or malignancy in endoscopic findings, such as ulceration, spontaneous bleeding and friability[1,12-18]. However, the indications for EP are expanding[10,19-24]. For example, the endoscopic piecemeal resection technique, is used to removing tumors that can't be removed "*en bloc*", and provided increasing resections, when properly performed[25]. The clinical results of this technique are very good, but the chance of recurrence is higher.

The ductal invasion in an extension less than 1 cm does not seem to be an absolute contraindication for EP, because the tumor can be exposed by endoscopic maneuvers, such as the use of an extractor balloon into the lumen, and thus it can be completely resected with a polypectomy snare[26-28].

The cancer arising within an adenoma without

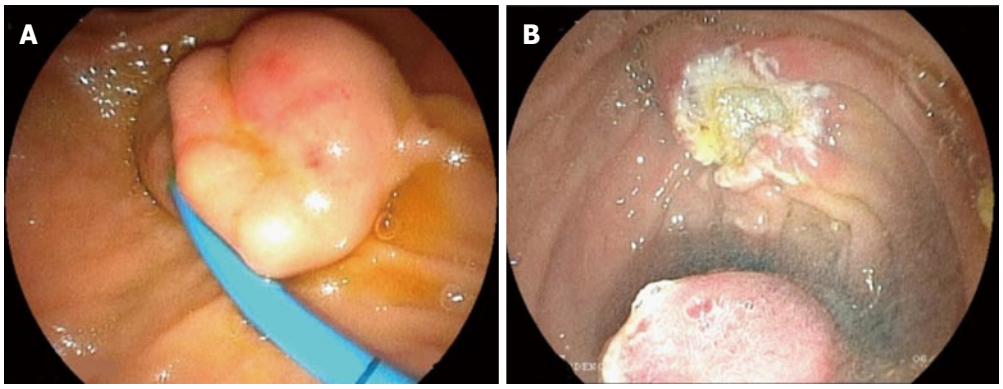

Figure 1 Endoscopic view of neuroendocrine tumor of the papilla with Fujinon intelligent chromo endoscopy. A: This picture show the depression in the center of the lesion; B: The picture shows the aspect of the papillary region after the "*en bloc*" resection.

invasion of duodenal muscularis propria and pancreas, or CBD and MPD, are liable to resection by EP[29-33]. However, in some situations, EP can be used as a macrobiopsy procedure for a simple local tumoral staging, if the resection margins are compromised[34].

PREOPERATIVE ENDOSCOPIC EVALUATION

The most common preoperative concern is to define if a papillary tumor is benign or malignant. The endoscopic aspect alone cannot always distinguish adenomas from carcinomas and even from adenomatous polyps, carcinoids, gangliocytic paraganglioma, and other tumors that may occur in this region[35,36]. Some endoscopic aspects like ulceration, friability, spontaneous bleeding are usually relate to malignant lesions. The use of endoscopic tools such as NBI, FICE and magnifying endoscopy are useful to select patients for EP (Figure 1)[37].

A definitive histological diagnosis is a basic prerequisite for adequate management of these patients, but we must remember that endoscopic biopsy of the duodenal papilla misses 30% of malignant tumors[38]. Moreover, the coexistence of carcinoma and adenoma cannot be excluded by endoscopic biopsy. Some authors advocate deep biopsy after sphincterotomy, to increase diagnostic accuracy of endoscopic biopsy[39]. We do not recommend this procedure, because endoscopic sphincterotomy eliminates the possibility of endoscopic *en bloc* resection of ampullary tumors, impeding a possible curative resection.

Favoring our impression, a prospective study showed that endoscopic biopsy is not reliable for preoperative diagnosis of tumors of the duodenal papilla (sensitivity of 21% before and 37% after sphincterotomy)[40]. Thus, in some cases, EP can be recommended as a technique for preoperative diagnosis because a high false negative rate of endoscopic biopsy[34].

PREOPERATIVE STAGING

EUS is the imaging modality of choice for local staging (T). EUS is superior to helical computed tomography (CT) for preoperative evaluation of tumor size, detection of regional lymph node metastasis, vascular invasion in patients with periampullary neoplasms and also to detect tumor infiltration of biliary and pancreatic ducts (Figure 2A)[40].

Many experts believe that EUS is not useful in lesions less than 1 cm in diameter, with no suspicious signs of malignancy (ulceration, induration, bleeding and/or biopsies with high-grade dysplasia or carcinoma)[12]. Our experience shows that, when EUS is performed for staging ampullary tumor prior to EP, it allows deciding for EP, because it shows the relationship between CBD and MPD, as well their diameter. EUS allows the verification of the relationship of the borders of the tumor in the duodenal wall, CBD and MPD, regardless of the size of the tumor. However, prospective studies are needed to evaluate the accuracy of these findings.

The use of intraductal ultrasound (IDUS), with a 20 MHz probe can be more accurate in visualizing mucosa layers compared to conventional EUS[41]. According to literature, EUS and IDUS accuracy before surgical resection or diagnostic EP was 97% and 94% for pTis, 73% and 73% for pT1, 50% and 50% for pT2 and 50% and 100% for pT3-4 respectively. The overall EUS and IDUS accuracy was 85% and 80% for T stage[42]. In our experience with this type of technology, the interpretation is more difficult, especially when the mini-probe is placed within the biliary or pancreatic ducts. If this is not done, the sensitivity is lower when compared with the conventional EUS[41].

From a technical standpoint, EUS and IDUS are able to detect, with high precision, tumoral infiltration of the common bile duct and main pancreatic duct (Figure 2B). Despite ERCP can detect CBD invasion, we believe that it should only be performed after EUS, if EP is indicated. EUS and IDUS can provide high precision diagnostic information for staging ampullary tumors, and are useful in identifying lesions selected for EP. However, these tools have limitations, because the occurrence of super and understating and the difficulty in assessing focal infiltration are relevant. The improvement of endoscopic procedures is necessary for an accurate assessment of

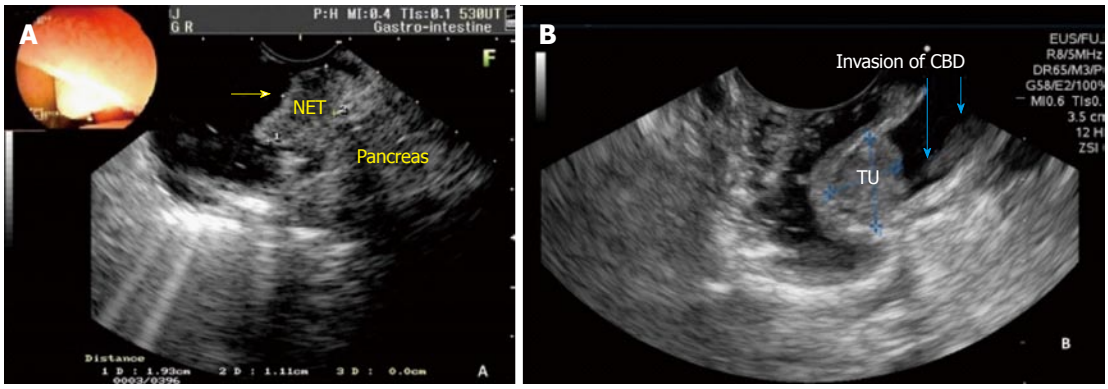

Figure 2 Endoscopic ultrasound staging of the duodenal papilla. A: Patient of the Figure 1. Endoscopic ultrasound staging shows the regular and hypoechoic nodule (1.93 cm) in the papilla without infiltration of the duodenal wall and pancreatic gland. The staging was uT1N0Mx; B: This picture shows the papillary tumor with 1.72 cm with invasion of the common bile duct wall (blue arrows). NET: Neuroendocrine tumor; TU: Tumor; CBD: Common bile duct.

ampullary tumors[43].

From a practical standpoint, ERCP should be performed before EP, if EUS is not available or inconclusive as to ductal involvement. Although intraductal invasion is usually an indication for surgery, it has been demonstrated that, when tumoral infiltration reaches ± 1 cm into CBD and MPD, tumor is amenable to endoscopic resection[26,27,44].

Positron computerized tomography (PET/CT) and magnetic resonance imaging (MRI) are highly sensitive for detection of distant metastases. MRI and CT was superior to EUS for assessment of nodal involvement[45].

ENDOSCOPIC PAPILLECTOMY TECHNIQUE

EP is performed after EUS staging confirming a less than 5.0 cm tumor confined to mucosa and/or submucosal (uT1), with intraductal tumoral infiltration less than 1 cm. It can be performed using the EUS device itself or a duodenoscope. With the duodenoscope rectified, a preferable monofilament polypectomy snare is used for grasping the tumor, always in the craniocaudal direction, *i.e.,* the snare tip is positioned on cranial tumor apex.

The snare is widely opened, duodenoscope is pushed in a craniocaudal direction, and tumor is grasped for en bloc resection (Figure 3). The papillary tumor is grasped at its base, always respecting a limit, up to 0.5 cm below the lesion border identified by FICE. Thereafter a constant tension is applied to the ring handle while using an electrocautery until tumor en bloc resection is completed. There are no specific equipment or a standard technique for EP.

There is also no guidance on the potency and mode of electronic current (cutting or coagulation). The authors prefer to use only cutting current (40 to 50 J) and the endocutter. Some authors recommend performing submucosal injection, ablative therapy after EP, and placement of a prophylactic pancreatic stent. The use of antibiotic prophylaxis before EP is not established[46]. The authors do not advocate its use.

Some experts use injection of contrast with methylene blue into MPD to identify the pancreatic orifice after tumor resection. This is not our practice. After complete removal of the lesion, which sometimes takes a few minutes, depending on its size and extension, a whitish rough area can be seen, which in some cases reveals the muscular layer of duodenal wall, as well two holes (biliary and pancreatic ducts).

Efforts should be exhaustive and mandatory to recover all resected tissue in all patients, for histopathological evaluation. Then CBD and MPD catheterization is performed, with contrast injection, to ensure easy recanalization after ampullary resection.

When *en bloc* resection is not feasible, a piecemeal resection is recommended. However, it should be noted that the en bloc resection is essential for the treatment of preneoplastic and/or malignant lesions, because this allows accurate histopathologic evaluation after tumoral resection[26].

The submucosal injection of diluted epinephrine is suggested as a means to lift the tumor from the wall, which at least theoretically may reduce the risk of bleeding. However, it is uncertain and questionable whether injection of adrenaline reduces the risk of bleeding and/or perforation[20,27,47]. The authors dismiss the submucosal injection of pharmacological agents, due to distortion of tumoral anatomy and its periphery, hindering an adequate grasping by the polypectomy snare. Moreover, a perforation following tumor resection may occur, due to a short distance between duodenal wall and pancreas, as seen by EUS.

If residual tumor tissue remains after resection, it should be destroyed! The use of coagulation with argon gas is the most widely used modality; it is safe because it is a non-contact technique, acting in tumor surface[12,46-48].

The use of stent in MPD, in order to reduce the risk of acute pancreatitis (AP) associated to EP, seems to be a consensus because it minimizes the risk of MPD stenosis, allowing the use of safer coagulation therapies. Anyway we must emphasize that this theory is unproven. Others advocate pancreatic stent placement only if MPD drainage is not sufficient after EP[49-52]. The only

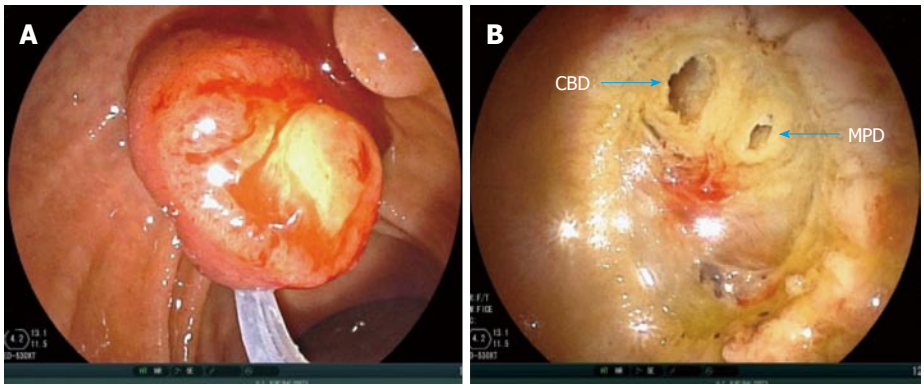

Figure 3 Endoscopic papillectomy immediately after endoscopic ultrasound for staging. prospective, randomized, controlled study, to evaluate the role of prophylactic stent in MPD, to reduce AP after EP, showed a statistically significant decrease in the rate of AP after stent procedure[53].

Otherwise, the adequate MPD diameter and length for stenting are uncertain. In other work, for example, the authors suggests that routine use of prophylactic pancreatic stent in all patients is unnecessary and efforts should be directed to know which groups of patients actually benefit from its insertion[54]. Most pancreatic stents migrate spontaneously from MPD within 2 wk after insertion. Abdominal X-ray after 2 wk can confirm this finding. A stent, which remains "*in situ*" for more than 2 wk, should be removed endoscopically. The placement of a prophylactic plastic biliary stent, to reduce the risk of cholangitis, has not been widely performed and cannot be uniformly recommended at the present moment, unless there is concern about inadequate biliary drainage after EP.

COMPLICATIONS

The EP is a "high risk" procedure, due to complications inherent to the method. They can be classified as early: AP, bleeding, perforation and cholangitis or late: papillary stenosis. The overall complication rate reported by major centers of tertiary care varies between 8% and 35%, and the most common complications are AP (5%-15%) and bleeding (2%-16%)[10,25,48,55]. Most episodes of bleeding can be controlled immediately by conservative treatment and endoscopic hemostasis and most episodes of AP are mild and resolve with conservative treatment only. The rate of pancreatic and/or biliary ductal stenosis varies between 0%-8%, and can be treated by sphincterotomy, stent placement, and balloon dilation.

The use of pancreatic stent can prevent an episode of AP and papillary stenosis[49-54]. Another interesting fact reported by a recent randomized study showed that prophylactic rectal indomethacin significantly reduced the incidence and severity of AP post-ERCP, providing an additional benefit in pancreatic temporary stenting[56]. The mortality after-EP is rare, but it has been reported to be 0.4% (range 0% to 7%)[57].

RESULTS

The results of the endoscopic treatment of ampullary

tumors reported in the literature are shown in Table 1. The EP results are based on retrospective case series studies with heterogeneous groups. As there is no consensus on the definition of "success" after EP, it is difficult to compare the results of the reported studies. Conventionally, "success" can be defined as a complete tumor resection (as the proven absence of visible residual adenoma by endoscopy and histological analysis during a 3-6 mo follow up). In the literature the rate of the success varies between 46% to 92% in the different series. The complication rate after EP varies between 8% to 42% and the major problems are acute pancreatitis, perforation and bleeding. The most important complication after EP is the acute pancreatitis that could be diminished with the insertion of the plastic pancreatic stent. This is a controversial point, because in our experience if you have a dilated main pancreatic duct the use of the PPS is unnecessary[58].

Recurrence of benign lesions occur in up to 33% of patients depending on the tumor size, final histology, presence of intraductal tumor, coexistence of FAP and endoscopist experience[21,57,59-64]. If you use the endoscopic ultrasound before the EP you could find with precision the presence of intraductal tumor. In this case there are contraindication to submitted the patient to EP. Recurrent lesions are usually benign and most can be removed endoscopically.

CONCLUSION

EP is a safe and effective therapy and should be established as the first-line therapy for ampullary adenomas. The accurate staging of ampullary tumors is important for selecting patients to EP or surgical treatment. Compared to surgery, EP is associated with lower morbidity and mortality, and seems to be a preferable modality of treatment for small benign ampullary tumors with no intraductal extension. The EP procedure, when performed by an experienced endoscopist, leads to successful eradication in up to 85% of patients with ampullary adenomas.

Abstract

AIM: To assess the endoscopic characteristics of gastric polyps and their association with *Helicobacter pylori* (*H. pylori*) status in a predominantly Hispanic population.

METHODS: We conducted a retrospective study of all esophagogastroduodenoscopies performed at our institution. Demographic, endoscopic and histopathological data were reviewed. Categorization of patients into Hispanic and Non-Hispanic was based on self-identification. Patients without resection/biopsy were not included in the analysis. Identification of polyps type was based on histological examination. One way analysis of variance was used to compare continuous

variables among different polyp types and Fisher's exact test was used compare categorical variables among polyp types. Unadjusted and adjusted comparisons of demographic and clinical characteristics were performed according to the *H. pylori* status and polyp type using logistic regressions.

RESULTS: Of 7090 patients who had upper endoscopy, 335 patients had gastric polyps (4.7%). Resection or biopsy of gastric polyps was performed in 296 patients (88.4%) with a total of 442 polyps removed or biopsied. Of 296 patients, 87 (29%) had hyperplastic polyps, 82 (28%) had fundic gland polyps and 5 (1.7%) had adenomatous polyps. Hyperplastic polyps were significantly associated with positive *H. pylori* status compared with fundic gland polyps (OR = 4.621; 95%CI: 1.92-11.13, *P* = 0.001). Hyperplastic polyps were also found to be significantly associated with portal hypertensive gastropathy compared with fundic gland polyps (OR = 6.903; 95%CI: 1.41-33.93, *P* = 0.0174). Out of 296 patients, 30 (10.1%) had a follow-up endoscopy with a mean duration of 26 ± 16.3 mo. Interval development of cancer was not noted in any of the patients during follow up period.

CONCLUSION: Gastric hyperplastic polyps were significantly associated with positive *H. pylori* status and portal hypertensive gastropathy as compared with fundic gland polyps.

Key words: Gastric polyps; Fundic gland polyp; Hyperplastic polyp; Adenomatous polyps; Chronic gastritis; *Helicobacter pylori*

Core tip: In a predominantly Hispanic population, the most common gastric polyps were hyperplastic and fundic gland polyps (more than half of gastric polyps). Gastric hyperplastic polyps were significantly associated with positive *Helicobacter pylori* status and portal hypertensive gastropathy as compared with fundic gland polyps. Hyperplastic polyps and fundic gland polyps were more prevalent in chronic gastritis, while adenomatous polyps were associated with intestinal metaplasia.

Gastric polyps: Association with *Helicobacter pylori* status and the pathology of the surrounding mucosa, a cross sectional study. *World J Gastrointest Endosc* 2015; 7(10): 995-1002 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i10/995.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i10.995

INTRODUCTION

Gastric polyps can be defined as abnormal luminal growths projecting above the plane of the mucosal surface. The incidence of gastric polyps has been estimated to be between 2% and 6%. The incidence of gastric polyps is gradually increasing due to expanded indications and widespread use of endoscopic examinations[1-4]. Gastric polyps are usually asymptomatic and discovered incidentally during endoscopic examination, but on rare occasions they can present with nonspecific symptoms such as abdominal pain, gastrointestinal bleeding, anemia, or symptoms of gastric outlet obstruction[5-8]. Determination of gastric polyp type is important as the risk for malignant transformation depends on the histopathological nature of the polyp[9-12]. The frequency of different types of gastric polyps varies widely depending on the population studied. It has been reported that hyperplastic polyps are relatively more frequent than fundic gland polyps in regions where *Helicobacter pylori* (*H. pylori*) infection is common[1,13]. A higher prevalence of *H. pylori* infection has been documented in Hispanics living in United States regions bordering Mexico compared with non-border areas[14,15]. There is a paucity of published data from the United States regarding the nature and various characteristics of gastric polyps, especially in Hispanics and other immigrant groups. The aim of this study is to assess the prevalence of gastric polyps and their endoscopic and histological characteristics in a predominantly Hispanic population on the United States-Mexico border.

MATERIALS AND METHODS

Study design

After receiving approval from Texas Tech University Institutional Review Board, we retrospectively reviewed all esophagogastroduodenoscopies (EGDs) performed at the University Medical Center, El Paso, TX for all indications. The review period of the study was from November 1, 2007 to July 30, 2013. The electronic database system (ProVation®, Minneapolis, MN) was used to identify the patient's demographic data, the indication for the procedure and gastric polyp characteristics. Categorization of patients into Hispanic and Non-Hispanic was based on self-identification. Patients without resection/biopsy were not included in the analysis. Identification of polyps type was based on histological examination.

Statistical analysis

Quantitative variables were described using the mean ± SD, whereas categorical variables were described using the frequency and proportion. One way analysis of variance was used to compare continuous variables among different polyp types and Fisher's exact test was used compare categorical variables among polyp types. Unadjusted and adjusted comparisons of demographic and clinical characteristics were performed according to the *H. pylori* status and polyp type using logistic regressions. The logistic regression analysis for *H. pylori* status was conducted after removing *H. pylori*

Table 1 Patient level summary of polyp histology

Polyp's type	Total patients (n = 296)	Percentage
Hyperplastic polyp	87	29.39
Fundic gland polyp	82	27.7
Chronic gastritis	41	13.85
Mixed	13	4.39
Intestinal metaplasia	12	4.05
Foveolar hyperplasia	10	3.38
Adenoma	5	1.69
Carcinoid tumor	4	1.35
Granulation tissue polyp	4	1.35
Adenocarcinoma	2	0.68
Gastric xanthelasma	2	0.68
Hamartomatous polyp	2	0.68
Lymphoid follicles	2	0.68
Submucosal Brunner glands	2	0.68
Lipoma	1	0.34
Normal	27	9.12

not tested patients. The logistic regression was used to find out factors associated with hyperplastic polyp type as compared with fundic polyp type after removing patients with adenoma, mixed polyps, and others. The results of logistic regression analysis were reported using odds ratio (OR), 95%CI and *P* values. Stepwise selection method using probability to enter = 0.10 and probability to stay = 0.05 was used to obtain the final model. All the statistical analyses were carried out using statistical analysis software (SAS) 9.3. Results were considered significant at the 5% level of significance. The statistical methods of this study were reviewed by Dr. Alok Dwivedi from the department of Biostatistics at Texas Tech University HSC at El Paso.

RESULTS

Demographic and clinical characteristics

A total of 7090 patients underwent 9450 EGD procedures. Of these, 335 patients had gastric polyps (4.7%). Resection or biopsy of 442 gastric polyps was done in 296 patients (88.4%). 39 patients did not undergo resection or biopsy of their gastric polyps because of the high risk of bleeding or obvious endoscopic diagnosis of fundic gland polyps (FGPs). The mean age of the patients was 58 years (SD: ± 12 years). The majority of the patients were females (74%) and most were Hispanics (85%). Portal hypertensive gastropathy was seen in 20 patients (7%).

Endoscopic and histopathological features

Polyps' histology: Of 296 patients, 87 (29%) patients had hyperplastic polyps and 82 (28%) patients had fundic gland polyps. There were 5 (1.7%) patients with adenomatous polyps while 13 (4.4%) patients had mixed types of polyps. Histology results of the remaining polyps revealed chronic gastritis in 41 patients (14%), intestinal metaplasia in 12 patients (4.1%), faveolar hyperplasia in 10 patients (3.4%), carcinoid tumor in 4 patients (1.4%) and granulation tissue polyps in 4 patients (1.4%). Adenocarcinoma, gastric xanthelasma, hamartomatous polyps, lymphoid follicles and submucosal brunner glands were each found in 2 patients (0.68%). There was one patient with lipoma. The histology of resected or biopsied polyp was normal in 27 patients (9.1%).

Pathology of the surrounding mucosa: Out of 296 patients, 266 (89.8%) patients had biopsies of the surrounding mucosa (Table 1).

Of these, 190 (64%) patients had chronic gastritis while 25 (8%) patients had intestinal metaplasia. Thirty (10%) patients were not biopsied. In regards to *H. pylori status, H. pylori* were positive in 71 (24%) patients, and negative in 211 (71%) patients, while 14 patients were not tested.

Clinical characteristics of gastric polyps: Table 2 shows the distribution of patient and clinical characteristics according to five categories (Adenoma, Hyperplastic, Fundic gland, Mixed and other) of polyps. The gender and ethnicity distributions were not found to be significantly different among different polyp types. The distribution of age, pathology of surrounding gastric mucosa, and *H. pylori* status were found to be associated with different polyp types. Adenomatous polyps were more common in advanced age ($P < 0.0013$). Fundic, hyperplastic and mixed polyps were more frequent in chronic gastritis while adenomatous polyps were more common (60%) in intestinal metaplasia ($P < 0.001$). Thirty-one percent of the patients with hyperplastic polyps tested positive for *H. pylori* status while 9.8% of the patients with fundic gland polyps tested positive for *H. pylori.* Portal hypertensive gastropathy was seen in 11.5% of patients with hyperplastic polyps compared to 2.4% of patients with fundic gland polyps.

Associations of *H. pylori* status and gastric pathology: The prevalence of hyperplastic polyps was 34% in the *H. pylori* positive group while the prevalence of fundic polyps was 10% in the *H. pylori* positive group. Table 3 shows the unadjusted and adjusted associations of cofactors with *H. pylori* status. Only the polyp type and the pathology of surrounding gastric mucosa were associated with *H. pylori* in unadjusted and adjusted models. Hyperplastic polyps have a 4.6 times higher odds of having a positive *H. pylori* status compared to fundic gland polyps (OR = 4.621; 95%CI: 1.92-11.13, $P = 0.001$).

Cofactors association of hyperlastic and fundic gland polyps: Table 4 shows the unadjusted and adjusted associations of cofactors with hyperplastic polyps as compared with fundic polyps. In the unadjusted analysis, age, *H. pylori* status and portal hypertension were found to be associated with hyperplastic polyps. Per unit increase in age increased the odds of hyperplastic polyp type by 3% as compared

with fundic gland polyp. After adjusting for all other factors, *H. pylori* status and portal hypertensive gastropathy were the only remained significant factors in the final adjusted model. Positive *H. pylori* status has 5.3 times higher odds to have hyperplastic polyps compared with negative *H. pylori* status (OR = 5.285; 95%CI: 2.17-12.89, *P* = 0.0003) after adjusting for portal hypertensive gastropathy. Patients with portal hypertensive gastropathy are 6.4 times more likely to have hyperplastic polyps after adjusting for *H. pylori*

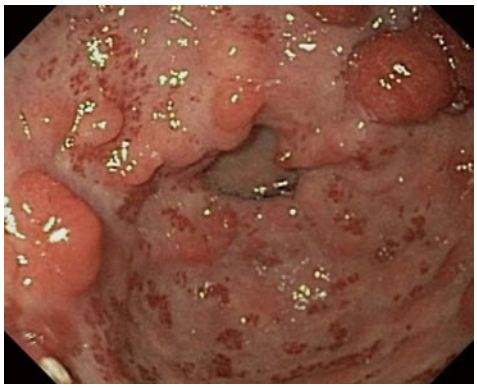

Figure 1 Multiple hyperplastic polyps in the setting of portal hypertensive gastropathy.

status (OR = 6.903; 95%CI: 1.40-33.93, *P* = 0.0174).

Long term follow-up

Out of 296 patients, 30 (10.1%) had a follow-up endoscopy with a mean duration of 26 ± 16.3 mo. Out of these 30 patients, 11 (36.6%) had hyperplastic polyps, 5 had chronic gastritis polyp, 4 had fundic gland polyp, two had intestinal metaplasia, two had carcinoid tumor, two had faveloar hyperplasia, one had adenomatous polyp and 3 patients were classified as other (gastric adenocarcinoma, brunner gland hyperplasia and normal pathology). Polyp's recurrence was noted in five out of eleven hyperplastic polyps and one out of four fundic gland polyps surveyed.

All Five adenomatous polyps were polypectomized during the initial endoscopy session. Four out of the five patients with adenomatous polyps were lost to follow-up in our system. Recurrence of the adenomatous polyp was noted in the one patient who had surveillance endoscopy.

Interval development of cancer was not noted in any of the patients during follow up period.

DISCUSSION

In this study, we found the prevalence of gastric polyps to be 4.7% in a predominantly Hispanic population, which is similar to the reported spectrum in previous series[1,13,16,17]. However, there is wide variation in the reported frequencies of different histological subtypes. Fundic gland polyps and hyperplastic polyps are the most prevalent types of gastric polyps in the current literature[1,2,16]. This was found in our study as well. We found 29% prevalence of hyperplastic polyps and 28% prevalence of fundic polyps. In addition, our data confirmed the positive association between *H. pylori* infection and hyperplastic polyps compared to fundic gland polyps.

There are several subtypes of gastric polyps which can be classified based on their endoscopic appearance or histopathological features. One of the most popular classifications is dividing the gastric polyps into two categories; epithelial and subepithelial. Epithelial polyps include fundic gland polyps, hyperplastic polyps, adenomatous polyps, polyps associated with familial adenomatous polyposis (FAP) and Peutz-Jeghers syndrome. Subepithelial polyps include gastrointestinal stromal tumors (GISTs]), inflammatory fibroid polyps, pancreatic heterotopia, leiomyomas, neuroendocrine tumors and granular cell tumors[17].

In our study, hyperplastic polyps were the most frequent subtype of polyps. We found a strong association between hyperplastic polyps, chronic gastritis and *H. pylori* infection which confirms what was reported in other studies[18,19]. A higher prevalence of *H. pylori* infection has been documented in Hispanics living in United States-Mexico border regions compared with non-border areas, which may explain the relatively high prevalence of hyperplastic polyps in our study population[14,15,20,21]. The risk of dysplasia and neoplastic progression of hyperplastic polyps is controversial with wide discrepancy between the reported rates (1.9% to 19%)[19,22-24]. However, this type of polyp has been reported to have an increased risk of neoplasia in the surrounding abnormal mucosa and is associated with higher incidence of synchronous gastric cancer[3,25]. In our series, 11 out of 87 patients who were found to have hyperplastic polyps, had follow-up endoscopy with a mean duration of 30 ± 18 mo. Five (45%) of these 11 patients were found to have residual polyps in follow up endoscopy and none (0%) of them developed dysplasia or cancer. Given this higher risk of developing adenocarcinoma in the surrounding mucosa of hyperplastic polyp, the guidelines recommend obtaining multiple biopsies of the intervening mucosa[26]. Polyp resection has been recommended for any hyperplastic polyp greater than 0.5 cm in size. Repeat surveillance endoscopy is recommended at 1 year after endoscopic resection[22,27,28]. Regression of hyperplastic polyps has been reported in many studies after effective treatment of *H. pylori* infection, it is thus essential to treat the patients with active *H. pylori* infection before entertaining any further management[18,19,29,30] (Figure 1).

FGPs were found to be the second most frequent type of polyp in our study population. The highest prevalence of fundic gland polyps was reported by Carmack *et al*[1] in a nationwide United States population from 2007-2008 in which FGP constituted 77% of the study cohort. FGP can be found sporadically or in patients with FAP syndrome[31,32]. Sporadic FGP has been reported in many studies to have a positive association with prolonged use of proton pump inhibitors (PPI)[33-36]. However, in other series this correlation was not confirmed[37,38]. Jalving *et al*[36] reported up to 4-times increased risk of fundic gland polyps with long-term proton pump inhibitor, and Ally *et al*[33] reported that the duration of PPI therapy greater than 4 years is an independent predictor for FGP development regardless of the used dosage. Due to the retrospective nature of our study, we were unable to obtain accurate data regarding PPI use among the study population. FGPs

have been reported to have a negative association with the presence of *H. pylori* infection[39]. This was found in our study as well. The risk of dysplasia in sporadic FGPs is rare, while it occurs in 25%-41% of FAP-associated polyps[31,40]. Biopsy of FGPs is recommended to exclude dysplasia or adenocarcinoma. Polyp resection is recommended for FGPs more than 1 cm in size to eliminate sampling error by missing any neoplastic foci within the polyp[26,41]. Further workup is recommended to exclude FAP in patients who are less than 40 years of age with numerous FGPs, or if the initial polyp biopsy showed dysplasia[26].

Raised Intraepithelial Neoplasia is the recent nomenclature for gastric adenomas as they are at increased risk for malignant transformation[3,42,43]. Three (60%) of the gastric adenomas in our study were associated with underlying atrophic gastritis and intestinal metaplasia which confirms what was reported in other studies[42,44]. The malignant potential of adenomatous polyps correlates with the polyp size and the age of the patient[3,24,45-47]. Polyps more than 2 cm in size had been reported to have higher risk of development of adenocarcinoma[3,45]. The guidelines recommend complete endoscopic removal of gastric adenomas or referral for surgical resection if lesions are not amenable to endoscopic resection or if they contain invasive carcinoma[26,27]. In addition, careful examination of the rest of the gastric mucosa and obtaining multiple biopsies is recommended to rule out any synchronous neoplastic process. In 2006, the American Society of Gastrointestinal Endoscopy guideline recommended endoscopic surveillance at 1 year for adenomatous polyps. The 2010 British Society of Gastroenterology guidelines recommended to repeat the endoscopic examination at 6 mo for incompletely resected adenomatous polyps or those with high grade dysplasia[26,27].

In our series, 20 (6.76%) patients were found to have portal hypertensive gastropathy. Half of these patients were found to have hyperplastic polyps. However, it has been reported that hyperplastic polyps in portal hypertensive patients are pathologically distinct from the typical hyperplastic polyps seen in nonportal hypertensive patients with uncertain malignant potential[48-52]. Management of portal hypertensive polyps is difficult as patients are at increased risk of post-polypectomy bleeding due to associated thrombocytopenia and coagulopathy. Conservative management and follow up endoscopy has been suggested as a safer strategy than multiple polypectomies[49,52].

There are some limitations to our study. One of the main drawbacks in our study is the lack of information on PPI use for the study cohort. As a result, we were unable to study the correlation between the various types of gastric polyps and PPI use. Second, this study was designed as a retrospective study with its obvious drawbacks. Although this study was performed in a unique practice setting on the United States-Mexico international border and the database used is significantly large, our results may not be applicable to all settings as our study is single-center study. However, one of the significant strengths of this study is the fact that the majority of the study population is Hispanic (85%) which may give more insight about the characteristics and the histopathologic features of gastric polyps in Hispanics.

In conclusion, the prevalence of gastric polyps in a predominantly Hispanic population is similar to what has been reported in the literature for other populations. Hyperplastic polyps were significantly associated with positive *H. pylori* status and portal hypersensitive gastropathy. Hyperplastic polyps and FGPs were more prevalent in chronic gastritis, while adenomatous polyps were associated with intestinal metaplasia.

COMMENTS

Background

Gastric polyps are usually asymptomatic and incidentally discovered during endoscopic examination. Determination of gastric polyp type is important as the risk for malignant transformation depends on the histopathological type.

Research frontiers

The relationship between *Helicobacter pylori* (*H. pylori*) and the different types of gastric polyps is not well studied.

Innovations and breakthroughs

This is one of a few studies focused on the prevalence and distribution of gastric polyps in Hispanic populations. Hyperplastic and fundic gland polyps accounted for more than half of the resected polyps in this study. Gastric hyperplastic polyps were significantly associated with positive *H. pylori* status and portal hypertensive gastropathy as compared with fundic gland polyps. Hyperplastic polyps and fundic gland polyps were more prevalent in chronic gastritis, while adenomatous polyps were associated with intestinal metaplasia.

Applications

When Hyperplastic polyp is suspected, biopsy of the surrounding mucosa should be done to rule out *H. pylori* infection. In case of an adenomatous polyp, biopsy of the surrounding mucosa should be done to rule out intestinal metaplasia.

Terminology

FGPs: Fundic Galnd Polyps; EGDs: Esophagogastroduodenoscopies.

Peer-review

The manuscript is concise, fluent and well-written. Strengths are the number of cases and the ethnicity orientation of the study group. The main drawback is that there is no new knowledge added, apart from ethnicity-targeted results. However, this is still of notice.

Abstract

Endoscopic management of biliary obstruction has evolved tremendously since the introduction of flexible fiberoptic endoscopes over 50 years ago. For the last several decades, endoscopic retrograde cholangiopancreatography (ERCP) has become established as the mainstay for definitively diagnosing and relieving biliary obstruction. In addition, and more recently, endoscopic ultrasonography (EUS) has gained increasing favor as an auxiliary diagnostic and therapeutic modality in facilitating decompression of the biliary tree. Here, we provide a review of the current and continually evolving role of gastrointestinal endoscopy, including both ERCP and EUS, in the management of biliary obstruction with a focus on benign biliary strictures.

Key words: Gastrointestinal endoscopy; Endoscopic cholangiopancreatography; Bile ducts; Biliary tract; Stricture; Stents

Core tip: Benign biliary strictures (BBSs) are commonly encountered by advanced endoscopists. As our understanding of longstanding techniques involving biliary dilation and plastic stent placement evolves, newer therapeutic options such as self-expandable metal stents and endoscopic ultrasound have become available. Here we review the literature pertaining to the most common etiologies of BBSs with current considerations for their respective endoscopic management.

INTRODUCTION

Benign biliary strictures (BBSs) originate from a variety of etiologies (Table 1), most commonly post-operative

Table 1 Etiologies of benign biliary strictures

Postsurgical
Cholecystectomy (open or laparoscopic)
Liver transplantation (*i.e.*, anastomotic biliary stricture)
Bilio-enteric anastomosis
Sphincterotomy
Inflammatory
Chronic pancreatitis
Primary sclerosing cholangitis
Immunoglobulin G4-related cholangiopathy
Acquired immune deficiency syndrome cholangiopathy
Vasculitis
Other
Ischemia (*e.g.*, post-liver transplantation)
Trauma
Portal biliopathy
Infection (*e.g.*, Clonorchiasis)
Radiation injury
Idiopathic

injury (*e.g.*, post-cholecystectomy), chronic pancreatitis, and chronic cholangiopathies (*e.g.*, primary sclerosing cholangitis). The clinical presentation of BBSs depends greatly on the context, including the onset, degree, and sterility of obstruction, and ranges from subclinical (*i.e.*, incidentally detected biochemical abnormalities) to severe and life-threatening[1,2]. The diagnostic evaluation to determine the etiology of a BBS and exclude the possibility of underlying malignancy generally entails cholangiography *via* magnetic resonance (MRCP) and/or endoscopic retrograde cholangiopancreatography (ERCP) (with biliary brushings for cytology and/or intraductal biopsies for histology) in addition to serologic testing with serum liver tests and tumor marker carbohydrate antigen 19-9 (CA 19-9). Therapeutic interventions are aimed at providing durable biliary decompression, with options including ERCP, percutaneous, and surgical techniques.

Given its efficacy, safety, and less disruptive nature, ERCP has become the first-line therapeutic option for management of most cases of biliary obstruction, including but not limited to BBSs[3]. Since the introduction of ERCP in the 1970s, this technique has progressively evolved and enhanced the management of a variety of disorders of the biliary tract[4]. Currently, a wide array of catheters, guidewires, papillotomes, stents, and other accessories are available to facilitate diagnostic and therapeutic maneuvers in the management of BBSs.

In this review, we discuss the current role of, evidence for, and approach to endoscopic management in patients with BBSs.

PRINCIPLES OF BBS MANAGEMENT

Pre-procedure preparation

Owing to advancements in non-invasive imaging, ERCP has largely been supplanted by cross-sectional imaging for purposes of initial diagnosis. MRCP, facilitated by the high T2-signal intensity of bile as well as improvements

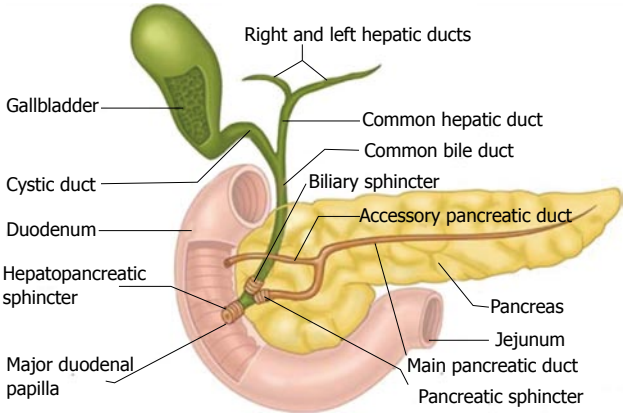

Figure 1 Normal biliopancreatic anatomy.

in MR imaging methods and post-processing tools, has essentially become the preferred modality for diagnostic cholangiography, with relatively few indications remaining for diagnostic ERCP[5]. Not all patients require cross-sectional imaging with MRCP or computed tomography prior to ERCP; however, having such data available can provide a useful roadmap and clarify the pre-procedural plan by shedding light on the patient's pancreatobiliary anatomy, which often does not follow the conventional teaching (Figure 1), and underlying disease. Patients who proceed to ERCP should, as with other endoscopic procedures, be fasting for a sufficient amount of time to allow gastric emptying (*e.g.*, 4-6 h), and careful review and management of antithrombotic medications (if applicable) should be undertaken[6]. Pre-procedural antibiotics should be administered in selected patients in whom adequate drainage is not anticipated such as those with complex hilar strictures and PSC.

Deep biliary access

Once bile duct cannulation has been achieved, attempts at guidewire passage beyond the BBS may prove challenging depending on the severity and anatomic location of obstruction. BBSs can be more difficult to traverse than neoplastic strictures due to greater asymmetry, angulation, and density of fibrous tissue[7]; nevertheless, forceful maneuvers should be avoided, as these may result in the creation of a false tract or perforation. If necessary, guidewire passage can be facilitated by: (1) positioning an inflated stone extraction balloon just below the stricture and withdrawing it, which allows for traction and better alignment between the guidewire and stricture axes; or by (2) selection of an alternative guidewire tailored to the particular stricture anatomy.

Multiple types of guidewires are commercially available and vary in their properties, including diameter, construction material (nitinol, stainless steel), type of coating (hydrophilic *vs* nonhydrophilic), and tip morphology (straight, angled) (Table 2). Comparative studies between guidewires are lacking, but standard 0.035-inch hydrophilic guidewires can be used for most BBSs, whereas tighter strictures may require

Table 2 Commonly used guidewires in endoscopic retrograde cholangiopancreatography

	Diameter (inch)	Length (cm)	Core material	Sheath material	Tip material/ properties	Tip shape	Comments	Cost ($)
Monofilament								
Amplatz (Boston Scientific)	0.038	260	Stainless steel	Uncoated	Platinum	Straight	Extremely stiff	149[1]
Coiled								
Standard (Cook Medical)	0.035	480	Stainless steel	Uncoated	Stainless steel coil	Straight	Must remove prior to sphincterotomy	90
Coated								
Tracer metro direct (Cook Medical)	0.021, 0.025, 0.035	260, 480	Nitinol	Teflon	Platinum; hydrophilic (5 cm)	Straight, angled	Kink resistant, graduated endoscopic markings	196
Delta (Cook Medical)	0.025, 0.035	260	Nitinol	Polyurethane	Hydrophilic (fully)	Straight	Kink resistant, fully hydrophilic, must remove prior to sphincterotomy	151
Roadrunner (Cook Medical)	0.018	260, 480	Nitinol	Teflon	Platinum	Straight, angled	Kink resistant, must remove prior to sphincterotomy	184
Jagwire (Boston Scientific)	0.025, 0.035 0.038 (260)	260, 480	Nitinol	Endo-Glide™	Tungsten, hydrophilic (5 cm)	Straight, angled; trim, round	Kink resistant, guidewire extension (0.035, 200) available	357/box of 2
Hydra Jagwire (Boston Scientific)	0.035	260, 450	Nitinol	Endo-Glide™	Tungsten, two hydrophilic tips (5 cm, 10 cm)	Straight, angled; round	Kink resistant; two tips of varying stiffness on a single guidewire	536/box of 2
NaviPro (Boston Scientific)	0.018, 0.025, 0.035	260	Nitinol	Endo-Glide™	Hydrophilic (fully)	Straight, angled	Fully hydrophilic; 0.035-in also available in stiff	1124/box of 5
Visiglide (Olympus)	0.025, 0.035	270, 450	Superelastic alloy	Fluorine	Hydrophilic (7 cm)	Straight; angled	0.025-in has same stiffness as 0.035-in guidewire	255
XWire (ConMed)	0.025, 0.035	260, 450	Regiliant™ Nitinol	PTFE	Nitinol and Tungsten and PTFE, hydrophilic (5 cm)	Straight; angled	5cm radiopaque tip; 0.035-in also available in stiff	460/box of 3 (260 cm) 583/box of 3 (450 cm)

Other less commonly used guidewires include Dreamwire (Boston Scientific), Savary-Gilliard (Cook Medical), Tracer Metro (Cook Medical), Fusion (Cook Medical), FXWire (ConMed), and Flex-Ez (Hobbs Medical). [1]Cost data obtained from ASGE "Guidewires for use in GI endoscopy," Table 1[97]. PTFE: Polytetrafluoroethylene.

guidewires with a smaller diameter and/or angled tip. Once a stricture has been traversed, the guidewire can be exchanged, if needed, for a stiffer or nonhydrophilic guidewire to facilitate dilation and stenting. Biliary sphincterotomy (*i.e.*, papillotomy) is also frequently necessary if large (cumulative) caliber stenting is anticipated.

Stricture dilation

Stricture dilation (*i.e.*, stricturoplasty) is primarily performed using a dilating balloon or bougie-like tapered catheter. Typical dilating balloon sizes range from 4 to 12 mm, and selection can generally be guided by upsizing 1-2 mm from the diameter of the distal bile duct. In the case of post-liver transplantation (LT) anastomotic biliary strictures (ABSs), dilating to the size of the adjacent donor or recipient duct, whichever is smaller, can be used as a guide[8]. Particular caution should be taken, however, when dilating ABSs during the early post-operative period (< 30 d after surgery) or while a patient is still on high dose immunosuppression, as both of these scenarios may be associated with a higher risk for anastomotic injury or disruption[8-12]. In such instances, less aggressive dilation using a smaller balloon or alternatively a tapered dilating catheter is advisable. With respect to duration of dilation intraprocedurally, most endoscopists adhere to 30 to 60 s of dilation, or until the stricture waist is fractured, before balloon deflation.

Stenting

Balloon dilation alone, although immediately effective, is associated with a high rate of stricture recurrence (up to 47%) depending on the underlying nature of the BBS[13]. Therefore, insertion of biliary stents is frequently required to maintain stricture patency while permitting ductal remodeling. Moreover, placement of several, large-bore plastic stents side-by-side (*i.e.*, multiple or "maximal" endoscopic stenting[8,14]) for up to 1 year has been shown to be superior than inserting only a single stent; this is therefore the currently recommended approach for the majority of BBSs[8,14-18].

The main limitation of endoscopic stenting in this setting is the need to undergo multiple ERCPs for stent exchange. This stems from the relatively short patency time of plastic biliary stents, although there is evidence to support that occlusion rates are similar between stents with dwell times shorter and longer than 6 mo[19]. In addition, and as alluded to above, placement of maximal stents may lessen the need

Table 3 Commonly used partially-covered and fully-covered self-expandable metal stents

Stent name (manufacturer)	Covering	Core material	Diameter (mm)	Length (cm)	Delivery system (Fr)	Features
Wallflex RX	Partial	Platinol	8, 10	4, 6, 8	8.5	Closed cell construction; retrieval loop; looped and flared ends; restrainable
(Boston Scientific)	Full	Platinol	8, 10	4, 6, 8	8.5	
Wallstent (Boston Scientific)	Partial	Elgiloy	8, 10, 12	2, 4, 4.2, 6, 6.8, 8, 9, 9.4	6, 7, 9	Closed cell construction; restrainable
Niti-S ComVi (Taewoong Medical)	Partial	Nitinol	6, 8, 10	4, 5, 6, 7, 8, 9, 10, 12	8	Open cell; triple layered construction: mesh, membrane, and mesh to reduce migration
	Full	Nitinol	6, 8, 10	4, 5, 6, 7, 8, 9, 10, 12	8	
Niti-S Kaffes (Taewoong Medical)	Full	Nitinol	6, 8, 10	4, 5, 6, 7, 8	9	Long retrieval string
Niti-S (Taewoong Medical)	Partial	Nitinol	6, 8, 10	4, 5, 6, 7, 8, 9, 10, 12	8	Retrieval string at proximal end
	Full	Nitinol	6, 8, 10	4, 5, 6, 7, 8, 9, 10, 12	8.5	
Niti-S Bumpy (Taewoong Medical)	Full	Nitinol	6, 8, 10	4, 5, 6, 7, 8, 9, 10, 12	8.5	Irregular cell sizes; retrieval string at proximal end; flared ends
Nitinella Plus (ELLA-CS)	Partial	Nitinol	8, 10	4, 6, 8, 10	9	Reconstrainable; kink-resistant
	Full	Nitinol	8, 10	4, 6, 8, 10	9	
Hanarostent (M.I. Tech)	Full	Nitinol	8, 10	4, 6, 8, 10	8	Larger flared ends
Micro-Tech (Micro-Tech)	Partial	Nitinol	10	4, 6, 8, 10	9	
	Full	Nitinol	10	4, 6, 8	9	
Gore Viabil (CONMED)	Full (with sideholes)	Nitinol	8, 10	6, 8, 10	8.5	Sideholes allow branch drainage; anchoring fins
	Full (without sideholes)	Nitinol	8, 10	6, 8, 10	8.5	
Allium BIS (Allium Medical)	Full	Nitinol	8, 10	6, 8, 10, 12	10	Anchoring segment; non-shortening

for frequent stent exchange, as biliary drainage can continue to occur even after stent occlusion *via* the inter-stent spaces (*i.e.*, "wick effect")[8]. Avoiding multiple ERCPs can also be facilitated by placement of one or more (covered) self-expandable metal stents (SEMSs) instead of plastic stents. SEMSs offer an attractive alternative because of innate properties that allow them to self-expand to diameters 3 times that of 10-Fr plastic stents, thus resulting in longer duration of patency. SEMSs can also be delivered using smaller deployment systems (*i.e.*, 8-8.5-Fr) that do not require as aggressive dilation at the time of stent placement or biliary sphincterotomy. SEMSs of various configurations and properties are currently available[1]; to date, however, none are approved by the United States Food and Drug Administration for the treatment of BBSs. The three major categories of stents, uncovered, partially-covered, and fully-covered, are briefly reviewed below.

Uncovered SEMSs are plagued by the ingrowth of reactive tissue (*i.e.*, epithelial hyperplasia), which can lead to stent occlusion as well as irretrievable embedding of a stent in the ductal wall[20]. As a result, uncovered SEMSs should not be used in the treatment of BBSs[17]. Partially-covered stents, which leave proximal and distal ends bare, are consequently less prone to becoming embedded in issue and thus have improved ease of retrieval. In the largest study of partially-covered SEMSs used to treat BBSs of various etiologies (n = 79), Kahaleh *et al*[21] reported a stricture resolution rate of 90% following a 4-mo stenting period and 12-mo follow-up time. Although all attempted stent retrievals were successful in this study, the potential for tissue hyperplasia involving the bare ends, as reported in other studies, still exists[22,23]. In an effort to further reduce the risk of stent ingrowth and improve removability, fully-covered SEMSs (lined with silicone, polyether polyurethane, polyurethane, expanded polytetrafluoroethylene, or other materials) have been developed and investigated in the treatment of BBSs (Table 3). Most studies of fully-covered SEMSs, barring those with a predominance of patients with particularly refractory strictures (*e.g.*, chronic pancreatitis), have reported favorable clinical success rates, ranging 80% to 90%, as well as low recurrence rates ($\leqslant$ 10%)[24-33]. A tradeoff of this stent design, however, is their predilection for migration, with several studies reporting fully-covered SEMS migration rates between 20% to 40%[24,25,28,31-33]. Of particular concern is the potential for a migrated SEMS to complicate stent removal (proximal migration) or cause bowel obstruction (distal migration). Recent studies investigating anti-migratory modifications to fully-covered SEMSs (*e.g.*, anchoring fins) have reported reduced albeit not clinically insignificant rates of migration[27,29,30]. The role of fully-covered and partially-covered SEMSs is described further in forthcoming sections.

CONSIDERATIONS FOR SPECIFIC BBS ETIOLOGIES

Post-operative strictures

Post-cholecystectomy: Cholecystectomy remains a common etiology of BBSs, with an incidence of 0.2% to 0.7% among patients undergoing laparoscopic cholecystectomy[34]. Post-cholecystectomy BBSs develop as a consequence of bile duct injury that may occur intraoperatively (dissection, electrocautery, clip

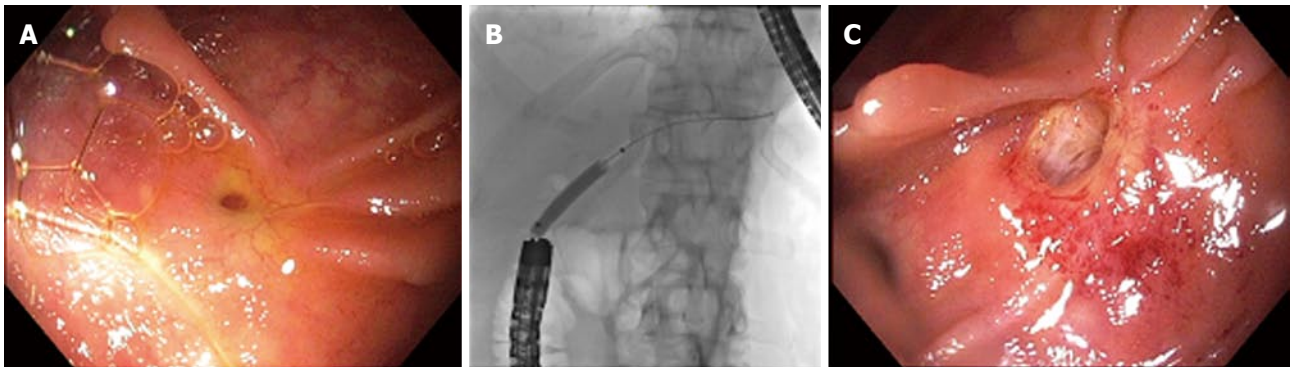

Figure 2 Anastomotic biliary stricture at the site of hepaticojejunostomy in a liver transplantation patient. A: Endoscopic view of hepaticojejunal anastomotic biliary stricture; B: Radiographic image taken during balloon dilation demonstrating the stricture waist; C: Endoscopic view immediately post-dilation of the anastomotic biliary stricture.

or suture placement, ligation) and/or post-operatively (adhesion formation)[35]. Long-term data of post-operative BBSs treated with multiple plastic stents and intermittent stent exchange (approximately every 3 mo) over the course of a year have demonstrated promising success rates ranging from 80% to 100%[15,18,36,37]. This approach has thus become the current standard of care when treating post-operative BBSs[38]. It should be noted, however, that post-operative strictures located at the hepatic ductal confluence may be less responsive to endoscopic stenting than strictures located more distally (25% *vs* 80% resolution rate)[15].

There are limited data regarding the use of fully-covered and partially-covered SEMSs in the treatment of post-cholecystectomy strictures. These data are derived from a small subset of patients with post-cholecystectomy strictures included in SEMSs studies. For example, in a large, multicenter study of fully-covered SEMS (n = 187), 18 patients with post-cholecystectomy strictures (14 of which were previously treated with plastic biliary stents) underwent SEMS placement. After 10-12 mo of stenting, 13 patients (72%) experienced stricture resolution without need for immediate re-stenting. Two-thirds, however, experienced stent migration by 12 mo, and 6 patients (33%) experienced cholangitis, fever or pancreatitis[39]. Based on these findings, SEMSs cannot be routinely recommended for treatment of post-cholecystectomy strictures.

Post-LT: Among patients who have undergone LT, BBSs are among the most common post-operative complications, with their incidence ranging from 5% to 15% and 28% to 32% following deceased donor and living donor LT, respectively, and even higher rates in cardiac death donor LT[12,40,41]. Post-LT BBSs can manifest early (< 30-90 d) or late (> 90 d) in the post-LT course and may occur at the anastomosis (*i.e.*, ABS) or elsewhere in the biliary tree (*i.e.*, non-anastomotic biliary stricture, NABS). Endoscopic therapy is the first line management approach for ABSs and for select NABSs, with percutaneous intervention and surgical revision or redo-LT being reserved for endoscopic treatment failures. ABSs and NABSs are further discussed below.

ABSs are a consequence of local trauma at the surgical juncture between the recipient's and donor's extrahepatic ducts (most commonly CBD-CBD choledocho-choledochostomy) and account for 80% of post-LT biliary strictures[42]. They appear as a short, single stricture localized to the anastomosis. Earlier presentations (< 30-90 d) generally respond well to endoscopic dilation (Figure 2) and a relatively brief period of plastic stenting (approximately 3 to 6 mo), whereas later presentations may require up to 1-2 years of stenting to avoid stricture recurrence based on the few available published series[42-44]. Unfortunately, most studies regarding management of ABSs are retrospective and heterogeneous (*e.g.*, in stricture etiology, severity, and other variables), yet several have shown consistent long-term success rates of approaching 90% to 100% with balloon dilation and multiple or maximal plastic stent therapy[8,45-49]. ABSs may also be treated with SEMSs, but this has been less studied and seldom practiced for a variety of reasons[23-26]. For example, a multicenter trial of partially-covered SEMSs was associated with a modest long-term success rate of 53%, and removal of the stent was technically demanding in 6 out of 21 (29%) patients due to embedding of the bare ends[23]. Conversely, studies using fully-covered SEMSs have reported more promising success rates (ostensibly due to longer dwell times), ranging 92% to 100%, but with higher stent migration rates (as high as 24%)[24-26].

NABSs account for 10%-25% of post-LT biliary strictures[50,51] and are typically a sequela of donor-recipient ABO incompatibility, prolonged graft ischemic time peri-LT, or post-LT hepatic artery thrombosis[52]. NABSs are often referred to as ischemic strictures, although it should be noted that not all NABSs have a clearly ischemic etiology. In contrast to ABSs, NABSs may be either unifocal or distributed diffusely throughout the extra- and/or intrahepatic biliary tree (Figure 3), are more technically challenging to access and treat, and have lower long-term endoscopic treatment success rates (50% to 75%)[45,53]. Nevertheless, maximal

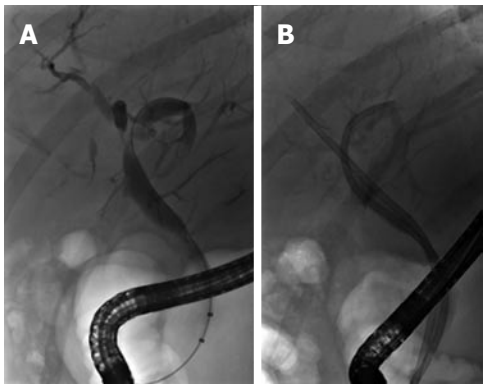

Figure 3 Anastomotic and nonanastomotic biliary strictures in a liver transplantation patient. A: Anastomotic biliary stricture and hilar nonanastomotic biliary strictures are present; B: Radiographic image taken immediately following placement of a 10-Fr 15 cm Cotton-Leung (Cook Medical) and a 10-Fr 22 cm (cut down to 16 cm) Johlin (Cook Medical) plastic biliary stent.

stenting, as with ABS, may result in graft preservation and overall favorable outcomes in a considerable proportion of patients with NABSs[14,45,53-55], although some will ultimately require re-transplantation[10,45,56].

Chronic pancreatitis

BBSs develop in approximately 25% of patients with chronic pancreatitis and represent a major clinical challenge[1]. These strictures occur in the distal CBD, and their refractory nature is largely attributable to robust periductal fibrosis secondary to the underlying chronic inflammatory process[57]. It is important to rule out underlying malignancy in this context, as it can have an initial presentation similar to BBSs and pancreatic cancer can occur in the setting of established chronic pancreatitis. With respect to treatment of chronic pancreatitis-associated BBS, biliary decompression is indicated in patients who are symptomatic (*e.g.*, cholangitic, deeply jaundiced), and as with post-operative BBSs, insertion of multiple plastic stents with 3-4 exchanges over a year appears to offer the highest likelihood of long-term benefit. Studies range in overall success of endoscopic therapy from 44% to 92%, with lower rates among those with dystrophic calcification of the pancreatic head[15,58-60]. Surgical intervention (*e.g.*, Puestow pancreaticojejunostomy, Traverso-Longmire pancreaticoduodenectomy[61]) is indicated in patients who fail endoscopic management and are fit for surgery[57,60].

A number of studies have investigated the role of fully as well as partially-covered SEMSs in chronic pancreatitis. Fully-covered SEMSs have demonstrated success rates ranging from 43% to 77% in patients with chronic pancreatitis-associated BBSs, but stent migration have historically been a common problem, as is the case with post-operative BBSs[21,27,62,63]. A recent, multicenter study of 118 patients with chronic pancreatitis-associated BBSs, however, found that fully-covered SEMS placement was associated with an 80% stricture resolution rate (median stent dwell time 11 mo) and a more acceptable stent migration rate (19% at 12 mo)[39]. Studies using fully-covered SEMSs with antimigratory modifications, or partially-covered SEMSs, have also reported encouraging stricture resolution rates (approximately 90%), and with even lower rates of stent migration[29,63,64].

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is an idiopathic disorder characterized by periductal inflammation and fibrosis involving the intrahepatic and/or extrahepatic biliary tree. Up to 50% of patients with PSC will develop "dominant" strictures, which are loosely defined as a CBD stenosis of $\leqslant$ 1.5 mm in diameter or hepatic duct stenosis $\leqslant$ 1 mm in diameter, during their disease course[65,66]. A major challenge in the setting of a PSC-associated dominant stricture is excluding underlying malignancy (*i.e.*, cholangiocarcinoma), which develops in up to 20% of patients with PSC[67-70]. At a minimum, brush cytology and/or intraductal biopsies, are required. If available, advanced cytologic and imaging methods should also be considered.

The overarching goal of endoscopic therapy in PSC-associated dominant BBSs is to improve signs, symptoms and sequelae of biliary obstruction; when performed appropriately (including both patient selection and procedural technique), endoscopic therapy can improve Mayo PSC risk score, which has been shown to translate into improved survival[68,71-74]. Biliary (balloon) dilation alone is the preferred therapeutic approach, as stenting has been shown to result in slightly higher rates of complications (*i.e.*, stent occlusion and cholangitis) in some series[75,76]. Repeated dilation (*i.e.*, multiple ERCP sessions) may be necessary in some patients to achieve maximal clinical benefit[77]. If dilation is unsuccessful (*i.e.*, persistent stricture waist), short-term stentings with plastic biliary stents has been shown to be safe and effective with durable benefit[78]. Prophylactic antibiotics should also be administered periprocedurally to reduce the risk of ERCP-related cholangitis unless full biliary drainage is highly anticipated[79,80].

Altered anatomy after hepatobiliary surgery

Biliary-enteric strictures can occur following pancreaticoduodenectomy (Whipple procedure), partial liver resection, and liver transplantation with Roux-en-Y hepaticojejunostomy in 12%-28% of patients[81,82]. Endoscopic therapy of these strictures was once felt to be impossible due to surgical alterations in intestinal anatomy that precluded access *via* conventional endoscopic methods. However, the use of colonoscopes and more recently, device-assisted enteroscopes (single, double, and short double balloon), combined with more widespread training of advanced endoscopists have brought these strictures within reach[83]. In patients post-standard Whipple, the hepaticojejunostomy is almost always reachable, whereas pylorus preserving Whipple, and choledocho- and hepaticojejunostomy

Roux-en-Y render more challenging, but often still conquerable anatomy in the hands of an experienced endoscopist with balloon-enteroscopes. A recent meta-analysis included 15 studies and 461 patients with surgically altered pancreaticobiliary anatomy (Roux-en-Y bypass, Roux-en-Y reconstruction, and standard and pylorus preserving Whipple) undergoing single-balloon enteroscopy-assisted ERCP. The pooled enteroscopy, diagnostic, and procedural success rates were 81%, 69%, and 62%, though a high degree of heterogeneity was reported[84]. Limiting analysis to patients with Roux-en-Y reconstruction or Whipple yielded higher diagnostic and procedural success rates at 79% and 63% with much lower heterogeneity[85]. In a retrospective study of patients with biliary-enteric strictures following surgical repair of iatrogenic cholecystostomy injuries (n = 32), Lee *et al*[86] reported balloon dilation alone to be successful in 66% of patients with only 1 (5%) recurrence over a mean 13.1 years of follow-up.

An endoscopic approach can be limited by time, availability, and endoscopist expertise. When unsuccessful, percutaneous transhepatic access (with or without rendezvous techniques)[86], percutaneous drains, and surgical revision remain alternative therapeutic options.

ENDOSCOPIC ULTRASOUND IN BBS MANAGEMENT

Even in expert hands, attempts at therapeutic ERCP for BBSs may fail in 2% to 10% of cases due to inability to cannulate the bile duct (*e.g.*, surgically altered anatomy, tumor infiltration) or traverse a tight bile duct stricture. In select cases, endoscopic ultrasound (EUS) may serve as ancillary therapeutic techniques prior to proceeding with options such as percutaneous or surgical intervention. EUS can be employed in a rendezvous technique that establishes transpapillary guidewire access, thereby allowing conventional ERCP with balloon dilation of a BBS followed by stent placement (if indicated).

EUS-guided biliary access and drainage can also be performed by needle puncture of the gastric wall and advancement into the left hepatic duct tributaries (*i.e.*, hepaticogastrostomy)[87-90] or through the duodenal wall into the CBD (*i.e.*, choledochoduodenostomy)[91,92]. Thereafter, drainage can be internalized through the papilla without requiring a rendezvous approach (although combination approaches can be useful as well)[93,94]. As alluded to before, this technique is particularly useful when biliary cannulation or access to the papilla cannot be achieved due to duodenal obstruction or other causes[95,96].

Adverse events

Adverse events related to endoscopic management of biliary strictures may occur secondary to stricture access or dilation, and stent placement or dwell time (early or late). Sphincterotomy can be associated with pancreatitis, luminal perforation, or bleeding, as seen in patients undergoing ERCP for other indications. Stricture dilation (particularly in the setting of a fresh surgical anastomosis) and stent deployment also run the risk of perforation. Stent-related adverse events include early or late migration, impaction or embedment (metal stents), or occlusion with the potential for cholangitis. Plastic stents therefore necessitate removal or exchange in 3 mo with concurrent removal of all stones and sludge.

CONCLUSION

Endoscopic therapy provides a minimally invasive, safe, and reliable first-line management option for most BBSs. An approach involving multiple plastic stent placement and intermittent stent exchanges works well in post-cholecystectomy strictures and ABSs, whereas other stricture types, such as NABSs and chronic pancreatitis-associated strictures, tend to be more challenging, with some patients ultimately requiring surgical intervention. The recent and rapid evolution of SEMSs may provide an alternative means to treat some BBSs while reducing the need for frequent ERCPs, but additional studies that better define their application, complications, and cost-effectiveness remain needed. Lastly, applications of therapeutic EUS for biliary disease are becoming increasingly recognized and implemented, and continued advancements in both ERCP and EUS are anticipated.

Abstract

In the present review we have analyzed the clinical applications of endoscopic ultrasound-guided-fine-needle-aspiration (EUS-FNA) and the methodological aspects obtained by cell-block procedure (CBP) in the diagnostic approach to the gastrointestinal neoplastic pathology. CBP showed numerous advantages in comparison to the cytologic routine smears; in particular, better preservation of cell architecture, achievement of routine haematoxylin-eosin staining equivalent to histological slides and possibility to perform immunohistochemistry or molecular analyses represented the most evident reasons to choose this method. Moreover, by this approach, the differential diagnosis of solid gastrointestinal neoplasias may be more easily achieved and the background of contaminant non-neoplastic gastrointestinal avoided. Finally, biological samples collected by EUS-FNA CBP-assisted should be investigated in order to identify and quantify further potential molecular markers.

Key words: Endoscopic ultrasound-guided-fine-needle-aspiration; Cell-block procedure; Gastrointestinal tract; Immunohistochemistry; Diagnosis

Core tip: Cell-block procedure (CBP) represents the most suitable complement in diagnostic cytopathology of many gastrointestinal lesions. Hence this method allows high quality morphological evaluation and immunocytochemical analyses. On this way, the differential diagnosis of solid gastrointestinal neoplasms may be more easily achieved and the background of contaminant non-neoplastic gastrointestinal avoided, with an evident gain compared to the traditional cytological techniques. In the present review, the application of CBP in gastrointestinal solid lesions approached by endoscopic ultrasound-guided-fine-needle-aspiration, the methodological aspects and the accuracy of this diagnostic process are analyzed and discussed.

INTRODUCTION

Endoscopic ultrasound-guided-fine-needle-aspiration (EUS-FNA) represents a useful diagnostic procedure in the field of gastrointestinal pathology[1-3]. It is performed by using a curved linear array video-echo-endoscope equipped with various needles which provide cytological samples; in this way, the ability to obtain cytologic material is greatly increased due to direct visualization, with a consequent better opportunity to perform an accurate diagnosis. Since its introduction, EUS-FNA emerged as a minimally-invasive, safe and accurate technique for the diagnosis of various luminal, submucosal and extra luminal gastrointestinal neoplasms[4].

The European Society of Gastrointestinal Endoscopy published the guidelines for EUS-guided sampling, with comments on the technical prerequisites for maximizing the diagnostic yield of this procedure[5]. However, the acquisition of diagnostic samples should be approached in different ways depending on the type of the lesion. Moreover, the actual efficacy of EUS-FNA partly depends on the site, size and characteristics of the target tissue as well as on the expertise, training and interaction between endosonographer and cytopathologist[6,7].

Cell-block procedure (CBP) is a diagnostic tool which has been carried out by using different procedural steps and protocols over the years[7-11]. This technique presents several advantages compared to the cytologic routine smear: preservation of cell architecture, achievement of routine haematoxylin-eosin staining equivalent to that of surgical samples and, finally, the possibility to perform ancillary methods, such as immunohistochemistry or molecular analyses[7,8,12,13]. In particular, CBP allows the availability of an adequate number of serial sections, with increased possibility to detect malignant cells and contaminating or reactive non-neoplastic elements[6,7,13].

Aims of the present review are to discuss the application of CBP in gastrointestinal solid lesions approached by EUS-FNA and to analyze the methodological aspects and accuracy of this diagnostic process.

Methodological aspects of EUS-FNA

One of the most debated issues on EUS-FNA relates to the number of needle passes required to provide adequate diagnostic material. The presence of a well trained cytopathologist, able to evaluate the quality of samples, is probably crucial in order to decrease the number of unsatisfactory results and to reduce the need for additional passes. Indeed, the prompt cytopathology response may be useful for the endosonographer to know whether the needle aspirate is diagnostic or not[2,4,14-19]. Although it has been repeatedly reported that on-site cytological evaluation improves the diagnostic yield and accuracy of EUS-FNA, other factors, such as the localization, nature, presentation, size and sonography characteristics of the lesion, may influence the number of needle passes[2-4,20]. In detail, the percentage of adequate specimens and sensitivity of EUS-FNA are lower in intra-parietal lesions of the gastrointestinal tract (GI) compared to those of lesions in other sites[1,21,22]. In addition, the diagnostic yield and accuracy for EUS-FNA also depend on the size of the lesion and they are significantly lower in lesions less than 10 mm in size[1,23,24]. On the whole, two to five needle passes are considered to be sufficient to obtain enough diagnostic material for a correct diagnosis by EUS-FNA[2,3,20,22,25,26]. The needle size is another relevant factor. 19-G needle seems to be the most adequate to provide higher amount of diagnostic material, especially when the cytopathologist is not present in the endoscopy room. Nonetheless the 22-G or 25-G are the most commonly used needles for the cytological sampling of gastrointestinal lesions because of their easier penetration without any further complications[2,16,27,28].

Finally, a special technical training in EUS-FNA should be mandatory, as recommended by the American Society of Gastrointestinal Endoscopy which codifies the minimum number of cases that should be analyzed depending on the site of lesion[29-31].

Needle-based confocal laser endomicroscopy (CLE) is a novel endoscopic method, in which imaging is based on tissue illumination and detection of tissue-reflected fluorescence; interestingly this technique gives high-quality images which are similar to those obtained by traditional histology[32-34]. The development of tissue specific contrast agents might further extend the application of CLE to pancreatic masses, either solid or cystic, intra-parietal or submucosal gastric and esophageal tumours, biliary tract and ampullary lesions[2,33,35].

Methodological aspects and advantages of CBP

CBP has been extensively used in cytology as a helpful tool to achieve a definitive diagnosis[8-10,36,37]. CBP may be carried out by using different protocols based on various fixatives and embedding techniques[8,10,38-40].

In the manual traditional method, following the rapid on-site evaluation of specimen adequacy and preliminary cytological diagnosis by quick stains, the needles and syringes used in the procedure are rinsed with 10 mL of 50% ethanol into a special container in order to recover further material. All content is centrifuged in a 10 mL disposable centrifuge tube at 4000 rpm for 6 min to create 1 or 2 pellets; the

supernatant fluid is decanted and the pelleted material obtained by sedimentation is immediately fixed in a freshly prepared solution of 4% neutral buffered formalin for 45 min. Then, the cell pellets are placed in a cassette and stored at 80% ethanol until they are ready for processing in an automatic tissue processor[36].

CBP may be based on thrombin or albumin methods. In the former, six drops of discarded human plasma and six drops of thromboplastin-DS are added to the cell sediment in order to form a clot, while in the latter 3-4 drops of 22% bovine albumin and 95% ethanol are added to the cell sediment to form a precipitate[9,41]. Whatever is the method, clots or/and precipitates are embedded in paraffin at 56 ℃ to realize cell blocks which are cut into 3 μm thick sections routinely stained with H and E or mounted on poly-lysine-coated glasses for immunocytochemical and molecular procedures.

A novel automated method for cell block production is the Cellient™ Automated Cell Block System. Compared to the traditional manual method, the automated one allows to achieve higher cellularity and better cellular presentation in terms of architecture and details; in addition it is faster and more reliable due to lack of operator dependency[9,39,42]. Gorman and coll. showed that Cellient cell blocks gives an adequate cellularity in all the analyzed cases, while formalin and thrombin cell blocks show a progressively decreasing adequacy[37]. The main drawback of Cellient system is methanol-based fixation, which may have negative impact on the following immunohistochemical analysis[8,9]. Indeed weaker staining intensity for ER, PR, MIB-1 and HER2 was shown by using this procedure[8,37,43,44]. However this issue may be overcome by formalin pre-fixation prior to Cellient[9]. Thirty minutes pre-fixation seems to be preferable to longer fixation to ensure good morphological quality[9].

On the whole, CBP allows the collection of higher quantity of diagnostic material. Hence it may be relevant in reducing the false negative diagnoses in EUS-FNA, which may depend, not only on erroneous interpretation of the cytological samples, but also on the availability of low cytological material. In addition it was shown that CBP greatly increases the diagnostic accuracy of EUS-FNA[7,22]. CBP also represents the most appropriate method to obtain cytological preparations for subsequent immunocytochemistry. Indeed immuno-stains on CBP sections show minimal background and appear similar to those observed in surgical pathology material. In addition, numerous serial sections may be obtained from a single cell block, allowing the evaluation of a large spectrum of antigens, also in archival samples. The number of antibodies that can be applied in routinely CBP has been expanding over the years[2,3,7-9,13,37]. The possibility to test serial sections with different antibodies may allow to identify and discriminate gastrointestinal hyperplastic or reactive contaminating cells from well differentiated tumour cells[7,13,45].

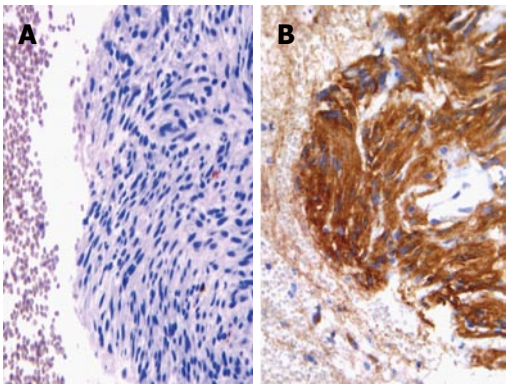

Figure 1 Cell block from gastrointestinal stromal tumour exhibiting aggregates of spindle cells with elongated nuclei (haematoxylin-eosin, × 200) (A), with an evident immunoreactivity for CD117 (immunoperoxidase, × 200, Mayer's Haemalum nuclear counterstain) (B).

CLINICAL APPLICATION OF EUS-FNA CBP-ASSISTED IN GI TRACT

Subepithelial/intramural neoplasms of the gastrointestinal wall

Although conventional endoscopy, CT scan and MRI may identify subepithelial/intramural lesions in the gastrointestinal wall, they can not reveal the nature and origin of those lesions. A wide range of subepithelial tumours, such as leiomyomas, neurinomas, granular cells tumours, gastrointestinal stromal tumours (GISTs), neuroendocrine tumours, leiomyosarcomas and lymphomas, may involve the GI tract[1,6,46] and many of those neoplastic entities exhibited over-lapping cytological features[6,46], being composed by monomorphic, uniform spindle shaped cells with eosinophilic cytoplasm, vesicular elongated nuclei characterized by finely granular chromatin, sometimes dispersed and inconspicuous nucleoli (Figure 1A). For this reason, the use of immunocytochemistry, which is easily applicable to CBP, may be helpful for the differential diagnosis. In detail, the coexistence of smooth muscle actin and desmin stains strongly supports the muscle origin of the lesion, while positivity for CD-34, CD-117 (Figure 1B) or S-100 suggests other diagnostic hypotheses, such as inflammatory fibroid polyp, GIST or schwannoma[6,46,47]. The assessment of the growth fraction by using Ki-67 labeling index (Figure 2A) may further discriminate the benign or malignant nature of intra-parietal neoplasias, and may allow distinction among leiomyoma, leiomyosarcoma, spindle cells amelanotic melanoma or undifferentiated sarcomatoid carcinoma[6,46,48].

The great efficacy of EUS-FNA associated with the higher accuracy obtained by CBP are helpful to achieve the correct preoperative diagnosis of a sub-epithelial mass which is relevant to establish the operative planning and type of surgery, and to avoid unnecessary procedures for extensive malignant lesions[6,46,49]. In addition, periodic follow-up with EUS is considered to be more acceptable to evaluate eventual changes in

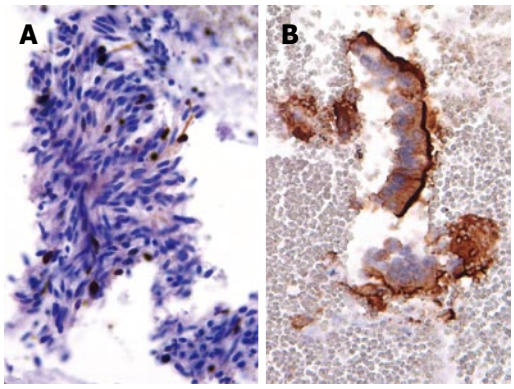

Figure 2 Spindle cells of gastric gastrointestinal stromal tumour documented only a sporadic nuclear Ki67 immunopositivity (immunoperoxidase, × 400, Mayer's Haemalum nuclear counterstain) (A) in benign contaminant gastrointestinal cells, the apical cytoplasm showed a peculiar CD10 immunoreactivity (immunoperoxidase, × 400, Mayer's Haemalum nuclear counterstain) (B).

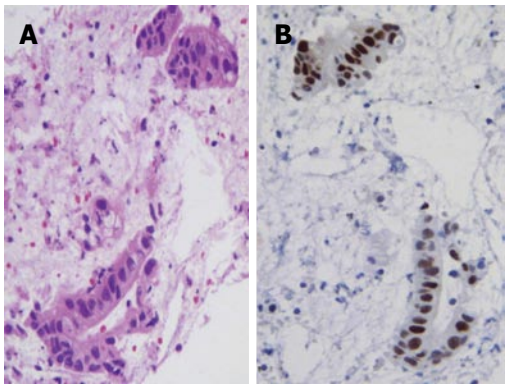

Figure 3 Well differentiated pancreatic carcinoma with a pseudoglandular pattern (haematoxylin-eosin, × 400) (A), a nuclear strong p53 immunostaining was encountered in neoplastic elements (immunoperoxidase, × 400, Mayer's Haemalum nuclear counterstain) (B).

tumour size in those patients who refused surgery[49-51].

Solid pancreatic masses

The pre-operative correct diagnosis of ductal pancreatic adenocarcinoma is crucial for patients management and prognosis, and to reduce costs due to unwarranted procedures[1,13,52,53]. The cytological detection of pancreatic ductal adenocarcinoma is usually not difficult for the experienced cytopathologist; indeed this neoplasia is characterized by distinctive cytological features, such as the presence of groups of atypical cells with irregular roundish hyperchromatic dense nuclei, evident nucleoli, mitotic figures and absence of the honeycomb benign pattern[13]. Frequently, pancreatic smears exhibited a hemorrhagic background with clusters or small aggregates of epithelial cells, occasionally arranged in glandular or pseudo-papillary structures. Nevertheless, in a subset of carcinomas the cytological diagnosis may be hard to achieve, due to the presence of extensive necrosis, associated inflammation, contaminating intestinal epithelial cells or limited sampling[7,13,54]. In those cases, again CBP appears as a significant tool for the pathologist, either the microscopic evaluation and application of immunostainings in serial sections. In fact, it has been shown that carcinoembryonic antigen was expressed in neoplastic pancreatic elements of great majority of ductal adenocarcinomas[13]. However, carbohydrate antigen (CA 19-9) represented the most widely used biomarker for pancreatic cancer, even if it showed limitations in differential diagnosis between pancreatic neoplasms, being positive also in solid pseudopapillary tumour and not only in cancer[55-61]. An intriguing challenge, even for the expert cytopathologist, is represented by the distinction between well differentiated pancreatic neoplastic cells and gastrointestinal epithelial contaminating elements, sampled by EUS-FNA through the stomach or the duodenum[7,13,55-58]. Several efforts were made to solve this crucial diagnostic point[7,13,20,55-58]. Firstly, it was reported that a mucin panel comprising four antibodies (MUC1, MUC2, MUC5AC, MUC6) may be helpful in differentiating normal/reactive gastroduodenal cells from neoplastic pancreatic elements[55]. Successively, the utility of immunocytochemistry against CD10 was highlighted (Figure 2B); indeed this antigen is expressed at the apical membrane of the benign contaminant gastrointestinal cells, but not in the neoplastic elements of well differentiated pancreatic adenocarcinoma[7,13,59,60]. The absence of CD10 stain in pancreatic adenocarcinomas has been also documented in surgical histological samples[59,60]. However, CD10 expression has been evidenced in 100% of solid pseudo-papillary pancreatic neoplasms[61-63] and in 30% of pancreatic endocrine tumours with focal staining[7,63,64]. As a consequence, CD10 immunostaining alone cannot be used for the differential diagnosis of pancreatic lesions[7]. An immunohistochemical panel against CK7, CDX2, chromogranin A and synaptophysin is useful for the differential diagnosis among invasive ductal carcinomas, endocrine tumours and acinar cell tumours of the pancreas[12,20,65]. Finally, a further analysis of p53 immunoreactivity may be of diagnostic help in pancreatic pathology (Figure 3); indeed immunocytochemical positivity for mutant p53 protein with long half-life has been recorded in 50%-70% of pancreatic carcinomas, but not in chronic pancreatitis[66-68].

Solid hepatic lesions

A variety of hepatocellular nodules (hyperplastic, benign, dysplastic and malignant) and secondary tumors can be detected in the liver and subjected to EUS-FNA, especially when they were confined to left hepatic lobe[3,69,70]. In particular, while a significant rate of lesions smaller than 1 cm in diameter is missed by CT and MRI, EUS shows excellent diagnostic accuracy in the identification of hepatic lesions less than 0.5 cm in size[69-72]. It is noteworthy that most of < 1 cm hepatic lesions are non-malignant, whereas the large majority of lesions exceeding 2 cm are represented

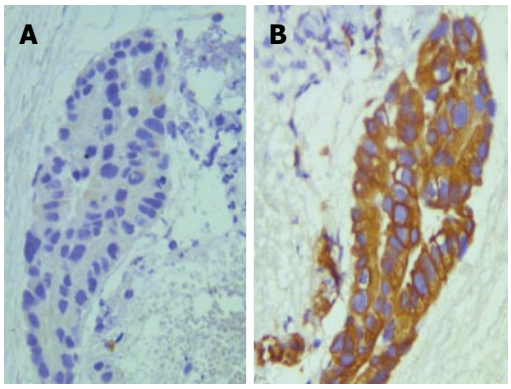

Figure 4 Peripheral cholangiocarcinoma with a papillary pattern (haematoxylin-eosin, × 400) (A), in a serial section obtained from CBP neoplastic elements exhibited an evident cytokeratin 7 immunoreaction (B) (immunoperoxidase, × 400, Mayer's Haemalum nuclear counterstain).

by hepatocellular carcinomas (HCCs); hence in the group of lesions greater than 2 cm a diagnosis of non-malignancy should induce the suspicion of a diagnostic error[73]. Although nodular precursors such as liver regenerative (LRN) or low-grade dysplastic (LGDN) and high grade dysplastic (HGDN) nodules are related to hepatocarcinogenesis, they should be discriminated from adenomas and differentiated HCCs. LGDN category also includes the so-called LRN and it shows mild increase in cell density with a monotonous pattern and bland cytological atypia[73]. On the other hand, HGDN always exhibit more marked cytological atypia and irregular trabecular pattern[73]. Discrimination of well differentiated and hypovascular HCCs from dysplastic nodules may be particularly challenging; in those cases, CBP associated with EUS-FNA or EUS-guided biopsy are warranted, as recently acknowledged[74]. Several immunomarkers were proposed for the distinction between well differentiated HCC and non-malignant lesions[75]. Specifically, Glypican 3 appeared as a good tissue marker with 77% sensitivity and 96% specificity for HCC[74]. In addition, Heat Shock Protein 70 was reported as the most abundantly up-regulated gene in early HCC, and the protein for which it encodes can be detected by immunocytochemistry in up to 78% of the cases with 95% specificity[74]. Finally, Glutamine Synthetase is overexpressed in malignant hepatocytes with diffuse and strong pattern in 50% of HCCs[74,76]. The combined use of the aforementioned was proposed in order to increase the diagnostic accuracy in cases with dubious morphology[76], and so the availability of serial consecutive sections obtained from CBP applied to EUS-FNA could represent the gold standard. With regards to cytokeratins (CK) profile, CK8 and 18 are expressed in both normal and neoplastic hepatocytes, while about 70% of HCC are negative for CK7, CK19, and CK20[73,77]. Furthermore, the combined use of CK7 and CK20 may help to identify the origin of adenocarcinomas occurring in GI tract; in particular, CK7 and CK20 expression in cholangiocarcinomas (CC) varies along the biliary tract, with higher sensitivity of $CK7^+/CK20^-$ profile in peripheral CC compared to non-peripheral ones (Figure 3)[73,77]. On the other hand, $CK7^+/CK20^+$ profile supports the diagnosis of pancreatic adenocarcinoma, while $CK7^-/CK20^+$ is the typical pattern of colonic cancer[73,77].

Gallbladder and biliary tract lesions

Approach by EUS-FNA of the lesions of biliary tract, and mainly of the hilar ones, may avoid the risk of unnecessary extensive surgery[78,79]. Indeed the sensitivity and specificity of obtaining diagnostic samples in biliary neoplasms is variable by endoscopic-retrograde cholangiography[3]. Moreover, the endoscopic retrograde cholangiopancreaticography (ERCP), used at times for hilar cholangiocarcinomas, has frequently inconclusive diagnosis[80]. Consequently, a morphological diagnosis on cytological samples provided by EUS-FNA and submitted to CBP may allow to recognize the nature of malignant biliary lesions (Figure 4) and to change the preplanned surgical approach. Generally, tumour cells appear in loosely structured groups or disorder flat sheets exhibiting as cytologic atypia that varies depending upon tumour grade; occasionally, tumour cells may exhibit cytoplasmic vacuolization and focal mucin secretion. What's more, regional lymph nodes may be evaluated for metastasis by EUS-FNA in patients with unresectable hilar carcinomas[81,82].

A sensitivity and accuracy of 95% have been recorded for EUS-FNA in distal biliary malignancies[7,83] and similar values have been reported in patients with obstructive jaundice due to nodular lesion such as epithelial and non-epithelial tumours, lymphomas and metastases[84-86].

In gallbladder masses, the CBP-assisted EUS-FNA procedure has been used either for diagnostic and staging purposes, with rates of sensitivity and specificity ranging between 80% and 100%, especially in lesions of the gallbladder wall[87-91].

In ampullary tumours, EUS-FNA has higher diagnostic accuracy in the distinction between benign and malignant tumours compared to other operative procedures such as biopsy or brushing cytology during ERCP[92,93]. In addition, it is of help in the identification of patients with low or high grade dysplasia or affected by adenocarcinomas[93].

In this anatomical district, some very severe complications such as bile peritonitis and cholangitis have been described[1]; they probably represent a consequence of inadvertent needle penetration inside intrahepatic or common bile ducts as well as gallbladder. By contrast, bleeding is mild and self-limited, even when patients were taken aspirin or anti-inflammatory drugs, in absence of portal hypertension[1].

CONCLUSION

The clinical applications of EUS-FNA and the methodological advantages obtained by CBP in the diagnosis of solid neoplasms of the GI tract were reviewed.

Although on-site cytological evaluation during the ultra-sonographic needle aspirative procedure may increase the diagnostic yield of EUS-FNA, in our opinion CBP represents its most appropriate diagnostic complement. Indeed this method allows high quality morphological microscopic evaluation and multiple immunocytochemical analyses. By this approach, the differential diagnosis of neoplasms may be more easily achieved, and the background of contaminant non-neoplastic gastrointestinal avoided, which represent evident advantages compared to the traditional cytological techniques. Finally, the identification and quantification of potential molecular markers may represent a promising field to be further investigated on the same biological samples collected by EUS-FNA CBP-assisted.

Abstract

Endoscopic retrograde pancreatography (ERP) is an accurate imaging modality in the diagnosis of pancreatobiliary diseases. However, its use has been substantially reduced due to the invasiveness of procedure, the risk of complications and the widespread availability of non-invasive cross-section imaging techniques (computed tomography, magnetic resonance imaging, and endoscopic ultrasound). Since the introduction of endoscopic sphincterotomy, ERP has transformed from diagnostic method to an almost exclusively therapeutic procedure. Pancreatic duct injection substantially increased the risk of post-ERP pancreatitis (1.6%-15.7%); therefore, according to international guidelines ERP is recommended only in cases where biliary intervention is required. However, the role of ERP in the management of pancreatic diseases is currently not clearly defined, but in some cases the filling of pancreatic duct may provide essential information complementing the results of non-invasive imaging techniques. The aim of this publication is to systematically summarize the literature dealing with the diagnostic yield of ERP. We would like to define the precise indications of ERP and overview a diagnostic protocol of pancreatic diseases depending on international guidelines and the opinion of Hungarian experts, because it may improve the diagnostic accuracy, minimize of burden of patients and reduce the risk of procedure related complications.

Key words: Endoscopic retrograde cholangiopancreatography; Endoscopic pancreatography; Autoimmune pancreatitis; Pancreas divisum; Chronic pancreatitis

Core tip: Since the development and widespread availability of non-invasive imaging techniques the importance of diagnostic endoscopic pancreatography (ERP) has substantially reduced. However, in some complicated cases or during pancreatic interventional endoscopic procedures such as minor papilla sphincterotomy, pancreatic sphincterotomy, pancreatic stent implantation, ERP may provide essential information. This article seeks to summarize the results of previous studies and recommendations of international guidelines

to define the diagnostic yield and correct indications of ERP.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is an invasive procedure that provides radiological visualization of the detailed structure and the pathological changes of the biliary tree and pancreatic ducts by injection of contrast agent into the common bile duct (CBD) and the main pancreatic duct (MPD). Since its development in 1968, it has become a widely used and accurate imaging modality in the diagnosis of pancreatobiliary diseases[1]. Since the introduction of endoscopic sphincterotomy in 1974[2], ERCP has become the most important minimal invasive treatment method for various biliary and pancreatic diseases including bile duct or pancreatic duct stones (choledocholithiasis or wirsungolithiasis), benign and malignant biliary and pancreatic duct obstructions. Recently ERCP has transformed from a diagnostic method to an almost exclusively therapeutic procedure due to the widespread availability of noninvasive cross-section imaging techniques such as abdominal ultrasound (AUS), computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound (EUS)[3]. Numerous studies emphasize the disadvantages of ERCP such as post-ERCP complications and the burden to patients. In a meta-analysis of 21 prospective trials the incidence of mild-to-moderate complications reached 5.17%, and that of severe events up to 1.67%[4] (Table 1). Post-ERCP pancreatitis (PEP) is the most frequent complication with approximately 3.5% but its incidence ranges widely (1.6%-15.7%) depending on the patient selection and the definition of pancreatitis[5-7]. Pancreatic duct injection substantially increased the risk of PEP, therefore the role of diagnostic endoscopic pancreatography (ERP) gradually decreased. International guidelines recommend ERCP only in cases where biliary intervention is required[3-8], but the indication of ERP is not clearly defined. According to the current guidelines routine rectal administration of 100 mg diclofenac or indomethacin immediately before or after ERCP is strongly recommended to prevent PEP. In patients with MPD filling and increased patient or procedure related risk factors for PEP temporary application of prophylactic small caliber pancreatic stents is also recommended to reduce the risk of severe PEP[9].

The aim of this article is to systematically review the literature dealing with the diagnostic yield of ERP in various pancreatic diseases, and to define the principles and indications of ERP depending on the recommendations of international guidelines and the opinion of Hungarian experts (Tables 2 and 3) .

Table 1 Frequency of procedure related complications of endoscopic retrograde pancreatography (6.85%) depending of the results of endoscopic retrograde pancreatography[4]

	Mild to moderate	Severe	Death
Pancreatitis	3.07%	0.40%	0.11%
Bleeding	0.95%	0.39%	0.05%
Perforation		0.60%	0.06%
Infection	1.15%	0.28%	0.11%
Total	5.17%	1.67%	0.33%

PANCREAS DIVISUM

Pancreas divisum (PD) is the most common congenital anomaly of the pancreas in which the dorsal and ventral pancreatic duct drain separately into the duodenum. Recently ERP has been the gold standard imaging modality for the diagnosis of PD due to its high diagnostic accuracy[10,11], but the rate of complete pancreatography and the success of minor papilla cannulation significantly influence the sensitivity of ERP[12] (Figure 1). The high rate of complications is the greatest disadvantage of ERP, therefore noninvasive procedures, such as MRCP and EUS are increasingly spreading worldwide in this indication as well. Sensitivity and specificity of MRCP in the detection of PD is 52%-73.3% and 96.8%-97%, and the diagnostic accuracy can further be improved with the use of secretin stimulation (73.3%-86% and 97%)[13,14] (Figure 2). A comparison study carried out by Lai *et al*[15]. has shown that adequate evaluation of the pancreatic duct by EUS is possible in 78% of cases, and the sensitivity, specificity, and positive and negative predictive values for EUS are 95%, 97%, 86%, and 99%.

ERP has an important therapeutic role in the endoscopic treatment (including minor papillotomy with or without pancreatic duct stenting) of patients with symptomatic PD. There is no prospective randomized controlled trial comparing endoscopic and surgical therapy, but previous retrospective studies could not detect any differences between the pooled overall response rates of the two treatment groups (endoscopic *vs* surgical treatment 54.3-79.2 *vs* 51.4-83.3 depending on the indication)[16].

ACUTE PANCREATITIS

The importance of ERCP in the identification of the etiology of acute pancreatitis (AP) has rapidly decreased in the recent decades due to the widespread availability of noninvasive imaging modalities[17]. The diagnosis of uncomplicated AP is mainly based on the clinical symptoms, elevated serum levels of pancreatic enzymes

Table 2 Indication of endoscopic retrograde pancreatography based on the opinion of Hungarian experts

	Indicated	Slightly indicated	Not indicated	Description
Pancreas divisum	83.6%	16.7%	0%	During therapeutic intervention
Acute pancreatitis	16.7%	50%	33.3%	Recurrent "idiopathic" acute pancreatitis
Chronic pancreatitis	83.3%	16.7%	0%	Complicated chronic pancreatitis (MPD stricture, pancreatic duct stones, chronic abdominal pain, obstructive jaundice)
Autoimmune pancreatitis	66.7%	33.3%	0%	Suspicion of autoimmune pancreatitis which has not identified by noninvasive imaging techniques
Pancreatic neoplasia	0%	50%	50%	Suspicion of pancreatic neoplasia with obstructive jaundice
Pancreatic cystic neoplasia	0%	16.7%	83.3%	In case of IPMN ERP associated with high risk of complications Pancreatic cysts and pseudocysts generally do not communicate with the pancreatic duct therefore the ERP cannot identify them
Pancreatic injury	100%	0%	0%	Suspicion of pancreatic ductal injury in stable patients
Postoperative pancreatic fistula	100%	0%	0%	Suspicion of pancreatic fistula Suspicion of fistula formation

ERP: Endoscopic pancreatography; MDP: Main pancreatic duct; IPMN: Intraductal papillary mucinous neoplasms.

Table 3 Indication of endoscopic retrograde pancreatography in the case of suprapapillary bile duct stenosis based on the opinion of Hungarian experts

Indicated	Not indicated	Description
50%	50%	ERP may help differentiate between cholangiocarcinoma and pancreatic illnesses

ERP: Endoscopic pancreatography.

(amylase, lipase) and the morphological changes in the pancreas on the AUS, CT or MRI images[18]. Therapeutic ERCP with biliary sphincterotomy and removal of CBD stones can effectively improve the outcome, and according to the recent international guidelines it is indicated in acute biliary pancreatitis within 72 h, if noninvasive examinations prove the presence of acute cholangitis or raise the suspicion of CBD obstruction in association with acute pancreatitis[19,20]. On the contrary, failed biliary cannulation and repeated MPD filling in patients with acute biliary pancreatitis may worsen the overall outcome and therefore some data suggest that small caliber prophylactic pancreatic stents may be applied as a bridging procedure to prevent complications in this group of patients[21].

In 10%-15% of patients with recurrent acute pancreatitis if the complete noninvasive diagnostic evaluation could not reveal the exact cause and etiology, and as a consequence the diagnosis of "idiopathic" acute pancreatitis may arise. Therefore in patients with idiopathic acute pancreatitis, after the cessation of an acute inflammatory attack an ERCP with biliary and/or pancreatic sphincter of Oddi manometry, an endoscopic ultrasound, and secretin enhanced MRCP may leads to a diagnosis of biliary microlithiasis, sphincter of Oddi dysfunction, PD, cystic fibrosis, a choledochocele, annular pancreas, an anomalous pancreatobiliary junction, small pancreatobiliary tumors, or early stage of chronic pancreatitis[22,23].

CHRONIC PANCREATITIS

Chronic pancreatitis (CP) is a progressive fibroinflammatory disorder with irreversible destruction of the pancreatic parenchyma and ducts. Frequently the complications, such as bile duct stenosis, obstructive jaundice, diabetes mellitus or malabsorption call the attention for the presence of the disease[24]. In advanced stages the recognition of parenchymal fibrosis and moreover calcification is relatively easy with AUS, CT, MRI and EUS, and typical ductal alterations with ERCP or MRCP[25]. The early recognition of CP and its differentiation from pancreatic cancer (PC) sometimes represents a real diagnostic challenge[26]. Currently ERCP has been replaced by EUS (especially with elastography), MRI, CT, and MRCP in the early diagnosis of CP. However, ERCP plays an essential role in the more precise identification of complications such as obstructive jaundice, pancreatic stones, MPD strictures, chronic abdominal pain, and also gives the opportunity for the minimally invasive treatment (pancreatic sphincterotomy or balloon dilatation, pancreatic duct stenting, *etc.*)[27] (Figure 3). The European Society of Gastroenterology recommends the endoscopic treatment as the first-line therapy for painful uncomplicated CP, and highlights its effectivity in the management of obstructive jaundice and pancreatic stones associated with CP[3] (Figures 4 and 5). In cases of complicated CP the long-term efficacy of surgical intervention is superior to endoscopy in most patients[28,29]. Despite the fact, that repeated pancreatography is usually necessary during the endoscopic intervention of the pancreatic duct, the risk of PEP is significantly reduced in CP as compared to the general population. However, the role of ERP as first examination in the diagnosis of suspected complicated CP is questionable[6]. Therefore, in our clinical practice, we perform ERCP in CP patients only in case of chronic pancreatic pain and suspected MPD obstruction (stricture with prestenotic dilatation) based on MRCP or EUS. In these patients, pancreatic sphincterotomy, pancreatic

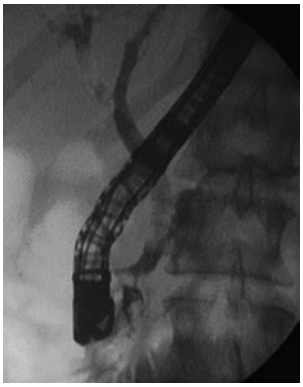

Figure 4 Endoscopic pancreatography image: Pancreatic duct stenosis with prestenotic dilatation after preventive pancreatic stent implantation.

stricture dilatation and multiple plastic or self-expanding metal stenting during ERP proved to be useful to achieve long term symptomatic improvement.

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis (AIP) is an uncommon inflammatory disorder of the pancreas with a presumed autoimmune etiology[30]. It may present with a wide variety of clinical and morphological features including painless obstructive jaundice, asymptomatic focal mass or diffuse enlargement of the pancreas which mimic PC[31]. The diagnosis of AIP requires a multidisciplinary approach including imaging studies, histology, serology, assessment of other organ involvement and the therapeutic response to steroid treatment[32,33]. There were differences in the diagnostic approach and the techniques used between different countries. For instance, ERP is usually ignored in Western counties to avoid PEP in contrast to Japan where this examination is usually performed[34]. The correct diagnosis requires detailed information equally about the pancreatic parenchyma and ducts. In typical cases of AIP a diffusely enlarged or "sausage shaped" pancreas with featureless borders and/or loss of lobular architecture can be detected with AUS, CT and MRI[35]. In 30%-40% of the cases focal mass is found, which can lead to false diagnosis of pancreatic malignancy[36,37]. Ductal imaging, ERP and MRCP may show a long, narrow ductal stricture (greater than one-third the length of the MPD) or multiple, non-continuous strictures without marked upstream dilation, and side branches arising from the stricture[38-40]. However, given that ERCP is an invasive method which debit the patient and can cause adverse effects (pancreatitis, bleeding), the noninvasive MRCP is becoming the first choice examination for pancreatobiliary diseases. Previous comparison studies have shown that MRCP is less sensitive in the differentiation of focal form of AIP and PC, therefore cannot completely replace ERCP for the diagnostic evaluation of AIP[41,42]. The multicenter study carried out by Suguma *et al*[43]. has highlighted the ability of ERP to diagnose AIP based on ERP feature alone is limited, but taken together with clinical symptoms, serology and/or histology it can be useful.

PANCREATIC NEOPLASIA

Previously ERCP was the gold standard in the diagnosis of PC. Localized MPD stenosis with focal ductal branch dilation and with distal dilation of MPD ("double duct" sign) were the most frequently detectable morphological

Figure 5 Endoscopic pancreatography image: Bile duct and pancreatic duct stent implantation in chronic pancreatitis.

Figure 6 Endoscopic retrograde pancreatography image: Postoperative pancreaticopleural fistula.

changes[44,45]. The current role of ERCP is therapeutic rather than diagnostic. In cases of inoperable locally advanced and metastatic pancreatic malignancy the development of obstructive jaundice constitutes an absolute indication of ERCP[46]. Malignant biliary stenosis may be treated with plastic, but preferably with self-expandable metallic stent implantation[3]. Pancreatography, ERCP-guided brush cytological sampling and/or biopsy of the pancreatic duct may be useful to prove malignancy, but EUS-guided fine needle aspiration (EUS-FNA) is the first-choice sampling procedure in suspected unresectable pancreatic solid and cystic lesions due to minimal invasiveness, lower complication rate and higher sensitivity compared to ERCP sampling[47]. A meta-analysis performed by Li *et al*[48]. showed that ERCP combined with EUS was associated with a high diagnostic yield compared to ERCP or EUS alone, but the complete length of procedures substantially increased, however, it can be reduced if the two examination are performed under the same sedation, but the rate of complication not changed[49].

CYSTIC PANCREATIC LESIONS

Cystic pancreatic lesions represent a great diagnostic problem because of the morphological similarities between benign and malignant cysts and because of the possibility of malignant transformation[50] and the increasing number of the detected lesions due to the improvement of the abdominal imaging modalities and their availabilities. The differentiation between the four types of pancreatic cystic neoplasms (PCN) substantially may influence the therapeutic approach. Serous cystadenomas (SCA) and solid pseudopapillary neoplasms (SPN) are associated with lower malignant potential compared to intraductal papillary mucinous neoplasms (IPMN) and mucinous cystic neoplasms (MCN). Previously ERP was the gold standard diagnostic procedure in the identification and classification of IPMN. Diffuse or segmental dilation of the MPD or its side branches connected to the cyst can be recognized on the ERP images, with no other cause of the dilatation. The pathognomonic characteristic of IPMN is the gaping orifice of Vater papilla with thick mucus oozing (fish mouth papilla)[51]. The international consensus guidelines do not recommend the routine ERP for the morphological and cytological diagnosis of IPMN (fluid sampling or brushing of MPD) due to the invasiveness of the procedure and the high risk of complications. Currently MRCP, EUS and EUS-guided sampling are most preferred[52,53]. The other malignant cyst type and the pancreatic pseudocysts generally do not communicate with the pancreatic duct, therefore the ERP cannot identify them.

PANCREATIC INJURY

Blunt pancreatic trauma can frequently lead to acute pancreatitis with or without MPD disruption. Pancreatic injuries caused by blunt abdominal trauma are relatively rare with an overall incidence of 0.2%-12%[54]. Pancreatic injury occurs as a result of the traumatic compression of the pancreas between the vertebral column and the anterior abdominal wall. Pancreatic injury is more common in children and young adults because of decreased protective intra-abdominal fat. CT is the primary imaging modality of choice in patients with blunt abdominal trauma, with the sensitivity for pancreatic parenchymal injury between 67%-85%[55]. Although pancreatic ductal injury can frequently be detected with non-invasive MRCP, ERCP is the most accurate diagnostic tool for the assessment of ductal injury[56]. Besides, it can also provide endoscopic treatment. Delays in ERCP have led to significantly higher complication rates[57]. Although ERCP is the most useful procedure for the diagnosis of pancreatic ductal injury in stable patients, surgery should be considered without hesitation if the patient's condition is unstable. Recently, some case series proved that pancreatic duct plastic stent placement with and without pancreatic sphincterotomy can be an effective endoscopic therapy in resolving pancreatic duct disruption and preventing chronic fistula formation[58]. Although stent implantation can improve the clinical condition and resolve fistula and pseudocyst, stent induced ductal stricture is a major

long-term complication.

POSTOPERATIVE PANCREATIC FISTULA

Postoperative pancreatic fistula (POPF) formation is a frequent and severe complication of pancreatic surgery[59,60]. Its incidence ranges from 2% to 51% depending on the definition used. POPF was defined by International Study Group on Pancreatic Fistula as a measurable drain output on or after postoperative day 3 with an amylase content greater than 3 times the serum amylase activity[61]. In the early postoperative phase the upper abdominal discomfort associated with fever, tachycardia, slower recovery and persistently high drain output raises the suspicion of postoperative complication, such as pancreatic fistula (Figure 6). The amylase level of drain fluid is extremely elevated in a typical case[62]. ERCP and MRCP are the two most widely used imaging modality in the confirmation of POPF with high diagnostic accuracy. In case of pancreaticopleural fistula their sensitivity may reach to 78% and 80%[63]. Recently ERCP was the most preferred investigation for confirming the diagnosis of POPF, but its use is reduced due to invasive nature and elevated risk of infective complications arising from fistula filling. However, it has the advantage of direct visualization of MPD and precise location of fistula, and the ability to simultaneously perform endoscopic therapeutic maneuvers[64].

PANCREATOBILIARY MALJUNCTION

Pancreatobiliary maljunction (PBM) is a rare congenital malformation in which the CBD and the pancreatic duct are united outside the duodenal wall with or without dilation of CBD[65]. The sphincter of oddi is located in the distal part of the common channel, therefore it cannot properly regulate the outflow of biliopancreatic juice, resulting regurgitation of bile into the MPD and pancreatic juice into the CBD. The elevated intraductal pressure often causes dilatation of CBD, and the chronic biliopancreatic reflux increases the risk of development of malignancy. The diagnosis of PBM is based on the identification of the anomalous union between the pancreatic and bile ducts by ERCP, MRCP, EUS or intraductal ultrasound. ERCP is the most accurate imaging method, and it provides an opportunity for the biliary intervention (biliary stone extraction, stent implantation) and bile sampling as well. High biliary levels of pancreatic enzymes are suggestive of regurgitation of pancreatic juice into the common bile duct[66]. In atypical PBM cases with relatively short common channel, the diagnostic accuracy of MRCP and EUS is lower, but they are very effective in the detection of PBM associated pancreatobiliary cancers at an early stage[67].

CONCLUSION

ERP is still one of the most accurate diagnostic procedures in patients with suspected pancreatic ductal disorders, including idiopathic acute recurrent pancreatitis, chronic pancreatitis, pancreatic ductal injuries and fistula formation, pancreatic cystic neoplasms and early pancreatic cancer. However, before performing ERP, endoscopists should carefully evaluate the extent of the clinically necessary pancreatogram, if there any, to establish the diagnosis. Increasingly widespread application of noninvasive methods for the diagnosis of pancreatobiliary diseases (such as MRCP and EUS), and less frequent use of diagnostic ERP could dramatically decrease post-ERCP complications. In contrast, pancreatic interventional endoscopic procedures, such as pancreatic sphincterotomy, dilatations and pancreatic stent implantation are necessitates for complete pancreatic ductal contrast filling and analysis of digitally enhanced pancreatogram with fluoroscopy to completely understand the anatomy and intraductal pathology before the initiation of endoscopic therapy.

In case of distal biliary obstruction, when the non-invasive imaging modalities are available we do not recommend the filling of pancreatic duct, selective biliary drainage is proposed. ERP should be considered in case of suspected pancreatic ductal abnormalities, such as pancreatic injury, fistula or congenital malformation, and when pancreatic ductal intervention is necessary.

Abstract

The management of jaundice and cholangitis is important for improving the prognosis and quality of life of patients with unresectable malignant hilar biliary strictures (UMHBS). In addition, effective chemotherapy, such as a combination of gemcitabine and cisplatin, requires the successful control of jaundice and cholangitis. However, endoscopic drainage for UMHBS is technical demanding, and continuing controversies exist in the selection of the most appropriate devices and techniques for stent deployment. Although metallic stents (MS) are superior to the usual plastic stents in terms of patency, an extensive comparison between MS and "inside stents", which are deployed above the sphincter of Oddi, is necessary. Which techniques are preferred remains as yet unresolved: for instance, whether to use a unilateral or bilateral drainage, or a stent-in-stent or side-by-side method for the deployment of bilateral MS, although a new cell design and thin delivery system for MS allowed us to accomplish successful deployments of bilateral MS. The development of techniques and devices for re-intervention after stent occlusion is also imperative. Further critical investigations of more effective devices and techniques, and increased randomized controlled trials are warranted to resolve these important issues.

Key words: Malignant hilar biliary obstruction; Biliary drainage; Metallic stents; Stent-in-stent; Side-by-side

Core tip: The development of useful surgical devices, such as plastic or metallic stents, catheters and guidewires, has allowed us to achieve successful endoscopic drainage for unresectable malignant hilar biliary strictures (UMHBS), a technically demanding procedure. However, the most appropriate method of endoscopic drainage for UMHBS remains a contentious issue: for instance, whether to use a unilateral or bilateral drainage, or a stent-in-stent or side-by-side method for the deployment of bilateral metallic stents (MS) to accomplish successful deployments of bilateral MS.

Further critical investigations of more effective devices and techniques, and increased randomized controlled trials are warranted to resolve these important issues.

Current status of endoscopic biliary drainage for unresectable malignant hilar biliary strictures. *World J Gastrointest Endosc* 2015; 7(11): 1032-1038 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i11/1032.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i11.1032

INTRODUCTION

The management of jaundice and cholangitis is important for improving the prognoses of patients with unresectable malignant hilar biliary strictures (UMHBS). In addition, effective chemotherapy, such as combination therapy with gemcitabine and cisplatin, for the treatment of cholangiocarcinoma requires the coincident effective management of both jaundice and cholangitis. Several methods exist for biliary drainage including: surgical drainage, percutaneous transhepatic drainage using ultrasound, and endoscopic transpapillary drainage. Of these, endoscopic transpapillary drainage has become the favoured method because of its minimal invasiveness while preserving the patient's quality of life. The development of useful surgical devices, such as plastic or metallic stents, catheters and guidewires, has allowed us to achieve successful endoscopic drainage for UMHBS, a technically demanding procedure. However, the most appropriate method of endoscopic drainage for UMHBS remains a contentious issue. In the present study, we review the current literature concerning endoscopic biliary drainage for patients with UMHBS.

PLASTIC *VS* METALLIC STENTS, AND NEWLY DESIGNED PLASTIC STENTS

Several studies have highlighted the advantages of metallic stents (MS) compared with plastic stents (PS) (Table 1)[1-4]. According to these studies, the median patencies of MS for UMHBS were of longer duration than those of PS (3.4-12.0 mo *vs* 1.2-6.7 mo); in spite of this, the technical success rate for the deployment of MS was similar to that of PS (83.3%-100% *vs* 85.2%-100%). In a randomized controlled trial comparing PS and MS as reported by Mukai *et al*[4], the 6-mo patency was significantly higher for the MS patient group than the PS group (81% *vs* 20%); the 50% patency period was 359 d for the MS group and 112 d for the PS group. In addition, the MS group had the advantage in terms of the number of re-interventions and the total cost of treatment compared with the PS group.

Reports concerning newly designed plastic stents are also increasing. PS occlusion occurs as a result of biofilm formation and bacterial adherence to the wall of the stent following the reflux of duodenal juice into the PS and bile duct. To avoid this phenomenon, Pedersen *et al*[5] reported a method of deploying PS above the sphincter of Oddi; such stents were named "inside stents". Recently, several reports have emerged on the deployment of "inside stents" with attached nylon thread that is easily removed from the distal end of the stent for UMHBS (Figure 1). Ishiwatari *et al*[6] reported on 26 patients with UMHBS and successfully deployed "inside stents" showing a median patency period of 136 d. Kaneko *et al*[7] reported that the patency of "inside stents" was 190 d. Inatomi *et al*[8] compared the patency period of conventional PS, MS and "inside stents" and found the patency period of "inside stents" to be significantly longer than that of conventional PS (142 d *vs* 32 d, $P = 0.04$), but was not significantly different to that of MS (142 d *vs* 150 d, $P = 0.83$). Further investigation is necessary to determine whether the patency period of "inside stents" is comparable to that of MS. However, the absolute advantage of PS, including "inside stents", are enable to be removed easily compared to MS. We intend to deploy PS more frequently as a temporal drainage procedure if UMHBS are completely cured *via* chemotherapy or other effective treatments.

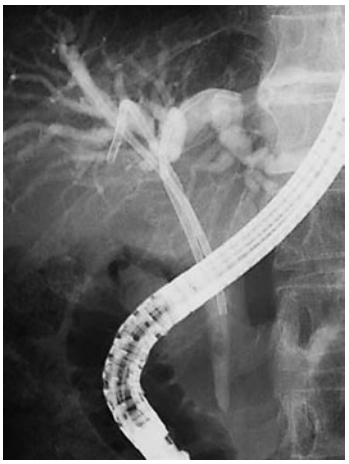

Figure 1 Multiple "inside stents" deployed above the sphincter of Oddi.

UNILATERAL *VS* BILATERAL DRAINAGE

One of controversies regarding unilateral and bilateral drainage is the perceived technical difficulty of these procedures, with bilateral stent deployment generally thought to be more difficult than unilateral stent deployment. There have only been two randomized controlled trials (RCTs) on this issue to date. In one undertaken by De Palma *et al*[9] comparing the unilateral and bilateral deployment of PS, the technical and clinical successes of the bilateral deployment group were significantly lower than those of the unilateral deployment group (Table 2). On the other hand, in a

RCT by Mukai *et al*[4] comparing PS and MS, successful deployment was achieved in all patients undergoing the deployment of PS or MS, regardless of what type of deployment was employed. In other retrospective studies comparing the unilateral and bilateral deployment of MS, the technical success rate was similar for these two groups[3,10-12]. However, evidences of no obvious differences on the difficulty between unilateral and bilateral deployment are not still enough. Further RCTs at high-volume centers are warranted.

Another matter in question is whether bilateral drainage is superior to unilateral drainage in the management of jaundice and cholangitis, which relates to stent patency and survival periods. There are several studies showing no difference between unilateral and bilateral drainage on stent patency and survival periods, but several studies highlight an opposite stance[3,4,9-12]. Bilateral drainage, as the initial drainage, may not always be necessary for patients with UMHBS for the management of jaundice cholangitis. However, the function of the drained segment of the liver will diminish as the tumor gradually occupies the drain segment, which impacts on patient mortality. Vienne *et al*[13] analyzed the outcomes of drainage effectiveness during endoscopic stenting for malignant hilar biliary strictures. The main significant factor associated with drainage effectiveness was a liver volume drainage of > 50% (odds ratio 4.5, $P = 0.001$), which was associated with longer survival (119 d *vs* 59 d, $P = 0.005$). In addition, Mukai *et al*[4] reported that around 50% of patients required bilateral drainage to reduce jaundice and cholangitis, but instead recommended unilateral drainage. Miura *et al*[14] reported the results of preoperative biliary drainage for malignant hilar biliary stricture. Thirty-one of 122 patients (25.4%) initially underwent multiple biliary drainage; however 69 of 122 (56.6%) required multiple biliary drainage by the time of the operation. They concluded that patients with Bismuth-II, Bismuth-IIIa, and Bismuth-IV were at high risk for multiple biliary drainage. These results suggest that effective drainage of a malignant hilar biliary stricture frequently requires bilateral or multiple drainage.

Uchida *et al*[15] reported on the relationship between the number of deployed MS, the effectiveness of chemotherapy, the patency period of MS, and the survival period. Patients were divided into two groups, one in which four or three MS were deployed (4- or 3-branched group), or a group in which two or one MS was deployed (2- or 1-branched group). Although neither patency period nor survival time exhibited significant differences between the two groups, among the patients achieving complete response, partial response, or stable disease defined by World Health

SIS: Stent-in-stent; SBS: Side-by-side; NA: Not available.

Figure 2 Multiple metallic stents deployed by the stent-in-stent method.

Figure 3 Multiple metallic stents deployed by the side-by-side method.

Organization during chemotherapy, the patency period and survival time of the 4- or 3-branched group were significantly longer than those of the 2- or 1-branched group. They concluded that the deployment of multiple MS prevented biliary infection and deterioration of liver function, which resulted in a long duration of stent patency and the continuation of stable chemotherapy in the disease control group. Consecutive and effective chemotherapy requires the preservation of the functional volume of the liver, and unilateral drainage is less effective than bilateral drainage for this perspective.

STENT-IN-STENT *VS* SIDE-BY-SIDE METHODS

Two methods exist for the endoscopic deployment of bilateral MS for UMHBS: stent-in-stent (SIS; Figure 2) and side-by-side (SBS; Figure 3) methods. Although several reports have been published on each method, no obvious difference was noted (Table 3). The technical success rate is 80%-100% for SIS[16-23] and 73.3%-100% for SBS[24-27], with the patency periods being 140-238 d and 130-169 d, respectively. There are only two retrospective reports on a comparison between SIS and SBS. The rate of successful deployment did not differ between SIS and SBS in both reports but several uncertainties existed surrounding complications and the patency period of these techniques. Naitoh *et al*[28] noted the incidence of complications was significantly higher (44% *vs* 13%, $P = 0.016$), and the cumulative stent patency was significantly longer, ($P = 0.047$) in the SBS, compared to the SIS, group. The median patency period was 469 in the SBS group and 181 d in the SIS group. On the other hand, no differences in complications rates and the patency period between SIS and SBS were reported by Kim *et al*[29]. A prospective randomized control trial, using the same type and diameter of MS, is needed for the evaluation of differences between SIS and SBS methods for the deployment of bilateral MS.

PROGRESS IN METALLIC STENTS FOR BILATERAL DEPLOYMENT

For the reliable and successful deployment of bilateral MS, several new MS designs have been described. The most difficult part for the successful deployment of a bilateral MS by SIS is the deployment of the second MS.

Table 4 The results of re-intervention after stent occlusion in the patients undergoing deployment of bilateral metallic stents

Ref.	Method for deployment	No. of patients	Occlusion % (*n*)	Endoscopic re-intervention % (*n*)	Bilateral or multiple drainage at endoscopic re-intervention % (*n*)
Naitoh *et al*[28]	SIS	24	42 (10/24)	90 (9/10)	NA
	SBS	25	20 (5/25)	100 (5/5)	NA
Lee *et al*[27]	SBS	40	45 (18/40)	92 (12/13)[1]	50 (6/12)
Fujii *et al*[33]	SIS	55	55 (30/55)	100 (30/30)	67 (20/30)
Lee *et al*[23]	SIS	78	31 (24/78)	96 (23/24)	83 (20/24)
Law *et al*[31]	SBS	17	53 (9/17)	75 (6/8)	75 (6/8)
	SIS	7	43 (3/7)	100 (3/3)	100 (3/3)

[1]Five patients with comorbidity underwent initial percutaneous intervention. SIS: Stent-in-stent; SBS: Side-by-side; NA: Not available.

This is because, in addition to the stricture, we have to negotiate the mesh of the first metallic stent when placing the second stent. Therefore, the clever cell design of a MS is crucial for the successful deployment of a bilateral MS by SIS. A newly designed MS with a large, open-celled wire mesh for the deployment of a bilateral MS has been reported in several studies[17,19,21], making the deployment of a bilateral MS for UMHBS a more feasible procedure. Lee *et al*[23] reported on the feasibility and efficacy of a newly designed, closed-cell and cross-wired MS: the technical success rate of endoscopic bilateral SIS deployment was 95.2%, and the median patency period was 238 d.

The difficulty of deployment of a bilateral MS by SBS is also related to the insertion of the second MS along the first MS. This is because we have to advance the second MS against the resistance of the first, already expanded MS. Therefore, although a delivery stuck in the mesh of the initially deployed MS sometimes results in an unsuccessful deployment, a thin delivery overcomes this issue. Kawakubo *et al*[30] reported that 6-Fr delivery systems could facilitate a single-step, simultaneous, SBS placement through the accessory channel of the duodenoscope. The rate of successful deployment was 84.6%, and the median procedure time was 25 min. Law *et al*[31] reported that a 6-Fr delivery MS were used for the deployment of a bilateral MS in 17 patients by SBS and seven patients by SIS. The rate of successful deployment was 100% for both groups, although SBS was attempted prior to SIS in four of seven patients in the SIS group. The 6-Fr delivery can pass through the mesh of the MS more easily, which may facilitate the deployment of a bilateral MS by not only the SBS, but also the SIS method.

RE-INTERVENTION AFTER STENT OCCLUSION IN PATIENTS UNDERGOING BILATERAL DEPLOYMENT OF METALLIC STENTS

Biliary tract cancer is the cause of most UMHBS, and effective chemotherapeutic agents, such as a gemcitabine plus cisplatin combination, have been described in several reports on the treatment of unresectable biliary tract cancer. Valle *et al*[32] reported that the median overall survival was 11.7 mo among 204 patients receiving a gemcitabine plus cisplatin combination, which is longer than the stent patency period already reported. Therefore, stent occlusion that causes jaundice and cholangitis will often happen in the course of chemotherapy, and re-intervention after stent occlusion plays an important role in continuing effective chemotherapy, especially in patients with the deployment of a bilateral MS whose re-intervention is thought to be difficult.

The results of re-intervention after stent occlusion in patients with a bilateral MS deployment are shown in Table 4. Few reports have analyzed the results of re-intervention in any great detail. Fujii *et al*[33] deployed multiple MS using a SIS method in 55 patients with UMHBS. Of these patients, 30 developed a MS occlusion. In twenty of the 30 patients, multiple PS deployments were attempted, with successful PS deployment and clinical success achieved in all 20 patients. Lee *et al*[23] reported on the success rate of bilateral stent deployment as a re-intervention procedure for patients undergoing the deployment of bilateral MS using a SIS method. Of 24 patients with a MS occlusion in which bilateral stent deployment was attempted, twenty patients achieved a successful deployment of bilateral stents. The clinical success of the deployment of bilateral MS was 79.2% (19/24). Law *et al*[31] reported on re-intervention after stent occlusion for 11 patients undergoing the deployment of bilateral MS using an SIS or SBS method. Successful re-intervention was defined as the ability to access and perform interventions in both the right and left hepatic ducts, and this was accomplished in 9 out of 11 patients (3/3 SIS, 6/8 SBS). Re-intervention after stent occlusion will be an important issue to resolve in coming years, with continued improvements seen in the prognosis of patients with UMHBS due to effective chemotherapy.

CONCLUSION

In the present review, we have described the current status of endoscopic biliary drainage in patients with UMHBS. Endoscopic biliary drainage for UMHBS is still technically demanding, with many unresolved issues,

including the choice of PS or MS, the choice of unilateral or bilateral drainage, and the use of either SIS or SBS deployment of bilateral MS. The development of new devices and techniques for stent deployment, and further randomized controlled trials are warranted to resolve these matters in question. The development of new methods of re-intervention after stent occlusion is also important to manage patient jaundice and cholangitis over a longer time period as continued advances in chemotherapy prolong the survival of patients with UMHBS.

Abstract

Endoscopic treatments for gastroesophageal reflux disease (GERD) have become increasingly popular in recent years. While surgical intervention with the Laparoscopic Nissen Fundoplication remains the gold standard, two endoscopic interventions, specifically, are gaining traction in clinical use (EsophyX and Stretta). The EsophyX (EndoGastric Solutions, Inc., Redmond, WA, United States) was developed as a method of restoring the valve at the GE junction through an endoluminal fundoplication (ELF) technique. Long-term data suggests that transoral incisional fundoplication (TIF) with EsophyX may be effective for symptom control and proton pump inhibitor reduction or cessation for up to 2-6 years. There is no evidence that EsophyX is more effective than surgical intervention. TIF may be most effective for patients with HH < 2 cm and Hill Grade I/II valves. Stretta (Mederi Therapeutics, Greenwich, CT, United States) was approved by the Food and Drug Administration in 2000. It delivers radiofrequency energy to the lower esophageal sphincter and gastric cardia. Published reviews of the literature are conflicted in their recommendations of Stretta in the management of GERD. The literature suggests that the Stretta procedure has an acceptable safety profile and may be effective in reducing symptom burden and quality of life scores up to 8 years post-intervention. However, there does not appear to be any sustained improvement in objective outcomes and there is no evidence that Stretta results in improved outcomes as compared to surgical intervention. Treatment modalities for GERD, as a field, suffer from a lack of standardization in primary and secondary outcomes. Although many studies have looked at health related quality of life, the tools used to do so are markedly heterogeneous. Future directions for the endoscopic treatment of GERD include novel techniques like endoscopic submucosal dissection.

Key words: Endoscopy; Reflux; Gastroesophageal reflux disease management; EsophyX; Stretta

Core tip: While surgical intervention with the Laparoscopic Nissen Fundoplication remains the gold standard for reflux, endoscopic treatments for gastroesophageal reflux disease have become increasingly popular in recent years. This review of endoscopic methods focuses on two procedures: the Esophyx, a procedure involving endoluminal fundoplication of the gastroesophageal junction, and Stretta, a procedure involving radiofrequency ablation of the gastro-esophageal junction. While these techniques have an acceptable safety profile and lead to subjective improvement in reflux, their objective efficacy remains unclear. The review highlights the lack of standardisation of outcome measures and heterogeneity of assessment tools.

INTRODUCTION

The most widely accepted definition of gastroesophageal reflux disease (GERD), developed by the International consensus group, is "a condition that develops when stomach contents cause troublesome symptoms and/or complications"[1]. In North America, it has a prevalence of 18.1%-27.8%[2] and is estimated to be the most common reason for an outpatient gastrointestinal clinic visit[3]. This translates into significant economic burden through health-care associated costs, as well as reduced quality of life (QOL) for affected persons.

GERD is a multifactorial disease process. Factors affecting the development of GERD include mechanical impairment of the gastroesophageal (GE) junction, hiatal hernias (HH), and esophageal acid exposure (EAE). Pathological reflux can result in GERD type symptoms (heartburn, regurgitation, heartburn) and mucosal disease (esophagitis, strictures, metaplasia and cancer)[4].

The treatment of GERD changed dramatically after the advent of proton pump inhibitors (PPIs)[5]. In conjunction with lifestyle modifications, they are the current first line therapy for GERD[6]. While PPIs are often effective, there are patients who will be non-responders, require chronic PPI use or be subject to side effects of PPI therapy[7]. These side effects include enteric infections (*Clostridium difficile*), increased susceptibility to pneumonia, hypergastrinemia, osteoporosis and drug-drug interactions[8,9]. Furthermore, PPIs have a high drug expense and patient compliance with chronic daily use may be limited[10,11].

More invasive treatment options include surgical and endoscopic interventions. Laparoscopic Nissen Fundoplication (LNF) is considered the gold standard of treatment[12]. LNF differs from medical treatment in that it is directed at the underlying cause of GERD. The literature has demonstrated that LNF is able to provide improved relief of GERD symptoms and reduced PPI use with good long-term cost efficacy[13,14]. Furthermore, LNF may be more effective for those patients with abnormal symptoms[7,15].

Endoscopic treatments for GERD have become increasingly prevalent in recent years. There has been increased interest in these interventions by both patients and practitioners as an alternative to surgical intervention[12]. Endoscopic intervention is less invasive, typically involves a day procedure and avoids side effects of LNF such as bloating and dysphagia[9,16]. They are less permanent interventions; yet do not preclude the patient from being a future candidate for LNF[17-19]. Historically, endoscopic treatments have been divided into three separate categories: radiofrequency (RF) treatment of the GE junction, plication of the lower esophageal sphincter (LES) and injection of biopolymers[6,9]. Currently, there are two endoscopic interventions being used clinically - transoral incisional fundoplication (TIF) with the Esophyx device and RF treatment with the Stretta device.

The intent of this review is to provide an update on more recently published data regarding the two endoscopic interventions for GERD that are currently in clinical use (Stretta and EsophyX). Prior reviews have summarized short-term effects and suggest that long-term efficacy be studied and the appropriate patient populations be identified[16,20]. In the majority of published studies to date, the most common primary endpoint is subjective reduction in daily symptoms ($\geqslant$ 50%) or improvement in health related quality of life (HRQL) scores. Objective end point outcomes (pH studies, resolution of esophagitis and reduction of HH) have not been routinely studied in all patients up to this point in time.

DISCUSSION

Esophyx

The EsophyX (EndoGastric Solutions, Inc., Redmond, WA, United States) was developed as a method of restoring the valve at the GE junction through an endoluminal fundoplication (ELF) technique. The device is inserted transorally under direct vision with an endoscope. It allows for creation of 2-3 cm and 210°-300° fundoplication at the level of the GE junction. Twelve or more polypropylene, full thickness fasteners are used to create the omega-shaped valve. In a revision of the device (TIF 2), the fasteners are deployed 3-5 cm above the GE junction to create a flap valve similar to that of a LNF[12,16,21].

Randomized controlled trials

The first published randomized controlled trial (RCT) in 2011 by Svoboda *et al*[22] compared TIF against the gold standard Nissen fundoplication. The authors concluded no significance difference between the two therapies,

with a significant reduction in length of stay in favor of TIF (2.9 d *vs* 6.4 d).

The RESPECT trial was published in 2015[18]. It included 129 randomized patients. Results included a significant elimination of troublesome regurgitation in 67% (58 of 87) of TIF patients as compared to 45% (19 of 42) of PPI/sham patients. TIF patients also had significant decrease in EAE. At 18-mo follow, 71% (30 of 42) of the PPI/sham had crossed over to TIF and 28% (24 of 87) of the TIF group had resumed PPI.

The TEMPO trial was an open-label, randomized study of 60 patients who were followed up to 6 mo, with a primary end point of elimination of daily bothersome symptoms[23]. Troublesome regurgitation was eliminated in 97% (29/30) of patients undergoing TIF and off PPI, *vs* 50% (9 of 18) in the PPI group. At 6 mo, 90% (35 of 39) patients undergoing TIF had complete cessation of PPI use. EAE was normalized in 54% (21 of 39) of the TIF group *vs* 52% (11 of 21) in the PPI group. At 6 mo, 90% (18 of 20) of the TIF group had reduction of complete healing of esophagitis *vs* 38% (5 of 13) in the PPI group. Overall, the authors demonstrated that TIF had a more significant effect on controlling GERD symptoms compared to PPI.

A RCT was performed by Witteman *et al*[24], comparing TIF *vs* PPI treatment for GERD in 60 patients. They were followed up to 12 mo, with crossover of the PPI group to TIF at 6 mo. At 6 mo follow-up, HRQL scores were increased by ⩾ 50% in 55% of the TIF group *vs* 5% of the PPI group. Change in EAE, normalization of pH and healing of esophagitis was non-significant between the groups. While TIF2 had a significant increase in LES pressure, the total number of reflux episodes did not improve. In the TIF group, PPI was discontinued in 74%. Hill grade Ⅰ valves were created in 90% at the time of TIF, with only 35% remaining at 12 mo.

Long-term follow-up trials

Trials with long-term follow-up are limited in the literature. Bell *et al*[25] looked at prospectively collected data on TIF performed on 127 patients. Two year follow-up was completed on 100 patients with a primary endpoint of ⩾ 50% improvement in their regurgitation score. Of the 88 patients presenting with daily symptoms, 70% (60) reached the primary endpoint. Of the 98 patients starting with daily PPI use, 69 (70%) had complete cessation of PPI. HRQL scores remained stable to the 24 mo follow-up point. In regards to objective endpoints, 31 patients underwent endoscopic screening with healing of esophagitis seen in 75% (12 of 16). Furthermore, pH testing was performed in 50 patients preoperatively and 14 patients at 2 years. Eight of 14 (57%) patients had normalization of esophageal acid exposure.

Testoni *et al*[26], followed 50 patients who underwent TIF 2.0 with EsophyX. Mean follow-up was 52.7 mo, with 14 patients reaching 6-year follow-up. HRQL scores were significantly reduced compared to pre-intervention. In regards to PPI use, ⩾ 50% reduction or cessation was seen in 87.8% (36 of 41) at 24 mo, 84.4% (27 of 32) at 3 years, and 85.7% (12 of 14) at 6 years. There was no significant change in LES pressure at any time point. Overall, long-term response was best predicted by initial response in the first 6-12 mo, with best candidates for TIF being patients with Hill grade Ⅰ/Ⅱ valves and a hiatal hernia < 2 cm.

Literature reviews

In 2013, Wendling *et al*[19], published a systematic review of 15 observational studies of TIF. There was significant improvement in HRQL score compared to baseline score on PPI. Overall, the patient satisfaction rate with TIF was 72% at a mean of 8.5 mo. PPI cessation rates varied widely, with an overall rate of 67% at a mean follow-up time of 8.3 mo. There was weak correlation between discontinuation and follow-up length. None of the included studies were able to demonstrate reduced post-procedure EAE time. In total, there were 18 complications, with the most common being hemorrhage (1.1%) and an overall failure rate of 8.1%.

Overall, the limited long-term data reviewed here suggests that TIF with EsophyX may be effective for symptom control and PPI reduction or cessation for up to 2-6 years. There is no evidence that EsophyX is more effective than LNF. TIF may be most effective for patients with HH < 2 cm and Hill Grade Ⅰ/Ⅱ valves[23,26,27]. The ideal patient population has yet to be fully elucidated. The safety profile is acceptable, with low complication rates and no associated mortality.

STRETTA

Stretta (Mederi Therapeutics, Greenwich, CT, United States) was approved by the FDA in 2000. It delivers radiofrequency energy to the LES and gastric cardia. A gastroscope is first inserted to measure the distance to the Z-line. The gastroscope is then withdrawn and a catheter with a four channel RF generator is placed 1 cm proximal to the Z-line. Radiofrequency energy is then delivered to the muscularis propria for approximately 60 s to a target temperature of 65-85 degrees Fahrenheit. Tissue temperatures are constantly monitored using a thermocouple incorporated into the active electrodes[28]. Additional treatments are delivered by rotating the catheter circumferentially, as well as advancing it distally for a span of 2 cm towards the gastric cardia[12,16]. The mechanism of action of radiofrequency treatment for GERD has yet to be fully elucidated, but is thought to work *via* neurolysis or tissue necrosis causing local inflammation, collagen deposition and muscular thickening of the LES, resulting in fewer transient relaxations in LES pressure[28-30]. Clinical use was previously limited by safety concerns for esophageal perforation. In recent studies, the most commonly seen side effect was chest pain, which was self-limited and did not require intervention[31].

Gastroparesis has also been identified[32].

As it has been on the market for approximately 15 years, Stretta has been the topic of multiple studies and reviews, including four RCTs[29,32-34]. More recently published studies have focused on long-term efficacy of the procedure.

RCTs

In 2003, Corley *et al*[34], published the first randomized, sham-controlled trial for RFA in GERD patients, with follow-up at 0, 6, and 12 mo. At 6 and 12 mo, patients treated with RFA had significantly improved heartburn symptoms as well as improved QOL scores. No improvement was seen in the sham group. Prior to a medication withdrawal protocol there was no difference in daily PPI use between groups. Following this protocol the RF group reduced PPI usage by 46% compared to 29% in the sham group. There was no difference in EAE between RF and sham groups at 6 mo. A sub-group analysis of responders (> 50% reduction in QOL score) was shown to have significant decreases in 24-h acid exposure. Additionally, there was no difference in LES pressure or esophagitis between groups.

In 2008, Coron *et al*[29] published a prospective, randomized trial comparing PPI use *vs* RF energy in patients with PPI-dependent GERD. Results for their primary outcome demonstrated reduction or discontinuation of PPI in 18/23 (78%) of patients treated with RFA *vs* 8/20 (40%) in their control group at 6 mo follow-up. At 12 mo, this decreased to 12/23 (56%) and 7/20 (35%), respectively. Their secondary outcomes showed no difference in heartburn scores, no difference in QOL surveys, no difference in mean daily dose of PPI at 6 or 12 mo (P = 0.05) and no change in 24 h pH monitoring or endoscopic grade of esophagitis.

In another prospective, randomized, double-blinded, sham-controlled trial by Aziz *et al*[32] in 2010, patients were treated with either a single dose Stretta, a double dose of Stretta or with a sham procedure. At 12 mo there was a significant improvement in GERD-related symptoms in both active treatments, but not the sham group. In the double-dose group 50% were completely off their PPI, while only 16.6% in the single-dose group and none in the sham group were completely off of PPI therapy. LES pressure and esophageal acid exposure time was improved in both the single and double-dose treatment groups, with non-significant changes seen in the sham group.

In the latest RCT in 2012, Arts *et al*[33] reported outcomes of a double blind, sham-controlled study looking at the effect of the Stretta procedure on GERD symptoms, esophageal acid exposure and GE junction distensibility. They hypothesized that the procedure may decrease GE junction distensibility, thereby reducing the volume of refluxate and subsequently symptomatology. Symptom score was significantly reduced after the Stretta procedure, but not following a sham procedure. No change between the Stretta and sham groups was demonstrated in 3 or 6 mo follow-up endoscopy or 24-h pH monitoring. Medication use was not affected by initial Stretta procedure of sham. Finally, resting LES pressure did not change at 0, 3 or 6 mo following Stretta or sham procedure.

Long-term follow-up trials

Triadafilopoulos, in 2002, looked at Stretta durability at 6 and 12-mo follow-up[31]. They demonstrated significant improvement in heartburn scores, HRQL scores and patient satisfaction scores at both time periods. Eighty-eight percent of patients required daily PPI use at baseline, which decreased to 30% at 12 mo. Distal esophageal acid exposure time also decreased from 10.2% to 6.4%.

A prospective observational study of long term outcomes by Liang *et al*[35] in 2014, reported follow-up results on 138 of 152 initial patients. Overall symptom score was reduced at 6 mo and was sustained to the 5-year follow-up mark. At 6 mo, 38 (27.5%) of patients were completely off of PPI, which increased to 59 (42.8%) at 5 years.

Dughera *et al*[36] published long-term follow-up results of their single center study. Eight-year follow-up was achieved in 26 of 86 patients. In total, 7 patients restarted daily use of a PPI, of which 5 went on to have LNF. Overall, there was a significant decrease in heartburn score and increase in HRQL score that was still present at 8 year follow-up. Furthermore, 20/26 remained completely off a PPI. While none of the 26 patients developed endoscopic evidence of esophagitis, median LES pressure did not demonstrate any improvement at 8 years.

In the longest reported follow-up data, Noar *et al*[37] performed a 10-year, open label, prospective trial of patients with refractory GERD treated with Stretta. In total, 149 of 217 patients reached the 10-year follow-up, of which 72% had normalization of HRQL. Furthermore, 64% had $\geqslant$ 50% reduction in baseline PPI use with discontinuation in 41% at the 10 year mark. Fifty-one of 149 patients had no endoscopic evidence of erosive esophagitis at 10 years.

Literature reviews

Published reviews of the literature are conflicted in their recommendations of Stretta in the management of GERD. The most recent systematic review in 2014 by Lipka *et al*[38] concluded that was no evidence for the efficacy of radiofrequency ablation for the treatment of GERD. Their review included 4 randomized trials, all of which were determined to be of poor methodological quality. Overall outcomes showed no significant benefit of Stretta over sham therapy for mean time pH was less than 4, mean change in LES pressure, increase in discontinuation of PPI or improvement in HRQL scores[38]. This was in direct contrast to an earlier Review by Perry *et al*[3] and a subsequent recommendation review by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES)[3,20,39]. Perry *et al*[3] found, in their 2012 review of 18 studies, that radiofrequency

produced significant improvement in reflux symptoms, with improved heartburn scores, esophageal acid exposure and QOL scores. The methodologically validity of both reviews continues to be debated[38,39].

Overall, the data suggests that the Stretta procedure has an acceptable safety profile and may be effective in reducing symptom burden and QOL scores up to 8 years post-intervention. There does not appear to be any sustained improvement in objective outcomes and there is no evidence that Stretta results in improved outcomes as compared to surgical intervention.

Limitations

Treatment modalities for GERD, as a field, suffer from a lack of standardization in primary and secondary outcomes. Although many studies have looked at HRQL, the tools used to do so are markedly heterogeneous. Furthermore, whether more subjective measures such as QOL and symptom control are equivalent to objective measurements has not yet been elucidated[17]. Subjective symptom improvement is clinically relevant, but there is no established correlation to severity of reflux[12]. PPI use is quantified in studies and is an objective outcome, but is not a specific marker for GERD and may be used for dyspepsia. Manometry and pH studies are more objective markers but may have less clinical relevance, particularly for the patient if symptom control is not improved.

Future direction

In a preliminary, prospective, single-arm trial, Ota *et al*[40], looked at a novel endoscopic fundoplication technique using endoscopic submucosal dissection (ESD) in 13 patients. Scarring post-ESD results in narrowing of the GE junction and reduced reflux. The demonstrated improved symptoms in 92% (12 of 13), cessation of PPI use in 23% (3 of 13) and reduced PPI use in 23% (3 of 13). There was no change demonstrated in pH studies.

Future directions may be aimed more towards novel surgical interventions, such as the LINX reflux management system, a ring of linked magnetic beads laparoscopically placed around the LES that improves pressure without any anatomical change[7,10]. The EndoStim is another device placed laparoscopically that delivers electrical energy to the LES in order to increase resting pressure[7,10].

CONCLUSION

In theory, endoscopic management of GERD is promising field with obvious advantages of a less invasive procedure, however the majority of procedures and devices released are no longer available for lack of reported efficacy. The published data for the two procedures with the most evidence, EsophyX and Stretta, generally show improvement over baseline (PPI therapy alone) or sham procedure but currently are second-line procedures to surgical intervention[20].

REVIEW

Laparoscopic surgery for rectal prolapse and pelvic floor disorders

Alexander Rickert, Peter Kienle

Alexander Rickert, Peter Kienle, Department of Surgery, University Medical Centre Mannheim, 68167 Mannheim, Germany

Author contributions: Rickert A and Kienle P designed the review, performed the literature search, interpreted the data, wrote the paper and finally approved the manuscript.

Conflict-of-interest statement: The authors have no conflicts of interest or financial ties to disclose.

Abstract

Pelvic floor disorders are different dysfunctions of gynaecological, urinary or anorectal organs, which can present as incontinence, outlet-obstruction and organ prolapse or as a combination of these symptoms. Pelvic floor disorders affect a substantial amount of people, predominantly women. Transabdominal procedures play a major role in the treatment of these disorders. With the development of new techniques established open procedures are now increasingly performed laparoscopically. Operation techniques consist of various rectopexies with suture, staples or meshes eventually combined with sigmoid resection. The different approaches need to be measured by their operative and functional outcome and their recurrence rates. Although these operations are performed frequently a comparison and evaluation of the different methods is difficult, as most of the used outcome measures in the available studies have not been standardised and data from randomised studies comparing these outcome measures directly are lacking. Therefore evidence based guidelines do not exist. Currently the laparoscopic approach with ventral mesh rectopexy or resection rectopexy is the two most commonly used techniques. Observational and retrospective studies show good functional results, a low rate of complications and a low recurrence rate. As high quality evidence is missing, an individualized approach is recommend for every patient considering age, individual health status and the underlying morphological and functional disorders.

Key words: Resection rectopexy; Pelvic floor disorders; Rectal prolapse; Laparoscopy; Mesh rectopexy; Suture rectopexy

Core tip: Pelvic floor disorders are dysfunctions of the pelvic organs which affect a substantial amount of people, predominantly women. Operative treatment is often necessary and laparoscopic procedures play a major role. Many different techniques are used but their functional and operative outcome is hardly evaluated in randomised studies. In this review we summarize the present status of laparoscopic surgery for pelvic floor disorders. The different techniques are described,

compared and rated concerning their operative outcome, functional results and recurrence rates. Clinically important topics like management of complications and surgery in elderly people are highlighted.

INTRODUCTION

The term pelvic floor disorders summarises different dysfunctions of gynaecological, urinary or anorectal organs. These dysfunctions can present as incontinence, outlet-obstruction and organ prolapse or as a combination of these symptoms. The underlying reasons for these problems can be functional or morphological. Rectocele, enterocele and rectal intussusception are the most frequently encountered morphological manifestations and are commonly associated with a descensus of the perineum. The judgement on to what extent these anatomic disorders are clinically relevant and account for the associated bowel dysfunctions (incontinence, constipation) is difficult, as they often occur in combination and are also frequently found in healthy people[1,2]. The prevalence in women is about 25% for at least one of the above morphological pelvic floor abnormalities, somewhat questioning the clinical implications of such diagnosis *per se*.

Complete rectal prolapse is defined as protrusion of all layers of the rectum through the anal canal, full thickness rectal prolapse (FRP). A protrusion of mucosa only is called mucosa prolapse (MP). The clinical differentiation between these two can be difficult.

A common classification divides three grades: Rectal prolapse Ⅰ°: inner (recto-rectal) intussusception of the rectum proximal of the anal canal; Rectal prolapse Ⅱ°: inner (recto-anal) intussusception into the anal canal; Rectal prolapse Ⅲ°: prolapse of the rectum beyond the anus (external prolapse).

The aetiology is unclear. Rectal prolapse is often associated with obesity, pregnancy, chronic constipation and other conditions that lead to increased abdominal pressure.

The most common anatomic varieties in patients with rectal prolapse are redundant sigmoid, diastases of the elevator ani, loss of the vertical position of the rectum and its sacral attachments and a deep cul-de-sac[3,4].

The pathological relevance of an internal prolapse is unclear. A rectal prolapse Ⅰ° is present in 20% to 50% of healthy individuals[2,5]. On the other hand a recent study on 86 patients with internal rectal prolapse found faecal incontinence in 55% and showed incomplete evacuation in 45% of patients[6]. The intussusceptions that are found in people without symptoms are more often only a MP, whereas patients with evacuation problems significantly more often have a full thickness prolapse[7].

The differentiation to anal prolapse which is a protrusion of anoderm is important as the latter prolapse is generally operated *via* a perineal approach.

A rectocele is a protrusion of the rectum into the vagina. An enterocele/sigmoidocele is a prolapse of the peritoneal sack between rectum and vagina with herniation of small bowel respectively sigmoid. The clinical relevance of these anatomical varieties is also unclear. It is thought that larger rectoceles can lead to outlet obstruction with incomplete emptying. Defecographies showed an incidence of up to 93% in healthy women. Enteroceles can be found in up to 20% of healthy woman[2,5].

A prospective evaluation of 100 patients with obstructive defecation syndrome (ODS) found a combination of rectocele and MP in 54% of patients[8]. Dvorkin *et al*[7] tried to define certain predictive symptoms in 896 patients with evacuation disorders. They used an evacuation proctography and found 125 patients with rectal intussusception, 100 patients with rectocele and 152 patients with both pathologies. Anal pain and sensation of prolapse were predictive for the subsequent finding of an isolated intussusception rather than a rectocele.

In a systematic review on laparoscopic ventral rectopexy (LVR) for ODS all patients had a rectocele, 90% had an intussusception and 51% had an enterocele[9].

OPERATION PROCEDURES

Multiple operations have been described for the therapy of pelvic floor disorders. In the following section techniques and results of operations as far as they are performed laparoscopically are explained and rated (Tables 1 and 2).

The aim of the operation generally is to correct the morphologic alteration and thereby treat the symptoms of the patient, *e.g.*, improve incontinence or constipation and incomplete emptying, depending on what major symptoms the patient is suffering from. This can be achieved by three ways: (1) fixation of the rectum (rectopexy); (2) resection or plication of redundant bowel; and (3) mobilisation of the rectum. Most operations combine the two principles of rectal mobilisation and rectopexy, some operations add bowel resection.

The approach can be transanal/perineal or transabdominal. Abdominal operations seem to result in lower recurrence rates, but there are no randomised controlled trials substantiating this[10,11]. Perineal procedures avoid laparotomy/laparoscopy and therefore may have a lower operative risk and morbidity. They may therefore be more suitable for older or high-risk

Table 1 Abdominal procedures for pelvic floor disorders

Type of procedure	Operation technique
Suture rectopexy (Sudeck)	Complete rectal mobilisation to level of levators Suture of rectum to presacral fasica
Anterior sling rectopexy (Ripstein)	Complete rectal mobilisation to level of levators circular wrapping of mesh around rectum and attachment to the promontory
Lateral mesh rectopexy (Orr-Loygue)	Anterior + posterior complete rectal mobilisation fixation by two lateral mesh strips to promontory
Ventral mesh rectopexy (D'Hoore)	Strictly anterior rectal dissection to level of levators Fixation of mesh strip on distal rectum and to promontory
Posterior mesh rectopexy (Wells)	Complete rectal mobilisation to level of levators Semicircular mesh around rectum posterior, fixation to promontory
Resection rectopexy (Frykman-Goldberg)	Complete rectal mobilisation to level of levators sigmoid resection and suture fixation of rectum to promontory
Rectal mobilisation without rectopexy	Complete rectal mobilisation to level of levators no fixation

Table 2 Outcome of laparoscopic procedures for pelvic floor disorders

	Minor compl.	Major compl.	Mortality	Conversion	Incontinence	Constipation	Recurrence
LSR	0%-16%	2%-11%	0%	0%-5%	48%-82% (+)	11% (-)-70% (+)	2%-20%
LMR	0%-5%	0%-3%	0%	0%-5%	76%-92% (+)	38% (-)-36% (+)	1.3%-6%
LVR	0%-36%	0%-5%	0%-0.4%	0%-7.4%	70%-90% (+)	60%-80% (+)	0%-14%
LRR	11%-21%	0%-4%	0%-0.8%	0%-6%	62%-94% (+)	53%-80% (+)	0%-11%

Data from studies that report data of laparoscopic rectopexy. Incontinence/constipation: Improvement (+), worsening (-); Minor compl.: Dindo Ⅰ-Ⅱ; Major compl.: Dindo Ⅲ-Ⅳ. LSR: Lap. suture rectopexy; LMR: Lap. mesh rectopexy (Wells, Orr-Loygue); LVR: Lap. ventral rectopexy; LRR: Lap. resection rectopexy.

patients with a relevant co-morbidity, although again there are no adequately powered RCTs to back these recommendations up.

Virtually all abdominal procedures that were originally described *via* laparotomy can also be performed laparoscopically. The laparoscopic management of rectal prolapse was first introduced in 1992 and consisted of a suture-less rectopexy with staples without bowel resection. In the meantime, besides the conventional laparoscopic approach, there are new reports of a robotic-assisted approach with the da-Vinci system[12,13]. The transabdominal operations differ mainly in the extent of rectal mobilisation, the method of rectal fixation and the additional sigmoid resection.

RECTOPEXY

The fixation of the rectum to the sacrum is supposed to restore the physiological position of the rectum and thereby also correct the descensus of the pelvic floor. The fixation can be achieved by simple stitching, stapling or by meshes.

SUTURE RECTOPEXY (SUDECK)

This method was first described by Sudeck in 1922. The operation includes a complete mobilisation of the rectum down to the level of the levators. The rectum is then attached to the promontory by suture or staples. The dorsal mobilisation induces fibrosis which helps to fixate and hold the rectum in place[14].

In the literature this technique was used mostly to treat full rectal-prolapse in some cases combined with outlet obstruction or occasionally for outlet obstruction alone. Morbidity rates of 0% to 16% and no mortality were reported[15-18]. Conversion rates were between 0% and 5%. Most reports showed an improvement of incontinence, while constipation was mostly unchanged or even slightly worsened. Recurrence rates were between 2% and 9%[19]. A study which performed a longer follow-up found a recurrence rate of 20% ten years after laparoscopic suture rectopexy[17].

RECTOPEXY WITH MESH OR GRAFT

A mesh or graft is used to achieve a broader fixation and induce more fibrosis. Used materials include fascia lata, synthetic meshes and bio-meshes[20]. The mesh can be placed anteriorly, posteriorly, laterally or around the rectum.

ANTERIOR MESH RECTOPEXY (RIPSTEIN SLING RECTOPEXY)

Ripstein[21] described this operative technique in 1952. After complete mobilisation of the rectum a graft constructed out of the fascia lata was wrapped around the rectum and sutured to the promontory. Later instead of a fascia lata graft, synthetic meshes are used.

There is only one case report on this procedure using a laparoscopic approach which found a good clinical outcome (no morbidity, no recurrence)[22].

LATERAL MESH RECTOPEXY (ORR-LOYGUE)

In this procedure the rectum is completely mobilised anteriorly and posteriorly. Two mesh strips are sutured laterally to the rectum on both sides. The mesh strips are then sutured under tension to the promontory[23].

Several studies examined this technique with a laparoscopic approach. Lechaux *et al*[24] performed 35 laparoscopic Orr-Loygue rectopexies. They reported a surgical morbidity of 5% and no mortality. Incontinence improved in 27% of patients, constipation improved in 19%, but worsened in 27%. The recurrence rate was 6% after a follow-up of 36 mo. A study on 73 patients with an Orr-Loygue procedure with limited lateral dissection found an improvement of incontinence in 90% and of constipation in 60% of patients[25].

POSTERIOR MESH RECTOPEXY (WELLS)

After a complete mobilisation of the rectum a mesh is placed around the posterior circumference of the rectum (2/3) and then fixed to the promontory. The ventral third of the rectal circumference is spared to avoid fibrosis and stenosis by shrinking of the mesh.

A prospective study examined the Wells' procedure in 77 patients with FRP. It observed no major post-operative complications. Incontinence improved in 89% of patients, constipation improved in 36%[26]. Recurrent prolapse occurred in one patient (1.3%). Older studies evaluating laparoscopic posterior mesh rectopexy found similar results, but with a worsening of constipation in 20%-30% of patients, which might be caused by injury of autonomic nerves during posterior dissection[27].

VENTRAL MESH RECTOPEXY (D'HOORE)

In 2004 D'Hoore *et al*[28] published the results of a novel, autonomic nerve-sparing rectopexy technique. The dissection in this operation is strictly ventral in the rectovaginal space down to the pelvic floor. A lateral or dorsal mobilisation is not performed. The rectum is attached to the sacrum by a mesh which is sutured to the anterior side of the rectum. The ventral dissection and position of the mesh has several advantages: (1) a supra-anal rectocele can be corrected; (2) the rectovaginal septum is reinforced which prevents an anterior recto-rectal intussusception which may be one of the relevant mechanisms to a full rectal prolapse; and (3) a colpopexy is performed. The avoidance of any lateral or posterior mobilisation preserves the autonomic nerves[29].

Although LVR is a comparably new method it was rapidly adopted and up to now, more than 30 retro- and prospective series have reported outcome and postoperative function. Two systematic reviews have summarized the data.

Indications for the procedures were intussusception as well as overt rectal prolapse, rectocele, ODS and vaginal vault prolapse.

The rate for minor complications was 0% to 36%, major complications were observed in 0% to 5%. Reported typical but infrequent complications were erosions of the bowel or the vagina caused by the mesh or a dislocation of the mesh in about 4% of patients. Two studies reported the rare event of a lumbosacral discitis at the site of the proximal mesh fixation in 3 patients[30,31].

The conversion rate ranged from 0% to 7.4%. In most cases the conversions had to be made due to pelvic or abdominal adhesions after prior surgery.

Recurrence rates in the literature range from 0% to 15%, with most studies reporting recurrences in less than 5% of patients after a follow-up of a minimum of two years.

The median hospital stay ranged from 1 to 7.1 d. One study showed that a same day discharge was possible in selected patients and that more than 90% of patients could be discharged the day after surgery with the same long term outcome[32].

Fifty percent to 93% of patients operated with LVR suffered from constipation pre-operatively, between 44% and 93% of patients had faecal incontinence. Bowel function improved significantly in all studies with improvement rates from 70% to 90% for incontinence and 60% to 80% for constipation. Seven percent to 27% complained of persisting constipation and 0% to 18% of persisting incontinence. A new onset of constipation was found in 2% to 7% of patients[9,28,33]. Sexual function also showed significant improvement postoperatively[34,35].

Despite the good results, the rapid adoption and distribution of this new method without any high level evidence has to be seen critically[36].

RESECTION RECTOPEXY (FRYKMAN-GOLDBERG)

A sigmoid resection is combined with a rectopexy, mostly a sutured rectopexy. The resection results in the following morphologic changes: (1) an area of fibrosis develops around the anastomosis and the sacrum which leads to a rectal fixation to the sacrum; and (2) the colon lies in a straighter course which avoids torsion and sigmoidocele[37].

Especially in patients with an elongated sigmoid and slow-transit constipation it is postulated that constipation improves through the resection of redundant colon. A recent study, however, could not confirm an improvement in abnormal colonic transit time in patients after resection rectopexy[38].

Furthermore it must be considered that a removal of a part of the colon can alter bowel function independently from the underlying pelvic floor disorder. A recent study reported impaired bowel function and quality of life after sigmoid resection for diverticulitis[39,40]. Resection

of the sigmoid and creation of an anastomosis can contribute to perioperative morbidity (leakage, stenosis, ureter lesion).

Indications for resection rectopexy in the available studies were intussusception, external rectal prolapse, rectocele and ODS.

In studies for laparoscopic resection rectopexy (LRR) a minor complication rate between 11% and 21% and a major complication rate between 0% and 4% were observed. Anastomotic leakages occurred very rarely (< 1%). Only an older study from 1998 reported a leakage rate of 3.3%[41]. A low mortality rate between 0% and 0.3% was observed.

The conversion rate for LRR ranges from 0% to 6%. The reasons for conversion were mainly adhesions[42-45].

The recurrence rates ranged from 0% to 11% after a follow-up of a minimum of 4 years. The median hospital stay ranged from 4 to 9.7 d.

LRR improved incontinence in 62% to 94% of patients and constipation in 53% to 80% of patients with rectal prolapse[44,45].

LRR was performed for ODS in one study. Sixty percent of patients showed a rectocele, 60% had a rectal prolapse Ⅰ°-Ⅲ° and 50% had sigmoidocele. In 40% of patients the incontinence and the constipation ceased, in further 40% the symptoms improved irrespective of the underlying morphologic pathology[46].

ROLE OF ABDOMINAL PROCEDURES AND LAPAROSCOPY

Concerning the large number of different operative methods and the poor evidence it does not surprise that evidence based guidelines for treatment do not exist for pelvic floor disorders.

A recent survey asked 391 surgeons over 50 countries for their preferred method for the treatment of rectal prolapse. It revealed that 60% of surgeons would treat healthy patients with an external prolapse with a laparoscopic abdominal procedure, 20% would chose an abdominal method *via* laparotomy and only 20% favoured a perineal approach. For internal prolapse still 40% of the surgeons preferred laparoscopy. While in Europe LVR is the most popular treatment for external prolapse, surgeons in North America favour LRR[47].

An expert consensus paper published in 2013 explicitly recommends a laparoscopic or robotic approach for ventral rectopexy[48].

LEARNING CURVE OF LAPAROSCOPIC RECTOPEXY

The learning curve for laparoscopic colorectal surgery has been found to be around 150 to 200 cases for achieving a constant level of proficiency[49,50]. This also seems to apply to laparoscopic rectopexy. One large single-surgeon series found a proficiency level of 54 patients for operation time and about 100 patients for clinical and functional outcome parameters even for an experienced colorectal surgeon[51]. This adds to the difficulties in evaluating different procedures, as in most studies the experience of the surgeon was not defined.

COMPARISON OF LAPAROSCOPIC AND OPEN PROCEDURES

Evidence from randomised studies that compared laparoscopic with open rectopexy is rare. A Cochrane systematic review from 2008 found that the laparoscopic approach resulted in fewer postoperative complications and a shorter hospital stay compared to the open approach. But these findings are based on only two randomised studies comprising altogether 60 patients. Both studies used a ventral mesh fixation without resection[52-54] (Table 3).

Postoperative major complications were only cardiorespiratory and occurred only in the group with an open operation. A faster recovery (return to solid diet) and a reduced requirement for morphine were found for the laparoscopic group, which altogether resulted in a shorter hospital stay. But no difference was found for functional parameters (incontinence, constipation, rectal capacity, anal squeeze pressure) and recurrence rates.

Two case controlled studies compared open and laparoscopic surgery for rectal prolapse. Kairaluoma *et al*[55] used different procedures in 106 patients (LRR, suture rectopexy, Wells rectopexy). A longer operation time (170 min *vs* 100.5 min) but a shorter hospital stay (5 d *vs* 7 d) was found for laparoscopy. Functional outcome, recurrence rates and complications did not differ between case- and control-group. Kariv *et al*[56] found similar results. In this study also different techniques were applied. One third of patients in each group had resection rectopexy respectively suture rectopexy respectively mesh rectopexy (predominantly Ripstein anterior rectopexy for open surgery, Well's procedure in laparoscopic surgery). Incontinence and constipation improved in all patients, with a significant higher improvement in the laparoscopic group (74% *vs* 54%). A likely explanation for this finding was the much more frequent use of the Ripstein procedure in the open surgery group where the circular anterior mesh placement can result in a stenosis which obviously in turn contributes to the occurrence of constipation[57]. For this reason a circular mesh placement is now considered obsolete by most authors.

de Hoog *et al*[58] compared open rectal prolapse surgery to a conventional laparoscopic and a robot-assisted approach in a prospective non-randomised setting. Half of the patients were operated with the Wells procedure, the other half with a ventral rectopexy. While the functional outcome (incontinence, constipation) improved significantly in all three groups, the recurrence rates during a 2-year follow-up were significantly increased in the robot-assisted (20%) and the conventional laparoscopic group (27%) *vs* 2% in

Table 3 Comparative rectopexy studies (open *vs* laparoscopic, different procedures)

Study	Procedure	Patients	Results
Sajid (2009)	LR	330	No difference in Mort, Morb, Inc, Cons, recurrence shorter hospital stay for LR
Meta-analysis (12 studies)	OR	358	Shorter operation times for OR
different procedures			
Caddedu (2012)	LR	192	No difference in Mort, Morb, Inc, Cons, recurrence
Meta-analysis (8 studies)	OR	275	
different procedures			
Senapeti (2013)	SR	38	No difference in morbidity, recurrence and functional outcome
Randomised	RR	40	
Forminje (2014)	LVR	40	More minor complications in LRR
Retrospective	LRR	28	No difference in major complications, recurrence and functional outcome
Sahoo (2014)	LPR	38	No differences in morbidity, recurrence and functional outcome
Retrospective	LSR	32	
Lechaux (2004)	LRR	13	Significant more patients with worsening of constipation in the LMR-group (26% *vs* 8%)
Prospective	LMR	35	No differences in morbidity and improvement of continence
Madbouly (2002)	LRR	12	No difference in complications and functional outcome
Prospective	LPR	12	

Data from studies that compare open *vs* laparoscopic rectopexies or studies that compare different procedures. Mort: Mortality; Morb: Morbidity; Inc: Faecal incontinence; Cons: Constipation; LR: Laparoscopic rectopexy; OR: Open rectopexy; SR: Suture rectopexy; RR: Resection rectopexy; LPR: Laparoscopic posterior mesh rectopexy; HS: Hospital stay; OT: Operation time.

the open group. However, there was an imbalance in patient distribution, with more young patients in the laparoscopic group. In these patients a vaginopexy was generally not performed, which proved to be a protective factor in regard to recurrence on multi-variate analysis.

In a recent meta-analysis, 12 comparative studies comprising 688 patients (330 with laparoscopic rectopexy) were analysed[59]. A drawback of this meta-analysis was that only one study was randomised and that several different procedures (resection, non-resection) were used even within studies. Nevertheless a significant shorter hospital stay was found for the laparoscopic group, while no differences between the open and laparoscopic approach were found for complication rates, postoperative functional outcome, recurrence rates and mortality. A meta-analysis from 2012 showed the same results[60].

As a conclusion: the laparoscopic approach for rectal prolapse is equivalent to the open approach in terms of functional and clinical outcome. The recurrences rates do not seem to differ, although single studies suggest higher recurrence rates after laparoscopic surgery. Advantages are a shorter hospital stay. It has to be remarked that the evidence is based on only two randomised and a few prospective and comparative case-controlled studies with significant heterogeneity in patient characteristics and in applied surgical procedures, making a relevant selection bias very probably.

COMPARISON OF DIFFERENT LAPAROSCOPIC PROCEDURES

Studies comparing the different operation techniques are rare. One randomised trial compared suture rectopexy (38 patients) with resection rectopexy (40 patients). After a median follow-up of 36 mo fewer recurrences were seen in patients with resection (13%) compared to patients with suture rectopexy (26%), but the difference was not statistically significant. Functional results were not different expect that the use of laxatives was more common at all time points in the suture rectopexy group. This suggests that resection has a positive effect on constipation[11].

Formijne Jonkers *et al*[45] compared 40 patients with LVR to 28 patients with LRR for full rectal prolapse in a retrospective cohort study. Patients with LRR suffered from significantly more complications (32% *vs* 7.5%), but these were mainly minor complications (wound infections, pneumonia), the rate of major complications was not different. Both groups showed a significant improvement in faecal incontinence (LVR 40% *vs* LRR 57%) and constipation (LVR 36% *vs* LRR 32%). In this study no recurrences were observed in a median follow-up period of 4 years.

Laparoscopic posterior rectopexy was compared to suture rectopexy retrospectively by Sahoo *et al*[61] in 70 patients. Suture rectopexy had a shorter operation time (100 min *vs* 120 min). The improvement of constipation (suture rectopexy 61% *vs* mesh rectopexy 47%) and incontinence (SR 90% *vs* MR 80%) was not different.

A comparison between LRR and LR without resection in 67 patients with FRP revealed that more patients with resection improved in incontinence while constipation improved similarly in both groups.

In a multi-centre randomised trial, Karas *et al*[62] evaluated, if a sole rectal mobilisation without rectopexy was equal to a posterior mesh rectopexy. Two hundred and forty-five patients were randomised. In case of constipation sigmoid resection was added. The degree of rectal mobilisation (posterior or 360°) was up to the surgeon's decision.

After a 5-year follow-up the recurrence rate in the group without rectopexy was significantly higher than in

the group with rectopexy (8.6% *vs* 1.5%, P = 0.003). This was despite the fact that sigmoid resection was significantly more often performed in the group without rectopexy[62].

Madbouly *et al*[63] compared LRR with laparoscopic posterior rectopexy in 35 patients with rectal prolapse. The choice of operation depended on the symptoms: patients with constipation or normal bowel habits underwent LRR, patients with incontinence LPR. Constipation was improved in 90% of patients after LRR and incontinence was improved in 80% after LPR. This emphasizes the need to consider the underlying symptoms besides the morphologic alterations in the choice of procedure.

Raftopoulos *et al*[64] conducted a retrospective multicentre pooled data-analysis on 645 patients with rectal prolapse in order to determine the impact of the surgical approach and the method of rectopexy on recurrence rates (464 open, 179 laparoscopic operations). Used techniques were LPR, LRR, LSR or mobilisation only. They found recurrent rates from 20%-30% after a ten-year follow up irrespective of what operation method was used. A limitation of the study was the heterogeneity of the data with a variation of recurrence rates between the centres from 0% to 85%.

The limited data allows only modest conclusions: (1) rectopexy and resection rectopexy show equivalent functional outcome with a slight advantage of resection rectopexy in the improvement of constipation; (2) resection rectopexy leads to an increase of minor complications; (3) rectopexy should be performed in any case, as recurrence rates are higher if only rectal mobilisation is performed; and (4) recurrence rates do not differ between the procedures and reach 20% when a long term follow-up (about 10 years) is conducted.

LAPAROSCOPIC RECTOPEXY IN ELDERLY PATIENTS

It is thought that the group of elderly patients especially profits from laparoscopic surgery. A recent systematic review showed significant advantages in short term outcome in laparoscopic colorectal surgery for elderly people[65]. As the incidence of rectal prolapse and pelvic floor disorders increases with age it is important to know if laparoscopic procedures are safe for this group of patients and if they offer a good alternative to perineal procedures.

For ventral rectopexy a recent French study evaluated 4303 patients from a national database. Patients aged more than 70 years were compared to patients younger than 70 years. Elderly patients had more minor complications (urinary, wound complications) and a longer hospital stay, but major complication rate and mortality were not different[66]. Another study used a modified laparoscopic Orr-Loygue technique in 46 elderly patients (median age 83 years) with rectal prolapse. A significant cardiac morbidity was observed. Two patients died of cardiac arrest. Two patients were re-operated for recurrent prolapse after 2 mo. The reasons for the recurrences were mesh dislocations. Faecal incontinence improved significantly (Wexner-Score decreased from 19 to 5 points after one year). Constipation did not improve. Most patients were satisfied with the operation, but there was no association seen between satisfaction and functional result[67].

A German study from 2012 studied the outcome of LRR in elderly patients (> 75 years). The complication rate was slightly increased compared to the younger population. Incontinence and constipation improved in half of the patients irrespectively of age[68].

Dryberg used a laparoscopic dorsal mesh rectopexy in 81 older patients with FRP[69]. A remarkable major complication rate of 14.8% was reported. Port site hernias with consecutive ileus and postoperative haemorrhage each occurred in 5% of patients. Thirteen point five percent of recurrences were observed at a median follow-up of 2 years.

TYPICAL COMPLICATIONS AND THEIR MANAGEMENT

A study in a tertiary referral centre analysed the typical complications after mesh rectopexy: Mesh fistulation or erosion of the rectum, vagina or the bladder, recto-vaginal fistula, early symptomatic recurrence, rectal stricture and chronic pelvic pain were observed. In this study all complications could be managed laparoscopically[70].

The reasons for early recurrence were in all 27 cases an inadequate technique during the prior operation (only limited or no ventral dissection, no sutures in the recto-vaginal space, detachment or incorrect position of the staples, wrong placement of the mesh to the lateral instead the anterior rectal wall with development of an enterocele). These cases were treated by placement of a new mesh and fixation with staples and sutures. Recto-vaginal fistulas were treated with removal of the mesh and abdominal or transvaginal fistula repair. Rectal injuries and strictures were operated by anterior resection and a placement of a bio-mesh. In all patients with rectal strictures the mesh had been stapled to the mid-sacrum rather than to the promontory. Erosions of the vagina or the bladder were managed by mesh removal, defect repair and insertion of a bio-mesh. All women with this complication were postmenopausal and had previous hysterectomy. In patients that complained about chronic pain unresponsive to pain medication, the mesh showed an excessive inflammation. A replacement of the mesh by a teflon-coated mesh improved symptoms. After revisional surgery, quality of life and bowel function improved significantly.

Two case reports describe a mesh fistulation in the rectum[71,72]. Typical symptoms were recurrent fever, pelvic pain and rectal bleeding. Diagnosis was made

by flexible sigmoidoscopy. In one case therapy was anterior rectum resection, in the other case the mesh was extracted laparoscopically and a loop-ileostomy was performed.

Tranchart *et al*[73] observed 6 rectal mesh migrations after 312 laparoscopic ventral mesh rectopexies (1.9%). The median time interval between surgery and onset of symptoms was 53 mo (range 4 to 124 mo). The treatment was transanal partial mesh resection, in one case where a recto-cutaneous fistula was present, a deviating colostomy was added. A recurrent mesh migration was again treated with partial mesh resection. After a median follow-up of 40 mo all patients were free of complaints and showed no recurrent mesh, migration.

As a rare but serious complication lumbosacral discitis at the site of rectal fixation was observed after ventral rectopexy and resection rectopexy. Only four cases are reported in literature. Patients presented typically 1 to 3 mo after the initial operation with severe lower back pain, fever and malaise. An magnetic resonance imaging revealed the diagnosis. A contrast enema was helpful to rule out a rectal fistula. Broad spectrum iv-antibiotics covering colonic flora are the treatment of first choice. In some cases, antibiotic treatment was not sufficient, and removal of mesh or suture material was necessary, in one case with a deviating colostomy[31,74,75]. A gynaecological review found 26 cases of discitis after sacrocolpopexy or rectopexy in a 50-year period[76]. Although this complication is rare it should always be considered in patients complaining of persisting back pain after any type of rectopexy.

FINANCIAL CONSIDERATIONS

An Australian study from 2004 conducted a cost-effectiveness analysis for posterior mesh rectopexy in a randomised setting. When costs for theatre time, staff, laparoscopic equipment and hospital stay were included, the laparoscopic operation was less costly than the open operation. The shorter hospital stay in the laparoscopic group accounted for this saving[77].

ASSESSMENT OF DIFFERENT APPROACHES

The evaluation of the different operation techniques is difficult, as the quality of available studies is low and outcome parameters are not defined consistently.

Regarding complications and conversion rates all laparoscopic procedures provide similar good results with each having their typical complications (anastomotic leakage, mesh complications). Recurrence rates for all methods are below 10% within a follow-up of up to 5 years but studies that extended follow-up to 10 years found recurrence rates of up to 20%.

LRR and LVR improve both constipation and faecal incontinence in a similar degree, but randomised studies are missing. LSR and LPR have about the same effect on incontinence, but they tend to have a lesser effect on constipation, in some studies these operations even worsened constipation in a relevant number of patients.

As high quality evidence is missing, an individualized approach is recommend for every patient considering age, individual health status and the underlying morphological and functional disorders. Moreover, as most operations actually show acceptable results, the choice of procedure also depends on the experience and learning curve of the surgeon.

Abstract

Various procedure-related adverse events related to colonoscopic treatment have been reported. Previous studies on the complications of colonoscopic treatment have focused primarily on perforation or bleeding. Coagulation syndrome (CS), which is synonymous with transmural burn syndrome following endoscopic treatment, is another typical adverse event. CS is the result of electrocoagulation injury to the bowel wall that induces a transmural burn and localized peritonitis resulting in serosal inflammation. CS occurs after polypectomy, endoscopic mucosal resection (EMR), and even endoscopic submucosal dissection (ESD). The occurrence of CS after polypectomy or EMR varies according previous reports; most report an occurrence rate around 1%. However, artificial ulcers after ESD are largely theoretical, and CS following ESD was reported in about 9% of cases, which is higher than that for CS after polypectomy or EMR. Most cases of post-polypectomy syndrome (PPS) have an excellent prognosis, and they are managed conservatively with medical therapy. PPS rarely develops into delayed perforation. Delayed perforation is a severe adverse event that often requires emergency surgery. Since few studies have reported on CS and delayed perforation associated with CS, we focused on CS after colonoscopic treatments in this review. Clinicians should consider delayed perforation in CS patients.

Key words: Endoscopy; Syndrome; Colorectal; Dissection; Coagulation

Core tip: Few studies have reported on coagulation syndrome (CS) and delayed perforation associated with CS. Thus, in this review, we focused on CS after

colonoscopic treatments. CS is found in around 1% of cases after polypectomy and endoscopic mucosal resection and in 7%-8% of cases after endoscopic submucosal dissection. The prognosis for CS is excellent. However, clinicians should be mindful of delayed perforation in CS patients.

INTRODUCTION

Various endoscopic treatments such as polypectomy, endoscopic mucosal resection (EMR), and endoscopic submucosal dissection (ESD) have been used to treat colorectal neoplasms[1-14]. Colonoscopic polypectomy reduces the incidence of colorectal cancer by 70%-80%, and it has been used worldwide[1,2]. EMR is indicated for the treatment of colorectal adenomas, intramucosal, and submucosal superficial cancers (SM1; invasion of < 1000 μm from the muscularis mucosae) because of the negligible risk of lymph-node metastasis and excellent clinical outcomes; however, there is a limit to the size of *en bloc* resection[3-11].

Recently, ESD is another procedure used to remove large colorectal lesions according to the EMR curative criteria. This procedure is frequently used for removing large lesions by *en bloc* fashion, which includes lesions that would require piecemeal EMR for removal[11-14].

With respect to these aforementioned procedures, various procedure-related adverse events have been reported. Serious complications included delayed bleeding and perforation. Previous studies on the complications of colonoscopic polypectomy or EMR have primarily focused on perforation or bleeding[15-17]. Coagulation syndrome (CS) following endoscopic treatment, which was first reported as post-polypectomy syndrome (PPS)[18], is another typical complication. This has syndrome has a variety of names, including post-polypectomy CS, post-polypectomy electrocoagulation syndrome, and transmural burn syndrome[17-33]. Recognizing CS is important to avoid unnecessary exploratory laparotomy, because the syndrome can resolve with conservative treatment in most patients[19,21,23,26,30,31]. However, little is known about the clinical characteristics, clinical outcomes, and risk factors associated with CS, and the frequency of CS varies in previous studies[17-33]. Additionally, CS occurs after polypectomy, EMR, and even ESD[26,34]. With the evolution of treatment, the occurrence of this syndrome is thought to increase. Furthermore, there is a possibility that CS causes delayed perforation, which is a very severe complication[25,26,33,35-42]. In this review, we clarify the present status of CS following endoscopic treatment for colorectal neoplasms.

Most previous studies have investigated CS after polypectomy and EMR. Thus, in this review, we defined PPS as CS associated with only polypectomy and EMR, while CS included ESD.

DEFINITION OF CS

CS is the result of an electrocoagulation injury to the bowel wall that induces a transmural burn and localized peritonitis resulting in serosal inflammation[17-33]. Patients with CS are diagnosed when they present with abdominal pain (sometimes tenderness with rebound); fever; leukocytosis; an elevated C-reactive protein level; or peritoneal irritation symptoms and signs that occur after colonoscopic treatment (polypectomy, EMR, and ESD) with electrocoagulation, in the absence of visualized perforation by abdominal radiography and/or computed tomography (CT)[26,34]. It is important to recognize that CS can be misleading, as it can resemble a true rupture of the colon and present with pain, a low fever, and mild leukocytosis. Typically, patients with CS present within a few hours to 7 d after colonoscopic treatment with fever, localized abdominal pain, and localized peritoneal signs[19,20,26,30]. It is important to recognize this condition, because it does not require surgical treatment in most cases[19,21,23,26,30,31]. There is a range in severity of PPS between admission to the intensive care unit and post-discharge, as it can lead to shock, additional surgery, or death from possible follow-up on an outpatient basis.

CLINICAL CHARACTERISTICS

The rate of occurrence

The occurrence rate of PPS varies widely from 0%-7.6% in previous reports; however, most studies report a rate around 1%. It is considered some reports had high percentages of occurrence due to small patient populations[18-21,23-26,28-33].

Risk factors

Some previous reports have investigated the risk factors of PPS Nivatvongs[18] showed that 83% of PPS patients had polyps in the right side of the colon, and all were sessile polyps. Choo *et al*[24] also showed that right-colon polypectomies had a statistically significantly higher tendency for developing PPS. Lee *et al*[20] reported that a polyp size > 2 cm (OR = 1.08) and hypertension (OR = 14.40) were associated with a significantly increased risk of PPS. The most recent report showed that hypertension, a large lesion size, and non-polypoid configuration of the lesion were independently associated with PPS according to multivariate analysis[19].

PPS develops when the electrical current applied during colonoscopic polypectomy extends past the mucosa into the muscularis propria and serosa, resulting in a transmural burn without perforation[17-33]. Therefore, larger lesions and non-polypoid configuration are logical

risk factors, as they usually require a large amount of thermal energy for a longer duration. However, the mechanism of hypertension to promote PPS is unclear. Patients with hypertension are more likely to have endothelial dysfunction[43] and atherosclerosis[44,45], which may be contributing factors.

However, with thinness of the wall, there is also concern regarding the frequency of PPS. The right colon wall is thin, and a large study that addressed major post-polypectomy complications reported barotraumatic perforations, and all of them were caused by cecal blow-out[34,46-48]. Regarding colonic perforation, it has been suggested that air insufflation during colonoscopy generates a higher pressure in the cecum than in the rest of the colon, increasing vulnerability to injury. In addition, Rutter *et al*[49] hypothesized that a more perpendicular approach to polypectomy in the cecum may increase the risk of complications. However, scientific evidence in support of these theories is lacking.

Loffeld *et al*[47] also reported that barotrauma caused by insufflated air occurs more often than therapeutic perforation due to polypectomy or coagulation.

Prevention of PPS

Theoretically, submucosal saline injections of large, non-polypoid lesions prior to EMR may reduce the risk of PPS. The rationale for this is that a submucosal saline injection may increase the thickness of the submucosal layer and consequently reduce the risk of PPS[32]. However, no studies have supported this assumption. Sethi *et al*[17] hypothesized that submucosal injection itself leads to serosal irritation and localized peritonitis, and then patients present with PPS symptoms. Therefore, the protective role of the saline "cushion" for PPS should be considered in future studies.

The improvement of devices would likely reduce PPS. Galloro *et al*[50] reported that steel snares induced significantly deeper tissue injury than tungsten snares in the pure cut mode; therefore, tungsten snares may reduce the risk of PPS[32]. Another way to reduce the risk of PPS is dependent on skill. Using lower risk procedures when clinically appropriate or referring patients to high-volume endoscopists can reduce the complication rates[51].

PPS is considered different from infection from a local mucosal defect. Min *et al*[52] reported that blood cultures at baseline and 5 min after the procedure were all negative, and a blood culture at 30 min after the procedure showed a positive result in only 1 of 40 patients (2.5%). However, this one positive sample was considered contamination. None of the 40 patients showed any signs or symptoms associated with infection. Therefore, the prior administration of antibiotics is considered controversial for preventing PPS.

Treatment and prognosis

Most cases of PPS have an excellent prognosis, and they are managed conservatively with medical therapy. In some reports, all patients were admitted to the hospital, while in other reports, some cases underwent outpatient observation[19,21,23,26,30,31]. Treatment of PPS requires bowel rest and the administration of intravenous fluids and broad-spectrum parenteral antibiotics to cover the colonic bacterial flora. Nothing is taken by mouth until the symptoms subside. Patients with mild symptoms and adequate outpatient follow-up can be managed with oral antibiotics and a clear liquid diet for 1-2 d.

In contrast, to diffuse peritoneal signs, there is an indication for immediate surgical intervention. Within the spectrum of post-polypectomy cautery injury, "mini-perforation" falls between a "serosal burn" and frank perforation (with diffuse peritonitis). It is a minimal defect that can be quickly covered by peri-intestinal fat and omentum[16]. Its clinical features include pneumoperitoneum without signs and symptoms of diffuse or spreading peritonitis, and with local tenderness that is characteristic of a full-thickness burn. The patient usually improves within 24 h, and the symptoms should resolve within 96 h with conservative treatment. The dilemma as to whether the conservative or surgical approach is more appropriate for managing this kind of perforation still exists[19-22,26,30,31].

Although conservative treatment can generally be performed in most patients, it is important to adopt careful measures such as prolonging the fasting period and considering the possibility of delayed perforation[26,35-39].

DELAYED PERFORATION

Immediate perforation is diagnosed by endoscopy during resection and by the presence of free air on plain abdominal film or abdominal CT scan[15-17,35,51,53]. This is very rare; however, delayed perforation, which is considered to be caused by an electrical or thermal injury after electrocoagulation, was reported in these cases. Delayed perforation after colonoscopic resection can begin as PPS, which can evolve into a perforation or as a free perforation with air and fluid leakage, resulting in pneumoperitoneum and peritonitis[35-39].

Japan Gastroenterological Endoscopy Society guidelines for colorectal ESD/EMR defined delayed perforation as an intestinal perforation that develops over a certain period postoperatively (*i.e.*, intestinal perforation that is detected after the scope has been withdrawn following completion of ESD/EMR during which perforation did not occur). This is diagnosed based on abdominal pain, abdominal findings, the presence of a fever, and an inflammatory response that is consistent with PPS. Most cases of delayed perforation occur within 14 h after endoscopic resection. However, approximately one-third of delayed perforation cases are confirmed within 24 h after treatment. Free air, which cannot be detected by simple radiographic imaging, is sometimes found on abdominal CT. Therefore, in cases where delayed perforation is suspected, abdominal CT should be performed. Surgeons must be called for emergency surgery, because it is essential in cases of delayed perforation[26].

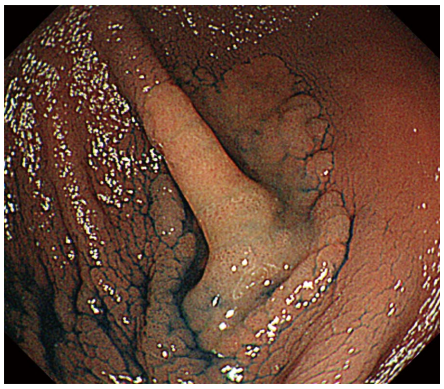

Figure 1 Chromoendoscopy showing a 30 mm laterally spreading tumor (non-granular type) located at the bottom of the cecum bottom.

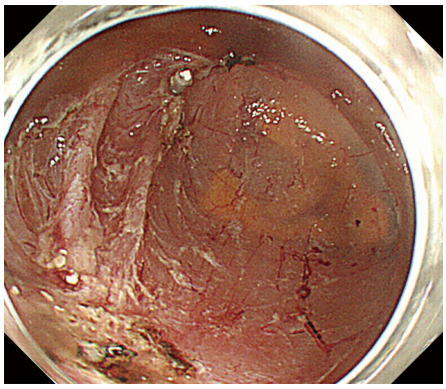

Figure 2 Endoscopic submucosal dissection is performed safely without intraoperative perforation. The procedure time is 47 min.

In 1994, Lo *et al*[54] reported that 43.8% of therapeutic perforations were managed conservatively with a mortality rate of 4.1%. This means that perforation is still a severe condition that reduces patients' quality of life[25,35-39]. Thus, prevention of PPS and its potential sequelae are most important, and clinicians must always consider the potential for delayed perforation due to PPS.

Only two studies have reported on the incidence of delayed perforation. Taku *et al*[39] reported delayed perforation in 7 of 15070 cases, while Waye *et al*[25] reported it in 1 of 777 cases. This is still not sufficient evidence. For ESD, the incidence of delayed perforation ranges from 0.1% to 0.4%[26,40-42].

THE RELATIONSHIP WITH ESD

CS after ESD

ESD has been a reliable method for en bloc resection of colorectal tumors regardless of the lesion size for years. Although colorectal ESD has been established as a procedure with reproducible safety and efficacy, complications such as intestinal perforation and delayed bleeding remain to be problematic. Similarly, few studies have reported CS after ESD[11-14,26].

Hong *et al*[48] reported that 8.6% showed CS after colorectal ESD. There were no differences in the demographic and endoscopic characteristics (age, sex, underlying disease, procedure time, tumor size, macroscopic type, location, and pathologic findings) between patients with CS and those without CS. The mean hospitalization stay was statically significantly longer in the CS group than that in the non-CS group. All patients with CS were treated with conservative (non-surgical) management (*e.g.*, fasting and intravenous antibiotics). CS showed a favorable progression even after ESD, and delayed perforation was not reported. See comment in pubmed commons below.

Delayed perforation after ESD

CS is reported even after ESD, and its frequency is clearly higher than polypectomy or EMR[26,34,48]. The procedure time and ulcer bed to energization that largely affects the characteristics of ESD procedures is evident theoretically. Delayed perforation in ESD is also a great concern. The indications for ESD are markedly different from those for conventional EMR, and the overall perforation rate is higher compared to conventional EMR[55]. Delayed perforation after ESD reportedly ranges from about 0.1%-0.4%; however, this may be because of the small number of reports[26,40-42,55].

Saito *et al*[41] reported that delayed perforations occurred in another 4 patients (0.4%) after ESD. Two of the 4 patients with delayed perforations were successfully treated conservatively, because the abdominal findings and inflammatory changes based on laboratory data were slight. However, other patients with delayed perforation required emergency surgery because of the risk of peritonitis. Saito *et al*[41] also reported that 0.11% (1/900) showed delayed perforation that required emergency surgery. Previous studies have cautioned that clinicians must carefully follow patients with delayed perforation, and continually close communication with consulting surgeons is essential since the number of such cases has been quite limited to date.

Few studies have reported on delayed perforation after ESD. While previous reports have shown the success of endoscopic clip closure with over-tube[42], the treatment and prognosis often require emergent surgery.

Case presentation

A 44-year-old woman underwent colonoscopy for surveillance of ulcerative colitis, and a 30 mm cecal sessile polyp was revealed (Figure 1). We diagnosed this tumor as a sessile serrated adenoma/polyp using the pit and narrow-band imaging patterns. Because of the size of the tumor and the tumor morphology, we chose ESD in order to perform en-bloc resection. ESD was performed safely without any perioperative complications (Figures 2 and 3), and she reported no symptoms. However, 24 h after ESD, she had a high fever (38.6 ℃) with slight abdominal pain and leukocytosis. Subsequently, she was diagnosed with CS after ESD. She fasted and received

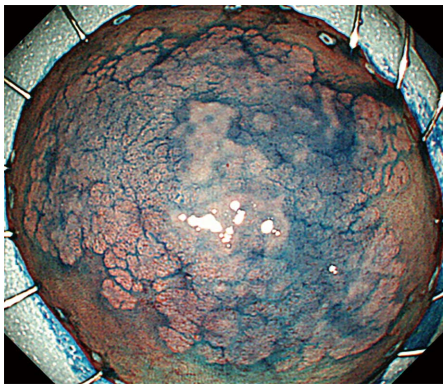

Figure 3 The tumor is resected in an *en bloc* fashion, and the specimen measures 51 mm × 40 mm.

Figure 4 Abdominal contrast enhanced computed tomography 24 h after endoscopic submucosal dissection. Free air is not recognized.

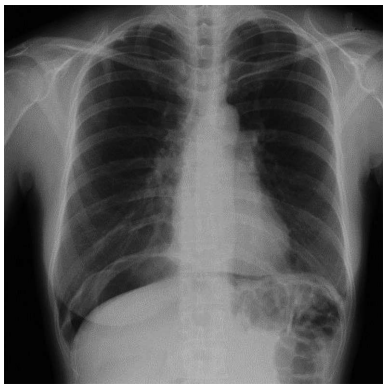

Figure 5 Abdominal radiography 36 h after endoscopic submucosal dissection because of a complaint of severe abdominal pain. A large amount of free air is observed under the diaphragm.

antibiotics (cefmetazole). CT was obtained immediately, but no findings were suggestive of perforation (*i.e.*, free air and ascites were not present) (Figure 4). Thirty hours after ESD, severe abdominal pain developed, and 36 h after ESD, free air appeared on radiography and CT (Figures 5 and 6). At this point, we diagnosed the patient with delayed perforation that developed after CS. Emergent laparoscopic surgery was performed, and a perforation site was found in the ESD ulcer at the bottom

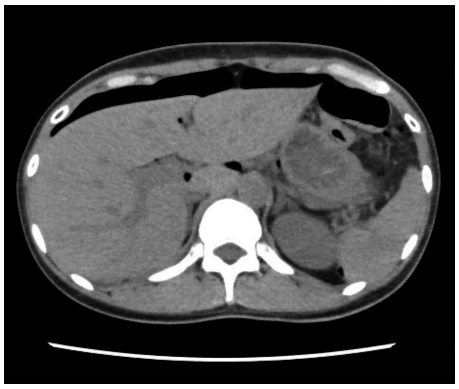

Figure 6 Abdominal computed tomography 36 h after endoscopic submucosal dissection. A large amount of free air is observed on the surface of the liver and the intraperitoneal cavity.

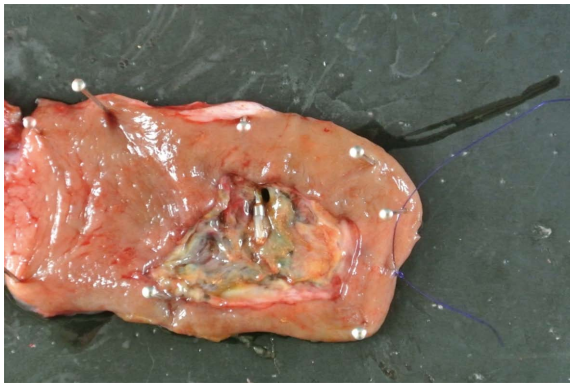

Figure 7 A small perforation site is present in the surgical specimen.

of the cecum (Figure 7). Partial cecum resection was performed, and the patient's condition improved rapidly.

CONCLUSION

CS is found in around 1% of cases after polypectomy and EMR and in 7%-8% of cases after ESD. Although the prognosis is excellent, clinicians should consider delayed perforation in CS patients.

Abstract

Different treatment modalities have been proposed in the treatment of early gastric cancer (EGC). Endoscopic resection (ER) is an established treatment that allows curative treatment, in selected cases. In addition, ER allows for an accurate histological staging, which is crucial when deciding on the best treatment option for EGC. Recently, endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) have become alternatives to surgery in early gastric cancer, mainly in Asian countries. Patients with "standard" criteria can be successfully treated by EMR techniques. Those who meet "expanded" criteria may benefit from treatment by ESD, reducing the need for surgery. Standardized ESD training system is imperative to promulgate effective and safe ESD technique to practices with limited expertise. Although endoscopic resection is an option in patients with EGC, surgical treatment continues to be a widespread therapeutic option worldwide. In this review we tried to point out the treatment modalities for early gastric cancer.

Key words: Early gastric cancer; Endoscopic submucosal dissection; Endoscopic mucosal resection; Pathological staging; Gastrectomy

Core tip: Gastric cancer is one of the main causes of cancer death. For early gastric cancer (EGC) endoscopic resection is an effective treatment modality for selected cases of EGC. Endoscopic submucosal dissection is designed to provide *en bloc* R0 resection regardless of size. Gastrectomy is the standard treatment for EGC with suspected lymph node metastases. This review describes the current different treatment modalities for early gastric cancer.

INTRODUCTION

Gastric cancer is one of the leading causes of cancer worldwide, causing high mortality. In Asian countries, the frequency of early gastric cancer (EGC) is far superior to that of Western countries. Currently early gastric cancer (EGC) is defined as one that is limited to the mucosa or submucosa, regardless of the existence of nodal metastases[1]. The incidence of lymph node metastasis in EGC is very low. If the EGC is confined to the mucosa, the incidence is estimated at around 3%. When the EGC reaches the submucosa, rises to nearly 20%[2]. The existence of nodal metastases influence the type of treatment to be used. In these cases, surgical treatment is recommended along with adjuvant therapy. Overall the EGC has a good prognosis, with a 5-year survival rate of over 90%[3]. There are different therapeutic options for the treatment of early gastric cancer. At present, endoscopic resection provides a minimally invasive treatment with a similar efficacy to surgery.

TREATMENT MODALITIES

Therapeutic modalities for EGC range from endoscopic resection to gastrectomy and adjuvant treatments. Therefore, it is essential to perform an adequate staging of cancer as to determine which patients are candidates for either therapy.

ENDOSCOPIC TREATMENT

Endoscopic therapy is a minimally invasive treatment that allows the patient to preserve the entire stomach and maintain a good quality of life. Moreover, the cost is usually less and efficacy comparable to surgery. The degree of difficulty in performing endoscopic resection depends on the location of the lesion in the stomach, being the difficulty higher for resection of lesions localized on the posterior wall and lesser curvature. Depressed type of EGC is the most common. To facilitate the visualization of the lesion mucolytic and defoaming agents are used (*e.g.,* Acetylcysteine and Dimethicone, respectively). Endoscopic therapy is directed to selected patients in whom there is no evidence or risk of lymph node involvement. Endoscopic resection *vs* ablative technique allows assessing the specimen thus becoming the optimal method of staging for early gastric cancer[4]. Also, endoscopic therapy does not prevent a subsequent surgical therapy if needed. EUS has limited staging accuracy (80%-90%) and therefore would result in unnecessary surgery in up to 10%-20% of patients[5,6]. Endoscopic resection allows the pathologist to assess the depth of invasion, degree of differentiation and lymphatic and vascular involvement, thus allowing for a prediction of the risk of metastases in the lymph nodes. This is crucial for a correct diagnosis and risk stratification of metastasis. The main endoscopic techniques used are endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD). According to the histological and morphological findings gastric carcinoma can be divided into differentiated (intestinal) and undifferentiated (diffuse)[7]. The risk for nodal metastasis for differentiated and undifferentiated EGC is around 0.4% and 4%, respectively. Endoscopic resection techniques can be applied, according to "standard" criteria, in patients with lesions resectable *en bloc* which meet histological criteria (intestinal type adenocarcinoma limited to the mucosa without venous or lymphatic invasion) and morphological criteria (< 20 mm without ulceration; < 10 mm for flat and depressed lesions)[8,9]. When these criteria are met, the risk of lymph node involvement is not more than 1.7%. In addition, "expanded" criteria for endoscopic resection have been defined which include: (1) EGC intestinal type mucosa confined to any size without ulceration; (2) EGC intestinal type confined to the mucosa < 3 cm with ulceration; and (3) EGC intestinal type < 3 cm confined to the upper 0.5 mm from the submucosa (sm1 < 500 μm) without lymphovascular involvement and 4. ECG poorly differentiated, < 2 cm, not ulcerated[10,11]. Expanded criteria for ER reduces the need for gastrectomy in EGC (Table 1). When ER has been performed for poorly differentiated type of EGC results for patients who declined surgical treatment showed: *en bloc* resection rate 83%, complete resection rate 81%, clinical remission 93%, and recurrence in only 7%[12].

Endoscopic mucosal resection

Currently endoscopic mucosal resection (EMR) is considered as an effective and safe treatment for superficial lesions. Requires specific endoscopic experience and the endoscopist needs to be prepared to try to resolve the possible complications that may arise during the implementation of the technique. Over the last years different EMR techniques have been described[13]: (1) Strip biopsy[14]. This resection technique designed to remove small lesions requires the use of a dual channel endoscope. It simultaneously uses a polypectomy snare and a biopsy forceps to achieve the resection; (2) Endoscopic double snare polypectomy; (3) EMR using a transparent plastic cap, initially developed in 1992 for resection of early oesophageal cancer and later for resection of early gastric cancer[15]; and (4) EMR using a ligation device (Multiband mucosectomy)[16,17] (Figure 1). These last two are the techniques for endoscopic mucosal resection most widely used in the treatment of EGC. However, in lesions greater than 20 mm, recurrence rate may be increased as they might require a piecemeal resection[18]. Therefore, EMR is the procedure of choice in patients with EGC who meet the standard criteria for endoscopic resection. Different studies have shown excellent results using EMR with figures for complete resection and survival at 5 years greater than 85%-90%[19,20]. The risk of local recurrence associated with EMR is variable. If the resection is piecemeal the risk of recurrence rate is set below 35%,

Table 1 Treatments options in a patient with early gastric cancer

Histology	Mucosal cancer					Submucosal cancer	
	⩽ 10 mm (flat/depressed)	⩽ 20 mm > 20 mm (No ulceration)		⩽ 30 mm > 30 mm (Ulceration)		Into the upper third (⩽ 30 mm)	Into the middle third (any size)
Intestinal type	EMR	EMR	ESD	ESD	Surgery	ESD	Surgery
Diffuse type	Surgery ESD[1]		Surgery	Surgery	Surgery	Surgery	Surgery

[1]Treatment option if the patient decline surgery. EGC: Early gastric cancer; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection.

Table 2 Process steps in endoscopic submucosal dissection treatment of the early gastric cancer

Process steps	Technique/devices
Estimation of lateral extension	Chomoendoscopy (indigo carmine) ± NBI
Marking	Mucosal markings are placed 5 mm lateral to the lesion margin
Submucosal injection	Injection of saline mixed with diluted epinephrine (1:100000) and indigo carmine into the submucosal layer
Mucosal incision (precutting)	A small initial mucosal incision is made to gain access to the submucosal space without to injure the muscularis propria (*e.g.*, by Dual knife)
Circumferential incisión	Carried out 5 mm lateral to the mucosal markings (*e.g.*, IT knife)
Submucosal dissection	The technique varies among endoscopist Adequate reinjection of fluid into the submucosa The parallel movement for muscle layer with the IT2 is typically lateral With the Dual knife forward

NBI: Narrow band imaging.

being practically nonexistent if *en bloc* resection was possible[21,22]. In cases of incomplete resection with EMR, gastrectomy might be indicated if the tumor has submucosal or lymphovascular involvement or positive resection margins. However, in cases where the patient is a poor surgical candidate further endoscopic resection could be considered with good results, especially if incomplete resection is due to the presence of positive lateral margins of resection[23,24]. In treatment with EMR a suitable distance of at least 2 mm between the EGC and the edge of the specimen is required to achieve complete resection. Indigo carmine chromoendoscopy is the most useful method to determine the lateral margin of EGC.

Endoscopic submucosal resection

Endoscopic submucosal resection (ESD) is a complex and demanding technique that allows *en bloc* resection of larger EGC, avoiding piecemeal resection of the EMR and therefore the risk of recurrence[25-27]. Similar to the EMR, its main indication is resection of superficial tumors with no risk of lymph node metastasis. Expanded criteria have been proposed for endoscopic resection with ESD, as with this technique large *en bloc* resections are possible. ESD for EGC with expanded criteria have long-term survival and outcomes similar to those of patients treated according to the traditional criteria (5-year survival rate 93% and 92%, respectively)[28]. In ESD, the lesion is marked circumferentially, usually by applying soft coagulation current. Then, a solution with saline (0.9% NS), adrenaline and dyes (indigo carmine, methylene blue) is injected into the submucosa allowing distinction between the submucosal and muscular layer. Some authors do not recommend the use of Methylene blue because it is absorbed into the cell nucleus, which results in intense staining that hampers visualization[29]. To avoid the short duration of the lifting effect of submucosal injection, others have suggested the use of substances with a viscosity grade higher than saline (0.9% NS). The use of hyaluronic acid has been proposed but its high price, has conditioned its use[30,31]. Glycerol 10% could be a good and cheap alternative[32]. Finally, the lesion is dissected and removed *en bloc* using different types of needles, specific for each step of the procedure (Needle Knife, IT Knife, Flex knife, Hook knife, Triangle-tip knife, Dual Knife, Hybrid Knife, Flush knife and others) typically done with coagulating current. Some needles have at the tip an insulating material with a protective function that allows for a safer dissection[33-35] (Figure 2). The main functions that must meet the ESD devices are: marking, injection, precutting, circumferential incision, submucosal disection and hemostasis (Table 2). However the choice of needle depends on the availability, familiarity and personal preference of the endoscopist as there are no studies that demonstrate the superiority of one over the other. Sometimes it can be useful to use a transparent plastic cap on the endoscope tip that allows more control during dissection. Moreover, these devices use cutting currents, coagulation or a mixture of both through electrosurgical generators. CO_2 insufflation is recommended because it causes less luminal distension. Furthermore, if there is a perforation the leaking CO_2 will rapidly be reabsorbed decreasing the intraperitoneal pressure and then the respiratory compromise[36]. From a technical point of view, ESD is more challenging than EMR and requires

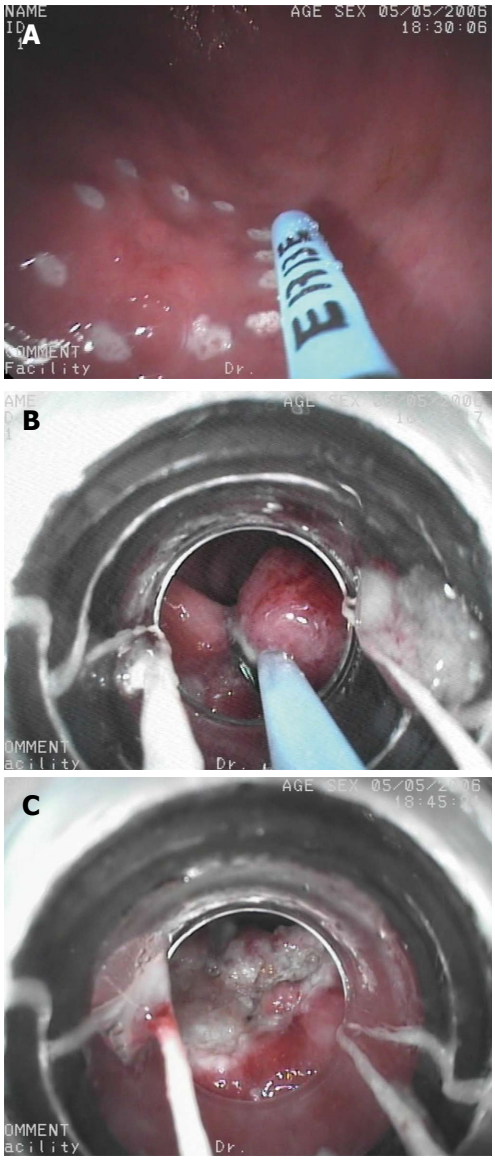

Figure 1 Endoscopic mucosal resection with Multiband Ligator for early gastric cancer. A: Argon plasma coagulation is used for marking early gastric cancer; B: A multiband ligator was used to create a pseudopolyp and it is removed by a minipolypectomy snare using pure coagulating current; C: Residual scar after Multiband Mucosectomy.

more "preparation". However, the main advantage of the ESD over other techniques is that it allows *en bloc* resection of larger lesions reducing the rate of local recurrence. As demonstrated in comparative studies between EMR and ESD, with ESD success rates between 95%-98% for in-bloc resection and survival at 5 years of 83%-97%[37,38]. The ESD requires skill and a long learning curve[39-42]. In cases when resection with ESD is incomplete (positive resection margins, invasion of the submucosa or muscularis, lymphovascular invasion or undifferentiated cancer), surgery should be considered (gastrectomy with perigastric nodal resection)[43]. The role of laparoscopic perigastric nodal resection is not clearly established but may be considered as an alternative[44]. ESD can be use in elderly patients as well as in those who require antiplatelet therapy for high risk of thrombosis[2]. Proposed strategy for endoscopic treatment by ESD set 4 levels: capability for EGC detection and knowledge of the indications of ESD, observation of several ESD procedures performed by expert endoscopists, perform dissections in *ex-vivo* animal models followed by procedures in animal models *in vivo* and finally performing selected (simple) ESD in humans under expert supervision. Then, continue with training in animal models to acquire more skill. About 20 annual cases of ESD are considered necessary to acquire competence in ESD[2]. In Japan and Korea the incidence of early gastric cancer is significantly higher compared to the West. Therefore in the West, the opportunities to conduct training in gastric EDS are scarce.

ENDOSCOPIC COMPLICATIONS

Various complications after endoscopic treatment for EGC have been described: bleeding, perforation, stenosis, aspiration pneumonia, phlegmonous gastritis, mediastinal emphysema. Of these, the most common is bleeding, the average incidence is set at 9% and usually occur during the process or within 24 h[45]. Depending on the time of onset, bleeding can be classified as: (1) immediate; (2) early (within the procedure); or (3) late (post-procedure). The immediate bleeding is less common in the distal portion of the stomach as the submucosal arteries are of lower caliber[46]. Acute bleeding may obscure the visual field, leading to a higher risk of complications. Therefore, endoscopic hemostasis should be immediately performed. The incidence of delayed bleeding after ESD is below 15%[37] and different factors have been related to its appearance: macroscopic appearance (large size > 40 mm, depressed or flat lesion), location in the middle or upper third, advanced age (> 80 years), limited endoscopic experience, timely procedure or treatment of recurrent lesions[47,48]. Late risk of bleeding after ESD may decrease significantly by prophylactic electrocoagulation of large visible submucosal vessels. This technique is preferable to other types of hemostasis such as clips that can hinder the completion of the procedure[49]. Currently, there is no evidence that the realization of a second-look contributes significantly to reduce the risk of late bleeding following ESD. While it is habitual to advice antisecretory therapy over the following weeks, this practice has not demonstrated benefit in lowering the rate of delayed bleeding[50]. The incidence of perforation ranges from 1%-20% depending on experience[51-53]. The use of dye injection (*e.g.,* Indigo carmine) allows to better identify the muscle layer making ESD a safer technique. Perforation can be diagnosed during or after the procedure (frank perforation or micro-perforation, respectively). However, no evidence of lymph node metastasis and/or peritoneal dissemination caused by gastric perforation has been reported[54]. If a perforation is immediately noticed during the procedure and its size is small, it can be treated endoscopically with clips

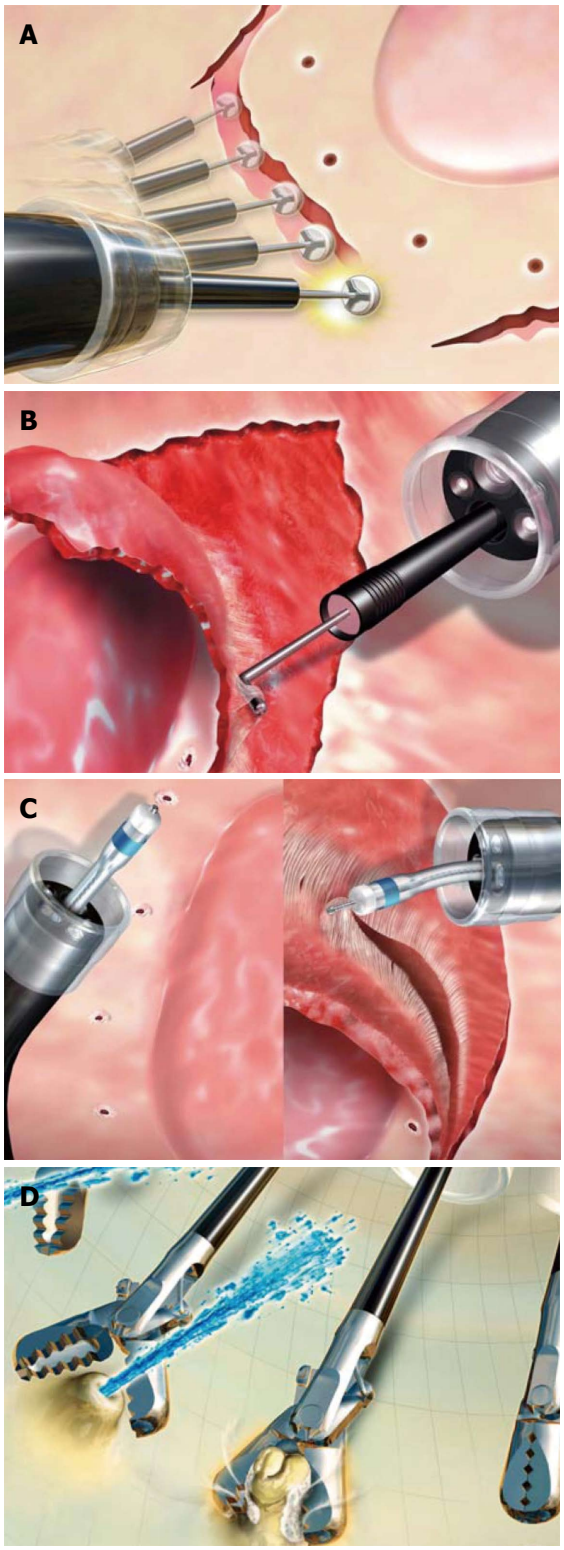

Figure 2 Different types of devices, specific for each step of the Endoscopic submucosal dissection procedure. A: ITknife-2; B: Hook knife; C: Dual knife; D: Grasper for haemostasis. (Courtesy of Olympus Medical Systems,Tokyo, Japan).

and broad spectrum antibiotics. In these cases absolute diet is recommended for at least 2 d[55]. Conversely, if the perforation is large, urgent surgery is required. It is possible that CO_2 insufflation may reduce the risk of perforation[56]. If free air is found on a plain chest X-ray after the ER (micro-perforation), the management (conservative or surgical) is not conclusively established. The appearance of scar stenosis is uncommon (0.6%-2%) and is associated with extensive resections in the gastric antrum[51]. Local administration triamcinolone can be used as an attempt to prevent this complication[57]. Balloon dilation is the endoscopic treatment most frequently used for this complication, but involves some risk of perforation[58]. Aspiration pneumonia is rare (0.7%-1.5%) and is associated with prolonged procedures.

FOLLOW-UP AFTER ENDOSCOPIC RESECTION

EGC patients treated by endoscopic resection with curative intent, require monitoring to detect local recurrence and metachronous gastric cancer. In patients with EGC who meet "standard" criteria for endoscopic resection, it is advisable to perform an upper gastrointestinal endoscopy yearly. Patients who meet "expanded" criteria, in addition to the annual endoscopy, monitoring can be performed alternating abdominal computed tomography and endoscopic ultrasound every 6 mo for 3 years. The objective of this additional monitoring is to detect lymph node and distant metastases[59].

SURGICAL TREATMENT

Although endoscopic resection is an option in patients with EGC who meet the above criteria, surgical treatment continues to be a widespread therapeutic option worldwide with survival rates at 5 years of 97%[60]. Currently, there are no comparative studies between gastrectomy and endoscopic treatment. However, several results show clinical prognosis to be similar although patients with endoscopic treatment benefit from a shorter hospital stay and lower costs[61,62]. Patients who do not meet the criteria for endoscopic resection have a higher risk of lymph node metastases which forces a gastrectomy with perigastric lymph node excision. Another indication for gastrectomy is the detection during staging of lymph nodes or a high suspicion of their existence. The type of gastrectomy (subtotal gastrectomy or total) is determined by the location of the lesion, reserving the subtotal gastrectomy for EGC located in the lower two thirds of the stomach. Another option is laparoscopic gastrectomy. Laparoscopic gastrectomy was initially reported in Japan in 1994[63]. Open gastrectomy is still performed more frequently in the Western countries than laparoscopic resection even for patients with early stage disease[64]. In Japan, EGC (T1N0 or T2N0) is considered as the only indication for laparoscopic gastrectomy. A recent review that included 22 studies show that laparoscopic gastrectomy *vs* open gastrectomy offers a similar prognosis with significantly lower postoperative morbidity, lower intraoperative

blood use, shorter hospital stay and no increased rates of recurrence. Furthermore conversion rates to open laparoscopic surgery were less than 3%[65].

The surgical outcome of gastric cancer in obese patients is controversial. The number of lymph nodes retrieved is, in these patients, higher[66]. Moreover, obesity is an independent risk factor for developing 30-d postdischarge complications[67].

ADJUVANT THERAPIES

It is known that chronic infection with *Helicobacter pylori* is a risk factor of developing gastric cancer. Currently, treatment of *Helicobacter pylori* infection in all patients with EGC is recommended, regardless of the chosen treatment option to reduce the risk of metachronous gastric cancer[68,69]. The need for adjuvant therapy (chemotherapy, radiotherapy) in patients with EGC treated with complete endoscopic resection is debated. Recent guidelines recommend observation, avoiding adjuvant therapy in patients with T1N0 disease without involvement of the resection margins. However, adjuvant treatment is clearly indicated in patients with positive lymph node involvement.

CONCLUSION

Endoscopic resection (EMR/ESD) is a safe and effective staging and therapeutic modality for selected patients with early gastric cancer. Patients with "standard" and "expanded" criteria can be successfully treated by EMR and ESD techniques, respectively. Surgical treatment continues to be a widespread therapeutic option in patients with incomplete endoscopic resection or advanced gastric cancer.

Abstract

AIM: To examine the efficacy of non-magnifying narrow-band imaging (NM-NBI) imaging for small signet ring cell carcinoma (SRC).

METHODS: We retrospectively analyzed 14 consecutive small intramucosal SRCs that had been treated with endoscopic submucosal dissection (ESD) and 14 randomly selected whitish gastric ulcer scars (control). The strength and shape of the SRCs and whitish scars by NM-NBI and white-light imaging (WLI) were assessed with Image J (NIH, Bethesda).

RESULTS: NM-NBI findings of SRC showed a clearly isolated whitish area amid the brown color of the

surrounding normal mucosa. The NBI index, which indicates the potency of NBI for visualizing SRC, was significantly higher than the WLI index (P = 0.001), indicating SRC was more clearly identified by NM-NBI. Although the NBI index was not significantly different between SRCs and controls, the circle (C)-index, as an index of circularity of tumor shape, was significantly higher in SRCs (P = 0.001). According to the receiver-operating characteristic analysis, the resulting cut-off value of the circularity index (C-index) for SRC was 0.60 (85.7% sensitivity, 85.7% specificity). Thus a lesion with a C-index $\geqslant$ 0.6 was significantly more likely to be an SRC than a gastric ulcer scar (OR = 36.0; 95%CI: 4.33-299.09; P = 0.0009).

CONCLUSION: Small isolated whitish round area by NM-NBI endoscopy is a useful finding of SRCs which is the indication for ESD.

Key words: Gastric cancer; Signet ring cell carcinoma; Narrow-band imaging; Intramucosal cancer; Endoscopic submucosal dissection

Core tip: Intramucosal signet ring cell carcinoma (SRC) $\leqslant$ 2 cm in diameter, for which endoscopic submucosal dissection is indicated, is very difficult to identify by white-light imaging (WLI) endoscopy. However, little is known regarding non-magnifying narrow-band imaging (NM-NBI) findings of early SRC. The strength and shape of the SRCs by NM-NBI and WLI were assessed with Image J. NM-NBI findings of SRC showed a clearly isolated whitish area amid the brown color of the surrounding normal mucosa. The NBI index, which indicates the potency of NBI for visualizing SRC, was significantly higher than the WLI index (P = 0.001).

INTRODUCTION

Gastric cancer ranks as the fourth most common cancer and the second most frequent cause of death from cancer in the world[1]. *Helicobacter pylori* (*H. pylori*) infection is considered to be a main risk factor for the development of gastric cancer of either intestinal or diffuse type[2]. However, according to recent reports, the *H. pylori* infection rate has decreased over the last 40-50 years in both Asia and Western countries, with an overall decline in *H. pylori* seroprevalence[3,4]. In Japan, the prevalence of *H. pylori*-negative gastric cancer is extremely low; therefore, the prevalence of gastric cancer may continue to decrease substantially as the *H. pylori* infection rate continues to decrease[5,6]. The pathological characteristics of *H. pylori*-negative gastric cancer are different from those of *H. pylori*-positive gastric cancer; histologically, the diffuse type is dominant, especially signet ring cell carcinoma (SRC) (60%)[6]. Commonly, SRC of the stomach is thought to arise in the mucosa without metaplastic change and is typically confined to the glandular neck region in the original proliferation zone[7]. It is considered, therefore, that early-stage SRCs can be present beneath a flat, intact mucosal surface epithelium, and may be very difficult to identify by white-light imaging (WLI) endoscopy due to their slightly whitish discoloration.

Recently, magnifying narrow-band imaging (NBI) has been reported to be useful for the accurate diagnosis of gastric cancers, even for small, depressed gastric mucosal cancers[8-11]. Several studies have demonstrated an association between the histology, *i.e.*, differentiated *vs* undifferentiated type, and magnified NBI appearance[8,11-13]. In cases of SRC, the cancer-specific findings and identifiable demarcation line of the lesion may not be identified even by magnifying NBI endoscopy or chromoendoscopy[12,13]. We have found intramucosal SRCs by non-magnifying NBI (NM-NBI) endoscopy that we failed to detect by WLI endoscopy. Nonetheless, there has been little research into NM-NBI findings focused strictly on intramucosal SRCs.

It has been reported that patients with SRC caught at an early stage can expect a better prognosis than they might with other gastric cancers[14] and SRC is not a prognostic factor in early cancer[15]. The prognosis of those at the advanced stage is still controversial; a report by Otsuji *et al*[14] from Japan showed no significant difference in 5-year survival rates between patients with SRC and those with other histological types of gastric cancer, while other studies from the West[16-18] have found that SRC has a worse prognosis due to specific characteristics such as high rate of lymph node metastasis and peritoneal carcinomatosis. Clearly, it is best to discover gastric SRC early, but the early detection of lesions located beneath a preserved surface epithelium may be very difficult.

Although NBI is increasingly available in endoscopy units, only a limited number of cases are subjected to magnifying NBI endoscopy, even in hospitals specializing in gastroenterology. Many gastroenterologists or endoscopists use a conventional NM-NBI endoscope lacking a magnification function to screen for gastric cancer. In the present study, we (1) retrospectively investigated endoscopic findings of SRC by NM-NBI endoscopy and WLI endoscopy; and (2) compared the NBI findings of SRC and whitish gastric ulcer scars, in order to clarify the NM-NBI features of SRC.

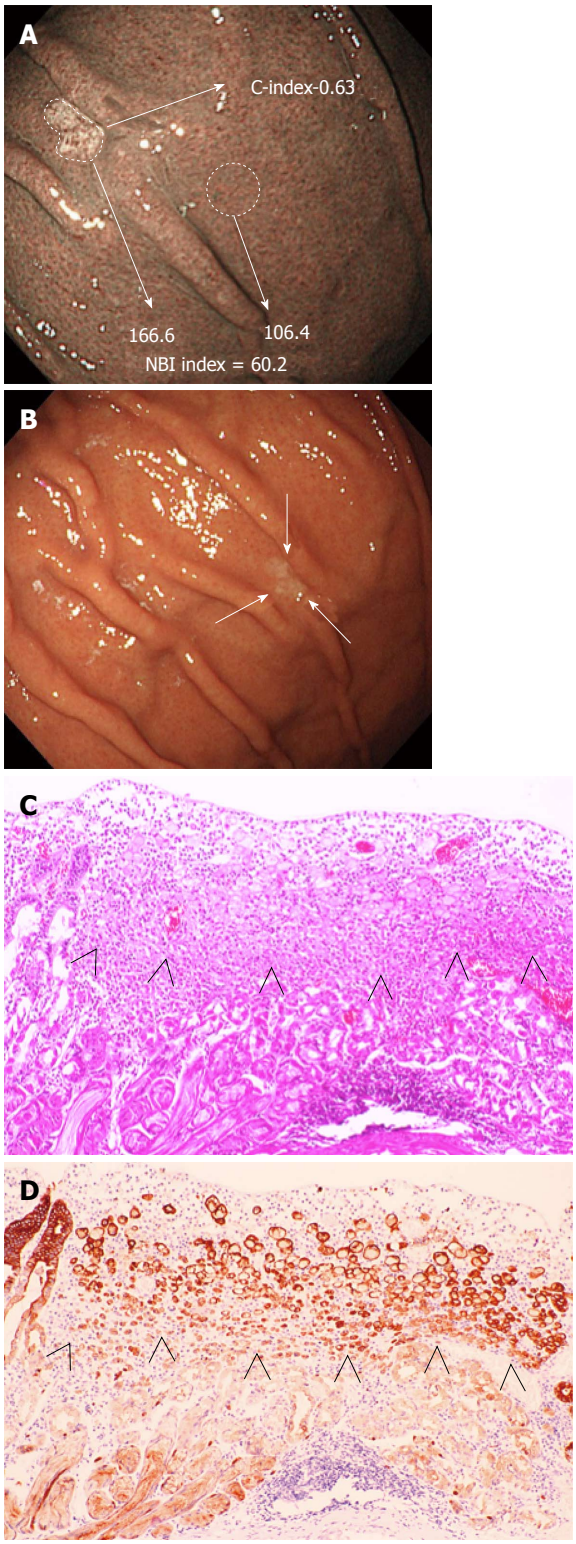

Figure 1 Endoscopic and histologic findings of signet ring cell carcinomas localized at the greater curvature of the corpus (Case 4). A: NBI of the cancer area showed an isolated oval-shaped whitish area. The NBI index was 60.2. The C-index was 0.63; B: Endoscopy with WLI showed a 0-IIc lesion with slight discoloration (arrows) at the greater curvature of the corpus. The WLI index was 4.5; C: The histology by endoscopic submucosal dissection showed an intramucosal SRC in the upper third of the gastric mucosa (arrowheads) with a partial defect of the foveolar epithelium; D: Immunohistochemical staining of SRC cells showed diffuse positive reactivity for cytokeratin AE1/AE3 (arrowheads). NBI: Narrow-band imaging; WLI: White-light imaging; SRC: Signet ring cell carcinoma.

MATERIALS AND METHODS

Patients

Between January 2011 and May 2014 in our department, 322 early gastric cancers or adenomas in 301 patients were treated with endoscopic submucosal dissection (ESD). The indications for ESD of intramucosal gastric cancer or adenoma, included the following[19]: (1) intramucosal differentiated-type adenocarcinoma of any size without ulceration; (2) intramucosal differentiated-type adenocarcinoma with an ulcer scar and measuring $\leqslant$ 3 cm in diameter; and (3) intramucosal undifferentiated-type adenocarcinoma, including poorly differentiated cancer or SRC, of less than 2 cm without an ulcer scar. In all cases, the histology, tumor location, macroscopic classification, and depth of invasion fulfilled the criteria of the Japanese Research Society for Gastric Cancer[20]. Among these cases treated with ESD, 14 (4.3%) were diagnosed histologically as intramucosal SRC ($\leqslant$ 2 cm) without any other findings of adenocarcinoma. During the same period, 14 patients with whitish gastric ulcer scars that were histologically confirmed by biopsy were randomly selected as controls.

Methods

Written informed consent was obtained from all patients who underwent a routine endoscopic examination and ESD, and this study was conducted in accordance with the guidelines of the Declaration of Helsinki. All patients underwent NM-NBI endoscopy by an endoscope (GIF-Q260) or high-vision endoscope (H260, H260Z, H290 and HQ290) with an electronic endoscopic system (Evis Lucera CV-260 SL or Elite CV-290; Olympus Medical Systems, Corp., Tokyo, Japan). The strengths of the NM-NBI and WLI images of 14 consecutive gastric SRCs undergoing ESD and the strength of the NM-NBI images of gastric ulcer scars (controls) were quantified with an image-analytical software program. Briefly, NBI images were converted into joint photographic experts group pictures; then the cancer or ulcer scar area on the pictures was manually traced with an image-analytical software program (ImageJ ver. 1.48; National Institutes of Health, Bethesda, MD). Using the default tool "Measure" under the "Analyze" menu, the mean gray value (MGV) of the cancer or ulcer area was calculated, and the MGV of a region of similar area of the perilesional normal mucosa was also measured. The MGV of the cancer or ulcer scar area minus that of the perilesional area was defined as the NBI index (Figure 1; note, a brighter image has a higher MGV). In addition, the values for several shape descriptors of the SRCs and gastric ulcer scars were also calculated to assess their shapes. Briefly, using the default tool "Measure" under the "Analyze" menu, "Circ." was adopted as the circularity index (C-index). The C-index value of a perfect circle is 1; as the shape deviates from perfectly circular, the C-index value decreases (Figure 2). The WLI strength was calculated as well as the NM-

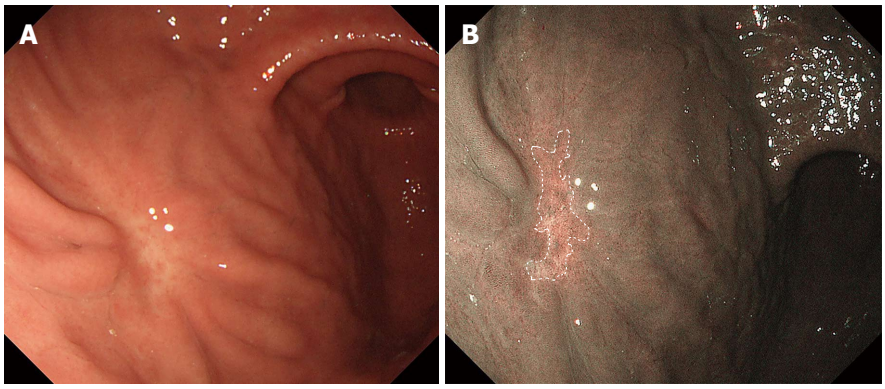

Figure 2 Endoscopic images of whitish gastric ulcer scars. White-light imaging (A) and non-magnifying narrow-band imaging (B). The NBI index and C-index were 44.9 and 0.29, respectively. NBI: Narrow-band imaging; C-index: Circularity index.

Table 1 Characteristics of signet ring cell carcinoma patients and controls

	SRC	Control	*P* value
Age, yr, mean ± SD	53.2 ± 14.2	69.1 ± 14.8	0.0008
Sex, male/female	7/6	10/4	0.44
Location: upper/middle/lower	2/7/5	4/8/2	0.36
NBI finding			
NBI index (mean ± SD)	27.9 ± 21.0[a]	24.8 ± 14.7	0.78
H. pylori: positive/negative	26.1 ± 20.5/29.0 ± 22.4	27.8 ± 15.4/19.3 ± 13.2	0.95 in SRC and 0.26 in control
WLI finding (mean ± SD)			
WLI index	5.3 ± 16.2[a]	-	0.001[a]
H. pylori: positive/negative	13.5 ± 16.4/0.7 ± 15.1	-	0.32
C-index (mean ± SD)	0.67 ± 0.13	0.50 ± 0.14	0.001

[a]*P* = 0.001 between NBI index and WLI index. SRC: Signet ring cell carcinoma; NBI: Narrow-band imaging; WLI: White light imaging; C-index: Circularity index.

NBI index, and was measured by "RGB Measure (R + G + B/3)" tool under the "Analyze" menu in "Plugins". The quantification was performed by an endoscopist who was not involved in the patients' original diagnoses or treatments.

To assess *H. pylori* infection, biopsy specimens, two from each site, were taken from the greater curvature of the antrum and body of the stomach. *H. pylori* status was analyzed in each patient by two methods: Giemsa staining and serum *H. pylori*-IgG antibody with an enzyme-linked immunosorbent assay kit using the E plate test (Eiken Kagaku, Tokyo, Japan). A patient was regarded as positive for *H. pylori* if at least one of these tests was positive.

Statistical analysis

The data were assessed by the Mann-Whitney *U*-test for comparisons between two independent groups and the Fisher's exact test for comparisons between two proportions. NM-NBI findings including the NBI-index and C-index were included as potential malignant features for SRC in univariate analysis. Multivariate logistic regression analyses were performed to identify significant predictive NBI findings. Odds ratios and 95%CIs were used to assess the statistical significance at the conventional level of 0.05. Statistical analysis was performed with StatView version 5.0 (SAS Institute Inc., Cary, NC). Receiver operating characteristic (ROC) curve was calculated for the highest diagnostic performance in terms of the shape of SRCs (C-index), and then the curve was plotted using JMP 10 software (SAS Institute Inc., Cary, NC). The area under the ROC curve and the optimal thresholds using the Youden index were calculated from ROC analysis[21].

RESULTS

Table 1 shows the characteristics of the 14 SRCs in the 13 patients who underwent ESD and the controls. In addition, clinical and endoscopic data of SRCs are shown in Table 2. Out of 14 SRCs, 10 lesions were detected at other hospitals and then referred to our department for ESD treatment. Two (cases 4 and 12) of the 14 SRCs were first identified by NM-NBI endoscopy, but not by WLI endoscopy, in our department (Figure 1). In SRC patients, the mean age was 53.2 ± 14.2 years (range: 23 to 74 years), and women accounted for 46.2% (6 of 13) of the group. In contrast, the mean age of the controls was 69.1 ± 14.8 years, significantly higher than that of the SRC patients. The *H. pylori*-negative rate was 69.2% (9 of 13) in the SRC patients, and none of these patients had received *H. pylori* eradication therapy. In the control group, 4 out of 5 *H. pylori*-negative patients (35.7%, 5 of 14) had undergone eradication

Table 2 Characteristics of signet ring cell carcinomas in the 13 patients

Hp: *Helicobacter pylori*; PDE: Partially defect of epithelium; L: Lower third of the stomach; M: Middle third of the stomach; U: Upper third of the stomach; GC: Greater curvature; LC: Lesser curvature; PW: Posterior wall; C-index: Circularity index; NBI: Narrow-band imaging; WLI: White light imaging.

therapy previously.

Most SRCs were located in the middle or lower portion of the stomach (85.7%, 12 of 14) and at the greater curvature (64.3%, 9 of 14), with no significant difference in the distribution of lesions compared to the control. The average diameter of the major axis of the SRCs was 6.4 mm (range: 2 to 15 mm). Histologically, a partial defect of the foveolar epithelium was identified in only 3 cases (21.4%); thus, most SRC cells were found beneath a preserved surface epithelium. In all SRC cases, the histological growth pattern of cancer cells corresponded to the non-whole-layer type according to the definition by Okada *et al*[13].

NM-NBI and WLI findings

In SRCs, NBI findings showed a clearly isolated whitish area amid the brown color of the normal mucosa. The NBI index (27.9 ± 21.0) was significantly higher than the WLI index (5.3 ± 16.2) (P = 0.001), indicating that the contrast between the cancer and surrounding normal mucosa was more intense by NM-NBI than by WLI. This result indicates that the cancerous areas were more clearly captured by NM-NBI endoscopy than by WLI endoscopy (Figures 1 and 3). The overall mean NBI index was 27.9 ± 21.0; this value was not significantly different from that (24.8 ± 14.7) of the control. Moreover, the NBI indices were not significantly different between the *H. pylori*-positive and -negative cases in either the SRCs or controls. In addition, the WLI index of the SRCs was not significantly different between *H. pylori*-positive and -negative cases. In contrast, the C-index was significantly higher in SRCs (0.67 ± 0.13) than in controls (0.50 ± 0.14) (P = 0.001), indicating that SRCs are rounder in shape than ulcer scars (Table 1). The C-index was the only factor significantly associated with SRCs in the NBI findings.

Association between the shape of SRCs and C-index

The association between the shape of SRCs and C-index was evaluated using ROC curve analysis (Figure 4). According to this analysis, the resulting cut-off value of the C-index for SRC was 0.60 (sensitivity, 85.7%; specificity, 85.7%).

Based on the ROC curve analysis and optimal cut-off points of the C-index of SRC determined above, a C-index of ⩾ 0.60 was used in the analysis. We investigated the strength of the association between the C-index (⩾ 0.60) in the NM-NBI findings and that in the SRCs by means of a logistic regression analysis. The C-index (⩾ 0.60) was found to be a significant predictor of SRCs (OR = 36.0; 95%CI: 4.33-299.09; P = 0.0009).

DISCUSSION

As the *H. pylori* infection rate continues to decrease, cardiac or junctional gastric cancer and histologically undifferentiated-type adenocarcinoma including SRC will increase in proportion. Therefore, there is need of an easy method for detecting these cancers in an early stage by routine endoscopy. Magnifying NBI is definitely useful for the accurate diagnosis of gastric cancer or dysplasia using the criteria for gastric cancer: irregularity or disappearance of the mucosal structure or a microvascular pattern in a definite demarcation line[8-13]. However, small intramucosal SRCs (⩽ 2 cm), which are best treated by ESD, have fewer of these magnifying NBI findings, because most intramucosal SRC cells are covered by a normal foveolar epithelium. To the best of our knowledge, this is the first study to report on the NM-NBI findings and clinical features of small SRC, for which endoscopic treatment is indicated.

In a previous magnifying NBI study of undifferentiated-type early gastric cancer including SRCs[8,11-13], Okada *et al*[13] found that gastric cancers with a preserved but irregular surface pattern corresponded histologically to the non-whole-layer type of mucosal cancer, whereas cancers with an irregular microvascular pattern or mixed pattern upon magnifying NBI corresponded histopathologically to the whole-layer type of intramucosal cancer or submucosal invasion

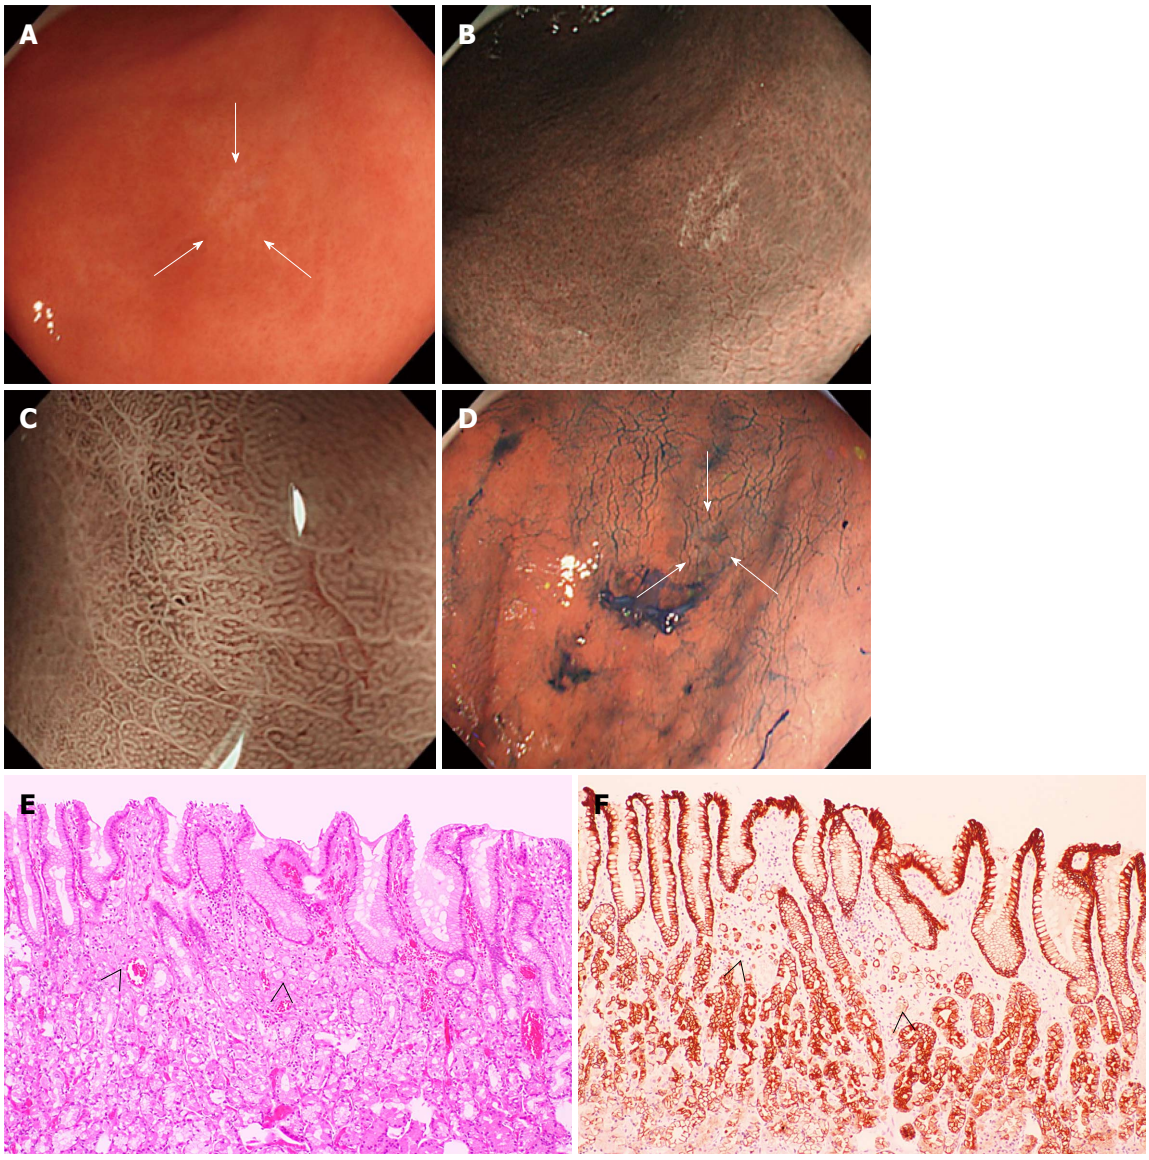

Figure 3 Endoscopic and microscopic images of signet ring cell carcinoma (Case 9). A: Endoscopy with WLI revealed a 0-IIb lesion with slight discoloration (arrows) at the greater curvature of the angulus; B: NM-NBI of the cancer area showed an isolated clear whitish area. The cancerous areas were more clearly captured by NM-NBI endoscopy than by WLI endoscopy. The NBI and WLI index were respectively 25.6 and 12.8, and the C-index was 0.77; C and D: The demarcation line of the SRC was not clearly identified even by magnifying NBI and chromoendoscopy (arrows); E: The histology of a specimen resected by endoscopic submucosal dissection revealed an intramucosal SRC (arrowheads) in the upper third of the mucosa beneath a preserved surface epithelium; F: SRC cells showed positive for cytokeratin AE1/AE3 staining (arrowheads). WLI: White-light imaging; NM-NBI: Non-magnifying narrow-band imaging; SRC: Signet ring cell carcinoma.

cancer[13]. In cases of small undifferentiated-type cancer in which cells infiltrate laterally in the lamina propria deep into the glandular neck, *i.e.*, the non-whole-layer type, magnifying NBI cannot detect any cancer-specific irregular microvascular or microsurface pattern[9]. Therefore, it is difficult to detect undifferentiated-type cancer developing laterally within the proliferative zone and to identify the demarcation line of the cancer even by magnifying NBI, as shown in Figure 3[13]. Moreover, the extent of the lateral margin in this type of cancer becomes less detectable by chromoendoscopy (Figure 3)[12].

In the current study, however, SRCs were captured more easily by NM-NBI without the use of a magnifying endoscope than by WLI endoscopy; on NM-NBI they appeared as isolated whitish round areas. It remains unclear why the cancerous area of the SRC is whitish when compared to the surrounding normal mucosa. One possibility is that the depth of the crypt is shallow and the surface of the mucosa is planarized because of closely aggregated SRC cells in the upper to middle third of the mucosa (Figures 1 and 3). Okada *et al*[13] similarly presumed that both the number and heights of the gastric pits were decreased due to the extension of cancer cells in the mucosa, which eventually obliterated the architecture of the microsurface. As *H. pylori* infection causes extensive infiltration of inflammatory cells into the gastric mucosa, one would think this inflammation might affect the NBI index. However, no significant difference in the NBI index was seen

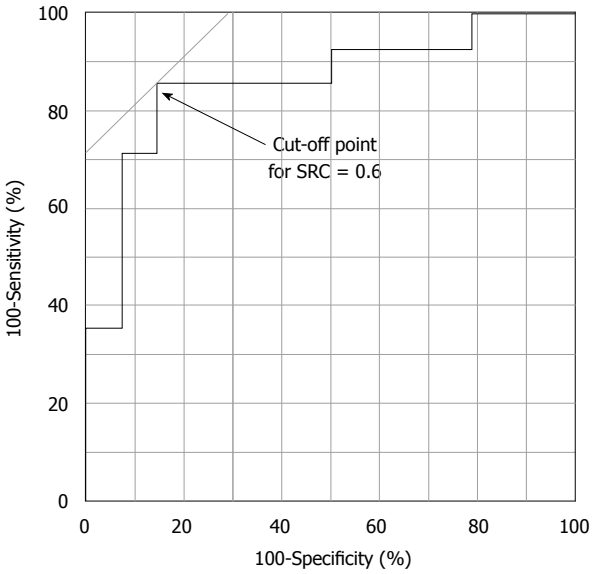

Figure 4 Receiver operating characteristic curve of the C-index of signet ring cell carcinoma. The curve is plotted as sensitivity (Y axis) and (100-specificity) (X axis). SRC: Signet ring cell carcinoma.

between patients with and without *H. pylori* infection in either SRCs or controls. There was also no significant difference in the NBI index between the SRC and control groups themselves, while the C-index results indicated that the SRCs were significantly rounder than the gastric ulcer scars of the controls. Since the 1980s, irregular shape lesion has been known to reflect malignant finding in the diagnosis of small gastric cancers, especially those of differentiated-type[22], and thus the NM-NBI shape of small SRC might be different from that of differentiated-type cancer. In the present work, a C-index exceeding 0.60 was considered to be the most reliable factor associated with SRCs. In logistic regression analysis, as well, the C-index ($\geqslant$ 0.60) was a highly significant predictor for SRC (OR = 36.0; 95%CI: 4.33-299.09; P = 0.0009). These results may suggest that NM-NBI could easily discriminate SRCs from gastric ulcer scars. However, gastric ulcer scars are histologically associated with complicated fibrosis in the submucosal layer, and thus it may not be surprising that their shape tended to be more irregular than that of SRCs.

More recently, novel electronic endoscopic systems (Evis Lucera Elite CV-290 and LASEREO, FUJIFILM Medical Co., Ltd., Tokyo) have been newly developed. These systems enable clearer and brighter NBI observation throughout the entire stomach than the existing systems (Evis Lucera CV-260 SL and Advancia, FUJIFILM Medical Co., Ltd., Tokyo). Therefore, it may be possible to identify small SRCs even from a relative distance by using a novel electronic endoscopic system. SRCs may be a form of incipient gastric cancer that may eventually develop into a linitis plastica-type cancer; hence, it is important to detect SRCs at an early stage. Our findings suggest the need to look carefully for isolated whitish round areas on NBI endoscopy, particularly in the greater curvature of the middle to lower portion of the stomach.

Nevertheless, the present study had some potential limitations. First, this was a retrospective study from a single institution with a small number of SRC cases. It will be important to perform a prospective study using the NBI criteria in order to confirm the reliability of these findings. However, the incidence of intramucosal SRC is low (4.3%) among the cases treated with ESD. Therefore, the incidence will be even lower in patients who undergo endoscopy for screening, indicating that a larger series of samples and an appreciable length of time will be required to assess the reliability. Second, ten of the SRC cases were referred to our department after biopsies at other clinics or hospitals; most lesions were biopsied prior to imaging. Thus, previous biopsy sites were covered by regenerated epithelium and might have influenced the NM-NBI findings[13]. However, the NBI index was not significantly different between biopsied and non-biopsied cases (data not shown).

In conclusion, it is best to look carefully for isolated whitish round areas by NM-NBI endoscopy for early detection of this malignancy. Here, we would like to emphasize that during an era when the incidence of *H. pylori* infection is decreasing, NM-NBI endoscopy should be used for the detection of small intramucosal SRCs.

COMMENTS

Background

As the authors described, the pathological characteristics of *Helicobacter pylori* (*H. pylori*)-negative gastric cancer are different from those of *H. pylori*-positive gastric cancer; histologically, the diffuse type is dominant, especially signet ring cell carcinoma (SRC). Since early-stage SRC develops beneath a flat, intact mucosal surface epithelium, it is very difficult to identify by white-light imaging (WLI) endoscopy.

Research frontiers

Magnifying narrow-band imaging (NBI) has been reported to be useful for the accurate diagnosis even in small gastric mucosal cancers. In cases of SRC, however, the cancer-specific findings and identifiable demarcation line of the lesion may not be identified even by magnifying NBI endoscopy or chromoendoscopy. To date, little is known regarding non-magnifying (NM)-NBI findings of small intramucosal SRC.

Innovations and breakthroughs

Intramucosal SRC could be clearly captured by NM-NBI as an isolated whitish area amid the brown color of the surrounding normal mucosa. SRCs were more clearly captured by NM-NBI endoscopy than by WLI endoscopy. Furthermore, although the NBI strengths of SRCs and whitish gastric ulcer scars were not significantly different, the two types of lesions' indexes of circularity determined by image-analytical software were significantly different, with the SRCs being distinctly rounder in shape than the ulcer scars.

Applications

This study emphasizes that during an era when the incidence of *H. pylori* infection is decreasing, NM-NBI endoscopy should be used for the detection of small intramucosal SRCs, which is indicated for endoscopic submucosal dissection. It is best to look carefully for isolated whitish round areas by NM-NBI endoscopy for early detection of this malignancy.

Terminology

NBI: Magnifying endoscopy with NBI is widely used in gastroscopy, especially in

the diagnosis of early gastric cancer. SRC: Signet ring cell carcinoma is thought to arise in the mucosa without metaplastic change and is typically confined to the glandular neck region in the original proliferation zone; therefore, it is difficult to detect those lesions.

Peer-review

The manuscript is excellent with perfect language.

Abstract

AIM: To study the transcolonic extraction of the proximally resected colonic specimens by colonoscopic assistance at laparoscopic colonic surgery.

METHODS: The diagnoses of our patients were Crohn's disease, carcinoid of appendix and adenocarcinoma of cecum. We preferred laparoscopic total mesocolic resections. Colon and terminal ileum were divided with endoscopic staplers. A colonoscope was placed per anal and moved proximally in the colon till to reach the colonic closed end under the laparoscopic guidance. The stump of the colon was opened with laparoscopic scissors. A snare of colonoscope was released and the intraperitoneal complete free colonic specimen was grasped. Specimen was moved in to the colon with the help of the laparoscopic graspers and pulled gently through the large bowel and extracted through the anus. The open end of the colon was closed again and the ileal limb and the colon were anastomosed intracorporeally with a 60-mm laparoscopic stapler. The common enterotomy orifice was closed in two layers with a running intracorporeal suture.

RESULTS: There were three patients with laparoscopic right-sided colonic resections and their specimens were intended to remove through the remnant colon by colonoscopy but the procedure failed in one patient (adenocarcinoma) due to a bulky mass and the specimen extraction was converted to transvaginal route. All the patients had prior abdominal surgeries and had related adhesions. The operating times were 210, 300 and 500 min. The lengths of the specimens

were 13, 17 and 27 cm. In our cases, there were no superficial or deep surgical site infections or any other complications. The patients were discharged uneventfully within 4-5 d and they were asymptomatic after a mean 7.6 mo follow-up (ranged 4-12). As far as we know, there were only 12 cases reported yet on transcolonic extraction of the proximal colonic specimens by colonoscopic assistance after laparoscopic resections. With our cases, success rate of the overall experience in the literature was 80% (12/15) in selected cases.

CONCLUSION: Transcolonic specimen extraction for right-sided colonic resection is feasible in selected patients. Both natural orifice surgery and intracorporeal anastomosis avoids mini-laparotomy for specimen extraction or anastomosis.

Key words: Colonoscopy; Colon cancer; Crohn's disease; Laparoscopic surgery; Natural orifice transendoscopic surger; Natural orifice specimen extraction

Core tip: Transcolonic extraction of the proximally resected colonic specimens by colonoscopic assistance can be an attractive method for some selected cases. This technique requires both advanced laparoscopic experience by intracorporeal anastomosis and interventional endoscopy. In this technique, there was a far distance between the resected specimen and the natural orifice. The specimen is moved about 100 cm in a hollow organ till the natural orifice. As far as we know, it has been the farthest distance that was reported yet for natural orifice specimen extractions. However, this technique is only suitable for small specimens which can pass through the sigmoid colon.

Laparoscopic right-sided colonic resection with transluminal colonoscopic specimen extraction. *World J Gastrointest Endosc* 2015; 7(12): 1078-1082 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i12/1078.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i12.1078

INTRODUCTION

Laparoscopic colectomy is going on to increase the number of its supporters. It lets smaller abdominal incisions and this reflects several advantages such as less pain, rapid recovery and wound problems. However, the required mini-laparotomy to extract the specimen during laparoscopic colectomy clearly compromise some advantages of the laparoscopic surgery. The use of natural orifices such as vagina or anus for colonic extraction is a new concept and it can avoid this mini-laparotomy and related morbidities. This new concept is called as Natural Orifice Specimen Extraction (NOSE) and the first laparoscopic colectomy with transanal specimen extraction has been described at the beginning of 1990's[1]. Up to the present time, transanal extraction was the main route for the rectal and left sided colonic specimens and transvaginal route was also available for both left and right sided colonic resections[1]. Transcolonic extraction by colonoscopic assistance can be an attractive method for some selected right-sided colonic resections but, as far as we know, there are only 12 cases reported yet[2-4]. Here, we reported three more patients with laparoscopic right-sided colonic resections and their specimens were intended to remove transanally by colonoscopy. The aim of this study was (1) to describe our initial clinical experience; (2) to outline our differences from the previous reports; and (3) to review all the available published cases.

MATERIALS AND METHODS

Mechanical bowel preparation was given the night before surgery. Broad-spectrum intravenous antibiotics were administered 30 min before skin incision and postoperatively for three days. Following induction of general anesthesia, a urinary catheter and a nasogastric tube were inserted. The patient were placed in the modified lithotomy position, with legs abducted and slightly flexed at the knees. The abdomen was insufflated by Veress and total of three or four abdominal trocars were used (two 5-12 mm and one or two 5 mm trocars) (Figure 1). The patient was placed in a 15 degree right-up lateral position. We preferred total mesocolic resections for all patients. Medial to lateral mesenteric dissection was carried out and when we identified the distal resection margin, we created a window in the mesocolon at this level and we divided the colon with a 60 mm endoscopic stapling device (EndoGIA, Covidien, Mansfield, MA). The lateral peritoneal attachments of the colon were mobilized from top-to-bottom until the cecum and terminal ileum was transected using the same endoscopic 60-mm linear stapler. A colonoscope was placed per anal and moved proximally in the colon till to reach the colonic closed end under the laparoscopic guidance. Laparoscopically, the stump of the colon was opened with endoscopic scissors and the colonoscope was visualized in the colon (Figure 2). A snare of colonoscope was released and the intraperitoneal complete free colonic specimen was grasped (Figure 3). Specimen was moved in to the colon with the help of the endoscopic graspers and pulled gently through the large bowel by colonoscope. If there was any invagination, it was reduced with graspers. The specimen was pulled through the remnant colon under laparoscopic guidance and extracted through the anus. The open end of colon was closed again with a laparoscopic stapler and the tiny remnant of colonic specimen removed through the 12 mm trocar. The ileal limb and the colon were anastomosed intracorporeally with a 60-mm laparoscopic stapler. The common enterotomy orifice was closed in two layers with a

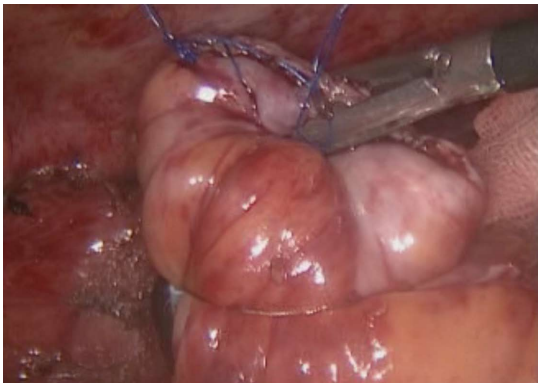

Figure 3 Colonoscopic transcolonic removal of the right colonic specimen.

running intracorporeal suture. An abdominal drain was placed. The nasogastric tube was removed at the end of the operation.

RESULTS

All the details of the patients, diseases and surgical procedures were summarized in Table 1. First patient had a Crohn's disease with intermittent bowel obstruction. He had a previous open appendectomy. Radiologically confirmed ileocolic stenosis was treated by laparoscopic ileocolic resection. There were bulky mesenteric lymph nodes which were very close to the stenotic part of the bowel. Bulky specimen caused some difficulties during transcolonic extraction and the specimen moved in the sigmoid colon in difficulty but the procedure was completed successfully without any complication. The second patient had a history of open appendectomy three months ago. The pathology reported carcinoid tumor with perineural invasion. A laparoscopic right hemi-colectomy with colonoscopy assisted transluminal specimen extraction was performed. There was no problem during transcolonic transit and extraction of the specimen. Pathological examination showed no malignancy. Last patient had a previous history of open pancreaticoduodenectomy due to chronic pancreatitis. While she was investigated for anemia, a 5-cm ulcerous cecal adenocarcinoma was detected. After laparoscopic right hemi-colectomy the specimen was tried to extract through the transcolonic route but it failed due to the bulky tumor and lymph nodes. In this case, we worried about jamming the specimen in the colon and it was removed from the vagina. The pathological analysis showed a pT3pN2 adenocarcinoma. None of the patients had early or late complication after a mean 7.6 mo (ranged 4-12) follow-up (Table 1).

DISCUSSION

Here, we intended to do a more minimal invasive colorectal surgery than the conventional laparoscopic technique and described three more cases of transcolonic extraction route for right-sided colonic pathologies. The potential advantages of natural orifice surgery are lower risks of incision related complications such as wound infections, postoperative pain, incisional hernias and better cosmesis. None of our cases had wound related early (surgical site infection) or late complication (hernia) in their follow-up. Because all our patients had previous open abdominal surgeries, there were no clear advantage of cosmesis. On the other hand, we learnt that previous abdominal surgery was not an obstacle for transcolonic specimen extraction.

There are two natural orifices for colorectal specimen extraction: the vagina and the anus. Transvaginal extraction can have some pitfalls. It is limited to female patients, requires an additional surgical trauma to an innocent organ and is not always suitable for patients of childbearing age, teenagers and virgins. Our second case was a virgin and she refused transvaginal access. She specified a preference for transabdominal extraction if the transcolonic extraction failed during surgery. The transanal route is more natural for colorectal specimen extractions and it can be considered as the first option for left sided colorectal resections[1] or total colectomies[5]. The transvaginal route can be kept particularly for bulky right sided colonic resections which are not suitable for transcolonic extraction. We preferred the transvaginal route for one case in which the transcolonic extraction failed due to a bulky specimen.

There is no clear description for the limitations of transcolonic specimen extraction. Splenic flexura of the colon (kinking) and the sigmoid colon (narrowing) are the two natural barriers during the transcolonic removal. It is a rational method to select the specimen sizes according to those natural narrow or kinking passes. After extractions, we measured the largest width of the specimens and they were 8, 6 and 12 cm (failed case), respectively. Although the largest width of the specimen is an important parameter, we believe that the largest diameter of the rolled specimen is more important. Eshuis *et al*[2] advocated performing transcolonic extraction of specimens with a maximum diameter of 5 cm in patients without inflammatory masses. They aborted two of ten cases due bulky volumes. It is not easy to estimate the largest diameter of every specimen by preoperative evaluation. Moreover, large masses at scans sometimes can be suitable for natural extraction and contrary, the procedure can fail for some small-looking lesions. Therefore we suggest intraoperative evaluation for decision. We decided to remove two specimens by transcolonic way and both resulted with successes but in one case we converted it to the transvaginal way. The overall success rate of the transcolonic removal of the proximal colon in all published cases was 12/15 (80%).

Transcolonic extraction of ileocolic resection has been first described for Crohn's disease[2]. Contrary to us, authors divided the mesentery close to the bowel for easier extraction. We believe that some modifications such as intracorporeal mesenteric division can reduce the largest diameter of the specimen and let the transcolonic extraction[6]. As a major morbidity, two postoperative intaabdominal abscesses were reported in the same study[2]. We believe that the main reason of high abdominal infection rate was related with the obstructed terminal ileum. In this study, the authors let the terminal ileum remained open freely to the abdomen for a long operating time. The authors created a side to side ileocolic anastomosis first and later they took out the specimen through this anastomosis. Till the end of the extraction, the distended small bowel went on to contaminate the abdomen. As a difference, we took the specimen into the colon before the anastomosis and the terminal ileum stayed as closed during the extraction time. The terminal ileum was opened just before the anastomosis and the common orifice of the linear stapler was closed immediately. We observed no deep or superficial surgical site infections.

For the first time, we reported that a right-hemicolectomy material was removed through the remnant colon. As mentioned before, Eshuis *et al*[2] preferred only ileocolic specimens, similarly Takayama *et al*[4] reported a case of ileocolic resection for a polyp. Lastly Saad *et al*[3] described a transverse colon resection for a polyp and extracted it through the transcolonic route. Those reported cases with owns all demonstrated that

transcolonic specimen extraction for ileocolic resection, transverse colon resection or even right hemi-colectomy is feasible in selected patients.

As a natural orifice surgery, transcolonic specimen extractions for some right-sided colonic resections and combination with intracorporeal anastomosis let to avoid mini-laparotomy during laparoscopic surgery.

COMMENTS

Background

At laparoscopic colorectal surgery, the use of natural orifices for colonic specimen extraction is a new concept. It can avoid mini-laparotomy and related morbidities.

Research frontiers

Transcolonic extraction of the proximally resected colonic specimens by colonoscopic assistance can be an attractive method for some selected cases. As far as we know, there are only 12 cases reported yet and here, the authors reported three more patients with laparoscopic right-sided colonic resections. All the specimens were intended to remove through the remnant colon by colonoscopy.

Innovations and breakthroughs

Transcolonic specimen extraction for ileocolic resection or even right hemicolectomy is feasible in selected patients.

Applications

Combination with natural orifice surgery and intracorporeal anastomosis avoids mini-laparotomy for specimen extraction or anastomosis.

Terminology

NOTES: Natural orifice transluminal endoscopic surgery. NOSE: Natural orifice specimen extraction.

Peer-review

The authors have performed a good study, the manuscript is interesting.

Abstract

High-resolution anoscopy (HRA) is a procedure where patients with an increased risk of anal cancer, like men who have sex with men, human immunodeficiency virus infected individuals, transplant patients and women with a history of lower genital tract neoplasia, with abnormal anal cytology results, are submitted to anal and perianal visualization under magnification. This will allow for a better detection of anal high-grade lesions that can be treated, in an effort to prevent anal cancer. Anal cancer screening follows the same principles that cervical cancer screening. During this procedure, an anoscope is inserted and a colposcope is used to examine systematically the squamocolumnar junction, the transformation zone and the perianal skin. Initially the observation is done with no staining and then with the application of acetic acid and Lugol's iodine solution, allowing for better lesion identification and characterization. Any suspicious lesion seen should be carefully evaluated and biopsied. Without HRA only a small percentage of suspicious lesions are identified. High-grade lesions that are detected can be ablated under HRA. This is a challenging exam to perform, with a long learning curve and the number of clinicians performing it is limited, although the growing number of patients that need to been screened. Specific equipment is required, with these patients ideally been followed by a multidisciplinary team, in a reference centre. HRA remains unfamiliar for many gastroenterologists.

Key words: High-resolution anoscopy; Anal cytology; High-grade squamous intraepithelial lesions; Low-grade squamous intraepithelial lesions; Anal cancer

Core tip: High-resolution anoscopy is a procedure where high-risk patients are submitted to anal and perianal visualization under magnification, allowing detection of anal high-grade lesions that can be treated. Anal cancer is histologically and biologically very similar to cervical cancer and the screening follows the same principles. The importance, difficulties and the description of the technique will be discussed. This is a difficult exam to perform, with a long learning curve that requires specific equipment and the need for a multidisciplinary team, ideally in a reference centre. It remains unfamiliar for many gastroenterologists.

Albuquerque A. High-resolution anoscopy: Unchartered territory for gastroenterologists? *World J Gastrointest Endosc* 2015; 7(13): 1083-1087 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i13/1083.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i13.1083

DEFINITION AND PRINCIPLES OF HIGH RESOLUTION ANOSCOPY

High-resolution anoscopy (HRA) is a procedure where high-risk patients are submitted to anal and perianal visualization under magnification, allowing detection of anal high-grade lesions that can be treated. HRA can simply be defined as a colposcopy applied to the anal canal and perianal region.

Men who have sex with men (MSM), human immunodeficiency virus (HIV) infected individuals, transplant patients and women with a history of lower genital tract neoplasia have an increased risk of anal cancer. HIV-negative MSM have an estimated incidence rate of 35 per 100000 person-year and anal cancer incidence rates in HIV-positive MSM are two times higher (about 70-100 per 100000 person-year)[1]. Anal cancer has become one of the most common non-AIDS-defining tumors in HIV-infected individuals[2]. Human papillomavirus (HPV) infection is almost always present in HIV-positive MSM, and infections with multiple HPV types are common[3]. Concerning transplantation, most data come from renal transplant recipients, and the relative risk of anal cancer in these patients is 10 fold[4,5].

Anal cancer screening follows the same principles that cervical cancer screening. Both tumors are caused by infection with oncogenic HPV strains, occur at the squamocolumnar transition zone and arise from same precancerous dysplastic lesions, anal intraepithelial neoplasia or cervical intraepithelial neoplasia[6]. Women are screened through cervical cytology and those with abnormal results are then referred for colposcopy. Abnormalities are biopsied, and if high-grade squamous intraepithelial lesions (HSIL) are present, the patient is treated, thereby preventing progression to cervical cancer. Cervical cancer rates have dramatically decreased through cytology screening[7,8], from 40-50 cases per 100000 individuals to about 8-10 cases per 100000 individuals. Anal cancer is likely preceded by HSIL, a colposcope may similarly be used to visualise it and permit biopsy and treatment in an effort to prevent anal cancer.

Progression of biopsy-proven anal HSIL to cancer in a group of 27 HIV-infected MSM has been recently reported[9] and confirmed that individual HSIL lesions can progress to cancer.

High-risk patients like HIV-positive men and women regardless of sexual orientation or HIV-negative MSM submitted to anal cytology as a screening test, that have an abnormal result should be refer to HRA. The prevalence of anal squamous intraepithelial lesions (SIL) has remained high among HIV-positive MSM after the introduction of highly active antiretroviral therapy (HAART); HAART is not associated with a reduced prevalence of anal SIL[10]. Other groups who should be considered for screening include women with cervical cancer, high-grade vulvar disease or cancer, individuals with perianal condyloma acuminata; and transplant recipients[11].

Anal cytology is classified on the basis of the 2001 revised Bethesda System of cervical cytology classification[12]. There is no specific terminology for anal cytology. The specificity and predictive value for anal high-grade lesions on biopsy are highest for HSIL, atypical squamous cells which cannot exclude high-grade squamous intraepithelial lesion(ASC-H), low-grade squamous intraepithelial lesions (LSIL) and atypical squamous cells of undetermined significance (ASC-US).

The severity of cytological findings and infection with high-risk HPV are the most significant predictors of significant preditors for HSIL, underscoring the importance of anal dysplasia screening[13]. A systematic review described that anal cytology has a sensitivity from 69% to 93% and a specificity from 32% to 59%, that is similar to those reported for cervical cancer screening[1]. Abnormal anal cytology seems highly predictive of anal dysplasia on biopsy, in a previous study by Cranston *et al*[14] 2007, the positive predictive value of anal cytological abnormality to predict any degree of anal dysplasia was 95.7%. Both sensitivity and specificity of anal cytology are higher for internal disease as compared to external disease (perianal region)[3].

HIGH RESOLUTION ANOSCOPY TECHNIQUE

Normally, during HRA the patient is in the left lateral position, in the foetal position, with the buttocks at the edge of the table. Bowel preparation is not needed. An anoscope is inserted and a colposcope is used to examine the squamocolumnar junction, the anal canal including the transformation zone and the perianal skin in a systematic manner. The inspection should be performed first with no staining and then with the topical application of acetic acid (3% or 5%), that will allow for better lesion identification and characterization. Most of the anal exam is done under 16 × magnification, once specific areas of interest are visualised, they should be examined under 25 × magnification and the anal verge is viewed with 10 × magnification[15]. After examination with acetic acid, application of Lugol's iodine solution may help to distinguish HSIL from LSIL, to assist the clinician in deciding where to biopsy, as well as to define the margin of the lesion[15].

Lesions seen during HRA should be carefully described concerning localization, contour, margins, acetic acid induced whitening, Lugol's staining, epithelial pattern, vascular pattern (mosaic pattern, punctation, warty vessels, atypical). This will help to distinguish between

low-grade and high-grade lesions. HSIL may be flat or thickened, and often have vascular changes including punctuation or a mosaic pattern, are acetowhite, with a poor uptake of Lugol's solution. In a study by Camus *et al*[16], the positive predictive value for HSIL increased to 68.6% with the following combination of criteria: Acetic acid-induced whitening, no Lugol staining, irregular epithelial pattern, and vascular changes. Many of these anal suspicious lesions have similar aspects to that initially describe in cervical colposcopy[7,8]. Cancers are often friable or ulcerated lesions with atypical vessels. Any suspicious lesion, namely of HSIL or anal cancer should be biopsied.

IMPORTANCE OF HIGH RESOLUTION ANOSCOPY

HRA is fundamental for high-grade lesion detection and subsequently guided treatment. Anal HSIL ablation treatment under HRA may reduce the rate of anal cancer[17].

Previous studies revealed that before HRA is performed, only a small percentage of suspicious lesions are identified. Camus *et al*[16], show that only 38.7% of the lesions were visible with the naked eye before HRA.

Few data are available on the progression of anal SIL to anal squamous-cell carcinoma (ASCC), the true rate of progression from high-grade dysplasia to invasive anal cancer remains unclear[1]. There are clearer data concerning perianal intraepithelial neoplasia or Bowen disease in which approximately 5% of lesions undergo malignant change[18].

Devaraj *et al*[19], published a series of 98 HIV-positive patients, with 40 patients with a follow-up of more than one year, with expectant management of anal squamous dysplasia. In this series, 28 of 40 patients had anal HSIL and three of these patients (11%) developed invasive carcinoma while under surveillance (expectant management). Scholefield *et al*[20] described a series of 35 non-infected HIV patients, all with anal HSIL. In this series, 7 patients where submitted to expectant management due to extensive or multifocal disease and three of these patients (9%) developed invasive ASCC during follow-up, median of 5 years after the initial diagnosis of anal HSIL. In a study by Sobhani *et al*[21], including 199 patients who were successfully treated for anal warts (HIV positive and HIV negative patients included), 38 (19%) later developed anal HSIL, and of these, seven (18%) developed ASCC, 13 to 108 mo after entry in the study.

Wide excision is a morbid procedure that also removes uninvolved healthy tissues to achieve widely clear margins. Nevertheless, there is still a risk of recurrence[22]. HRA guided ablation of anal HSIL has several advantages: It permits a full evaluation of the anorectal anatomy, detection of grossly invisible disease, allowing target therapy with protection of normal tissues, minimal morbidity and reducing the risk of anal stenosis[22]. Cervical HSIL is usually treated with the loop electrosurgical excision procedure, removing the squamocolumnar transformation zone where most dysplasia develops. This is not possible for anal HSIL and treatment most often relies on ablation of individual lesions with laser, electrocautery (ECA), and infrared coagulation (IRC). There is no significant difference in treatment success between IRC and ECA[17]. A recent study by Goldstone *et al*[17] showed that patients undergoing ablation of anal HSIL have high recurrence, but the probability of developing anal cancer is low. The recurrence 1 year after the first ablation for HIV-positive and -negative patients was 53% and 49%, respectively; at 2 and 3 years, the rate of recurrence was 68% and 77% for HIV-positive patients and 57% and 66% for HIV-negative patients. The probability of cancer 3 years post-ablation was 1.97%.

Perianal high-grade dysplasia (Bowen disease) it is traditionally treated with mapping (blind biopsies) and wide excision. A recent study by Johnstone *et al*[23], showed that perianal dysplasia can be successfully treated with HRA-guided targeted ablation (ECA, laser or IRC) with no morbidity, although recurrence remains high. Almost all of these patients have anal canal dysplasia and HIV-positive patients are at the greatest risk for disease and recurrence.

Recommendations on post-treatment follow-up intervals are lacking.

DIFFICULTIES IN PERFORMING HIGH RESOLUTION ANOSCOPY, CAN WE DO IT?

Probably due to the long learning curve, the number of clinicians performing HRA is limited. Although the similarities of HRA and colposcopy, HRA is a more challenging and demanding technique due to the anal anatomy, anal pathology and difficulties in the treatment (excision is not a real option). Previous training in colposcopy is important to understand how to work with the colposcope and detect the aspect of the lesions. To perform this technique, a colposcope is required, and this equipment is not normally available outside a gynaecology clinic. In some cases, patients have not been referred to this technique due to the lack of knowledge of the indications or trained clinicians that can observe these patients. These patients need to be followed by a multidisciplinary team, including the clinicians performing HRA, pathologists, infectiologists, and colon and rectal surgeons.

This is extremely important because there is a growing number of patients, namely, HIV and MSM who need to been screened. It will be a long journey until all of these high-risk patients are referred for screening and more clinicians feel motivated to learn this technique. Recently the results of an internet-based survey on attitudes and practice of Colon and Rectal surgeons (United States members of the American Society of

Colon and Rectal Surgeons) on anal dysplasia revealed that, although most of them treated patients at risk for anal cancer and had read research on HSIL, only one-third had performed HRA and of these less than half (46%) were formally trained. When evaluating patients for HSIL in surgery, only 31% used acetic acid with magnification[24]. Another internet-based survey to members of international surgical and dermatological societies concerning diagnosis, treatment and surveillance of patients with HPV-related anal diseases revealed that to detect dysplastic lesions, 42.0% of surgeons used acetic acid only, 23.2% used this in combination with HRA and 19.5% applied intra-anal cytological smears. Likewise, 64.6% of dermatologists applied acetic acid only, 16.5% combined acetic acid with HRA and 30.2% performed intra-anal cytological smears[25].

It is fundamental to have more and better trained clinicians performing it. This will never be a technique that can be performed by all.

Several clinicians can perform anal cytology, especially those involved with high-risk patients, namely infecciologists, dermatologists, gynaecologists, nephrologists. If an abnormal result is detected, patients should be referred, ideally to a reference centre, to a clinician properly trained in HRA and with a multidisciplinary team. Thus, regarding anal cancer screening, we should inform all clinicians, cytology should be performed by most and HRA by some.

HRA was developed in the 90's, but remains unfamiliar to many, including gastroenterologists, although in some countries gastroenterologists are also proctologists. Much of the gastroenterology daily routine involves diagnostic and interventional therapeutic procedures. These are central concepts of HRA. Basic knowledge regarding the technique and even proper training may well be in the present and future realm of gastroenterologists.

HRA is fundamental for high-grade anal and perianal lesion detection and subsequently guided treatment in an effort to prevent anal cancer in high-risk patients.

Abstract

Upper non-variceal gastrointestinal bleeding is a condition that requires immediate medical intervention and has a high associated mortality rate (exceeding 10%). The vast majority of upper gastrointestinal bleeding cases are due to peptic ulcers. *Helicobacter pylori* infection, non-steroidal anti-inflammatory drugs and aspirin are the main risk factors for peptic ulcer disease. Endoscopic therapy has generally been recommended as the first-line treatment for upper gastrointestinal bleeding as it has been shown to reduce recurrent bleeding, the need for surgery and mortality. Early endoscopy (within 24 h of hospital admission) has a greater impact than delayed endoscopy on the length of hospital stay and requirement for blood transfusion. This paper aims to review and compare the efficacy of the types of endoscopic hemostasis most commonly used to control non-variceal gastrointestinal bleeding by pooling data from the literature.

Key words: Upper gastrointestinal bleeding; Non-variceal bleeding; Endoscopic hemostasis; Endoscopic therapy

Core tip: Review and comparison the efficacy of the most commonly used types of endoscopic hemostasis for the control of non-variceal gastrointestinal bleeding in clinical practice by pooling data from the literature.

INTRODUCTION

Acute upper gastrointestinal bleeding (UGIB) is a common medical entity for which endoscopy has become

the primary diagnostic and therapeutic technique. Endoscopy performed in patients with UGIB corresponds with a reduction in required blood transfusions and length of intensive care unit/total hospital stay[1]. Upper endoscopy is required for most patients with UGIB and should be performed within 24 h of hospital admission after adequate prior fluid resuscitation[2]. The key to improving outcomes is the proper initial management of individuals who present with UGIB. In most clinical conditions, the vast majority (80%-90%) of episodes of acute upper gastrointestinal bleeding are secondary to non-variceal origin. This review addresses different endoscopic techniques of hemostasis that are used to treat acute upper gastrointestinal bleeding of non-variceal origin (NVUGIB) in the world practice.

EPIDEMIOLOGY

UGIB is mostly non-variceal in origin and still remains one of the most common challenges encountered by surgeons, gastroenterologists and endoscopists in a daily clinical setting. The incidence rate of non-variceal UGIB ranges from 50 to 150 per 100000 adults/year[3]. In spite of major advances in the approaches used to manage non-variceal UGIB over the past 2 decades, including the peptic ulcer bleeding prevention, the optimal use of endoscopic therapy, as well as the use of adjuvant high-dose proton pump inhibitors (PPIs) to eradicate *Helicobacter pylori*, it is still associated with considerable morbidity, mortality, and health care costs. The most common non-variceal bleeding etiologies include gastroduodenal peptic ulcer (20%-50%), gastroduodenal erosions (8%-15%), Mallory-Weiss tears (8%-15%), erosive esophagitis (5%-15%), arteriovenous malformations/GAVE (5%); several other conditions [*e.g.*, Dieulafoy's lesion, upper gastrointestinal (GI) tract malignancy] make up the remaining causes[4-7]. Peptic ulcer disease still remains the most common cause of acute NVUGIB and accounts for at least 50% of cases. Ulcers with signs of active spurting (Forrest class ⅠA) or oozing blood (Forrest class ⅠB) and ulcers with a nonbleeding visible vessel (Forrest ⅡA) are at high risk of recurrent bleeding when only medical therapy is used. Thus, endoscopic hemostasis is required for patients with high-risk stigmata [ⅠA, ⅠB] or a visible vessel in an ulcer niche [ⅡA]. Clean-based ulcers (Forrest class Ⅲ) or flat pigmented spots in the ulcer bed (Forrest class ⅡC) are low-risk lesions that only rebleed in 4% to 13% of cases and can therefore be treated with pharmacotherapy alone and considered for outpatient management[8,9]. Ulcers with adherent clots (Forrest class ⅡB) have an intermediate risk of rebleeding (approximately 25%) that depends on the underlying lesion. For that reason, clot removal should be performed with vigorous irrigation and manipulation with an endoscope, forceps, or snare. In patients suffering from peptic ulcer disease, duodenal ulcer bleeding appears more frequently than from gastric ulcers[10]. A Blatchford score or pre-endoscopic Rockall score (based on age, comorbidity, and the presence or absence of hemodynamic instability) should be used to stratify risk and determine which patients require prompt endoscopy or, conversely, to determine suitability for early discharge (Table 1). The Blatchford score, a validated risk-stratification tool based solely on clinical and laboratory variables, is used to predict the need for endoscopic intervention in patients with acute upper GI hemorrhage. A higher score indicates a higher likelihood of needing endoscopic intervention (score ranges from 0 to 23). The clinical Rockall score (*i.e.*, the score obtained before endoscopy is performed) is calculated solely on the basis of clinical variables at the time of patient presentation. The complete Rockall score makes use of both clinical and endoscopic criteria to assess patient risk of re-bleeding and mortality. Rockall score ranges from 0 to 11 points, with higher scores indicating a higher risk for a poor outcome (Table 2)[11,12].

Table 1 Blatchford scoring: Admission risk markers and associated score component values[13]

Admission risk marker	Score component value
Blood urea, mmol/L	
6.5 to ≤ 8	2
8.0 to < 10.0	3
10.0 to < 25	4
≥ 25	6
Hemoglobin for men, g/dL	
12.0-13.0	1
10.0 to < 12.0	3
< 10.0	6
Hemoglobin for women, g/dL	
10.0 to < 12.0	1
10	6
Systolic blood pressure, mmHg	
100-109	1
90-99	2
< 90	3
Other markers	
Pulse ≥ 100/min	1
Presentation with melena	1
Presentation with syncope	2
Hepatic disease	2
Cardiac failure	2

ENDOSCOPIC MANAGEMENT

The aim of therapeutic endoscopy is to stop any ongoing bleeding and to prevent rebleeding. Cooper *et al*[13] studied the effectiveness of performing an early endoscopy within the first 24 h of an acute UGIB episode and found it to be associated with reductions in the length of hospital stay, the rate of recurrent bleeding, and the need for emergent surgical intervention. According to the 2010 international consensus on non-variceal upper gastrointestinal bleeding, early endoscopy (within 24 h of presentation) is appropriate for most patients with UGIB[2]. In cases of rebleeding, a second attempt at endoscopic therapy is recommended to reduce the need for surgery. In patients who have undergone failed endoscopic therapy, surgery should be considered.

Table 2 Complete rockall risk scoring system for assessment after an episode of acute upper gastrointestinal bleeding[12]

Variables	Score 0	Score 1	Score 2	Score 3
Age	Younger than 60 yr	60-79 yr	80 yr or older	-
Shock symptoms, systolic blood pressure, heart rate	Shock absent, blood pressure 100 mmHg or greater, heart rate 100 bpm or greater	Tachycardia, blood pressure 100 mmHg or greater, heart rate 100 bpm or greater	Hypotension, blood pressure less than 100 mmHg	-
Comorbidities	No major comorbidity	-	Heart failure, coronary artery disease, any major comorbidity	Renal failure, liver failure, disseminated malignancy
Endoscopic diagnosis	Mallory-Weiss tear or no lesion identified, and no stigmata of recent hemorrhage	All other diagnoses	Malignancy of upper GI tract	-
Stigmata of recent hemorrhage	Low-risk	-	High-risk	-

Low-risk stigmata of bleeding: Clean base ulcer, pigmented spots; High-risk stigmata of bleeding: Adherent clot, visible or spurting vessel, active bleeding; Bpm: Beats per minute; GI: Gastrointestinal.

Table 3 Recommendations of the american society for gastrointestinal endoscopy concerning upper gastrointestinal bleeding management[38]

We recommend that patients with UGIB be adequately resuscitated before endoscopy
We recommend antisecretory therapy with PPIs for patients with bleeding caused by peptic ulcers or in those with suspected peptic ulcer bleeding awaiting endoscopy
We suggest prokinetic agents in patients with a high probability of having fresh blood or a clot in the stomach when undergoing endoscopy
We recommend endoscopy to diagnose the etiology of acute UGIB. The timing of endoscopy should depend on clinical factors. Urgent endoscopy (within 24 h of presentation) is recommended for patients with a history of malignancy or cirrhosis, presentation with hematemesis, and signs of hypovolemia including hypotension, tachycardia and shock, and a hemoglobin < 8 g/dL
We recommend endoscopic therapy for peptic ulcers with high-risk stigmata (active spurting, visible vessel). The management of PUD with an adherent clot is controversial. Recommended endoscopic treatment modalities include injection (sclerosants, thrombin, fibrin, or cyanoacrylate glue), cautery, and mechanical therapies
We recommend against epinephrine injection alone for peptic ulcer bleeding. If epinephrine injection is performed, it should be combined with a second endoscopic treatment modality (*e.g.*, cautery or clips)
We recommend that patients with low-risk lesions be considered for outpatient management
We recommend against routine second-look endoscopy in patients who have received adequate endoscopic therapy
We recommend repeat endoscopy for patients with evidence of recurrent bleeding

UGIB: Upper gastrointestinal bleeding; PPIs: Proton pump inhibitors; PUD: Peptic ulcer disease.

Despite adequate initial endoscopic therapy, recurrent UGIB can occur in up to 24% of high-risk patients. The use of PPI therapy in addition to endoscopic therapy reduces the rate of recurrent bleeding to approximately 10%. Patients with recurrent bleeding generally respond favorably to repeated endoscopic therapy. Routine second-look endoscopy, defined as a planned endoscopy performed within 24 h of the initial endoscopy, is not recommended. In cases where the initial endoscopy failed to identify the source (*e.g.*, because of a large clot in the stomach) or if there are concerns that inadequate therapy was delivered, second-look endoscopy may be appropriate (Table 3).

Currently, the efficacy and safety of endoscopic hemostasis rely on the identification of lesions that are suitable for endoscopic therapy, the selection of the appropriate hemostatic devices, attention to technique, and prompt recognition and management of procedure-related adverse events. The suitable technique should be chosen based on the appearance of the bleeding focus and the related risk for persistent or recurrent bleeding.

The traditional endoscopic modalities are injection, mechanical therapy, and thermal approaches. Injection agents include saline, dilute epinephrine, sclerosing agents (ethanolamine, polidocanol, absolute alcohol, and sodium tetradecyl sulfate), and tissue adhesives (cyanoacrylate, thrombin, and fibrin glue). Mechanical therapy offers endoscopic clips and band ligation. Thermal devices deliver electrical current (through direct contact or *via* an inert gas plasma) or heat to the target tissue. Moreover, a few new technologies have emerged, such as hemostatic powders.

INJECTION TREATMENT

Injection needles consist of an outer sheath (plastic, Teflon, or stainless steel) and an inner hollow-core needle (19-25 gauge)[14]. Using a handle on the end of the needle sheath, the operator can retract the needle into the sheath for safe passage through the working channel of the endoscope. When the catheter is placed near the target tissue, the needle is extended a preset distance out of the end of the sheath, and a syringe attached to the handle is used to inject liquid agents into the target tissue. Dilute epinephrine in saline (1:10000) is applied with an injection needle in 0.5-1.0 mL boluses to the four quadrants around the high-risk

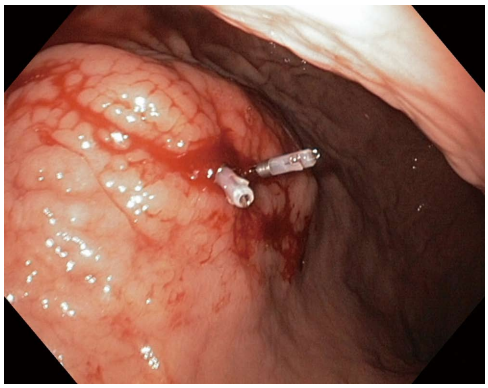

Figure 1 Endoscopic clips.

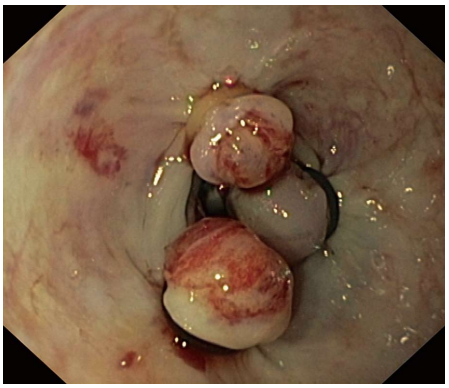

Figure 2 Endoscopic band ligation.

stigmata or to the base of the active bleeding site and then in the middle of it, up to a total of 10 mL[15,16]. Some practitioners prefer to use absolute alcohol in much smaller volumes (1-2 mL in 0.1 mL aliquots) or combinations of epinephrine and alcohol or sclerosants, which are used for the treatment of varices. Epinephrine injection therapy promotes initial hemostasis through a combination of vasoconstriction, compression (local tamponade), and platelet activation, but this effect declines after 20 min. If epinephrine injection is performed, it should usually be combined with a second endoscopic treatment modality (*e.g.*, electrocautery or clips)[17]. If epinephrine is used alone, there is a significant risk of rebleeding. This can be reduced by injecting large volumes, as high as 30 mL, which are associated with no clearly described cardiologic adverse events, and the rebleeding rate decreases linearly with the injected volume[18,19]. Dilute epinephrine injection is inferior at preventing rebleeding and surgery when compared with bipolar electrocoagulation, clips, or fibrin glue[20]. Other injected substances, such as sclerosing agents (*e.g.*, polidocanol, ethanolamine, and ethanol), have similar efficacy but more side effects, including transmural necrosis or perforation[21]. Another class of injectable agents are tissue adhesives, including cyanoacrylate glues, thrombin and fibrin, which are used to create a primary seal at the site of bleeding by inducing thrombosis through direct tissue injury. However, they may also evoke tissue necrosis and, hence, the limit for injected volumes is less than 1 mL. Cyanoacrylate (n-butyl-2-cyanoacrylate, Histoacryl; Braun, Germany) is a liquid tissue adhesive that consists of monomers that rapidly polymerize (creating long and strong chains) in an exothermic reaction after contact with hydroxide ions[22]. Cyanoacrylate is widely used for the management of bleeding esophageal and gastric varices, but it is not recommended for acute non-variceal upper gastrointestinal bleeding. However, in difficult-to-arrest non-variceal bleeding, it could be a useful and safe therapeutic tool.

MECHANICAL THERAPY

Mechanical therapy refers to the use of a device that causes physical tamponade at a bleeding site[15]. It includes endoscopic clips and band ligation (Figures 1 and 2). Metal clips are particularly useful for small bleeding ulcers (*i.e.*, Dieulafoy lesions), for Mallory-Weiss tears, and for large, visible vessels. Endoscopic clips are deployed over a bleeding site (*e.g.*, visible vessel) and typically slough off within days to weeks after placement. Endoscopic clips function by mechanical compression of the bleeding vessel and theoretically cause less tissue injury than cautery methods. Band ligation is widely used in variceal bleeding. However, it has also been found to be effective in treating bleeding Dieulafoy's lesions[23].

The Over-The-Scope Clip (OTSC; Ovesco, Tübingen, Germany) is a modern endoscopic clipping device designed for tissue approximation. It has been used for the closure of fistulas and perforations. OTSC consists of a nitinol clip mounted on an applicator cap that is affixed to the tip of the endoscope. The deployed clip captures and closes tissue suctioned into the applicator cap, thus compressing the lesions until healing. Studies on animal models and limited data from clinical use support the efficacy of OTSC for the treatment of GI bleeding, and a number of small case series have shown effective hemostasis resulting from the use of OTSC in patients for whom epinephrine injection or standard clip placement failed[24]. The OTSC is now available on the market and gives the physician a tool for the immediate management of complications, such as deep-wall lesions, difficult bleeding or perforations.

THERMAL THERAPY

Thermal therapies include electrocautery probes (monopolar, bipolar or multipolar) and heater probes, which are referred to as contact thermal modalities, and argon plasma coagulation (APC) and laser phototherapy, which are known as noncontact techniques. Bipolar and multipolar probes provide constant bipolar electrocoagulation, which is assumed to be safer than monopolar diathermy (which produces an unpredictable depth of damage and a higher risk of perforation). A foot pedal controls the delivery of energy. The power output is in watts (W). Maximum power settings are dependent

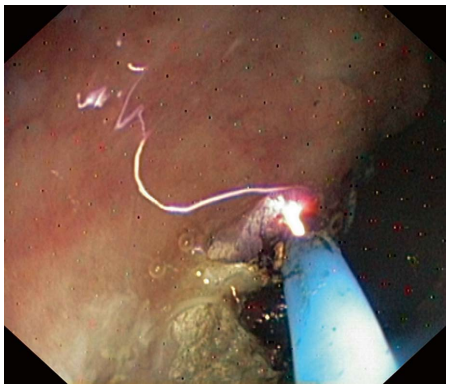

Figure 3 Argon plasma coagulation.

on the generator used but usually do not exceed 50 W. A standard setting is 20 W.

A heater probe provides constant heat at 250 ℃, which is released by a diode in the probe tip and directly transferred to tissue to affect coagulation. Contact treatment devices share some common principles. All can be applied tangentially but are better used face-on, if possible. When the vessel is actively bleeding, direct probe pressure on the vessel or feeding vessel will reduce the flow and increase the effectiveness of treatment. Mechanically pressuring the probe tip directly to the bleeding site, combined with heat or electrical current to coagulate blood vessels, is a process known as "captive coagulation". The bipolar and heater probes incorporate a flushing water jet, which helps to prevent sticking.

Argon plasma coagulation, which is performed without tissue contact, uses the electrical conductivity of argon gas (Figure 3). The argon, passed down an electrode catheter and energized *via* an intelligent-circuitry electrosurgical unit and patient plate, ionizes to produce a local plasma arc. The produced heating effect is inherently superficial (2-3 mm at most, unless the current is applied in the same place for many seconds). Therefore, APC is used to treat superficial mucosal lesions, such as vascular malformations and gastric antral vascular ectasias. The APC probe should be positioned 2-10 mm from the lesion and the argon gas flow should be 1.5-2 L/min at a power of 40-50 W[25,26].

Laser phototherapy uses an Nd:YAG laser to create hemostasis by generating heat to induce direct vessel coagulation. This is a noncontact thermal method. It is not as effective as captive coagulation because it lacks the use of compression to create a tamponade effect[27]. An additional deterrent to its use is expense.

To perform laser coagulation, the area near the vessel is first injected with epinephrine to reduce blood flow (reducing the heat-sink effect). Then, the laser is applied around the vessel, producing a wall of edema. Caution must be taken to avoid drilling into the vessel with the laser, which can cause increased bleeding.

TOPICAL HEMOSTATIC AGENTS

Topical hemostatic agents are new tools used in endoscopic hemostasis. Three different powders are available: Hemospray (Cook Medical, Winston-Salem, NC, United States), Ankaferd BloodStopper, and EndoClot (EndoClot Plus Inc., Santa Clara, CA, United States)[28].

Hemospray (TC-325), a novel proprietary inorganic powder, has recently been approved in Canada for the management of NVUGIB[29]. The powder is administered through a 10- or 7-French catheter *via* a CO_2-pressurised canister. It achieves hemostasis by adhering to the bleeding site, leading to mechanical tamponade and, by concentrating and activating platelets and coagulation factors, promoting thrombus formation. Its ability to cover large areas with multiple bleeding points makes it a suitable choice for hemorrhagic gastritis, gastric antral vascular ectasia, radiation-induced mucosal injury and malignancy-related bleeding[29]. Other advantages include ease of use, the lack of need for precise lesion targeting and access to lesions in difficult locations.

Hemostatic sprays derived from plants have also been invented. Clinical use of these agents for endoscopic hemostasis is currently limited to the off-label use of ankaferd blood stopper (ABS) (Ankaferd Health Products Ltd., Istanbul, Turkey), a mixture of extracts from several plants that is approved in Turkey for the topical treatment of dental and postsurgical external bleeding. ABS is delivered through the working channel of the scope using a spray catheter.

The EndoClot Polysaccharide Hemostatic System (EndoClot Plus Inc., Santa Clara, CA, United States) is the latest available hemostatic powder. It consists of starch, which explains its availability in European countries, Australia, Malaysia, and Turkey, despite a lack of rigorous scientific evidence for its efficacy. The effectiveness of the powder at controlling and preventing bleeding related to endoscopic mucosal resection has been recently described[28].

PRE-ENDOSCOPY PHARMACOLOGIC THERAPY

Prokinetic agents, such as intravenously administered erythromycin or metoclopramide, should be considered for use 30 min prior to endoscopy to improve visibility[30]. Intravenous prokinetic agents, when administered 20 to 120 min before endoscopy in patients with acute UGIB, decrease the need for a repeat endoscopy to determine the site and cause of bleeding. However, their use has not demonstrated any benefit to other clinical parameters, such as transfusion requirement, length of hospital stay, or need for surgery.

Proton pump inhibitor (PPI) therapy is another pharmacologic intervention that should be considered in patients suspected to have UGIB (*e.g.*, pantoprazole 80 mg bolus followed by 8 mg/h continuous drip or 40 mg intravenously every 12 h). The infusion is continued for 48-72 h. The relative efficacy of PPIs may be due to their superior ability to maintain gastric pH at a level above 6.0, thereby protecting ulcer clots

from fibrinolysis. Multiple analyses have shown that applying PPI therapy before a procedure significantly reduced the rate of high-risk stigmata that are identified by endoscopy and the need for endoscopic therapy. Therefore, intravenous PPI therapy is recommended for patients who are suspected of having acute NVUGIB.

EFFICACY AND COMPARATIVE ANALYSIS

Gastroduodenal peptic ulcers are by far the most common etiology of UGIB, accounting for 50% of admissions among patients with upper gastrointestinal hemorrhage[28]. Multiple meta-analyses evaluating endoscopic therapies for bleeding peptic ulcers have demonstrated that thermal devices, injectable agents other than epinephrine (*i.e.*, sclerosants and thrombin/fibrin glue), and clips were all effective methods for achieving hemostasis in PUD, with no single modality being superior to the others. In particular, hemoclip placement, thermocoagulation (*e.g.*, heater probe), and electrocoagulation (*e.g.*, Gold probe, BICAP probe) all seem to be equivalent alternatives[20,31-34]. Dual combination therapy (*i.e.*, epinephrine injection plus other injections or thermal or mechanical methods) was proven to be significantly superior to epinephrine injection alone, but displays no advantage over thermal or mechanical monotherapy. This means that epinephrine should no longer be applied as a monotherapy for treating lesions with high-risk stigmata and should only be used in combination with other methods as these combinations significantly reduce the risk of rebleeding and surgery. Prospective randomized trials have demonstrated that thermal therapy results in significant reductions in bleeding, blood transfusions, length of hospital stays, and the need for urgent surgery in patients with actively bleeding ulcers or nonbleeding ulcers with visible vessels[35]. A meta-analysis of randomized trials that evaluated rebleeding rates following injection, thermal therapy, clips, or combination therapy showed that clips were superior to thermal therapy[33]. The remaining causes of UGIB account for up to 50% of cases. For gastric antral vascular ectasia (GAVE), APC remains the most commonly reported modality that is usually performed over multiple endoscopic sessions. APC is associated with a decrease in transfusion requirements[36]. Mallory-Weiss tear bleeding usually spontaneously stops, with the rates of rebleeding from this etiology reaching up to 10%. Patients with active bleeding or oozing require endoscopic therapy. Bipolar electrocoagulation, epinephrine injection, clips, and band ligation have all been used successfully with no difference in immediate hemostasis or rebleeding. Endoscopic therapy is the first choice in bleeding Dieulafoy's lesions and is usually performed *via* clipping or banding of the lesion[23]. Endoscopic clipping is superior to endoscopic injection and is comparable to thermocoagulation in securing hemostasis in bleeding peptic ulcers and Dieulafoy's lesions[28]. Endoscopic hemostasis of bleeding upper GI tract tumors has proven to be less effective and to have higher rates of rebleeding. Various endoscopic treatment modalities have been described with no clear recommendations. Several studies have reported that cyanoacrylate was used for acute non-variceal gastrointestinal bleeding cessation[21]. Application of cyanoacrylate (by injection and/or spraying) is a safe and effective method for achieving immediate hemostasis when conventional endoscopic treatment has been unsuccessful. This technique is easy to perform and should be considered in cases of patients with difficult-to-arrest acute NVGIB. Recently, promising preliminary data have been reported following the use of the hemostatic powder TC-325 (Hemospray) for bleeding control from upper GI tract tumors[37].

CONCLUSION

Endoscopy is the mainstay for the modern management of NVUGIB. Ideally, endoscopy should be performed within 24 h of presentation, after adequate resuscitation has been performed. Many safe and effective devices are available for endoscopic hemostasis. Combination therapy using the injection of epinephrine plus another hemostatic technique is more effective than epinephrine alone. Hemospray is a new and promising endoscopic therapy. Patients with high-risk stigmata should receive continuous intravenous PPI administration for 72 h after endoscopy. After the acute phase, the underlying cause of the lesion should be verified and treated, when possible. The choice of therapy should remain at the discretion of the physician, based on the nature and position of the lesion, the availability and experience of the endoscopist and the previous endoscopic therapy that the patient has received.

Abstract

AIM: To assess the outcome of different treatments in patients admitted for esophageal achalasia in the United States.

METHODS: This is a retrospective analysis using the Nationwide Inpatient Sample over an 8-year period (2003-2010). Patients admitted with a primary diagnosis of achalasia were divided into 3 groups based on their treatment: (1) Group 1: patients who underwent Heller myotomy during their hospital stay; (2) Group 2: patients who underwent esophagectomy; and (3) Group 3: patients not undergoing surgical treatment. Primary outcome was in-hospital mortality. Secondary outcomes included length of stay (LOS), discharge destination and total hospital charges.

RESULTS: Among 27141 patients admitted with achalasia, nearly half (48.5%) underwent Heller myotomy, 2.5% underwent esophagectomy and 49.0% had endoscopic or other treatment. Patients in group 1 were younger, healthier, and had the lowest mortality when compared with the other two groups. Group 2 had the highest LOS and hospital charges among all groups. Group 3 had the highest mortality (1.2%, $P < 0.001$) and the lowest home discharge rate (78.8%) when compared to the other groups. The most frequently performed procedures among group 3 were esophageal dilatation (25.9%) and injection (13.3%). Among patients who died in this group the most common associated morbidities included acute respiratory failure, sepsis and aspiration pneumonia.

CONCLUSION: Surgery for achalasia carries exceedingly low mortality in the modern era; however, in complicated patients, even less invasive treatments are burdened by

significant mortality and morbidity.

Key words: Esophageal achalasia; Outcomes; Myotomy

Core tip: We aimed to assess the outcomes of different treatments in patients hospitalized for esophageal achalasia in the United States. We queried the Nationwide Inpatient Sample database from 2003 to 2010. Patients admitted with a primary diagnosis of achalasia were divided into 3 groups, based on treatment, and compared. About half of the patients did not actually undergo a surgical procedure; yet, they had the highest mortality and lowest home discharge rate. Our data suggest that when achalasia has gone too far and previous treatments have been untimely or ineffective, patients may face non-negligible mortality and morbidity even with endoscopic treatment or supportive care.

INTRODUCTION

Achalasia is a chronic, progressive disease characterized by loss of peristalsis of the distal esophagus, failure of the lower esophageal sphincter to completely relax with deglutition, and elevated baseline intraluminal esophageal pressure[1]. The pathophysiology of the impaired peristalsis is represented by the progressive degeneration and destruction of a subpopulation of inhibitory neuronal ganglion cells of the Auerbach myenteric plexus of the esophagus[2]. The resulting long lasting contraction of the lower esophageal sphincter (LES) causes stasis of food within the esophageal lumen until the rising intraesophageal pressure overcomes the obstacle represented by the cardial spasm and the bolus slowly transits into the stomach. The outflow obstruction inevitably leads, over time, to progressive esophageal dilation and tortuosity, if the condition is left untreated.

The treatment of achalasia is substantially palliative and aims to relieve symptoms and to contrast the natural history of the disease through improvement of passive esophageal transit. The distal esophageal obstacle to food progression can be eliminated with endoscopic pneumatic dilation or surgical myotomy, both with similar short-term success of about 80%-90% and a long-term control of symptoms of approximately 50% with dilation, and 80%-90% with myotomy[3-6].

The therapeutic options for achalasia also include endoscopic botulin toxin injection, especially for the high-risk patients or those patients with contraindications to pneumatic dilation or surgery; this procedure, however, is burdened by high long-term costs, short lasting results and a high recurrence rate[7]. Pharmacological treatment of achalasia, targeted to induce LES relaxation with nitrates and calcium channel blockers, has been shown to yield unsatisfying results with poor control of symptoms[8,9].

We believe that the severity of the disease is often underestimated, especially in more advanced stages, due to its slow progression and to its common classification as a benign condition. We therefore queried the Nationwide Inpatient Sample (NIS), in order to assess the outcome of different treatments in patients admitted for esophageal achalasia in the United States.

MATERIALS AND METHODS

Data source and study population

A retrospective review was performed using the NIS database from 2003-2010. NIS consists of 20% stratified sample of all United States hospitals, and it provides discharge weights to produce a 95% of all discharges in the United States[10]. International Classification of Diseases, ninth revision (ICD-9) coding was used to establish the desired study population. All patients admitted with a primary diagnosis of achalasia (ICD-9 diagnosis code of 530.0) were included in the study. These patients were divided into 3 groups based on their in-hospital treatment: (1) Group 1: Achalasia patients who underwent Heller myotomy during their hospital stay (ICD-9 procedure code of 42.7); (2) Group 2: Achalasia patients who underwent esophagectomy (ICD-9 procedure codes of 150, 150.1, 150.2, 150.3, 150.4, 150.5, 150.8, 151); and (3) Group 3: Achalasia patients not undergoing surgical treatment. This study was limited to adult patients (> 17 years old) without a diagnosis of esophageal cancer (ICD-9 diagnosis codes of 150, 150.1, 150.2, 150.3, 150.4, 150.5, 150.8, 151). This study was granted exempt status by the Johns Hopkins Medicine Institutional Review Board.

Outcomes

The primary outcome was in-hospital mortality. Secondary outcomes included length of stay (LOS), discharge destination (home/transfer), total hospital charges (TOTCHG), and complications such as, pneumonia, urinary tract infection (UTI), shock/sepsis, and pulmonary compromise. These complications were obtained by using previously validated ICD-9 diagnosis codes (1-2) (Table 1). Total hospital charges were adjusted for inflation to reflect 2011 United States dollars.

Statistical analysis

All statistical analyses were performed using STATA/MP, version 11.2 (Stata Corp, College Station, Texas). Weighting strategy was applied prior to conducting statistical analysis. Adjusted Wald test and Pearson's χ^2 were used for continuous and categorical variables, respectively. Multivariable logistic regressions were performed to compare odds of each outcome while

adjusting for age, gender, and Charlson Index score. Adjusted TOTCHG and LOS were obtained from a multiple regression, while adjusting for age, gender, and Charlson Index score. A level of significance was set at $\alpha = 0.05$.

RESULTS

Baseline demographic and clinical characteristics

A total of 31769 achalasia patients met the study criteria, including, 15567 Heller patients (49.0%), 785 esophagectomy patients (2.5%), and 15417 non-surgical patients (48.5%) (Table 2). The overall mean age was 59 (median 59), with 54.3% females, and 70.8% white patients. Heller group was the youngest (median age of 51) and the healthiest (mean Charlson score of 0.34). While the non-surgical group was the oldest (median age 72) with the highest comorbidity (mean Charlson score of 0.93). Among the most common procedures performed for patients who underwent non-surgical treatment of achalasia (group 3) were: esophagogastroduodenoscopy (65.2%), dilation of esophagus (26.9%), and injection of therapeutic/prophylactic substance-including botulism antitoxin (17.3%) (Table 3).

Unadjusted outcomes

The overall in-hospital mortality was 0.65%, with the highest unadjusted mortality seen in the esophagectomy group (1.96%) (Table 4). There was no significant difference between the in-hospital mortality for the esophagectomy group *vs* non-surgical group. The esophagectomy group stayed in the hospital the longest (median LOS of 13 d) and had highest total hospital charges (median TOTCHG of $134670.40). Achalasia patients undergoing Heller myotomy were the most likely to be discharged home (97.2%) and were less likely to acquire pneumonia, UTI, shock/sepsis, and pulmonary compromise (3.3%, 2.0%, 0.3%, and 1.6%, respectively). Pneumonia, shock/sepsis, and pulmonary compromise were the most common complications in the esophagectomy group. Mean LOS, TOTCHG, and pneumonia were significantly different across all three groups (even when the pairwise comparison was applied).

Adjusted outcomes

Multivariable logistic regression was performed for the two surgical groups *vs* the non-surgical group, while adjusting for age, gender, and Charlson Index score.

Heller vs non-surgical group

The likelihood of in-hospital mortality was more than four times higher in the non-surgical group (OR = 4.73, 95%CI: 1.16-19.31, $P = 0.03$), and the chance to develop pneumonia and UTI was doubled (OR = 1.91, 95%CI: 1.42-2.58, $P < 0.001$; OR = 2.31, 95%CI: 1.67-3.18, $P < 0.001$, respectively) when compared to the Heller group. Moreover, the non-surgical group was significantly more likely to be transferred (OR = 3.76, 95%CI: 2.85-4.97, $P < 0.001$). The non-surgical achalasia patients paid $14594.24 less ($P < 0.001$) in TOTCHG and stayed in the hospital about one day longer ($P < 0.001$) than the Heller patients (Table 5).

Esophagectomy vs non-surgical group

The esophagectomy group was seven times as likely to have an in-hospital mortality (OR = 7.28, 95%CI: 2.06-25.79, $P = 0.002$) and nearly twice as likely to be transferred compared to the non-surgical group (OR = 1.84, 95%CI: 1.16-2.94, $P = 0.01$). Achalasia patients who underwent esophagectomy had also higher complications such as pneumonia, shock/sepsis, and pulmonary compromise (OR = 3.68, 95%CI: 2.40-5.64, $P \leqslant 0.001$; OR = 16.53, 95%CI: 6.36-42.96, $P < 0.001$; OR = 37.97, 95%CI: 22.85-63.07, $P < 0.001$, respectively). Esophagectomy patients stayed in the hospital twelve days longer ($P < 0.001$) and paid $181167.90 more ($P < 0.001$) than the non-surgical patients (Table 6).

DISCUSSION

Our study shows that more than 30000 patients were hospitalized over an 8-year period for the treatment of esophageal achalasia in the United States. It would be intuitive to assume that most patients were admitted to undergo surgery, since endoscopic treatment is commonly performed in the outpatient setting. Only half of them underwent a surgical procedure instead, thus suggesting that the natural history of the disease can potentially lead to complications severe enough to require admission.

As broadly demonstrated in previous studies, we confirmed that patients treated with Heller myotomy benefit from low mortality, morbidity and LOS. The most frequent procedures performed among the non-surgical group were endoscopic pneumatic dilatation (25.9%) and endoscopic drugs injection (13.3%). It is common and widespread practice to elect non-surgical,

thus less invasive, treatment as the best option for high-risk patients. This phenomenon can be indeed observed in demographics of group 3, which included the oldest patients and those with highest comorbidity. Nevertheless, it is interesting to remark that, even after adjusting for age, gender, and Charlson Index score, the non-surgical group was more than four times as likely to have in-hospital mortality, and twice as likely to have pneumonia and UTI compared to the Heller group. This finding, which might appear counterintuitive at first glance, finds a logical explanation when recalling that non-surgical treatment of achalasia is usually administered in the outpatient setting. The youngest and most fit patients undergoing non-surgical treatment were therefore likely not captured by this analysis focusing on hospitalized patients. Conversely, many of

Table 5 Adjusted odds ratios of outcomes and complications for the non-surgical group (in comparison to the Heller group)

	OR	*P*	95%CI
In-hospital mortality	4.73	0.03	1.16-19.31

All the analyses were adjusted for age, gender, and Charlson Index score.

the patients of our group 3 were probably complicated patients, such as subjects affected by advanced stage, recurrent or refractory achalasia, or individuals at high risk for surgery. In addition, our analysis is likely to have included in group 3 also those patients who faced serious complications of endoscopic treatments. Pneumatic dilation, although offering fast recovery and low overall complication rate, is burdened by a tangible risk of esophageal full-thickness perforation, especially when the procedure is repeated multiple times to maintain satisfactory results[11,12].

Heller myotomy is usually performed laparoscopically and an antireflux procedure is commonly added; randomized studies have in fact confirmed its efficacy in decreasing postoperative gastroesophageal reflux disease[13,14]. It is reasonable to hypothesize that the ongoing technical advancements in minimally invasive surgery, along with the widespread of advanced laparoscopic skills to an increasing number of surgeons, will strengthen the role of Heller myotomy as the safest and most durable choice for the treatment of achalasia.

The findings of our analysis outline the potential risks resulting from the insidious, slowly progressive nature of achalasia. When the disease has gone too far and previous treatments have been untimely or ineffective, patients may face non-negligible mortality and morbidity even with endoscopic treatment or supportive care. We therefore think that Heller myotomy should be strongly considered early in patients with esophageal achalasia and should be offered to all patients as the first therapeutic option, in absence of absolute contraindications to surgery.

This recommendation might change in the future, once the long term outcomes of patients treated with per-oral endoscopic myotomy (POEM) will become available. POEM, in fact, represents the cutting edge of minimally invasive treatment for achalasia and offers comparable early outcomes to Heller myotomy with the adjunctive benefit of being performed endoscopically[15,16]. Therefore, if randomized studies will demonstrate long-term outcomes similar to those of laparoscopic Heller procedure, POEM might become the new gold standard for the treatment of esophageal achalasia.

Pulmonary symptoms as well as functional abnormalities have been demonstrated to be present in a significant percentage of patients with achalasia and are readily apparent in the poor pulmonary outcomes of our non-surgical group[17]. Respiratory complications represent one of the most frequent causes of morbidity in patients with achalasia, if the natural history of the disease is not radically modified by treatment. In addition, radiological pulmonary abnormalities in the form of consolidation, ground glass opacities, nodular opacities, air trapping, fibrotic changes and bilateral alveolar findings that resemble aspiration pneumonia have been widely described in achalasia patients[18]. Data in the literature support the hypothesis that surgery could not only improve the symptoms, but also lead to regression of the functional and radiological pathologic findings[17,18].

The results of our analysis confirm that esophagectomy, as previously shown, is an operation burdened by significant mortality and morbidity. It has been reported that laparoscopic myotomy may still play a role and improve outcomes in patients with stage IV disease, even when a remarkable esophageal dilation is present; this is particularly true for patients with an enlarged but linear esophagus[19].

However, about 5% of all patients with achalasia will eventually require esophagectomy and it is our belief that this procedure remains a reasonable option and a precious last resort in patients with end stage disease[20-22]. Moreover, we have previously shown that operative outcomes, including mortality, overall morbidity, and LOS are comparable between patients undergoing esophagectomy for achalasia and for esophageal cancer[23].

Our study presents some limitations worth mentioning. First of all, NIS is an administrative database, which is prone to errors due to missing or inaccurately entered ICD-9 codes. This database does not include any outpatient information, therefore patients that may have been treated by pneumatic dilation and sent home the same day are not captured. In addition, ICD-9 coding system is not perfect and specific procedures might be difficult to identify using the current ICD-9 procedure codes. For example, there is no specific

code for pneumatic balloon dilation, but there exists an ICD-9 code (42.92) for dilation of esophagus. There is no way to know if these dilations were merely routine dilations *vs* true pneumatic dilations with a 30 mm balloon. This fact, together with a small number of patients in the endoscopic injection group, did not allow us to meaningfully compare treatment subgroups among the non-surgical patients. No information is given on symptomatic relief and functional outcomes with this database, nor there is trace of postoperative events occurred after patients' discharge. Finally, it is not possible to know the stage of patients' disease at admission or if previous treatments for achalasia had been attempted.

That said, this study provides a useful general overview of the trends and outcomes of achalasia management and, in particular, it sheds light over the less studied populations of non-surgical patients who nonetheless needed hospitalization.

In conclusion, it is important to remark that the common labeling of achalasia as "benign condition" can be misleading and delay referral for definitive treatment. If left untreated or if treated with less than optimal approach, the disease will progress and can lead to complications, which will significantly affect patients' quality of life or potentially become life threatening. Although this database does not allow us to compare outcomes between endoscopic and surgical treatment of achalasia, the analysis of our data suggests that a timely and effective relief of esophageal obstruction may avoid future complications brought by the natural history of the disease.

We would like to acknowledge Mr. Edwin Lewis for his generous support of Dr. Lidor's Department of Surgery Research Fund.

COMMENTS

Background

Achalasia is a chronic, progressive disease characterized by loss of peristalsis of the distal esophagus, failure of the lower esophageal sphincter to completely relax with deglutition, and elevated baseline intraluminal esophageal pressure. The treatment of achalasia is substantially palliative and aims to relieve symptoms and improve passive esophageal transit. The authors believe that the severity of the disease is often underestimated, especially in more advanced stages, due to its slow progression and to its common classification as a benign condition. Comparing the outcomes after different treatments in patients hospitalized for achalasia can help provide additional clinical insights for providers who care for these patients.

Research frontiers

Early intervention and modification of the history of achalasia is paramount, since the disease is prone to an insidious and burdensome progression, as evidenced by several studies, including the authors'. Awareness should be raised and efforts focused on early diagnosis and treatments. Surgical treatment remains the gold standard for improving symptoms, however less invasive procedures, like per-oral endoscopic myotomy (POEM), are being frequently used. Studies of POEM's long-term outcomes is a current hotspot in the field.

Innovations and breakthroughs

This study takes an innovative approach, since it focuses on a different population than most other publications. It provides data and analysis of patients that were hospitalized for traditional treatments for achalasic in addition to patients that were admitted for complications of achalasia itself.

Applications

The data raises awareness for the common misconception in considering achalasia a benign condition. It is, in fact, an insidious disease that can lead to non-negligible mortality and morbidity when treated late or not incisively. This becomes apparent when analyzing the outcomes and characteristics in the authors' non-surgical group.

Peer-review

The authors have provided a valuable review on surgical treatment options in achalasia. The study design, discussion and conclusion are fine.

Abstract

AIM: To determine the frequency of identification of the triradiate fold during colonoscopy and evaluate its reliability as a marker of caecal intubation.

METHODS: One hundred consecutive patients undergoing colonoscopy in a tertiary hospital colorectal unit from May to September 2013 were studied. Video documentation of the caecum was recorded and shown to consultant colorectal surgeons on the unit. Each reviewer was asked through a series of questions to independently identify the triradiate fold. The main outcome was the frequency of visualisation of the triradiate fold in the caecum.

RESULTS: The triradiate fold was seen on average in 18% of cases, but inter-observer agreement was poor. There were only four patients (4%) in which all reviewers agreed on the presence of a triradiate fold. In patients who had undergone previous appendicectomy, the appendiceal orifice was less frequently seen compared with patients who had not undergone appendicectomy.

CONCLUSION: The triradiate fold is infrequently seen during colonoscopy and is therefore an unreliable landmark of caecal intubation.

Key words: Colonoscopy; Triradiate fold; Appendiceal orifice; Caecal intubation; Prospective study

Core tip: The triradiate fold is often described as a major landmark of caecal intubation in colonoscopy, but its frequency of visualisation has not been previously documented. This study shows that identification of the triradiate fold is infrequent and its presence is subjective. Inclusion in guidelines or colonoscopy software programs as a sole marker of complete colonoscopy is questionable.

Triradiate caecal fold: Is it a useful landmark for caecal intubation in colonoscopy? *World J Gastrointest Endosc* 2015; 7(13): 1103-1106 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i13/1103.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i13.1103

INTRODUCTION

Accurate assessment of the extent of colonoscopy relies on the identification and cognitive integration of several caecal landmarks to the trained endoscopist. These landmarks may include the ileocaecal valve, ileal mucosa, appendiceal orifice and caecal folds.

Of these many landmarks, the ileocaecal valve has been shown to be the single most reliable landmark, being viewed 98% of the time when caecal intubation had been confirmed with fluoroscopy[1]. The same study found the appendiceal orifice to be the second most reliable landmark. Others contend that the most accurate method to ensure caecal intubation is to enter the terminal ileum and confirm with a biopsy of ileal mucosa[2].

Various names and descriptions have been given to the folds in the caecum. The converging folds have been named the triradiate fold, Mercedes sign, crows-foot and caecal strap fold[2-5]. The term triradiate fold is used in many computerized colonoscopy databases and also by the Australian National Bowel cancer screening project as a landmark for caecal intubation with colonoscopy[6]. Last's Anatomy textbook describes the three taenia of the colon converging at the base of the appendix[7]. However in practice, a clearly defined triradiate fold is not always seen at colonoscopy. We undertook this study to document how frequently a triradiate fold is seen at the caecal pole during colonoscopy.

MATERIALS AND METHODS

This study was approved by the Melbourne Health Human Research Ethics Committee at the Royal Melbourne Hospital, Parkville, Australia. All consecutive patients undergoing colonoscopy from May to September 2013 either performed or supervised by two colorectal fellows were included in the study. Exclusion criteria were previous caecal resection, inadequate bowel preparation, technical issues with recording equipment and incomplete colonoscopies.

All colonoscopies were performed with an Olympus colonoscope. Once caecal intubation was reached, a short video was recorded on the Olympus Endobase® program. The caecal pole was thoroughly irrigated to adequately display the caecum. Caecal intubation was confirmed on collective visualisation of the ileocaecal valve, blind-ending caecal pole and appendiceal orifice when present. It was not routine in our institution to perform ileal intubation as a marker of complete colonoscopy unless clinically indicated. The videos were recorded in a standard fashion to give a panorama of the caecal pole including established landmarks of the appendiceal orifice and ileocaecal valve, and then zoomed in on the appendiceal orifice and surrounding folds.

All 100 videos were then edited using Corel Video Studio Pro® to delete unnecessary footage. The videos submitted for analysis included continuous footage so that each caecum was easily identifiable. The final length of edited videos ranged from 3 to 26 s. The shortest videos were those where all features of the caecum were very easily seen.

Each video was then shown to six consultant surgeons on the unit who then individually evaluated them. Prior to evaluation, a photograph of what we considered to be a triradiate fold was shown to all surgeons (Figure 1). A photograph showing an appendiceal orifice with no triradiate fold was also shown (Figure 2). For each video the following questions were asked:

Are you satisfied that this is a video of the caecum?

Can you identify the appendiceal orifice?

Is there a triradiate fold at the appendix orifice?

If the reviewer was not satisfied that the caecum was represented in the video, the remaining two questions were obsolete and not answered. Similarly if the appendiceal orifice could not be identified, no judgment could be made on the presence of a triradiate fold.

Statistical analysis

Statistical analysis was performed using Microsoft Excel®. Positive responses from the six reviewers were tallied for each of the 100 videos analysed and for each of the three questions asked. Individual and overall proportions of positive responses were calculated. Inter-rater reliability was measured using Conger's kappa coefficient for multiple raters. The relationship between previous appendicectomy and visualisation of the appendiceal orifice was analysed using Fisher's exact test on a 2 × 2 contingency table. Differences were considered significant when the probability was less than 0.05.

RESULTS

One hundred and thirty-four consecutive colonoscopies were either performed or supervised by two fellows. Of these 134 patients, 34 were excluded, leaving 100 colonoscopies for analysis. Of the patients excluded, 11 had a previous caecal resection, 14 had inadequate bowel preparation, 6 were incomplete colonoscopies and

Reviewer	Caecum	Appendiceal orifice		Triradiate fold	
1	99	76	77%	13	17%
2	95	79	83%	17	22%
3	96	76	79%	13	17%
4	93	89	96%	18	20%
5	100	89	89%	11	12%
6	97	73	75%	13	18%
Average	97	80	83%	14	18%

Percentages are calculated with denominator being number of "Yes" answers from previous question.

3 had technical problems with the recording equipment. Of the 100 included patients, there were 43 males and 57 females with a mean age of 61 ± 15.8 years. The indications for their colonoscopies are given in Table 1.

A Conger's Kappa coefficient for multiple raters was calculated to assess agreement between the answers to each of the three questions. This showed a strong agreement for each of the three questions, with coefficients of 0.93 for identification of the caecum, 0.79 for identification of the appendix and 0.81 for identification of the triradiate fold.

On average, the reviewers were satisfied the video depicted the caecum in 97% of cases. In those cases where the caecum was identified, the appendiceal orifice could be seen in 83%. In those cases where the appendix orifice was identified, a triradiate fold was seen in 18% (Table 2).

The Kappa coefficient for the triradiate fold was high due to strong agreement among observers about the non-visualization of the triradiate fold. In the smaller percentage of cases where the triradiate fold was identified, there was poor agreement among reviewers. There were only four patients in which all reviewers agreed on the presence of a triradiate fold. The appendiceal orifice was seen in 38 of 54 videos (70.4%) where the patient had undergone previous appendicectomy. When the patient had not undergone an appendicectomy the appendiceal orifice was seen in 444 of 527 videos (84.3%, $P = 0.014$).

DISCUSSION

Accurate identification of the caecum at colonoscopy relies heavily on visualising certain landmarks. The caecal folds have been previously suggested to be an unreliable landmark[8]. In this study we have demonstrated that a triradiate caecal fold is only seen 18% of the time when averaged across all observers. In cases where it was identified, there was poor inter-observer agreement.

Anatomically, the triradiate fold must be centred on the appendiceal orifice. Our study showed that the appendiceal orifice was less frequently seen in patients who had undergone previous appendicectomy. Elsewhere in the colon the intersection of haustral folds and a taenia coli may create a triradiate appearance that could be confused with the triradiate fold of the caecum.

This study is limited by its subjective design. The six consultants who analysed each video were aware of the study hypothesis, which may have influenced their response to the questions. However, they were not aware that all videos were of the caecum. Variables that may influence the identification of the caecal folds include the amount of insufflation. A large amount of inflation of the caecum may flatten the caecal folds,

and thus a triradiate fold that may have been seen in a less distended caecum may have "disappeared" with inflation. Although this theory was not directly tested, we did not observe that inflation had any bearing on the visualization of a triradiate caecal fold through the process of recording, reviewing and editing the videos.

Photo documentation of caecal intubation has been recommended as routine practice although some studies have shown that still photography has poor reliability[9]. Video documentation has previously been shown to be superior to still photography in identifying the caecum to independent observers[3]. Our initial proposal was to use photo rather than video documentation. On review of the first still photographs taken it was our belief that a photograph alone was not sufficient to identify the caecum with certainty. The video however, gave greater detail and provided an accurate depiction of the caecum as demonstrated by the 97% agreement among reviewers. If caecal intubation documentation is to become a marker of quality and successful completion, video documentation appears to be a more reliable method.

This is the first study to look specifically at the triradiate caecal fold as a landmark during colonoscopy. The triradiate fold is an infrequently seen feature of the caecum and as such should not be relied upon to confirm caecal intubation.

ACKNOWLEDGMENTS

We would like to thank the staff of the endoscopy suite at the Royal Melbourne Hospital for their assistance in the technical aspects of video recording.

COMMENTS

Background

Caecal landmarks are important for accurate assessment of the extent of colonoscopy. The triradiate fold in the caecum is referenced as a major landmark in some guidelines and endoscopy programs. This study was conducted to determine the frequency of identification of the triradiate fold.

Research frontiers

Colonoscopy is a common investigation modality. Quality assurance has become a global focus. One quality measure in colonoscopy is completion rate. This study explores the role of visualisation of the triradiate fold as a marker of colonoscopy completion.

Innovations and breakthroughs

This is the first study that quantifies the rate of visualisation of the triradiate fold, and shows that it is infrequently seen.

Applications

The inclusion of the triradiate fold as a marker of colonoscopy completion in guidelines and endoscopy programs is questionable.

Terminology

Triradiate fold is the appearance of three caecal folds converging upon the appendiceal orifice as seen at colonoscopy.

Peer-review

This is a very interesting, concise and "clever" paper. It is also written in excellent English, fluent and easy to read.

Abstract

Pseudoaneurysm is a known complication of pancreatitis associated with significant mortality and morbidity. Imaging plays an important role in the diagnosis and management. Computed tomography (CT) helps localize the lesion and the severity of the background pancreatitis but digital subtraction angiography with coil embolization is recommended to avoid bleeding and inadvertent surgery. However, in cases where angiographic coil embolization is not feasible due to technical reasons, thrombin injection *via* CT or ultrasound guidance remains a viable option and often described in literature. In this series, effort has been made to highlight the role of endoscopic ultrasound guided thrombin instillation especially in patients with poorly visualized pseudoaneurysm on ultrasound thereby avoiding surgery and the associated mortality and morbidity.

Key words: Pseudoaneurysm; Angiography; Endoscopic ultrasound; Thrombin; Pancreatitis

Core tip: In cases where angiographic coil embolization is not feasible due to technical reasons, thrombin injection *via* computed tomography or ultrasound guidance remains a viable option. Endoscopic ultrasound guided thrombin injection is a new development in this realm especially in those patients where the visualization of the pseudoaneurysm is difficult on transabdominal ultrasound thereby avoiding the need of surgery and the associated morbidity.

Endoscopic ultrasound guided thrombin injection of angiographically occult pancreatitis associated visceral artery pseudoaneurysms: Case series. *World J Gastrointest Endosc* 2015; 7(13): 1107-1113 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i13/1107.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i13.1107

INTRODUCTION

Pancreatitis is associated with high morbidity and mortality. Pseudoaneurysm is a commonly seen fatal complication of pancreatitis, noted in 10% of patients with chronic pancreatitis with the risk of rupture as high as 50% and the mortality after rupture as high as 15%-40%[1,2]. Hence, prompt diagnosis and treatment of pseudoaneurysm is recommended. Diagnostic modality like computed tomography (CT) angiography helps in picking up the lesion and delineating the vessel of origin however, digital subtraction angiography (DSA) and subsequent coil embolization is necessary to occlude the pseudoaneurysm to eliminate the risk of rupture and uncontrolled bleeding. Occasionally, coil embolization is not possible due to varied reasons like inaccessible vascular territory due to small caliber vessel or short neck of pseudoaneurysm. Some pseudoaneurysms may be angiographically occult and seen on ultrasound or CT only. In such cases ultrasound or CT guided percutaneous thrombin injection can be performed. Endoscopic ultrasound (EUS) guided thrombin injection is a new development in this realm especially in those patients where the visualization of the lesion is difficult on transabdominal ultrasound thereby avoiding the need of surgery and the associated morbidity. However, it requires a great deal of expertise. We review a few cases where pseudoaneurysms were occluded using endoscopic guided thrombin injection in our hospital.

CASE REPORT

We encountered three cases of pancreatitis related pseudoaneurysms, which were technically difficult to manage by endovascular route either because of previous surgical clipping of gastroduodenal artery by a laparoscopic surgeon (Figure 1) or that were angiographically occult.

In our center, in hemodynamically stable patients, the usual approach to manage the pancreatitis related pseudoaneurysm is to perform CT angiography for localization of pseudoaneurysm and also to provide road map for endovascular/surgical approach. Subsequently DSA is performed, depending upon the location of pseudoaneurysm on CT angiography; selective cannulation of the culprit vessel is done. If we are able to reach the pseudoaneurysm, coil embolisation is done by occluding the back door, neck and front door of the pseudoaneurysm, so that there is no collateral refilling of pseudoaneurysm. In our present series, we could not reach the pseudoaneurysm by endovascular route due to the reasons mentioned in Table 1. In all three cases, we attempted endoscopic ultrasound guided thrombin injection to treat these technically difficult pseudoaneurysms, after discussing with gastroenterologist experienced in EUS guided procedures. All these three pseudoaneurysms were easily visible on endoscopic ultrasound (Figure 2), which was performed prior to the thrombin injection for technical feasibility.

Technique of EUS guided thrombin injection

Gastroenterologist, who has got experience in EUS guided procedures, in collaboration with interventional radiologist performed this procedure. The procedure was performed without any anaesthesia. Initially EUS was performed using curved linear array transducer (Olympus-GF-UCT180) in conjunction with EVIS EXERA Ⅱ CLV-180 light source (Olympus Medical system Corp, Tokyo, Japan) was performed, pseudoaneurysm was localized and shortest path was chosen to target the pseudoaneurysm. We used the thrombin component of a Tisseel® kit (Baxter AG; Vienna, Austria), containing thrombin 500 IU/mL. Prior to targeting the pseudoaneurysm, thrombin component of Tisseel kit was reconstituted with 1 mL of calcium chloride and the reconstituted 1 mL thrombin was further diluted with normal saline to a total of 5 mL, so that each milliliter of reconstituted solution contains 100 IU of thrombin. Now, each milliliter of reconstituted thrombin was transferred to 1 mL insulin syringe and five such thrombin-loaded syringes were kept ready. Using 22G Echo Tip Ultra endoscopic ultrasound needle (Cook Medical Endoscopy, IN, United States), pseudoaneurysm was punctured under endoscopic ultrasound guidance, and then thrombin was injected in aliquots of 100 IU till the pseudoaneurysm become echogenic resulting in thrombosis. Under color Doppler, success of thrombosis was confirmed and the needle was removed when no color filling was seen inside the pseudoaneurysm sac. The entire procedure from start of localization of pseudoaneurysm to complete thrombosis of pseudoaneurysm lasted for about 15-20 min. After the procedure, patients were monitored closely for signs of internal bleeding. None of our patients developed any

immediate or late complications. The next day, repeat EUS was done to reconfirm the success of the procedure. In one case we performed, CT angiography to confirmed the success of procedure (Figure 3). All three patients showed complete thrombosis of pseudoaneurysm on next day EUS. Clinical follow up was done after a month and none of these patients had recurrence of symptoms of bleeding.

DISCUSSION

Pseudoaneurysm formation is a known vascular complication of acute pancreatitis due to vessel injury as a result of proteolytic and lipolytic enzymes released due to severe inflammation and pancreatic necrosis[3].

The management of psuedoaneurysm in the setting of pancreatitis is challenging in view of the associated risk of rupture and haemodynamic compromise besides the background association of increased morbidity in pancreatitis itself. A diagnostic modality like CT angiography remains a preliminary imaging modality in acute pancreatitis. This provides a vascular road-map to the vessel of origin of the aneurysm besides adding vital information on the background pancreatitis.

DSA with coil embolization is the gold standard treatment. This offers the advantage of avoiding the associated surgical risks. Besides, it ensures adequate thrombosis of the pseudoaneurysm in most cases.

In situations where the access to the pseudoaneurysm is not possible due to previous clipping/tortuous anatomy (case 1) or not visible on DSA due to slow filling and narrow neck (Figure 4), angiographic coil embolization may not be feasible. Some pseudoaneurysms are occult and detected only with other imaging modality such as CT or endoscopic ultrasound, as seen in one of our case (Figure 5). If left alone, these pseudoaneurysms can rupture or rebleed. The risk of rupture in pancreatic pseudoaneurysms has been as high as 15%-40%[1].

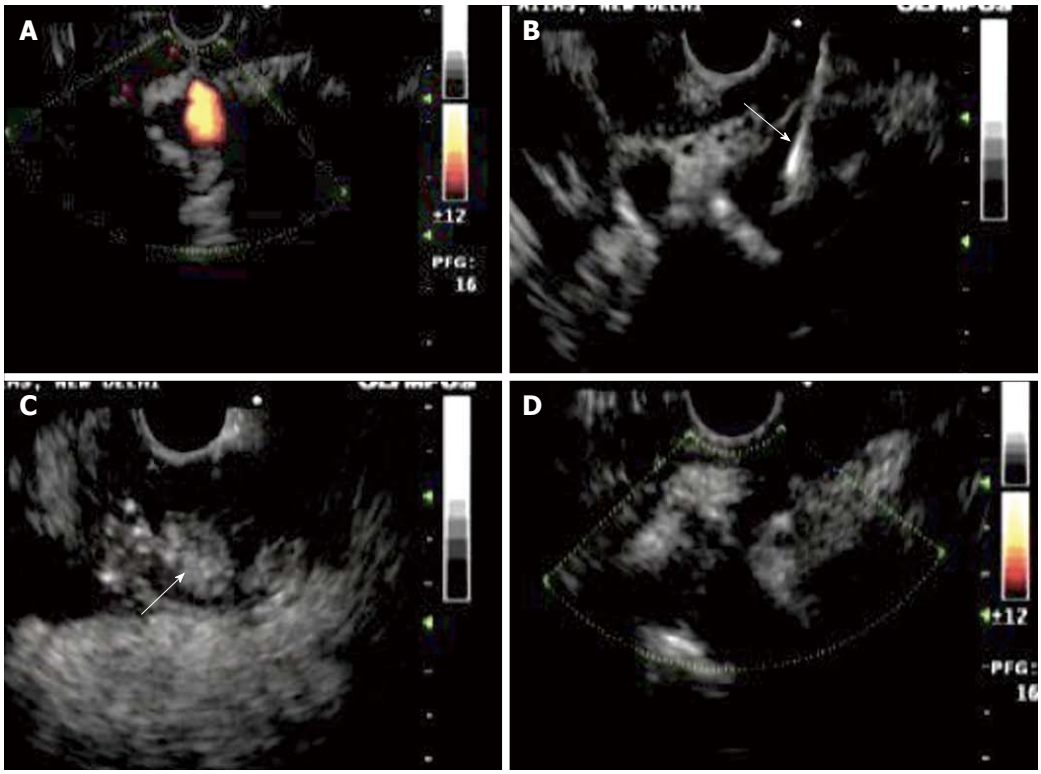

Figure 2 Endoscopic ultrasound guided thrombin instillation procedure (case 1). A-D: Endoscopic ultrasound images. There is a pseudoaneurysm sac (A) filling from pancreatic arcade (shown in Figure 1) with EUS needle (arrow, B) in the center of pseudoaneurysm sac with formation of echogenic thrombus (arrow, C) within the pseudoaneurysm sac following thrombin injection; D: No flow is seen within the pseudoaneurysm sac suggesting successful obliteration of pseudoaneurysm sac. EUS: Endoscopic ultrasound.

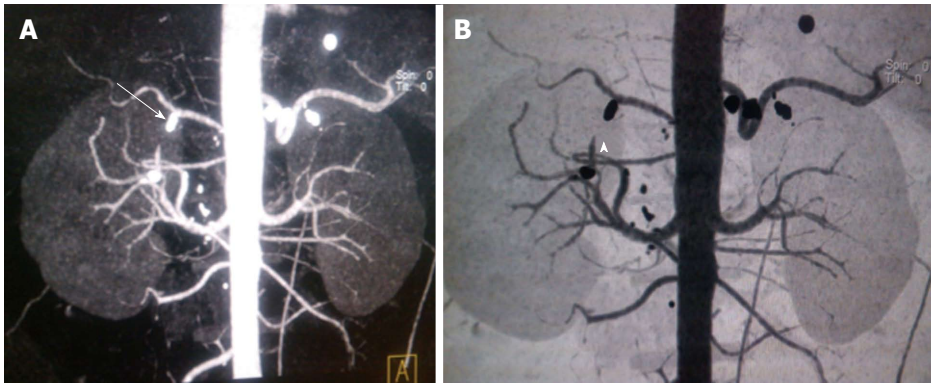

Figure 3 Follow up scan following thrombin injection procedure (case 1). A and B: Coronal MIP (3-D reformatted) CT images. There is non-visualization of the pseudoaneurysm sac (arrowhead, B) with metallic clip (arrow, A) seen at the gastroduodenal artery stump due to previous laparoscopic surgical clipping. CT: Computed tomography; MIP: Maximum intensity projection.

So, embolization is necessary to avoid rupture and rebleeding. Thrombin remains an alternative to coils. It can be instilled directly at the bleeding site and the flow cessation can be assessed. Thombin is a good alternative in those cases not feasible by endovascular route. The success of thrombin for embolization of peripheral pseudoaneurysms[4-6] as well as those of pancreas[7-10] have been described in literature.

Thrombin can be given through transcutaneous route through ultrasound or CT guidance. However, in our patients transabdominal ultrasound could not delineate the lesion clearly posing great challenge for thrombin instillation. EUS was the next step as most of these pseudoaneurysms were in the vascular territory in the vicinity of the peripancreatic region. The advantage of EUS lies in clearly delineating the extent and size of the pseudoaneurysm. Instillation of thrombin under EUS guidance requires a great deal of expertise. Thrombin could ensure immediate occlusion of pseudoaneurysms in all cases (Figure 6). Response assessment can also be done easily. The hallmark finding is the complete thrombosis of the pseudoaneurysm. No associated complications were noted. Follow up scans did not reveal rebleeding or rupture in our cases.

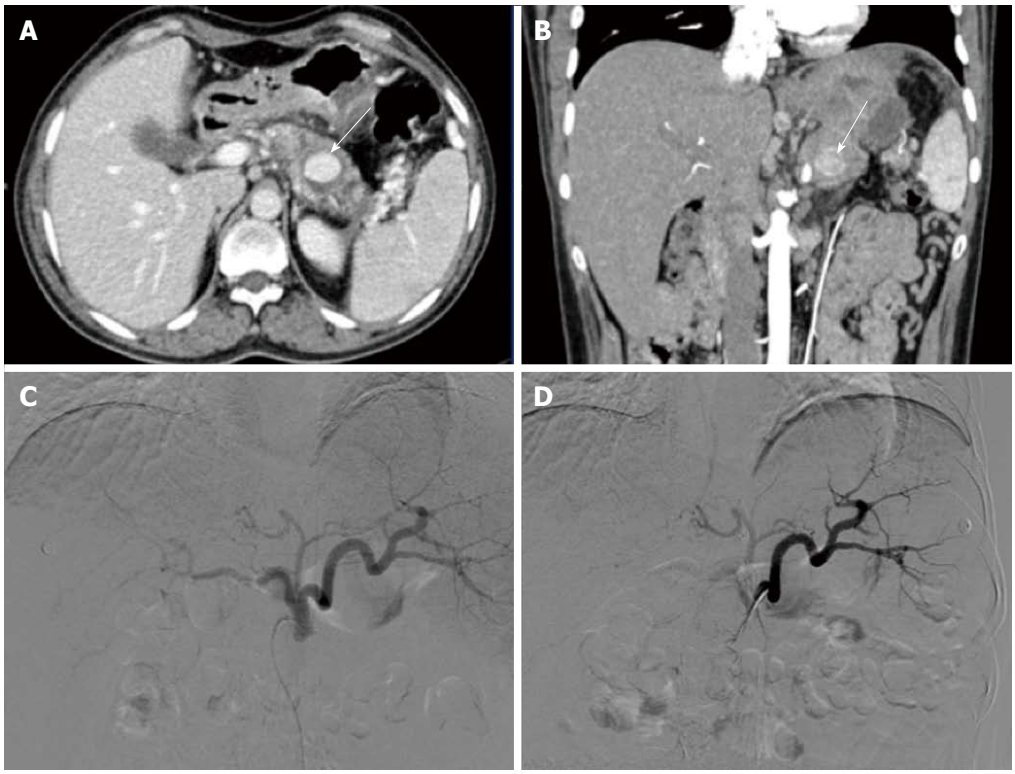

Figure 4 Pancreatitis related pseudoaneurysm (case 2). A: Axial contrast enhanced CT; B: Coronal maximum intensity projection CT images; C and D: Digital substraction Images. In the background of pancreatitis there is a pseudoaneurysm in the distal body of the pancreas (arrow, A and B) which was not revealed on either left gastric artery (C) or splenic artery (D) angiograms. CT: Computed tomography.

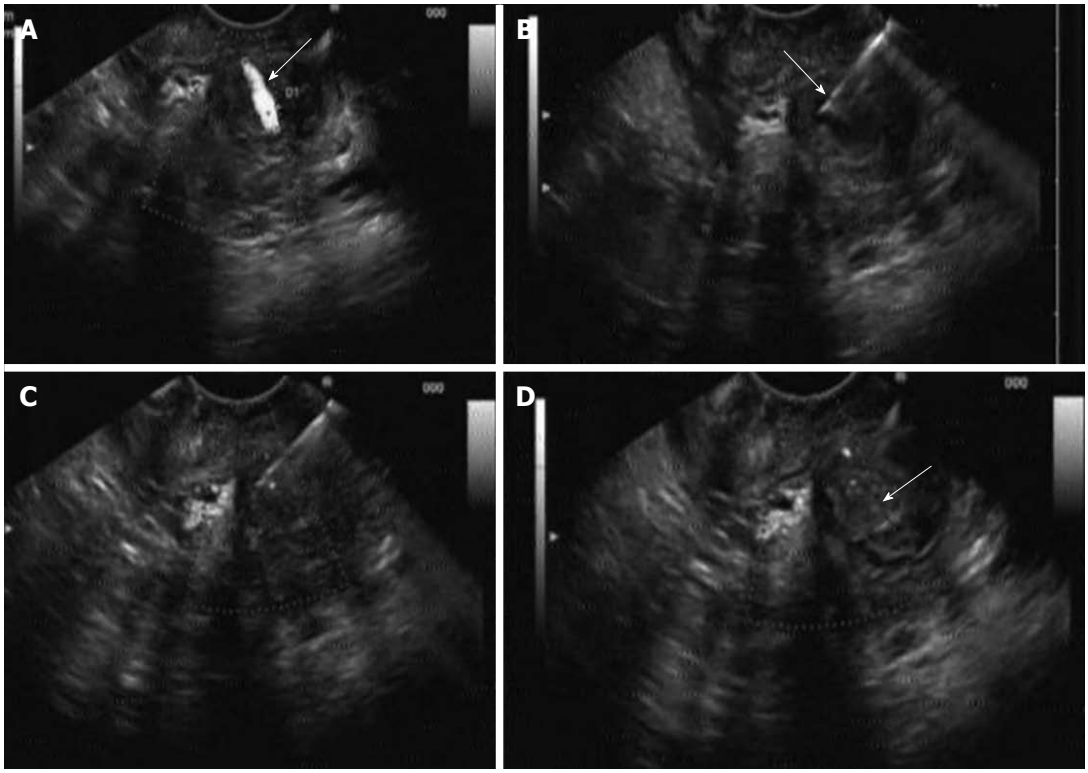

Figure 5 Endoscopic ultrasound guided thrombin instillation procedure (case 2). A-D: Endoscopic ultrasound images. There is a pseudoaneurysm sac (arrow, A) within pancreatic body region (A) with endoscopic ultrasound needle (arrow, B) inside the pseudoaneurysm sac, which was managed by instillation of thrombin (C) with subsequent thrombosis of the pseudoaneurysm sac as shown by echogenic pseudoaneurysm sac (arrow, D).

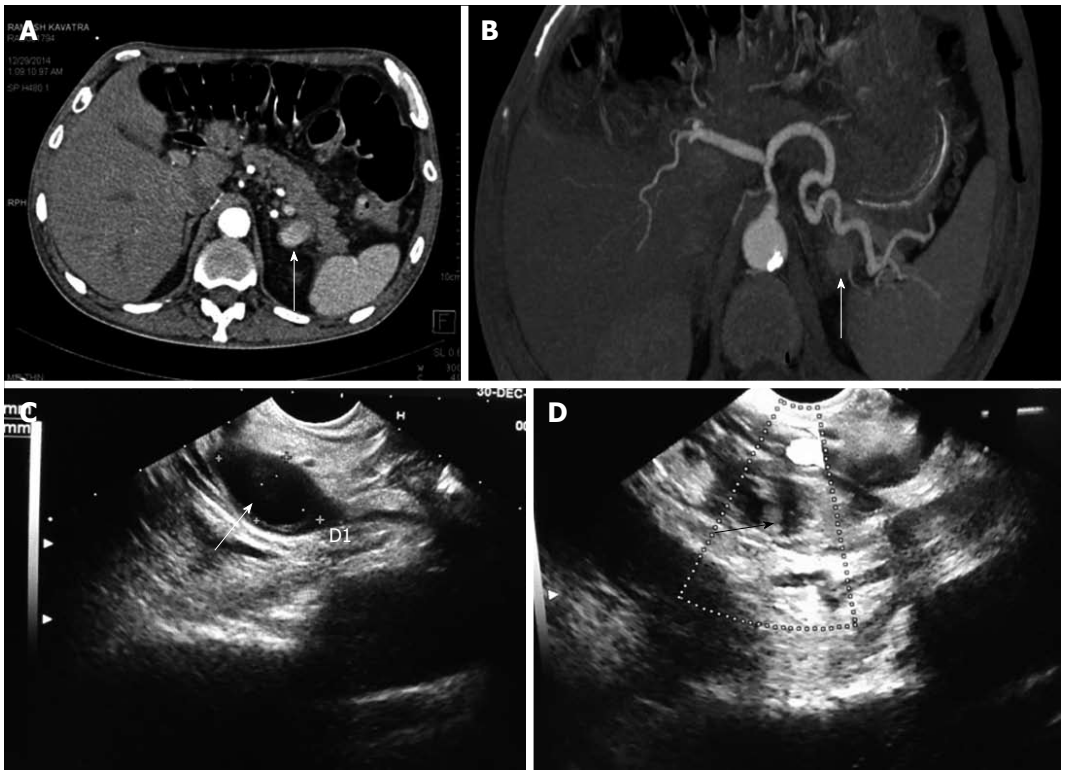

Figure 6 Chronic calcific pancreatitis with upper gastrointestinal bleed. A: Axial contrast enhanced; B: Axial MIP (3-D reformatted) CT images; C and D: Endoscopic ultrasound images. There is a pseudoaneurysm sac (arrow, A) in relation to distal body of the pancreas, in close relation to the splenic artery (arrow, B) and confirmed by endoscopic ultrasound (arrow, C) and subsequently managed by instillation of thrombin under EUS guidance with complete thrombosis of the pseudoaneurysm was achieved as revealed by the transformation of the previously anechoic lesion to an echogenic sac (arrow, D). CT: Computed tomography; MIP: Maximum intensity projection; EUS: Endoscopic ultrasound.

There are very few literature describing the use of EUS guided thrombin instillation of pancreatic pseudoaneurysm. In one of the earliest description Roach *et al*[11] described the EUS guided thrombin occlusion of a pseudoaneurysm arising from a branch of the superior mesenteric artery in a patient presenting with upper gastrointestinal bleed. This was done following failure to embolise angiographically as the feeding artery could not be catheterized.

Use of thrombin is recommended in cases of haemodynamically stable patients with small pseudoaneurysm[12]. Also it can be used in large lesions as an adjunct to coil embolization.

In haemodynamically unstable patients and those with large pseudoaneurysms or those with failure after repeated embolization, surgery remains the only option. But in the setting of pancreatitis, surgery is associated with a grim outcome. Non-invasive imaging modalities like ultrasound and CT have provided good alternatives as means of thrombin instillation. The advent of thrombin instillation through EUS guidance has opened an altogether new arena for managing the difficult pseudoaneurysms and thereby avoiding the surgical risks. Though one cannot undermine the expertise needed in EUS guidance, it offers a new hope to this special group of patients.

Some limitations of thrombin instillation, though rare, include risk of distal thrombosis though thrombin is rapidly diluted and inactivated by fast flowing blood stream[10]. Immunological reactions like sensitivities and cross-reactions are also known[10]. Recanalization after initial successful thrombosis of pseudoaneurysm is another complication. Lastly, the duration of follow-up required after treatment of pseudoaneurysms is not known.

The use of EUS guided thrombin instillation provides a new option for management of pseudoaneurysms caused by pancreatitis specially for those cohort of patients inaccessible angiographically or through transabdominal ultrasound. The avoidance of high risk surgeries, prompt occlusion of the pseudoaneurysm and ease of monitoring and follow-up are the hallmark features of this method though studies are needed to provide data as to efficacy of this method.

COMMENTS

Case characteristics

The three middle-aged male patients presented with similar symptom of upper gastrointestinal bleeding. One patient had surgical clipping of gastroduodenal artery.

Clinical diagnosis

Upon physical examination, all three patients were haemodynamically stable except for tachycardia. Pulse rates were in range of 110-120/min. No other

significant physical findings noted.

Differential diagnosis

Pancreatitis related bleeding pseudoaneurysm, variceal bleeding, peptic ulcer disease.

Laboratory diagnosis

All the patients had low hemoglobin level (range of 4-7 gm/dL). Upper gastrointestinal endoscopy showed blood clots within the stomach and duodenum. No active bleeding site could be seen on endoscopy.

Imaging diagnosis

All three patients had contrast enhanced computed tomography showed pseudoaneurysm arising from gastroduodenal artery (patient 1) and splenic artery (patients 2 and 3). There was evidence of surgical clip at the gastroduodenal (GDA) origin and chronic calcific pancreatitis in first patient.

Treatment

All the patients underwent digital substraction angiography. In first patient pseudoaneurysm could not be reached due to previous surgical clipping of GDA and tortuous collaterals feeding the pseudoaneurysm. In rest two patients, pseudoaneurysms were occult on angiography. All three patients were successfully managed by endoscopic ultrasound (EUS) guided thrombin injection in to the pseudoaneurysm.

Related reports

Thrombin injection into the iatrogenic related peripheral pseudoaneurysm is well known. Very few cases describing the use of EUS guided thrombin instillation of pancreatic pseudoaneurysm have been reported in literature. The advent of thrombin instillation through EUS guidance has opened an altogether new arena for managing the difficult pseudoaneurysms and thereby avoiding the surgical risks.

Term explanation

Thrombin (bovine/human), is available as powder form and is reconstituted with calcium chloride solution, injected into the pseudo aneurysm after direct puncture percutaneously under image guidance. Thrombin converts fibrinogen into fibrin resulting in formation of clots.

Experiences and lessons

This case series represents a new option of EUS guided thrombin instillation for management of pseudoaneurysms caused by pancreatitis especially for that cohort of patients where pseudoaneurysm is inaccessible angiographically.

Peer-review

This is an interesting paper highlighting a method of occluding pseudoaneurysms, which are otherwise difficult to reach.

Abstract

Endoscopic submucosal dissection (ESD) is very useful in *en bloc* resection of large superficial colorectal tumors but is a technically difficult procedure because the colonic wall is thin and endoscopic maneuverability is poor because of colonic flexure and extensibility. A high risk of perforation has been reported in colorectal ESD. To prevent complications such as perforation and unexpected bleeding, it is crucial to ensure good visualization of the submucosal layer by creating a mucosal flap, which is an exfoliated mucosa for inserting the tip of the endoscope under it. The creation of a mucosal flap is often technically difficult; however, various types of equipment, appropriate strategy, and novel procedures including our clip-flap method, appear to facilitate mucosal flap creation, improving the safety and success rate of ESD. Favorable treatment outcomes with colorectal ESD have already been reported in many advanced institutions, and appropriate understanding of techniques and development of training systems are required for world-wide standardization of colorectal ESD. Here, we describe recent technical advances for safe and successful colorectal ESD.

Key words: Endoscopic submucosal dissection; Colorectal tumors; Mucosal flap; Clip-flap method

Core tip: Endoscopic submucosal dissection (ESD) is useful for *en bloc* resection of large colorectal tumors but is a technically difficult procedure. Good visualization of the submucosal layer is crucial for safely and successfully performing colorectal ESD because poor visualization of the operative field may result in perforation or unexpected bleeding. Creating a mucosal flap solves these problems; however, it is the

process that requires the most skill in this procedure. To facilitate the mucosal flap creation, we developed the clip-flap method, which is simple and very effective for colorectal ESD. We described recent advances in colorectal ESD techniques and devices.

Yamamoto K, Michida T, Nishida T, Hayashi S, Naito M, Ito T. Colorectal endoscopic submucosal dissection: Recent technical advances for safe and successful procedures. *World J Gastrointest Endosc* 2015; 7(14): 1114-1128 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i14/1114.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i14.1114

INTRODUCTION

Endoscopic submucosal dissection (ESD) was recently developed for *en bloc* resection of early stage gastrointestinal neoplasms with negligible risk of lymph node metastasis[1-5]. Higher rates of *en bloc* resection of large colorectal tumors have been reported with colorectal ESD than with endoscopic mucosal resection (EMR); however, colorectal ESD confers an increased risk of perforation[6-10]. A high degree of technical skill and the development of specific strategies for colorectal ESD are required because of the anatomical characteristics of the colon, namely being a long and winding tube with a thinner wall than other regions of the gastrointestinal tract[4,6]. To prevent complications such as perforation and uncontrollable bleeding, it is crucial to maintain good visualization of the submucosal layer to be dissected[4,11,12]. Therefore, the mucosal flap creation is the key procedure[12], although this process is technically challenging. To facilitate the mucosal flap creation, we recently developed the clip-flap method in which an endoclip is initially substituted for the mucosal flap[13-15]. Several types of endoknives were developed and properly utilizing them according to the requirements is also important. In this review, recent advances in techniques using various devices in colorectal ESD will be described.

INDICATION FOR COLORECTAL ESD

Before performing colorectal ESD, the determination of the indications for ESD by preoperative examination is highly important. EMR using a snare remains the main treatment for superficial colorectal tumors. However, EMR is not adequate for *en bloc* resection of flat lesions larger than 20 mm in diameter because incomplete removal and local recurrence are occasionally observed[16,17]. The indications for ESD are therefore considered for a tumor when using EMR for *en bloc* resection is difficult. The guidelines on the indications for colorectal ESD were published in Japanese and Spanish academic societies of gastrointestinal endoscopy[18,19]. Basically, the indications for ESD are colorectal tumors for which endoscopic *en bloc* resection is required but *en bloc* resection with EMR is difficult to apply. The primary objective lesions are large colorectal tumors, such as the laterally spreading tumor granular type (LST-G) with a large nodule or the laterally spreading tumor non-granular type (LST-NG)[20,21], which are suspected to be intramucosal or with slightly invaded submucosal cancers > 20 mm in diameter in the preoperative examinations. Large protruding lesions are also indications for colorectal ESD[18,19]. However, an abundance of caution is required to treat large protruding lesions because even experienced endoscopists sometimes cannot avoid discontinuation of submucosal dissection due to severe submucosal fibrosis and retracted muscle[22]. Even if the size of the tumor is less than 20 mm, mucosal lesions with submucosal fibrosis, which cannot be resected with EMR, can be the indications for ESD.

In contrast, the technical simplicity of EMR can permit its utilization for colorectal tumors > 20 mm in diameter when the preoperative diagnosis is adenoma or mucosal cancer in adenoma[18-20], although piecemeal mucosal resection includes the problem of a high local recurrence rate[20]. Magnifying chromoendoscopy for pit pattern observation[23] and magnifying image-enhanced endoscopy (narrow band imaging[24,25] or blue laser imaging[26], *etc.*) are useful for preoperative differential diagnosis of adenoma, intramucosal cancer, and submucosal invasive cancers. It is better to avoid preoperative biopsy if the endoscopic treatment is planned to be performed because biopsy often causes submucosal fibrosis, complicating further endoscopic treatment[18]. In addition, the endoscope maneuverability should be analyzed before performing ESD because poor endoscope maneuverability may cause incomplete resection or complications[27,28].

METHOD FOR SAFE AND SUCCESSFUL ESD

Preparation and oral intake

Bowel preparation is required for adequate visualization of the operative field and as prophylaxis against bacterial peritonitis in case of perforation. Patients are restricted to a low-fiber diet on the day before colorectal ESD and are instructed to orally consume 10 mL picosulfate after the last meal on the day before the procedure. Two-four liters of an electrolyte solution is orally administrated before the procedure[11,29].

In contrast, no food or drink is allowed on the day of the procedure or the following day. Provided that there are no signs or symptoms of complications, patients will begin drinking water on day 1 and have light meals (rice porridge) on day 2. Meals are upgraded to normal food with alcohol excluded from day 2 until day 3-5 or the date of hospital discharge[30-32].

Sedation and patient's position

Light or conscious sedation is appropriate for colorectal ESD because deep sedation makes alteration of the patient's position difficult and often leads to severe

respiratory fluctuations[11]. At our institution, midazolam (2 mg) and pethidine (17.5-35 mg) is initially intravenously administered. Light sedation is maintained with additional administration of midazolam or pethidine during the procedure. In cases where a long procedure duration is expected, the use of dexmedetomidine may be useful in maintaining good sedation levels[33,34]. Use of a carbon dioxide (CO_2) insufflation system (UCR; Olympus Co., Tokyo, Japan) is extremely helpful for reducing the patient's discomfort and risk of peritonitis in case of perforation[35-37]. Excessive air present during the procedure decreases the endoscope maneuverability, but carbon dioxide can be quickly absorbed[35-37]. Yoshida *et al*[38] reported that CO_2 insufflation during colorectal ESD was safe even for patients with obstructive ventilator disturbance.

Scopolamine butylbromide (10 mg) is administrated to all patients except those contraindicated because of reduced bowel movement immediately prior to the procedure. Additional doses may be administered during the procedure. Administration of intravenous glucagon[39] or intraluminal peppermint oil[40] may be useful for patients who are contraindicated for scopolamine.

The patient's position is critical in performing successful colorectal ESD. In principle, the lesion should be moved upward as far as possible against the force of gravity prior to ESD and followed by a postural change to take advantage of the counter-traction of gravity[4,11,41,42]. The direction of gravity can be understood by the pooling of water or indigo carmine dye[11]. However, the intestinal lumen may become narrower or broader on alteration of the patient's position due to the movement of air. ESD becomes particularly challenging in narrowed lumen. Therefore, it is recommended that ESD should be commenced after each position (supine, prone, left lateral decubitus position, and right lateral decubitus position) has been adequately assessed as far as possible. In case of large lesions, changing the patient's position during the procedure is often required to ensure optimal operative field[4].

Selection of endoscope

ESD is generally performed using a single-channel colonoscope. At our institution, PCF-H290I or CF-H290I (Olympus), which have a water-jet function, are currently predominantly used because the water-jet function is convenient for hemostasis during ESD. Moreover, a gastroendoscope (GIF-HQ290, GIF-Q260J; Olympus) may be used for lesions in the rectum or distal sigmoid colon because the shorter endoscope can be easily operated in such locations[11,43]. In addition, a gastroendoscope can be used to approach lesions from the oral side in retroflexion more easily than with a conventional colonoscope.

Endoscope maneuverability is crucial to precisely perform ESD. ESD is challenging in cases of poor endoscope maneuverability, although experts can overcome these difficulties in most cases. Straightening of the endoscope is important for maintaining good endoscope maneuverability. Single-balloon[44] (OBCU; Olympus) or double-balloon endoscopy systems[45,46] (PB-20; Fujifilm Co., Tokyo, Japan) may be useful in cases of extremely poor maneuverability.

Distal attachments (Hoods)

The use of distal attachments is essential in safely performing colorectal ESD. The cutting area can be broadened and visualized with the use of distal attachments during the procedure. The shapes of distal attachments for colorectal ESD are mainly divided into straight types (D-201; Olympus, Figure 1A) and tapered types. Straight distal attachments allow larger working spaces for the operation of endoknives or forceps; however, the submucosal layer must be cut more deeply to insert the attachment under the exfoliated mucosa compared with tapered distal attachments. At our institution, a distal attachment (F-050/020, M-02/03/01; Top Corp., Tokyo, Japan, Figure 1B and C), which is slightly tapered, is attached to the tip of the endoscope. Small-caliber tip transparent hoods (ST-hood; Fujifilm) (Figure 1D) are useful for accessing narrow cutting areas[4,47]. Furthermore, this distal attachment is used for the tunnel[41,48] or pocket-creation method[49].

Endoknives and high-frequency generators

Various types of endoknives are used for colorectal ESD. Short-needle knives are the most widely used type of endoknife for colorectal ESD. The DualKnife[50] (Olympus, Figure 2A) is a short-needle endoknife that has a small disk at the tip of a short needle. The FlushKnife BT[51] /FlushKnife (Fujifilm, Figure 2B), Jet B-knife (Zeon Medical, Tokyo, Japan, Figure 2C)[52], and Splash needle (Pentax Medical, Tokyo, Japan) are all short-needle knives with a water-jet function that enable submucosal injection without requiring the injection needle to be changed. The HookKnife[53] (Olympus, Figure 2D) has a hook on the tip that enables hooking and cutting of submucosal tissue. The HookKnife is particularly useful when the tangential approach is difficult or submucosal fibrosis is present because the submucosal tissue can be easily hooked and cut with this endoknife. The SBknife Jr[54-56] (Sumitomo Bakelite, Tokyo, Japan, Figure 2E) and Clutch Cutter[57] (Fujifilm) (Figure 2F) are scissor-type endoknives that have a rotation function. Scissor-type endoknives can be easily operated in the manner of forceps even by inexperienced operators. In addition, it can be efficiently operated even in cases when the tangential approach is difficult or endoscope maneuverability is extremely poor, because the submucosal tissue can be dissected simply by grasping, lifting, and applying an electrical current. The ITknife-nano (Olympus, Figure 2G) is an endoknife with an insulator on the tip of the blade that was developed for colorectal or esophageal ESD. Its use may allow increased dissection speeds[21] because it has a long blade between the insulated-tip and the sheath. The Mucosectom[58] (PENTAX, Figure 2H and I) and Swanblade (PENTAX, Figure 2J) have blades on

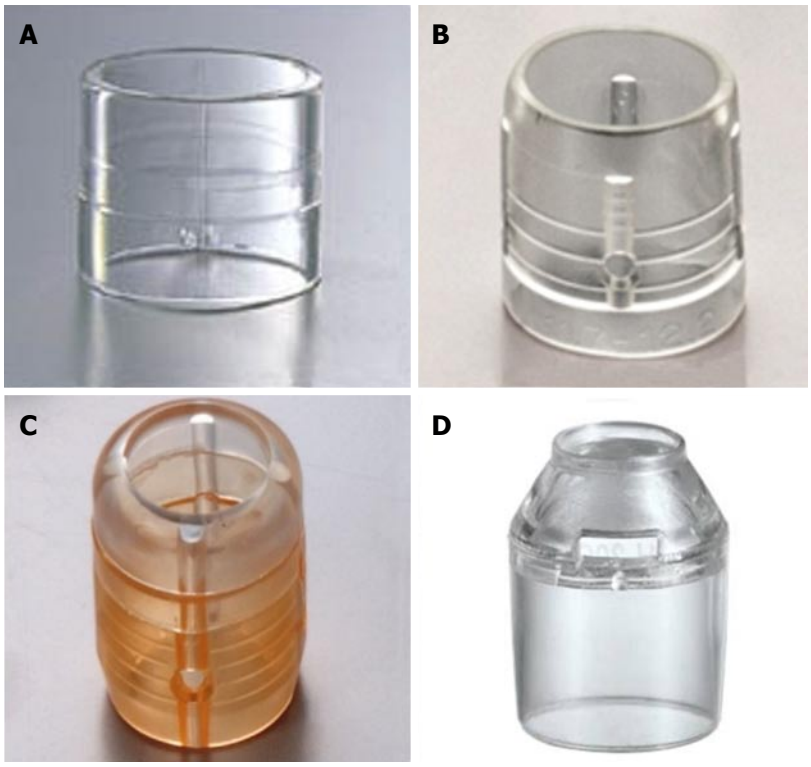

Figure 1 Distal attachments for colorectal endoscopic submucosal dissection. A: D-201; B: F-050; C: M-02; D: Short ST-hood.

an insulated rod that has a rotation function. These endoknives were developed for the safe and rapid dissection of the submucosal layer. At our institution, the FlushKnife BT (DK2618JB15/20) is predominantly used. According to the specific situation, other endoknives may be used in conjunction.

A high-frequency generator with an automated control system is required for ESD. At our institution, the VIO 300D (Erbe Elektromedizin GmbH, Tubingen, Germany) is predominantly used. ICC-200 (Erbe) or ESG-100 (Olympus) are also used for colorectal ESD. The settings on each instrument when using short-needle knives (FlushKnife BT, DualKnife) and hemostatic forceps (FD-410LR, FD-411QR; Olympus) are shown in Table 1[11,50,59].

Strategies for improving safety and efficacy of ESD

ESD is usually initiated either from the anal side of the lesion in a forward direction or from the oral side in retroflexion[11,43]. There are benefits and limitations to both methods. Dissection from the anal side can be performed in almost all cases; however, endoscope

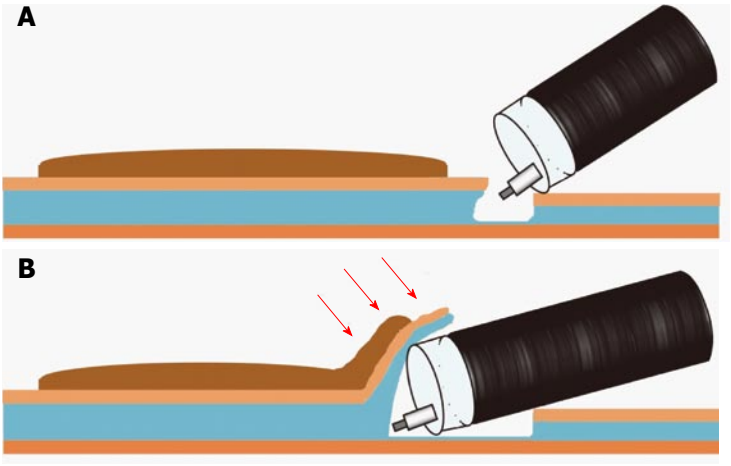

Figure 3 Schema of the mucosal flap. A: After injecting a solution in the submucosal layer, mucosal incision and deeper cut are made; B: Continuing to dissect the submucosal layer allows the creation of the "mucosal flap" (Red arrows point to the "mucosal flap"). Inserting the distal attachment under the mucosal flap provides good counter-traction to the submucosal layers and allows good visualization of the operative field. Therefore, completion of the mucosal flap facilitates subsequent submucosal dissection.

maneuverability is somewhat unstable, and the treatment of the mucosa just beyond a haustrum or a colonic flexure is occasionally challenging. Dissection from the oral side in retroflexion requires adequate space with a broad lumen; however, endoscope maneuverability is comparatively stable using this method[11,60]. The method selection by endoscopists largely depends on the institutions' established procedures and lesion location. At our institution, dissection from the anal side is predominantly performed and dissection from the oral side in retroflexion is occasionally performed in cases where approaching from anal side is difficult.

In either case, it is important to start dissecting the submucosa immediately proximal to the tip of the endoscope to avoid complications, such as perforation and unexpected bleeding, caused by blind procedures. Therefore, insertion of a distal attachment under the exfoliated mucosa of the lesion side is a crucial step in safely and effectively dissecting the submucosal layer. The lesional exfoliated mucosa is called the mucosal flap (Figure 3B)[12,61]. Formation of the mucosal flap facilitates safe and sequential dissection.

Submucosal injection, mucosal incision, and deeper cut

While approaching from the anal side, a solution is injected in the submucosal layer of the anal side of the lesion and then the lesion tends to be more tangentially approached and more easily dissected (Figure 4B). Saline, 0.4% sodium hyaluronate solution (MucoUp; Johnson and Johnson, Tokyo, Japan) (Sigmavisc; Hyaltech Ltd., Livingston, United Kingdom), or 10% glycerin with a small amount of indigo carmine dye and 0.001% epinephrine are usually used as the injected solution[11,41,47,62]. Sodium hyaluronate solution is the most long-acting agent that can be locally injected for colorectal ESD[63]. Suvenyl (2% hyaluronate, Chugai, Tokyo, Japan) or Artz (1% hyaluronate, Seikagaku Corp. Tokyo, Japan) may be used after coordinating their concentrations[4,47,63].

Following submucosal injection, the mucosa adjacent to the lesion is incised with an adequate margin before incision of the submucosal layer. A complete or partial circumferential mucosal incision is initially made according to the institutions' established procedures or characteristics of the lesion. A partial circumferential mucosal incision has recently been introduced at an increasing number of institutions because initial complete circumferential mucosal incision can make insertion of the distal attachment under the exfoliated mucosa difficult because of the loss of mucosal tension caused by extensive mucosal incision[4,11,30]. At our institution, a partial circumferential mucosal incision

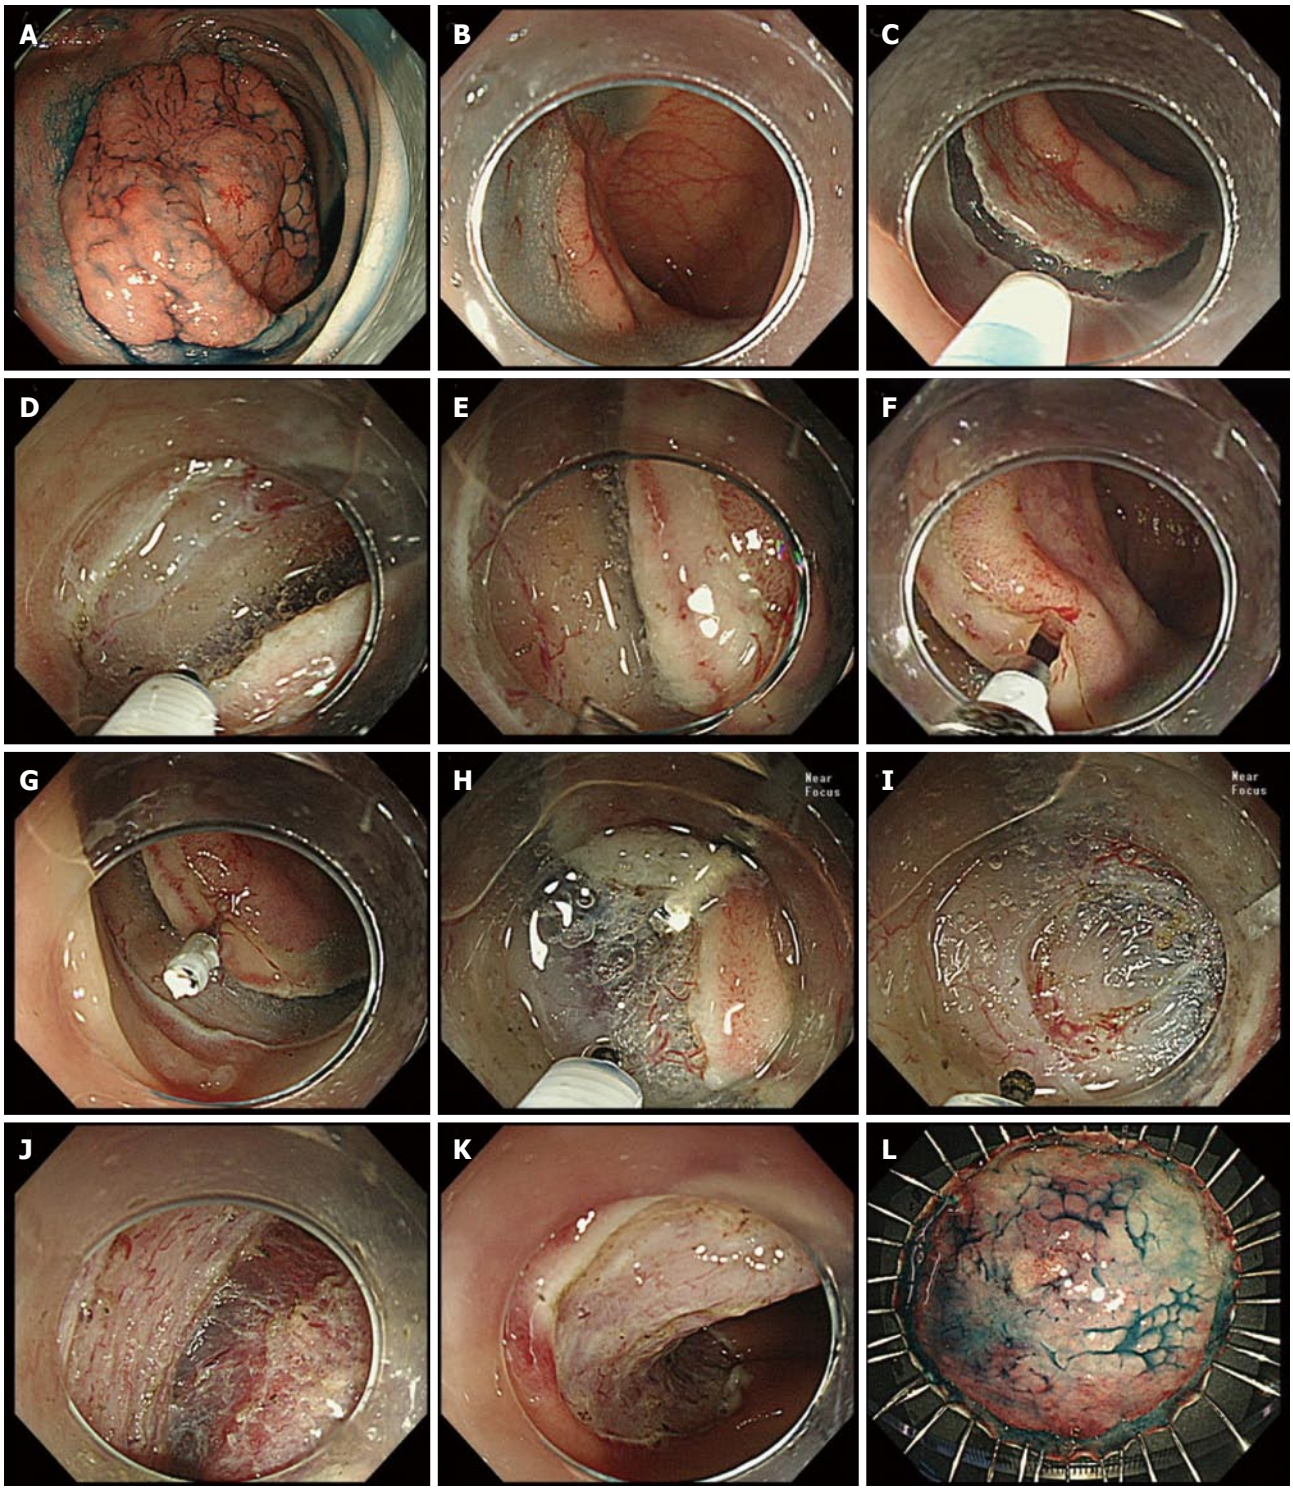

Figure 4 Endoscopic submucosal dissection of a laterally spreading tumor, non-granular type lesion using the clip-flap method. A: A 45 mm, LST-NG was located at the sigmoid colon. The patient was first positioned so that the bowel wall containing the lesion was uppermost, and this maximizes the assistance of gravity during ESD; B: Submucosal injection was performed from the anal side; C: Mucosal incision from the anal side was made using FlushKnife BT; D: Deeper cut of the anal side was made; E: The submucosal layer could not be adequately visualized because it was hidden by the exfoliated mucosa at this region. Insertion of the distal attachment under the exfoliated mucosa was difficult because of the tight space between the exfoliated mucosa and muscle, despite the condition after submucosal injection; F: After the width of endoclip's prongs was slightly narrowed, the edge of the exfoliated mucosa was clipped with an endoclip while lifting the exfoliated mucosa with the prongs of the endoclip, so that the deep layer of the submucosa was not grasped by the endoclip; G: The endoclip was attached to the exfoliated mucosa. The tail end of the endoclip attached to the mucosa slightly fell toward the intestinal lumen due to gravity, allowing the attachment to be easily inserted under the endoclip; H: The distal attachment was inserted under the endoclip, and then mucosa and the submucosal layer were elevated by the endoclip. The submucosal layer could be clearly visualized and dissected with the endoknife under the direct vision; I: The distal attachment could be inserted under the exfoliated mucosa by cutting the vasculature; J: Following mucosal flap formation, the submucosal layer could be dissected more easily; K: Dissection was completed following complete circumferential incision without any complications. Artificial ulcer after ESD; L: Resected specimen. Histopathological examination confirmed intramucosal cancer, and margin (-). LST-NG: Laterally spreading tumor, non-granular type; ESD: Endoscopic submucosal dissection.

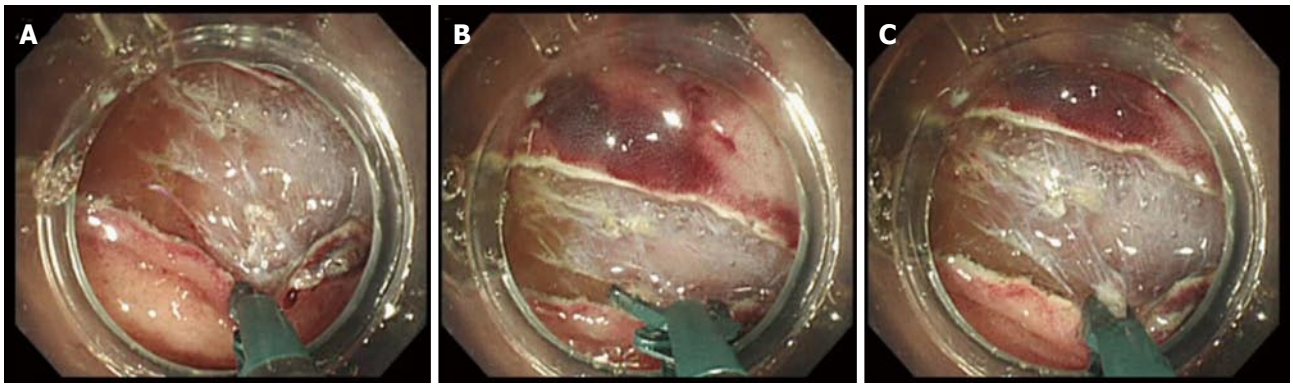

Figure 5 Three steps of safe submucosal dissection using a scissor-type endoknife (SBknifeJr) in case of a vertical approach. A: The endoscope was rotated and the exfoliated mucosa was turned down with a tip of an endoknife to clearly visualize the submucosal layer to be dissected along with the scissor tips; B: The edges of the scissor-type endoknife was opened; C: The submucosal layer under the exfoliated mucosa could be safely dissected by grasping and pulling up with the endoknife before application of an electrical current. Repeating these procedures led to the creation of the mucosal flap and successful endoscopic submucosal dissection.

from the anal side is usually made (Figure 4C) because it allows widening of the gap between lesional and non-lesional mucosa and greater ease of insertion of the distal attachment under the exfoliated mucosa. In partially circumferential mucosal incision, a complete circumferential mucosal incision is made after the creation of the mucosal flap.

At our institution, mucosal incision with the FlushKnife BT is performed with the endocut I mode. Deeper cut of the submucosal layer is performed with the forced coagulation or swift coagulation mode.

Creation of the mucosal flap

Insertion of the distal attachment under the exfoliated mucosa is critical in allowing dissection of the submucosal layer while maintaining a good operative field. However, adequate visualization of the submucosal area at the beginning of the dissection is difficult because it is commonly hidden under the exfoliated mucosa. Poor visualization of the submucosal layer to be dissected may cause perforation and unexpected bleeding. To enhance visualization and ensure safe dissection of the submucosal layer, a mucosal flap must be created. Insertion of the distal attachment under the mucosal flap elevates the mucosal flap and provides counter-traction to the submucosal layer that allows easier dissection (Figure 4J). Therefore, creation of the mucosal flap is the most important step of the ESD procedure[12]; however, this process requires the most technical skill. The presence of submucosal fibrosis or vasculature often hinders smooth dissection and vertical approaches make creation of the mucosal flap more challenging. Changing the type of endoknife (Figure 5A-C) or using a tapered-type distal attachment may have utility in cases where the creation of the mucosal flap proves difficult.

The Clip-flap method

To facilitate the mucosal flap creation, we developed the clip-flap method, in which an endoclip is substituted for the mucosal flap until the flap is completed[13-15]. The basic procedure is as follows.

After submucosal injection, the mucosa adjacent to the lesion on the anal side is incised with an adequate margin and then the submucosal layer is cut deeply (Figure 4A-E). The edge of the exfoliated mucosa is clipped with an endoclip (EZ Clip, HX-610-135; Olympus; Figure 4F and G) while lifting the exfoliated mucosa with the prongs of the endoclip, so that the deep layer of the submucosa is not grasped by the endoclip. The distal attachment is inserted under the endoclip, and then the endoclip is lifted with the distal attachment. Consequently, the exfoliated mucosa is pulled up by the endoclip, allowing clear visualization and effective dissection of the submucosal layer by counter-traction using the endoclip (Figure 4H and I). In addition, the distal attachment can be easily inserted under the endoclip when the tail end of the endoclip is directed toward the intestinal lumen (Figure 4G) by using gravity after a postural change or temporarily lifting the endoclip with the endoknife.

Other than a single endoclip (Figure 4G and H), a cross pattern of endoclips created by attaching one endoclip to another endoclip is used to provide good counter-traction according to the situations[14]. We use the EZ clip in the clip-flap method because it can be easily rotated, and it has a joint between the metal prongs and sheath, most of which is made of plastic. The joint may be utilized as a step difference with which to hook it to the distal attachment. A long endoclip may be inappropriate because it can be a hindrance in a narrow lumen.

In our experience, the clip-flap method was effective in most cases, even in the presence of submucosal fibrosis or with a vertical approach, but can be difficult to use in some situations. When lesions are located within a very narrow lumen, such as in the anal tube, just beyond the colonic flexure, or when endoscope maneuverability is extremely poor, attaching the endoclip to the exfoliated mucosa and inserting the

distal attachment under the endoclip may be difficult[14].

The clip-flap method is very simple and requires no special equipment other than common rotatable endoclips. Furthermore, various types of distal attachments, including a tapered type, can be used in the clip-flap method.

The endoscopists may apply the clip-flap method or change the endoknife or distal attachment according to the situation, when inserting the distal attachment under the exfoliated mucosa is difficult.

Submucosal dissection

Following mucosal flap formation, adequate visualization of the submucosal layer to be dissected is ensured by lifting the mucosal flap with the distal attachment. Many vessels are present in the submucosal layer. Bleeding worsens the translucency of submucosal layer and makes dissection of the submucosal layer much more challenging after bleeding. Thick vessels are pre-coagulated with hemostatic forceps using the soft coagulation mode and cut after precoagulation with an endoknife[12]. Fat tissue is occasionally observed in the submucosal layer, and the translucent layer to be dissected is found below submucosal fat tissue. The deep submucosal layer should be dissected to determine the presence or absence of massive malignant submucosal invasion[12].

At our institution, submucosal dissection is predominantly performed with the FlushKnife BT using forced or swift coagulation mode. Forced coagulation mode is superior to swift coagulation mode for hemostasis but inferior for incision. Therefore, we initially use forced coagulation mode and change to swift coagulation mode in cases where the submucosal tissue cannot be easily incised with forced coagulation mode because of submergence, fat rich tissue, fibrosis, or burnt tissue. Endocut I mode can also be used for incision of burnt tissue or tissue with severe fibrosis.

Submucosal fibrosis is an important factor that has a large impact on the technical difficulty of dissection[10,27,64-66]. Submucosal fibrosis complicates dissection by losing the translucency of the submucosal layer or narrowing the space between the mucosa and muscle. Furthermore, the presence of submucosal fibrosis is often preoperatively unexpected. Endoscopists must dissect the submucosal layer more carefully in cases of submucosal fibrosis because submucosal fibrosis increases perforation risk. Additional submucosal injection of solution widens the gap between the exfoliated mucosa and muscle layer and enhances the safety of submucosal dissection. A short needle knife with a water-jet function, such as FlushKnife BT, is very useful in these situations because it enables repeated submucosal injection without changing the injection needle[12,51,67,68]. A HookKnife or scissor-type endoknife, which enable the endoscopists to resect the submucosal tissue while pulling up on it, may also be useful in those situations[55].

SUCCESS RATES AND COMPLICATIONS

Single- and multi-center studies of colorectal ESD have reported *en bloc* resection rates of 61%-99.3%, perforation rates of 0%-20.4%, and bleeding rates ranging from 0% to 11.9% (Table 2)[8-10,12,14,29,52,54,56,62,64,65,69-88]. Numerous studies regarding colorectal ESD were reported in Japan where colorectal ESD was initially developed; furthermore, the reports from some other Asian countries and Western countries are continuously increasing. Direct comparison of treatment outcomes is difficult because the technical difficulty of ESD is greatly affected by tumor location, tumor size, the presence of submucosal fibrosis, and endoscope maneuverability. In addition, in some studies, treatment outcomes do not include data of earlier stage of colorectal ESD. However, recent single- and multi-center studies have reported improved treatment outcomes compared with previous studies[6,61,72,86,89]. Nakajima *et al*[86] recently reported a comparatively high *en bloc* resection rate (94.5%) and low perforation rate (2.0%) of colorectal ESD in a Japanese large multi-center prospective study. The development of various devices and improvement of the endoscopist's skill appear to have contributed to recent improvements in treatment outcomes[21,52,55,90,91]. Probst *et al*[62] reported low perforation rate (1.9%) and permissible *en bloc* resection rate (81.6%) of colorectal ESD in a European single-center study. Furthermore, higher *en bloc* resection rate (96.2%) in their late stage was reported compared with that in their early (60.0%) and middle stage (88.0%). These data reveal that colorectal ESD may be widely spread even in European countries where ESD experience is low.

In contrast, some studies have compared the local recurrence rates after EMR and ESD for large colorectal tumors (Table 3)[92-96]. Those studies demonstrated that local recurrence rates after ESD were significantly lower than after EMR because of the high *en bloc* resection rates with ESD despite the larger tumor sizes compared with EMR[92,93,95,96]. Oka *et al*[96] reported that piecemeal resection was the most important risk factor for local recurrence regardless of EMR or ESD in a large multicenter prospective study. Most local recurrences of mucosal lesions may be addressed with additional endoscopic treatment; however, close follow-up colonoscopy is required to detect local recurrence after piecemeal resection[92-96], even with ESD.

Perforation is a major complication of colorectal ESD; however, most cases of perforation can be conservatively treated by closure with endoclips (Figure 6A and B). However, endoscopists should give particular attention to the risks of perforation because open or laparoscopic surgery may be required for bacterial peritonitis, particularly with delayed perforations[77,85,97]. Larger lesional size, submucosal fibrosis, colonic location, and less experienced ESD operators have all been reported as risk factors for perforation during colorectal ESD[10,27,28,77,87].

Post-operative bleeding is less common with colorectal ESD than with gastric ESD and can conservatively managed with hemostatic forceps or endoscopic clipping in the majority of cases[77,85].

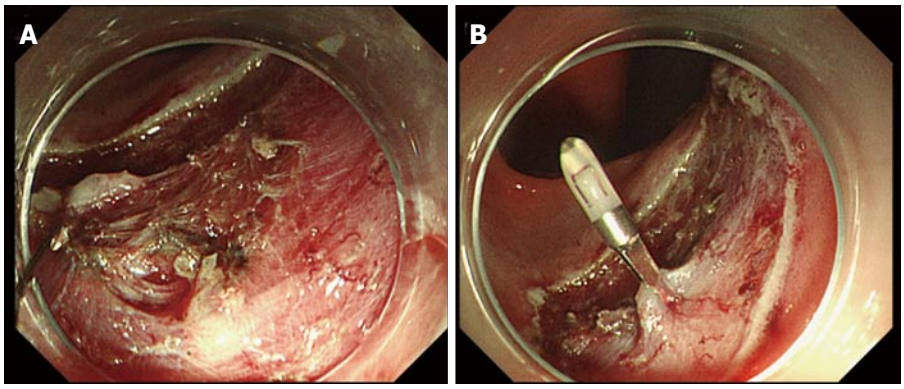

Figure 6 Management of perforation by clipping. A: Perforation occurring during colorectal endoscopic submucosal dissection; B: Perforation closure using an endoclip.

Abdominal pain or fever due to electrocoagulation syndrome after ESD is occasionally observed, particularly in the proximal colon, and when conservatively managed[98]. The occurrence of adverse events may cause an extension in hospital stay[31,32,98].

CURRENT STATUS AND FUTURE PERSPECTIVES

The safety and success rates of colorectal ESD have recently improved to favorable levels predominantly in advanced institutions in Japan, some Asian, and a few Western countries. However, colorectal ESD is still a technically difficult procedure for majority of endoscopists, and development of training systems is required for world-wide adoption of colorectal ESD[99,100]. ESD for rectal and smaller lesions, which is less technically difficult, is suitable for initial adoption of colorectal ESD. Substantial experience of gastric ESD, which is less technically challenging than colorectal ESD, is highly useful for performing colorectal ESD; however, it is difficult in Western countries because of the low morbidity rate of gastric cancer. EMR with circumferential mucosal incision may be option in cases where ESD cannot be successfully performed[101]. Before performing colorectal ESD, ESD training using animal models or observing the performance of procedure by ESD experts at other institutions have been shown to be extremely useful in improving operator skill[102-104].

In contrast, some cases are challenging even for experts in colorectal ESD, particularly because of the poor endoscope maneuverability or poor visualization of the operative field due to colonic flexure. Colonic flexure and extensibility commonly causes paradoxical movement of the endoscope. Therefore, double- or single-balloon endoscopy systems have recently been introduced for colorectal ESD at several institutions[44-46] because these endoscopy systems enable the endoscope to be straightened more easily than conventional endoscopy. Ohya *et al*[44] reported that a short-type single-balloon overtube through which a thin conventional endoscope can be introduced was useful for colorectal ESD, particularly for poor endoscope maneuverability in the proximal colon.

Sinker-assisted ESD[105], magnet anchor-guided ESD[106], clip with line-assisted ESD[107,108], clip with rubber- or spring-assisted ESD[109,110], clip-band ESD[111], a double-channel scope method[112,113], and a double endoscopic intraluminal procedure[114,115] have all been described as traction systems that facilitate ESD. Each system has a unique traction system that utilizes specialized equipment to provide counter-traction[107]. Because these traction systems are somewhat complicated or commercially unavailable, they are not widely used in colorectal ESD at present. The improvement of these traction systems or development of new tractions systems or devices[116] may facilitate improvements in the safety or efficacy of colorectal ESD in the future.

CONCLUSION

In this review, we have described the technical aspects and recent progresses in colorectal ESD. Maintaining good visualization of the operative field is the most important for safely and successfully performing colorectal ESD. Developments of various devices, novel procedures, and appropriate strategies have resulted in the recent improvement of the treatment outcome in colorectal ESD. Further development of training systems or devices will promote world-wide standardization of colorectal ESD.

ACKNOWLEDGMENTS

We would like to thank Dr. Takashi Toyonaga, Dr. Yoshinori Morita, and CE Ken Yoshimura, all at Kobe University Hospital, Japan, for their technical advice.

Abstract

Peroral endoscopic myotomy (POEM) is an emerging minimally invasive procedure for the treatment of achalasia. Due to the improvements in endoscopic technology and techniques, this procedure allows for submucosal tunneling to safely endoscopically create a myotomy across the hypertensive lower esophageal sphincter. In the hands of skilled operators and experienced centers, the most common complications of this procedure are related to insufflation and accumulation of gas in the chest and abdominal cavities with relatively low risks of devastating complications such as perforation or delayed bleeding. Several centers worldwide have demonstrated the feasibility of this procedure in not only early achalasia but also other indications such as redo myotomy, sigmoid esophagus and spastic esophagus. Short-term outcomes have showed great clinical efficacy comparable to laparoscopic Heller myotomy (LHM). Concerns related to postoperative gastroesophageal reflux remain, however several groups have demonstrated comparable clinical and objective measures of reflux to LHM. Although long-term outcomes are necessary to better understand durability of the procedure, POEM appears to be a promising new procedure.

Key words: Endoscopy; Achalasia; Peroral endoscopic myotomy; Myotomy

Core tip: With recent advancements in endoscopic techniques and technology, peroral endoscopic myotomy, also known as peroral endoscopic myotomy (POEM), has emerged as a promising minimally invasive procedure for treating achalasia. POEM uses the technique of endoscopic submucosal dissection to create a myotomy and palliate symptoms of achalasia. Although long-term outcomes are still needed, short-term outcomes show good safety and efficacy of the procedure that are comparable to laparoscopic Heller myotomy. In this review we will review the technical details of the procedure itself as well as the reported outcomes.

INTRODUCTION

Achalasia is a rare motility disorder of the esophagus that is characterized by non-relaxation of the lower esophageal sphincter (LES) and aperistalsis of the esophagus. No cure exists for this idiopathic disease and thus treatment is aimed at palliation of the esophagus to allow for adequate emptying of the esophagus and improvement of symptoms. Palliation requires disruption of the LES, which has been traditionally accomplished by botulinum toxin injection, balloon dilation or surgical myotomy. Endoscopic botulinum toxin treatment is not often the therapy of choice in these patients, due to the short-term therapeutic effect in this chronic disease. Pneumatic balloon dilation forcefully disrupts the sphincter fibers and although several groups have demonstrated efficacy with this technique, dilation is still associated with a significant risk of perforation[1]. Surgical myotomy has been conventionally performed laparoscopically by dividing the LES above and below, known as a laparoscopic Heller myotomy (LHM) and typically performed with concurrent anti-reflux procedure. Reports of long-term outcomes have shown the superior efficacy of LHM and thus are often the therapy of choice in many of these patients. However with the advances in technology and endoscopic techniques, this concept of a surgical myotomy has lead to the development of an endoscopic approach, peroral endoscopic myotomy (POEM).

HISTORY AND DEVELOPMENT OF POEM

The use of endoscopic treatment for achalasia was first reported in a case series in 1980 by Ortega *et al*[2]. In this series of 17 patients, an endoscopic myotomy was performed using a modified needle knife to directly dissect through the mucosa into the muscular layer to perform a myotomy. Although showing good outcomes, at the time the technique was thought to be unsafe because a direct mucosal approach not only resulted in poor visualization of the muscular layer, but also could result in mediastinal contamination from luminal content. Additionally with limited available devices, the use of the needle knife did not allow for precise and controlled movement, which could potentially lead to high risks of perforation as well as injury to nearby structures. Although abandoned at that time, several decades later the evolution of natural orifice transluminal endoscopic surgery (NOTES) allowed for improvements in endoscopic techniques and technology that subsequently lead to the development of what we now know of as POEM.

As the growth of NOTES procedures continued, submucosal endoscopy developed as a method to not only work below the mucosa to remove mucosal disease, but also to safely enter sterile cavities by creating a mucosal flap to minimize contamination[3,4]. In 2007 using a pig mode, Parischa *et al*[5] reported submucosal tunneling with a balloon dilator to create a mucosal flap and a distal esophageal myotomy effectively reducing LES pressure. This addressed the first problem of direct dissection through the mucosa and risk of mediastinal contamination, but the use of the balloon dilator has limitations, due to the inability to accurately position within the wall as well as the associated risks of injury. However in 2010, Inoue *et al*[6] reported a modified technique and presented the first case series of successfully performed POEM in humans. The two important alterations included: (1) the use of electrosurgery for the endoscopic submucosal dissection rather than a balloon dilator, which is described below; and (2) the use of a triangle-tip knife for muscle dissection, which allowed for precise dissection under direct visualization. Variations of this technique are now performed by specialized centers worldwide for the treatment of achalasia.

OPERATIVE TECHNIQUE

Under general anesthesia patients are positioned supine. POEM places these patients at high risk for subcutaneous emphysema and accumulation of gas in the body cavities thus CO_2 should be used for insufflation and if possible positive pressure ventilation should be maintained at pressures higher than that of endoscopic insufflation to reduce the risk of these complications. Initial evaluation of the esophagus and stomach with a high-definition standard upper endoscope is performed to identify the gastroesophageal junction (GEJ). Once the GEJ is identified, an overtube is placed over the endoscope and dissecting cap placed on the endoscope. Approximately 10-15 cm proximal to the GEJ, the mucosa is injected with a mixture of methylene blue, saline, and epinephrine to create a mucosal bleb. Most groups perform this on the anterior aspect of the esophagus, however there may be variation to this positioning. If the patient is presenting for redo myotomy, the operator should typically perform the procedure on the right lateral aspect of the esophagus to avoid the previous myotomy site. The mucosotomy is then made to enter the submucosal space.

The submucosal tunnel is created from the mucosotomy along the lesser curvature to 2-3 cm distal to the GEJ where blanching is identified on the stomach side. The method to dissect this space is based on operator preference. The use of electrosurgery allows for a controlled dissection, with the use of either a triangular-tip knife (Olympus, Center Valey, PA, United States) or a T-type hybrid knife (ERBE, Tubingen, Germany). The alternative option is balloon dilation to develop

Table 1 Complications after peroral endoscopic myotomy

Complication	Treatment
Mucosal injury	After completion of myotomy, mucosal defects should be closed to minimize risk of leak with clips or suturing device
Full thickness injury	Although certain centers have demonstrated safety with full thickness myotomy, if occurs at site of mucosectomy the operator must consider closure of this myotomy site to prevent potential leakage
Gas escape related complications	
Subcutaneous emphysema	Observation
Pneumomediastinum	Observation, unless physiologic symptoms
Pneumothorax	Small volume closely observed with oxygen only. Volume > 30% may require decompression
Pneumoperitoneum	Large volume or physiologic symptoms requires decompression of the abdomen with Veress needle insertion
Pleural effusion	Small volume can be observed and will absorb. Larger volumes with symptoms require drainage
Bleeding	Most common at the GEJ or distal on stomach side due to increased vascularity. Supportive care and transfusions, endoscopic re-exploration if warranted for hemostasis
Leak/mediastinitis	Depending on time of presentation and extent of perforation will determine the interventions required, which may be as simple as endoscopic treatment or as severe as invasive surgical treatment

GEJ: Gastroesophageal junction.

the plane, however this is a less controlled method, as previously discussed.

The myotomy is started 2-3 cm distal to the mucosotomy and continued to the end of the tunnel at 2-3 cm distal to the GEJ. A partial myotomy is most commonly performed by careful dissection of the circular fibers only, avoiding the longitudinal fibers to avoid entry into the mediastinum. However several groups have explored the option of a complete myotomy through the longitudinal fibers as well[7,8]. The mucosotomy is then closed to avoid leak with the use of endoscopic clips or an endoscopic suturing device. After completion of the procedure, the scope should easily traverse the GEJ. The scope can be then removed and patient extubated and recovered.

COMPLICATIONS AND ADVERSE EVENTS

This invasive endoscopic procedure is not without risks and should only be performed at centers that are capable of treating these complications. Additionally POEM requires operators with specific surgical and endoscopic skills as well as a good understanding of esophageal motility disorders and the available interventions. All standard operative procedures should be followed, including appropriate preoperative evaluation and risk stratification of the patient. The most common complications encountered during or after POEM are listed in Table 1.

Inadvertent mucosotomy is a relatively common complication, especially early in the operators experience, due to the challenges in technique of submucosal tunneling. Although the clinical implications of mucosal injuries are unclear, most centers would recommend closing any defects prior to completion of the procedure to avoid any potential leaks. This is similar to full-thickness muscular injuries that in particular occur at the site of the initial mucosotomy.

Complications related to the insufflation are fairly common. These complications can be minimized by the use of CO_2 rather than room air, due to the quick diffusion of CO_2, and by also maintaining low insufflation pressures if possible. The subsequent complications due to insufflation are listed in Table 1 and in most cases have minimal clinical sequelae. However depending on the degree of gas accumulation in these cavities, the patient may require decompression as described in Table 1. All operators performing POEM should be aware of these risks and capable of treating them.

Similarly pleural effusions may commonly occur and depending on the degree of fluid accumulation and patient symptoms, may or may not require intervention. Delayed bleeding appears to be a rare complication of POEM (0.8%-2.7%)[9,10], but if diagnosed must be promptly intervened on. Lastly the most feared complication, esophageal leak with reported rates from 0% to 5.6%[7,11,12], can be a devastating complication if occurs. If the patient is slow to recover there should be high suspicion for gastrointestinal leak and appropriate work up with either endoscopy or imaging. The time to diagnosis of the leak in addition to the extent of the leak will largely determine the required interventions.

SHORT TERM OUTCOMES

Most centers perform this new procedure under institutional review board oversight as suggested by the NOSCAR POEM White Paper Committee[13] and thus several groups have published their initial outcomes. These preliminary results demonstrate highly skilled endoscopists can safely perform the procedure and short-term data suggests promising efficacy. Table 2 summarizes the reported outcomes seen by the experienced centers around the world.

Most centers evaluate efficacy based on symptomatic relief as measured by the Eckardt score and measure clinical success as Eckardt score $\leqslant$ 3. All of the centers described in Table 2 demonstrated significant improvement in Eckardt scores after POEM. At mean follow up from 1.5 to 12 mo, 89%-100% of patients

Table 2 Reported outcomes for Large Volume Single Centers after peroral endoscopic myotomy

Ref.	Study size	Myotomy thicknes/length	Morbidity	Follow up (mo)	Clinical outcome - before/after	Manometry before/after	Postop PPI
Inoue *et al*[14] 2013	300	Partial 14.1 cm	Pneumothorax 0.3% Mucosal Injury - 2.0%	12	Eckardt - 6.13/1.33 98.2% success	27.3/13.4	4.9%

received clinical success from POEM treatment[7,9-12,14,15]. Several centers also routinely use manometry postoperatively to evaluate the diagnostic outcomes after POEM, which revealed significant improvement in LES resting pressures[9,12,14]. When compared to patients undergoing a standard LHM, patients undergoing POEM had similar symptomatic relief and manometry findings[9,11,12,16]. Additionally quality of life improvements after POEM seem to be comparable to reported outcomes after LHM[17]. All of these results are promising, but only provide short-term results. Further observation is required to determine the durability of POEM outcomes at long-term follow up.

In addition to the durability, postoperative reflux after POEM has and continues to be a concern with the long-term outcomes. LHM, the gold standard for treatment of achalasia, has a reported occurrence of gastroesophageal reflux (GERD) anywhere from 20% to 100% after surgical myotomy without fundoplication[18,19]. This iatrogenic reflux due to the extensive disruption of the LES has lead to routine performance of an anti-reflux procedure in concurrence with the Heller myotomy. Thus without an anti-reflux procedure, GERD after POEM is an important endpoint for efficacy. Objective measures of GERD after POEM such as erosive esophagitis have been found at rates of 6%-40%[6,7,12,20] and abnormal pH studies at rates of 20%-40%[9,21]. Clinically, 4.9%-33%[6,7,12,20] of these patients have reflux symptoms and 4.9%-22% of patients appear to be restarted on proton pump inhibitor therapy after POEM[7,14,17]. However, all of these objective and clinical findings appear to be equivalent to LHM with fundoplication in several series[9,11,12,22]. The leading theory for possible comparable reflux outcomes is related to the maintained hiatal anatomy after POEM. With an endoscopic approach to the myotomy, the opportunity to preserve the longitudinal muscle fibers as well as not disrupting the GEJ innervation or the diaphragm and the phrenoesophageal ligament, may in fact be enough to avoid significantly worse GERD. However these reported outcomes of GERD are fairly short-term results and are difficult to compare to LHM outcomes because of the highly variable reported outcomes of reflux after LHM with fundoplication in the literature itself.

SPECIAL PATIENT COHORTS

Certain special patient cohorts have been studied as possible indications for POEM. These include patients with a previous failed Heller myotomy or POEM, sigmoid type achalasia, spastic esophagus and the pediatric patient. Due to the rarity of these cases, outcomes are not well understood but initial reports discussed below are encouraging.

Redo myotomy

Patents with failed LHM are difficult to treat. Traditionally patients who fail myotomy can be candidates for additional interventions including repeat Heller myotomy and as a last resort esophagectomy. However due to scarring and adhesive disease that develops around the GEJ from the initial operation, these redo cases can be quite challenging. Moreover, although repeat Heller myotomy is often successful, 20%-30% of patients will undergo this relatively risky procedure and still fail after second Heller myotomy[23,24]. Thus, POEM provides a unique opportunity to potentially treat these patients without enduring a challenging and involved operation. Several centers including our own have reported the use of POEM to treat patients with failed Heller myotomy. Initial outcomes show the procedure is safe and at short-term follow-up has 90%-100% success[25-27]. Even with previous fundoplication, the procedure is performed in these patients almost identical to patients without previous myotomy with exception of the location of the second myotomy. The recommendation is to avoid the previous myotomy that is conventionally performed anterior and to perform the repeat myotomy right lateral on the esophagus. Similar outcomes have been observed in those patients with previous POEM

presenting for redo POEM[28].

Sigmoid esophagus

Sigmoid-shaped esophagus is often seen in advanced achalasia cases and can be a complicated disease to treat. Although initial approaches to treatment are debatable, most would advocate for treating these patients with myotomy before discussing esophagectomy[29-32]. The use of POEM in these advanced staged patients has been reported with good feasibility and short-term success[6,33]. However, due to the anatomical changes in the esophagus these cases are particularly challenging, especially when developing the submucosal space, and should only be performed by highly experienced operators.

Spastic esophagus

Spastic disorders of the esophagus are characterized by abnormal contractility of the esophagus and can be divided into spastic achalasia, diffuse esophageal spasm, and hypercontractile or jackhammer esophagus. These motility disorders are difficult to treat and often long-term clinical success is only accomplished with surgical myotomy[34]. Treating these patients with POEM is safe and at initial short term follow up is efficatious[35,36]. In a recent multicenter study which included 73 patients with spastic esophagus, when an extended myotomy was performed with POEM, 93% clinical success was observed at an average of 8 mo[37]. However as with POEM in the typical achalasia patient, longer term studies are necessary to understand the durability of these treatments.

Pediatric patients

Though rare, achalasia presenting in pediatrics patients can lead to significant problems with malnutrition and subsequently mental and physical development. These patients are not good candidates for endoscopic therapies due to short term durability with the growing child and the gold standard of treatment is surgical myotomy. Chen *et al*[38] demonstrated POEM can be safely performed for pediatric patients and in 27 patients showed 100% clinical success at an average of 25 mo and thus can be considered in a pediatric patient.

CONCLUSION

POEM is an emerging new technique for treating achalasia that evolved from the era of NOTES. POEM may also expand the therapeutic options for patients with challenging esophageal disease due to the growing indications, including patients with previous myotomy, sigmoid esophagus and spastic esophagus. Short-term results from experienced centers allow for cautious optimism with this minimally invasive technique, however questions remain as to long-term durability and subsequent GERD. Patients offered POEM should be counseled about our limited knowledge of long-term outcomes as well as the potential risk of GERD. Continued observation of long-term outcomes will be necessary as we continue to understand this procedure.

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) has become an important therapeutic modality for biliary and pancreatic disorders. Perforation is one of the most feared complications of ERCP and endoscopic sphincterotomy. A MEDLINE search was performed from 2000-2014 using the keywords "perforation", "ERCP" and "endoscopic sphincterotomy". All articles including more than nine cases were reviewed. The incidence of ERCP-related perforations was low (0.39%, 95%CI: 0.34-0.69) with an associated mortality of 7.8% (95%CI: 3.80-13.07). Endoscopic sphincterotomy was responsible for 41% of perforations, insertion and manipulations of the endoscope for 26%, guidewires for 15%, dilation of strictures for 3%, other instruments for 4%, stent insertion or migration for 2% and in 7% of cases the etiology was unknown. The diagnosis was made during ERCP in 73% of cases. The mechanism, site and extent of injury, suggested by clinical and radiographic findings, should guide towards operative or non-operative management. In type I perforations early surgical repair is indicated, unless endoscopic closure can be achieved. Patients with type II perforations should be treated initially non-operatively. Non-operative treatment includes biliary stenting, fasting, intravenous fluid resuscitation, nasogastric drainage, broad spectrum antibiotics, percutaneous drainage of fluid collections. Non-operative treatment was successful in 79% of patients with type II injuries, with an overall mortality of 9.4%. Non-operative treatment was sufficient in all patients with type III injuries. Surgical technique depends on timing, site and size of defect and clinical condition of the patient. In conclusion, diagnosis is based on clinical suspicion and clinical and radiographic findings. Whilst surgery is usually indicated in patients with type I injuries, patients with type II or III injuries should be treated initially non-operatively. A minority of them will finally require surgical intervention.

Key words: Endoscopic retrograde cholangiopancreatography; Endoscopic sphincterotomy; Perforation

Core tip: Perforation is one of the most feared complications of endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy. The

incidence of ERCP-related perforations is low (0.39%) with an associated mortality of 7.8%. Endoscopic sphincterotomy is responsible for 41% of perforations and endoscope manipulations for 26%. The mechanism, site and extent of injury, suggested by clinical and radiographic findings, should guide towards operative or non-operative management. Classification into types permits a tailored approach to management. Whilst surgery is usually indicated in patients with type Ⅰ injuries, patients with type Ⅱ or Ⅲ injuries should be treated initially non-operatively. A minority of them will finally require surgical intervention.

INTRODUCTION

In the era of minimally invasive therapy, endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy has become an important therapeutic modality for the treatment of biliary and pancreatic disorders. Although considered as a safe procedure, it is associated with complications such as pancreatitis, bleeding and perforation. The incidence of ERCP-related complications is 5%-10% and the overall mortality 0.1%-1%[1-5].

Perforation is one of the most feared complications of ERCP and sphincterotomy. In a review of 21 prospective studies[6], addressing ERCP complications, between 1987-2003, perforations occurred in 101 patients (0.6%, 95%CI: 0.48-0.72) with a perforation related mortality of 9.90% (95%CI: 3.96-15.84).

Traditionally, the standard treatment for iatrogenic duodenal perforations has been early surgical repair. Recently, non operative management of ERCP-related perforations has increased. However, it is difficult to evaluate the efficacy of different treatments, because of the rarity of the complication and there is no consensus for optimal management.

This review aims to evaluate the incidence, diagnosis and treatment of ERCP-related perforations.

RESEARCH

A MEDLINE search was performed from 2000-2014 using the keywords "perforation", "ERCP" and "endoscopic sphincterotomy". All articles including more than nine cases were reviewed. No randomized controlled trial could be identified.

CLASSIFICATION

There are two proposed classifications of ERCP-related perforations. In 1999, Howard *et al*[7] classified perforations into three distinct types: type I, guidewire perforation; type Ⅱ, periampullary perforation; type Ⅲ, duodenal perforation remote from the papilla. In 2000 Stapfer *et al*[8] classified ERCP-related perforations into four types, based on the mechanism, anatomical location and severity of injury, which may predict the need for surgery. The Stapfer classification is the most commonly used and it divides perforations into: Type Ⅰ, lateral or medial wall duodenal perforation; type Ⅱ, perivaterian injuries; type Ⅲ, distal bile duct injuries related to guidewire-basket instrumentation and type Ⅳ, retroperitoneal air alone. Type Ⅳ is questionable and it is not a true perforation. Due to the excess compression of air in the duodenum, air bubbles can leak through the sphincterotomy area outside the duodenal lumen, into the retroperitoneal space. The presence of retroperitoneal air is a common finding after endoscopic sphincterotomy. CT scan, when used routinely after ERCP and sphincterotomy, may detect retroperitoneal air in 13% to 29% of patients[9,10]. In the absence of symptoms, it has no clinical significance and these patients do not require any further intervention.

INCIDENCE AND RISK FACTORS

Reviewing 18 studies[8,11-27], between 2000-2014 (mainly retrospective), addressing only ERCP-related perforations, including 142847 patients, the incidence was 0.39% (95%CI: 0.34-0.69). According to Stapfer classification, type Ⅰ counted 25%, type Ⅱ 46% and type Ⅲ 22%. The overall mortality was 7.8% (95%CI: 3.80-13.07) (Table 1).

A multivariate analysis to reveal risk factors was performed in two studies[4,14]. Precut, Billroth Ⅱ gastrectomy and intramural injection of contrast medium were significant risk factors for retroperitoneal duodenal perforation by Loperfido *et al*[4]. In Enns *et al*[14]'s study, factors existing prior to ERCP which predicted perforation included sphincter of Oddi dysfunction and a dilated common bile duct. Predictive factors related to ERCP itself included duration of procedure, biliary stricture dilation and performance of a sphincterotomy. Precut didn't reach statistical significance in that study.

ETIOLOGY

The mechanism of injury is mentioned in 573 patients from 18 studies[8,11-15,17-23,25-29] (Table 2). Endoscopic sphincterotomy was responsible for 41% of perforations, insertion and manipulations of the endoscope for 26%, guidewires for 15%, dilation of strictures for 3%, other instruments for 4%, stent insertion or migration for 2% and in 7% of cases the etiology was unknown.

DIAGNOSIS

Early diagnosis and prompt treatment during the endoscopic procedure are vital for a better outcome[7,30].

ES: Endoscopic sphincterotomy.

ERCP-related perforations can usually been diagnosed during ERCP, from the endoscopic view or using fluoroscopy. In a review of 437 cases from 15 studies[8,12-15,17-24,26,27] the diagnosis was made during ERCP in 73% of cases (Table 3). The definition of delayed diagnosis was inconsistent between studies, but it was considered to be associated with worst prognosis[11,16,22]. Type Ⅰ perforations can be diagnosed from direct visualization of the retroperitoneal space (Figure 1) or the abdominal cavity. In doubtful cases with bleeding and not clear endoscopic view, the use of fluoroscopy with or without contrast injection can confirm the diagnosis. Type Ⅱ perforations can be suspected after a large or wrong direction sphincterotomy and can be confirmed by fluoroscopy. Fluoroscopy will reveal the presence of retroperitoneal air, especially around the right kidney with delineation of kidney margin (Figure 2) and occasionally the outlining of psoas muscle. The injection of contrast can also show leaking from the sphincterotomy site. Type Ⅲ perforations can be diagnosed by the unusual passage of the guide wire or by the injection of contrast.

At the end of every endoscopic procedure, thorough control for any possible perforation should be performed.

ERCP: Endoscopic retrograde cholangiopancreatography.

Table 4 Comparison of different types of stents used for type II, III perforations

	Technical success	Biliary drainage	Covering the perforation	Repeat ERCP for removal	Cost
SEMS	+++	+++	+++	Y	+++
Plastic biliary stents	+++	++	+	Y	+
Nasobiliary drain	+++	+	_	N	+

SEMS: Covered self expanding metallic biliary stents; Y: Yes; N: No; ERCP: Endoscopic retrograde cholangiopancreatography.

The endoscopist should inspect the circumference of the duodenum carefully and check the X-ray for the presence of retroperitoneal air. This concern is especially true when the procedure is technically difficult; needle-knife precut has been performed; there are variations in the usual anatomy due to previous operative interventions; strictures are dilated. If there is high suspicion contrast medium can be infused through the endoscope to facilitate identification of the injury.

Patients with undetected leaks can present hours after the ERCP with pain, fever and leukocytosis. In cases of intraperitoneal type I perforations, the diagnosis is usually obvious with severe pain and signs of peritonitis. When a patient experiences severe pain after ERCP, a differential diagnosis between acute pancreatitis and perforation should be made. In cases of retroperitoneal perforations the diagnosis is not so obvious. The patient may complain of mild epigastric pain but signs of peritonitis may develop after several hours or may not develop at all, depending on the size of the leak. The presence of subcutaneous emphysema may be evident from the first hours, especially at right abdominal wall, back or even cervix. Tachycardia is a constant finding, but it can be caused by other factors including pain. Leukocytosis and fever are often seen

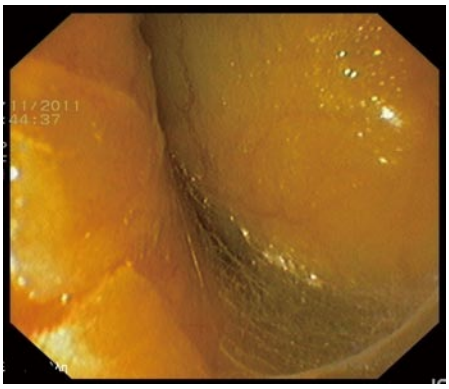

Figure 1 Endoscopic view of the retroperitoneal space after an endoscope-related perforation.

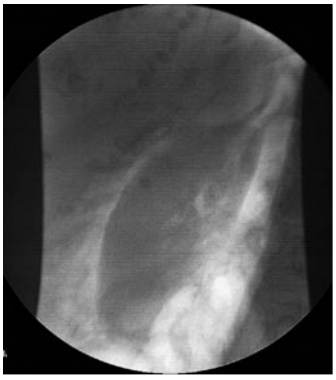

Figure 2 Retroperitoneal air delineating kidney margin after a sphincterotomy-related perforation.

12 h or more after completion of the procedure. A mild elevation of serum amylase levels is caused from the absorption of pancreatic fluid from the retroperitoneal space.

In cases with suspicion of perforation, a CT scan with oral contrast should be obtained. The presence of retroperitoneal air can also be detected by plain films, but CT scan is more sensitive[10,31], it may demonstrate the leak and the presence of fluid collections.

TREATMENT

After the recognition of an ERCP-related perforation, the first dilemma is conservative treatment or surgery. That depends on the mechanism of injury, site and degree of leak and patient condition[28,32]. Endoscope related perforations (type I) should be referred for immediate surgery, unless endoscopic closure can be achieved. Endoscopic closure using fibrin glue, endoloops and endoclips or an over the scope clipping device has been described[33-36].

In cases of endoscopic sphincterotomy related perforations (type II), when diagnosed during the procedure, biliary drainage is essential in order to prevent leakage of bile into the perforation site. In Enns study[14], 5/13 patients with type II injuries were managed successfully either with plastic biliary stents

Table 5 Outcome after initial non-surgical management of type II and III perforations

Ref.	Type II				Type III		
	n	Surgery (%)	Mortality (%)		*n*	Surgery (%)	Mortality (%)
			After surgery	Overall			
Assalia *et al*[11], 2007	17	2 (11)	1 (50)	1 (6)	2	0	0

or percutaneous transhepatic biliary drainage. In Alfieri *et al*[28]'s study, 12/30 patients with early diagnosis were successfully treated conservatively with nasobiliary drainage.

Several case series have reported the use of fully covered self expandable metallic stents (SEMS) in sphincterotomy related perforations. SEMS have the advantage of covering the laceration and permit free flow of bile into the duodenum instead of into the retroperitoneal space. It seems better to use a covered SEMS because plastic stents or nasobiliary drains may not prevent bile flow into the perforation site completely. SEMS can also be used later with a repeat ERCP when the leak persists[37-40]. The advantages and disadvantages of different types of stents are shown in Table 4.

When a sphincterotomy related perforation is diagnosed after the procedure it should be assessed by a CT scan with contrast orally to demonstrate the degree of leak. Major contrast leak is an indication for immediate surgery, whilst minimal or no leak can be treated non-operatively[30,32]. Non-operative treatment includes nil by mouth, nasogastric tube, intravenous fluid resuscitation, broad spectrum antibiotics, repeat endoscopy for stenting in selected cases, and radiologic interventions for percutaneous drainage of fluid collections. Total parenteral nutrition is recommended in undernourished patients or when adequate enteral feeding will be impeded for at least seven days[41]. Generally, indications for surgery are: Major contrast leak; sepsis despite non-surgical treatment; presence of peritonitis or retroperitoneal fluid collections not amenable to percutaneous drainage; unsolved problems like stones or retained hardware (baskets)[28,30,32,41]. The clinical condition of the patient should be the key factor determining the mode of treatment[14,28,42]. Knudson *et al*[20] devised a clinical index score to predict the need for operative intervention. This 4-point scoring system assigned 1 point for each of the following: fever, tachycardia, guarding on examination and leukocytosis. The odds ratio for requiring operative management in patients with a score of greater than or equal to 3 was 40 (5.3-303.1, $P < 0.001$). In two studies[15,26] applying multivariate logistic regression analysis only ASA score and site of perforation remained significant for predicting operative treatment.

Reviewing 11 studies[8,11,14,18,21-27], after initial non-surgical treatment, surgery was required in 29/137 (21%) of patients with type II perforations, with an overall mortality of 9.4% (Table 5). The mortality of patients who required surgery was high (38%). Non-surgical management was successful in all patients with type III perforations (Table 4). In a recent review[32] conservative management was successful in 92.9% of patients with both types of injuries, treated initially non-operatively, with a final mortality of 0.6%.

In the available literature there are no prospective comparative studies between surgical techniques for ERCP-related perforations. Surgical technique depends on site and size of defect, timing of surgery and clinical condition of the patient.

The main goal of immediate surgery is to repair the perforation and diversion of bile and gastric fluid, if required. Endoscope related duodenal perforations (type I) can be closed primarily in one or two layers, following debridement of devitalized tissue. The closure should be oriented transversely in order to avoid compromising the duodenal lumen. In cases with large defects the options are jejunal serosal patch closure or tube duodenostomy. Leak from the duodenal closure line is a major concern and duodenal diversion should be suggested in large defects or delayed diagnosis. The rationale is to divert the gastrointestinal content and proteolytic enzymes from the duodenal repair site. In sphincterotomy related perforations (type II), a non-operative approach is successful in nearly 80% of cases. When the clinical condition of the patient or the size of the leak requires immediate surgery, a transduodenal approach and repair, by performing sphincteroplasty within 24 h, has been described with good results[43].

The main goals of delayed surgery are to control sepsis, to repair the perforation if possible, and diversion, if required[28,30,32,43,44]. Delayed surgery is performed in patients who remain septic despite non-

operative treatment, and debridement and drainage of the retroperitoneal space is required. That can be achieved by an extraperitoneal approach (right posterior laparostomy)[28] or transperitoneal approach when cholecystectomy, common bile duct exploration with T-tube placement or diversion techniques are required. The perforation site cannot be found in 16% to 80% in delayed surgery[24,27,44] or the tissues are too edematous for primary repair. The transduodenal approach is not indicated for delayed surgery.

Diversion of gastric and duodenal fluid is mandatory and can be achieved by: placement of a nasogastric or nasoduodenal tube; tube duodenostomy; pyloric exclusion and gastrojejunostomy; gastrojejunostomy alone; T-tube placement for bile diversion; duodenal diverticulization[7,8,11,12,15,20,23,25,27,29]. Duodenal diverticulization consists of Billroth Ⅱ gastrectomy, placement of a decompressive catheter into the duodenum, closure of duodenal wound and drainage[45]. The main drawback of duodenal diverticulization is that it is an extensive procedure which may be inappropriate in septic, unstable patients. Pyloric exclusion is a less invasive alternative. This procedure consists of duodenal wound repair, closure of the pylorus with a running suture or by stapling and gastrojejunostomy. Pyloric exclusion is a less extensive procedure, less time consuming, causes less physiological disturbances and it is advocated by most clinicians, when duodenal diversion is required.

In conclusion, ERCP-related perforation is uncommon (0.39%), but it is associated with an overall mortality of 7.8%. Early diagnosis and treatment are essential for a better outcome. The mechanism, site and extent of injury, suggested by clinical and radiographic findings, should guide towards conservative or surgical management. In type Ⅰ perforations early surgical repair is indicated, unless endoscopic closure can be achieved. Patients with type Ⅱ perforations should be treated initially non-operatively. Non-operative treatment is successful in 79% of patients with an overall mortality of 9.4%. Non-operative treatment is sufficient in all patients with type Ⅲ injuries. Surgical technique depends on size and site of defect, timing and clinical condition of the patient.

Abstract

AIM: To compare the usefulness of endoscopic ultrasonography-guided fine-needle aspiration biopsy (EUS-FNAB) without cytology and mucosal cutting biopsy (MCB) in the histological diagnosis of gastric submucosal tumor (SMT).

METHODS: We prospectively compared the diagnostic yield, feasibility, and safety of EUS-FNAB and those of MCB based on endoscopic submucosal dissection. The cases of 20 consecutive patients with gastric SMT $\geqslant$ 1 cm in diameter. who underwent both EUS-FNAB and MCB were investigated.

RESULTS: The histological diagnoses were gastrointestinal stromal tumors (n = 7), leiomyoma (n =

6), schwannoma (n = 2), aberrant pancreas (n = 2), and one case each of glomus tumor, metastatic hepatocellular carcinoma, and no-diagnosis. The tumors' mean size was 23.6 mm. Histological diagnosis was made in 65.0% of the EUS-FNABs and 60.0% of the MCBs, a nonsignificant difference. There were no significant differences in the diagnostic yield concerning the tumor location or tumor size between the two methods. However, diagnostic specimens were significantly more frequently obtained in lesions with intraluminal growth than in those with extraluminal growth by the MCB method (P = 0.01). All four SMTs with extraluminal growth were diagnosed only by EUS-FNAB (P = 0.03). No complications were found in either method.

CONCLUSION: MCB may be chosen as an alternative diagnostic modality in tumors showing the intraluminal growth pattern regardless of tumor size, whereas EUS-FNAB should be performed for SMTs with extraluminal growth.

Key words: Submucosal tumor; Endoscopic ultrasonography-guided fine-needle aspiration biopsy; Gastrointestinal stromal tumor; Mucosal cutting biopsy; Endoscopic submucosal dissection

Core tip: We prospectively compared the diagnostic yield and the safety between endoscopic ultrasonography-guided fine-needle aspiration biopsy (EUS-FNAB) without cytology and mucosal cutting biopsy (MCB) based on endoscopic submucosal dissection. Although no significant difference in histological diagnosis was found between EUS-FNAB and MCB, diagnostic specimens were significantly more frequently obtained in the lesions with intraluminal growth compared to those with extraluminal growth by the MCB method. All submucosal tumors (SMTs) with extraluminal growth were diagnosed only by EUS-FNAB. No complications were found in either method. Therefore, MCB may be chosen as an alternative diagnostic modality in tumors showing intraluminal growth, whereas EUS-FNAB should be performed for SMTs with extraluminal growth.

Histological diagnosis of gastric submucosal tumors: A pilot study of endoscopic ultrasonography-guided fine-needle aspiration biopsy *vs* mucosal cutting biopsy. *World J Gastrointest Endosc* 2015; 7(14): 1142-1149 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i14/1142.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i14.1142

INTRODUCTION

Gastric submucosal tumors (SMTs) including gastrointestinal stromal tumors (GISTs), leiomyomas, schwannomas, aberrant pancreas and more are frequently identified during routine upper endoscopies. Although endoscopic ultrasonography (EUS) is a useful modality for diagnosing gastric SMTs[1], it is not always possible to differentiate a GIST from a leiomyoma or schwannoma by EUS, especially when the tumor originated from the muscularis propria layer. GISTs are rare neoplasms that account for only 0.1%-3% of all gastrointestinal (GI) malignancies[2-4], whereas they represent approximately 80% of GI mesenchymal tumors[5]. As GISTs are potentially malignant, histological diagnosis by an EUS-fine-needle aspiration biopsy (FNAB) is recommended[6,7]. It is thus very important to discriminate these lesions from benign SMTs originating from the muscularis propria, such as leiomyomas and schwannomas. However, it may be difficult to arrive at the correct histological diagnosis with only a standard endoscopic biopsy, because the surface of an SMT is covered with normal epithelium.

EUS-FNAB is a reliable, useful and suitable method for the histological evaluation of SMTs[8-10]. Although EUS-FNAB is used widely, only a limited number of cases are subjected to this method, even in hospitals specializing in gastroenterology. In addition, EUS-FNAB systems including an echoendoscope and its observing system are very expensive and require not only experienced pathologists but also cytology technicians capable of handling and processing biopsy specimens[7]. The successful diagnostic rate for SMT by an EUS-FNAB combined with cytology has been reported to be relatively high (83%), but the success rate for histology is not satisfactory (50%)[9,11-13]. An alternative modality for the histological diagnosis of SMTs is thus needed.

Endoscopic submucosal dissection (ESD) was developed in Japan in the 2000s[14] and has since been widely adopted for the treatment of superficial gastric neoplasms. By applying this method, Lee *et al*[15] described cases in which an ESD-associated technique rather than EUS-FNAB was useful for the tissue sampling of SMTs. The applications of several similar methods for the histological diagnosis of gastrointestinal (GI) SMTs were also reported: mucosal cutting biopsy (MCB), a mucosal incision-assisted biopsy technique, and an "unroofing" biopsy based on endoscopic mucosal resection (EMR)[16-20].

A comparison of the histological diagnostic yield of SMTs between EUS-FNAB without its combination with cytology and MCB has not been published, to our knowledge. The aim of the present study was to prospectively compare the diagnostic yield of gastric SMTs and the feasibility, safety and complications between EUS-FNAB and MCB by performing both diagnostic modalities simultaneously for the same SMT patients.

MATERIALS AND METHODS

Patients

Between May 2012 and February 2015 in our depart-

ment, both EUS-FNAB and MCB were prospectively performed for 20 consecutive patients with gastric SMTs ⩾ 1 cm in diameter which were diagnosed by EUS (UM2000, UM-2R and 3R; Olympus Optical Corp., Tokyo) prior to the EUS-FNAB and MCB procedures. If the EUS finding of SMT showed mainly inward or outward growth from the gastric wall, the lesion was judged as intraluminal or extraluminal growth, respectively. Since hyperechoic lesions on EUS that originate from the submucosal layer are generally diagnosed as lipoma, these lesions were excluded from the study. All patients were admitted on the day of EUS-FNAB and MCB, and were usually discharged the day after the procedures. Thus the hospital stay for the patients without any clinical complications was generally 1 d, based on the clinical protocol at our hospital.

Written informed consent was obtained from all patients prior to the study, and the study design was approved by the Ethics Committee of Hyogo College of Medicine (No. 1710).

Operators of the EUS-FNAB and MCB procedures

Operator skill may affect the diagnostic yield and the complications of these procedures. In Japan, endoscopists receive board certification from the Japan Gastroenterological Endoscopy (JGES) after 5 years of training in a JGES-approved educational institution of endoscopy and after passing an examination administered by the JGES. Accordingly, the EUS-FNAB and MCB procedures in the present study were performed by expert endoscopists with board certification from the JGES. The same endoscopist performed the EUS-FNAB and MCB in a given patient.

EUS-FNAB procedure

The EUS-FNAB procedure was performed first with the patient under conscious sedation by midazolam with or without pethidine. The EUS-FNAB procedure was performed by expert endoscopists. Fundamentally, a convex linear-array echoendoscope (GF-UCT260; Olympus Optical) connected to an observing system (UM-ME1; Olympus Optical) was used in this procedure. A 22-gauge needle (EchoTip ProCore High Definition Ultrasound Biopsy Needle; Cook Japan, Tokyo) was used to obtain specimens for the histological analysis. After properly targeting the mass, the endoscopist punctured the lesion with the needle. Thereafter, the inner needle was pulled out, and the endoscopist moved the needle back and forth 20 times while applying suction using the connected 10-mL syringe. The EUS-FNAB was performed by making 1 to 4 passes, at the discretion of the endoscopist. That is, when the endoscopist judged that grossly visible material was obtained, the procedure was stopped.

The obtained material was immediately and directly exposed to 10% formalin, and then processed as a tissue block for histopathological evaluation using hematoxylin-eosin and immunohistochemistry (IHC) staining. Cytology was not performed as an on-site cytologist was not available in this procedure, and a cell block for confirmatory IHC was also not prepared.

Mucosal cutting biopsy

Immediately following the EUS-FNAB in each patient, an MCB was performed. The MCB technique was as follows: first, saline was injected into the submucosa and then mucosal cutting was performed using a needle-knife (KD-1L-1; Olympus Optical). Under direct vision of the SMT, several biopsy specimens were taken using conventional biopsy forceps (Radial Jaw™ 4: Boston Scientific, Natick, MA). One to six biopsy samples were taken at the discretion of the operators. As in the EUS-FNAB procedure, when the endoscopist judged that grossly visible material was obtained, the procedure was stopped. Thereafter, the mucosal incision was closed with hemoclips (EZ Clip™; Olympus Optical) to prevent post-procedure bleeding (Figure 1) and to reduce the risk of ulceration that may cause peritoneal dissemination.

The patient's oral intake was allowed starting the morning after the day of the procedure, and then the patient was discharged. A proton pump inhibitor was administered for 2 wk after the procedure.

IHC staining of the samples obtained by both methods was performed using the following antibodies: c-kit, CD34, S100 protein, and desmin. Patients diagnosed with a GIST were offered surgical resection.

Analysis parameters

We evaluated the diagnostic yield and post-procedure bleeding and other complications between the EUS-FNAB and MCB methods, and we tried to determine the causes of nondiagnostic cases.

Statistical analysis

The data were assessed by Welch's *t* test between two groups, and the chi-square test or Fisher's exact test was used to examine differences between two proportions. Statistical significance was defined as a P value < 0.05. Statistical analyses were performed with GraphPad Prism5 software (GraphPad Software, La Jolla, CA).

RESULTS

Patient characteristics and clinicopathological data of SMTs

Table 1 provides the characteristics of the 20 patients and a summary of the targeted SMTs. All patients underwent EUS prior to the EUS-FNAB and MCB procedures and were diagnosed as having a gastric SMT originating from the submucosal (third layer) or the muscularis propria layer (fourth layer). The mean age of the patients was 61.8 ± 12.5 years (range 39-77 years), and women accounted for 50.0% of the patients. The tumors had a mean size of 23.6 mm (range 10-57). Among the 20 cases, four showed extraluminal growth on EUS. The histological diagnoses were GIST

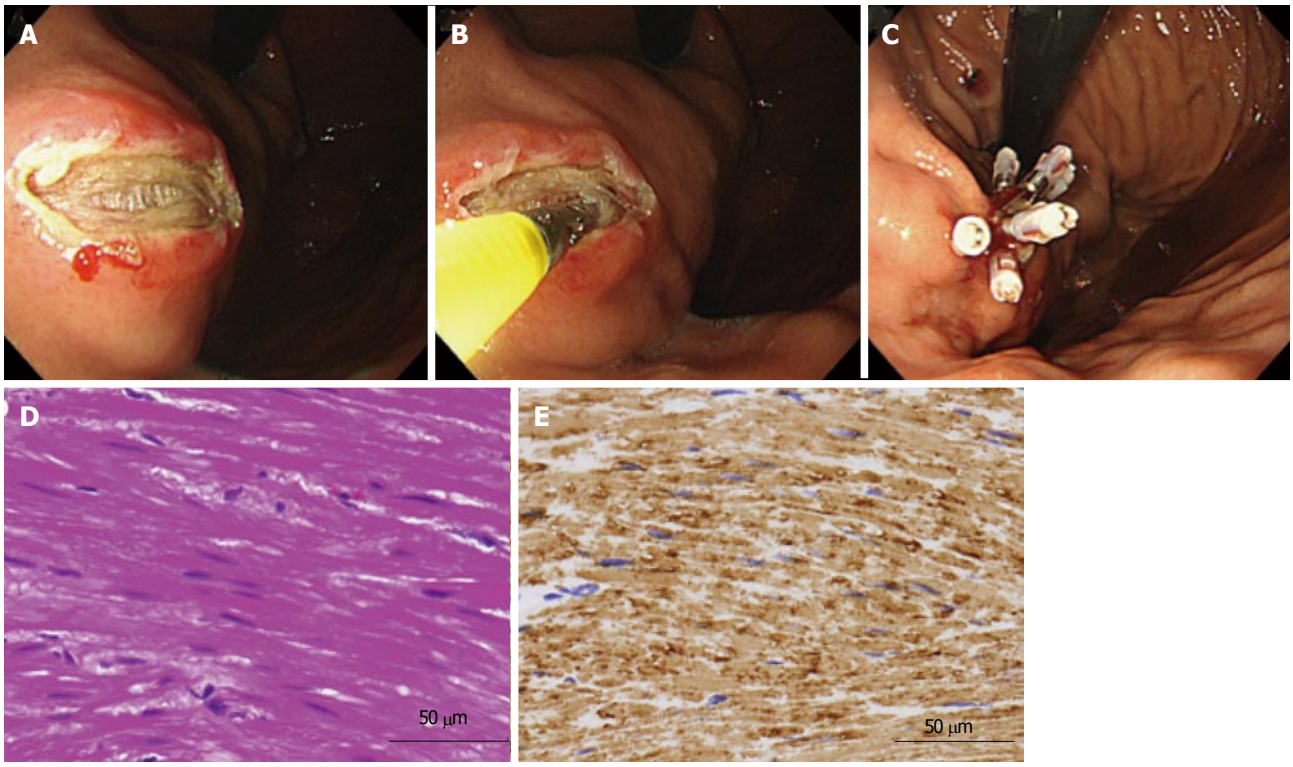

Figure 1 Mucosal cutting biopsy of a submucosal tumor with intraluminal growth in the lesser curvature of the corpus. A: The mucosal incision was made by a needle-knife after an injection of saline; B: Biopsy specimen obtained from the tumor using biopsy forceps under direct observation; C: The incision was closed with hemoclips; D: Histological examination of the biopsied specimen showing a spindle cell without mitotic figures (HE); E: Immunohistochemical staining was positive for desmin. This lesion was diagnosed histologically as a leiomyoma.

Table 1 Summary of the 20 patients with submucosal tumors who underwent endoscopic ultrasonography-guided fine-needle aspiration biopsy and mucosal cutting biopsy

Age, mean ± SD (yr)	61.8 ± 12.5
Male: Female	10:10
Tumor location (upper/middle/lower)	11/8/1
Tumor size ± SD (range) (mm)	23.6 ± 11.5 (10-57)
≤ 20 mm : > 20 mm	7:13
Growth pattern	
Intraluminal	16
Extraluminal	4
Histological diagnosis	
Gastrointestinal stromal tumor	7

Schwannoma	2
Aberrant pancreas	2
Glomus tumor	1
Metastatic hepatocellular carcinoma	1
Not diagnosed	1

(*n* = 7), leiomyoma (*n* = 6), schwannoma (*n* = 2), aberrant pancreas (*n* = 2), glomus tumor (*n* = 1), metastatic hepatocellular carcinoma (HCC, *n* = 1), and nondiagnostic (*n* = 1).

Of the three cases that could not be diagnosed by either method, two were treated surgically and diagnosed histologically as a schwannoma and a glomus tumor, respectively, and the third case is being followed closely without treatment. The tumors were located at the lesser curvature of the middle corpus in the schwannoma, at the greater curvature of the fornix for the glomus tumor, and at the greater curvature of the antrum in the nondiagnostic case. All seven GIST cases diagnosed by EUS-FNAB or MCB were surgically resected and confirmed histologically as GISTs.

Diagnostic yields of EUS-FNAB and MCB

The median values 3.0 [interquartile range (IQR): 2.0, 4.0] for the EUS-FNAB samples and 3.0 (IQR: 1.5, 4.5) for the MCB samples were obtained per patient. All 15 cases of GIST, leiomyoma and schwannoma were diagnosed by IHC. The rates of histological definitive diagnosis were 65.0% (13 of 20) by EUS-FNAB and 60.0% (12 of 20) by MCB, a nonsignificant difference. The concordance rate of the histological diagnosis between the two methods was 100%. There were also no significant differences in the diagnostic yield regarding tumor location or tumor size between the EUS-FNAB and MCB methods (Table 2). However, diagnostic specimens were significantly more frequently obtained in lesions with intraluminal growth than in those with extraluminal growth in the MCB method (*P* = 0.01). All four of the SMTs that showed extraluminal growth, including three GISTs and the single HCC, were correctly diagnosed only by EUS-FNAB (Figure 2), and not by MCB (*P* = 0.03). Seventeen of the SMTs (85.0%) were histologically diagnosed by both methods.

Complications in both procedures

Two cases showed mild bleeding during the MCB procedure, but both were successfully managed by

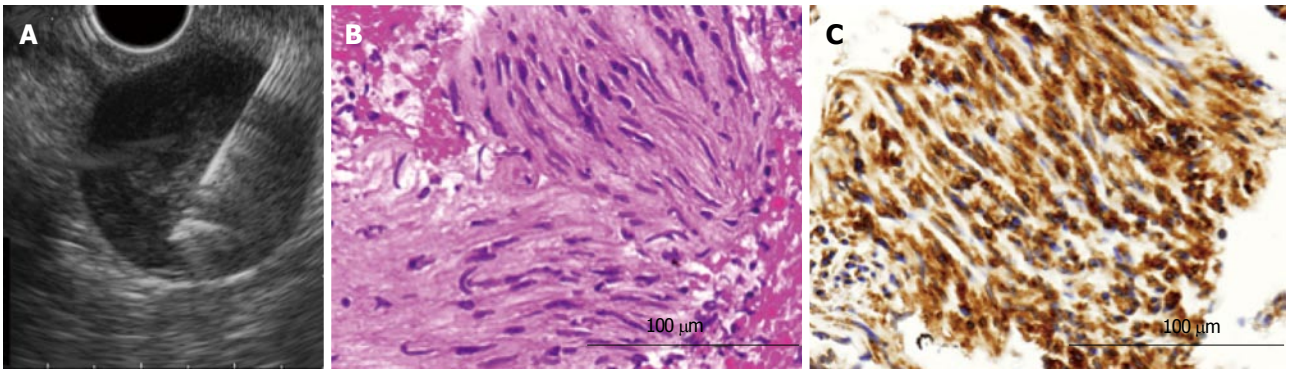

Figure 2 Endoscopic ultrasonography-guided fine-needle aspiration biopsy of a gastrointestinal stromal tumor with extraluminal growth. A: EUS-FNAB of a hypoechoic lesion in the muscularis propria layer showing extraluminal growth; B: Histological finding showing spindle cells in the EUS-FNAB specimen (HE); C: Immunohistochemical staining is positive for c-kit. EUS-FNAB: Endoscopic ultrasonography-guided fine-needle aspiration biopsy.

[1]*P* values were calculated using Fisher's exact test; [a]*P* = 0.67 between EUS-FNA and MCB in tumor size ≤ 20 mm; Fisher's exact test; [c]*P* = 0.31 between EUS-FNA and MCB in tumor size > 20 mm; Fisher's exact test; [e]*P* = 0.46 between EUS-FNA and MCB in intraluminal growth pattern; Fisher's exact test; [b]*P* = 0.03 between EUS-FNA and MCB in extraluminal growth pattern. EUS-FNAB: Endoscopic ultrasonography-guided fine-needle aspiration biopsy; IQR: Interquartile range; MCB: Mucosal cutting biopsy.

hemoclips. The mean number of hemoclips for closing the incised mucosa was 3.4 (range: 1-6 clips). No post-procedural hemorrhage, fever, or peritonitis was seen following either procedure.

DISCUSSION

To date, there are many reports on the methods of tissue acquisition from SMTs: EMR, MCB and EUS-FNAB. Histological diagnosis by a standard biopsy or EMR may be confined to SMTs that arise from the muscularis mucosa or submucosa, which corresponds to second- or third-layer lesions on EUS. In contrast, it may be impossible to make a histologic diagnosis of the lesions located in the muscularis propria by these methods. Therefore, EUS-FNAB was suggested to play an important role in histological diagnoses such as gastric SMTs, although the results can be quite variable[10]. However, although the use of EUS-FNAB is quite prevalent, only a limited number of patients undergo this procedure - even in hospitals specializing in gastroenterology - because an expensive dedicated endoscopic system is needed to conduct an EUS-FNAB. For example, the price of the needle for EUS-FNAB is approximately $300 United States dollars (USD), and the total prices of devices such as the needle knife, injection needle and EZ Clip™ for MCB are also approximately $100 USD, and thus the cost may be

significantly cheaper in the MCB method than in the EUS-FNAB method. Additionally, the needle knife used in the MCB method is reusable. The EUS-FNAB system comprised of an echoendoscope and its observing system is very expensive, over $100000 USD. Therefore, MCB may be the less expensive procedure compared to EUS-FNAB.

Generally, the accuracy rates of EUS-FNAB in the histological diagnosis of gastric SMTs vary from approximately 60% to 80%[9,11]. It was noted that the sensitivity of EUS-FNAB for the diagnosis of GIST, especially in cases of small GISTs, is relatively low compared to that for other types of SMTs[21,22], indicating that the diagnostic yield may be influenced by the lesion's size[11,21-24], because technical expertise is required to diagnose smaller lesions by EUS-FNAB. Several studies showed that the diagnostic rate increased with the increase of tumor size[22-24], but another study did not observe this association[11]. A recent report by Sekine *et al*[25] showed that cytological or histological specimens obtained by EUS-FNAB met the diagnostic criteria of GIST in 81.3% of the cases, even among small GISTs (< 20 mm). In their procedure, the samples obtained by EUS-FNAB were examined immediately with a rapid staining method to verify the adequacy of the specimen and to provide a presumptive diagnosis. It was reported that when an on-site cytopathologist immediately reviewed the adequacy of the samples, the sensitivity of EUS-FNAB was > 90%[23,26]. It was also suggested that the sensitivity of EUS-FNAB drops by 10%-15% in the absence of an on-site pathologist to evaluate the cellular adequacy of the samples[27]. However, this diagnostic procedure for cytology during an EUS-FNAB may be troublesome for not only endoscopists but also cytology technicians in daily medical practice. For this reason, an easy and useful diagnostic tool for SMT regardless of the tumor size is needed.

In the present study, the histological diagnosis rate of MCB was significantly higher than that of EUS-FNAB in the lesions with intraluminal growth (P = 0.01). In addition, all four extraluminal-growth tumors could be histologically diagnosed only by EUS-FNAB. The diagnostic capability of MCB was thus increased from 60% to 75% when the four cases with extraluminal growth were excluded. Additionally, when we examined the histological diagnosis for both methods together, the accurate histological diagnosis increased to 85%. In previous studies, the accurate histological diagnosis of MCB ranged from 85% to 100%[16-18], which is relatively higher than that of our study. One of the reasons for the differences in diagnostic yield may be that the numbers of cases in those studies were relatively small, and they were retrospective studies. To date, there are two studies that compared the diagnostic yield between the jumbo biopsy "unroofing" technique and EUS-FNAB[28,29]. The results of both studies indicated a lower diagnostic yield than ours. In those studies, the diagnostic procedures (*i.e.*, jumbo biopsy *vs* EUS-FNAB) were not performed during the same session in the same patients, as was done in our study. In addition, both studies[28,29] included many cases of lipoma (16.6%-22.1%), which is considered to be easily diagnosed by the jumbo biopsy unroofing technique or only by EUS.

The diagnostic yield of the EUS-FNAB method in the present study was relatively lower compared to previous reports[26,30]. One of the reasons might be an effect of the difference in the FNA needle size used for the EUS-FNABs. The larger-bore 19-gauge needle may actually show a higher diagnostic yield compared to the 22-gauge needle used in the present study[24,31], but the exact difference in diagnostic yield between 19- and 22-gauge FNA needles remains unclear[24,30]. We did not adequately assess procedural factors such as the needle gauge and the number of needle passes in the present study. More passes or the use of a larger-bore needle would provide more tissue. However, Sepe *et al*[23] reported that the number of passes did not significantly affect the diagnostic capability of EUS-FNAB. In their study, as is standard practice, this decision regarding the number of passes was made at the discretion of the individual endosonographer and was based on a real-time assessment of presumed tissue adequacy, as in our study, and our finding is in agreement with their result[23].

No major complications were caused by either the EUS-FNAB or MCB method in the present study, although mild bleeding occurred in two cases during the MCB; both were successfully managed by hemoclips. Perforation did not occur in any of the 20 patients during MCB, but extra care should be taken to prevent perforation in cases with extraluminal growth[17]. A laparoscopic and endoscopic cooperative surgery (LECS) is now being performed for the treatment of gastrointestinal SMTs[32,33]. However, the MCB method is unlikely to preclude LECS for the treatment of SMTs.

The present study had some potential limitations. First, the sample size of this study was small and drawn from a single institution. When the diagnostic yield is assumed to be approximately 70% for the EUS-FNAB without cytology method and approximately 90% for the MCB method, 62 patients with SMT are needed in each group in order to have a power of 80% to detect a difference at the level significance of α = 0.05 (two-sided).

Second, there is the issue of EUS-FNAB- and MCB-related dissemination as a late complication, but this has not been reported to date. It is important to close the mucosal incisions appropriately with endoclips after tissue sampling to prevent post-procedure complications in MCB[17]. Third, if the diagnostic yield of the combination of EUS-FNAB and MCB is assessed, the histological diagnosis by the two methods should be compared to that of a surgically resected whole specimen as a "golden standard."

In conclusion, although EUS-FNAB is the widely used gold standard for the histological and cytological diagnoses of gastric SMTs, MCB may be chosen as an alternative diagnostic modality in tumors showing the

intraluminal growth pattern. A randomized controlled trial to compare the capability of MCB with that of EUS-FNAB is needed.

COMMENTS

Background

As gastric submucosal tumors (SMTs) comprise both benign and malignant lesions, histological diagnosis is needed. Endoscopic ultrasonography-guided fine-needle aspiration biopsy (EUS-FNAB) is a useful method for the histological evaluation of SMTs. However, EUS-FNAB systems are very expensive and require experienced pathologists and cytology technicians, and thus this procedure may be unavailable in hospitals not specializing in gastroenterology.

Research frontiers

Although the diagnostic yields of EUS-FNAB and mucosal cutting biopsy (MCB) have been reported, there are no studies comparing the diagnostic capabilities of EUS-FNAB and MCB based on endoscopic submucosal resection in the same patients. The authors prospectively compared the diagnostic yield, feasibility, and safety of these two methods.

Innovations and breakthroughs

In this prospective study, no significant difference in histological diagnosis was found between EUS-FNAB and MCB regardless of tumor location and tumor size. However, diagnostic specimens were significantly more frequently obtained in the lesions with intraluminal growth compared to those with extraluminal growth by the MCB method. All SMTs with extraluminal growth were diagnosed only by EUS-FNAB, not by MCB. No complications were produced by either method.

Applications

MCB may be chosen as an alternative diagnostic modality in tumors showing an intraluminal growth pattern regardless of tumor size, whereas EUS-FNAB should be performed for SMTs with extraluminal growth.

Terminology

EUS-FNAB: This method is a needle biopsy procedure considered to be a reliable and accurate method for the evaluation of SMTs in the gastrointestinal tract; gastrointestinal stromal tumor (GIST): GISTs are the most common mesenchymal neoplasms of the gastrointestinal tract.

Peer-review

The authors present an interesting result regarding the efficacy of MCB in the histological diagnosis of SMTs. This procedure will be accepted widely even in hospitals not specializing in gastroenterology.

Abstract

Laparoscopic wedge resection is a useful procedure for treating patients with submucosal tumor (SMT) including gastrointestinal stromal tumor (GIST) of the stomach. However, resection of intragastric-type SMTs can be problematic due to the difficulty in accurately judging the location of endoluminal tumor growth, and often excessive amounts of healthy mucosa are removed; thus, full-thickness local excision using laparoscopic and endoscopic cooperative surgery (LECS) is a promising procedure for these cases. Our experience with LECS has confirmed this procedure to be a safe, feasible, and minimally invasive treatment method for gastric GISTs less than 5 cm in diameter, with outcomes similar to conventional laparoscopic wedge resection. The important advantage of LECS is the reduction in the resected area of the gastric wall compared to that in conventional laparoscopic wedge resection using a linear stapler. Early gastric cancer fits the criteria for endoscopic resection; however, if performing endoscopic submucosal dissection is difficult, the LECS procedure might be a good alternative. In the future, LECS is also likely to be indicated for duodenal tumors, as well as gastric tumors. Furthermore, developments in endoscopic and laparoscopic technology have generated various modified LECS techniques, leading to even less invasive surgery.

Key words: Cooperative surgery; Endoscopy; Gastrointestinal tumor; Laparoscopy; Submucosal tumor

Core tip: Resection of intragastric-type submucosal tumor can be problematic due to the difficulty in accurately judging the location of endoluminal tumor growth, and often excessive amounts of healthy mucosa are removed; thus, full-thickness local excision using laparoscopic and endoscopic cooperative surgery (LECS) is a promising procedure for these cases. The important advantage of LECS is the reduction in the resected area of the gastric wall compared to that in conventional laparoscopic wedge resection using a linear

stapler. Developments in endoscopic and laparoscopic technology have generated various modified LECS techniques, leading to even less invasive surgery.

Laparoscopic endoscopic cooperative surgery as a minimally invasive treatment for gastric submucosal tumor. *World J Gastrointest Endosc* 2015; 7(14): 1150-1156 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i14/1150.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i14.1150

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are common mesenchymal tumors among submucosal tumors (SMTs) of the gastrointestinal tract. Complete resection of GISTs is recommended because of their malignant potential, such as risk of tumor recurrence and progression to metastatic disease[1,2]. Lymphadenectomy is not recommended as lymph node involvement is rare. Laparoscopic surgery for GISTs is safe and effective and provides a minimally invasive approach for tumors less than 5 cm in diameter[3-5].

Extragastric-type SMTs can be treated relatively easily using a conventional laparoscopic wedge resection with adequate margins. However, resection of intragastric-type SMTs can be more problematic due to the difficulty of accurately judging the tumor's location under laparoscopic examination. This results in the necessity of removing relatively large sections of healthy stomach to remove the tumor, which sometimes leads to postoperative deformity of the stomach[6].

Laparoscopic endoscopic cooperative surgery (LECS) was first reported by Hiki *et al*[7,8] in 2008, and is a minimally invasive surgical technique designed to resect SMTs originating in the gastrointestinal tract. In recent years we have performed LECS in patients presenting with gastric SMT with mainly intraluminal growth. In the present study, we reviewed a number of clinical reports describing LECS, including our own series, to evaluate the procedure and its clinical outcomes.

CASE REPORT

LECS requires the participation of experienced laparoscopic surgeons and experienced endoscopists[7,8]. After inducing general anesthesia, a port for a camera is inserted through the umbilicus using an open technique, and a pneumoperitoneum is established by insufflation of carbon dioxide to 8-10 mmHg abdominal pressure. Four additional ports, two 5-mm ports and two 12-mm ports, are inserted into the upper left and right and lower left and right quadrants, respectively. The proximal jejunum near the ligament of Treitz is clamped using detachable forceps to avoid air inflating the distal intestine during endoscopic manipulation. When confirmation of the tumor location from the serosal side is difficult, it is confirmed by an intraluminal approach using endoscopy (Figure 1A). Blood vessels in the excision area around the tumor are then prepared using ultrasonically activated laparoscopic coagulating shears (Figure 1B).

The location of the tumor is first confirmed endoscopically, followed by submucosal dissection using intraluminal endoscopy to determine an appropriate resection line (Figure 1C). Endoscopic submucosal dissection (ESD) is widely accepted as the standard treatment for early gastric cancer without lymph node metastasis and enables a clinician to resect a target lesion *en bloc*[9]. This technique is applied to LECS using various endoscopic devices such as a needle knife to mark the mucosal resection line and an insulation-tipped diathermic electrosurgical (IT) knife to dissect the submucosal layer. After circumferential dissection of the mucosal to submucosal layers, a full-thickness incision into the serosal layer around the lesion is made using the needle knife to connect the endoscopic and laparoscopic approaches.

Subsequently, an ultrasonic coagulation incision device is inserted into the artificial perforation under laparoscopic view, and the seromuscular layer is dissected along the incision line made by ESD (Figure 1D). After circumferential full-thickness resection (Figure 1E), the resected specimen is put into a plastic bag, which is then removed through the umbilical incision. The edges of the incision line are then lifted up by an assistant using forceps, and the incision line is closed using laparoscopic stapling devices (Figure 1F). After completing the full-thickness closure, the endoscope can be inserted into the stomach to confirm that there is no air leakage, despite insufflation of the stomach. Gross examination of the resected specimen reveal that the resection margin of healthy gastric wall is limited to the minimum necessary (Figure 2).

Table 1 details the clinicopathological results of 19 patients who underwent laparoscopic resection for SMT in the stomach at the Kochi Medical School Hospital. Conventional laparoscopic resection of the tumor was undertaken in 11 patients, and LECS was performed in 8 patients. Basically, the indications of laparoscopic surgery including LECS for gastric SMT include the tumors less than 5 cm detected on esophagogastroduodenoscopy, computed tomography or upper gastrointestinal barium study. We performed LECS for gastric SMT when the main tumor location was intragastric type. Until the advent of LECS, we performed conventional laparoscopic resection for the gastric SMT less than 5 cm in diameter even if the main tumor location was intragastric type.

The median age of patients was 72 years (range, 35-86 years), and there was a female predominance, with a male-to-female ratio of 5:14. The tumor was located in the upper third of the stomach in 9 patients, in the middle third in 6 patients, and in the lower third in 4 patients. The tumor circumference included the lesser curvature in 7 patients, greater curvature in 7 patients, posterior wall in 4 patients, and anterior wall in 1

Table 1 Characteristics of patients who underwent laparoscopic surgery for a gastric submucosal tumor

Patient	Age	Gender	Tumor location	Main location of tumor	Operation method	Operating time (min)	Estimated blood loss (mL)	Tumor size (cm)	Histology
1	78	M	M, Less	Extragastric	Conventional laparoscopic approach	145	20	4.0 × 3.5	GIST (low risk)

LECS: Laparoscopic endoscopic cooperative surgery.

patient. The median tumor diameter was 3.5 cm (range, 1.7-5.5 cm), the median operating time was 175 min (range, 85-250 min), and the median estimated blood loss was 5 mL (range, 0-130 mL). The main location of the tumor was intragastric in 9 patients, extragastric in 6, and mixed (both intragastric and extragastric) in 4. The histological diagnosis was GIST in 17 patients, and schwannoma in 2 patients. Of the patients with GISTs, 2 were classified as very low risk, 12 as low risk, 2 as intermediate risk, and 1 patient as high risk, according to the modified Fletcher classification[10,11]. There were no remarkable postoperative complications including mortality, leakage or surgical site infection.

Table 2 compares the clinicopathological characteristics of the 19 patients in our current series who underwent either conventional laparoscopic surgery (n = 11) or LECS (n = 8) for gastric SMT. The clinicopathological characteristics included the tumor location, major axis of the tumor, estimated blood loss, and operating time. The median estimated blood loss in patients who underwent LECS tended to be smaller than in those who underwent conventional laparoscopic surgery (5 mL *vs* 20 mL, respectively; P = 0.06). The median operating time of patients who underwent LECS also tended to be longer than those who underwent conventional laparoscopic surgery (213 min *vs* 155 min, respectively; P = 0.05). There were no significant differences in the median age, gender, tumor location,

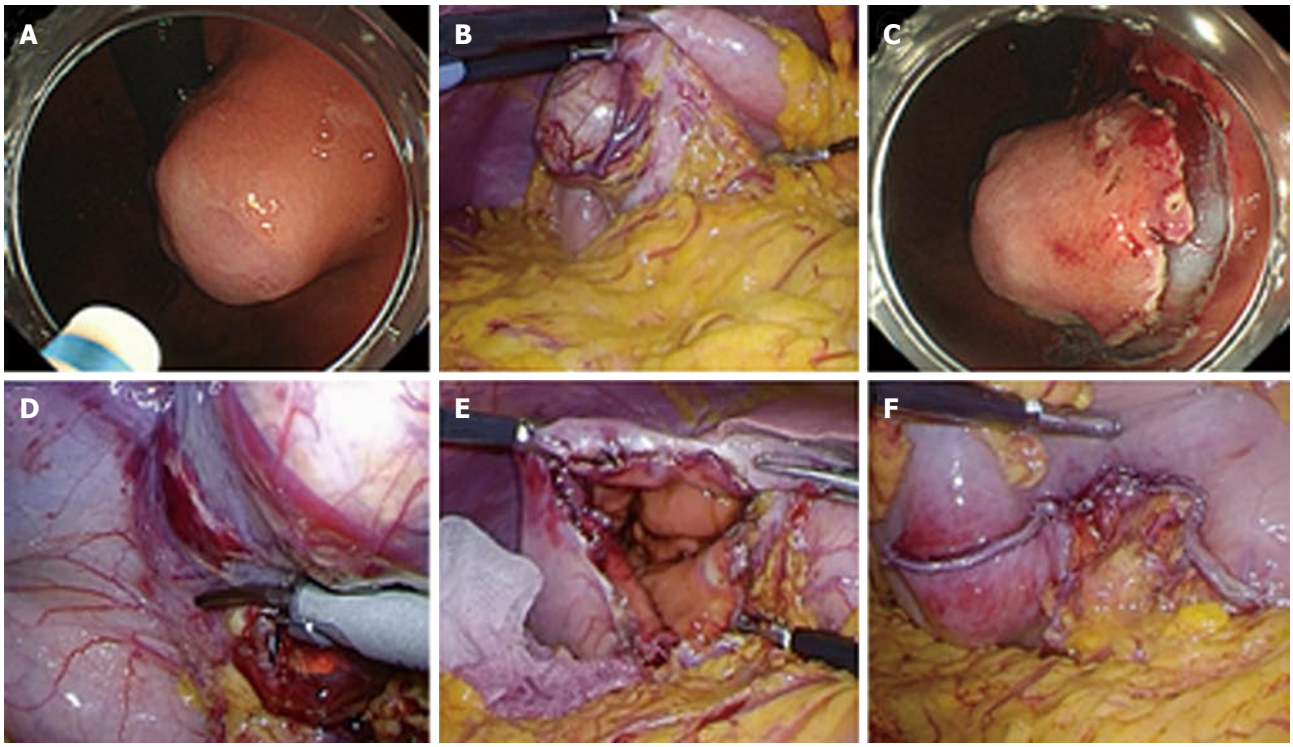

Figure 1 Laparoscopic endoscopic cooperative surgery for gastric submucosal tumor. A: The tumor is located in the lesser curvature of the middle third of the stomach; B: The stomach was mobilized by dividing the gastrocolic omentum and the lesser curvature vessels near the tumor by laparoscopic dissection; C: A circumferential incision was made around the tumor by an endoscopic submucosal dissection technique using an insulation-tipped diathermic electrosurgical knife; D: The seromuscular layer of the stomach was dissected along the incision line using the laparosonic coagulating shears; E, F: The post-excisional hole in the stomach was closed using a laparoscopic linear stapling device.

Figure 2 Gross appearance of the resected specimen. The tumor is a mixed-type, with a predominant intragastric component. The resection margin of healthy gastric wall is limited to the minimum necessary. The pathological diagnosis confirmed a gastrointestinal stromal tumor, classified as low risk.

or median tumor size in patients who underwent conventional laparoscopic surgery compared to LECS.

DISCUSSION

Conventional surgical operations may be excessively invasive for the treatment of gastrointestinal SMT. Successful laparoscopic wedge resection has been reported for 2-5 cm gastric GISTs, and confirmed by studies examining long-term surgical outcomes[3,12,13]. However, it is sometimes difficult to determine the appropriate resection line from the outside of the stomach when tumors are located intragastrically. There have been several reports on the use of LECS for SMT of the stomach including GISTs, leiomyomas, and schwannomas[6,7,14-19]. Table 3 summarizes the clinical variables of patients from a number of studies who underwent LECS, including our own series.

Kawahira *et al*[14] reported that the median ratio of the longest diameter of the tumor divided by the longest diameter of the surgical specimen was significantly greater in LECS compared to laparoscopic wedge resection (0.86 *vs* 0.69, respectively; P = 0.02). This means that LECS results in the resection of a smaller area of healthy gastric wall, which is an important advantage of LECS over conventional laparoscopic wedge resection using linear staplers. Therefore, LECS has good prospects for the treatment of GISTs, applying the modern concept of minimally invasive surgery, regardless of the location of the tumor even if it is adjacent to the esophagogastric junction or pyloric ring[16].

In our series, there was a tendency for the estimated blood loss to be lower in the LECS group than in the conventional laparoscopic resection group, with the difference just failing to reach significance. A major reason for this lower blood loss is that in the case of intragastric-type SMT, division of the extended gastric vessels or the omentum in the excision area around the tumor is needed to maintain a safe margin from the

tumor. There was also a tendency for longer operation times in the LECS group than in the conventional laparoscopic resection group, although this difference was not significant. This longer operation time for LECS is not surprising since time is required for both the ESD and laparoscopic procedures. Previous studies have not shown any difference in perioperative outcomes between LECS and the conventional approach, and a larger sample size would be useful to clarify this issue.

Developments in endoscopic and laparoscopic technology have yielded various modified LECS techniques aimed at further minimizing invasiveness. Examples of these improved techniques include the laparoscopy-assisted endoscopic full-thickness resection, a full-thickness resection method using the non-exposure technique (CLEAN-NET), and non-exposed endoscopic wall-inversion surgery (NEWS)[20-22]. Because LECS has an inherent risk of peritoneal infection due to the necessity for gastric perforation, CLEAN-NET and NEWS have been developed to prevent the risk of cancer cells seeding during open gastrectomy. These procedures might thus have potential minimally invasive resections of gastric tumors, even those in an ulcerated state[22].

Single-port LECS, which is a single-incision laparoscopic surgery combined with an endoscopic approach, might provide an alternative to gastric wedge resection with minimal transformation of the stomach[23]. It may contribute to reduced pain, faster recovery, and improved cosmesis for patients. However, careful selection of patients based on the tumor location and growth morphology is needed to clearly identify the risks and benefits of this new approach, also taking into account the need for needlescopic instruments.

Initially, the indication criteria for LECS was limited to SMT of the stomach measuring up to 5 cm in diameter without ulceration of the mucosa[7]. In the future, it is likely that LECS will also be indicated for tumors of the duodenum[24,25]. Although ESD is widely accepted as the standard treatment for gastric lesions including early gastric cancer, the duodenal wall is generally thinner than that of the stomach and ESD for duodenal tumors is associated with an increased risk of perforation[25]. Furthermore, maneuvering a flexible endoscope is technically difficult in the tiny duodenal lumen. In these cases, LECS might be a useful therapeutic modality not only for avoiding perforation of the duodenal wall by ESD, but also for achieving a more precise incision line[24].

Moreover, Nunobe *et al*[26] reported the successful use of LECS for a large spreading mucosal cancer in the stomach that would have been difficult to treat with ESD because of the high likelihood of complications and the long surgical time required for ESD. Thus, early gastric cancer that fits the criteria for endoscopic resection, but presents difficulties for ESD, is likely to be a candidate for the LECS procedure[26].

In conclusion, recent advances in endoscopic and laparoscopic techniques have facilitated several variations of endoscopic procedures derived from ESD, and created a fusion of endoscopy and laparoscopy technologies suitable for upper gastrointestinal SMTs. LECS is a useful and safe procedure for SMT that avoids excessive resection of healthy gastric wall. Further investigations, including a prospective randomized controlled trial and a study exploring long-term consequences, are needed to verify the usefulness of the LECS for gastrointestinal SMT.

COMMENTS

Case characteristics

The authors demonstrated the patients with gastric submucosal tumor treated by laparoscopic surgery.

Clinical diagnosis

The subjects were the gastric submucosal tumors including intragastric and extragastric type.

Differential diagnosis

Histopathological diagnosis of submucosal tumors includes gastrointestinal stromal tumor and schwannoma.

Laboratory diagnosis

Laboratory findings were within the normal range.

Imaging diagnosis

The gastric submucosal tumors were diagnosed by computed tomography and esophagogastroduodenoscopy.

Pathological diagnosis

Pathological findings of gastrointestinal stromal tumor were characterized by

interlacing bundles of elongated cells with c-KIT expression.

Treatment
The patients were treated by conventional laparoscopic wedge resection or laparoscopic endoscopic cooperative surgery.

Related reports
The authors summarized the clinical variables of patients from a number of studies who underwent laparoscopic endoscopic cooperative surgery, including their own series.

Term explanation
Laparoscopic surgery for submucosal tumors effective and provides a minimally invasive approach for tumors less than 5 cm in diameter.

Experiences and lessons
Laparoscopic endoscopic cooperative surgery is a useful and safe procedure for submucosal tumor that avoids excessive resection of healthy gastric wall.

Peer-review
Further investigations, including a prospective randomized controlled trial and a study exploring long-term consequences, are needed to verify the usefulness of the laparoscopic endoscopic cooperative surgery for gastrointestinal submucosal tumors.

Abstract

Recent advances in imaging technology have resulted in an increase in incidental discoveries of pancreatic cystic lesions. Pancreatic cysts comprise a wide variety of lesions and include non-neoplastic cysts and neoplastic cysts. Because some pancreatic cysts have more of a malignant potential than others, it is absolutely essential that an accurate diagnosis is rendered so that effective care can be given to each patient. In many centers, endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA) has emerged as the modality of choice that enables one to distinguish between mucinous and non-mucinous lesion, diagnose malignancy and collect cyst fluid for further diagnostic studies, such as pancreatic enzyme levels, molecular analysis and other tumor biomarkers. The current review will focus on EUS-guided FNA and the cytological diagnosis for pancreatic cysts.

Key words: Pancreatic cyst; Endoscopic ultrasound; Fine needle aspiration; Diagnosis; Cystic fluid analysis; Cytology

Core tip: Pancreatic cysts comprise non-neoplastic cysts and neoplastic cysts. It is absolutely essential that an accurate diagnosis is rendered so that effective care can be given to each patient. In many centers, endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA) has emerged as the modality of choice that enables one to distinguish between mucinous and non-mucinous lesion, diagnose malignancy and collect cyst fluid for further diagnostic studies, such as pancreatic enzyme levels, molecular analysis, and other tumor biomarkers. The current review will focus on EUS-guided FNA and the cytological diagnosis and new classification for pancreatic cysts.

INTRODUCTION

The overall prevalence for cystic lesions of the pancreas has been estimated to be no more than 1% of all pancreatic neoplasms[1]. However, the advent of high-resolution imaging modalities has led to the increased frequency of incidentally discovered pancreatic cysts. In the United States, a prevalence of incidental pancreatic cysts estimates about 2.6% to 13.5% of adults[2-4]. The increasing incidence of pancreatic cystic lesions has been directly linked to increasing age[5]. Pancreatic cystic lesions are also being detected sooner rather than later as reflected in the decreasing median sizes of pancreatic cysts both in the United States and in other countries[6]. Although a recent study suggests that only 2% of pancreatic cysts are malignant at diagnosis[7], the trend of increasing discovery of pancreatic cysts is significant because some types of pancreatic cystic lesions carry an augmented risk for malignant transformation.

Pancreatic cysts comprise a wide variety of lesions and include non-neoplastic cysts and neoplastic cysts. The classification and nomenclature of pancreatic cysts are very important for pathologic and clinical diagnosis. The non-neoplastic cysts include pseudocysts, retention cysts, lymphoepithelial cysts, benign epithelial cysts, and congenital cysts. Non-neoplastic cysts are believed to have low to no malignant potential. Neoplastic cysts are typically categorized as mucinous and non-mucinous based on the type of epithelium they possess[8]. The mucinous cysts consist of mucinous cystic neoplasms (MCN) and intraductal papillary mucinous neoplasms (IPMN). The non-mucinous cysts include serous cystadenomas, solid pseudopapillary neoplasms (SPN), cystic pancreatic neuroendocrine tumors (PNET), cystic pancreatic ductal adenocarcinomas (PDA) and its variants, cholangiocarcinoma, acinar cell carcinoma, high-grade neuroendocrine carcinoma (small cell and large cell), pancreatoblastoma, lymphomas, sarcomas, and metastatic tumors. The neoplastic cysts are categorized as being malignant (*i.e.*, PDA, PNET) or having malignant potential (*i.e.*, MCN, IPMN, SPN). Among mucinous subtypes of cysts, it has also been suggested that branch duct IPMN (BD-IPMN), while having malignant potential, may exhibit more indolent behavior compared to main duct-IPMN[9,10].

The management options for pancreatic cystic lesions are as varied as the lesions they are designed to diagnose and treat. Endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA) is a major technique used in many institutions to sample pancreatic cystic lesions. As will be described in this review, there are multiple ways available to further study these lesions, including cytologic diagnosis and cystic content analysis by chemical and molecular tests. A new histologic classification system for pancreatic lesions has also been introduced to help clinicians and patients understand the malignant potential of each type of pancreatic lesion. Based on new diagnosis and classification of the cystic lesions, most patients need no further treatment. However, many patients require surveillance or other more invasive therapies (*i.e.*, surgical resection) depending upon the risk of malignant transformation. Hence, obtaining an accurate differential diagnosis is of utmost importance in properly managing these patients in such a way that minimizes risk of complications[11].

EUS-GUIDED FNA SAMPLES FOR PANCREATIC CYSTS

Initial imaging studies

The initial clinical workup for incidentally discovered pancreatic cysts involves the use of radiologic imaging to further characterize the lesion[12]. MRI with magnetic resonance cholangiopancreatography (MRCP) is the preferred method over pancreatic protocol multidetector (MD) CT because MRCP is able to evaluate the presence of septa, nodules, main-duct involvement, and branch duct involvement. In many cases, it is also able to accurately distinguish between mucinous and non-mucinous cysts[13,14]. Studies have also found that, within the proper clinical context, MRI and CT are capable of determining which pancreatic cystic lesions are more likely to be malignant[15,16]. This is especially true if the features pathognomonic for a given lesion are present. However, in many instances, the combined clinical and radiologic picture is unable to elucidate the type of lesion or its likelihood of harboring malignancy, thus making definitive treatment difficult to achieve. Much of this has to do with the fact that morphologic features of many pancreatic cystic lesions frequently overlap and can appear similar on imaging studies[17]. In this regard, cytologic diagnosis with EUS-FNA is a good means to arriving at a more definitive diagnosis.

EUS-FNA procedure for pancreatic cysts

EUS-guided FNA is a safe procedure that employs the use of an image guidance system and an endoscope that is passed through the esophagus and into the stomach and/or duodenum. Because the importance of obtaining a good sample as well as adequate sample preparation cannot be overemphasized, many centers perform EUS-guided FNA in conjunction with rapid on-site evaluation (ROSE) by a cytopathologist or cytotechnologist. ROSE has been shown to improve the diagnostic yield of specimens and turnaround time obtained by EUS-guided FNA[18-21]. During ROSE, a cytopathologist or cytotechnologist screens air-dried smears that are first stained with rapid-Romanowsky method, such as Diff-Quik® and Hemacolor®, in order to

determine specimen adequacy and to give a preliminary diagnosis, if possible. The rest smears can be alcohol-fixed and stained with the Papanicolaou stain. Additional FNA samples are collected in saline or other alcohol-rich preservative solutions for liquid-based preparations (*i.e.*, ThinPrep®, SurePath®), cytocentrifuge preparations, or cell blocks. Cell blocks are especially helpful in the event that immunohistochemistry is needed to differentiate between the different types of pancreatic lesions. Specimens obtained by EUS-guided FNA can also be used for further diagnostic studies, such as enzymatic testing and molecular testing (to be discussed below in detail in this review).

The advantages of EUS-guided FNA are numerous and include direct real-time visualization of the needle, identification of smaller lesions that can be missed by imaging studies, as well as identification of local metastases and invasion of structures[22]. One study recently showed that the incremental increase in diagnostic yield of EUS and fluid analysis over CT and MRI for prediction of a neoplastic cyst is 36% and 54%, respectively. Complication rates were also low, with pancreatitis being the most common complication (1.1%)[23]. One large prospective multicenter study revealed a complication rate of 6%; bleeding was the most common complication[24]. An extremely rare complication associated with EUS-guided FNA is tumor seeding, especially with IPMN[25-27].

Despite the high specificity of EUS-guided FNA, the main disadvantage that comes with EUS-guided FNA is that samples obtained are often hypocellular. The study by de Jong *et al*[28] showed that a cytopathologic diagnosis was only possible in one-third to one-half of all cases examined. However, it has also been suggested that the sensitivity, which can range from 60% to 100%, often depends upon an institution's experience with the technique[29]. One way to potentially overcome the low sensitivity of this procedure is to do cystic wall puncture (CWP), a procedure in which a targeted FNA of the cyst wall is performed after removal of cyst fluid. One study utilizing this method reported adequate cytologic material in 81% of all cases. Complication rate was minimal with only one patient developing mild pancreatitis post-CWP[30]. The study by Rogart *et al*[31] also showed that CWP may also be helpful in increasing the diagnostic yield of mucinous cystic lesions of the pancreas. Furthermore, there are some important diagnostic pitfalls. For example, GI contamination can cause one to interpret an inadequate specimen as adequate, thus leading to a false-negative diagnosis. Conversely, markedly reactive epithelial cells can be mistaken for malignancy[32,33]. Fortunately, it is possible to avoid these diagnostic pitfalls by making sure cytopathologists have a working knowledge of normal, reactive, and neoplastic pancreatic conditions as well as being sure to correlate all cytologic findings with each patient's clinical history and imaging studies.

DIAGNOSIS OF PANCREATIC CYSTS BY CYTOLOGY

Standardized terminology and classification of pancreatic cysts

Aspirates obtained from EUS-guided FNA are graded in much the same way as aspirates obtained for other non-gynecological specimens. Specimens that lack sufficient cytologic material to render a diagnosis are designated as "unsatisfactory". Specimens that have adequate cytologic material and that are helpful in explaining the presence of a radiologically detected lesion are designated as "satisfactory". Satisfactory specimens are further characterized as "negative for malignancy", "atypical", "benign neoplasm", "suspicious for malignancy" or "positive for malignancy" depending upon the degree of cytologic atypia, cellularity (or lack thereof) and other background features present. Wherever possible, more descriptive terms are also used if a specific pathologic diagnosis can be made. However, there is variable, if not conflicting terminology, used in different institutes and even by individual pathologists. Therefore, tremendous effort has been made to develop a standardized system of classification for pancreatic cytopathology. Recently, Pitman *et al*[34] published a "standardized terminology and nomenclature for pancreatobiliary cytology: The Papanicolaou Society of Cytopathology Guidelines" (see modified guideline in Table 1). In their categorization, "Non-Diagnostic" lesions are in Category I, lesions classified as "Negative for Malignancy" are in Category Ⅱ, "Atypical" lesions are in Category Ⅲ, lesions classified as "Suspicious for Malignancy" are in Category Ⅴ, and lesions that are "Malignant" are in Category Ⅵ. Category Ⅳ consists of Category ⅣA for "Neoplastic: Benign" and Category ⅣB for "Neoplastic: Other". Serous cystadenoma is the main neoplasm in Category ⅣA. In Category ⅣB, they include both mucinous neoplasms, such as IPMN and MCN, and non-mucinous neoplasms, such as pancreatic endocrine tumor. However, as detailed below, the morphologic, molecular, and immunohistochemical features are very different for these lesions, with mucinous neoplasms having a greater potential to become malignant than non-mucinous neoplasms. Therefore, we suggest that Category ⅣB should be further separated into Category ⅣB1 as "Neoplastic: Mucinous neoplasm" and Category ⅣB2 as "Neoplastic: Non-mucinous neoplasm". IPMN, MCN, and intraductal papillary neoplasm of the bile ducts should be included in Category ⅣB1, and pancreatic endocrine neoplasm, SPN, and the rare gastrointestinal stromal tumor should be in Category ⅣB2. Nevertheless, this classification system serves a significant step towards a much needed uniform categorization of these lesions. Ultimately, the authors hope that each category of pancreatic tumor will be further discussed with gastroenterologists, GI surgeons, and GI oncologists. The following section will

Table 1 Pancreatic cytology terminology (modified from pitman *et al*[34], 2014)

Terminology category	Definition	Example interpretations
Category Ⅰ: Non-diagnostic	No diagnostic or useful information about the solid or cystic lesion sampled	Gastrointestinal contamination only; Non-specific cyst contents with insufficient cyst fluid volume for ancillary testing; Evaluation limited by scant cellularity
Category Ⅱ: Negative (for malignancy)	Adequate cellular and/or extracellular tissue to evaluate	Benign pancreatobiliary tissue in the setting of vague fullness and no discrete mass Acute pancreatitis Chronic pancreatitis Autoimmune pancreatitis Pseudocysts Lymph epithelial cyst Spleenful/accessory spleen
Category Ⅲ: Atypical	Cells present with cytoplasmic, nuclear, or architectural features that are not consistent with normal or reactive cellular changes of the pancreas or bile ducts and are insufficient to classify them as a neoplasm or suspicious for a high-grade malignancy	Atypical ductal cells obscured by crush artifact Scant population of small monomorphic polygonal cells of unclear origin: Normal cigar cells *vs* endocrine proliferation Atypical bile duct epithelium with nuclear features suggestive of repair in a background of acute inflammation Atypical bile duct epithelium with mucinous metaplasia and mild nuclear atypia
Category ⅣA: Neoplastic: Benign	The presence of a cytological specimen sufficiently cellular and representative, with or without the context of clinical, imaging and ancillary studies, to be diagnostic of a benign neoplasm	Scant non-mucinous cuboidal epithelium and scant hemosiderin-laden macrophages in a non-mucinous cyst fluid consistent with the clinical impression of a serous cystadenoma
Category ⅣB1: Neoplastic: Mucinous neoplasm	Premalignant such as intraductal papillary neoplasm of the bile ducts (IPN-B), IPMN or MCN with low, intermediate or high-grade dysplasia by cytological criteria	MCN: Typically a multiloculated, mucin-producing epithelial neoplasm with sub epithelial ovarian-type stroma that in almost all cases does not communicate with the pancreatic ductal system and in almost all cases occurs in women; located in the body or tail; easily removed comparing life-long surveillance IPMN: Primarily intraductal proliferations of ductal epithelium creating a macroscopic lesion resulting in ductal dilatation, cyst formation and/or a mass lesion 1 Main-duct IPMN: Associated with diffuse dilatation of any portion of the main pancreatic duct or the entire pancreas 2 BD-IPMN: Cysts adjacent to a non-dilated main pancreatic duct IPN-B: A papillary proliferation of mucin containing neoplastic cells that may occur anywhere in the ductal system; similar to IPMN
Category ⅣB2: Neoplastic: Non-mucinous neoplasm	A low-grade malignant neoplasm such as well-differentiated PanNET, SPN or rare GIST	PanNET (pancreatic endocrine tumor and pancreatic endocrine neoplasm): A well-differentiated proliferation of the pancreatic endocrine cells creating a mass lesion greater than 0.5 cm that may or may not be functional by producing inappropriate levels of various hormones and that may or may not demonstrate aggressive features on histological examination SPN: A solid, secondarily cystic low-grade epithelial neoplasm with established clonal mutations in cancer-associated genes and an ability to metastasize GIST: Spindle cell and/or epithelioid mesenchymal neoplasms with differentiation along the lines of the interstitial cell of Cajal that usually expression c-kit protein (CD117), DOG1 and CD34 by immunohistochemistry; located in a peripanreatic location
Category Ⅴ: Suspicious (for malignancy)	when some, but an insufficient number of the typical features of a specific malignant neoplasm are present, mainly pancreatic adenocarcinoma	Rare markedly atypical epithelial cells suspicious for adenocarcinoma Mucinous cyst with high-grade epithelial atypia and abundant coagulate necrosis suspicious for invasive carcinoma Solid cellular neoplasm with features suspicious for acinar cell carcinoma. Tissue for confirmatory ancillary studies is not available
Category ⅥA: PDAC and variants	A group of neoplasms that unequivocally display malignant cytological characteristics and include PDAC and its variants, cholangiocarcinoma, acinar cell carcinoma, high-grade neuroendocrine carcinoma (small cell and large cell), pancreatoblastoma, lymphomas, sarcomas and metastases to the pancreas	PDAC: A malignant invasive gland (duct) forming epithelial neoplasm typically composed of classic tubular glands; 85%-90% of all pancreatic malignancies Colloid carcinoma (mucinous, non-cystic): Abundant extracellular mucin production, with at least 80% of the tumor on histology demonstrating large pools of extracellular mucin and cuboidal epithelial cells "floating" in the mucin

		Medullary carcinoma: Poor histologic differentiation, syncytial growth pattern, pushing borders and an intense lymphoplasmacytic response Undifferentiated carcinoma with osteoclast-like giant cells: Distinctive type of sarcomatoid carcinoma with the striking and unique cytohistologic features characterized by a prominent component of reactive osteoclast-like giant cells in a background of spindle cells. Undifferentiated carcinoma: A high-grade carcinoma composed of large, undifferentiated, markedly pleomorphic cells; 2%-7% of PDAC
Category ⅥA: Malignancy: Others	A group of neoplasms that unequivocally display malignant cytologic characteristics excluding PDAC and its variants; including acinar cell carcinoma, high-grade neuroendocrine carcinoma (small cell and large cell), cholangiocarcinoma, pancreatoblastoma, lymphomas, sarcomas and metastases to the pancreas	Cholangiocarcinoma: The diagnostic criteria for invasive cholangiocarcinoma are the same as for ductal adenocarcinoma; usually diagnosis by bile duct brushings with high false negative rate due to overlying benign epithelium, insufficient sampling, reactive change with stent; degeneration due to bile Acinar cell carcinoma: A rare malignant epithelial neoplasm with exocrine acinar differentiation Poorly-differentiated neuroendocrine carcinoma (small cell carcinoma or large cell neuroendocrine carcinoma): Rare high-grade neuroendocrine tumor with < 1% of pancreatic tumor and 2%-3% of PanNETs Pancreatoblastoma: A rare neoplasm, primarily of childhood, characterized by acinar differentiation, endocrine differentiation and distinctive squamoid nests Non-Hodgkin lymphoma: Rare and usually involve the pancreas secondarily Metastatic tumors: Secondary neoplasms involving the pancreas are rare; most common: Renal cell carcinoma

MCN: Mucinous cystic neoplasms; IPN-B: Intraductal papillary neoplasm of the bile ducts; IPMN: Intraductal papillary mucinous neoplasm; cPanNET: Pancreatic neuroendocrine tumor; SPN: Solid pseudopapillary neoplasms; PDAC: Pancreatic ductal adenocarcinomas.

now describe the cytologic features of some of the more common pancreatic cystic lesions in accordance with the current classification described by Pitman *et al*[34].

Pseudo cyst (category Ⅱ: Negative): Pseudocysts are the most common type of pancreatic cysts, accounting for at least 75% of all pancreatic cystic lesions. They generally arise in the setting of acute pancreatitis and are due to autodigestion of the pancreatic parenchyma. By definition, pseudocysts lack an epithelial lining and are instead composed of an inflammatory, fibrous capsule surrounding a region of necrosis. Aspirates are typically paucicellular and consist of granular debris, hemosiderin-laden macrophages, and bile (Figure 1A).

Lymphangiomas and lymphoepithelial cysts (category Ⅱ: Negative): Lymphangiomas and lymphoepithelial cysts are both very rare benign lesions of the pancreas. The former is characterized cytologically by a uniform population of small, round lymphocytes accompanied by histiocytes, plasma cells, centrocytes, and centroblasts, whereas the latter is characterized by numerous anucleated squamous cells and amorphous debris with rare to no lymphocytes present. Aspirates from lymphangiomas tend to be very cellular[35] (Figure 1B); however, aspirates from lymphoepithelial cysts are largely acellular. Although EUS-guided FNA may have a limited role in identifying lymphoepithelial cysts, it has been proposed that paying attention to signal intensity on MRI may be helpful in identifying these lesions preoperatively[36].

Serous cystadenoma (category ⅣA: Neoplastic: benign): Serous cystadenomas comprise 1% to 2% of all pancreatic neoplasms. There are two types that are named based on the number and size of its cysts. Serous microcystic adenomas, which are the more common of the two types, have numerous small cysts, whereas serous oligocystic adenomas have fewer but larger cysts. Serous cystadenomas occur most frequently in older women, with the preferred sites being the body and tail of the pancreas. Aspirates of serous cystadenomas are sparsely cellular and may contain rare fragments of flat sheets and/or loose clusters of cuboidal cells with glycogenated cytoplasm and indistinct cytoplasmic borders (Figure 1C).

Mucinous neoplasm (category ⅣB: Neoplastic: others): There are two distinctive types of mucinous tumors, namely MCN and IPMN. Because both of these entities share many morphologic features, it is almost impossible to tell the difference between the two based on cytomorphologic features alone. In these cases, direct correlation with clinical and imaging studies is required. In general, MCNs occur almost exclusively in middle-aged women, with most being located in the body or tail of the pancreas. Of note, these lesions are closed cysts that do not communicate with the ductal system. A defining histologic feature of these lesions is the presence of ovarian-type stroma directly beneath mucinous epithelium that is positive for estrogen and progesterone receptors. On the other hand, IPMN is seen more commonly in men and are typically seen in the head of the pancreas. Unlike MCN, IPMN is radiologically shown to communicate with the ductal system (typically involving the main pancreatic duct)

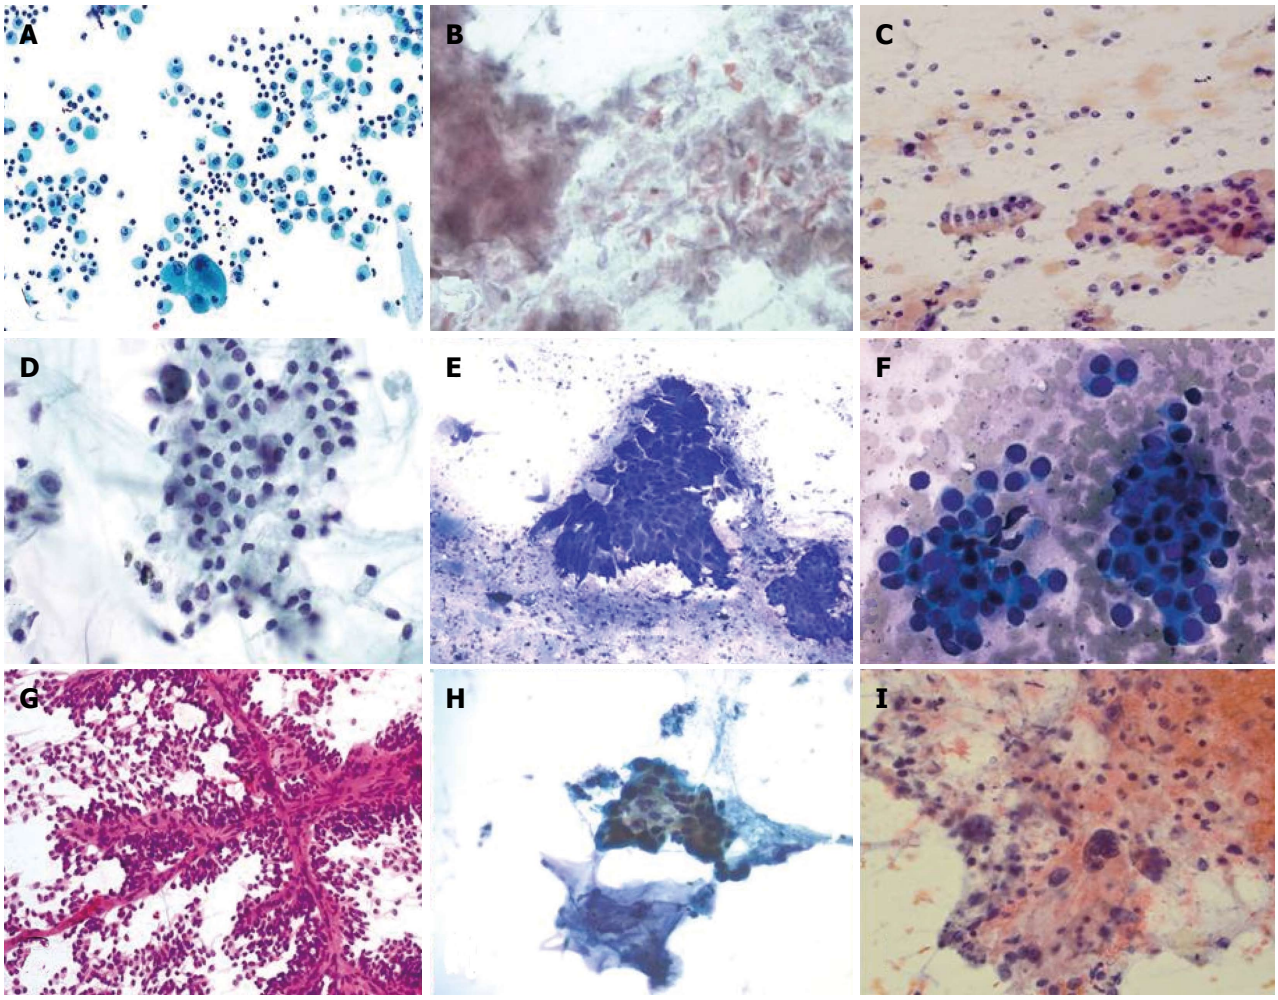

Figure 1 Cytopathologic features of pancreatic cysts. A: Pseudocyst: Notice the macrophages and inflammatory cells; epithelial cells are not seen; B: Lymphoepithelial cyst: Numerous anucleated squamous cells and keratinized debris are seen; C: Serous cystadenoma: One group of bland, monomorphic epithelial cells is present along with background histiocytes; D: Mucinous cystic neoplasm: A sheet of columnar cells with low-grad dysplasia in the background of mucin; E: Intraductal papillary neoplasm: Large papillary clusters are lined by tall, columnar cells containing intracytoplasmic mucin in the background extracellular mucin; F: Pancreatic neuroendocrine neoplasm: Bland, monomorphic epithelial cells with eccentrically placed nuclei arranged singly and in clusters characterizes this lesion; G: Solid pseudopapillary neoplasm: Notice the delicate, branching vessels and the poorly cohesive, bland epithelial cells; H: Pancreatic ductal adenocarcinoma with mucinous cyst: The ductal cells are arranged haphazardly and are characterized by hyperchromasia, nuclear pleomorphism and irregular nuclear contour; I: Undifferentiated carcinoma with osteoclast-like giant cells and mucinous cystic neoplasm: Multiple osteoclast-like giant cells and large haphazardly nucleus in the background of mucin.

and has the ability to grow along the entire length of the pancreatic duct and its branches. Aspirates of MCN and IPMN are hypocellular specimens that contain thick mucin and, if present, columnar mucinous sheets (Figure 1D and E). Cytologic interpretation is somewhat less problematic if nuclear and architectural atypia indicative of dysplasia or malignancy is identified. The WHO uses a three-tier classification based on degree of dysplasia present: benign, borderline, or malignant. Recent years, molecular tests such as KRAS and GNAS mutation are developed for differentiating MCN and IPMN. Nevertheless, given the malignant potential of these lesions, surgical resection is the most often utilized treatment of choice. Since cystic mucinous neoplasms have unique cytopathologic, molecular features and high risk for malignancy compared to non-mucinous neoplasms, we suggest that the Category Ⅳ B should be separated into two subcategories: Category ⅣB1: Neoplastic: Mucinous and ⅣB2: Neoplastic: Non-mucinous.

Cystic PNET (category ⅣB: Neoplastic: others): PNET represent approximately 1% to 2% of pancreatic neoplasms. Most PNET are small, functional solid tumors, but cystic pancreatic neuroendocrine tumors (cPanNETs) account for 13% to 17% of PanNETs[37]. PNET can secrete a variety of hormones, including insulin, glucagon, and somatostatin, and adrenocorticotrophic hormone. Although they can occur in any age group, they most commonly occur in adults. Aspirates of well-differentiated PNETs can range from sparsely cellular to highly cellular specimens consisting predominantly of abundant isolated cells and numerous bare nuclei. However, loosely cohesive clusters of cells and pseu-

dorosette formation are not uncommon. The cells are characterized by uniformly round, eccentrically placed nuclei with "salt-and-pepper" chromatin and moderate amounts of cytoplasm (Figure 1F). More poorly differentiated PNETs display more nuclear pleomorphic and higher mitotic activity. In doubtful cases, immunohistochemical stains for chromogranin and synaptophysin can be extremely helpful in confirming the diagnosis if the cell block is available. The surgical resection is the first line treatment. Enucleation or cytoreductive surgery is also recommended for patients with locoregional recurrences or hepatic metastases. Regional adjuvants such as radiofrequency ablation, transarterial chemoembolization, and others are often employed in an attempt to palliate symptoms and prolong survival[38]. Again, because cystic PNETs can be both functional and non-functional tumors with special morphological and immunohistochemical features, it should be separated from MCN into category IVB2: Neoplastic: Non-mucinous.

SPN (category ⅣB: Neoplastic: others): SPN are uncommon tumors of unknown malignant potential that predominantly occur in young women. Aspirates of these lesions are highly cellular, with the most characteristic features being myxoid or hyalinized vascular stalks lined by single or multiple layers of cells exhibiting round to oval nuclei, nuclear grooves, and indistinct cell borders (Figure 1G). Immunostain for β-catenin with nuclear positivity has emerged as a helpful attribute in diagnosing SPN. Other immunohistochemical stains that are helpful in confirming the diagnosis include CD10, CD56, vimentin and SMAD4. Surgical resection of these tumors leads to a good prognosis. With the special morphological features and immunohistochemical features of these lesions, SPN should be classified as Category ⅣB2: Neoplastic: non-mucinous.

Pancreatic ductal adenocarcinoma with cystic neoplasm (Category Ⅵ: Malignant): Pancreatic ductal adenocarcinomas (PDAC) with cystic neoplasm is the most common malignant cystic neoplasm of the pancreas and usually arises from MCN and IPMN. PDAC typically occur in older individuals, with smoking and alcohol abuse being major risk factors. Despite being able to detect these lesions at earlier stages, long term survival remains abysmal, with 90% of all patients dying within one year of diagnosis. Cytologically, aspirates are usually very cellular and consist of atypical ductal cells with irregular nuclear contours and prominent, centrally placed nucleoli arranged singly or in clusters and sheets (Figure 1H). Mitotic figures can also be seen.

Sensitivity and specificity of cytology based EUS-guided FNA

Although it has been established that EUS-guided FNA has a valuable role in the multidisciplinary approach to the management of pancreatic cystic lesions, much controversy remains in regards to its ability to accurately triage patients with incidentally discovered lesions that appear benign on imaging. In one of the early studies performed by Frossard *et al*[39] in 2003, it was determined that EUS-guided FNA successfully identified the lesion of interest in 65 cases (97%). The overall sensitivity, specificity, positive predictive value, and negative predictive value for EUS-guided FNA in this study were 97%, 100%, 100%, and 95%, respectively[39]. The cytologic diagnosis of cystic lesions with EUS-FNA has been studied extensively with widely variable sensitivity[40-44]. The sensitivity has been reported to range from 23% to 100% and specificity has been reported to range from 71% to 100%[40,45,46]. One meta-analysis showed that the pooled sensitivity and specificity in diagnosing mucinous cystic lesions were 63% and 88%, respectively, in 11 studies and 54% and 92%, respectively, in 4 prospective studies[45]. In one recently published meta-analysis study, the sensitivity and specificity of cytology was 0.42 and 0.99; the sensitivity and specificity of K-RAS was 0.39 and 0.95; and the sensitivity and specificity of the combined test of cytology and K-RAS was 0.71 and 0.88, respectively[47]. The sensitivity in our study (47%) was between two meta-analysis results[46]. We further studied the false negative rate of EUS-FNA, and we found that the false-negative rate (3%) caused by an interpretative error was significantly lower than that caused by a sampling error (23%) (P = 0.003). This finding suggests that sampling error, rather than interpretative error by cytology, is a major cause of high false-negative rates. We further examined the false-negative rate for solid lesions and cystic lesions. The false-negative rate for cystic lesions was significantly higher than that for solid lesions (53% *vs* 15%; P = 0.005). Recently, Rogart *et al*[31] reported that cyst wall puncture performed during FNA improved the diagnostic yield for mucinous cysts[31]. In addition, cytologic classification with high-grade epithelial atypia in cystic lesion FNA specimens demonstrated a higher prediction for malignancy and added value for the clinical evaluation of cystic lesions[42,48]. One study also found that certain factors, such as the identification of a solid component and performing more than one pass, resulted in significant increases in sensitivity (as high as 78%)[49]. In light of these issues with sensitivity, a newer series has suggested that EUS-guided FNA, when used in conjunction with other "screening" tests, contributes to a triple-negative screening test (*i.e.*, no high-risk stigmata, no worrisome features, and no high grade atypia on cytology) that has a negative predictive value for malignancy of 99%[50]. In general, EUS-guided FNA has a low sensitivity, but good specificity[45]. More sensitive and specific techniques are needed and should be developed as new technologies emerge, such as cystic fluid analysis by chemical or molecular tests and confocal laser endomicroscopy.

Recently, cystic PNET diagnosis and management received a lot of attention. In one study, cytology made a specific diagnosis of a cystic PNET in 71% of the biopsies

compared with a specific diagnosis by EUS in 38% of cases[37]. All cysts but one revealed low carcinoembryonic antigen (CEA) levels (range, 0.2 to > 500 ng/mL; mean, 29.5 ng/mL), and amylase levels were < 500 U/L in all but 2 cases (range, 16-1493 U/L; mean, 205 U/L). In another study, cystic PNETs were found to be larger than solid PNETs (mean 26.8 mm *vs* 20.1 mm, $P = 0.05$) and more frequently nonfunctional (96% *vs* 80%, $P = 0.03$). With histology as the reference standard, EUS-FNA accuracies for malignancy of cystic and solid PNETs were 89.3% and 90%, respectively; cystic PNETs were less associated with metastatic adenopathy (22% *vs* 42%, $P = 0.03$) and liver metastasis (0% *vs* 26%, $P < 0.001$). Cystic fluid analysis ($n = 13$), showed benign cystic PNETs had low CEA, Ki-67 ⩽ 2%, and no loss of heterozygosity (LOH). Patients with cystic and solid PNETs had similar recurrence risk up to 5 years after complete resection[51]. In one review which compared EUS and EUS-FNA for cystic PNET, they found that EUS-FNA cytology and cyst fluid analysis is a useful adjunct to abdominal imaging in the diagnosis of pancreatic cystic lesions. They hypothesize that cyst fluid characteristics, including cytomorphological features, is the most accurate test to achieve a preoperative diagnosis and to provide a basis for prognostic prediction[52].

Another technique that shows promise in improving the sensitivity and specificity of detecting and diagnosing pancreatic cystic lesions is confocal laser endomicroscopy. Confocal laser endomicroscopy is a novel imaging technology in which a low-power laser illuminates and scans a single focal plane of the tissue[53-56]. This technique allows for the detection of the microscopic detail of the surface epithelium in pancreatic cysts. Needle-based confocal laser endomicroscopy (nCLE) utilizes a sub-millimeter probe that is compatible with an EUS needle and enables real-time imaging with microscopic detail of pancreatic cystic lesions[56]. The presence of epithelial villous structures based on nCLE was associated with pancreatic cystic neoplasm ($P = 0.004$) and provided a sensitivity of 59%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 50%. This technique is rather new for evaluating the pancreatic cystic lesions. However, we believe that the development of this new technique may facilitate sampling the most suspicious area of a cyst in the future.

CYST FLUID ANALYSIS

As mentioned previously, pancreatic cystic neoplasms represent a diagnostic challenge for EUS-guided FNA because lining cells may or may not be adequately sampled, thus precluding further classification. The current way of solving this dilemma relies upon a combination of methods and includes visual cyst fluid evaluation at the time of immediate assessment, chemical analysis of cyst fluid, and molecular testing. All of these tests can be utilized to help to differentiate between mucinous and non-mucinous cysts.

Non-molecular methods

The possibility of a mucinous cyst can be strongly suggested by looking for the "string sign". This can be assessed by stretching out a drop of cyst fluid between the thumb and index finger and subsequently measuring the length of the string of cyst fluid. A length of at least 3.5 mm is believed to be consistent with that of a mucinous cyst. Studies have also shown that mucinous cysts consistently have a higher relative viscosity compared to serum, whereas the opposite is true for non-mucinous cysts, which a lower relative viscosity compared to serum[57].

Amylase: The chemical analysis of cyst fluid relies upon examining pancreatic enzyme levels as well as the presence of tumor markers. Pancreatic enzyme levels are typically used to differentiate between pseudocysts and neoplastic cysts. One of the most important enzymes studied in making this distinction is amylase. Pseudocysts and other non-neoplastic cysts consistently show elevated levels of amylase. In fact, one study showed that an amylase level below 250 U/L virtually excludes pseudocysts from the differential diagnosis[58]. Conversely, amylase is low in neoplastic cysts.

CEA: A variety of tumor markers have been studied for their ability to discriminate between mucinous and non-mucinous cysts[57-60]. According to many studies, CEA levels are the most accurate[60,61]. Although CEA cutoff values of > 192 ng/mL have been shown to have an accuracy of 79%[60], levels > 800 ng/mL have been shown to be highly predictive of mucinous neoplasms with a specificity of 98%. Unfortunately, the sensitivity, even at these markedly elevated levels, is still less than 50%[58]. It is also important to note that CEA cannot be used to distinguish between benign and malignant lesions[62,63]. Amylase, however, may be helpful in this regard[64]. In contrast, a very low CEA level ⩽ 5 is 95% specific for pseudocysts, neuroendocrine tumors, and serous cystadenoma[58].

Other markers: Multiple biomarkers have also been studied to identify pancreatic ductal carcinoma (PDAC). Plectin-1, a marker related to PDAC, was found to be a potentially promising biomarker for the detection of malignancy in IPMNs[65]. Plectin-1 expression was assayed using immunohistochemistry in cyst fluid and tissue sample from benign and malignant IPMN, as well as lymph node metastasis from carcinoma arising from IPMN. The sensitivity and specificity were 84% and 83%, respectively. In animal models, Cathepsin E is specifically and highly expressed in PDAC and pancreatic intraepithelial neoplasias (PanINs), A prospective double-blind control study was performed to evaluate the accuracy of this method in diagnosing PDAC and PanINs of all grades (> 82.7%)[66].

Molecular methods

K-RAS mutation: Molecular analysis of cyst fluid shows

Table 2 Criteria for integrated molecular pathology diagnostic categories

Diagnostic category	Molecular criteria[1]	Co-existing concerning clinical features[2]
Benign	DNA lacks molecular criteria	Not considered for this diagnosis
Statistically indolent	DNA meets 1 molecular criterion	None
SHR	DNA meets 1 molecular criterion	1 or more
Aggressive	DNA meets at least 2 molecular criteria	Not considered for this diagnosis

[1]Four molecular criteria that have been independently correlated with pancreatic malignancy or high-grade dysplasia are used to make an integrated molecular pathology diagnosis: (1) a single high-clonality mutation; (2) elevated level of high-quality DNA; (3) multiple low-clonality mutations; and (4) a single low-clonality oncogene mutation; [2]Include any of the following: cyst size > 3 cm, growth rate > 3 mm/year, duct dilation > 1 cm, carcinoembryonic antigen level > 1000 ng/mL, cytologic evidence of high-grade dysplasia. (Table 2 from Al-Haddad *et al*[75] 2015 was permitted by publisher). SHR: Statistically higher risk.

promise in distinguishing not only between mucinous and non-mucinous cysts, but also in the diagnosis of malignant cysts. One study that examined surgically resected specimens showed that the identification of the K-RAS mutation had a sensitivity of 54% and a specificity of 100% for mucinous cysts. The combined used of CEA and K-RAS improved the sensitivity to 83% while decreasing the specificity to 85%[67]. However, a smaller study found that there was no increase in sensitivity when combining CEA and K-RAS[68]. LOH and increased DNA quantity have also been tried as a means of accurately predicting the presence of a mucinous lesion, but the sensitivity for each method is less than 11%. However, the detection of any molecular changes (*i.e.*, K-RAS mutation, LOH, or increased DNA quantity) has been found to be 90% specific for mucinous cysts[12]. Recently, one meta-analysis study found that the sensitivity and specificity of K-RAS was 0.39 and 0.95; and the sensitivity and specificity of the combined test of cytology and K-RAS was 0.71 and 0.88, respectively[47]. The K-RAS mutation combined with cytology test greatly increases the sensitivity of EUS-FNA. K-RAS mutation analysis may also prove to be a powerful ancillary for testing cystic samples with scant cellularity.

GNAS mutation: Another diagnostic marker that has received considerable interest is the presence of GNAS mutations. Recent studies have shown that GNAS mutations can be detected in IPMNs[69,70]. It has also been shown that the combination of GNAS and KRAS mutations in cyst fluid is very specific for IPMNs. One study found GNAS mutations to be significantly more prevalent in IPMNs (42%) than in SCAs (10%), adenocarcinomas (0%), and MCNs (0%). This same study also showed that double GNAS and KRAS mutations only occur in IPMNs (P = 0.006) and that mutations in either gene equated to a sensitivity of 98% and a specificity of 84%[71]. GNAS mutations are rare to absent in MCN, SCA, PNET, or PDAC.

MicroRNA change: MicroRNA (miRNA) expression profiles have also received considerable interest and are currently being studied as another way to characterize pancreatic lesions. miRNA is nineteen to twenty-four nucleotide long single-stranded, non-coding regions of RNA that are highly stable and which may be useful in diagnosing various malignancies as well as pancreatic cystic neoplasms. In a recent study, together with IPMN surgical specimens, 65 cyst fluid samples were examined for differential selective miRNA candidate expression. A subset of 18 miRNAs separated high-grade from low-grade lesions. A logistic regression model using nine miRNAs allowed prediction of high-grade IPMNs, PNET and SPN *vs* low-grade IPMNs and SCA with a sensitivity of 89%, a specificity of 100% and area under ROC curve of 1[72]. Another study evaluated miRNA in 69 pathology specimens and identified several miRNA panels that enabled them to differentiate SCA from MCN and IPMN, and MCN from BD-IPMN with a sensitivity ranging from 85%-100% and a specificity of 100%[73].

Integrated molecular pathology: Perhaps the greatest dilemma in managing pancreatic cysts is the fact that none of the currently recommended guidelines can accurately predict the malignant potential of pancreatic cysts. For example, the current IAP 2012 criteria risk stratifies patients into two categories: "surveillance" criteria (low malignant potential) and "surgery" criteria (high malignant potential). Symptomatic patients with mucinous cysts and at least one other "high-risk stigmata" (*i.e.*, obstructive jaundice with a cyst located in the pancreatic head, a post-contrast enhancing solid component, a main pancreatic duct diameter $\geqslant$ 1 cm, abrupt change in duct caliber, cyst size $\geqslant$ 3 cm, presumptive diagnosis of MCN, and "suspicious" cytology) as detailed by the 2012 International Association of Pancreatology (IAP) guidelines should be referred for surgery[74]. Patients with cysts less than 1 cm and no concerning radiologic features can be monitored with periodic imaging studies. If more worrisome features are detected, the patients are subsequently referred for EUS-guided FNA to help determine the nature of the cyst (*i.e.*, mucinous versus non-mucinous) and whether malignancy is present. Nevertheless, given the high mortality rate for pancreatic cancer, the IAP ultimately recommends that any patient with "worrisome" features associated with malignancy undergo surgery. However, it has

been shown that approximately 60%-80% of patients undergoing surgery often have non-malignant disease. Therefore, other methods that prevent overtreatment of benign disease while providing early detection of cancer are needed.

Integrated molecular pathology (IMP) testing addresses this need it that incorporates all of the testing methods mentioned above (*i.e.*, cytology, imaging studies, fluid chemistry, and molecular analysis). Unlike other guidelines, it utilizes four different diagnostic categories of "benign", "statistically indolent", "statistically higher risk", or SHR, and "aggressive" based on both the number of molecular criterion met and other clinical features, if applicable (Table 2)[75]. In one study, 492 patients were categorized using IMP. Follow up for at least three years was available for 46% of patients. The overall accuracy was found to be 90%, and the specificity and negative predictive value were 91% and 97%, respectively. The sensitivity for malignant outcome with this cohort of patients was 83%, and the positive predictive value was 58%. When compared to the 2012 IAP criteria, it was found that the IAP criteria and IMP showed similar sensitivity and negative likelihood ratios. However, there was a statistically significant difference between the IAP guidelines and the IMP in that the specificity and positive likelihood ratios were higher using IMP criteria. These findings suggest that IMP is very useful in not only risk stratifying patients, but also in preventing patients with indolent disease from undergoing unnecessary surgeries[75].

CONCLUSION

EUS-guided FNA serves a pivotal role in the accurate diagnosis of incidentally discovered pancreatic cysts. Its advantages over imaging alone include the ability to confirm the presence or absence of suspicious features identified on radiologic imaging, determine whether a lesion is malignant, and monitor for changes in cystic lesions. The new classification schema, while not perfect, goes hand-in-hand with the role of EUS-guided FNA in that it helps clinicians and patients to have a better understanding of which lesions need to be treated as opposed to those which do not, thus sparing patients from undergoing procedures that may result in increased morbidity and/or mortality. Despite these advantages, arriving at a proper diagnosis still requires the integrated use of clinical, radiologic, and cytological findings. Newer chemical and molecular studies show promise in improving the ability of clinicians to effectively diagnose and treat these lesions.

Abstract

Imaging of common bile duct (CBD) can be done by many techniques. Endoscopic retrograde cholangiopancreaticography is considered the gold standard for imaging of CBD. A standard technique of imaging of CBD by endoscopic ultrasound (EUS) has not been specifically described. The available descriptions mention different stations of imaging from the stomach and duodenum. The CBD lies closest to duodenum and choice of imaging may be restricted to duodenum for many operators. Generally most operators prefer multi station imaging during EUS and the choice of selecting the initial station varies from operator to operator. Detailed evaluation of CBD is frequently the main focus of imaging during EUS and in such situations multi station imaging with a high-resolution ultrasound scanner may provide useful information. Examination of the CBD is one of the primary indications for doing an EUS and it can be done from five stations: (1) the fundus of stomach; (2) body of stomach; (3) duodenal bulb; (4) descending duodenum; and (5) antrum. Following down the upper 1/3rd of CBD can do imaging of entire CBD from the liver window and following up the lower 1/3rd of CBD can do imaging of entire CBD from the pancreatic window. This article aims at simplifying the techniques of imaging of CBD by linear EUS.

Key words: Endoscopic ultrasound; Common bile duct; Pancreas; Pancreatic duct; Portal vein

Core tip: Endoscopic ultrasound (EUS) is a new technology which has a steep learning curve. It is difficult to learn EUS as the standard techniques of EUS imaging have not been established. The common description of every organ or structure has been done by a station-wise imaging by most of the authors. The imaging of common bile duct (CBD) is an important part of EUS examination. The techniques of imaging of CBD by EUS have not been defined so far. This article aims at simplifying the techniques of imaging of CBD by linear EUS.

INTRODUCTION

The common bile duct (CBD) can be imaged by many imaging modalities. Endoscopic ultrasound (EUS) is closest to endoscopic retrograde cholangio pancreaticography, which is the gold standard for imaging of CBD. A standard technique of imaging of CBD by EUS has not been specifically described and the available descriptions mention different stations of imaging from the stomach and duodenum[1-12]. Most operators prefer multi station imaging during EUS and the choice of selecting the initial station varies from operator to operator. The CBD lies closest to duodenum and choice of imaging may be restricted to duodenum for many operators where the imaging scanners do not allow deep image penetration. Detailed evaluation of CBD is frequently the main focus of imaging during EUS and in such situations multi station imaging with a high-resolution ultrasound scanner may provide useful information. In this article we review the techniques of linear imaging of CBD by EUS.

Applied anatomy of extra hepatic biliary tract

The right and left hepatic ducts unite in the hilar plate close to the right end of porta hepatis in front of right branch of portal vein to form the common hepatic duct (CHD). The cystic duct (length, 3-4 cm) runs postero inferiorly and to the left from the neck of gall bladder to join the right border of CHD at an acute angle. The CBD is 6.0 to 8.0 cm long and is generally divided into supraduodenal (upper 1/3rd), retroduodenal (middle 1/3rd), retropancreatic (lower 1/3rd) and intraduodenal segments. The supraduodenal CBD lies in the right border of lesser omentum (hepato-duodenal ligament) anterior to portal vein and to the left of hepatic artery proper[1]. The retroduodenal part passes behind the superior part of duodenum, to the right of gastroduodenal artery and in front of portal vein. The retropancreatic part runs behind the head of the pancreas to reach the medial border of second part of duodenum. In the retropancreatic course, CBD is intrapancreatic in 83% and retropancreatic in 17% cases[2]. The CBD and the main pancreatic duct (of Wirsung) unite to form the common channel (hepatopancreatic ampulla of Vater) which opens at the major duodenal papilla 8 cm distal to pylorus. The formation of a common channel occurs in 85% cases and in the rest 15% cases, the two ducts either open separately or form a V junction before opening.

Materials and methods

All images in the present study have been generated from a detailed review of real-time recordings using the curved linear scanning echoendoscope EG-3830 UT (Pentax corporation, Tokyo, Japan), coupled with a Hitachi Avius and Hitachi 7500 processor (Hitachi Aloka Medical, Tokyo, Japan). Our image orientation is with the cranial aspect of the patient directed towards the right side of the screen. Four positions are commonly used during imaging from EUS: (1) the neutral position is where the front of the handle is facing the patient; (2) the open position to left is where the front of the handle is facing the patient's feet. It is reached by turning anti clockwise through 90° from the neutral position; (3) the open position to right is the opposite of the open position to left. It is reached by turning clockwise through 90° from the neutral position; and (4) a further 90° rotation from open position to right can bring the handle in a position opposite to the neutral position.

Stations of imaging

EUS of the CBD can be done from five stations: (1) the fundus of stomach; (2) body of stomach; (3) duodenal bulb; (4) descending duodenum; and (5) antrum (Figure 1 and Table 1).

MOVEMENTS DURING IMAGING

Rotation of the scope is the most important key to linear imaging of CBD. Rotation moves the imaging axis from one part of bile duct to other. Imaging with the scope in a straight position is helpful in transferring the effect of rotation of scope to the tip of ultrasound transducer. Most of the movements are done in a straight position of scope, except during imaging from station of duodenal bulb where the scope is placed in a J shaped position. Appropriate adjustments in right and left knobs along with in and out movement are also required to gain proper contact with the wall from all stations.

Imaging from fundus of stomach/OG junction

Manipulation around/ just beyond OG junction (40 cm) should be done under vision to avoid perforation. The imaging around/just beyond OG junction is best started from an open left position but can be also tried from an open right position.

Table 1 Common bile duct imaging from various stations during endoscopic ultrasound

Station	Home base structure	Main part of bile duct seen	Part of CBD seen on clockwise rotation[1]	Part of CBD seen anti clockwise rotation[2]
OG junction	l tributaries of LPV segment 2 and 3	Segment 2 and 3 duct	Upper 1/3	None
Body of stomach	Portal vein, splenic vein	Mid 1/3	Lower 1/3	Upper 1/3, left hepatic duct
Duodenal bulb	Portal vein	Mid 1/3	Lower 1/3	Upper 1/3
Descending duodenum	SMV	Lower 1/3	Mid 1/3, upper 1/3	Intrapancreatic
Antrum	SMV	Lower 1/3	Mid 1/3, upper 1/3	None

[1]Clockwise rotation needs to be combined with additional push in and out, and up and down movements; [2]Anti-clockwise rotation needs to be combined with additional push in and out, and up and down movements. Each of these positions brings the transducer closer to one of the four parts of CBD (upper 1/3, mid 1/3, lower 1/3 or intraduodenal) and the rest of CBD can be imaged by appropriate movement (clockwise or anti clockwise rotation, right or left movement or up and down movement). If mid 1/3 of CBD is identified in bulb an anti-clockwise rotation shows upper 1/3 CBD and clockwise rotation shows lower 1/3 of CBD. Similarly in stomach once mid 1/3 of CBD is identified clockwise rotation traces CBD towards lower 1/3 and anti-clockwise rotation traces CBD towards upper1/3. CBD: Common bile duct; SMV: Superior mesenteric vein; LPV: Left portal vein; OG: Oesophagogastric junction.

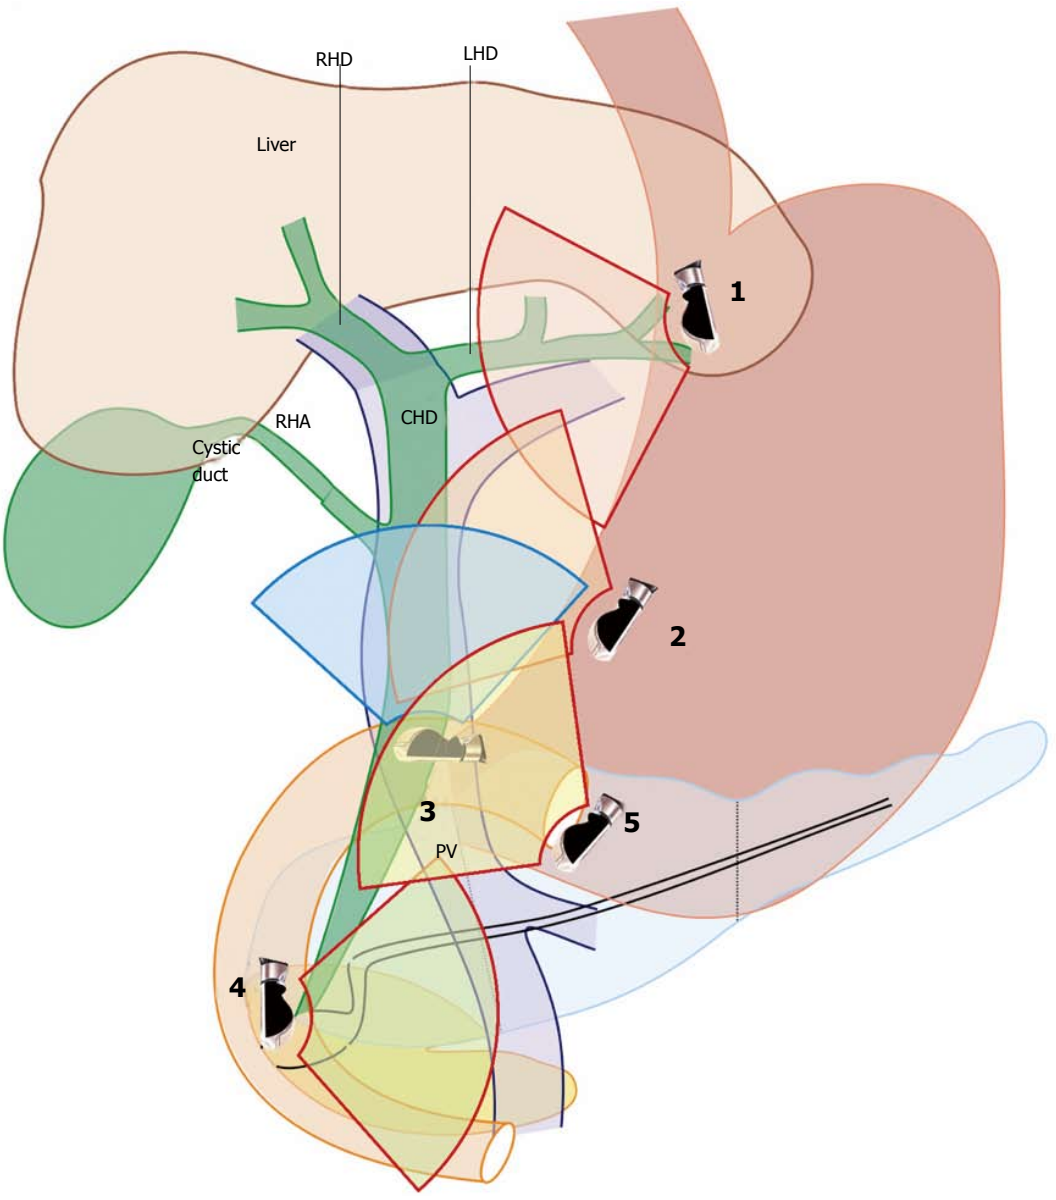

Figure 1 Five positions of Common bile duct imaging by endoscopic ultrasound are shown. CHD: Common hepatic duct; RHA: Right hepatic artery; RHD: Right hepatic duct; LHD: Left Hepatic duct.

Imaging from open left position: Clockwise rotation from an open left position follows the left lobe segment

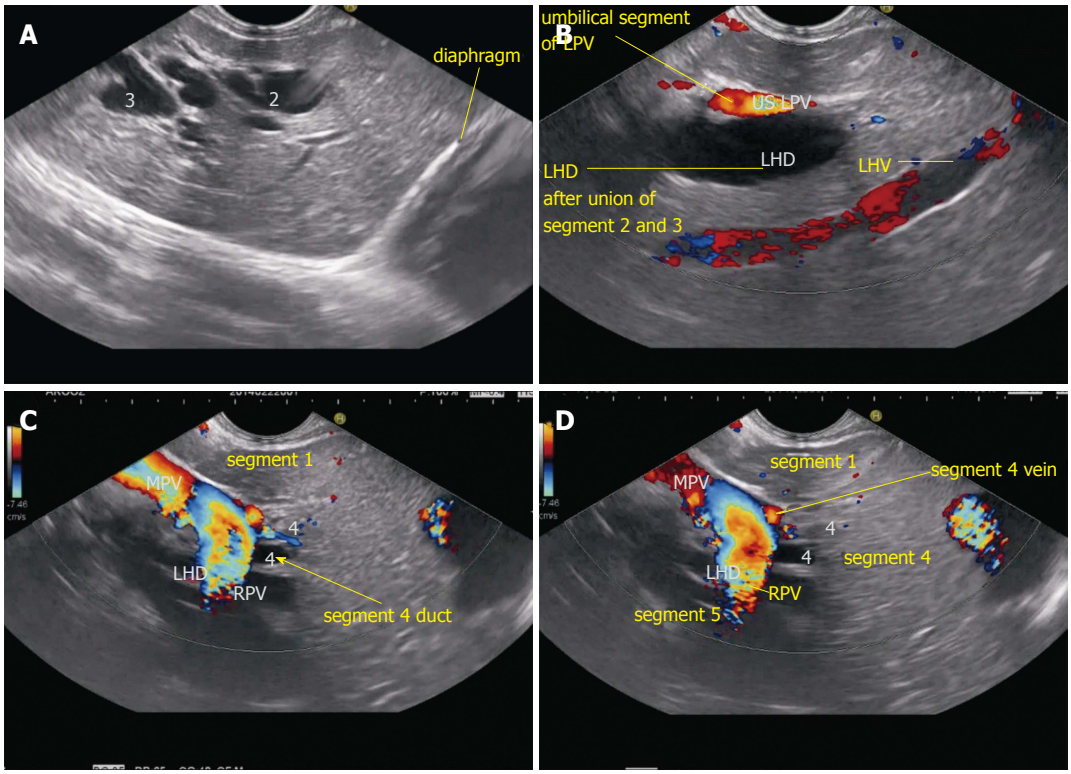

Figure 2 Segmental ducts as seen on endoscopic ultrasound. A: The dilated ducts of segment 2 and 3 ducts are seen in an open position to left; B: On clockwise rotation the segment 2 and 3 ducts fuse together in front of umbilical part of left portal vein. The left hepatic vein is also identified going from 2 o'clock position to 7 o'clock position; C: On further clockwise rotation the fused part of segment 2 and 3 ducts is joined by segment 4 duct from the cranial aspect (arrow) in front of the transverse segment of left portal vein; D: On further clockwise rotation the right portal vein is seen joining the left portal vein and the liver segment lying below the plane of right portal vein belongs to segment 5. RPV: Right portal vein; LPV: Left portal vein; LHD: Left hepatic duct; LHV: Left hepatic vein.

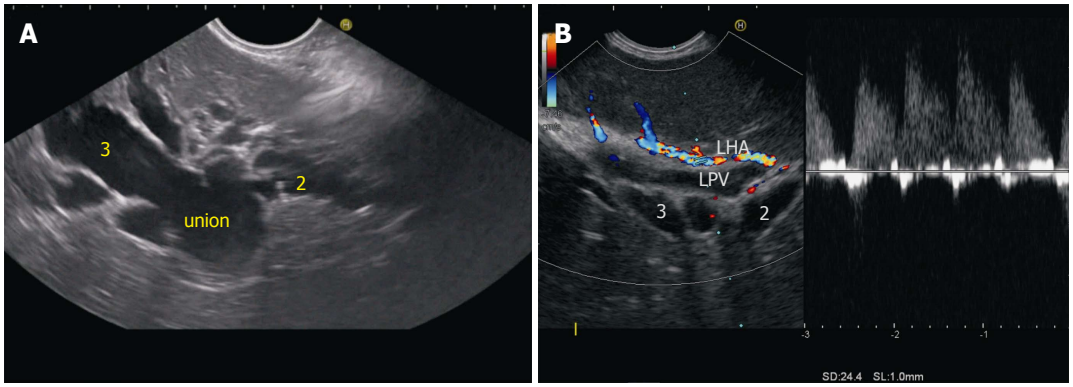

Figure 3 Union of segmental ducts. A: Segment 2 is identified as duct coming from cranial part of liver segment and segment 3 duct is identified as duct coming from caudal part of liver segment; B: Sometimes the ducts are not dilated and in such situation the tributaries of left portal vein can be identified after application of color doppler and followed to the union and formation of umbilical part of portal vein. LPV: Left portal vein; LHA: Left hepatic artery.

2 and 3 ducts to left hepatic duct and further rotation traces the left hepatic duct towards the liver hilum. If the intrahepatic biliary radicles (IHBR's) are dilated it is easy to follow the course of ducts by clockwise rotation. If the IHBR's are not dilated the segmental portal vein radicles should be followed. The gastrohepatic ligament (GHL), which come between the EUS probe and left lobe of liver, interferes with the imaging during rotation (Figures 2-4).

Imaging from open right position: Generally imaging of right lobe of liver is not possible from OG junction, as the right lobe ducts generally lies farther away from the probe. However the GHL does not interfere in imaging of right hepatic duct and with suitable adjustments of focus and frequency the right lobe and ducts of segment 4/5 (if dilated) can be identified and followed towards the upper CBD near the hilum by anti-clockwise rotation.

Imaging from body of stomach

Following down the upper 1/3rd of CBD can do imaging

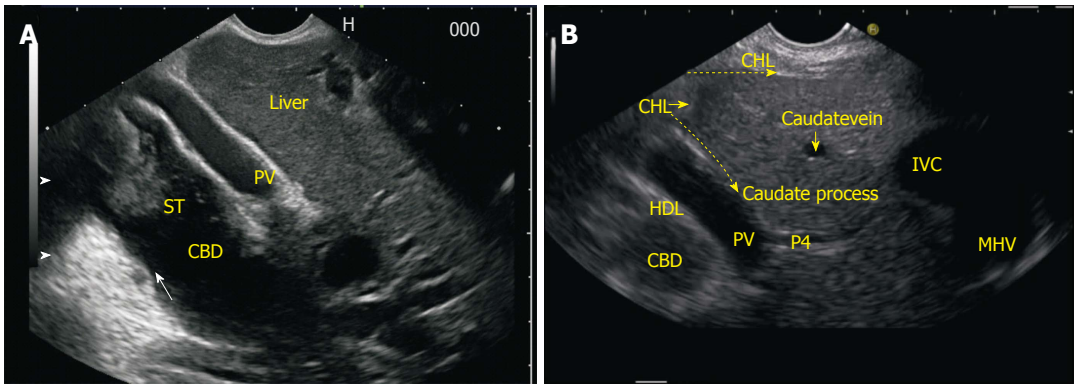

Figure 4 Common bile duct as seen from the gastroesophageal junction. A: A clockwise rotation moves the axis of imaging from an anterior position in stomach to a lateral position where the liver hilum is placed and follows the segmental duct towards the confluence of both the right and left hepatic ducts; B: In this figure the two limbs of GHL are seen. One of the limb runs on the under surface of liver and the other limb goes in the area between abdominal part of esophagus and liver. As the rotation is executed the presence of hyperchaotic GHL between esophagus and liver and the hepatoduodenal ligament near the liver hilum may interfere with imaging of part of the left or right hepatic ducts near the confluence. CHD: Common hepatic duct; IVC: Inferior venacava; HDL: Hepatoduodenal ligament; IVC: Inferior venacava; GHL: Gastrohepatic ligament.

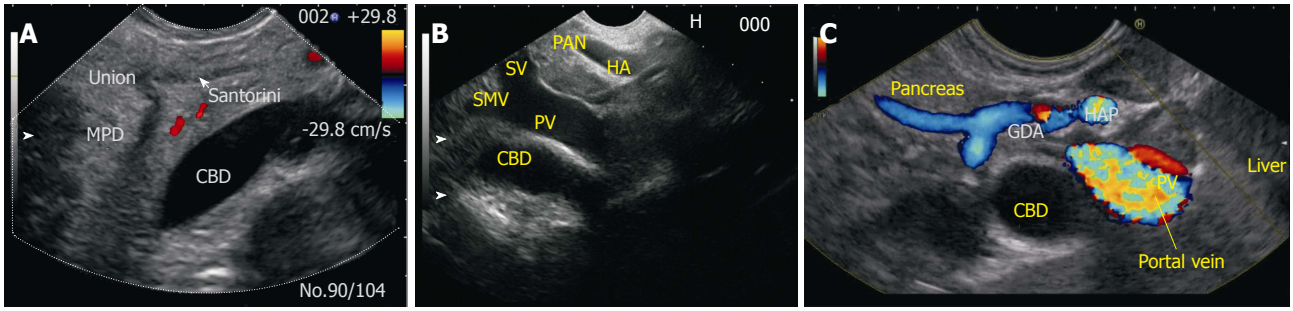

Figure 5 Following down from upper 1/3. A: A dilated bile duct can be easily followed down and push of the scope in a forward direction along with slight rotation changes the window of imaging from the liver window to pancreatic window. The parenchyma of head of pancreas provides an excellent window for visualization of dilated CBD. With experience even a non-dilated duct can be easily visualized from this position; B: When the probe comes to lie in fundus of stomach the stack of hepatic artery, portal vein and common bile duct can be seen through the liver window. In this picture the hepatic artery lies closest to the transducer, the portal vein lies on the undersurface of liver and the CBD is seen beyond the portal vein. The portal vein and the bile duct can be followed down towards the pancreas from the liver. The portal vein is followed down as SMV; C: When the probe comes to lie anterior to head of pancreas the stack of gastroduodenal artery, portal vein and bile duct can be seen with the help of the pancreatic window. CBD: Common bile duct; SV: Splenic vein; PV: Portal vein; HA: Hepatic artery; MPD: Main pancreatic duct; SMV: Superior mesenteric vein.

of entire CBD from the liver window and following up the lower 1/3rd of CBD can do imaging of entire CBD from the pancreatic window.

Following down from liver window: Imaging of CBD while following it down from the fundus towards body of stomach requires a movement of the EUS probe along lesser curvature. This movement can be easily executed under vision after distension of stomach with air but the presence of air usually creates interference with ultrasound imaging. To avoid this interference due to air, a smooth combination of three movements: (1) push in of about 25 to 30 cm. from fundus; (2) clockwise rotation of 90 degree; and (3) up movement of up and down knob for about 90 degree is generally preferred. This movement allows a relative blind slide of the transducer along lesser curvature with nil or minimum distension of air and follows down the CBD from upper 1/3rd towards the lower 1/3rd. Once the movement is completed the scope comes to lie in a position near the antrum and the left hand comes to lie close to the chest of the operator (Figure 5).

Following up from pancreatic window: A reversal of the movement described above can be done under vision by initially proceeding towards antrum after air inflation and subsequently coming back after air suction from antrum towards the fundus. This reversal movement follows up the CBD from the lower 1/3rd towards the upper 1/3rd. If it is difficult to trace the course of CBD by this movement, the home base of portal venous confluence of splenic vein with superior mesenteric vein is initially located in the neck of pancreas. The lower 1/3rd of CBD is easily identified behind the portal venous confluence (Figure 6).

Imaging from bulb

The pylorus is located by "setting sun sign" and slight down angulation of tip may be required to get an end view of pylorus. Once the pylorus is seen the scope is

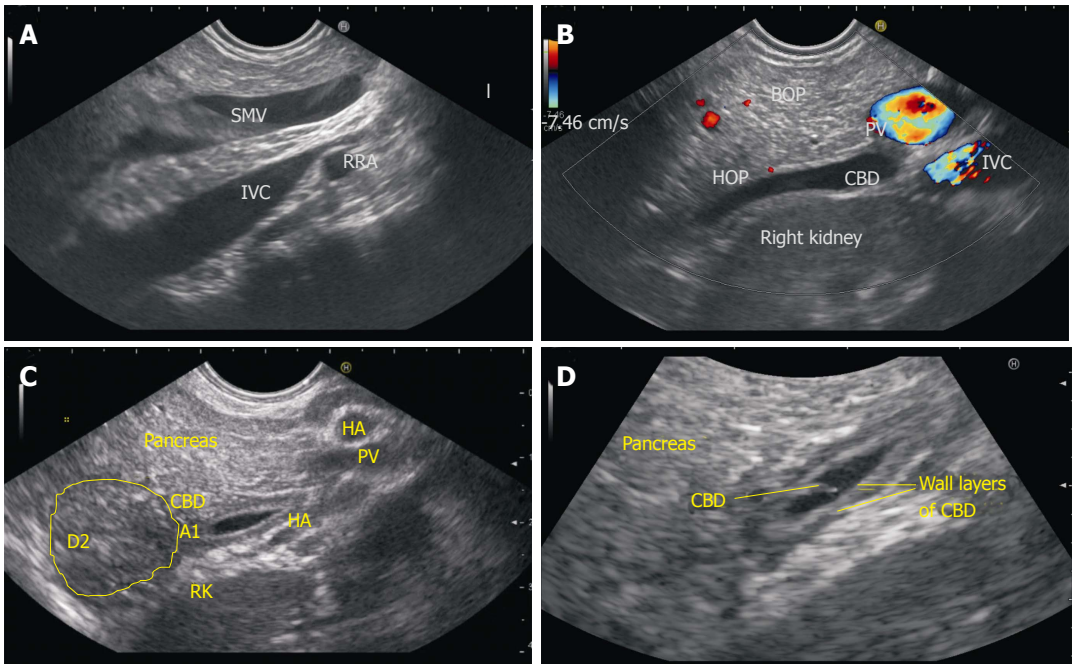

Figure 6 Lower Common bile duct imaging from D2-D3. A: In the hilum of liver the CBD lies anterior to the portal vein and both CBD and portal vein are positioned anterior to inferior vena cava. As the CBD is followed down towards ampulla the IVC remains goes posterior to head of pancreas whereas the SMV (followed down as a continuation of portal vein) comes to lie anterior to posterior part of head of pancreas. The CBD occupies the area of posterior part of head of pancreas between the SMV and IVC. This figure shows the typical appearance of SMV lying in front of IVC from stomach. If it is difficult to trace the course of CBD, the IVC, portal vein or superior mesenteric vein can be followed as a vascular home bases for tracing of CBD; B: In this figure the CBD is identified in posterior part of head of pancreas with slight anticlockwise rotation after visualizing the typical appearance of SMV lying in front of IVC; C: Once the Lower 1/3 of CBD is located it can be followed down towards the intrapancreatic part of CBD and zooming can help in imaging of papilla as well as 2nd part of duodenum; D: With selective zooming of bile duct the individual layers of bile duct can be identified. SMV: Superior mesenteric vein; CBD: Common bile duct; IVC: Inferior venacava; HOP: Head of pancreas; BOP: Body of pancreas; PV: Portal vein.

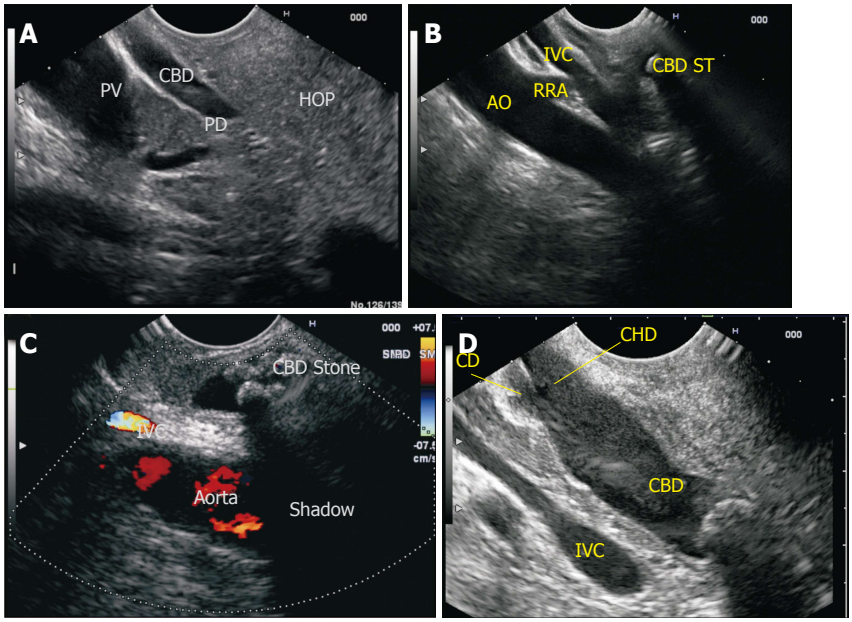

Figure 7 Common bile duct Imaging from duodenal bulb. A: The portal vein is identified as the home based position from duodenal bulb. From the home base position a limited range of movement of 90 degree to either side traces the entire CBD. A clockwise rotation traces the CBD towards the ampulla and identifies the middle and lower 1/3 of CBD and anticlockwise rotation traces the CBD towards the upper 1/3 and the GB/CD/CHD are also identified near the liver hilum. In this image the CBD is seen in a long axis for a long distance and the PD and portal vein are seen in a long axis for a short distance. This has been called as reverse stack sign; B: In this figure the stack of bile duct (with a stone) aorta and IVC is seen from duodenal bulb. The right renal artery is seen going behind the IVC. The CBD in this case lies in the retropancreatic part anterior to IVC; C: Two stones are seen in the path of acoustic shadow. Although both stones have same acoustic impedance yet it is the second stone, which is causing acoustic shadow. The second stone is surrounded by fluid and the sound waves go through acoustic medium of different acoustic impedance; D: The pyramidal shaped neck of pancreas and pancreatic duct are commonly identified between the probe and portal vein. CBD: Common bile duct; CHD: Common hepatic duct; IVC: Inferior venacava; PV: Portal vein; PD: Pancreatic duct; HOP: Head of pancreas; RRA: Right renal artery; AO: Aorta.

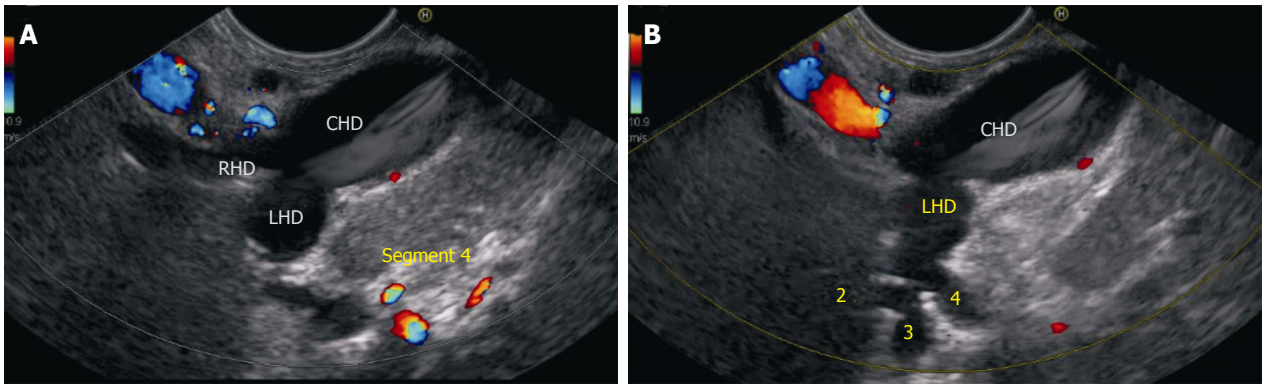

Figure 8 Hilum imaging from duodenal bulb. A: Imaging from duodenal bulb shows the proximity of CBD to the probe. The middle and upper 1/3rd of CBD and CHD dividing into RHD and LHD are seen. The RHD (average length 0.9 cm) and left hepatic duct (Average length 1.7 cm) unite in the hilar plate, close to the right end of porta in front of right branch of portal vein, to form the CHD; B: In this case it is possible to see the segmental ducts to segment 2, 3 and 4 through upper 1/3rd of CBD. CBD: Common bile duct; CHD: Common hepatic duct; RHD: Right hepatic duct; LHD: Left hepatic duct.

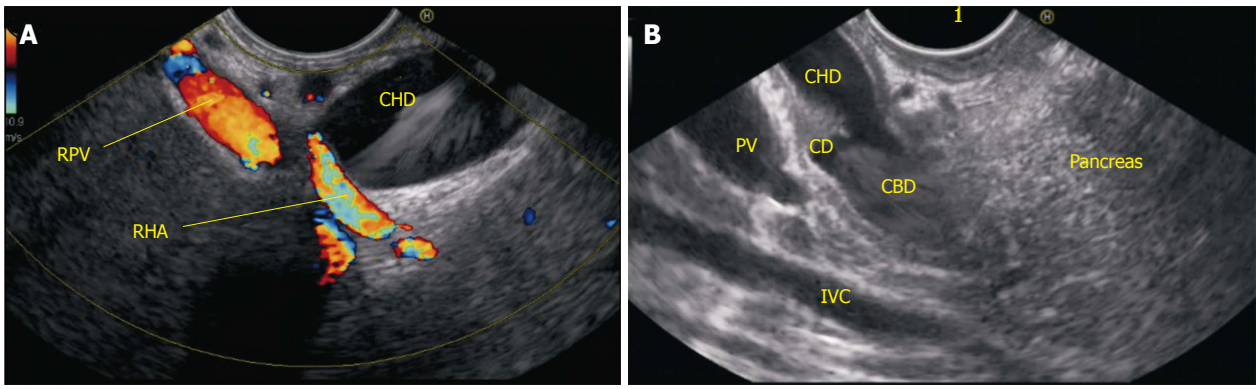

Figure 9 Hepatocystic triangle seen from the duodenal bulb. A: Imaging from duodenal bulb shows the relationship of right hepatic artery which goes behind the CHD to come and lie in the hepatocystic triangle; B: The bulb provides an opportunity to visualize the mid 1/3rd of CBD and usually provides an excellent window to see the division of CBD into CHD and CD. Most of the time the structure lying farther away from the screen is CD and can be traced towards the gall bladder. CBD: Common bile duct; CHD: Common hepatic duct; CD: Cystic duct; RPV: Right portal vein; RHA: Right hepatic artery; IVC: Inferior venacava.

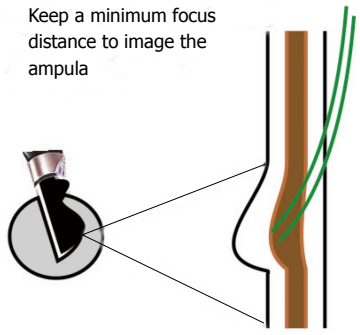

Figure 10 Imaging of Common hepatic duct at papilla can be done after apposition of transducer with the papilla, which is the main endoscopic landmark. It is appreciated as a thickening of the duodenal wall and a rounded 5-layered structure. Good views of papilla require three things: (1) transducer perpendicular to papilla; (2) good water coupling; (3) and motionless duodenum). If a balloon is used only a small amount of water should be filled in balloon to avoid smashing the delicate papilla. The imaging of papilla after instillation of about 50 to 100 mL water keeps the transducer away from papilla, increases the focal distance of imaging of transducer from papilla and places the papilla as well as lower 1/3 of CBD in the optimum focal distance of imaging (usually about 1 cm). CHD: Common hepatic duct.

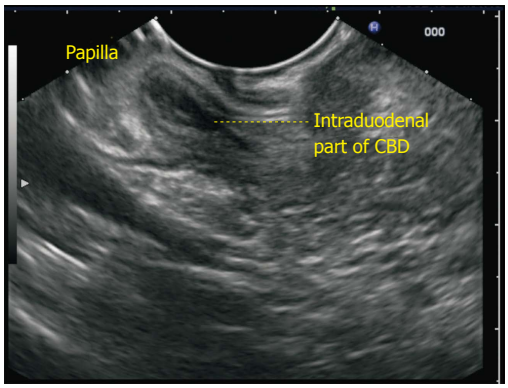

Figure 11 The papilla is the protruding structure in the lumen of the duodenum and is covered on both sides by the muscular layer of the wall. At the point of the entry of papilla into the duodenal bulb the continuity of muscular layer as a smooth duodenal fall is absent. At the point of union of bile duct and pancreatic duct the dilation of both ducts is named as ampulla. An attempt should be made to trace the intra papillary part of pancreatic duct all the way to the tip of the papilla or into a common ampulla. This can help in identifying the three patterns of opening of the bile duct and pancreatic duct, *i.e.*, common channel, V shaped or separate opening. CBD: Common bile duct.

pushed into 1st part of duodenum with slight upwards angulation and imaging from bulb is started after

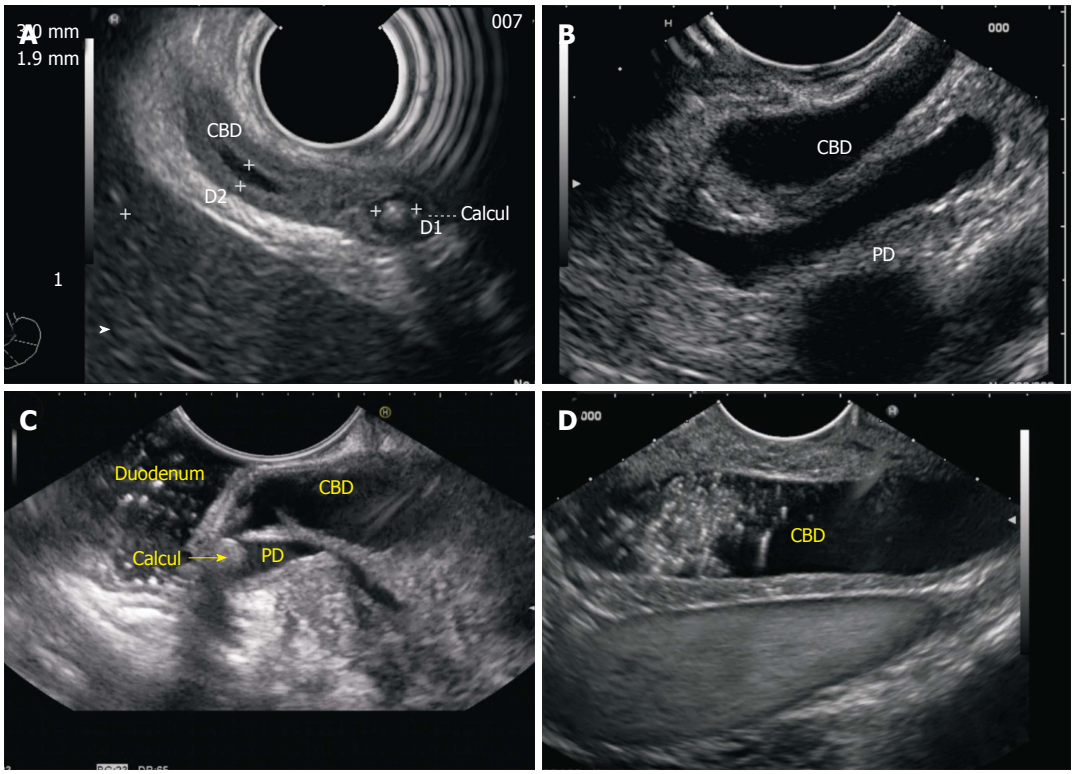

Figure 12 Imaging from 2nd part of duodenum. A: The intrapapillary part of CBD and the lower 1/3 of CBD is sometimes best visualized with the radial EUS scope as they provide a long axis of imaging of the entire bile duct in a long axis; B: However good view of CBD in a long axis can be also obtained by linear EUS scope. This image shows the dilated CBD and PD in a long axis in a case of periampullary carcinoma; C: The distended CBD may not provide room for good visualization as it comes very close to probe in a pathology involving papilla. This figure shows good view of CBD after instillation of 100 mL water which provides good coupling and also provides adequate focal distance. The stone is impacted in the common channel where it is also obstructing and dilating the pancreatic duct; D: The dilated CBD with sludge is seen from 2nd part of duodenum. On the far side of screen the IVC is also seen beyond the IVC. CHD: Common hepatic duct; EUS: Endoscopic ultrasound; IVC: Inferior venacava; CBD: Common bile duct; PD: Pancreatic duct.

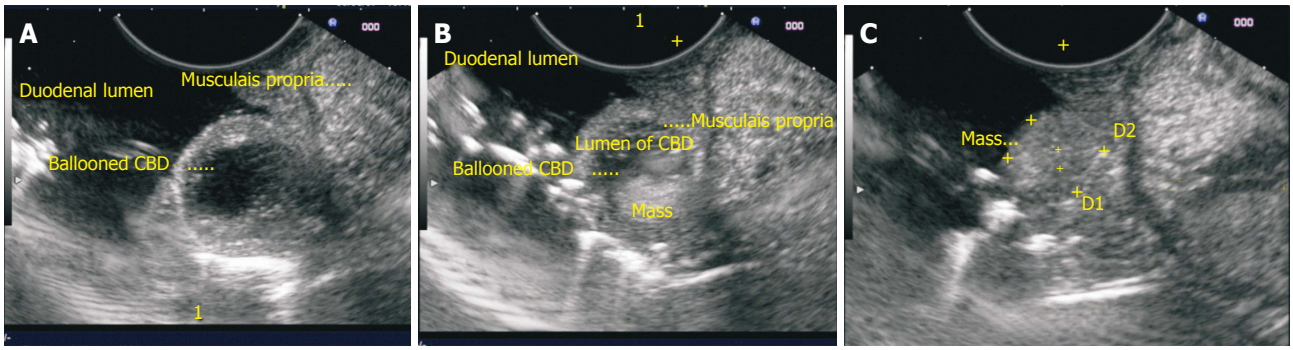

Figure 13 Imaging of common hepatic duct from second part of duodenum. A: A distended CBD is seen after good water coupling from 2nd part of duodenum but this image does not provide a clue to the diagnosis; B: An Ampulloma is seen within the distended intraduodenal part of bile duct; C: The tumor is seen within the intraduodenal part of CBD but it appears separate from the muscularis propria layer. CBD: Common bile duct.

establishing contact with posterior duodenal wall. The contact with wall is generally established by turning in an anticlockwise (ACW) direction with down angulation of up and down knobs. Sometimes in this imaging the ACW rotation of the scope may take the scope down and below the level of table in a straight scope position. With suitable rotation and minor adjustments of knobs a home base position is identified where the portal vein is seen on the far side of the screen going from 5 o' clock position to 11 o'clock position. In this home base position the middle 1/3rd of CBD is commonly identified with slight adjustments of right and left knobs between the transducer and portal vein. Clockwise rotation from this position traces the lower 1/3rd of CBD and ACW rotation traces the upper 1/3rd of CBD as well as the cystic duct and gall bladder (Figures 7-9).

Imaging from duodenum

Imaging from duodenum requires two key movements. The first is entry into 2nd part of duodenum and the

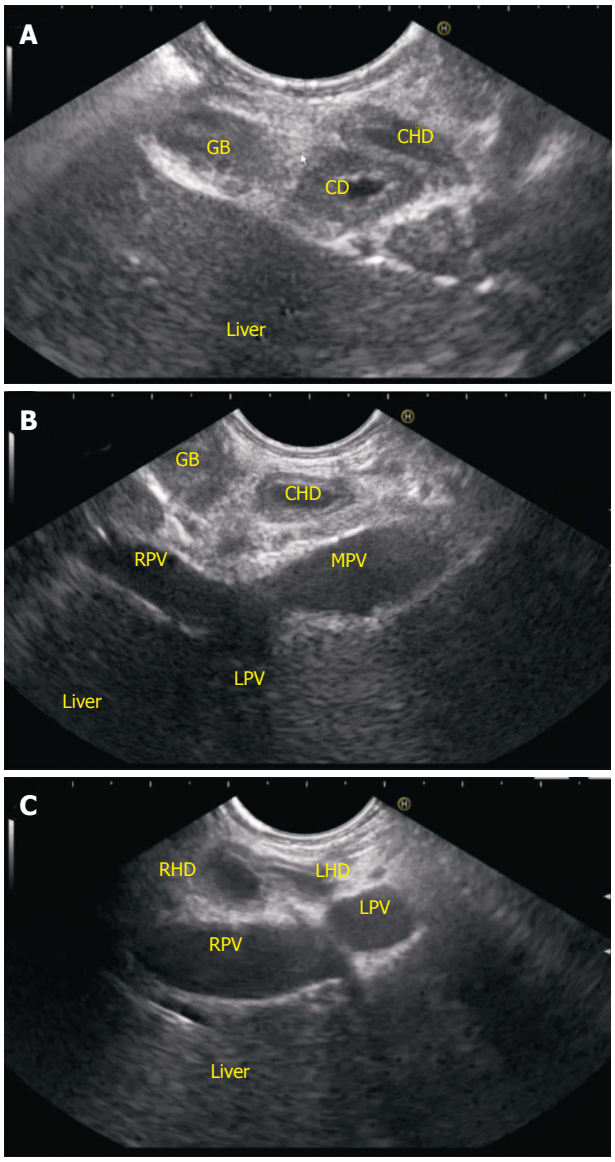

Figure 14 Hilum imaging from D2. A: Anticlockwise rotation from the 2nd part of duodenum traces the CBD towards the hilum. The cystic duct is seen taking origin from the aspect away from transducer and the gall bladder is visualized; B: When imaging is done from below upwards the imaging shows the CHD going towards the right portal vein; C: Further anticlockwise rotation towards hilum can show the left and right hepatic duct. The division of CHD into RHD and LHD occurs in front of right branch of portal vein. CBD: Common bile duct; CHD: Common hepatic duct; RHD: Right hepatic duct; LHD: Left hepatic duct; LPV: Left portal vein; RPV: Right portal vein.

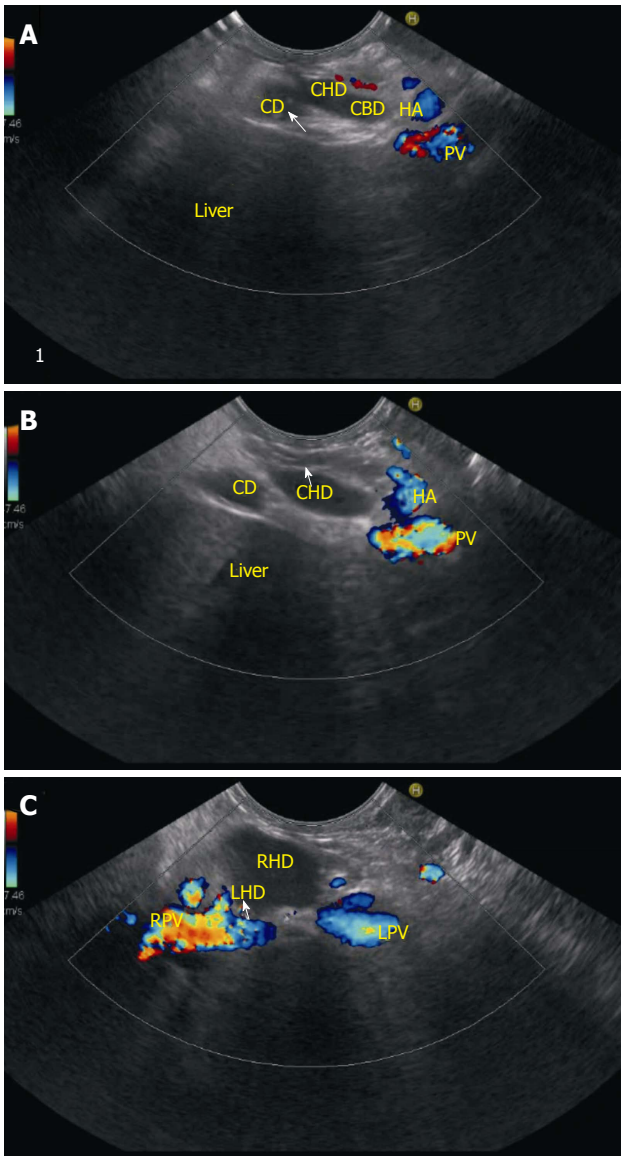

Figure 15 Cystic duct and common hepatic duct imaging. A and B: The cystic duct terminates at the right wall of the common hepatic duct in 85 to 90% of cases. In this case the CD is seen joining the right aspect of CHD; C: When the CHD is followed up it divides into right and left hepatic duct and this bifurcation generally lies in front of the right branch of the portal vein. As the echoendoscope is rotated counter clockwise the portal vein is followed up to its bifurcation and the RPV is seen on the right side of the screen. CHD: Common hepatic duct; CD: Cystic duct; CBD: Common bile duct; PV: Portal vein; HA: Hepatic artery; RHD: Right hepatic duct; LHD: Left Hepatic duct; LPV: Left portal vein; RPV: Right portal vein.

second is deep intubation into 3rd part of duodenum.

Passage into D2: Entry into D2 is facilitated by engagement of the tip of the probe at D1/D2 junction (superior duodenal angle). Four movements of knob at the superior duodenal angle, *i.e.*, "right turn of knob, up turn of knob, clockwise rotation of the scope and pulling back of the scope" help in passage of probe into second part of duodenum. These movements bring the scope in a short position and place the tip of scope near the papilla once the scope is shortened to about 55 cm. Slow pulling back for shortening can be done by pulling the shaft of scope with the use of right hand or by the use of outward pressure on the shaft of scope by ulnar aspect of the left hand in an open right position. Endoscopic view should be always maintained during a combination of these movements while shortening to avoid a sudden jerk and entry of the transducer into 2nd part of duodenum.

Passage into D3: Once the second part of duodenum is entered two to three times pushing in and out is required to position the scope deeper into the third part

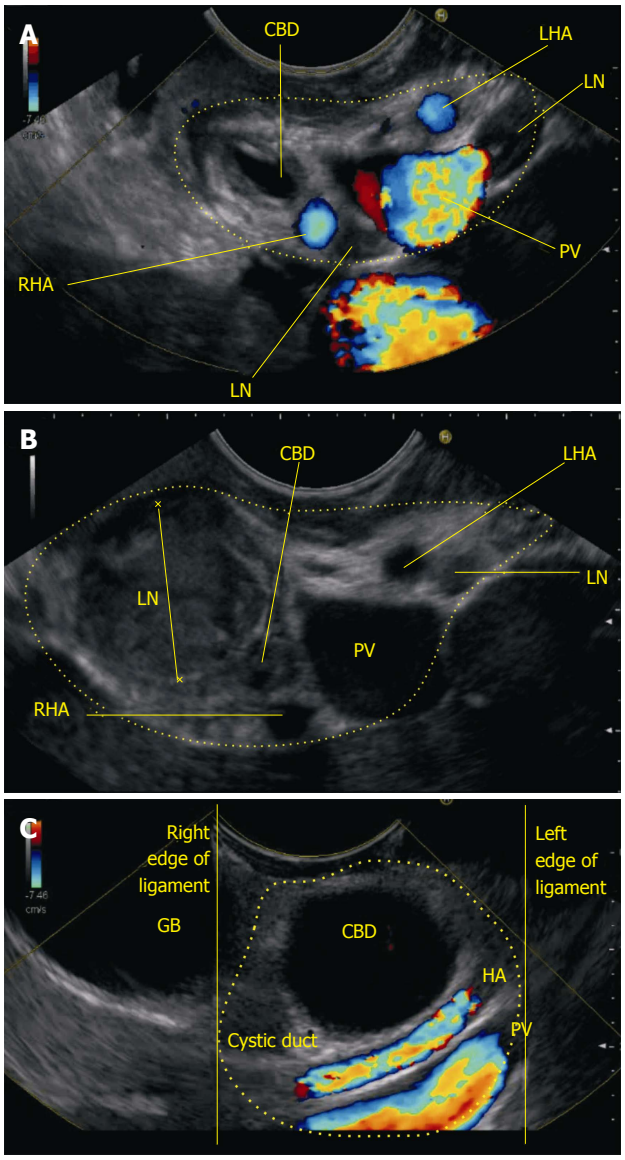

Figure 16 Hepatoduodenal ligament. A: The anticlockwise rotation takes the probe towards the hilum of liver the bile duct is demonstrated in a transverse axis. The HDL contains the structures of portal triad; B: Further anticlockwise rotation shows an abnormal lymph node within the hepatoduodenal ligament which is causing obstruction of CBD; C: On further anticlockwise rotation the probe moves towards the hilum of liver and the dilated bile duct is demonstrated in a transverse axis along with cystic duct and gall bladder. The portal vein and hepatic artery are demonstrated in long axis. All these structures shown lie in the hepatoduodenal ligament near the hilum except the gallbladder. CBD: Common bile duct; CHD: Common hepatic duct; RHA: Right hepatic artery; LHA: Left hepatic artery; LN: Lymph node; PV: Portal vein; HDL: Hepatoduodenal ligament.

of duodenum.

Imaging from duodenum: From the third part of duodenum a combination of three movements, *i.e.*, slow withdrawal up to the first part of duodenum, clockwise and ACW torque and upward movement of the up and down knobs is required for getting good views of lower 1/3rd of bile duct. This combined movement traces the CBD from the lower 1/3rd towards the upper 1/3rd but as the scope comes towards the first part of

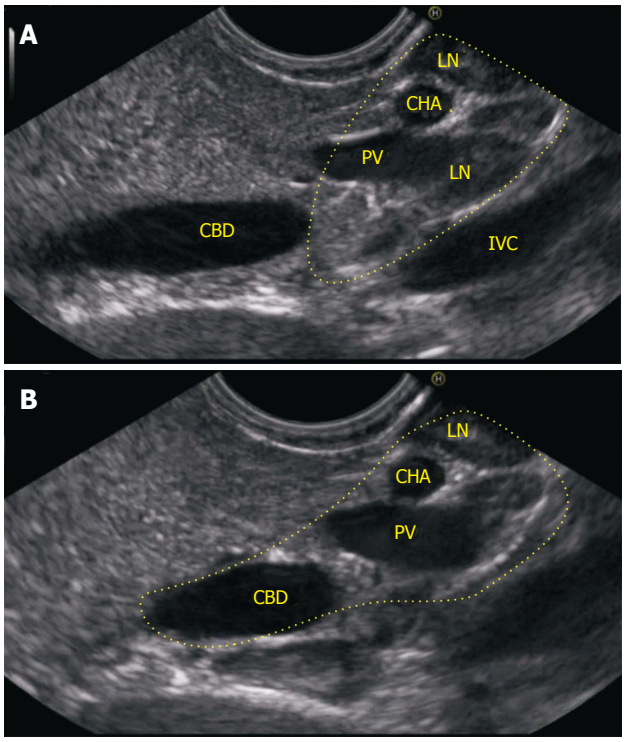

Figure 17 When the scope comes to lie in antrum the splenic vein can be followed towards the portal venous confluence easily. Once the portal venous confluence is identified a slight anticlockwise torque with push generally identifies the lower 1/3 of CBD in head of pancreas. Once the duct is identified the adjustment of focus, on the far side of screen with adjustment to lower frequency may be required for proper visualization of CBD behind the confluence. CBD: Common bile duct; LN: Lymph node; CHA: Common hepatic artery; PV: Portal vein; LN: Lymph node; IVC: Inferior venacava.

duodenum it tends to slip back into stomach. Movement of the up knob in a fully up position and maintaining a clockwise stance during slow torque from the 2nd part of duodenum helps in preventing the scope from slipping back. Wedging the scope at D1/D2 junction with an inflated balloon is an alternative, which is preferred by some operators to prevent slipping back, but carries a small disadvantage of reverse intussusception of the 2nd part of duodenum into stomach.

In a small number of cases it may be difficult to trace a normal CBD during this combined movement as most of the lumen of CBD gets compressed due to the pressure of transducer. In such cases the combined movement should be done with a main thrust on ACW rotation till it visualizes the anechoic bile duct within the bean shaped hepatoduodenal ligament. A clockwise rotation with slight push and relaxation of the pressure on up and down knob (reverse of the combined movement) now traces the CBD from the liver hilum towards the papilla.

Imaging of CBD should be done from below the papilla from the third part of duodenum after instillation of water whenever pathology of papilla (stone or a periampullary tumor) causes distension of intraduodenal part of CBD. This technique provides adequate focal distance for imaging of papilla and good water coupling

(Figures 10-16).

Imaging from antrum

This imaging is similar to imaging through the pancreatic window from stomach as already described above. It can be done if evaluation of CBD is considered necessary once the scope slips back from the 2nd part of duodenum or once the examination from duodenum is completed. As the scope comes to lie opposite the head of pancreas the pancreatic window provides optimum imaging of lower 1/3rd of CBD (Figure 17).

CONCLUSION

The techniques described in the above section can be expected to reproduce the images as discussed in majority of cases and from most of the stations. The only station of CBD imaging which may not reproduce the images as described is from duodenal bulb. This difference in reproducing the images and a great variability of images comes mainly due to the variability of the position of scope (short loop, or J shaped position) and due to the use of balloon (nestled, wedged, withdrawn wedged, intussuscepted). The basic concept of imaging however remains simple: stomach shows mainly the upper 1/3rd of CBD, bulb shows mainly the middle 1/3rd of CBD and duodenum shows mainly the lower 1/3rd of CBD. The follow up imaging to trace entire CBD requires a clockwise rotation and push from upper 1/3rd of CBD. The follow up imaging to trace entire CBD requires an ACW rotation and pull from lower 1/3rd of CBD. The follow up imaging to trace entire CBD requires a clockwise rotation to trace the lower 1/3rd and an ACW rotation to trace the upper 1/3rd when imaging is started from middle 1/3rd of CBD.

Abstract

Endoscopic ultrasound (EUS) is used for diagnosis and evaluation of many diseases of the gastrointestinal (GI) tract. In the past, it was used to guide a cholangiography, but nowadays it emerges as a powerful therapeutic tool in biliary drainage. The aims of this review are: outline the rationale for endoscopic ultrasound-guided biliary drainage (EGBD); detail the procedural technique; evaluate the clinical outcomes and limitations of the method; and provide recommendations for the practicing clinician. In cases of failed endoscopic retrograde cholangiopancreatography (ERCP), patients are usually referred for either percutaneous transhepatic biliary drainage (PTBD) or surgical bypass. Both these procedures have high rates of undesirable complications. EGBD is an attractive alternative to PTBD or surgery when ERCP fails. EGBD can be performed at two locations: transhepatic or extrahepatic, and the stent can be inserted in an antegrade or retrograde fashion. The drainage route can be transluminal, duodenal or transpapillary, which, again, can be antegrade or retrograde [rendezvous (EUS-RV)]. Complications of all techniques combined include pneumoperitoneum, bleeding, bile leak/peritonitis and cholangitis. We recommend EGBD when bile duct access is not possible because of failed cannulation, altered upper GI tract anatomy, gastric outlet obstruction, a distorted ampulla or a periampullary diverticulum, as a minimally invasive alternative to surgery or radiology.

Key words: Endoscopic ultrasound; Rendezvous; Biliary drainage; Obstrutive cancer; Papillary obstrution

Core tip: In this minireview, we will discuss about endoscopic ultrasound-guided biliary drainage (EGBD) and new interesting endoscopic ultrasound therapeutic biliary methods. We recommend EGBD when bile duct access is not possible because of failed cannulation, altered upper gastrointestinal tract anatomy, gastric outlet obstruction, a distorted ampulla or periampullary diverticulum, as a minimally invasive alternative to surgery or radiology.

Guedes HG, Lopes RI, de Oliveira JF, de Almeida Artifon EL. Reality named endoscopic ultrasound biliary drainage. *World J Gastrointest Endosc* 2015; 7(15): 1181-1185 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i15/1181.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i15.1181

INTRODUCTION

Endoscopic ultrasound (EUS) is used for diagnosis and evaluation of many diseases of the gastrointestinal tract. In the past, it was used to guide a cholangiography[1], but nowadays it emerges as a powerful therapeutic tool in biliary drainage.

Endoscopic retrograde cholangiopancreatography (ERCP) is the procedure of choice for drainage of an obstructed common bile duct (CBD) in patients with distal obstruction. Lower success rates are seen in patients with surgically altered anatomy and neoplastic diseases due to failure to access the duodenum or more difficult duct access[2]. However, EUS-guided biliary drainage (EGBD) may be a viable alternative to ERCP in patients with malignant distal CBD obstruction[3].

In 2001, Giovannini *et al*[4] performed the first palliative hepaticogastrostomy (HGS) under EUS guidance in a patient with inoperable hepatic hilar obstruction. Recently, experience from EUS-guided biliary duct drainage attempts at 6 international centers was reviewed and showed successful bile duct drainage for all techniques combined in 87% cases[5]. Although performed for almost two decades, during the last five years there was a substantial increase in this type of procedure. These publications suggest that EGBD can provide high levels of technical success with acceptable complication rates[6].

The indications for EGBD include: failed conventional ERCP; altered anatomy; tumor preventing access into the biliary tree; and contra-indication to percutaneous access[7].

If the papilla is accessible, a rendezvous technique (EUS-RV) can be adopted wherein EUS is used to puncture the bile duct and a wire is negotiated through the papilla and further therapy is carried out through ERCP. If the papilla is not accessible then EUS is used to access the bile duct and create a fistula for placement of a stent called the transmural technique[8].

The objectives of this review are: Outline the rationale for EGBD; detail the procedural technique; evaluate the clinical outcomes and limitations of the method; and provide recommendations for the practicing clinician.

RATIONALE FOR USE EGBD

In cases of failed ERCP, patients are usually referred for either percutaneous transhepatic biliary drainage (PTBD) or surgical bypass. Both these procedures have high rates of undesirable complications. EGBD is an attractive alternative to PTBD or surgery when ERCP fails[9]. In a prospective single-center randomized study, EGBD and PTBD were compared in patients with unresectable malignant biliary obstruction. Technical success and clinical success were 100% in both groups. The complication rate for PTBD was 15.3% and the complication rate for EGBD was 25% (P = 0.2), and the cost of the procedures was similar (7570 USD and 5573 USD respectively, P = 0.39)[10]. The surgical bypass is an option only for patients who are good surgical candidates. Despite the more invasive approach, surgery produced better drainage.

ERCP may be challenging or may fail in certain situations, including post-surgical anatomy, periampullary diverticula, ampullary tumor invasion, and high-grade strictures. EUS-guided interventions may allow access or direct therapy in ERCP failures. In a retrospective single-center cohort study, if the primary intended EUS-guided anterograde cholangiopancreatography (EACP) intervention failed, crossover to other type of EACP therapy was performed, when clinically appropriate-in 95 of 2566 ERCP procedures (3.7%). EUS-guided cholangiography and pancreatography were successful in 97% and 100%, respectively (Figure 1). EUS-RV and ERCP was successful in 75% of biliary procedures and in 56% of pancreatic procedures. Direct EUS-guided therapy was successful in 86% and 75% of biliary and pancreatic procedures, respectively[11]. Another systematic review evaluated the efficacy of EGBD in patients with surgically altered anatomy with 74 cases included for analysis. The pooled technical success, clinical success, and complication rates of all reports with available data were 89.18%, 91.07% and 17.5%, respectively[12].

We recommend surgical bypass for patients with both duodenal and biliary obstructions who are good surgical candidates, but EGBD might be better than PTBD in patients with large volume ascites or patients who refuse external drainage[13].

A gallbladder biliary drainage is necessary in acute cholecystitis with poor performance status and septic shock patients. Jang *et al*[14] showed that EUS-guided naso-gallbladder drainage *via* transluminal technique is safe, effective and similar compared to percutaneous transhepatic gallbladder drainage, with a significant lower rate of postoperative pain (1 *vs* 5; P < 0.001).

Others therapeutics modalities guided by EUS are transmural drainage of pancreatic pseudocysts[8], treatment of distal inflammatory biliary stricture[15], renal biopsy by fine neddle aspiration (EUS-FNA)[16], preoperative fine-needle tattooing insulinoma[17].

PROCEDURAL TECHNIQUE

EGBD can be performed at two locations: transhepatic (TH), through segment Ⅲ, when the probe is placed at the stomach cardia and lesser curvature or jejunum (in altered anatomy) or extrahepatic (EH) when the needle access the CBD directly, either using the

Figure 1 Intra-hepatic cholangiography.

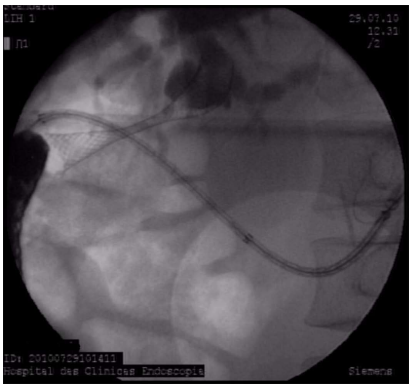

Figure 3 Cholangiographic aspect after biliary stent release.

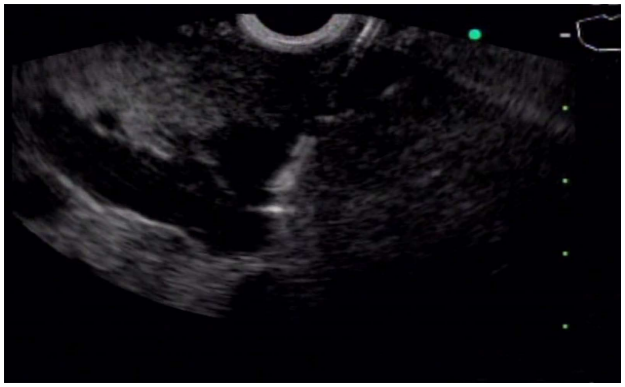

Figure 2 Biliary puncture.

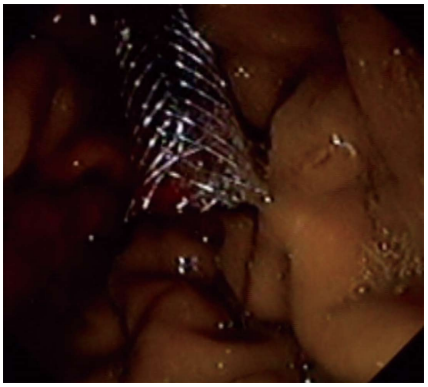

Figure 4 Endoscopic final aspect.

transmural access from the antral part of the stomach or duodenum[7] (Figure 2). Some endoscopists consider the latter as a route of access to the biliary system due to the anatomical position of the CBD (located in the retroperitoneal space), which might be safer in patients with ascites[18].

The stent can be inserted in the direction of the papilla (antegrade insertion, AG) or in the direction of the liver (retrograde insertion) (Figure 3). Finally, the drainage route can be transluminal {between the bile duct and either the stomach HGS or the duodenum [choledochoduodenostomy (CDS)]} or transpapillary, which, again, can be antegrade or retrograde (rendezvous, EUS-RV)[19].

The best EGBD route is not defined. Dhir *et al*[20] compare the success, complications, and duration of hospitalization for patients undergoing EUS-RV by the TH or the EH route. A total of 35 patients were analysed (17 TH, 18 EH). The mean procedure time was significantly longer for the TH group (34.4 *vs* 25.7 min; $P = 0.0004$). There was no difference in the technical success (94.1% *vs* 100%). However, the TH group had a higher incidence of post-procedure pain (44.1% *vs* 5.5%; $P = 0.017$), bile leak (11.7 *vs* 0; $P = 0.228$), and air under diaphragm (11.7 *vs* 0; $P = 0.228$). All bile leaks were small and managed conservatively. Duration of hospitalization was significantly higher for the TH group (2.52 *vs* 0.17 d; $P = 0.015$)[20]. Nevertheless, Artifon *et al*[21] compared the outcomes of 2 non-anatomic EGBD routes: Hepaticogastrostomy (HPG) - 25 patients and CD - 24 patients. HPG and CD techniques were similar in efficacy and safety (Figure 4).

Khashab *et al*[22] compared outcomes of rendezvous and transluminal techniques. During the study period, 35 patients underwent EGBD (rendezvous $n = 13$, transluminal $n = 20$). Technical success was achieved in 33 patients (94%), and clinical success was attained in 32 of 33 patients (97.0%). The mean post-procedure bilirubin level was 1.38 mg/dL in the rendezvous group and 1.33 mg/dL in the transluminal group ($P = 0.88$). Similarly, length of hospital stay was not different between groups ($P = 0.23$). There was no significant difference in adverse event rate between rendezvous and transluminal groups (15.4% *vs* 10%; $P = 0.64$). Long-term outcomes were comparable between groups, with 1 stent migration in the rendezvous group at 62 d and 1 stent occlusion in the transluminal group at 42 d after EGBD. Both rendezvous and direct transluminal techniques seem to be equally effective and safe[22].

According to previous reports, a 19G or 22G FNA needle or needle knife is used to puncture the CBD, followed by the passage of a 0.025-inch or 0.035-inch guidewire was inserted through the needle and looped in the biliary tree[7]. However, there are no randomized controlled trials comparing the outcomes of various FNA needles in the aforementioned procedure[23]. Various

devices have been previously described for dilatation of the fistula after puncturing the CBD[23]. The most common devices for transmural tract dilation are the rigid dilator 6 Fr up to 10 Fr, 4-8 mm balloon catheter, diathermic dilator or needle knife. The feasibility of graded dilation in EUS-HGS was superior to that of EUS-CDS[24].

In a series of 101 cases, Poincloux *et al*[25] placed the EUS in the cardia or the lesser curvature of the stomach and oriented it to view the dilated intrahepatic lateral sector bile ducts. Color Doppler ultrasound was used to confirm absence of vascular structures before EUS-guided puncture through the gastric body. The left bile duct puncture was performed using a 19-gauge access needle and a 0.035- inch super stiff guidewire was introduced through the EUS needle and advanced in an antegrade fashion to the main left bile duct. A hepatogastric fistula was created using a 5.5-Fr wire-guided needle-knife. 6-Fr and 7-Fr tapered biliary dilator catheters to dilate the fistula tract. Under EUS and fluoroscopic view, a stent was placed through the hepatogastrostomy between the main left bile duct and the gastric lumen.

Dhir *et al*[20] used a 19-gauge needle to puncture in the EUS-RV procedure. Attempt was made to puncture with the echoendoscope in a straight position and the needle pointing in the direction of the CBD. Once biliary access was confirmed by aspiration of 5-10 cc bile, contrast was injected to evaluate the ductal system and, a 0.032-inch hydrophilic angled-tip guide wire was inserted through the needle and directed in an anterograde fashion downstream across the stricture and/or the papilla into the duodenum. Once the guide wire crossed the papilla and looped in the duodenum, the echoendoscope was withdrawn and an ERCP scope was positioned at the papilla. Due to the short length of wire, continuous water injection was used to keep the wire in position. The guide wire was pulled into the biopsy channel of duodenoscope with a snare and ERCP was completed[20].

The stent selection is very important. Plastic stent has a low cost, but, self-expandable metal stents offer superior patency to plastic stents for palliation of malignant distal bile duct obstruction. Even though, the superiority of covered self-expandable metal stents to multiple plastic stents for treatment of benign biliary strictures has not been proven[26]. Covered metal stents may be useful to reduce bile leakage in EGBD.

PROCEDURAL LIMITATIONS

Most studies about EGBD are single center and based on case reports or small series. Many studies described this procedure with high success rates (more than 90%) and low rate of procedure-related complications (around 19%)[27], however, data from a large multicenter retrospective trial failed to report advantages of any of these techniques[5].

The main risk of EGBD is bile leakage. Complications of all techniques combined included pneumoperitoneum in 5%, bleeding in 11%, bile leak/peritonitis in 10%, and cholangitis in 5%. Complication rates were similar in benign and malignant disease. No significant difference in complication rates was noted when comparing plastic to metal stents, although a trend toward a better outcome was observed for metal stents (P = 0.09). There was a significantly higher incidence of cholangitis in patients with plastic stents (11% *vs* 3%; P = 0.02)[5].

The use of a needle-knife for fistula dilation was the single risk factor for post procedural adverse events after EGBD. Thus, use of a needle-knife for fistula dilation should be avoided if possible[24], with a risk of creating an unhealthy fistula. This problem does not arise with a cystotome or ring knife fistula creation.

In Dhir *et al*[19] retrospective multicenter study, death was a major complication reported in 4% of cases. All cases used EUS-RV TH route. Nevertheless, the success rate was equal for the various techniques.

CONCLUSION

Data involving mostly small series from expertise centers suggest that EGBD can be performed with high therapeutic success (87%) but it might be associated with 10% to 20% morbidity (mostly mild to moderate) and rare serious adverse events[28].

We recommend EGBD when bile duct access is not possible because of failed cannulation, altered upper GI tract anatomy, gastric outlet obstruction, a distorted ampulla, a *in situ* enteral stent or periampullary diverticulum, as a minimally invasive alternative to surgery or radiology.

Abstract

AIM: To demonstrate the feasibility and reproducibility of a pure natural orifice transluminal endoscopic surgery (NOTES) gastrojejunostomy using holing followed by interrupted suture technique using a single endoloop matched with a pair of clips in a non-survival porcine model.

METHODS: NOTES gastrojejunostomy was performed on three female domestic pigs as follows: Gastrostomy, selection and retrieval of a free-floating loop of the small bowel into the stomach pouch, hold and exposure of the loop in the gastric cavity using a submucosal inflation technique, execution of a gastro-jejunal mucosal-seromuscular layer approximation using holing followed by interrupted suture technique with endoloop/clips, and full-thickness incision of the loop with a Dual knife.

RESULTS: Pure NOTES side-to-side gastrojejunostomy was successfully performed in all three animals. No leakage was identified *via* methylene blue evaluation following surgery.

CONCLUSION: This novel technique for preforming a gastrointestinal anastomosis exclusively by NOTES is technically feasible and reproducible in an animal model but warrants further improvement.

Key words: Endoscopic gastrojejunostomy; Endoloop; Endoscopic clips; Natural orifice transluminal endoscopic surgery; Pigs

Core tip: A pure natural orifice transluminal endoscopic surgery gastrojejunostomy procedure may be successfully performed in a non-survival porcine model using holing followed by interrupted suture technique using one endoloop matched with a pair of clips, without the need of any additional devices.

Chen SY, Shi H, Jiang SJ, Wang YG, Lin K, Xie ZF, Liu XJ. Transgastric endoscopic gastrojejunostomy using holing followed by interrupted suture technique in a porcine model. *World J Gastrointest Endosc* 2015; 7(15): 1186-1190 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i15/1186.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i15.1186

INTRODUCTION

Gastro-jejunal side-to-side anastomosis is clinically designed for palliation of malignant gastric outlet obstruction (GOO)[1], performed primarily *via* open[2] and laparoscopic surgery[3]. Natural orifice transluminal endoscopic surgery (NOTES) may represent an alternative for the execution of gastro-jejunostomy procedures[4-10] due to less invasiveness and postoperative pain compared with the above-mentioned two procedures. To date, dozens of successful gastric bypass procedures by pure or hybrid NOTES have been reported, however, these methods are associated with some limitations, including being time-consuming, technically demanding and requiring specialized suturing devices.

Our experimental study aimed to demonstrate the feasibility and reproducibility of a pure NOTES gastrojejunostomy procedure using holing[11] followed by interrupted suture technique using a single endoloop matched with a pair of clips[12] in a non-survival porcine model.

MATERIALS AND METHODS

Animal model

Our study involved three healthy female domestic pigs weighing between 15 and 20 kg. All animals were fasted for 24 h prior to surgery. Induction of anesthesia was achieved *via* an intramuscular injection of 100 mg ketamine, 10 mg droperidol and 1 mg atropine, and anesthesia was maintained by intravenous drip of propofol at a rate of 10 mL/h with endotracheal intubation. Heart rate and oxygen saturation were monitored during the operation. Animals were kept in a supine position to allow for the best access and optimal peritoneal exploration. This study was approved by the Institutional Animal Use and Care Committee of Fujian Provincial Tumor Hospital, Teaching Hospital of Fujian Medical University, Fuzhou, China.

NOTES gastrojejunostomy

Gastrostomy: A small incision was created in the horizontal portion of the anterior pre-antral zone, which was determined *via* finger indentations of the abdominal wall, away from the small and large curvature, using a Dual knife (KD650L Olympus), followed by dilation using an 18-mm CRE balloon. The dual-channel therapeutic endoscope (GIF2TQ260M, Olympus Tokyo Japan) was subsequently advanced into the peritoneal cavity through the gastrostomy site.

Selection and retrieval of a free-floating loop of the small bowel into the stomach pouch: Loop selection was guided by loop proximity to the gastrostomy site to minimize the risk of tension and possible ischemia. An appropriate segment of the upper small intestine on its anti-mesenteric side was grasped by an endoscopic alligator forceps (FQ-46L-1, Olympus) through one channel of the endoscope and dragged through the incision into the stomach for the intra-gastric anastomosis, taking care not to include the mesenteric vascular supply to avoid unexpected incarceration.

Hold and exposure of the loop in the gastric cavity *via* submucosal inflation: An endoscopic injector (NM-400L-0423 Olympus) was passed through the other channel of the endoscope. Five to ten mL mL of saline solution mixed with 0.1 mL of 2% methylene blue was immediately injected into the submucosal layer circumferentially along the periphery of the gastrostomy site. Submucosal inflation temporarily decreased the size of the orifice of the gastrostomy to prevent the loop from falling back to the peritoneal cavity.

Execution of a gastro-jejunal mucosal-seromuscular layer approximation using holing followed by interrupted suture technique with endoloop/clips: First, a total of five to seven holes were made circumferentially along the periphery of the gastrostomy by using the Dual knife. An endoloop followed by an endoclip delivery system was inserted into the gastric cavity through the double-channel endoscope and placed at the side of one hole. One prong of the clip

Anastomotic leak	-	-	-

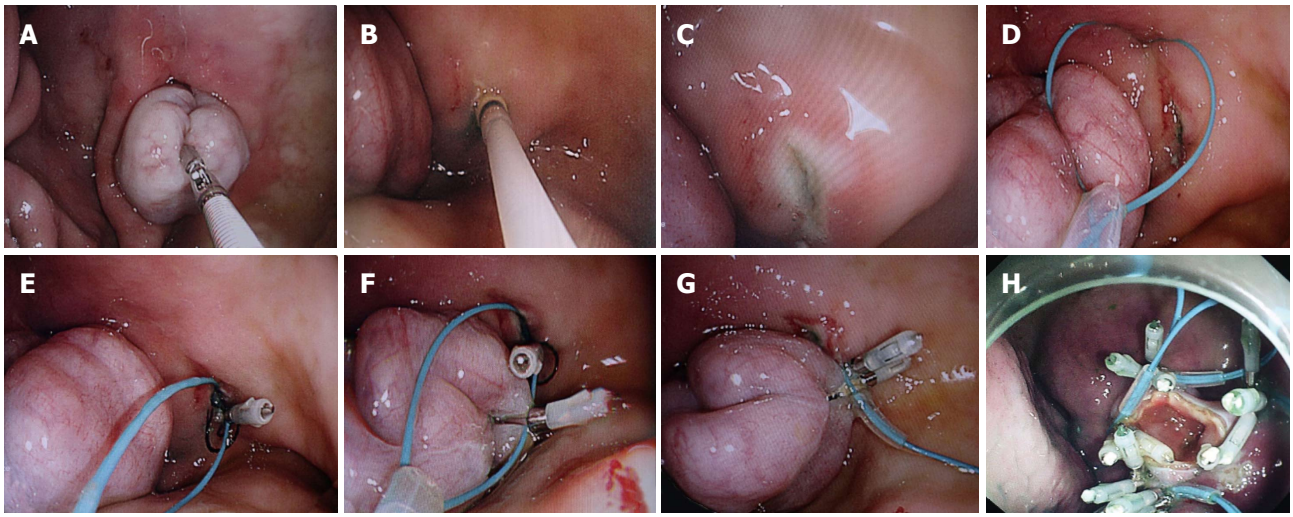

Figure 1 Step-by-step procedure of pure natural orifice transluminal endoscopic surgery side-to-side gastrojejunostomy. A: Endoscopic view of a loop of the small bowel in the stomach grasped by an endoscopic alligator forceps on its anti-mesenteric side; B: Image taken during submucosal injection around the loop; C: Endoscopic view of one hole made on gastric mucosal surface; D: Endoscopic view of an endoloop placed around the hole; E: Endoscopic view of one clip clipped to anchor the endoloop on the side of the stomach after the prong of the clip was inserted in the hole of the stomach wall; F: Endoscopic view of the second clip clipped to anchor the endoloop on the side of the small intestine; G: Endoscopic view of the endoloop tightened to approximate the gastric mucosal layer and the intestinal serosal layer; H: Endoscopic view of gasto-jejunal mucosal-seromuscular layer anastomosis followed by the loop full-thickness incision.

was then inserted in the hole of the stomach wall and clipped to anchor the endoloop. The second clip was used to anchor the same endoloop to the serosal surface of the small intestine. The gastric mucosal layer and the intestinal serosal layer were approximated by tightening of the endoloop. Briefly, gastro-jejunal mucosal-seromuscular layer anastomosis was created in pairs through the mucosa of the stomach and the serosa of small intestine to join the tissues based on the cooperation between one loop and a pair of clips. Five to seven pairs of interrupted sutures were placed to secure the anastomosis.

Full-thickness incision of the loop with the Dual knife: Jejunal loop incision was made longitudinally on its anti-mesenteric aspect to turn the inside mucosa out.

Euthanasia and necropsy

Euthanasia was performed immediately after the procedure. Necropsy results including injuries to adjacent organs, vascular bleeding, anastomotic patency and leakage evaluation were recorded.

RESULTS

Detailed data of pure NOTES side-to-side gastrojejunostomy performed on the three animals are shown in Table 1 and Figure 1. The procedure was technically successful in all cases. The duration of the procedure ranged from 1.0 to 1.5 h. Minor bleeding occurred from the right gastroepiploic artery during gastrostomy in 2 pigs and treated efficiently with the endoscopic hemostatic forceps (FD-410LR, Olympus) (80 W/soft-coagulation). On the postmortem examination, the immediate patency of the anastomosis was satisfactory, and no evidence of anastomotic leakage was identified *via* methylene blue evaluation[13] (Figure 2).

DISCUSSION

The advent of NOTES has made a minimally invasive endoscopic technique possible for creation of gastrojejunal anastomosis, being faced with opportunities and challenges at the same time.

Previous studies[4,7,8-10] have reported three full-thickness suturing methods summarized as the small intestine being pulled into the stomach lumen and

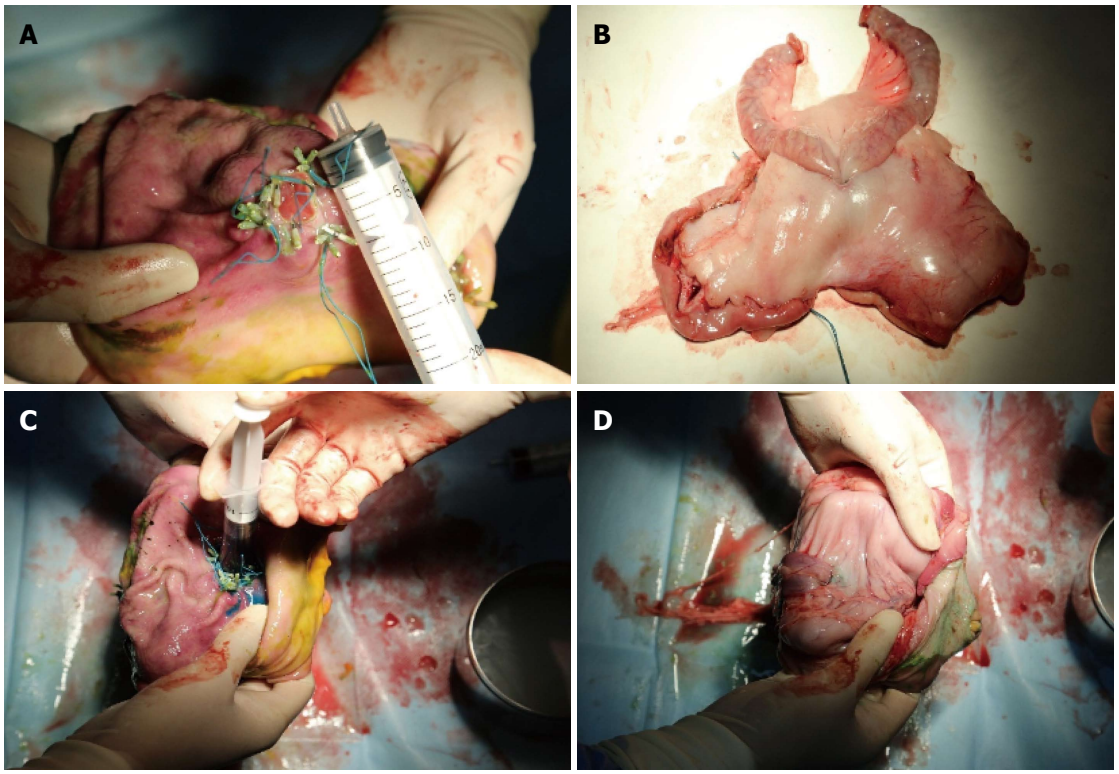

Figure 2 Postmortem appearances of anastomosis. A: Macroscopic appearance showing that the intestinal wall had been joined to the stomach wall; B: Macroscopic appearance of gastrointestinal side-to-side anastomosis; C: Methylene blue instilled into the anastomotic lumen; D: No methylene blue observed on the surface of gastric serosa around the anastomosis.

then sutured to the stomach wall using newly designed endoscopic suturing devices as follows: (1) a prototype endoscopic suturing device (Eagle Claw; Olympus)[7]; (2) a prototype "T-tag" suture system (BraceBar; Olympus)[4,9,10]; and (3) an EndoGIA stapler (Covidien)[8]. Here we reported for the first time, the use of interrupted suture technique using one endoloop matched with a pair of clips in a non-survival porcine model. This new technique resembles T-tag suture system, one of the aforementioned three methods, with its own unique characteristics. First, submucosal saline solution injection around the gastrostomy site made a slight cushion that prevented unexpected perforation by electric knives and allowed space to create holes deep enough to insert the prongs of the clip and to facilitate the subsequent secure clipping. Furthermore, submucosal inflation temporarily decreased the size of the orifice, and the smaller orifice allowed us to manipulate the loop of the small intestine in place more easily. Second, creating several holes at the edge of gastrostomy provided strong anchoring points for one prong of a clip in order to avoid clip slippage during grasping gastric thick mucosal surface. Third, interrupted suture method using one endoloop matched with a pair of clips was derived from the principle of "sewing" using a pair of T-tags with a single puncture needle, which may be done successfully by using only endoscopes and common endoscopic accessories, without the need of any extra devices.

In particular, if the small intestine was inadvertently dropped during the procedure, no leakage of small bowel contents occurred because the bowel wall was not incised until the anastomosis was complete.

Our pilot study had several limitations, however. First, endoscopic selection of an appropriate loop of the small bowel and secure fixation of the small bowel to the gastric wall without intra-peritoneal manipulation remains challenging[14]. In our current study, the appropriate portion of the small bowel was identified based on its proximity to the gastrostomy site and the left upper abdominal anatomical landmarks such as the spleen. For clinical studies, EUS guidance could be used to direct the targeted jejunal segment near the ligament of Treitz in non-altered anatomy patients[1,15]. Second, both of the endoscopic endoloop/clips utilized in our study, as well as the sewing devices (such as T-bar sutures) predominantly approximate the mucosa, and the reliability and durability of the anastomosis under gastric pressure should be estimated in the porcine model of GOO. Ryou *et al*[16] demonstrated that gastric mucosal closure with endoscopic clips may result in significant air and fluid leakage *via* the line of clips, however, this was not observed in our study.

In conclusion, this novel technique of performing gastrointestinal anastomosis exclusively by NOTES is technically feasible and reproducible in an animal model, although further improvement is warranted.

COMMENTS

Background

Gastro-jejunal side-to-side anastomosis is clinically designed for palliation of malignant gastric outlet obstruction (GOO), mostly performed *via* open and

laparoscopic surgery. Natural orifice transluminal endoscopic surgery may represent an alternative method of performing gastro-jejunostomy procedures due to its less invasiveness and lower incidence of postoperative pain compared with the above-mentioned two methods.

Research frontiers

To date, dozens of successful gastric bypass procedures *via* either pure or hybrid natural orifice transluminal endoscopic surgery (NOTES) have been described, however, these methods are associated with some limitations, as they are time-consuming, technically demanding and require specialized suturing devices.

Innovations and breakthroughs

A pure NOTES gastrojejunostomy procedure may be successfully performed in a non-survival porcine model using holing followed by interrupted suture technique using one endoloop matched with a pair of clips, without the need of any additional devices.

Applications

This study demonstrates the potential application of pure NOTES gastrojejunostomy using holing followed by interrupted suture technique using one endoloop matched with a pair of clips for palliation of malignant GOO.

Terminology

A NOTES gastrojejunostomy using interrupted suture technique with a single endoloop matched with a pair of clips resembles the technical principle of T-tag suture system, without the need of any additional devices.

Peer-review

The advent of NOTES has made a minimally invasive endoscopic technique possible for creation of gastrojejunal anastomosis, being faced with opportunities and challenges at the same time. A pure NOTES gastrojejunostomy procedure may be successfully performed in a non-survival porcine model using holing followed by interrupted suture technique using one endoloop matched with a pair of clips.

Abstract

AIM: To evaluate the pain relieving effect of intervention with "Lamaze method of colonoscopy" in the process of colonoscopy.

METHODS: Five hundred and eighty-five patients underwent colonoscopy were randomly divided into three groups, Lamaze group, anesthetic group and control group. Two hundred and twenty-four patients of Lamaze group, the "Lamaze method of colonoscopy" were practiced in the process of colonoscopy. The Lamaze method of colonoscopy is modified from the Lamaze method of childbirth, which helped patients to relieve pain through effective breathing control. One hundred and seventy-eight patients in anesthetic group accepted sedation colonoscopy. For 183 patients in control group, colonoscopy was performed without any intervention. The satisfactory of colon cleaning, intestinal lesions, intubation time, success ratio, pain grading and complications were recorded. All data were statistically analyzed.

RESULTS: There were no significant differences at base line of the three groups ($P > 0.05$). Anesthetic group shows advantage in intubation time than the other two groups ($P < 0.05$). Lamaze group shows no advantage

in intubation time than that in control group ($P > 0.05$). The anesthetic group showed an apparent advantage in relieving pain ($P < 0.01$). Therefore, the "Lamaze method of colonoscopy" performed in colonoscopy could relieve pain effectively comparing with control group ($P < 0.05$). The patients in anesthetic group had the highest incidence of complications ($P < 0.05$).

CONCLUSION: The performance of the "Lamaze method of colonoscopy" in the process of colonoscopy could relieve patients' pain, minimize the incidence of complications, and is worthy promotion in clinical practice.

Key words: Colonoscopy; No sedation; Pain; Lamaze technique

Core tip: Colonoscopy is used as primary investigation of colorectal neoplasm worldwide and is of great value in detection of colorectal cancer in early stage. Though, it is not widely accepted by patients due to the uncomfortable feeling, especially pain, during the process. Recent years, sedation colonoscopy has developed rapidly, it has led to a great promotion of the increase of the patients' acceptance of follow up examination. Therefore, complication of sedation colonoscopy such as bleeding, perforation, cardiopulmonary events happens once in a while. Some kinds of unsedation colonoscopy had been reported by several scholars. Music, warm water infusion is the two most often reported methods. Here we evaluated the effect of a new method of unsedation colonoscopy we called "the Lamaze method of colonoscopy"(Lamaze colonoscopy) modified from the Lamaze method of childbirth. Our study suggested that Lamaze colonoscopy is an effective way to relief pain during colonoscopy.

Yu SP, Lin XD, Wu GY, Li SH, Wen ZQ, Cen XH, Huang XG, Huang MT. Unsedation colonoscopy can be not that painful: Evaluation of the effect of "Lamaze method of colonoscopy". *World J Gastrointest Endosc* 2015; 7(15): 1191-1196 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i15/1191.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i15.1191

INTRODUCTION

Colonoscopy plays a big part in primary investigation of colorectal diseases and screening for colorectal neoplasm[1]. Some patients find it difficult to endure the procedure and refuse the follow up examination due to the pain during the procedure. In recent years, the administration of anesthetics during endoscopy introduced by some scholars has achieved extraordinary results[2,3]. Meanwhile, some patients are susceptible to intestinal bleeding, bowel perforation and sedation-related cardiopulmonary adverse reaction due to the loss of pain and throat reflex in anesthesia[4,5].

"The Lamaze method of childbirth", developed by the French obstetrician Ferdinand Lamaze, has been used to decrease the level of maternal pain during natural birth since late 1950s, and plays a good role in the area[6]. Pain during delivery is mainly caused by contraction of uterus. Colonoscopy requires gas infusion during the process, which can stretch the colon like a balloon if gas accumulated; the retroaction against stretching of colon may cause the pain and uncomfortable feeling[7]. The mechanism of pain in childbirth and colonoscopy is similar. We created "The Lamaze method of colonoscopy" (Lamaze colonoscopy), which was modified from "The Lamaze method of childbirth", and practiced it in the process of colonoscopy. In our study, we verified the effect of Lamaze colonoscopy in reducing pain during colonoscopy.

MATERIALS AND METHODS

Patients

The study included consecutive patients underwent colonoscopy at endoscope center in our hospital from November 2012 to October 2014. The first 3 patients whom underwent sedation colonoscopy were enrolled in anesthetic group every Monday (Monday is our sedation colonoscopy day) except for holidays and those whom needed endoscopic treatment such as polypectomy. The first 3 patients whom underwent unsedation colonoscopy were enrolled in Lamaze group every Tuesday. Those whom needed endoscopic treatment were also ruled out. The first 3 patients whom underwent unsedation colonoscopy were enrolled in control group every Thursday. Those whom needed endoscopic treatment were excluded too. Patients with severe cardiopulmonary dysfunction, stroke, moderate to severe ascites, renal insufficiency, severe malnutrition and patients who were bed ridden were excluded from the study. All patients enrolled in the experiment had signed a consent form of colonoscopy examination. Patients in anesthetic group all signed a consent form of sedation. A total of 585 patients aged from 25-82 years old were enrolled. There were 224 patients in Lamaze group, 178 patients in anesthetic group and 185 patients in control group finally.

Examination

Bowel preparation was routinely accomplished with a 2 L electrolyte solution of polyethylene glycol (all patients were chinese which belongs to yellow race). All patients were given supplemental oxygen intranasal (2 L/min). Heart rate, blood pressure and oxygen saturation were monitored throughout the procedure. Intravenous sedation-analgesics provided by the anesthetist in anesthetic group using a combination of fentanyl (0.5-1 μg/kg) and propofol (1.5-2 mg/kg) at the discretion of the endoscopists. Five doctors with at least 5-years-experience of performing colonoscopy performed the procedure. We began to insert

Table 1 Lamaze method of childbirth and the Lamaze method of colonoscopy

Lamaze method of childbirth[8,9]	Thoracic breathing: Used in initial stage of uterus contraction, method: (1) completely relaxed; (2) eyes fixed on a certain point; (3) abdominal stay relaxed while breath in from nose, breath out from mouth; (4) a total of 6-9 times of inspiration and expiration per minute; and (5) practice 5 times a day, 60 s each time Shallow and slow accelerating breathing: Use when the uterus contracts each 2-4 min, cervix opened to 2-8 cm. Method: Step (1-3) is the same with thoracic breathing; and (4) accelerate the breathing when uterus contraction enhanced, slow it down while contraction relieves Shallow breathing: Use when the uterus contracts lasts for 60-90 s each 30-90 s , cervix opens to 8-10 cm Method: Step (1-2) is the same with thoracic breathing; (3) open mouth slightly to help breath (making a sound "hee-hee"); (4) breathing with nose, making noise from the larynx; (5) adjust the respiratory rate according to intensity of the contraction; (6) inspiration and expiration the same volume of air to avoid hyperventilation; and (7) 4-6 quickly continue inspiration and expiration then vigorously exhale, repeat until uterus contraction stops Close air-way and force movement: Used when cervix is full opened to 10 cm. Method: (1) legs apart, hands holding handrail of obstetric delivery bed; (2) vigorously aspirated and close air-way, force down; (3) head up slightly staring at navel with jaw neck down forward; and (4) hold breath for 20-30 s as far as possible, exhale and hold breath at once and force movement until uterus contraction stops Halitus movement: Used when cannot exert herself but cannot help to do it. Method: (1) mouth open, breathing quickly like gasping; and (2) the whole body is relaxed totally
The Lamaze method of colonoscopy	Thoracic breathing: Used when the procedure begins, method: (1) completely relaxed; (2) eyes fixed on a certain point; (3) abdominal stay relaxed while breath in from nose, breath out from mouth; and (4) a total of 6-9 times of inspiration and expiration per minute Shallow and slow accelerating breathing: Used when the scope is crossing the junction of sigmoid colon and descending colon from the sigmoid colon. Method: Step (1-3) is the same with thoracic breathing; and (4) accelerate the breathing when pain enhanced, slow it down while pain relieved Shallow breathing: Used when the scope is crossing the splenic flexure. Method: (1) completely relaxed; (2) eyes fixed on a certain point; (3) open mouth slightly to help breath (making a sound "hee-hee"); (4) breathing with nose, making noise from the larynx; (5) adjust the respiratory rate according to pain intensity; (6) inspirate and expirate the same volume of air to avoid hyperventilation; and (7) 4-6 quick continue inspirate and expirate then vigorously exhale, repeat until the pain disappear Close air-way and force movement: Used when the pain is moderate or severe. Method: (1) vigorously aspirated and close air-way, force down; and (2) hold breath for 20-30 s as far as possible, exhale and hold breath at once and force movement until pains relieves or disappeared

colonoscope when patients fell asleep when their eyelash reflex disappeared, breathed calmly and muscle relaxed. Patients in Lamaze group were trained "the Lamaze method of colonoscopy" (detailed in Table 1), by the assigned nurse in endoscope center, 5-8 min before examination. It would be continuously practiced during the whole process of colonoscopy. The control group was given no intervention. The colonoscopy was categorized as completed when reached the cecum or the ileocolic anastomosis (in case of colonic surgery).

The endoscopists graded the quality of bowel preparation immediately after the procedure. Grade 1 as excellent with no stool visualized, Grade 2 as satisfactory with a small amount of stool visualized not blocking the view, Grade 3 as unsatisfactory with stool blocking the view and/or the passage of the colonoscope. He/she also evaluated the difficulty of insertion of the colonoscopy on a 100 mm visual analog scale, with 0 "very easy" and 100 "very difficult." All patients were asked to finish a questionnaire after the procedure in which they graded abdominal pain using a visual analogue scale (VAS) from 0 to 10 (0 as extremely acceptable/least severe, 10 as least acceptable/extremely severe). Patients marked the point on the line that they feel representing their pain grade. The VAS score is determined by measuring in millimeters from the left hand end of the line to the point that the patient marks.

Equipment and record

Age, gender, history of previous colonoscopy or previous abdominal surgery was recorded before examination. The satisfaction of colon cleaning, intestinal lesions, intubation time, success ratio and complications were also recorded after examination.

Equipment and personnel

Bowel preparation was done in all patients before the examination using 2 L electrolyte solution of polyethylene glycol. Colonoscopy examinations were performed by an experienced endoscopist, using a video colonoscope (FUJINON). Technique assistance is performed by the same assistant when needed during examination. Patients were sedated in presence of an aesthetist. The endoscopists, assistant and nurse received the "Lamaze method of childbirth" course before trial. They were also trained to perform Lamaze colonoscopy using the method above.

Statistical analysis

SPSS 19.0 was used to process data. Quantitative data were reported as means ± SD. One-way ANOVA was used to compare the age and intubation time of the three groups, least-significant difference is used to compare the differences within groups if difference is significant between groups and the test of homogeneity of variances shows $P < 0.05$. χ^2 test was used to compare gender, history of previous colonoscopy, previous abdominal surgery history, intestinal lesions, success ratio and complications. The satisfactory of colon cleaning and the pain grades of the three groups were

Table 2 Comparison on patients' age, gender, previous colonoscopy history and previous abdominal surgery history

	Age (yr)	Gender (male/female)	Previous colonoscopy(Y/N)	Previous abdominal surgery(Y/N)
Lamaze group	54.9 ± 9.9	118/106	88/136	43/181
Anesthetic group	55.6 ± 9.7	76/102	62/116	25/153

	Normal	Colon polyps	Colonic diverticulum	IBD	Colon cancer
Lamaze group	127	69	11	8	9
Anesthetic group	107	46	9	9	7
Control group	115	39	8	12	9

$\chi^2 = 6.293$; $P = 0.614$. IBD: Inflammatory bowel disease.

compared with crosstable Pearson χ^2 test. Criterion for statistical significance was $P < 0.05$.

RESULTS

There were no significant differences between the three groups in age, gender, history of previous colonoscopy and history of abdominal surgery (Table 2).

According the endoscopists' finding, there was no difference in the quality of colon cleanliness and the intestinal lesions between the three groups (Tables 3 and 4).

The anesthetic group was much more successful in alleviating pain comparing to the other two groups, 57.3% (102/183) of patients feel completely no pain at all. The Lamaze group of colonoscopy is also more efficient in relieving pain than the control group (Tables 5 and 6).

The time required for intubation in anesthetic group is shorter than the other two groups. But the Lamaze group did not demonstrate its improvement compared with control group in this aspect (Tables 7 and 8).

Only 1 case failed to complete colonoscopy in anesthetic group, the patient was a thin women who had a previous history of cesarean section. That number in Lamaze group and control group are 7 and 12. But there is no significant difference between the three groups ($P = 0.06$) (Table 9).

The complication rates of both the Lamaze group and control group were lower and complication is milder than the anesthetic group. In anesthetic group, 5 patients incurred a decrease of pulse oxygen saturation (< 90%), and 2 of the patients' heart rate drops to < 60 bpm, but all of them recovered immediately after effective intervention. There were no deaths in all three groups. The difference on complications of the three groups was significant ($P = 0.001$) (Table 10).

Table 5 Comparison on patients' pain grading

	0-2	2-4	4-6	6-8	8-10
Lamaze group	47	96	77	3	1
Anesthetic group	142	35	1	0	0
Control group	6	7	71	88	11

$\chi^2 = 506.579$; $P < 0.001$.

Table 6 Further pair-wised comparison of patients' pain grading

	χ^2	*P*
Lamaze group *vs* control group	194.43	< 0.001
Lamaze group *vs* anesthetic group	150.92	< 0.001
Anesthetic group *vs* control group	310.68	< 0.001

Table 7 Comparison on intubation time

	Intubation time (min)
Lamaze group	9.21 ± 2.76
Anesthetic group	7.46 ± 2.93
Control group	9.45 ± 2.38

F = 29.696, $P < 0.001$

DISCUSSION

Colonoscopy is used as primary investigation of colorectal neoplasm worldwide and is of great value in detection of colorectal cancer in early stage[1]. Though, it is not widely accepted by patients due to the uncomfortable feeling, especially pain, during the process. Recent years, sedation colonoscopy has developed rapidly, it has led to a great promotion of the increase of the patients' acceptance of follow up examination[10-12]. Therefore, complication of sedation colonoscopy such as bleeding, perforation, cardiopulmonary events happens once in a while[13]. Some kinds of unsedation colonoscopy had been reported by several scholars. Music, warm water infusion is the two most often reported methods[14-16]. Here we evaluated the effect of a new method of unsedation colonoscopy we called "the Lamaze method

Table 8 Further pair-wised comparisons on intubation time

	Mean difference	Standard error	*P*	95%CI	
				Lower bound	Upper bound
Lamaze group *vs* control group	-0.243	0.269	0.368	-0.77	0.29
Lamaze group *vs* anesthetic group	1.75	0.271	< 0.01	1.22	2.28
Anesthetic group *vs* control group	-1.993	0.285	< 0.01	-2.55	-1.43

Table 9 Comparison on the quality of bowel cleanliness

	Success(Y/N)
Lamaze group	217/7
Anesthetic group	177/1
Control group	171/12

$\chi^2 = 9.918$, $P = 0.06$.

Table 10 Comparison on complications

Lamaze group	224	2	0	1	221
Anesthetic group	178	9	0	7	162
Control group	183	3	0	1	179

$\chi^2 = 18.043$; $P = 0.001$.

of colonoscopy" (Lamaze colonoscopy) modified from the Lamaze method of childbirth. The Lamaze method of childbirth could reduce pain by effective breathing and relaxation training. Acknowledge of pre-delivery and delivery rule could be applied to different stages and different grades of pain to intentionally control pain caused by contractions and other discomfort feeling. The pain was transferred since mothers focus on breathing control[17]. In our study, we found Lamaze colonoscopy which modifying from "the Lamaze method of childbirth" according to the characteristics of colonoscopy. It was applied to the examination. The results indicated that the pain could be alleviated when use Lamaze colonoscopy. The mechanism of pain during colonoscopy is similar to that of childbirth. Both are caused by the spasm of smooth muscle. But the pain during colonoscopy is artificially caused by the insertion of endoscope. Also, severe pain is caused by the knotting of endoscope during operation. Lamaze colonoscopy may could maintain a relatively constant position of intestinal tract by deepening abdominal respiration, made colonoscope passed easily.

This study compared with the difference of anesthetic group, Lamaze group and control group from several aspects at the same time. Judging from the outcome, the applications of Lamaze colonoscopy did not shorten the time of intubation. The main reason of time increasing is due to the needs of helping patients get into the right step during operation. Considering from the success ratio, the anesthetic group got the highest success ratio, but it did not demonstrate a statistical difference. Too many factors working on the success ratio, research shows that age, gender, preparation of intestine, history of previous abdominal surgery, chronic colitis all contribute to it[18,19]. There is no statistical difference among the three groups in age, gender, preparation of intestine, history of previous abdominal surgery and intestinal lesions.

The usage of sedatives in colonoscopy obviously improves the acceptance and tolerance of the examination in patients. However, some issues still cannot be avoided in anesthetic colonoscopy. Venous channel must be built before the exam, medical fee increased, recovery time was prolonged, complications such as cardiopulmonary events happens. The usage of sedatives can suppress respiratory directly, causing blood pressure drops. Severe allergic reaction can be life threatening, anesthetic colonoscopy causing aspiration pneumonia leads to Acute Respiratory Distress Syndrome (ARDS) finally caused death is reported in China[20]. In this study, 2 subjects' heart rate decrease to < 60 beat per minute, 5 subjects' SPO_2 declined to less than 90% in anesthetic group, all those recovered after proper intervention. The incidence rate of complication especially severe complication is lower in Lamaze group and control group than that in anesthetic group. There is some deficiency in our study, the follow-up period is only one week, some delayed complication might be neglected. Some studies expended the follow-up period up to 30 d in accordance with complication[5,21]. This is a single center study, multiple center study using the same standard may provide more evidences of the value of Lamaze colonoscopy.

To sum up, the application of "the Lamaze method of colonoscopy" in colonoscopy can ease the pain of patient effectively, enhance the tolerance of colonoscopy and avoid the adverse effect of anesthetics. This method is worthy of wide promotion, summary and improvement.

ACKNOWLEDGMENTS

Thanks to Dr. Professor Yang Bai from the Southern Medical University, he reviewed this article, and offered several pieces of professional advice. Professor Jin-Hua Xu, major of statistics from the Ningxia Medical School gave us some suggestions about the data processing. Thanks to Stephen John Rose from London in the United Kingdom for his kind reviewing of the language. He also gave us some nice advice of the language. Here

we would like to thank them all for their generous help.

COMMENTS

Background

Colonoscopy plays a big part in primary investigation of colorectal diseases and screening for colorectal neoplasm. Some patients find it difficult to endure the procedure and refuse the follow up examination due to the pain during the procedure. Sedation colonoscopy developed quickly in recent years, but the adverse reaction happens once in a while. Some unsedation colonoscopy had been used to relieve patients' pain.

Research frontiers

Some kinds of unsedation colonoscopy had been reported by several scholars. Music, warm water infusion is the two most often reported methods. They can all relief pain during unsedation colonoscopy, but not as effect as sedative colonoscopy. New method could be explored.

Innovations and breakthroughs

The use of Lamaze colonoscopy modified from Lamaze childbirth had never been reported. They explored the possibility of it, which is another way of pain-relief in patient undergoes colonoscopy.

Applications

The application of "the Lamaze method of colonoscopy" in colonoscopy can ease the pain of patient effectively, enhance the tolerance of colonoscopy.

Peer-review

The study is interesting and can be very useful in the pain-relief area of study.

Abstract

Insulinomas are rare pancreatic neuroendocrine tumors that are most commonly benign, solitary, and intra-pancreatic. Uncontrolled insulin overproduction from the tumor produces neurological and adrenergic symptoms of hypoglycemia. Biochemical diagnosis is confirmed by the presence of Whipple's triad, along with corroborating measurements of blood glucose, insulin, proinsulin, C-peptide, β-hydroxybutyrate, and negative tests for hypoglycemic agents during a supervised fasting period. This is accompanied by accurate preoperative localization using both invasive and non-invasive imaging modalities. Following this, careful preoperative planning is required, with the ensuing procedure being preferably carried out laparoscopically. An integral part of the laparoscopic approach is the application of laparoscopic intraoperative ultrasound, which is indispensable for accurate intraoperative localization of the lesion in the pancreatic region. The extent of laparoscopic resection is dependent on preoperative and intraoperative findings, but most commonly involves tumor enucleation or distal pancreatectomy. When performed in an experienced surgical unit, laparoscopic resection is associated with minimal mortality and excellent long-term cure rates. Furthermore, this approach confers equivalent safety and efficacy rates to open resection, while improving cosmesis and reducing hospital stay. As such, laparoscopic resection should be considered in all cases of benign insulinoma where adequate surgical expertise is available.

Key words: Pancreatic insulinoma; Laparoscopic surgery; Technique; Outcomes; Minimally invasive surgery

Core tip: Insulinomas have always fascinated physicians and surgeons alike, due to the difficulties in: (1) diagnosing them; (2) obtaining accurate preoperative and intraoperative localization; and (3) actually performing

the operation safely and effectively. Laparoscopy stands out in the current literature as the approach of choice, and is employed for virtually all benign insulinomas. Enucleations for insulinomas in the head and body, as well as distal pancreatectomies for lesions in the body and tail of the pancreas, have been shown to be safe and effective in the current series. Laparoscopic intraoperative ultrasound localization has emerged as a standard adjunct to these procedures.

Antonakis PT, Ashrafian H, Martinez-Isla A. Pancreatic insulinomas: Laparoscopic management. *World J Gastrointest Endosc* 2015; 7(16): 1197-1207 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i16/1197.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i16.1197

INTRODUCTION

Insulinomas are insulin-secreting neuroendocrine tumors deriving from neoplastic pancreatic islet cells, and occurring almost exclusively in the pancreas[1,2]. They are gastroenteropancreatic neuroendocrine tumors (GEP-NETs) belonging to the subgroup of neuroendocrine tumors (NETs) known as pancreatic endocrine tumors (PETs)[3]. In contrast to other PETs, approximately 90% of insulinomas are sporadic, solitary, and benign, measuring less than 2 cm in diameter[1,2,4-6]. These characteristics, along with their highly symptomatic presentation, make complete surgical removal the treatment of choice for affected patients[2,7,8]. Surgical treatment options include tumor enucleation and regional pancreatic resection[8]. However, until recently, the only available approach was open surgery.

Laparoscopic enucleation and distal pancreatectomy were first reported in the 1990s by Gagner *et al*[9]. In fact, the small, benign, and solitary nature of insulinomas makes them ideal candidates for a laparoscopic approach, particularly in overweight or obese patients. In the last 20 years, several case reports[10,11] and case series[9,12-31], including our own[32-34], have explored the technical aspects of laparoscopic insulinoma resection. The results presented in these studies demonstrate the feasibility, safety, and reproducibility of laparoscopic insulinoma resection in experienced hands. Consequently, recently published guidelines now consider laparoscopic enucleation an appropriate treatment modality for the majority of insulinomas[8,35-37]. This article reviews the current status of laparoscopic insulinoma management and discusses both the strategic and technical aspects of surgical care in these patients.

BACKGROUND

Insulinomas are rare and exhibit a number of unique characteristics when compared to other PETs. These differences in the epidemiology, clinical features, and biological behavior of insulinomas impact significantly on their management and define the role and limitations of laparoscopic surgical intervention.

EPIDEMIOLOGY: SURGICAL MANAGEMENT OF RARE PATHOLOGY

The estimated annual incidence of insulinomas is 0.7-4 diagnosed cases per million persons[38]. Their rarity, combined with the unique challenges presented throughout the course from diagnosis to therapy, requires expert referral and management. Centralization of care is therefore of utmost importance for these patients, and tertiary referral to centers of excellence that follow a multidisciplinary approach is strongly advocated in current treatment guidelines[8,35-37]. The low incidence of insulinomas makes it difficult for any surgeon outside of pancreatic centers of excellence to gain sufficient experience in insulinoma resection[8,35-37]. Furthermore, although a laparoscopic approach is encouraged, the choice between open and laparoscopic surgery should be left to the discretion of the surgical team. It is therefore paramount that surgeons making such decisions are experienced in both open and minimally invasive procedures, in order to offer their patients the optimal treatment.

INSULINOMAS IN THE CONTEXT OF MULTIPLE ENDOCRINE SYNDROME TYPE 1

The vast majority of insulinomas are sporadic, but in 5%-10% of cases they present in the context of multiple endocrine syndrome type 1 (MEN1)[6,7]. MEN1-related insulinomas are frequently multifocal and coincide with several other pancreatic lesions (most commonly non-functioning pancreatic endocrine tumors)[6,39]. It therefore becomes very difficult preoperatively to determine with certainty the lesions for resection that are responsible for the clinical syndrome. This is further confounded by the fact that not all pancreatic lesions with immunohistochemically proven insulin production capacity produce clinical symptoms[39,40].

As such, it is both difficult to determine preoperatively the lesions responsible for the clinical syndrome and to definitively state whether surgical resection has been curative, even when insulin-producing lesions are documented in the pathology report. Consequently, significantly higher failure and recurrence rates are documented after surgery for MEN1-related insulinomas when compared to sporadic lesions[39,41].

In view of the difficulty in achieving complete clearance, a more radical surgical approach is preferred in MEN1-associated insulinomas[39,41,42]. Current surgical practice depends on the site of the tumor. For distal lesions, distal pancreatectomy with or without splenic preservation is required. Proximal tumors located in the pancreatic head may be enucleated, but total pancreatectomy may be required in selected

cases[35,36,39,41-44]. Local resections are not routinely indicated, despite some recently promising results in selected solitary or dominant lesions[45]. Moreover, the procedure of choice should be decided after careful preoperative localization, and take into account the need for symptom alleviation (*i.e.*, complete resection of all insulinomas), the malignant potential of all existing pancreatic lesions (including, but not limited to, insulinomas), and the expected complications, together with the existence of any previous surgical attempts. It is notable that laparoscopic resection in the context of MEN1 requires advanced minimally-invasive surgical skills due to the inherent difficulties of laparoscopic distal pancreatectomy, particularly where combined enucleations in the head of the pancreas are required. Finally, it should be mentioned that, in our recent experience, enucleation of single lesions in the head of the pancreas in the context of MEN has been successful in rendering the patient asymptomatic 12 mo after surgery.

BIOLOGICAL BEHAVIOR

Although the majority of insulinomas are benign and curable by surgical resection, approximately 5%-10% show malignant behavior[38]. However, with an annual incidence of approximately 0.1 per million persons per year[46], malignant insulinomas are extremely rare. Similar to all other neuroendocrine pancreatic tumors, the malignant potential of insulinomas is assessed by tumor differentiation (extent of resemblance to normal cells), grade (degree of biologic aggressiveness), and stage (extent of tumor spread)[47]. Of note, although a number of different pathological grading and clinicopathologic staging classifications have been suggested, no single system has been universally adopted[47].

Local invasion and/or evidence of liver metastases clearly demonstrate malignancy[7]. However, in the absence of these findings, malignant behavior must be determined from the pathologic characteristics of preoperative tissue biopsies when they were taken, because in most cases, EUS-guided Fine Needle Aspiration is performed at most. Although the course of malignant insulinomas is more indolent than other malignant neuroendocrine pancreatic tumors, the median survival is only 2 years, while the 10-year survival rate is only 29%[5,6,48]. Although, in some cases, malignant insulinomas have been reported with higher survival rates[49], this prognosis remains significantly poorer than for benign insulinomas, which present a 95%-100% surgical cure rate[5-7,48].

These key facts define the role and the limitations of both laparoscopic and open surgery in patients with malignant insulinoma. However, it is possible that extensive surgical resection of the primary tumor, affected lymph nodes, and distant metastases may provide alleviation for hypoglycemia and long-term survival when combined with adjunctive therapy such as medical treatment, radiofrequency ablation, transarterial chemoembolization, somatostatin analogues, chemotherapy, or biological agents. In resectable malignant disease, surgical options may provide a cure, and include distal pancreatectomy, pancreaticoduodenectomy with or without metastasectomy, segmentectomy, formal hepatectomy, or even liver transplantation[6,30,36,37,49,50]. Where the disease is unresectable in its entirety, debulking surgery may provide symptomatic relief when combined with medical and ablative therapy. Whenever malignancy is determined preoperatively, these operations are performed exclusively *via* laparotomy. Laparoscopic resection is not routinely practiced and no guidelines currently exist as to the role of laparoscopic intervention in these cases. Conversely however, in some cases the malignant potential of an insulinoma may only be acknowledged after laparoscopic resection as a result of specimen histology, symptom recurrence, and/or metastasis development during follow-up. In these cases, a multidisciplinary assessment is mandatory, and is most commonly followed by secondary radical open resection in combination with adjunctive therapy.

CLINICAL SYMPTOMS AND BIOCHEMICAL DIAGNOSIS

Insulinomas most commonly present with hypoglycemia caused by inappropriate excessive endogenous insulin production. Physical exercise and fasting usually provoke the symptoms, which fall in two major categories: Neurologic and adrenergic[4,6,7,43,51]. Neurologic symptoms are attributed to the effects of low blood glucose on the nervous system (neuroglycopenia) and include visual disturbances (diplopia and blurred vision), altered mental status, abnormal behavior, seizures, amnesia, and even coma[4,6,7,43,51]. Adrenergic symptoms are attributed to reactive catecholamine overproduction and include nausea, excessive sweating, anxiety, palpitations, weakness, tremors, increased appetite, and heat intolerance[4,6,7,43,51]. Each patient usually reports a specific collection of symptoms[52,53], which are relieved almost immediately after carbohydrate consumption, a feature that is included in Whipple's diagnostic triad[54]. Furthermore, the combination of weakness and increased appetite, alongside the ability of carbohydrate consumption to act as a relieving factor, frequently leads to excessive calorie consumption, weight gain, and eventual obesity[4,43,51].

When there is clinical suspicion of insulinoma, the autonomous overproduction of endogenous insulin must be confirmed biochemically. The basis of this diagnosis is the Whipple's triad[54] of biochemically-proven hypoglycemia, hypoglycemic symptom development, and swift reversal after carbohydrate consumption that occurs during a supervised fasting period. When symptoms occur concurrently with hypoglycemia (glucose levels around or below 2.2 mmol/L), increased insulin ($\geqslant$ 6 μIU/mL with standard non-specific insulin radioimmunoassay or $\geqslant$ 3 μIU/mL

with immunoradiometric or immunochemiluminescent insulin specific assays which are devoid of cross-reactivity for proinsulin and proinsulin-like components), proinsulin (≥ 5 pmol/L), and C-peptide (≥ 200 mmol/L) levels, this suggests the presence of an autonomous source of insulin production which is insensitive to hypoglycemia[1,8,43]. In order to rule out the presence of exogenous insulin (factitious hypoglycemia), a negative sulfonylurea/meglitinide screen test is also required that corroborates with the increased levels of C-peptide[1]. Surrogate markers of insulin presence, including low β-hydroxybutyrate levels (no more than 2.7 mmol/L) and a generous rise of glucose levels (more than 1.4 mmol/L) after the administration of 1 mg glucagon at the end of the fasting period[55], have been used by some authors for decades[56], especially for patients in which their blood glucose does not fall below 2.5 mmol/L during fasting. Indeed, β-hydroxybutyrate levels have now been included in recent guidelines[8,57], despite recent contradicting reports[58].

The actual cut-off points for insulin during fasting vary throughout the literature[52,59-61]. The reasons for this variation are complex and reflect both the altered biochemistry of insulin produced by insulinomas (increased proinsulin and proinsulin-like components, as well as insensitivity *vs* partial sensitivity of insulinomas to hypoglycemia) and the inherent limitations of detection assays (minimum detection levels and non-specificity to insulin in older radioimmunoassays). As such, despite a general agreement in the published cut-off values for insulinoma diagnosis, it is likely that this will remain a matter of contention. In fact, results from a recent comparative study have demonstrated proinsulin levels exceeding 5 pmol/L to be a more reliable diagnostic test for endogenous hyperinsulinism than absolute insulin levels at the time of hypoglycemia (< 2.5 mmol/L)[62]. Subsequent to this study, proinsulin measurement has since been recognized in recent consensus guidelines[8].

Practically, it is important to also consider the duration of these fasting tests when providing a biochemical diagnosis of endogenous hyperinsulinism. Traditionally, the gold standard has been a 72-h supervised inpatient assessment[52,53]. More recently however, modern insulin and pro-insulin specific assays have shown that a fasting period of 48 h is sufficient[60]. The lower cost and reduced invasiveness of this 48-h test have led to its rapid uptake across many institutions, thereby providing a new standard of care[1,43] that is reflected in updated diagnostic guidelines[8,57].

Surgeons currently have a limited role in the diagnosis of insulinoma, as this is usually confirmed prior to surgical referral. However, this by no means obviates the need for careful clinical assessment and thorough review of the patient's records and biochemistry prior to intervention. In a recent study, out of 17 patients referred to the United States National Institute of Health after a failed blind distal pancreatectomy, 5 were eventually diagnosed as having factitious hypoglycemia[63]. These patients underwent completely unnecessary major surgery. It is therefore the surgeon's professional and ethical responsibility to comprehend and fully agree with the diagnosis of insulinoma prior to undertaking any surgical intervention.

PREOPERATIVE AND INTRAOPERATIVE LOCALIZATION

Once biochemical diagnosis of insulinoma has been confirmed, the next important and demanding task is to accurately determine the location of the lesion within the pancreas[1,2,4-6,48]. In the past, surgeons were reliant on blind distal pancreatectomies for occult impalpable insulinomas due to limited imaging and diagnostic tools[64-66]. However, blind distal pancreatectomy was associated with a high failure rate (> 20%) that was exaggerated by the fact that non-palpable insulinomas often reside in the thicker pancreatic head[63]. Over the past 25 years, novel diagnostic modalities have rendered this blind approach obsolete[67] in favor of targeted resection.

Although in the past open surgeons had often bypassed preoperative localization in favor of intra-operative palpation and ultrasound (IOUS)[64-66], this approach was never widely adopted[1,53,67,68] and is certainly unacceptable for laparoscopy. Reliance on laparoscopic intraoperative ultrasound (LIOUS) alone led to open conversion in one of every three cases[16]. As a result, more recent series[17-19,31], including our own, reflect the current guidelines advocating accurate localization prior to laparoscopic surgical intervention[8]. We strongly advise against laparoscopic intervention without accurate preoperative localization[32] for a number of reasons: Firstly, the lack of intraoperative tactile feedback removes the ability to assess the tumor by palpation; secondly, patient positioning and trocar placement is determined by the location of the tumor; and finally, whilst LIOUS is a mandatory intraoperative adjunct for accurate localization and delineating regional anatomy, it is certainly not a diagnostic tool. Furthermore, the prolonged time required and inability to apply the probe to the whole pancreas without additional port placement limits its diagnostic role. Appropriate use of LIOUS requires knowledge of the regional location of the tumor (head, uncinate process, body, or tail) from preoperative investigations. In this way, the surgeon may utilize this tool to exactly locate and delineate the anatomic relationships of non-palpable lesions. It is the failure of accurate preoperative imaging that makes some authors use LIOUS to detect undiagnosed lesions or those found not to be located in the area indicated by preoperative assessment[9,16,69]. However, it is our opinion that this use limits the diagnostic yield of LIOUS, making it much lower than when used in conjunction with accurate preoperative localization. As such, we believe that accurate preoperative localization is a requirement of the laparoscopic approach. Failure to adequately assess tumor location should initially lead to repeat imaging and reassessment in an attempt

to improve localization accuracy. However, where this fails, surgeons should reconsider the appropriateness of laparoscopic intervention.

STRATEGY FOR PREOPERATIVE LOCALIZATION

There is no consensus on either the optimal type of preoperative localization modalities or on the exact order in which they should be performed. Recent guidelines suggest that non-invasive imaging should be performed first[8,35-37,57], and should include one or two from the following: transabdominal ultrasound (US), computerized tomography (CT), and magnetic resonance imaging (MRI). These modalities are usually readily available and, with the recent addition of contrast enhancement (CE), have been reported to have a high sensitivity in insulinoma detection (about 90% for CE US[70] and about 100% for CE CT and MRI[71]). However, due to variation in technology and radiological expertise, not all institutions may be able to achieve such excellent detection rates. In our experience, transabdominal unenhanced ultrasound has been associated with a sub-optimal diagnostic yield and, as such, we do not routinely employ this modality in our preoperative assessments. Although this approach is in line with recent guidelines[35-37,57], it is contrary to the reports of some authors who have had excellent results from the use of US[7].

Failure to obtain diagnosis through CT or MRI should lead to further assessment using endoscopic ultrasound (EUS)[8,35-37,57]. Although this modality is invasive, operator dependent, and of limited availability, it may yield an accuracy exceeding 90%[72,73], and is thus now advocated in all established guidelines[8,35-37,57]. As EUS performs better in the head, but less well in the body and worse in the tail of the pancreas[74,75], it may be considered a complementary modality to CT[73], which may miss lesions in the pancreatic head[76]. Notably, in our experience, lesions of greater tumor density are best detected on the arterial phase of the CT.

Following these investigations, the next test we routinely employ is selective pancreatic angiography with venous sampling after intra-arterial calcium stimulation (ASVS)[67,77]. Although highly invasive, ASVS is associated with a sensitivity of approximately 95% and is indispensable when previous tests are equivocal. ASVS allows hypervascular insulinomas to be detected by arteriography, with added regional localization in difficult cases through stimulated venous sampling. Using this technique, localization can be determined according to the arterial branch injected. The presence of insulinoma in a particular territory is indicated by a greater than two-fold elevation in insulin levels (sampled at 30 and/or 60 s from the hepatic vein) on calcium gluconate stimulation[78]. The use of ASVS is now widespread[7,79] and is included in most[8,36,37,57], but not all[35], recent guidelines.

Whilst other authors advocate the use of PET/CT[80] and SPECT/CT[81], this is not routine practice in our experience, as both techniques remain investigational[8]. However, promising results have recently been reported with glucagon-like peptide-1 (GLP-1) analogue SPECT/CT[82] imaging. Insulinomas are known to overexpress GLP-1 receptors in high density[83], thus overcoming the limitations of somatostatin-like tracers. The high selectivity of GLP-1 receptor agonists and their high affinity for insulinoma cells provides a promising future for preoperative insulinoma localization, and is likely to have increasing clinical importance with the development of novel tracers and improved imaging diagnostics[84].

SURGICAL DECISION-MAKING

Multidisciplinary assessment should form the cornerstone of insulinoma management. However, prior to intervention, the surgeon must be certain of both the biochemical diagnosis and localization of the insulinomas. Where results remain equivocal, we strongly advocate further testing or repeat imaging until adequate information is provided.

A summary of our surgical decision-making is shown in Figure 1. Of note, although we do not recommend enucleation of lesions less than 2 mm (preferably 3 mm) from the main pancreatic duct (MPD) or portal vein (due the risk of pancreatic fistula), solitary lesions in the head close to the MPD should be considered an exception, as the only alternative is a duodenopancreatectomy.

Malignant insulinomas are generally not amendable to laparoscopic surgery[7,8,35,49,50]. In these cases, resection of liver metastases ideally precedes excision of the pancreatic lesion[35], and the resultant extensive adhesions preclude a laparoscopic approach. When suspicion of malignancy is raised during planned laparoscopic surgery (Table 1), we prefer to convert to open resection[85-87], however we do acknowledge the work of other surgeons who advocate laparoscopic resection of malignant lesions[26].

In the context of MEN1, we follow a conservative but widely-accepted approach[8,37], due to the increased failure and reoperation rate inherent in the resection of MEN1-related insulinomas[43]. However, laparoscopic management of insulinomas in the context of MEN1[20,88,89] is possible in appropriate cases, particularly where only a single lesion is identified preoperatively. Where multiple lesions are present, distal pancreatectomy combined with multiple enucleations of pancreatic head lesions may also be considered. However, the laparoscopic approach to MEN1-related insulinomas is not currently widely accepted, and it should also be noted that MEN1 is considered a contraindication to laparoscopy in several large comparative series[30,31]. As mentioned previously, in our recent experience, enucleation of a single lesion in the pancreatic head has been successful in a single case.

Table 1 Features suggestive of malignant insulinoma[43]

Features suggestive of malignant insulinoma
Hard lesions
Infiltration of the surrounding pancreatic parenchyma
Evidence of tissue scarring
Major pancreatic duct dilatation

Contrary to several other published studies[16-18,21,29], we routinely perform laparoscopic enucleation of solitary pancreatic head insulinomas, not only for protruding lesions, but also for those embedded in the parenchyma, provided there is sufficient distance from the main pancreatic duct and the portal vein (Figure 1). We appreciate that some authors have expressed concern over the high complication rates in these cases[90], however we do believe that enucleation has a valuable role to play in the treatment of solitary lesions of the pancreatic head and uncinate process. Exposure is of paramount importance when dealing with pancreatic head and uncinate process insulinomas, however there are a number of techniques that can be employed to provide direct access to the posterior aspect of both[33,91]. Such approaches minimize unnecessary damage to the pancreatic parenchyma and the subsequent risk of complications.

Non-visible lesions embedded in the pancreatic head present a particular challenge, and classically have been treated with multiple extensive pancreatotomies. However, we have recently described a technique similar to wire-guided breast biopsy, which may enable the surgeon to accurately localize and laparoscopically resect these difficult insulinomas[34], thus minimizing the number and size of pancreatotomies. Assisted by LIOUS, an 18 G fine-needle may be inserted directly into the lesion to act as a probe, accurately defining the position of the insulinoma. The parenchyma of the pancreas can subsequently be divided following the needle, until the dome of the insulinoma is identified and a localized resection is performed[34].

The decision to plan a distal pancreatectomy over enucleation based on preoperative data is a rather difficult one. For lesions > 3 mm away from the pancreatic duct, enucleation is always the procedure of choice; however, we have a low threshold for distal pancreatectomy, and the more distal the position of the insulinoma, the greater the likelihood that this will be required. This is evident in several series[19,29-31] and is a natural consequence of the fact that the metabolic effects of added resection become less as the pancreatic parenchyma becomes thinner towards the tail.

TECHNICAL CONSIDERATIONS

Patient positioning can either greatly assist or hinder laparoscopic resection, and is thus crucially important to surgical set-up. For lesions in the anterior aspect of the head, isthmus, and body/proximal tail of the pancreas, the patient may be placed in a supine position with an anti-Trendelenburg tilt. A right tilt (left side up) is applied for lesions in the body/proximal tail of the pancreas. For lesions of the posterior aspect of the pancreatic head, both supine[12] and left semi-lateral positions have been reported in the literature[88]. In our experience, a full left lateral position is preferable, especially when combined with a retroduodenal and retropancreatic approach to the lesion following full kocherization[33]. We prefer this to the gastrocolic ligament approach proposed by other authors[88]. For lesions in the distal pancreatic tail, positioning may be either supine with a right tilt, right semi-lateral, or right full lateral. The choice of position for these lesions is therefore a matter of personal preference, similar to that with laparoscopic splenectomy[91]. Our practice is the right full lateral position because: (1) the chances of a distal pancreatectomy for lesions located in this area are higher and a right table tilt always facilitates this procedure; and (2) this position can easily be changed to semi-lateral with a generous left table tilt, giving the surgeon the liberty to choose between an anterior approach of the tail without spleen mobilization and a posterior one with full medial mobilization of the spleen.

Similarly, the number and position of trocar placements is at the discretion of the operating surgeon and varies throughout published reports[12,17,24,26,91]. Generally, we use a standard array of five ports: the first for the laparoscope at the center of the operating field, then two working ports for the surgeon on each side of the first, one laterally to the surgeon's right hand for the assistant, and one 5 mm in the epigastric area for a Nathanson liver retractor. For lesions in the posterior aspect of the pancreatic head where retraction of the kidney is sometimes required, a sixth trocar may be introduced to accommodate a second liver retractor for this purpose[33].

Gaining wide access to the pancreatic region of interest is of utmost importance in order to provide adequate space for surgical maneuvers and instruments such as the LIOUS probe and endoscopic stapler. For insulinomas of the posterior aspect of the pancreatic head, full mobilization of the hepatic flexure and the placement of two Nathanson liver retractors (one for the liver and possibly one for the right kidney) greatly facilitates surgical access[33]. On the other hand, for insulinomas of the anterior aspect of the pancreatic head, body, and tail, mobilization of the splenic flexure and retraction of the stomach to access the lesser cavity serves the same purpose.

After adequate mobilization of the pancreatic region of interest, the next step is LIOUS performed by a dedicated radiologist. This forms an integral part of laparoscopic insulinoma resection, as it not only allows for accurate localization of the lesion, but also outlines the surrounding anatomy in terms of tumor size, local invasion, and distance from the pancreatic duct and/or portal vein. If the combination of careful inspection and thorough LIOUS evaluation fails to adequately localize or characterize the insulinoma, we advocate that further

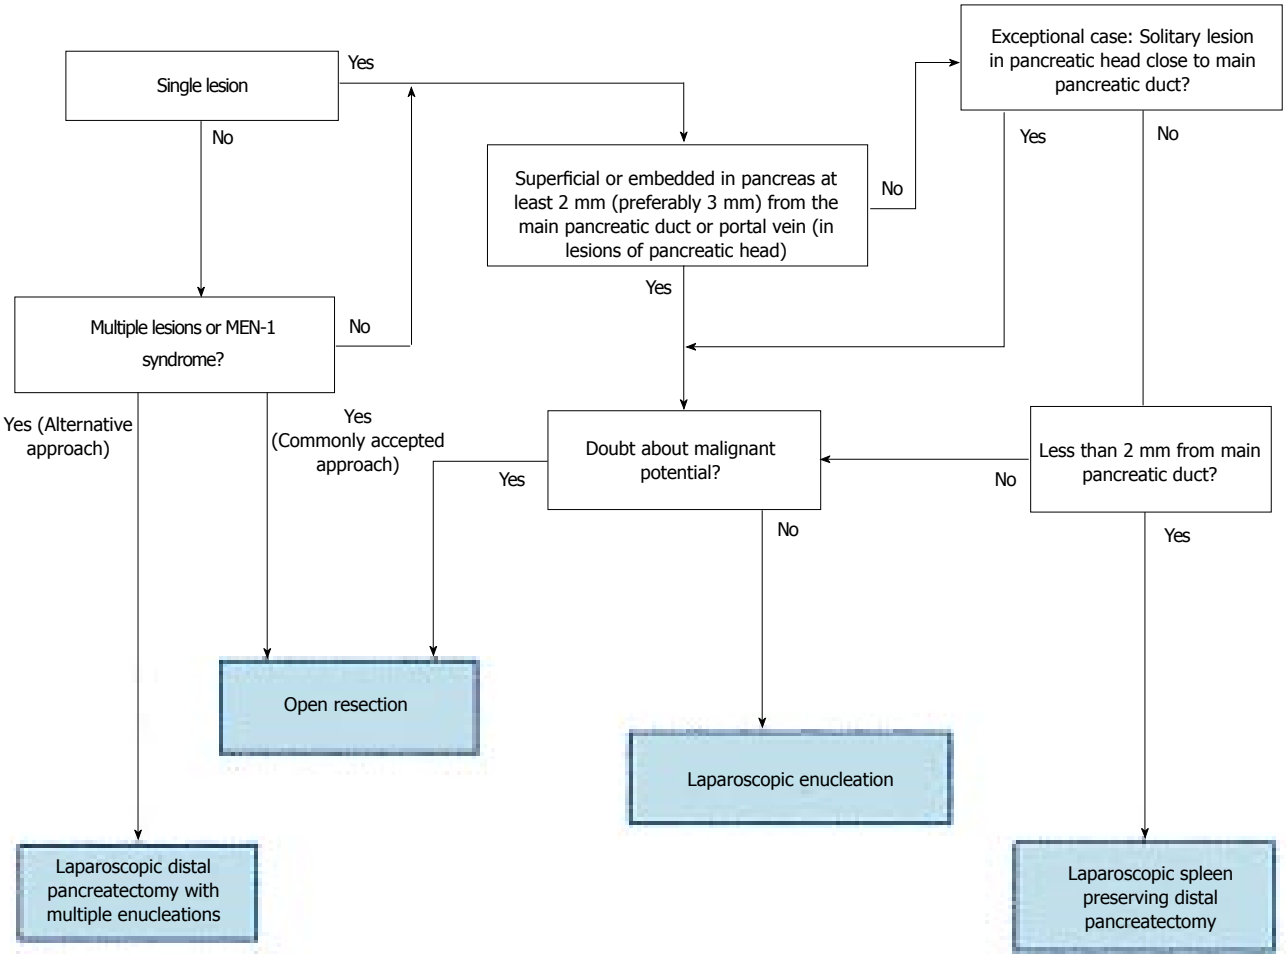

Figure 1 Flow chart demonstrating our surgical decision-making in pancreatic insulinomas. MEN-1: Multiple endocrine syndrome type 1.

surgical intervention be postponed in favor of repeat imaging and biochemical testing[92].

Once accurate intraoperative localization has been determined, surgical dissection is straightforward and performed with hook electrocautery and/or ultrasonic dissection. Generally, this is greatly helped by the placement of a traction suture through the insulinoma, which then can be exteriorized using an Endo Close. For lesions embedded in the pancreatic parenchyma but amenable to enucleation (Figure 1), the shortest route is chosen for dissection in order to minimize surgical trauma to the normal pancreatic parenchyma. As previously described, the LIOUS-guided placement of a fine needle in the center of the insulinoma greatly facilitates this dissection, which may be further aided by the placement of additional traction sutures to progressively open the pancreatotomy. Again, when the dome of the insulinoma becomes apparent, a further traction suture may be placed to improve the ease of enucleation.

For lesions in the body/tail of the pancreas that are not amendable to enucleation, the procedure of choice is spleen-preserving distal pancreatectomy. Careful dissection is necessary to avoid bleeding, particularly in the groove of the pancreas in which the pancreatic vein lies. In the event of inadvertent injury to the splenic vessels, if the left gastroepiploic and short gastric vessels remain intact, splenectomy can be avoided in favor of spleen-preserving distal pancreatectomy without splenic vessel preservation. However, where the left gastroepiploic and the short gastric vessels are not preserved, splenectomy is mandated. Division of the pancreas is usually carried out with an endoscopic linear stapler, combined with either oversewing the entire staple line or selectively oversewing the main pancreatic duct.

LAPAROSCOPIC SURGICAL OUTCOMES IN INSULINOMA MANAGEMENT

Due to the rarity of insulinomas and the retrospective nature of published series, it is difficult to extract robust data on the outcomes of laparoscopic insulinoma resection. Furthermore, these results have often been grouped with other pancreatic NETs and/or pancreatic tumors (*e.g.*, cystadenoma) making it impossible to separate insulinoma specific outcome data[9,17,85,89,93]. This is likely to be as a result of the small number of cases reported in early series and from the collective approach to tumor categorization later employed by major governing bodies and reflected in

published guidelines[8,35-37]. Whilst this classification is taxonomically accurate, it produces difficulties when studying insulinoma-specific outcomes, as insulinomas exhibit very distinct characteristics to other PETs and non-endocrine pancreatic tumors. Fortunately, however, the intriguing nature of these tumors has resulted in a number of laparoscopic case series specific to insulinomas[7,12-16,19-23,28,32], as well as those in the context of other PETs[26] and those comparing open and laparoscopic cases[18,24,25,27,29-31]. Furthermore, a recent meta-analysis comparing safety outcomes between laparoscopic and open approaches has been published[94].

The majority of published series[14,15,18-22,24-32] report established preoperative localization in > 90% of patients, with very few exceptions[12,16]. This highlights that preoperative localization has now become common practice, rather than the sole reliance on intraoperative LIOUS. Furthermore, this practice has increased the intraoperative accuracy of LIOUS to almost 100%, as well as almost eliminating inadequate localization as a cause for open conversion in the majority of cases[14,15,20-22,26,28,32]. Conversely, it is also notable that series reporting low preoperative localization rates[12,16] or limited use of LIOUS[19] also often describe inadequate localization as a common reason for conversion.

Median operative time is between 2 and 3.5 h, and varies significantly in published series[12,14-16,19-22,26,28,32]. However, these figures may be somewhat misleading due to small patient numbers and significant outliers. For example, in our own experience, operating time demonstrates a broad range from 25 to 420 min, with a median of 120 min[32]. Furthermore, although comparative studies demonstrate, as expected, that laparoscopic procedures take longer than their open counterparts[18,24,31] and that enucleation may be performed in a shorter time than distal pancreatectomy[16,19,20,28], this was not evident when pooled operative time was examined in the aforementioned meta-analysis[95].

Estimated median blood loss during laparoscopic insulinoma resection is limited and varies between 50 and 300 mL. Notably, however, there was no reported requirement for blood transfusion[12,15,28,32], and laparoscopic procedures resulted in significantly reduced blood loss when compared to open procedures[18,25,29,30,95]. Again, however, it is important to consider these results in the context of small sample numbers.

Laparoscopic treatment of insulinomas is safe and accompanied by minimal mortality in almost all published series[12,14-16,19-22,26,28,32]. Morbidity, on the other hand, may be high, and is reported to vary between 15% and 77%[12,14-16,18-22,24-32]. The most common complication is pancreatic fistula[95], however these are usually simple to manage and commonly resolve spontaneously within 2-3 wk. Nonetheless, in rare cases, specific treatment, drainage, or reoperation may be required. Importantly, the aforementioned recent meta-analysis has highlighted that laparoscopic insulinoma resection is not associated with a higher rate of fistula formation compared to open surgery[94]. Surgical precautions to avoid fistula formation first and foremost require respect for the minimum distance between the insulinoma and main pancreatic duct. Secondly, it is paramount to limit tissue damage by avoiding unnecessary dissection and keeping electrocautery heat production to a minimum. Oversewing the transection line after distal pancreatectomy and suture closure, or fibrin glue application to the site of enucleation, may also reduce fistulation, however in no cases do these measures counterbalance lacerations in the pancreatic duct, extensive destruction of the parenchyma, or inappropriately applied staples.

The length of in-hospital stay after laparoscopic insulinoma resection is difficult to determine, due to the inherent differences in institutional protocols and because patients from far away can be referred to a tertiary center. Indeed, uncomplicated laparoscopic resection required a hospital stay of one to two days in some studies[16,22,32], while patients remained hospitalized for 5-7 d in others[18,21]. However, it is notable that laparoscopic procedures are associated with a significantly shorter overall hospital stay than open procedures (without significant heterogeneity) when pooled data from directly comparative studies are meta-analyzed[94].

Importantly, laparoscopic insulinoma resection is associated with good long-term outcomes. In fact, whilst some series report long-term normoglycemia to be maintained in at least 95% of cases[24,25,30,31], others demonstrate a long-term cure rate of 100%[12,14,19-22,26,28,32].

CONCLUSION

Insulinomas are rare pancreatic neuroendocrine tumors that may be definitively cured with surgical resection. A dedicated multidisciplinary assessment is paramount prior to surgical intervention and should include thorough clinical and biochemical diagnosis. Localization of the tumor should be achieved through an array of non-invasive (US, CT, and MRI) and inevitably some invasive (EUS and AVSV) investigations, and the subsequent decision to undertake laparoscopic resection should only be made by an experienced laparoscopic pancreatic surgeon. For solitary benign insulinomas, laparoscopic enucleation suffices irrespective of location, provided the lesion lies a safe distance from the pancreatic duct and associated large vessels. Where these conditions are not met, laparoscopic distal pancreatectomy is advisable for lesions of the body/tail of the pancreas. This decision should be aided by LIOUS, which forms an indispensable part of any laparoscopic resection. In this way, localization of the lesion can be confirmed intraoperatively, and the tumor can be clearly delineated from adjacent structures. From a technical perspective, it is paramount to ensure ample access to the operating field in order to minimize damage to the

normal parenchyma, pancreatic duct, and associated vessels. Although no prospective randomized trials exist comparing laparoscopic and open approaches to insulinoma resection, case series, comparative series, and a recent meta-analysis supports the notion that laparoscopic resection is equally as safe and effective as an open approach. Moreover, laparoscopic intervention may not only improve cosmesis, but also reduce post-operative stay. Further large series and comparative studies are required in order to establish the true potential for laparoscopic resection and to continue to advance both diagnostic and technical aspects of surgical insulinoma management.

Abstract

Recently, several studies have reported local full-thickness resection techniques using flexible endoscopy for gastric tumors, such as gastrointestinal stromal tumors, gastric carcinoid tumors, and early gastric cancer (EGC). These techniques have the advantage of allowing precise resection lines to be determined using intraluminal endoscopy. Thus, it is possible to minimize the resection area and subsequent deformity. Some of these methods include: (1) classical laparoscopic and endoscopic cooperative surgery (LECS); (2) inverted LECS; (3) combination of laparoscopic and endoscopic approaches to neoplasia with non-exposure technique; and (4) non-exposed endoscopic wall-inversion surgery. Furthermore, a recent prospective multicenter trial of the sentinel node navigation surgery (SNNS) for EGC has shown acceptable results in terms of sentinel node detection rate and the accuracy of nodal metastasis. Endoscopic full-thickness resection with SNNS is expected to become a treatment option that bridges the gap between endoscopic submucosal dissection and standard surgery for EGC. In the future, the indications for these procedures for gastric tumors could be expanded.

Key words: Gastrointestinal stromal tumor; Early gastric cancer; Full-thickness resection; Laparoscopic and endoscopic cooperative surgery; Sentinel node navigation surgery

Core tip: Several studies have investigated local full-thickness resection techniques using flexible endoscopy for gastric tumors. These techniques are advantageous because a resection line can be determined more precisely using intraluminal endoscopy. Thus, it is possible to minimize the resection area and subsequent deformity, and better secure the surgical margins. In the near future, endoscopic full-thickness resection is expected to become a treatment option that bridges the gap between endoscopic submucosal dissection and standard surgery for gastric tumors.

INTRODUCTION

Laparoscopic wedge resection (LWR) has been accepted as a minimally invasive surgical technique for gastric tumors such as gastrointestinal stromal tumor (GIST)[1], early gastric cancer (EGC) without the risk of lymph node metastasis[2,3]. However, patients frequently experience severe deformity and gastric stasis as a result of excessive gastric resection. This occurs because identification of the proper incision line is complicated. From this point of view, several studies have reported that endoscopic submucosal dissection (ESD) and endoscopic submucosal enucleation are feasible for the resection of gastric tumors in the muscularis propria[4,5]. Furthermore, ESD has performed for the diagnosis of suspected submucosal EGC. However, some tumors are resected incompletely because they have positive surgical margins; thus, the risk of recurrence exists[6]. Therefore, a full-thickness resection would be more appropriate to secure the surgical margins. This suggests the need for function-preserving or reductive surgeries that bridge the gap between ESD and standard surgery. Recently, some publications have described local resection techniques using peroral flexible endoscopy. Endoscopic full-thickness resection (EFTR) of the gastric wall using a snaring technique has been applied for gastric subepithelial tumors[7-9]. In addition, Hiki *et al*[10] reported that classical laparoscopic and endoscopic cooperative surgery (classical LECS) provides an alternative gastric wedge resection. However, these procedures (EFTR and classical LECS) have inherent risks of peritoneal infection and cancer cell seeding because intentional perforation of the gastric lumen is required during the procedures. As a result, some procedures [*e.g.,* inverted LECS[11], a combination of laparoscopic and endoscopic approaches to neoplasia with non-exposure technique (CLEAN-NET)[12] and non-exposed endoscopic wall-inversion surgery (NEWS)[13]] have been developed to mitigate these risks. These techniques are advantageous because a more precise resection area can be determined using intraluminal endoscopy, thus minimizing the resection area. This will result in less deformity and better surgical margins.

In the current review, recent developments related to full-thickness resection using flexible endoscopy for gastric tumors are presented and discussed.

EFTR WITHOUT LAPAROSCOPIC ASSISTANCE

Endoscopic full-thickness resection of the gastric wall using a snaring technique has been applied for gastric subepithelial tumors[7]. Nevertheless, this technique has limitations from the perspective of the localization and size of the lesion. Ikeda *et al*[14]. reported EFTR using an ESD technique with a sewing method and have shown that it is possible to resect larger specimens. In addition, Zhou *et al*[8] and Feng *et al*[15] reported successful resection of gastric subepithelial tumors originating from the muscularis propria layer[8,15] (Table 1).

Table 1 Representative publications reporting endoscopic full-thickness resection for upper gastrointestinal tumors

Ref.	*n*	Mean operation time (min)	Mean tumor diameter (mm)	Complete resection rate (%)	Complication rate (%)
Zhou *et al*[8]	26	105	28	100	0
Feng *et al*[15]	48	60	16	100	0
Huang *et al*[16]	35	90	28	100	0
Schmidt *et al*[17]	31	60	20.5	90.3	9.7 (perforation)
Guo *et al*[9]	23	40.5	12.1	100	0

After the periphery of the lesion is marked endoscopically, a solution is injected into the submucosal layer circumferentially. A circumferential incision is then made to the depth of the muscularis propria around the lesion using ESD devices and techniques. Next, the serosal layer around the lesion is incised using ESD devices to create an intentional perforation. The tumor, including the surrounding muscularis propria and serosa, is subsequently removed using the snare. Finally, the gastric wall defect is closed with several metallic clips (Figure 1).

There are difficulties associated with these techniques. For example, it is unknown whether a large iatrogenic perforation can be successfully closed using the endoscopic technique. Guo *et al*[9] have reported the safety and feasibility of the over-the-scope clip system for the closure of gastric defects following EFTR. After all, EFTR is expected to prevent the severe complications can occur due to iatrogenic perforation. Although EFTR seems to be an effective and minimally invasive treatment for patients with gastric subepithelial tumors, it is necessary to demonstrate the efficacy and safety of EFTR in a large number of cases.

CLASSICAL LECS

Hiki *et al*[10] reported that the LECS technique provides an alternative gastric wedge resection for the removal of GISTs, and combines gastrointestinal endoscopy and laparoscopy. The advantage of this technique is that it avoids excessive resection of the gastric wall because a resection line can be determined more precisely using intraluminal endoscopy.

The periphery of the lesion is first marked endoscopically, and after a submucosal injection around the lesion, a circumferential incision is made using ESD devices and techniques. Then, an artificial perforation

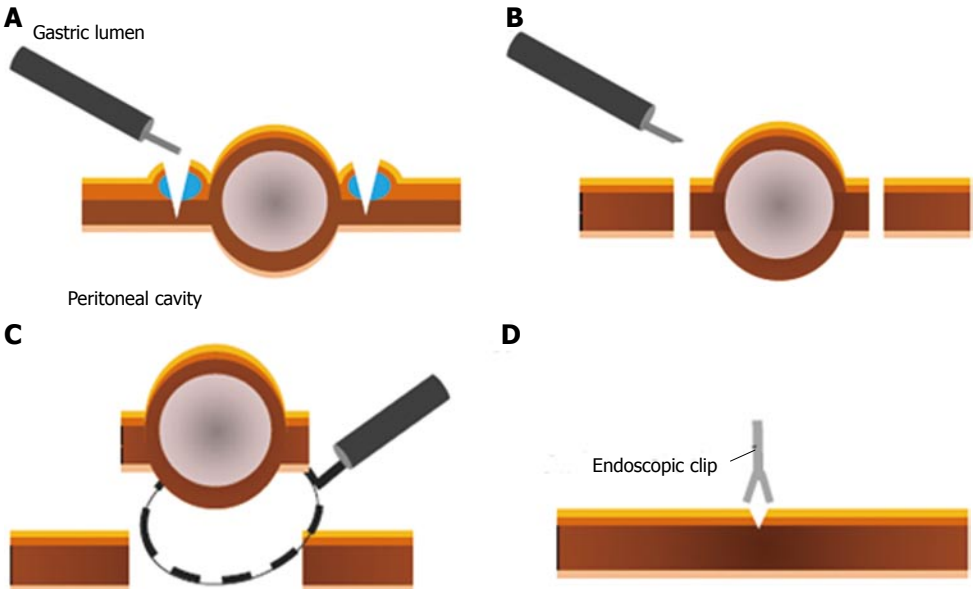

Figure 1 Illustration of the procedure for endoscopic full-thickness resection without laparoscopic assistance. A: A circumferential incision is made to the depth of the muscularis propria around the lesion using endoscopic submucosal dissection (ESD) devices and techniques; B: After intentional perforation, the serosal layer around the lesion is incised using ESD devices; C: The tumor, including the surrounding muscularis propria and serosa, is removed using the snare; D: The gastric wall defect is closed with several metallic clips.

is performed from the inside of the stomach and a seromuscular incision is performed, as much as possible, with laparoscopic assistance. Next, a laparoscopic incision of the remaining seromuscular layer is performed. Finally, the defect closure of the gastric wall is performed by laparoscopic linear staplers or a laparoscopic hand sewn suture technique[16,17] (Figure 2).

Some pilot studies have reported the feasibility of LECS for GISTs, and have presented favorable results[18-20]. This procedure is also feasible for lesions that cannot be treated with LWR[1,21] (*e.g.,* the esophagogastric junction)[22]. However, there is a major limitation associated with classical LECS. This technique requires opening the gastric wall, and the gastric lumen is opened to the abdominal cavity. As a result, gastric contents (*e.g.,* bacteria and tumor cells) flow into and contaminate the clean peritoneal cavity, increasing the risk of bacterial contamination and dissemination of peritoneal tumor cells.

INVERTED LECS

As described above, there are several drawbacks associated with classical LECS especially for gastric cancer. Therefore, a modified LECS procedure, referred to as inverted LECS, was developed to prevent the implanting of tumor cells[11].

The procedure, from placing the markings to performing the artificial perforation, is similar to the classical LECS. To prevent contact between the tumor and the visceral tissue, the gastric wall is pulled up circumferentially to the incision line as a crown using some stitches. Then, the seromuscular layer is dissected using ESD or laparoscopic devices around the incision line of the submucosal layer. The tumor is then resected into the abdominal cavity and the specimen is retrieved perorally. Finally, the gastric wall defect is closed by laparoscopic linear staplers.

This procedure was developed to prevent stomach contents from spilling into the clean abdominal cavity. However, since the gastric lumen is opened to the peritoneal cavity, there is still a risk of gastric content contamination. Furthermore, there is a risk of cancer recurrence caused by instrument contact.

CLEAN-NET

CLEAN-NET is another promising non-exposure method[12]. After mucosal markings are made endoscopically around the tumor, the mucosal layer is fixed to the seromuscular layer with four full-layer stay sutures, and a sub-mucosal cushion is created circumferentially using an endoscopic injection. The seromuscular layer is then dissected laparoscopically around the four stay sutures. Consequently, the full-layer specimen and the mucosal layer that surrounds it are lifted by the stay sutures. Finally, the specimen is resected using a linear stapler (Figure 3). The CLEAN-NET is useful as a non-exposure technique for full-thickness resection.

NEWS

NEWS was developed as a novel, full-thickness resection technique, without intentional perforation[13,23,24]. With this procedure, markings are made around the tumor on the mucosa while serosal markings are made laparoscopically. The serosal markings are made by pressing on the gastric wall, on the side opposite the mucosal markings. A sodium hyaluronate solution, that includes a small amount of indigo carmine dye, is

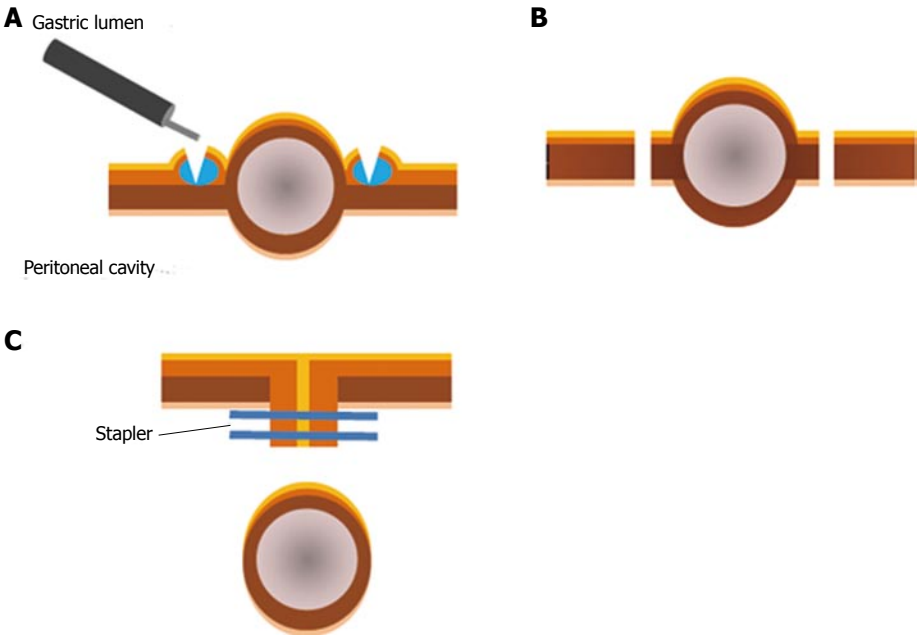

Figure 2 Illustration of the procedure for classical laparoscopic and endoscopic cooperative surgery. A: A circumferential incision is made using endoscopic submucosal dissection (ESD) devices and techniques; B: An artificial perforation is performed from the inside of the stomach and a seromuscular incision is performed along the incision line with laparoscopic assistance. A laparoscopic incision of the remaining seromuscular layer is performed; C: The defect closure of the gastric wall is performed by laparoscopic linear staplers.

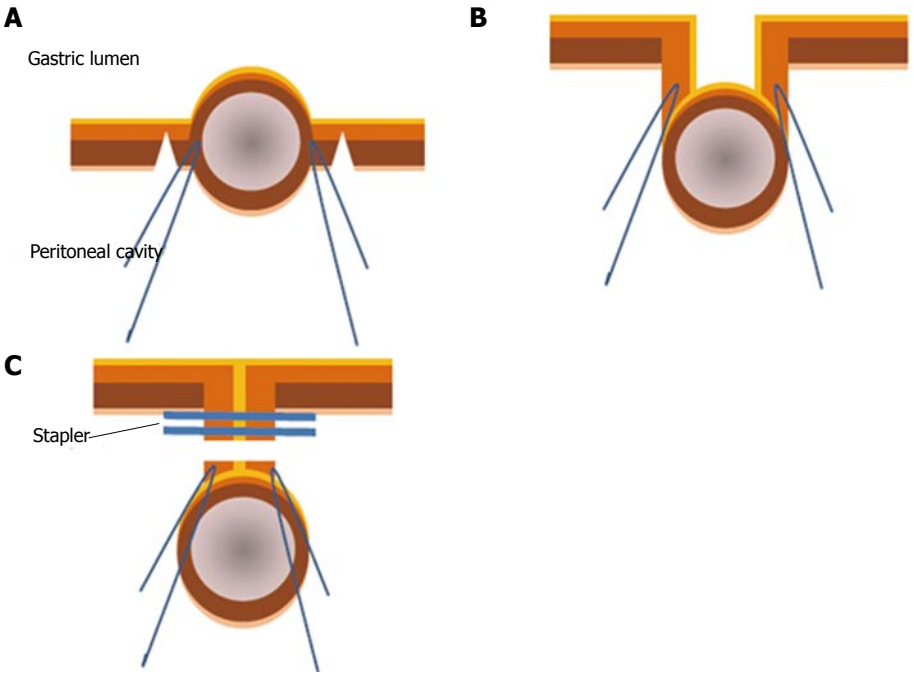

Figure 3 Illustration of the procedure for a combination of laparoscopic and endoscopic approaches to neoplasia with non-exposure technique. A: Seromuscular layer is dissected using a laparoscopic electrocautery knife; B: Full-layer specimen is lifted by the stay sutures; C: Full-layer specimen is resected using a linear stapler.

endoscopically injected into the submucosal layer circumferentially. A circumferential seromuscular incision is performed laparoscopically around the serosal markings. After a flap is created by cutting the submucosa deeper toward the outside, the seromuscular layers are linearly sutured with the lesion inverted toward the inside of the stomach. Prior to the suturing, a laparoscopic surgical sponge is inserted as a spacer between the serosal layer of the inverted lesion and the suture layer. This is done to provide counter-traction to the mucosa and prevent cutting of the suture. Finally, the circumferential mucosal incision and the subsequent incision of the remnant submucosal tissue are made a few millimeters outside of the mucosal markings around the inverted

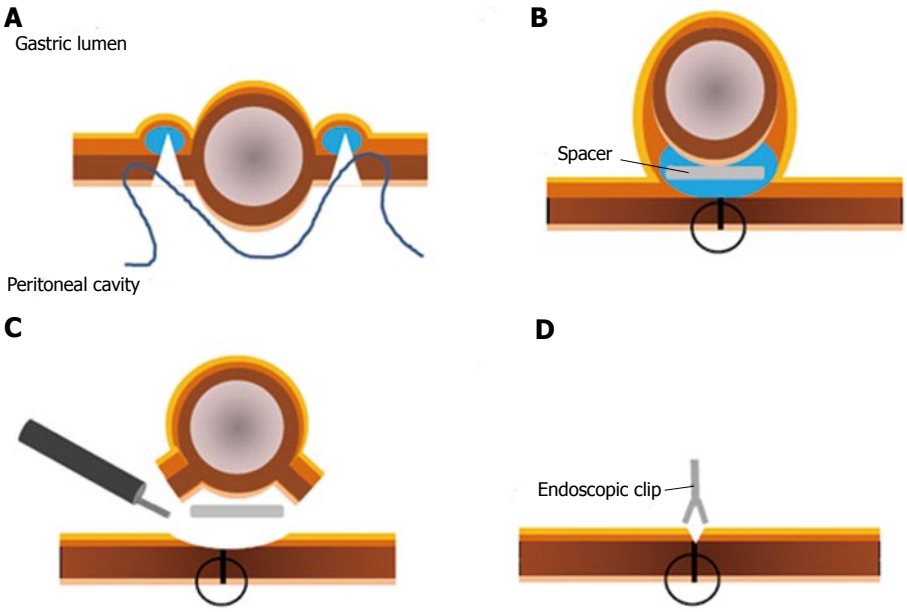

Figure 4 Illustration of the procedure for non-exposed endoscopic wall-inversion surgery. A: circumferential seromuscular incision is performed laparoscopically outside the serosal markings after endoscopic submucosal injection; B: seromuscular layers are linearly sutured with the lesion inverted toward the inside of the stomach. A surgical sponge as a spacer is inserted between the serosal layer of the inverted lesion and the suture layer; C: Circumferential mucosal incision and the remnant submucosal incisions are made using ESD devices and techniques; D: Defect is closed with several metallic clips. ESD: Endoscopic submucosal dissection.

Table 2 Comparison of each procedure

	Instruments	Indication for EGC	Retrieval route	Intentional gastric perforation	Advantage	Limitation
EFTR	Endoscopy only	No	Transroral	Required	Simple methods using intraluminal endoscopy only	Risk of contamination, endoscopic skills required
Classical LECS	Endoscopy = laparoscopy	No	Transabdominal	Required	Accurate to determine the resection line, laparoscopic assistance	Risk of contamination Risk of contact to tumor surface
Inverted LECS	Endoscopy = laparoscopy	Indefinite	Transoral	Required	Accurate to determine the resection line, laparoscopic assistance	Risk of contact to cancer surface, tumor size
CLEAN-NET	Endoscopy < laparoscopy	Yes	Transabdominal	Not required	No transluminal communication	Excessive resection of the mucosa, difficult to determine the resection line
NEWS	Endoscopy = laparoscopy	Yes	Transoral	Not required	Accurate to determine the resection line, laparoscopic assistance, no transluminal communication	Tumor size, experience required, time-consuming

EFTR: Endoscopic full-thickness resection; LECS: Laparoscopic and endoscopic cooperative surgery; CLEAN-NET: Combination of laparoscopic and endoscopic approaches to neoplasia with a nonexposure technique; NEWS: Nonexposed endoscopic wall-inversion surgery; EGC: Early gastric cancer.

lesion using ESD techniques. The resected specimen and the spacer are retrieved perorally and the mucosal edges are closed with several endoscopic clips (Figures 4 and 5).

The NEWS technique has been developed as a full-thickness resection method without transluminal communication and is similar to the CLEAN-NET. It is a non-exposure technique. However, there are several differences between the two procedures. First, the seromuscular hand suturing and circumferential mucosal incision can be skipped in CLEAN-NET, which results in a shorter procedural time than that for NEWS. Secondly, the incision line is determined from the serosal side; as a result, proper mucosal incision could be complicated to determine resulting in a relatively large resection area. However, due to the lower risk of peritoneal cavity infection and the seeding of tumor cells, NEWS has already been clinically introduced for gastric subepithelial tumors as well as gastric cancers at selected hospitals[24]. This procedure is technically feasible and, theoretically, safe.

APPLICATION TO GASTRIC CANCER

ESD is widely accepted as a minimally invasive curative treatment for early stage gastrointestinal cancer[25-27]

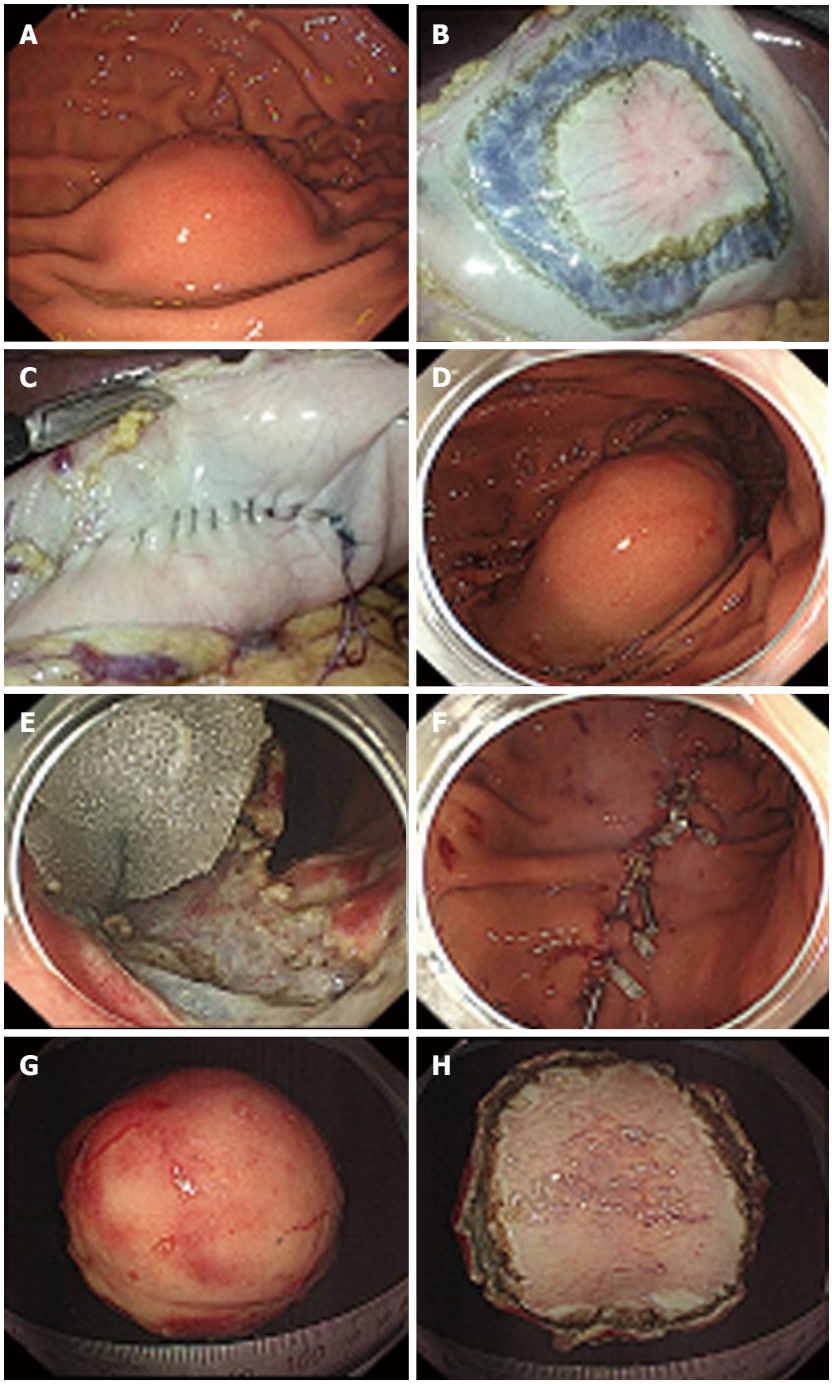

Figure 5 Procedures of non-exposed endoscopic wall-inversion surgery. A: Protruding submucosal lesion is seen at the greater curvature of the middle gastric body; B: Circumferential seromuscular incision is made outside the serosal markings after endoscopic submucosal injection; C: Lesion is inverted with a surgical sponge used as a spacer; D: Massive protrusion of the inverted tissue; E: Surgical sponge as a spacer and a suturing line during endoscopic mucosal incision; F: Mucosal clipping after the resection; G: Resected specimen: Mucosal side; H: Resected specimen: Serosal side.

that enables the preservation of function and maintains the patients' quality of life. However, ESD still requires a skilled and experienced surgeon for large lesions located at the greater curvature of the upper gastric body and fornix, and for lesions with severe ulcerative changes. In these situations, ESD has a higher incidence rate of complications such as perforation and bleeding. Furthermore, ESD may be associated with longer operation times[28]; therefore, LECS may be an alternative treatment option especially for lesions difficult to resect by ESD[11].

In contrast, EGC with possible lymph node metastasis should be treated with gastrectomy with wide resection of the regional lymph nodes because the presence and site of lymph node metastasis are unclear. Approximately 10%-20% of patients with EGC, especially those with deep submucosal invasion, have lymph node metastasis[29]. In other words, the incidence of node-negative gastric cancer accounts for at least 80% of all EGCs and therefore, most of the patients

with EGC have undergone an unnecessarily wide gastrectomy with lymphadenectomy. If node-negative gastric cancer is confirmed, local resection (*e.g.,* full-thickness resection) might be the best option.

Sentinel node navigation surgery (SNNS) is expected to be able to diagnose lymph node metastasis intraoperatively, and this could result in minimally invasive and function-preserving gastrectomy with selective lymphadenectomy[30]. Theoretically, the sentinel node (SN) is the first lymph node or group of nodes capable of draining cancer cells and is considered the first site of metastasis along the route of lymphatic drainage. However, it remains controversial whether the SN concept is feasible in EGC. In response, the Japan Society of Sentinel Node Navigation Surgery conducted a prospective multicenter trial to confirm the SN concept. It reported that patients with clinical T1N0 ($\leqslant$ 4 cm) gastric cancer can undergo sentinel node mapping and biopsy without limitation of tumor location[31]. Currently, surgical treatment of cT1N0 gastric cancer, of $\leqslant$ 4 cm, can be individualized on the basis of the SN concept. Furthermore, some studies have reported that in the absence of metastasis to the SNs, a surgery that combines ESD and SNNS[32] may be adequate. However, ESD cannot guarantee secure vertical margins or accurate preoperative diagnosis of tumor invasion. Hence, for submucosal EGC, a full-thickness resection would be more appropriate to secure the vertical margins and identify intramural cancer cells. Abe *et al*[33] first reported EFTR for EGC under laparoscopic guidance, combined with lymphadenectomy. Similarly, Hur *et al*[34] reported laparoscopy-assisted endoscopic full-thickness resection with sentinel node navigation surgery. However, as previously mentioned, these procedures require opening of the gastric wall, thus opening the gastric lumen to the peritoneal cavity. As a result, cancer cells may spill into the peritoneal cavity. Consequently, peritoneal dissemination of cancer cells as well as bacterial contamination during the procedure might occur. Therefore, it is desirable to use a non-exposure technique to prevent bacterial contamination and peritoneal dissemination of tumor cells. Hence, full-thickness resection such as NEWS and CLEAN-NET, in combination with sentinel node basin dissection, may be an ideal treatment that bridges the gap between ESD and standard surgery with respect to the invasiveness of the treatment[35,36] (Table 2).

CONCLUSION

The endoscopic full-thickness resection for upper gastrointestinal subepithelial tumors and EGC has been developed as a novel and minimally invasive surgery. In particular, NEWS with sentinel node basin dissection may be an ideal, minimally invasive, and function-preserving gastrectomy with selective lymphadenectomy for EGC. However, reports of these procedures are limited to case reports. Pilot studies need to be performed, and the long-term efficacy of these procedures need to be clarified. Therefore, further studies such as prospective clinical trials with a large number of patients are required to show the feasibility of these treatment methods, especially with regard to safe and complete resection. In the near future, the concept of endoscopic full-thickness resection is expected to become a treatment option that bridges the gap between ESD and standard surgery for subepithelial tumors and EGC.

Abstract

Endoscopy using magnification narrow band imaging (mNBI) allows detailed assessment of mucosal surface and vascular pattern. This may help in better identification and prediction of the nature of the lesion. The role of this technology in duodenum is still evolving. Studies have shown that mNBI has high accuracy in predicting villous atrophy in the duodenum. Limited data suggests that this technique can provide additional information on duodenal polyps, nodules and ampullary tumour which can help guide their management. In this paper we describe the technique for duodenal assessment using NBI and review the existing literature evaluating its role in diagnosis of various duodenal pathologies.

Key words: Narrow band imaging; Duodenum; Villous atrophy; Correlation; Polyp

Core tip: Narrow band imaging endoscopy with magnification (mNBI) enables detailed assessment of duodenal villous morphology. This advantage over white light endoscopy has potential clinical benefits. There is good evidence to show that villous morphology on mNBI correlates well with histopathology. Hence villous atrophy can be diagnosed with good accuracy during mNBI and targeted biopsy can be obtained from abnormal appearing areas. Preliminary data suggest that this technology may also aid in assessment of neoplastic lesions in duodenum.

INTRODUCTION

Endoscopic examination of mucosal surface of the gut

is an integral part of evaluation of patients presenting with gastrointestinal symptoms. The quest for obtaining additional information from direct visualisation of mucosa has led to several advances in imaging techniques. These include narrow band imaging (NBI, Olympus), optical coherence tomography, Fujinon intelligent chromo endoscopy (FICE, Fujinon) system, I-Scan (Pentax) and confocal laser endomicroscopy[1,2]. NBI, as the name suggests, uses a narrow wavelength of light in the blue and green region instead of the entire visible spectrum which gives a dark appearance to blood vessels[3]. This in combination with magnification endoscopy enables characterisation of microsurface and microvascularity of mucosa and identifies abnormalities in different part of digestive tract[4]. Magnification NBI (mNBI) has been shown to play a useful role in evaluation of duodenal villus abnormalities seen in diseases associated with malabsorption as well as in assessment of polyps and tumours of the duodenum[5-9]. A search of published literature reveals that among the more than one thousand publications relating to NBI, less than thirty have focussed on duodenum. However, the number of publications on the role of NBI in duodenum has risen in recent years as its value in assessment of duodenal disorders is recognised. In this paper we have reviewed the available literature on use of NBI in evaluating the duodenum.

ASSESSMENT OF DUODENUM USING MAGNIFICATION NBI

In our experience we have found the following scheme of examination adequate for comprehensive assessment of duodenum[5]. The examination should begin with an initial assessment of duodenal mucosa with conventional white light endoscopy. Any debris on the mucosal surface should be cleared. In most situations examination is performed upto second part of duodenum. The characteristics of duodenal mucosal folds including atrophy, scalloping and nodularity should be assessed and presence of any surface lesion like polyp, nodule or tumour determined. Duodenal ampulla should also be examined although a forward viewing endoscope makes this slightly difficult.

Next the endoscope should be switched to magnification NBI mode. mNBI examination is undertaken in two steps. In the first step, the morphology of duodenal villi in second part of duodenum is evaluated. The magnification and contrast offered by mNBI enables clear visualisation of duodenal villi. Bile appears pink and blood appears black on NBI. Due to use of narrow band of light, the images on NBI are not very bright but as the duodenal lumen is narrower than stomach, this is less of a problem. This limitation is also being overcome by newer endoscope processors. Some centers have reported the use of water instillation in lumen to improve the visualisation of villi and we have also found it useful in our experience[10]. This technique can be used in selected situations where the assessment is otherwise difficult. Several studies have reported excellent performance of mNBI in assessing villous morphology[5,7,11,12]. In normal subjects the villi have greater length than breadth which gives them a leaf or finger like appearance (Figure 1)[5,7]. Atrophy of villi alters this ratio and makes them appear shortened or convoluted or stubbed or even absent in patients with total villous atrophy (Figure 1)[5,7]. The next step involves assessment of any protruding mucosal lesion like polyp, nodule and tumour. The microsurface and microvascular pattern with special attention to irregularity should be determined. There are only few reports on mNBI characteristics of various duodenal mucosal lesions which makes confident correlation of surface/vessel pattern with histology of lesion difficult but presence of irregularity of pattern generally signifies a high grade lesion[6,13].

NBI IN ASSESSMENT OF DUODENAL VILLOUS MORPHOLOGY

Emerging data from several studies have shown that mNBI has a very good correlation with histology in assessment of duodenal villous atrophy[5,7,10,11]. This has few potential benefits: (1) in situations where duodenal biopsy is taken only to evaluate for villous atrophy, normal villi on mNBI may preclude biopsy and save procedure cost and time. The same is not the case with white light endoscopy where mucosal fold abnormalities like atrophy, scalloping and nodularity have a poor sensitivity when compared to histology[14]. Therefore all patients undergoing white light endoscopy for suspected celiac disease will require duodenal mucosal biopsy irrespective of endoscopic appearance; (2) in subjects with patchy villous atrophy, mNBI may help target the biopsy to regions with atrophy and improve the diagnostic yield[15]; (3) ease of the procedure which does not require spray of dye to improve contrast; and (4) ease of identification of villous morphology as evidenced by most studies reporting very good interobserver agreement[5,10,11].

While celiac disease is the dominant cause of villous atrophy in developed nations, other diseases like tropical sprue associated with villous atrophy and malabsorption are seen in tropical countries. It is therefore not surprising that about half of the studies on the role of NBI in duodenal villous assessment are from India[5,11,16]. We have recently published a prospective study from our center in India on a hundred patients with suspected malabsorption and evaluated the ability of mNBI to assess duodenal villi[5]. Celiac disease was present in seven patients with villous atrophy while conditions like tropical sprue, infections and Crohn's disease were present in eight patients and the cause of atrophy was unknown in one. Overall, villous atrophy was present in 16 patients and mNBI had a sensitivity of 87.5% and specificity of 95.2% in detecting this

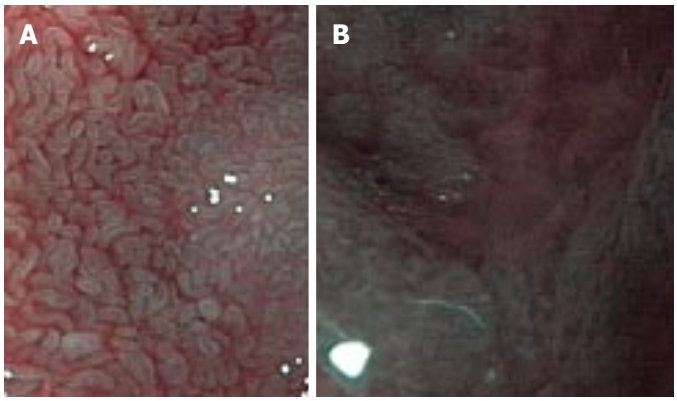

Figure 1 Appearance of normal duodenal villi on magnification narrow band imaging (A) and severe villous atrophy on magnification narrow band imaging (B).

by one of the two examiners. The sensitivity and specificity were 81.3% and 92.9% respectively for the second assessor with high interobserver agreement (kappa 0.87). We therefore found mNBI examination of duodenum to be a promising modality in predicting villous atrophy. Subsequently another study from India on 105 subjects with suspected malabsorption (villous atrophy in 58 on histology) showed that mNBI had a sensitivity of 95% and specificity of 90.2% (interobserver kappa 0.89)[11] in predicting villous atrophy. A third study from north India, published only in abstract form also assessed correlation of mNBI with histology for detection of duodenal villous atrophy in 80 patients and reported a sensitivity of 87.03% and specificity of 84.61%[16].

A couple of studies have been published from Italy comparing standard white light endoscopy and mNBI in patients with celiac disease. De Luca *et al*[12] prospectively studied 44 patients and found that mNBI was able to identify villous atrophy in all 17 patients with confirmed celiac disease (100% sensitivity) while standard white light endoscopy showed abnormalities in only 7 of them (41% sensitivity). All cases of partial villous atrophy were identified on mNBI while standard endoscopy was normal in all of them. The mean additional time required for NBI examination was four and half minutes. Another study from Italy on pediatric patients with suspected celiac disease investigated the use of NBI with water immersion technique and obtained single NBI guided biopsy instead of conventional multiple biopsies[10]. NBI guided single biopsy had a sensitivity of 87.5% in diagnosing celiac disease, suggesting that this technique has the potential to reduce the need for multiple biopsies. An earlier study from Australia assessing villous atrophy using mNBI showed mNBI to have a sensitivity of 93.3% and specificity of 97.8% in patients with suspected celiac disease[7].

We performed a meta-analysis on diagnostic accuracy of mNBI to detect duodenal villous atrophy with histology as a reference standard. The above six studies were screened for inclusion[5,7,10-12,16]. The study by Sinha *et al*[16] was excluded as only abstract was published and more data was required for meta-analysis[16]. The study by Singh *et al*[7], included 10 videos from 3 patients with celiac disease which implied multiple assessments for same patient. This significantly differed from other study designs and hence was not appropriate for pooling of data with other studies. Valitutti and colleagues studied pediatric patients only and for this reason their data was also not included. Finally we included three studies in the meta analysis[5,11,12]. The analysis was performed using the software Meta-DiSc[17]. The pooled sensitivity (Figure 2) was 0.96 (95%CI: 0.89-0.99) and the pooled specificity (Figure 3) was 0.94 (95%CI: 0.89-0.97). These impressive data further strengthen the evidence in favour of mNBI in assessing duodenal villous atrophy.

Atrophy of villi may be patchy in some patients with celiac disease and this may be missed on random mucosal biopsy. By identifying atrophic villi based on morphology, mNBI can overcome this limitation and help obtain targeted biopsies. Few case series and reports have demonstrated the capability of mNBI to detect patchy villous atrophy[15,18,19]. This perhaps is one area where mNBI can play an important role in avoiding false negative biopsies but more data is required. It is clear from the above studies that mNBI can play a useful role in aiding the diagnostic evaluation of celiac disease and other malabsorption syndromes.

NBI IN ASSESSING PROTRUDING DUODENAL MUCOSAL LESIONS

Unlike gastric, colonic and esophageal lesions, mNBI characteristics of duodenal mucosal lesions like polyps and tumours have been less well studied. Most of the available studies are from Japan and except for a few, these are in the form of case reports[6,13,20,21]. In contrast to assessment of villous morphology where surface characteristic is the focus of attention, both surface and vascular characteristics are important in assessing neoplastic lesions. Abnormal angiogenesis is a feature of neoplasia and alteration in vascular pattern is a reflection of this.

Kikuchi *et al*[6] retrospectively analysed the surface/vascular pattern of duodenal non-ampullary tumours on mNBI and identified characteristics suggestive of high grade dysplasia and invasive tumour. The surface patterns were classified as monotype or mixed type

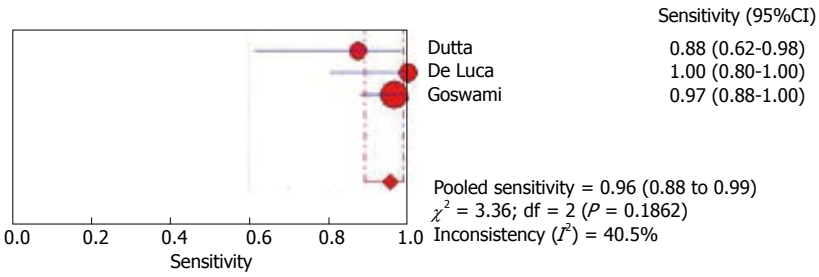

Figure 2 Pooled sensitivity of narrow band imaging in detecting duodenal villous atrophy.

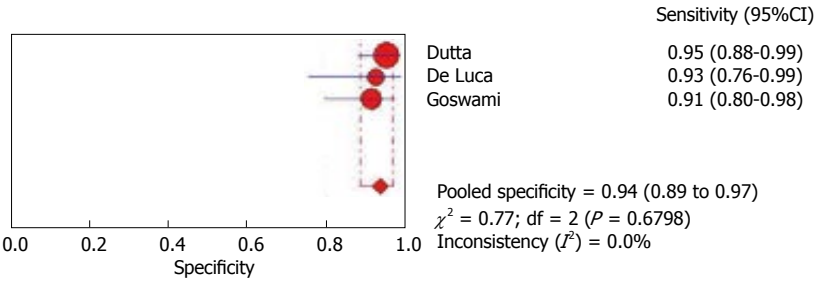

Figure 3 Pooled specificity of narrow narrow band imaging in detecting duodenal villous atrophy.

when they had single or multiple surface patterns respectively. Vascular patterns were classified as network, intrastructural vessel, unclassified or absent. They found that presence of mixed type surface pattern was suggestive of high grade dysplasia or invasive lesion in all 23 cases. In the remaining 23 lesions which had monotype surface, presence of unclassified vascular pattern and intrastructural vessels were associated with advanced lesions. Other vascular patterns were also seen with advanced lesions. The study therefore suggested that a mixed surface pattern was strongly suggestive of advanced lesion but confident diagnosis of low grade dysplastic or non-neoplastic lesion based on surface/vessel characteristics was not accurate. Another study assessed 65 duodenal sites in 36 subjects which were normal or had polyps[22]. Duodenal polyp with dysplasia was seen at 24 sites and mNBI had sensitivity of 83% and specificity of 78% in detecting dysplasia. They also examined the mucosa using probe based confocal endomicroscopy which was found to be better than mNBI. These data suggest that mNBI may help the endoscopist avoid biopsy (which makes subsequent resection difficult) and proceed directly to EMR in suspected dysplastic lesions.

A couple of case reports have described the appearance of follicular lymphoma in duodenum on mNBI. Chowdhury *et al*[20] from Morioka, Japan reported coiled, elongated microvascular pattern in two patients with follicular lymphoma and similar findings was observed by Iwamuro *et al*[23] in a 57-year-old patient from Niihama, Japan[20,23]. Inoue *et al*[24] reported whitish areas in enlarged villi in a patient with primary follicular lymphoma of duodenum. Elongated microvessels with white spots on surface was observed in a case of duodenal lymphangioma[21]. Another case report described saucer shaped lesions and multiple swollen villi like "moth eggs" on mNBI in a case of interdigitating dendritic cell sarcoma in duodenum[25]. While mNBI showed interesting abnormalities in the above reported lesions, its impact on management of patient is uncertain as biopsy may still be required.

NBI TO SCREEN FOR DUODENAL POLYPS IN POLYPOSIS SYNDROMES

Duodenum is an important site of polyps in familial adenomatous polyposis[26]. Surveillance endoscopy is recommended as duodenal tumours are the second most common cause of mortality in FAP after colonic tumours[27]. A study from Netherlands on 37 patients with FAP who underwent surveillance endoscopy using mNBI found NBI detected more adenomas than high resolution endoscopy and increased the Spigelman stage in 2 patients[28]. Another group used NBI for surveillance of polyps in patients with carriers of PTEN mutation seen in Cowden's syndrome[29]. Nine out of ten patients were found to have duodenal polyps but the role mNBI in this high diagnostic yield was not very clear.

NBI FOR DUODENAL AMPULLARY LESIONS

Ampullary adenomas may harbour malignant foci which may be missed on random biopsy due to sampling error. A study on 14 patients with bulky ampulla investigated the correlation between findings on mNBI and histology[13]. The surface pattern was divided into three types (type Ⅰ - oval villi; type Ⅱ - pinecone/leaf

Table 1 Overview of current status of magnification narrow band imaging technology in duodenum

Merits	Real time assessment of duodenal villous morphology with excellent accuracy
	Enables targeted biopsy of abnormal appearing area
Demerits	Added procedure time and cost
Potential applications	Assessment of duodenal villous atrophy in malabsorption syndromes
	Data on role in assessing duodenal neoplastic lesion is still preliminary

shaped villi; type Ⅲ - irregular or nonstructured villi). Presence of tortuous, dilated and network vessels were considered abnormal. Inflammatory and hyperplastic lesions had type Ⅰ surface pattern while adenomas and adenocarcinomas had type Ⅱ and/or Ⅲ surface pattern. Adenomas did not have abnormal vessels. A case report also showed the absence of vascular abnormality to be associated with no foci of malignancy on histology[30]. This is another potential area where NBI may play a role in obtaining targeted biopsies and help decide management strategy. Apart from assessing lesion characteristics, mNBI may also help in determining the lesion margin in patients undergoing duodenal papillectomy. Itoi *et al*[31] found mNBI to be better than indigo carmine chromoendoscopy for this indication. These preliminary observations suggest that mNBI may be useful in assessment and management of ampullary lesions. Larger studies are however required before recommending this technique for routine use.

CONCLUSION

Magnification endoscopy with NBI (mNBI) seems to have a potential role in evaluating duodenal mucosal morphology. Table 1 summarises the merits, demerits and potential application of this technology in clinical practice. While there is robust evidence for its role in assessing villous morphology, more data is required before recommending it for routine use in assessment of duodenal neoplastic lesions. There is also a need for uniform terminology and classification in describing villous morphology and protruding lesions which can enable comparison of published literature and facilitate training. The recent increase in interest on NBI in duodenum is encouraging because it can lead to new diagnostic possibilities which may impact therapy.

Abstract

AIM: To determine the optimal generator settings for endobiliary radiofrequency ablation.

METHODS: Endobiliary radiofrequency ablation was performed in live swine on the ampulla of Vater, the common bile duct and in the hepatic parenchyma. Radiofrequency ablation time, "effect", and power were allowed to vary. The animals were sacrificed two hours after the procedure. Histopathological assessment of the depth of the thermal lesions was performed.

RESULTS: Twenty-five radiofrequency bursts were applied in three swine. In the ampulla of Vater (n = 3), necrosis of the duodenal wall was observed starting with an effect set at 8, power output set at 10 W, and a 30 s shot duration, whereas superficial mucosal damage of up to 350 μm in depth was recorded for an effect set at 8, power output set at 6 W and a 30 s shot duration. In the common bile duct (n = 4), a 1070 μm, safe and efficient ablation was obtained for an effect set at 8, a power output of 8 W, and an ablation time of 30 s. Within the hepatic parenchyma (n = 18), the depth of tissue damage varied from 1620 μm (effect = 8, power = 10 W, ablation time = 15 s) to 4480 μm (effect = 8,

power = 8 W, ablation time = 90 s).

CONCLUSION: The duration of the catheter application appeared to be the most important parameter influencing the depth of the thermal injury during endobiliary radiofrequency ablation. In healthy swine, the currently recommended settings of the generator may induce severe, supratherapeutic tissue damage in the biliary tree, especially in the high-risk area of the ampulla of Vater.

Key words: Endobiliary radiofrequency ablation; Biliary stricture; Ampullary tumor; Endoscopic retrograde cholangio-pancreatography

Core tip: The use of endoscopic retrograde cholangio-pancreatography-guided endobiliary radiofrequency ablation is expanding quickly, from the clearing of obstructed biliary stents in malignant biliary stenoses, to the treatment of benign biliary strictures. However, the morbidity associated with this procedure remains high, of course because of the severity of the disease treated, but also possibly due to suboptimal generator settings. Therefore, we conducted an animal study in live pigs. We report novel data, highlighting the importance of the effect setting on the generator, and suggesting specific settings for radiofrequency ablation in the ampulla of Vater.

INTRODUCTION

Radiofrequency (RF) ablation is currently used for the destruction of a wide range of liver neoplasms, including hepatocarcinoma, intrahepatic cholangiocarcinoma, and colorectal metastases[1]. RF waves can be applied either intraoperatively or percutaneously. The recent development of endobiliary RF ablation devices has been justified by two situations in which pre-existing methods were non or partially satisfactory: (1) unresectable extrahepatic cholangiocarcinoma[2], in which chemotherapy is poorly efficient and tumor response is difficult to assess[1]; and (2) obstruction of biliary stents by tumor ingrowth in unresectable pancreatic head cancers, which requires endoscopic desobstruction. Endobiliary RF ablation is currently performed using a device which can be used percutaneously[3,4] or through retrograde endoscopic cannulation of the main bile duct[5]. After preclinical studies in *ex vivo*[6] and *in vivo* pig livers[7], early endobiliary RF experience has been reported in patients. Because of the lack of control group in these retrospective or pilot prospective studies, the clinical efficacy of the method cannot be assessed with a high degree of confidence. However, endobiliary RF ablation in the setting of malignant biliary strictures of the common bile duct was technically feasible in a small series of patients presenting one of the above-mentioned indications. The method seems capable of clearing occluded metal stents[4] and may have the potential to improve medium to long-term biliary stent patency[5,8]. Other indications of choice could be foreseen, such as the destruction of benign biliary lesions or the ablation of shallow intraductal or intra-ampullary neoplasia. However, in view of the limited preclinical data and the need for an accurate assessment of tolerable electrosurgical settings before using endobiliary RF in such indications, additional animal data is needed. We therefore conducted a preclinical study on live pig liver to assess the tissular effect of endobiliary RF ablation in the intrahepatic, common, and periampullary bile ducts with various generator settings.

MATERIALS AND METHODS

Landrace pigs weighing 30-35 kg and stemming from the same farm were used for the study. The pigs were accommodated at our facility for 48 h prior to the procedure. Procedures were performed under general anesthesia. The animal protocol was designed to minimize pain or discomfort to the animals. All animals were prepared for anesthesia with a 12-h diet, and administered an intramuscular injection of 10 mg/kg ketamine and 2 mg/kg azaperone 30 min before induction. After induction with 8 mg/kg intravenous 1% propofol and endotracheal intubation, anesthesia was maintained through inhalation of 1% to 2% isoflurane. All animals received an intravenous infusion of 10 mg/kg per hour crystalloid solution. Median laparotomy was performed, and anterior duodenotomy at the level of the first portion of the duodenum was made in order to expose the duodenal papilla, which is located 15 mm distal to the pylorus. The common bile duct was cannulated using a 0.035 Inch guidewire (Jagwire, Boston Scientific, Natick, MA, United States) and its actual position was ascertained by direct visualization of the hepatic pedicle. A Habib EndoHPB™ (EMcision UK, London, United Kingdom) probe was used for RF ablation. It is a bipolar device, 8 F (2.6 mm) in diameter, 1.8 m long, that passes over 0.035-inch guidewires, has 2 ring electrodes disposed on the catheter 8 mm from one another, with the distal electrode 5 mm from the leading edge; bipolar current activation allows for tissue ablation by creating coagulation necrosis over a 2.5 cm length[9]. The endoHPB™ probe was connected to a VIO300D electrosurgical generator (Erbe, Tübingen, Germany) in bipolar mode, delivering a high-frequency (450 kHz) electrical effect. The catheter was

introduced manually inside the common bile duct and RF ablation was performed: (1) in the ampulla of Vater by positioning the space between both electrodes, which is the zone of highest energy deposition, exactly within the ampullary area, meaning that the most distal electrode was inside the bile duct and the most proximal one mostly within the duodenum; and (2) in the common bile duct. One or two separate thermal lesions could be performed along the bile duct, and only one in the ampullary region. The RF procedures on the ampulla of Vater are shown on Figure 1. Because of the limited space in the biliary tract and the ampullary region, separate tests were performed on the hepatic parenchyma prior to those biliary lesions, in order to predetermine a range of parameters most likely to provide the best safety-to-effectiveness balance for biliary lesions. Liver thermal injuries were performed by inserting the RF probe into the liver after a small incision in the Glisson's capsule. Different ablation parameters, such as effect and power, but also duration of RF shots, were allowed to vary. Two hours after the procedure, with the animals still under general anesthesia, the pigs were euthanized with 100 mg/kg intravenous injection pentobarbital. The liver, the common bile duct, and the duodenum were collected en-bloc with the pancreatic head and fixed for 24 h in 10% buffered formalin. After macroscopic examination, ablated segments were embedded in paraffin, processed into 3 μm-thick sections, and stained with hematoxylin, eosin and saffron. Histological assessment was performed by a pathologist experienced in digestive pathology (AR), using an ocular micrometer to measure the maximal extent of tissue necrosis in depth from the epithelial surface. Tissue presenting disorganization of the layers, absence of normally shaped native cells, edema and/or inflammatory cell infiltrate was considered necrotic. Statistical analysis was performed using Graphpad Software (GraphPad Software Inc., San Diego, CA). Results are expressed as mean values ± SD.

The experimental protocol was approved by the scientific committee of the Surgery School of Paris (Ecole de Chirurgie de l'Assistance Publique-Hopitaux de Paris, France) and the experiments were performed according to the standard animal research guidelines established by the French Ministry of Agriculture.

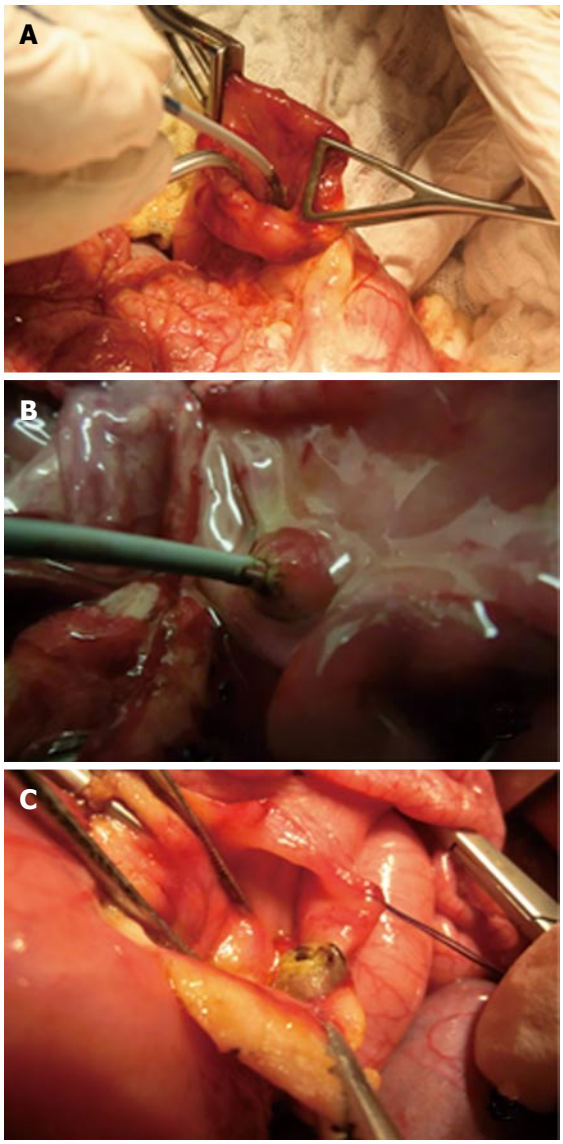

Figure 1 Radiofrequency ablation on the ampulla of Vater. A: The introduction of the probe (pig #3); B: The early mucosal changes visible during radiofrequency procedure (pig #2); C: Features of early and excessive tissue damage after probe withdrawal (pig #1).

RESULTS

Three pigs, on which 25 RF ablations were conducted, were included in the study. Eighteen RF ablations were conducted in the hepatic parenchyma allowing the testing 11 ablation conditions. The depth of tissue necrosis ranged from 1620 μm for an effect of 8, a power of 10 W, and a 15 s ablation time, up to 4480 μm for an effect of 8, a power of 8 W, and a 90 s ablation. The full set of corresponding figures is displayed in Table 1. Based on those results, RF shots conducted in the common bile duct allowed the testing of three ablation settings. With an effect varying from 4 to 8, a

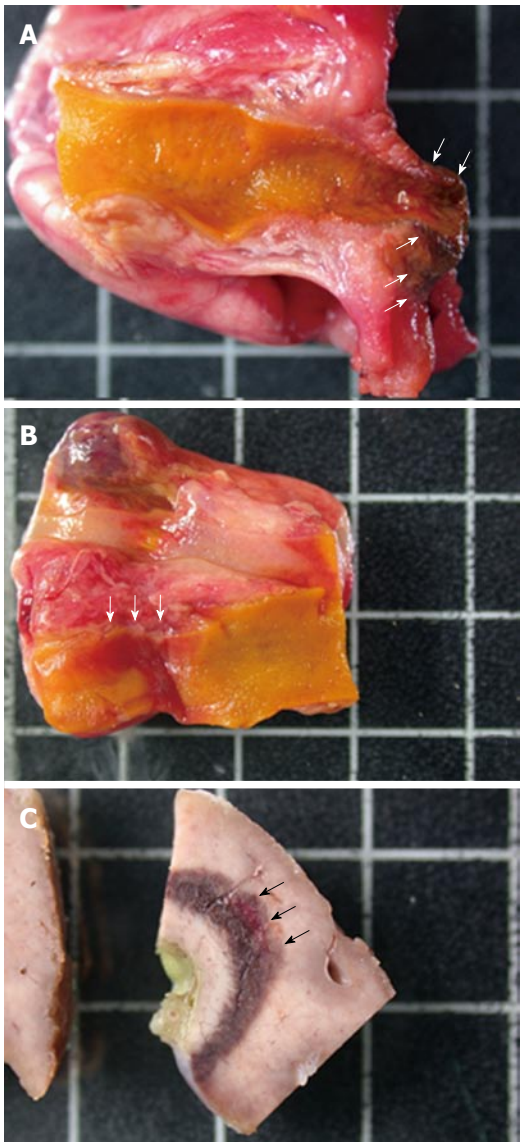

Figure 2 Macroscopic findings on the bile tract after radiofrequency ablation in pig #2. A: The papillary region and distal common bile duct, with tissue damage reaching the duodenal wall (arrows); B: An ablated zone limited to the wall of the common bile duct (arrows); C: An example of intrahepatic parenchymal damage up to 4 mm away from the bile ducts (arrows).

power output from 6 to 20 W, and shot duration from 30 to 90 s, a depth of tissue injury allowing for deep, yet non transmural tissue necrosis up to 1075 μm was obtained with an effect set at 8, a power of 8 W, and a short ablation time of 30 s; longer or more powerful or intensive shots led to transmural tissue necrosis up to 2700 μm away from the epithelium, with destruction of the peribiliary adipose tissue. Finally, three RF ablations were conducted in the ampullary region under three different ablating conditions. Effect was set at 8, power varied from 6 to 10 W, and the duration of ablation shots from 30 to 90 s. The depth of the tissue injury ranged from 350 μm, with ablation limited to the mucosa, for a power output of 6 W and an ablation time of 30 s, up to 2810 μm, with extensive tissue necrosis involving the adipose tissue and the pancreas, for a power of 10 W and a 90 s long shot. The results of RF in the bile duct and the ampulla of Vater are presented in Table 2. Macroscopic assessment of the ablated tissues is presented in Figure 2, and histological views of ablated ampullae are shown in Figure 3. Figure 4 presents the respective impact of power and ablation time variation on tissue damage after RF. Whereas power and ablation time appeared to be linearly correlated to the depth of tissue damage, variations in effect settings only had a modest influence on tissue damage, although our results showed an inverse relationship between effect and power output (Figure 5).

Table 2 Outcomes of endobiliary radiofrequency ablation in the main bile duct and ampulla of Vater

Effect setting	Power output (W)	Shot duration (s)	Shot location	Depth of tissue injury (μm)	Observations
4	20	90	Bile duct	2700	Transmural necrosis
6	10	90	Bile duct	2600	Transmural necrosis
8	10	90	Ampulla	2810	Extensive necrosis of the papilla, involving pancreas and adipose tissue
8	10	30	Ampulla	1530	Deep coagulation, necrosis of the duodenal wall. No significant pancreatic injury
8	6	60	Bile duct	1420	Deep transmural coagulation, involving peribiliary adipose tissue
8	8	30	Bile duct	1075 ± 417[1]	Coagulation involving almost the entire duct wall
8	6	30	Ampulla	350	Superficial coagulation, moderate duodenal lesion

[1]Mean ± SD, 2 measurements have been performed.

DISCUSSION

Clinical studies of RF endobiliary ablation with the EndoHPB™ probe have not been undertaken without previous animal studies designed to assess the depth of tissue damage[6,7,10]. It is noteworthy that EndoHPB probes are designed to be used only with VIO200-300, which is one of the most popular HF units in endoscopy wards. This should make comparisons between studies relatively easy and reliable, since the parameters used are strictly comparable. Itoi *et al*[6] assessed thermal injury in the hepatic parenchyma in three *ex vivo* pig livers, and tested 12 ablation settings, with power varying from 5 to 20 W and ablation times ranging from 60 to 120 s. Their observations were mainly macroscopical, and the authors reported tissue necrosis extending from 4.3 ± 0.6 mm to 11.3 ± 1.2

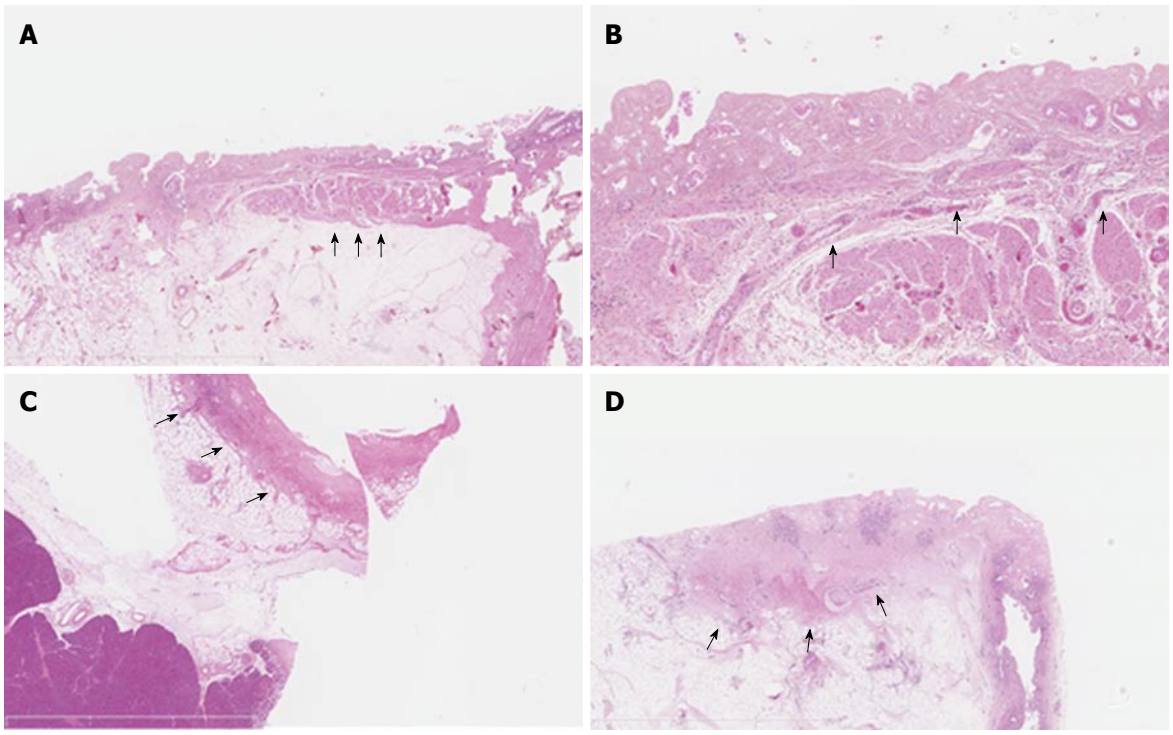

Figure 3 Histological findings in the three ampullae Vaterii treated by radiofrequency ablation. A: Taken from pig #3, shows satisfying ablation of the ampulla of Vater sparing the submucosa; arrows indicate the intact submucosa; hematoxylin eosin and saffron, original magnification × 25; B: The vertical extension of tissue damage in pig #1, reaching the muscularis mucosae; arrows indicate the muscularis mucosae; hematoxylin eosin saffron, original magnification × 100; C and D: The ampullae of pigs #1 and 2 (respectively), with deep tissue necrosis extending far beyond the muscularis propria up to the adipose tissue; arrows indicate the extent of coagulation necrosis; hematoxylin eosin and saffron, original magnification × 25.

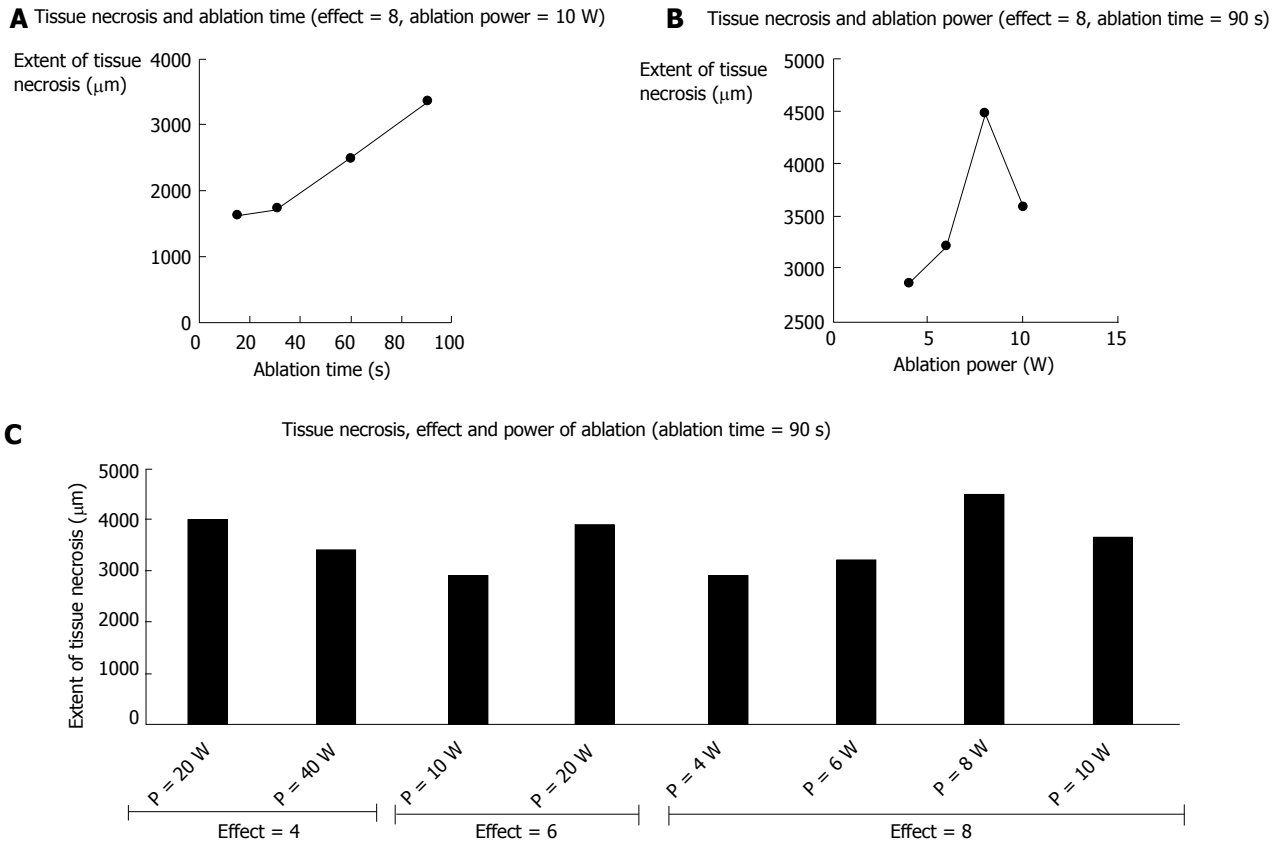

Figure 4 Variation of the extent in depth of thermal tissue damage after radiofrequency ablation in the liver according to electrical settings (VIO 300D). A: Variation of depth with shot duration; B: Variation of depth with power output setting; C: Variation of depth with effect.

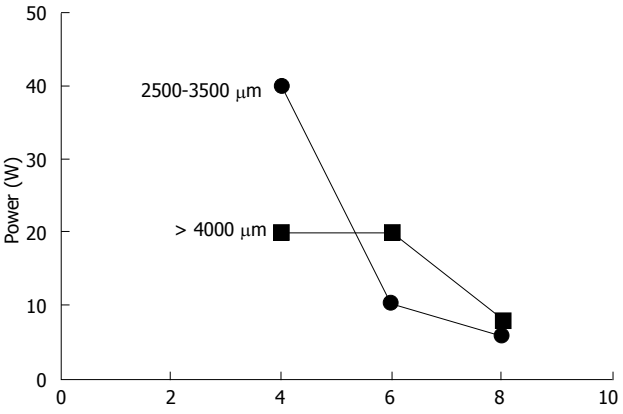

Figure 5 Relative variation of power output and effect setting for a given depth of tissue ablation and a 90 s ablation time in the liver.

mm in depth. However, these numbers are hardly comparable with ours, as the authors measured the entire thickness of the damaged tissue, including the proper width of the catheter. They concluded that: (1) for the 5 W power value, 60 and 90 s ablation times were insufficient to achieve tissue necrosis; (2) the 5-10 W power output range was a zone of continuously increasing tissue damage, as opposed to power values of 15 W and over, for which tissue necrosis seemed to be stable. However, this study was performed *ex vivo*, lacked thorough histological analysis, was limited to the liver parenchyma, and did not take into account the effect parameter, which was set a priori at 8. In a study closer to clinical conditions, Zacharoulis *et al*[7] assessed the effects of endobiliary RF ablation on the bile ducts of 20 live pigs. The authors tested 10 different conditions of power output ranging from 1 to 10 W, left a plastic stent in the common bile duct, and performed histological assessment of the common bile duct 24 h after the procedure. They concluded that power as well as ablation time had an impact on the depth of tissue damage, and found the optimal settings to be a power of 6-7 W and an ablation time of 60 s[7]. In this study however, the variation of the effect was also not taken into account, histological assessment was semi-quantitative, and only the common bile duct was studied.

Based on the results of those preclinical studies, it has been suggested that the Habib EndoHPB™ probe be set at a power of 10 W, an effect of 8, and a shot duration of 90-120 s[9]. In published clinical reports, endobiliary RF has been associated with a 10%-20% morbidity rate[5,8,11,12], including cases of cholangiosepsis, liver infarction, hepatic coma, cholecystitis, and pancreatitis, all of which can be explained at least in part by excessive tissue damage to the distal bile duct or to the hepatic parenchyma. Moreover, generator settings reported in clinical studies have been heterogeneous, ranging from 5 W and 120 s[13] to 10 W and 120 s[4], and frequent use of intermediate power values or ablation times[5,8,11,12]. Only one publication reported the use of endobiliary RF ablation on a periampullary tumor, but RF was actually used to treat a malignant stricture at the proximal end of a biliary stent, thus at a distance from the ampulla[14]. For these reasons, we chose to re-assess the effects of RF on living pig liver before undertaking evaluations on the healthy bile duct and the ampullary region.

In its step-by-step guide to endobiliary RF procedures, the manufacturer suggests that for periampullary procedures, the power should be lowered to 7 W, and the procedure should be stopped as soon as the duodenal mucosa started blanching[9]. We first confirmed that the standard settings of the RF generator (effect 8, power 10 W) resulted in excessive damage to the ampulla of Vater, even with very short RF ablation times such as 30 s. An effect of 8, a low power of 6 W, and a short ablation time of 30 s seemed to provide optimal tissue ablation of the epithelium and the lamina propria in the ampulla. In the common bile duct, we observed a deep tissue necrosis reaching the entire bile duct wall and the peribiliary adipose tissue with settings as low as effect 8, power 6 W, and a 60 s ablation. This is consistent with the observations of Zacharoulis *et al*[7] who observed damage to adjacent organs or full thickness tissue necrosis (leading to bile duct perforation in three cases out of four at 24 h) in all animals treated with a power > 6 W. We can also conclude from these data that the effect setting has a major importance in the RF energy delivered: indeed, for a 90 s RF shot, a four point variation (from 4 to 8) of the effect causes the same tissue damage as a 30 W variation of the power (from 10 to 40 W). In the hepatic parenchyma, a 3 mm tissue damage around the probe could be achieved equally with either high power values or a 2 point increase of the effect setting. Power values, as reported by others, seemed to clearly influence the depth of tissue damage up to 10 W[6,7]: The impact of raising the power beyond 10 W did not appear to be significant. By contrast, the time of RF ablation was linearly correlated to the extent of tissue necrosis.

To our knowledge, this is the first study that considers the impact of effect variation in endobiliary RF. Furthermore, based on consistent data obtained in the hepatic parenchyma, we tested RF ablation in the whole biliary tree, including the ampulla of Vater.

However, our study presents some limitations; first, given the small number of animals, we only tested a limited number of generator settings, and did not duplicate the measurements for most values obtained in the common bile duct, although the figures found are in keeping with those reported by other authors[6,7]. Second, the short time span between RF and the sacrifice of animals could have led us to overlook the actual extent of the lesions. However, we waited for two hours before the animals were euthanized in order for the tissue damage to appear, which was sufficient to make coagulation necrosis clearly visible with standard staining. Third, although the *in vivo* pig liver is currently the cheapest and most easily available, it may not be a perfect model for thermal ablation, since it lacks

tumoral or inflammatory thickening of the biliary wall. This could account for the supratherapeutic effects of the recommended RF generator settings in swine. Other explanations have been suggested, such as different blood supplies between the swine and human common bile duct, or major heat sink phenomenon in humans compared with swine due to higher blood flow in the hepatic pedicle[7]. Furthermore, the dramatic RF impact in other swine epithelia, such as esophageal has also been reported to be more severe than in humans[15].

In conclusion, our work demonstrates that the currently recommended settings for endobiliary radiofrequency ablation may result in supratherapeutic effects in the pig liver, bile duct and periampullary region. Our data also underlined the critical importance of the effect setting on the VIO™ RF generator for this application. These points should be kept in mind when designing RF ablation clinical trials, especially since clinical indications of endobiliary RF ablation tend to spread outside the field of malignant stricture management, such as benign biliary stricture[16] or possibly residual neoplastic tissue after endoscopic papillectomy.

ACKNOWLEDGMENTS

The authors wish to thank Mrs Alice Bertucat for her help in the animal experiments, as well as the animal attendants from the Ecole de Chirurgie de l'Assistance Publique-Hopitaux de Paris.

COMMENTS

Background

Endoscopic endobiliary radiofrequency (RF) ablation has been developped for the treatment of malignant biliary obstructions. It currently allows to clear occluded metal stents and may have the potential to improve medium to long-term biliary stent patency.

Research frontiers

Endobiliary RF ablation has mainly been studied for lesions of the common bile duct. The optimal generator settings for the treatment of ampullary or intrahepatic lesions is uncertain. Moreover, the consequences of the variations of « effect » parameter of the generator have not been studied.

Innovations and breakthroughs

This is the first study that considers the impact of effect variation in endobiliary RF. Furthermore, based on consistent data obtained in the hepatic parenchyma, the authors tested RF ablation in the whole biliary tree, including the ampulla of Vater.

Applications

Results of this study should be kept in mind when performing endobiliary radiofrequency ablation for intrahepatic or ampullary lesions, or for non-neoplastic, shallow lesions of the common bile duct.

Terminology

Endobiliary radiofrequency ablation consists in the application of radiofrequency energy using a bipolar probe inserted into the biliary tree, either percutaneously, or by retrograde cannulation *via* endoscopic retrograde cholangiopancreatography.

Peer-review

This study gave a good result for using endobliary radiofrequency ablation or not in clinic, and did have clinical value to guide the treatment procedure.

Abstract

A recent paper by Boal Carvalho *et al* demonstrates the potential of PillCam COLON 2© (PCC2) as a pan-enteric investigation in Crohn's disease (CD). Our own prospective data in patients with known CD also shows good correlation between PCC2 and small/large bowel investigations (R = 0.896, $P < 0.0004$/R = 0.6667, $P < 0.035$). Larger studies are warranted to prospectively validate the use of PCC2 in the investigation and monitoring of both small and large bowel CD.

Key words: Capsule endoscopy; Panenteroscopy; Small bowel Crohn's disease; Mucosal healing; Colon capsule

Core tip: Mucosal healing has been shown to reduce the need for surgery and hospitalisation in patients with Crohn's disease. Currently, assessing small bowel and colonic mucosal healing requires separate imaging/endoscopic modalities. Recent data suggests that the PillCam Colon 2© (PCC2) is capable of assessing mucosal healing of the small intestine and colon in a single, non-invasive test. Our own prospective data corroborates these findings demonstrating good correlation between investigations. Larger studies assessing the viability of PCC2 as a pan-enteric investigation are warranted.

TO THE EDITOR

We read with interest the recent article by Boal Carvalho *et al*[1] entitled "PillCam COLON 2© in Crohn's disease: A new concept of pan-enteric mucosal healing assessment". Mucosal healing in Crohn's disease (CD) remains a current hot topic. Numerous colonic studies suggest that mucosal healing leads to increased steroid-free remission and decreases surgical and hospitalisation rates[2-5]. More recent studies have established that small bowel capsule endoscopy (SBCE) is capable

Table 1 Bowel preparation regime for study participants undergoing same day colon capsule and colonoscopy

Schedule	Intake
Day 1	
All day	10 glasses of water throughout the day
Evening	Four senna tablets
Day 2	
All day	Clear liquid diet
Evening	2l Klean prep
Day 3 (exam day)	
Morning	2l Klean prep
10-11 am	Colonoscopy + capsule ingestion
1st boost	1 sachet sodium picosulfate
(upon small bowel entry)	
2nd boost (4 h later)	1 sachet sodium picosulfate

Table 2 Baseline characteristics of study patients (n = 10)

Median age in years (range)	31 (19-47)
Female	7 (70%)
Smoker	5 (50%)
Disease extent	
Ileo-colonic	10 (100%)

Stricturing	6 (60%)
Previous resection	
Ileo-caecal surgery	4 (40%)
Ilealsurgery	1 (10%)
Medications	
Thiopurine	3 (30%)
Biologic	9 (90%)

of safely monitoring small bowel mucosal healing[6,7] although long-term follow up studies are required to demonstrate the efficacy of small bowel mucosal healing. The use of PillCam COLON 2 (PCC2) as a pan-enteric device has been previously investigated by Negreanu *et al*[8].

This current study by Boal Carvalho *et al*[1] again demonstrates the potential of PCC2 as a "one-stop", non-invasive mucosal healing assessment of both the large and small bowel. In total, 12 patients were enrolled in the study. Each patient underwent an ileocolonoscopy and SBCE at diagnosis. All patients had a PCC2 performed following one year from diagnosis. The aim was to evaluate the ability of PCC2 to assess mucosal response to therapy in both the large and small bowel. At one year, mucosal healing of the small bowel and large bowel was 33% and 50%, respectively. The combined mucosal healing rate was only 25%. However, perhaps most importantly, PCC2 was shown to be capable of adequately assessing both small and large bowel CD.

Our own data would appear to support these findings in terms of the viability of PCC2 as a pan-enteric device. We performed a prospective comparative study of PCC2 *vs* both ileo-colonoscopy and SBCE in patients with known CD. Following ethical approval, patients were recruited from our clinic at Tallaght hospital over a 6-mo period. Major exclusion criteria included known small bowel stricture, recent gastrointestinal surgery (within 3 mo of study recruitment) and chronic NSAID use or NSAIDS within 6 wk of study recruitment (apart from 5-ASA therapy). SBCE and PCC2 investigations were performed using PillCam technology (Given Imaging, Yoqneam, Israel). SBCE followed our standard protocol without bowel preparation. PCC2 and colonoscopy were performed no longer than 14 d following SBCE. Bowel preparation regimen was performed over a 3 d period (Table 1). One experienced endoscopist performed all study colonoscopies. PCC2 was performed on the same day as ileo-colonoscopy. All SBCE and PCC2 images were reviewed by two clinicians experienced in reading and interpreting capsule examinations. The capsule endoscopy CD activity index (CECDAI) was utilised to assess the severity of disease activity. The CECDAI divides the small bowel into proximal and distal segments and uses three major criteria to grade severity: Inflammation, extent of disease and the presence of stenosis with the addition of proximal and distal scores leading to an overall CECDAI score. The authors utilised the CECDAI score for this study due to the fact that it is the only capsule scoring system which has been prospectively validated to date[9]. Activity was graded as follows; inactive disease (CECDAI = 0), mild disease activity (3.5 < CECDAI < 5.8), moderate to severe disease activity (CECDAI $\geqslant$ 5.8). Colonic disease activity was based on the Simple Endoscopic Score for Crohn's Disease (SES-CD); inactive disease (SES-CD = 0-3), mild disease activity (SES-CD = 4-10), moderate disease activity (SES-CD = 11-19) and severe disease activity (SES-CD $\geqslant$ 20).

In total, 10 participants were enrolled; median age of 31 years (range 19-47), 7 (70%) female. Every participant had previously documented ileo-colonic disease. Baseline demographics are summarised in Table 2. All capsules reached the caecum ensuring complete small bowel views for both SBCE and PCC2. Overall image quality was adequate for both modalities. Upon review of SBCE images, 2 (20%) had no small bowel disease activity, 5 (50%) had mild/moderate severity with the remaining 3 (30%) having severe small bowel CD. In terms of disease distribution, the majority 7 (88%) had distal ileal disease only with only one (12%) participant having evidence of more proximal small bowel disease. In comparison, PCC2 detected the following disease activity; 2 (20%) normal, 6 (60%) mild/moderate with the remaining 2 (20%) having severe disease. There appeared to be good correlation between SBCE and PCC2 images in terms of the recognition and grading of disease activity (R = 0.896, P < 0.0004). The caecal intubation rate for colonoscopic procedures was 100%. Overall, the terminal ileum was intubated in 9 (90%) participants. All CCE procedures successfully reached the rectum. Of note, there were no complications with any of the capsule or colonoscopic procedures. On colonoscopy, 8 (80%) had no disease activity with 2 (20%) having mild disease. The majority of participants (9, 90%) had

no disease activity on PCC2 with only one participant meeting the criteria for mild disease activity. There was good correlation between the two modalities (R = 0.6667, $P < 0.035$).

Despite limited numbers between all of the studies performed to date, PCC2 does appear capable of successfully examining the small and large bowel and also accurately detecting small bowel and colonic CD. With regard to our own data, PCC2 did appear to miss disease in the proximal small bowel that was detected by SBCE. This may be due to the PCC2 technology itself which "shuts down" in the proximal small bowel to conserve battery life. Alternatively, reader error may be at fault. The development of a "pan-enteric" capsule designed specifically for both small and large bowel imaging may ultimately be required. In terms of colonic disease, the correlation between modalities was not quite as strong as that witnessed for small bowel images. However, this may be due to the scoring system utilised. There was discrepancy between PCC2 and colonoscopic disease activity scores in only two participants. The actual numerical difference in the SES-CD scores for both participants was a solitary point. In both cases, this increased the disease severity into a higher bracket of disease activity which likely skews the correlation between the two modalities. The development of a combined scoring system encapsulating both small and large bowel disease activity may be a viable option in the progression of this technology. Certainly based on the evidence to date, larger studies are warranted to prospectively validate the use of PCC2 in the investigation and monitoring of both small and large bowel CD.

Abstract

Despite significant improvements in our understanding of Crohn's disease (CD) and ulcerative colitis (UC) in recent years, questions remain regarding the best approaches to assessment and management of these chronic diseases during periods of both relapse and remission. Various serologic biomarkers have been used in the evaluation of patients with both suspected and documented inflammatory bowel disease (IBD), and while each has potential utility in the assessment of patients with IBD, potential limitation remain with each method of assessment. Given these potential shortcomings, there has been increased interest in other means of evaluation of patients with IBD, including an expanding interest in the role of gene expression profiling. Among patients with IBD, gene expression profiles obtained from whole blood have been used to differentiate active from inactive CD, as well as to differentiate between CD, UC, and non-inflammatory diarrheal conditions. There are many opportunities for a non-invasive, blood based test to aid in the assessment of patients with IBD, particularly when considering more invasive means of evaluation including endoscopy with biopsy. Furthermore, as the emphasis on personalized medicine continues to increase, the potential ability of gene expression analysis to predict patient response to individual therapies offers great promise. While whole blood gene expression analysis may not completely replace more traditional means of evaluating patients with suspected or known IBD, it does offer significant potential to expand our knowledge of the underlying genes involved in the development of these diseases.

Key words: Inflammatory bowel disease; Ulcerative colitis; Gene expression analysis; Whole blood gene expression analysis; Biomarkers; Crohn's disease; Gene

profiling

Core tip: Questions remain regarding the best approaches to the assessment and management of patients with inflammatory bowel disease (IBD) during periods of both relapse and remission. Given the existing limitations of other serologic biomarkers, the development of whole blood gene expression profiling as a non-invasive method of assessment of patients with IBD is appealing. In an era of increased focus on personalized medicine, the potential expansion of our understanding of the genes underlying these diseases and their potential utility in predicting an individual's disease course or response to therapy offers great promise.

Barnes EL, Liew CC, Chao S, Burakoff R. Use of blood based biomarkers in the evaluation of Crohn's disease and ulcerative colitis. *World J Gastrointest Endosc* 2015; 7(17): 1233-1237 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i17/1233.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i17.1233

INTRODUCTION

Though great strides have been made in our understanding of Crohn's disease (CD) and ulcerative colitis (UC) in recent years, questions remain regarding the best approaches to assessment and management of these chronic diseases during periods of both relapse and remission. These two subtypes of inflammatory bowel disease (IBD) have a presumed genetic predisposition, which when combined with multiple environmental exposures including changes to the gut microbiome, lead to clinically evident CD or UC. While the traditional evaluation of patients with IBD has been largely centered on endoscopic and radiographic examination, along with histological assessment of biopsy specimens, newer techniques focusing on gene expression profiling have been increasingly utilized to examine the differential expression of genes between disease states and normal. The use of gene expression profiling has significant potential within the field of IBD, both in differentiating CD and UC from non-IBD conditions, as well as determining activity of disease and response to treatment.

CURRENT APPROACHES TO EVALUATION

Various serologic biomarkers have been used in the evaluation of patients with both suspected and documented IBD. Erythrocyte sedimentation rate and C-reactive protein (CRP) are non-specific markers of inflammation that can be elevated in patients with active CD and UC. Although CRP can be useful in differentiating IBD from other non-inflammatory gastrointestinal conditions[1], given their non-specific nature, reliance on these biomarkers alone can be problematic. While CRP is an acute phase protein thought to increase in patients with active IBD, up to 50% of patients with an active flare of UC can demonstrate normal CRP levels[2]. In patients with clinically active CD, normal CRP levels can be noted[3,4], as biomarker levels are not necessarily correlated with mucosal lesions noted on endoscopy[3]. Additionally, certain populations of patients with CD can demonstrate persistently low CRP levels in the setting of active disease, including patients with an ileal disease distribution or low body mass index[5].

Other strategies have been developed in attempts to use serologic testing to differentiate CD from UC, such as the tests for anti-Saccharomyces cerevisiae antibodies (ASCAs) and perinuclear antineutrophil cytoplasmic antibodies (pANCAs). Increased titers of ASCA have been associated with CD, whereas increased levels of pANCA are more commonly seen in patients with UC[6]. However, when evaluated in a meta-analysis of 60 studies, the sensitivity and specificity of a $ASCA^+/pANCA^-$ pattern for identification of CD was only 55% and 93% respectively[7]. In addition to ASCA, multiple other antibodies to bacterial proteins (Omp-C and I2), flagellin (CBir1), and bacterial carbohydrates have been studied and associated with CD, including laminaribioside (ALCA), chitobioside (ACCA[2]) and mannobioside (AMCA). These existing serological markers tend to have low sensitivity and specificity due to the potential for elevation in levels caused by autoimmune diseases, infectious processes, and inflammation outside the GI tract[8].

In contrast to the serologic biomarkers, fecal markers such as fecal calprotectin (FC) and fecal lactoferrin are more specific for intestinal inflammation. FC serves as an indirect estimate of the neutrophil infiltrate in the bowel mucosa. When evaluating a patient with suspected IBD, one meta-analysis concluded that measuring FC can be used as a screening tool for identifying patients who are likely to need endoscopy for further evaluation of suspected IBD[9]. Among patients with previously diagnosed IBD, FC serves as a reliable indicator of disease activity, though it's greatest utility may be in the evaluation of UC[10]. While FC has demonstrated significant utility in differentiating IBD from other chronic abdominal syndromes such as Irritable Bowel Syndrome[1,11], FC does not reliably differentiate between UC and CD[12].

DEVELOPMENT OF NEW BIOMARKERS

Given the shortcomings of these established serologic and fecal biomarkers in the evaluation of a patient with suspected or documented IBD, there has been an increased interest in other means of evaluation, including gene expression profiling. One of the more recent advances in this field has been the development of techniques allowing for the evaluation of mRNA extracted from whole blood[13,14]. The use of whole blood

mRNA gene expression methodology has been validated and utilized to stratify an individual into high and low risk groups for the development of colorectal cancer[15], as well as to predict an individual's current risk for having colorectal cancer[16], Additionally, RNA expression profiles obtained from whole blood have been used to identify patients with other conditions such as lung cancer[17], bladder cancer[18], kidney diseases[19,20], cardiovascular diseases[21-23], osteoarthritis[24], and psychiatric disorders such as schizophrenia and bipolar disorder[25,26]. Among patients with IBD, gene expression profiles obtained from whole blood have demonstrated the ability to differentiate active from inactive CD[27], as well as the ability to differentiate between CD, UC, and non-inflammatory diarrheal conditions[28].

The ability of a blood based biomarker to differentiate active from inactive disease states, as well as the ability to differentiate between CD, UC, and non-inflammatory conditions, holds great promise as a clinical tool in the evaluation of patients with suspected or known IBD. While mucosal biopsy and histologic evaluation remains a gold standard in the traditional evaluation of patients with IBD, the ability of a non-invasive, blood based test to differentiate disease states could indicate significant promise as a tool for monitoring IBD disease activity and predicting response to therapy.

Few studies have evaluated whole blood gene expression analysis as a biomarker and clinical tool in the evaluation of patients with UC and CD. One recent study utilized Affymetrix GeneChip technology to generate genome-wide expression profiles used in the prediction of disease activity in patients with UC and CD[8]. In this study, whole blood gene panels reliably distinguished UC and CD, in addition to determining the activity of disease with high sensitivity and specificity[8]. As previously noted, whole blood gene panels have previously demonstrated the ability to differentiate active CD from CD in remission[27], as well as UC from CD and non-inflammatory diarrhea[28]. One early study utilized transcriptional profiling of peripheral blood mononuclear cell RNA to distinguish UC from CD with high accuracy[29]. Another study used peripheral blood-derived mononuclear cells to evaluate mRNA expression levels among patients with IBD, rheumatoid arthritis, and psoriasis[30]. Using this technique, the authors were able to identify disease specific gene panels that could differentiate each disease type and could separate the disease state from healthy controls[30]. Other authors have used peripheral blood MicroRNAs (miRNAs) to distinguish active CD and UC from healthy controls[31]. Finally, in an evaluation of pediatric patients with IBD, patients in clinical remission had distinct gene expression profiles obtained from peripheral blood leukocytes when compared to healthy controls[32].

Gene expression profiling from mucosal biopsies has also been an area of increasing interest. One prior study utilized gene expression profiling from mucosal biopsies to differentiate between normal mucosa, adenoma, colorectal cancer and IBD[33]. Other studies have utilized gene expression profiles obtained from mucosal biopsies to differentiate patients with UC from controls[34], patients with IBD from infectious colitis[35], and patients with IBD from normal controls[36]. Arijs *et al*[37,38] have published data demonstrating the ability of mucosal gene expression profiles to predict response to infliximab in patients with UC and CD. While each of these studies is indicative of the significant promise for gene expression analysis as a clinical tool in predicting disease activity, response to therapy, and disease course in patients with IBD, the fact that they require mucosal biopsy for analysis makes the non-invasive option for gene expression analysis *via* whole blood potentially more attractive.

When evaluating specific patterns identified by gene expression profiling, trends along biological processes have been identified. In an evaluation of response to infliximab among patients with UC[37] using mucosal biopsies, patterns along several biological functions were identified including immune response, cell to cell signaling, cellular movement, cell death and tissue morphology and development. In addition, there was considerable overlap when the gene sets used in this study were compared to the gene sets identified in patients with the colitis subtype of CD[38]. When evaluating patterns identified by whole blood gene expression analysis, a similar trend around immune functions has been demonstrated. A four gene panel used to differentiate UC from CD included *CD300A* which potentially plays a role in modulating proinflammatory stimuli among neutrophils, as well as *IL1R2* which is involved in cytokine-cytokine receptor interactions[28]. In an evaluation of the ability of biomarkers to predict disease activity among patients with UC and CD, some of the genes that were identified within groups of patients with active disease had previously been associated with UC and CD[39]. These target genes included *NLRP12* (a member of the Nod-like receptor family) and *TAGAP*, which is one of 22 genes previously identified as downregulated at week 8 and week 30 among responders to infliximab in the Active Ulcerative Colitis Trial 1 (ACT 1)[39].

CONCLUSION

Given these recent successes, there remain many opportunities for further utilization of whole blood gene expression analysis to evaluate and treat patients with IBD. Current work is ongoing to evaluate the ability of whole blood gene expression analysis to predict response to biologic therapy for UC and CD. Additionally, given the initial success in differentiating UC from CD and other non-inflammatory diarrheal illnesses, further attention will be paid to the potential clinical utility of whole blood gene expression as a clinical biomarker used in the assessment of patients with IBD. Recent work has demonstrated the utility of whole blood gene expression analysis as a measure of effectiveness of

novel therapies such as leukocytopharesis for UC[40], and further studies will be necessary to evaluate the utility of gene expression biomarkers in monitoring clinical improvement in that population.

Despite the recent successes, some limitations of this expanding area of research must be identified. To date, the majority of the studies evaluating the use of whole blood gene expression analysis in the evaluation of patients with IBD have examined small populations. These small study populations may lead to evaluations of heterogenous patient groups, including patients with varying degrees of disease activity. This introduces heterogeneity into the ultimate population of cells used for the sample analysis, and thus larger studies are still necessary for further exploration. In addition, when target genes have been identified in IBD and other inflammatory conditions, difficulty in the evaluation of which genes represent underlying etiologies and which represent consequences of the disease remains[30].

Each of the significant developments outlined indicates the potential for this non-invasive serologic test to become an important blood based biomarker in the evaluation of patients with IBD. While we do not expect whole blood gene expression analysis to completely replace the traditional means of evaluating patients with suspected or known IBD, it does offer significant potential to expand our knowledge of the underlying genes involved in the development of these diseases. Perhaps most promising, whole blood gene expression analysis offers a non-invasive method of evaluation that may ultimately lead to personalized predictions of disease activity, disease course, and response to therapy.

Abstract

As endoscopic technology has developed and matured, the endoscopic resection of gastrointestinal tract polyps has become a widely used treatment. Colorectal polyps are the most common type of polyp, which are best managed by early resection before the polyp undergoes malignant transformation. Methods for treating colorectal tumors are numerous, including argon plasma coagulation, endoscopic mucosal resection, endoscopic submucosal dissection, and laparoscopic-endoscopic cooperative surgery. In this review, we will highlight several currently used clinical endoscopic resection methods and how they are selected based on the characteristics of the targeted tumor. Specifically, we will focus on laparoscopic-endoscopic cooperative surgery.

Key words: Colorectal tumor; Endoscopic resection

Core tip: The best case scenario for patients with lower digestive tract tumors is to detect and resect the tumor before it undergoes malignant transformation. However, modern technologies for tumor resection are numerous and there may be specific indications for the implementation of one technology over another. Therefore, we will discuss the current clinical endoscopic resection methods and the process for selecting specific interventions. We wish to highlight laparoscopic-endoscopic cooperative surgery, because it may be of assistance in endoscopic treatment and could remarkably decrease the rate of later surgical repair.

INTRODUCTION

Colorectal tumors are common in modern society and

although numerous new technologies have become available to locate, identify, and treat these tumors, early detection and removal (*e.g.,* during the polyp stage before malignant transformation) are still the key to long term survival and a favorable overall prognosis[1,2]. As a result, endoscopic methods have steadily developed to better meet these requirements. A study by Winawer *et al*[3] showed that endoscopic removal of colorectal adenomas can reduce the incidence rate of colorectal cancer by about 76%-90%. The current clinical endoscopic polypectomy methods are numerous and varied. Through careful observation of the distribution, size, morphology, and pathological features of colorectal polyps, clinicians/endoscopists can select the appropriate endoscopic resection treatment to avoid repeated unsuccessful procedures and improve the quality of life of the patient[2].

ENDOSCOPIC DIAGNOSIS BEFORE RESECTION

Before endoscopic resection, a comprehensive evaluation of the lesion is required. Ordinary endoscopy, magnifying endoscopy, or narrow-banding imaging (NBI) can be used to make a preliminary observation[4]. If the pathology confirms that the lesion is an adenoma, endoscopic resection can be performed. Pedunculated adenomas can be removed easily by endoscopic resection, regardless of the size of tumor; if the adenoma is sessile, the resection will be based on relevant patient parameters (age, body condition, and the patient's wishes)[5]. If pathological examination shows that the lesion is malignant, a "lifting sign" should be judged by injecting normal saline and indigo dye at the basal submucosal layer of the lesion. If the "lifting sign" is negative, the tumor has invaded and extended into the submucosa or even below[6]. Research has confirmed that for lesions confined to the mucosal layer, lymph node metastasis generally does not occur. Tumors that extend deeper into the submucosal layer can be divided into categories SM1-SM3. SM1 tumors (submucosal invasion < 1000 μm) have a low risk of lymph node metastasis, while the SM2 and SM3 tumors (submucosal invasion more than 1000 μm) have a higher lymphatic metastasis risk-up to 12.5%[7-9]. Tumors with a negative "lifting sign" should be surgically removed, rather than removed endoscopically.

ENDOSCOPIC RESECTION METHODS

Argon plasma coagulation

The principle of argon plasma coagulation (APC) is to use a specialized device to deliver ionization energy from argon; this high frequency energy can be implemented to solidify the tissue surface. Presently, APC plays an important role in maintaining hemostasis and cauterizing lesions during surgical and endoscopic procedures taking place in the human gastrointestinal tract[10]. The advantages of APC for treating colorectal lesions are that it is a rapid and efficient procedure that produces only a small vulnus and is generally well-tolerated by patients[11]. Some studies show that the most outstanding advantage of APC is its self-limited solidification depth. The damage of solidification generally does not extend more than 3 mm, minimizing the risk of perforation[12]. Based on the characteristics of the laser and the high frequency electric knife, APC can effectively be used to stop bleeding during a gastrointestinal procedure. Furthermore, during the operation, the probe does not need to contact the tissue, reducing the risk for adhesions or hemorrhages[13]. However, APC does have some limitations. Mainly, it is difficult to obtain pathological specimens with this technique, making it nearly impossible to determine the invasion depth, such that the cutting edge of the polyps is unclear.

Endoscopic mucosal resection

Endoscopic mucosal resection (EMR) has become a routine method for the treatment of early gastrointestinal mucosal lesions[14]. The general method of EMR is adapted to the submucosal injection of liquid saline to separate the lesions from the underlying muscle layer, after which lesions can be completely removed with a snare. The method is simple, safe, produces a small vulnus, is easily adaptable, and fairly easier to master, even for less experienced endoscopists[15,16]. However, there is the risk for rare and serious complications, such as intestinal perforation and bleeding, although these can be remedied by endoscopy or surgery. The incidence of perforation is very low (0.7%-1.3%), and the risk for bleeding is also fairly low (5.0%-8.1%)[17,18]. Some studies show that effective/optimized submucosal injection can help to prevent complications and ensure the safety of EMR[19]. Compared to APC, EMR has some advantages. Namely, EMR allows for pathological examination of the lesion after EMR to determine invasion depth and the cutting edge. However, due to the likelihood for electrocoagulation through snaring, EMR is only suitable for the complete resection of tumors with diameters that are less than 20 mm. Here, the complete resection rate is 64.3%-77.4%, and the recurrence rate is very low (0%-3.6%)[20,21]. If the tumor is larger than 20 mm, the complete resection rate drops significantly to 48.1%-32.9%, while the recurrence increases to 16%-25.7%[22,23]. Therefore, EMR is not an appropriate choice for the treatment of particularly large (greater than 20 mm) gastrointestinal tumors.

Endoscopic submucosal dissection

Endoscopic submucosal dissection (ESD) was developed based on EMR techniques and was named after it was approved as a new resection method in 2003. In this procedure, an insulation tipped knife (knife IT) is

instrumental for performing ESD. Compared to EMR, ESD can not only provide complete specimens for more reliable pathological examination, but it can also be used to fully resect the tumor with a low rate of recurrence[24]. For tumors less than 20 mm, the complete resection rate is 82.6%-97.7% and the recurrence rate is nearly 0%[21,25,26]. However, if the tumor is larger than 20 mm, the complete resection rate drops a little to 74%-91.8%, but the recurrence rate remains 0%-1%[17,22,23,25]. During the ESD procedure, the operator should pay attention to the "lifting sign" after submucosal injection, which can be used to determine the lesion depth. If the lesion is located in the mucous layer with a proper boundary to the muscularis propria and has a positive "lifting sign," it can be removed by ESD[27,28]. However, the rate of perforation in ESD is higher than that for EMR, because the submucosal layer is nearer to the muscularis. For this procedure, which is more complicated than EMR, the incidence of complications also correlates with the operator's technical proficiency[29]. Nonetheless, in some studies, the bleeding rate of ESD remains low (0.4%-2.5%), although the risk of perforation is slightly higher (2.9%-5.3%)[30,31].

Laparoscopic-endoscopic cooperative surgery

At present, endoscopic therapy is not only applied to resecting colorectal polyps, but also to the treatment of early colorectal cancers that are located in the mucosal layer. Through endoscopic resection, patients can avoid laparotomy, sustain lesser injury, and recover quickly[32]. However, the colonoscopy field of vision is limited in the intestinal lumen, such that the condition of the bowel wall or abdominal cavity is unclear. Some lesions located in the splenic or hepatic flexure can make endoscopic resection difficult. Laparoscopic-endoscopic cooperative surgery (LECS) takes advantage of characteristics of both laparoscopic and colonoscopic procedures. LECS is often implemented when the lesion is difficult to be removed or cannot be completely resected by endoscopic methods alone[33]. Under the guide of a colonscope, the laparoscope can look for and identify the intestinal site where the lesion is located and dissociate it from this site if necessary. By pulling and pushing the laparoscope upward, the lesion may be exposed so that endoscopists can use EMR or ESD to remove the lesion. During this process, the operator can focus on the complete excision of the lesion and does not need to be concerned with possibility of perforation. If perforation or bleeding occurs, laparoscopy can be used to repair the perforation and return to hemostasis immediately. However, no randomized controlled trials have been performed to evaluate LECS in the treatment of lower digestive tract tumors. Nonetheless, select published LECS cases suggest that it is a feasible procedure for the *en bloc* resection of some colonic lateral spreading tumors that would be otherwise difficult to resect using exclusively endoscopic methods[34-36].

CHOOSING THE ENDOSCOPIC TREATMENT

Tumors with a diameter less than 3 mm

For small tumors less than 3 mm in diameter, APC can be used for solidification of the lesion. However, as this technique cannot be used to collect pathological specimens, long-term endoscopic follow-up is required[37].

Tumors with a diameter less than 20 mm

For lesions in this size category, according to a study by Lee *et al*[26], there are no significant differences in the complete resection rate between EMR (82.6%) and ESD (64.3%) techniques. Although EMR has a recurrence rate of 3.6%, the risk of cancer progression for small tumors is minimal and the main pathological type for this size tumor is adenoma; therefore, EMR is suitable for the removal of small lesions and is a fairly easy technique to master, even for less experienced endoscopists. The risk of perforation with EMR is lower than that with ESD, and it is regarded as a quicker and safer choice for lesions with a relatively smooth surface without signs of bleeding and erosion[18,38]. However, there are some exceptions. If the endoscopic diagnosis (NBI or magnifying endoscope) strongly indicates that the lesion is malignant and the pathological examination shows the same results, the tumor must be excised by ESD and the patients should undergo close follow-up in the future.

Tumors with a diameter more than 20 mm

Some studies report that the proportion of adenocarcinomas significantly increases in tumors larger than 20 mm in diameter, since the degree of tumor malignancy is often associated with the relative tumor size[39]. Other studies report that the size of the tumor can be at least partly used as an index to predict the degree of malignancy. The possibility of recurrence for tumors greater than 10 mm diameter is relatively high[26]. Early adenocarcinomas have characteristics of invasion, recurrence, and metastasis, and due to a lower complete resection rate and high recurrence rate, EMR is not suitable for these kinds of tumors. Fortunately, ESD can be used to remove larger tumors with much higher complete resection rates and lower recurrence rates. However, ESD still has some limitations, especially for larger laterally spreading tumors. Here the excised area is often too large, translating to an extremely high risk of perforation[40]. Once a perforation occurs, a surgical repair or intestinal resection is needed to repair the large defect left by ESD. Therefore, LECS may be a better choice to ensure a complete resection, while minimizing the risk of serious complications. Based on the assistance of a laparoscope, the visibility of lesion is greatly enhanced and the operator can focus on the complete excision of the lesion while not worrying about the possibility of perforation, which can easily

and rapidly be repaired using the laparoscope to stitch the perforated area. Rapid detection and repair of any perforations greatly reduce the risk of abdominal infection. Therefore, in certain situations, LECS can not only be minimally invasive, but also offers better and safer therapeutic effects[41,42].

CONCLUSION

Endoscopic resection presents a great technological leap in the diagnosis and treatment of colorectal tumors, as well as an important preventive measure to remove polyps in their premalignant stages. In recent years, some new technologies, such as magnifying endoscopy and NBI have improved the detection rate of early colorectal cancers, which improves long term survival and the resulting quality of life. At the same time, with the continuous development of endoscopic treatment equipment and the introduction of new technologies, most colorectal polyps and early cancers can now be resected by minimally invasive EMR, ESD, or LECS techniques, which can now achieve the same effects as surgery. However, when endoscopic treatment is to be used, the indications should be carefully considered following evaluation of the relevant patient and pathological parameters, along with the likelihood of complete resection and risk for complications. Therefore, initial colonscopy examination is crucial. Although minimally invasive and often successful in full resection, endoscopic resections do have some limitations. If the cancer invades deep into the submucosal layer, belongs to the lower differentiation, or contains a lymphatic or venous tumor thrombus, additional radical surgical operation will still be required.

Abstract

AIM: To compare the short term outcome of endoscopic submucosal dissection (ESD) with that of laparoscopic colorectal resection (LC) for the treatment of early colorectal epithelial neoplasms that are not amenable to conventional endoscopic removal.

METHODS: This was a retrospective cohort study. The clinical data of all consecutive patients who underwent ESD for endoscopically assessed benign lesions that were larger than 2 cm in diameter from 2009 to 2013 were collected. These patients were compared with a cohort of controls who underwent LC from 2005 to 2013. Lesions that were proven to be malignant by initial endoscopic biopsies were excluded. Mid and lower rectal lesions were not included because total mesorectal excision, which bears a more complicated postoperative course, is not indicated for lesions without histological proof of malignancy. Both ESD and LC were performed by the same surgical unit with a standardized technique. The patients were managed according to a standard protocol, and they were closely monitored for complications after the procedures. All hospital records were reviewed, and the following data were compared between the ESD and LC groups: patient demographics, size and location of the lesions, procedure time, short-term clinical outcomes and pathology results.

RESULTS: From 2005 to 2013, 65 patients who underwent ESD and 55 patients who underwent LC were included in this study. The two groups were similar in terms of sex (P = 0.41) and American Society of Anesthesiologist class (P = 0.58), although patients in the ESD group were slightly older (68.6 ± 9.4 *vs* 64.6 ± 9.9, P = 0.03). ESD could be accomplished with a shorter procedure time (113 ± 66 min *vs* 153 ± 43 min, P < 0.01) for lesions of comparable size (3.0 ± 1.2 cm *vs* 3.4 ± 1.4 cm, P = 0.22) and location (colon/rectum:

59/6 *vs* colon/rectum: 52/3, $P = 0.43$). ESD appeared to be associated with a lower short-term complication rate, but the difference did not reach statistical significance (10.8% *vs* 23.6%, $P = 0.06$). In the LC arm, a total of 22 complications occurred in 13 patients. A total of 7 complications occurred in the ESD arm, including 5 perforations and 2 episodes of bleeding. All perforations were observed during the procedure and were successfully managed by endoscopic clipping without emergency surgical intervention. Patients in the ESD arm had a faster recovery than patients in the LC arm, which included shorter time to resume normal diet (2 d *vs* 4 d, $P = 0.01$) and a shorter hospital stay (3 d *vs* 6 d, $P < 0.01$).

CONCLUSION: ESD showed better short-term clinical outcomes in this study. Further prospective randomized studies will be required to evaluate the efficacy and superiority of colorectal ESD over LC.

Key words: Early colorectal neoplasia; Laparoscopic colectomy; Endoscopic submucosal dissection

Core tip: This is the first study that compares endoscopic submucosal dissection (ESD) *vs* laparoscopic colorectal resection (LC) for endoscopically benign lesions that could not be adequately removed by conventional polypectomy. Case inclusion was based purely on the pre-operative/pre-procedure endoscopic findings. Although the difference in morbidities did not reach statistical significance, the absolute number of complications and the number of patients involved were much higher in the LC arm. The current study provided evidence that surgeons are capable of performing high-quality colorectal ESD procedures. We expect that the participation of the surgeons as well as the close collaboration with gastroenterologists will play a pivotal role in the formulation of a management plan for patients with early colorectal neoplasms.

INTRODUCTION

Laparoscopic colorectal resection (LC) is currently a widely accepted treatment for colorectal neoplasms that are deemed not amenable to endoscopic removal[1-4]. However, LC carries an inherent complication rate of over 15%[1,2]. Therefore, one could argue that surgery may be too invasive or aggressive as a treatment for early colorectal neoplasms. The potential risks of laparoscopic resection may outweigh the estimated risk of lymph node metastasis if the neoplasms are not resected[5-7]. On the contrary, endoscopic piecemeal removal of large sessile or flat polyps by conventional polypectomy or by endoscopic mucosal resection (EMR), although it is less invasive, is known to be associated with a high local recurrence rate of 14%-19.5%[8,9]. Endoscopic submucosal dissection (ESD) is a novel technique that was originally developed in Japan more than 10 years ago. ESD was developed to achieve an *en bloc* mucosal resection with wider margins[10-13]. Currently, an increased number of endoscopists throughout the world have acquired this skill and have published promising outcomes of ESD[14-19]. The recent retrospective analysis reported by Kiriyama *et al*[20] that compared ESD for colorectal intramucosal or slightly submucosal invasive cancers *vs* LC for T1 cancer demonstrated a lower complication rate in the ESD group. Another similar prospective study also compared ESD for adenoma or T1 cancer with less than SM-s (superficial submucosal invasion) *vs* LC for SM-d (deep submucosal invasion)[21]. Until now, no worldwide consensus has been adopted as to whether the treatment of benign colorectal neoplasms with advanced endoscopic techniques (*i.e.*, ESD) is superior to surgical approaches[22]. From the very beginning of the development of colorectal ESD, the procedure was performed primarily by gastroenterologists. No published data exists on the comparison of the clinical outcomes of ESD *vs* those of LC when both procedures were performed by the same group of surgeons. Surgeons who can perform both procedures may be in an advantageous position in that they can balance the risks and benefits of the endoscopic approach *vs* the surgical approach. Therefore, we performed a retrospective cohort study that aimed to compare ESD *vs* LC for endoscopically benign lesions that could not be adequately removed by conventional polypectomy. This is the first comparative study of a similar topic, and this is also the first series where both procedures were performed by the same group of surgeons.

MATERIALS AND METHODS

This was a retrospective cohort study conducted at Prince of Wales Hospital at, The Chinese University of Hong Kong. Since 2005, LC has been the gold standard surgical treatment for all colorectal lesions that are not amenable to endoscopic removal. Colorectal ESD was first established at our centre in 2008, and since that time, it has enriched the armamentarium of endoscopic interventions. Consecutive patients who underwent ESD or LC for early colorectal neoplasms (endoscopically benign lesions larger than 2 cm in diameter) from 2005 to 2013 were included.

Lesions were excluded when endoscopic signs of massive submucosal invasion were present as evidenced by the existence of excavated/depressed morphology or

Kudo's pit pattern type Ⅴ. Lesions proven to be malignant by initial endoscopic biopsies were also excluded. Mid and lower rectal lesions were not included because total mesorectal excision, which intrinsically bears a more complicated post-operative course and has a negative impact on gastrointestinal function, would not be offered to patients who were diagnosed with benign lesions by endoscopy. Nevertheless, the input of the patients would also influence the selection between ESD and LC because ESD was a relatively new procedure at that time.

Patients were instructed to eat a low residue diet two days before ESD or laparoscopic colectomy. They received four litres of polyethylene glycol solution as a mechanical bowel preparation on the day of ESD or one day before LC. Both ESD and LC were performed by surgeons who were capable of executing these procedures independently.

All hospital records were reviewed, and the following data were compared between the ESD and LC groups: patient demographics, size and location of the lesions, procedure time, short-term clinical outcomes and pathology result.

The ESD procedure and postoperative care

Our techniques for colorectal ESD have been previously reported[23]. In short, all ESDs were performed when the patients were under conscious sedation after intravenous administration of midazolam and pethidine. Intravenous Buscopan was used if significant colonic spasms were encountered during the ESD procedure. All procedures were performed with a water-jet gastroscope or with a paediatric colonoscope with a transparent cap attached to the tip. Carbon dioxide insufflation was routinely used to reduce patient discomfort. The margins of the lesions were determined by either dye (0.4% indigo carmine spray) or digital (narrow band imaging) chromoendoscopy. Submucosal cushions were created by a mixture of normal saline, adrenaline, indigo-carmine and sodium hyaluronate. Circumferential mucosal incision and submucosal dissection were performed by dual knife or insulated tip knife (Olympus Medical System, Tokyo, Japan), depending on the location of the lesion and the preference of the endoscopists. Haemostasis after ESD was achieved by Coagrasper (Olympus Co. Ltd., Tokyo, Japan).

When perforations were encountered during the ESD procedure, they were immediately closed by endoscopic clips; otherwise, salvage surgery was arranged. For optimal procedures without significant bleeding, a diet would be resumed on the following day. Stable patients who managed to tolerate a full diet were discharged. For those patients with perforations that were managed by endoscopic clipping, they were kept nil per oral and monitored closely for signs of sepsis including fever, tachycardia, leukocytosis and peritonism. Depending on the clinical parameters, parenteral antibiotics were given and diet was gradually introduced. Salvage surgery was offered in cases of persistent or deteriorating sepsis.

All patients were encouraged to maintain mobility, and a diet was introduced gradually as tolerated. Patients were discharged when they could tolerate a full diet without signs of sepsis and the absence of rectal bleeding.

The LC procedure and postoperative care

All LCs were performed under general anaesthesia by the same group of colorectal surgeons, as described in our previous study[24]. In short, the colon or rectum was mobilized laparoscopically from the lateral to the medial area. The isolated lymphovascular pedicles were then transected with either laparoscopic linear staplers or with self-locking plastic clips. One of the working ports was later extended for specimen retrieval. Extracorporeal anastomosis was fashioned for a right-sided resection, while intracorporeal stapled anastomosis was performed for a left-sided resection.

After surgery, the patients were allowed to ingest oral fluid on day one. Diet was resumed gradually during the days following the surgery and depended on the progression of the patients. All patients received regular physiotherapy and were mobilized as soon as possible after surgery. Pain control was achieved by either regular analgesics or by patient-controlled analgesia. Ambulatory patients were discharged if they could tolerate a full diet with no signs of sepsis.

Histological assessment

All ESD specimens were mounted on a foam board for pathological examination by a designated pathologist. Deep and peripheral margins, cellular differentiation as well as the depth of submucosal invasion were recorded. R0 resection was defined as a complete *en bloc* resection with deep and circumferential margins that were free of adenomatous proliferation or dysplasia. Colectomy specimens were evaluated after fixation in 10% formalin and after staining with haematoxylin and eosin. Macroscopic and microscopic examinations for histological type, depth of invasion, lymph node status and resection margins were performed. Malignant lesions were classified according to the AJCC Cancer Staging Manual, 7th Edition (2010)[25].

Outcomes measurement

In regards to the short-term clinical outcomes, we studied the procedure time, the time to resume diet, the time to full ambulation, the duration of the total hospital stay and the complication rate.

Lesions that were located in the colon and at the rectosigmoid junction were defined as "colon", while lesions in the upper rectum were defined as "rectum".

Complications were defined as any event that required re-intervention, re-operation, re-admission or a prolonged hospital stay (namely, Clavien-Dindo Grade Ⅱ or above). Bleeding from the ESD procedure was defined as any bleeding episodes after ESD that warranted

Table 1 Demographic background

	Lap colectomy	ESD	*P* value
Number of patients	55	65	
Age (yr), mean ± SD	64.6 ± 9.9	68.6 ± 9.4	0.03
Sex	Female: 27 Male: 28	Female: 27 Male: 38	0.41
ASA	< 3 *vs* ≥ 3 : 43 *vs* 12	< 3 *vs* ≥ 3 : 48 *vs* 17	0.58
Size of lesion (cm), mean ± SD	3.4 ± 1.4	3.0 ± 1.2	0.07
Location of lesion	Colon: 52 Rectum: 3	Colon: 59 Rectum: 6	0.43

ASA: American Society of Anaesthesiology; ESD: Endoscopic submucosal dissection.

Table 2 Comparisons of the short-term outcome

	Lap colectomy	ESD	*P* value
OT/procedure time (min), mean ± SD	153 ± 43	113 ± 66	0.000
Post-op stay (d), median (range)	6 (3-41)	3 (1-13)	0.000
Days to diet, median (range)	4 (1-13)	2 (0-5)	0.000
Short-term complications	13/55 (23.6%)	7/65 (10.8%)	0.06
Pathology	Benign: 39 T1: 16	Benign: 56 T1: 9	0.04

ESD: Endoscopic submucosal dissection; OT: Operation time.

re-intervention, readmission, or a blood transfusion. ESD-related perforations were either detected during the procedure or were diagnosed radiologically by the presence of intra-peritoneal free gas.

Statistical analysis

Categorical data were analysed using χ^2 or Fisher's exact test, while continuous variables were analysed by *t* test, as appropriate. *P* values < 0.05 were considered statistically significant. All calculations were conducted with SPSS statistical software package (SPSS version 15.0, Chicago, IL, USA). Data analysis was based on the intention to treat principle.

RESULTS

From 2005 to 2013, 55 patients who underwent LC and 65 patients who underwent ESD were included in this study. The mean age of the patients in the ESD group was slightly higher than that of the patients in the LC group. The two groups shared comparable sex and ASA class distributions (Table 1).

No statistically significant differences were observed in terms of lesion size or location, yet ESD could be accomplished with a significantly shorter procedure time (113 ± 66 min *vs* 153 ± 43 min, *P* < 0.01) and a faster recovery course, as illustrated by earlier resumption of a full diet (2 d *vs* 4 d, *P* = 0.01) and a shorter hospital stay (3 d *vs* 6 d, *P* < 0.01) (Table 2).

The overall short-term complication rate for ESD and LC was 10.8% and 23.6%, respectively. Although we could not demonstrate a significant difference between the two groups (*P* = 0.06), the ESD group exhibited a trend towards a lower short-term complication rate. In the LC arm, a total of 22 complications occurred in 13 patients (Table 3). These included 1 anastomotic leak, which necessitated a laparotomy and stoma formation, 1 mechanical small bowel obstruction, which required re-operation, 6 wound infections, 1 chest infection, 4 urinary tract infections, 1 acute urine retention, 6 cases of prolonged ileus, 1 deep vein thrombosis and 1 mental confusion. A total of 7 complications occurred in the ESD arm, including 5 perforations and 2 bleeding episodes. The remainder of the patients in the ESD arm experienced a smooth intra- and post-procedure course without complications. All of the perforations were observed during the procedure and were successfully managed by endoscopic clipping. Therefore, no emergency surgical intervention was needed. One of the bleeding episodes was successfully stopped during the procedure, and blood transfusion was required. Unfortunately, the other incident was encountered during the removal of a caecal lateral spreading tumour (LST). As a result of malfunction in the water-jet, a clear endoscopic view could not be achieved for safe haemostasis and dissection. Hence, the procedure was abandoned and was followed by emergency LC. The patient was discharged home 4 d after surgery. No delayed perforation, bleeding or other post-procedure complications were recorded in the ESD arm (Table 4).

En bloc resection was achieved in 81.5% (53/65) of the ESD procedures. For the remaining 12 lesions, 6 were completely removed by piecemeal EMR. Endoscopic removal had to be abandoned for the other six lesions due to instrumental failure in one case and the presence of dense adhesions in five cases. Amongst the 5 lesions that harboured these dense adhesions, 3 were confirmed T1 adenocarcinomas.

In this study, histological analysis revealed the presence of T1 adenocarcinomas in 25 lesions (LC: 16 and ESD: 9). The proportion of invasive neoplasms was significantly higher in the LC arm (29.1% *vs* 15.3%, *P* = 0.04. *En bloc* ESD resection was successfully achieved in 4 of 9 malignant lesions, and all four of these patients were subsequently managed according to the level of submucosal (sm) invasion and other associated histological features. Although salvage surgery was offered to the two patients with sm2 lesions, they both rejected this procedure. On the contrary, one patient with an sm3 lesion agreed to undergo LC, and the pathology of the resected specimen showed no residual primary tumour; however, one metastatic lymph node was identified. The remaining patient with an sm1 lesion was put under close surveillance in light of an adequate resection margin and the absence of lymphovascular permeation. ESD was abandoned in 3 of 9 malignant lesions due to dense submucosal adhesion, of which 2 were salvaged by LC and 1 by TEO (transanal endoscopic operation).

Table 3 Complications of laparoscopic colectomy (22 events in 13 patients)

	Number of complications	Surgical intervention required
Anastomotic leak	1	1
Mechanical small bowel obstruction	1	1
Wound infection	6	0
Chest infection	1	0
Urinary tract infection	4	0
Urinary retention	1	0
Ileus	6	0
Deep vein thrombosis	1	0
Confusion	1	0

Table 4 Performance indicators of endoscopic submucosal dissection

	n	(%)
En bloc resection	53	81.5
R0 resection	47	72.3
Perforation	5	7.7
bleeding	2	3.1

No other complication apart from perforation and bleeding were observed.

Piecemeal resection was performed in the other 2 of 9 lesions, of which one refused salvage surgery and the other one accepted salvage LC.

DISCUSSION

Since the development of colorectal ESD, its feasibility, safety and oncological outcome have been reported in numerous contemporary studies[14-20]. Currently, nearly 3000 colorectal ESDs are performed each year in Japan[26]. The Japanese healthcare insurance system has also approved a reimbursement scheme for colorectal ESD[26]. On the contrary, the adoption rate of ESD is variable in the rest of the world, especially among surgical societies. To explain this, two potential hurdles have been identified. First, the technique of LC had already been widely practised and supported by a high level of evidence at the time when colorectal ESD was introduced outside of Japan. Second, the volume of cases did not justify a large number of endoscopists having to learn and master the technique of ESD. Moreover, current literature that directly compares LC *vs* ESD for early colonic neoplasms is not available. Two recent studies compared ESD for mucosal or slight submucosal invasive lesions *vs* LC for T1/deep submucosal invasive lesions[20,21], but the pathological nature of the two comparative groups was different.

This is a retrospective cohort study that compared ESD *vs* LC for endoscopically confirmed benign lesions that could not be adequately removed by conventional polypectomy. Case inclusion was based purely on the pre-operative/pre-procedure endoscopic findings, and no crossover of abandoned ESD to LC occurred. The results of this study suggested that ESD was superior to LC with respect to short-term outcomes and that ESD leads to a faster recovery. Despite the fact that perforation and bleeding did occur in the ESD arm, all but one of these events could be managed endoscopically. The post-operative course of the only patient who underwent salvage surgery for complications was also uneventful. Although the difference in morbidities did not reach statistical significance, the absolute number of complications and the number of patients involved are much higher in the LC arm.

Moreover, all ESD procedures were performed when the patients were under conscious sedation without general anaesthesia. This definitely avoided the risks of general anaesthesia and post-operative wound pain. Almost immediate mobilization was feasible once the sedative effect subsided. Therefore, we believe that ESD might be more reasonable and acceptable for patients with early colorectal neoplasia or LSTs.

The ESD perforation rate in this study was 7.7%, which was comparable with quoted figures in the literature. In a recent meta-analysis, the highest reported perforation rate was 12%[18], and most of the reported rates in published series were well below 10%[27]. Although these perforation rates might be considered higher than those at some of the high-volume Japanese centres[14,28,29], they were comparable with large series that have been conducted outside of Japan[30,31]. This cohort study only reflected the early phase of our learning curve, and we expect a further reduction in morbidity in the future. Due to the increasing popularity of screening colonoscopy and image-enhanced endoscopy, a greater number of early colorectal lesions might be detected. Therefore, we expect a higher ESD throughput and an improved performance at our centre.

In reality, whether an endoscopically assessed benign lesion is subjected to ESD or colectomy depends to a large extent on who detects the lesion. For instance, if a gastroenterologist who is capable of performing ESD detects an LST, then an ESD procedure might be attempted. Likewise, if the same lesion is detected by a surgeon who does not possess the skills to perform ESD, then colectomy would be offered instead. In our locality, it is rather unique that surgeons actively participate in advanced diagnostic and therapeutic endoscopies. At our centre, we have a group of surgeons who have acquired the skills to perform both LC and colorectal ESD, and who can confidently counsel patients and offer them both options (ESD *vs* LC). One can also comprehensively balance the risks and benefits between conservative management *vs* salvage surgery for histologically confirmed malignant lesions that are removed by ESD. The current study provided evidence that surgeons are capable of performing high-quality colorectal ESD. We expect that the participation of the surgeons as well as the close collaboration with gastroenterologists will pay a pivotal role in the formulation of a management plan for

patients with early colorectal neoplasms.

The major limitation of the current study was its retrospective nature that extended through a period of eight years, during which time major advances in both laparoscopic and endoscopic technology occurred. Most of the LC cases were recruited prior to the availability of image-enhanced endoscopy (2005-2008), when endoscopic diagnoses were less accurate. This explained why patients in the LC arm had more malignant lesions, which was also a major bias of the current study. During the past few years, we have introduced enhanced recovery protocols in our unit, and thus the same LC group may experience a faster recovery and potentially fewer morbidities. To address these biases, a randomized controlled trial is necessary to provide a higher level of evidence to compare these two intervention modalities. We are currently awaiting the results of our randomized controlled trial.

In conclusion, by a comparison of LC and ESD performed by the same group of surgeons for the treatment of early colorectal neoplasms, ESD produced better short-term clinical outcomes with respect to a shorter procedure time and an earlier recovery. Therefore, ESD may be superior to LC for the treatment of this specific type of colorectal lesion.

COMMENTS

Background

Before the development of colonic endoscopic submucosal dissection (ESD), colorectal lesions that were not deemed to be suitable for conventional endoscopic removal were classically treated by colorectal resection. Currently, although minimally invasive surgery can often be performed, the risks associated with surgery should be considered especially for the treatment of benign lesions. While colorectal ESD has become popular in Japan, its adoption rate and its performance quality are still variable in all other areas of the world. It is unknown whether ESD leads to a better short-term outcome for the treatment of early colorectal epithelial neoplasms.

Research frontiers

Results from this study may help surgeons to appreciate the potential benefits of ESD, which has not yet been widely adopted by surgical societies outside of Japan for the treatment of early colorectal epithelial neoplasms.

Innovations and breakthroughs

To date, no worldwide consensus has been adopted as to whether the treatment of benign colorectal neoplasms with ESD is superior to the use of colorectal resection. Moreover, there is no published data on the clinical outcomes of ESD *vs* laparoscopic colorectal resection (LC), where both procedures were performed by the same group of clinicians. In this retrospective study, the authors compared the short-term outcomes between ESD and LC and focused on the immediate recovery course and the complications.

Applications

This retrospective cohort study suggested that ESD produced better short-term clinical outcomes. The results from future randomized controlled trials would be expected to provide a higher level of evidence in regards to the potential superiority of ESD.

Terminology

In this study, early colorectal epithelial neoplasms referred to lesions without endoscopic signs of massive submucosal invasion, as evidenced by the absence of an excavated/depressed morphology or Kudo's pit pattern type Ⅴ.

Peer-review

The authors evaluated one hundred and twenty patients (ESD: 65, LC: 55) who underwent treatment for early colorectal epithelial neoplasms. ESD could be accomplished in a shorter time, and patients experienced a faster recovery. Although the difference in the occurrence of morbidities did not reach statistical significance, the absolute number of complications and the number of patients involved were much higher in the LC arm. Therefore, the option of ESD should be seriously considered in the contemporary management of early colorectal epithelial neoplasms.

Abstract

AIM: To investigate the feasibility of cold snare polypectomy (CSP) in Japan.

METHODS: The outcomes of 234 non-pedunculated polyps smaller than 10 mm in 61 patients who underwent CSP in a Japanese referral center were retrospectively analyzed. The cold snare polypectomies were performed by nine endoscopists with no prior experience in CSP using an electrosurgical snare without electrocautery.

RESULTS: CSPs were completed for 232 of the 234 polyps. Two (0.9%) polyps could not be removed without electrocautery. Immediate postpolypectomy bleeding requiring endoscopic hemostasis occurred in eight lesions (3.4%; 95%CI: 1.1%-5.8%), but all were easily managed. The incidence of immediate bleeding after CSP for small polyps (6-9 mm) was significantly higher than that of diminutive polyps (≤ 5 mm; 15% *vs* 1%, respectively). Three (5%) patients complained of minor bleeding after the procedure but required no intervention. The incidence of delayed bleeding requiring

endoscopic intervention was 0.0% (95%CI: 0.0%-1.7%). In total, 12% of the resected lesions could not be retrieved for pathological examination. Tumor involvement in the lateral margin could not be histologically assessed in 70 (40%) lesions.

CONCLUSION: CSP is feasible in Japan. However, immediate bleeding, retrieval failure and uncertain assessment of the lateral tumor margin should not be underestimated. Careful endoscopic diagnosis before and evaluation of the tumor residue after CSP are recommended when implementing CSP in Japan.

Key words: Colonoscopy; Endoscopic gastrointestinal surgery; Colorectal neoplasm; Polypectomy; Cold snare polypectomy

Core tip: Cold snare polypectomy (CSP) was completed for 232 of the 234 polyps. Immediate postpolypectomy bleeding requiring endoscopic hemostasis occurred in eight lesions (3.4%), but all were easily managed. The incidence of immediate bleeding after CSP for small polyps (6-9 mm) was significantly higher than that for diminutive polyps (≤ 5 mm; 15% *vs* 1%, respectively). Three (5%) patients complained of minor bleeding after the procedure but required no intervention. In total, 12% of the resected lesions could not be retrieved for pathological examination. Tumor involvement in the lateral margin could not be histologically assessed in 70 (40%) lesions.

INTRODUCTION

Colorectal cancer is one of the most common causes of cancer-related death worldwide[1]. The adenoma-carcinoma sequence is thought to be the main route of colorectal cancer development[2], and the removal of colorectal adenomas is known to reduce the risk of subsequent colorectal cancer development and colorectal cancer death[3,4]. Endoscopic removal of all detected adenomas during colonoscopy screening is the standard strategy for the prevention of colorectal cancer, although more than 90% of the polyps are less than 10 mm in size, and most will never develop into cancer during the lifetime of the patient[5]. However, in this context, it is important to note that endoscopic resection is associated with potential complications that include bleeding and perforation[6-8]. Thus, endoscopists should always consider the most likely natural history of the lesion and balance those considerations against the risks associated with endoscopic resection[5]. Indeed, Japanese guidelines do not recommend the removal of diminutive (≤ 5 mm) colorectal polyps[9], and most Japanese endoscopists follow up diminutive colorectal polyps that are not endoscopically removed based on their experience[10].

Several techniques are available for the removal of diminutive or small (6-9 mm) (subcentimetric) polyps, although the optimal method remains unclear, and the method selection is often based on expert opinion. One approach that is used in Western countries for the removal of subcentimetric polyps is cold polypectomy, *i.e.*, removal without electrocautery. This approach seems to minimize the risks of complications when removing subcentimetric lesions[11]. Two different cold polypectomy techniques are available. Cold forceps polypectomy (CFP) is a simple and easy procedure using endoscopic forceps without electrocautery[12]. The second technique is cold snare polypectomy (CSP), which uses snare resection without electrocautery and has been reported to be a safe method for the removal of subcentimetric polyps[13]. Although CSP appears to be a promising procedure for endoscopic removal of subcentimetric colorectal polyps, CSP is not yet widely used in Japan because of the lack of sufficient data about this procedure. Therefore, the purpose of the present study was to examine the feasibility of the use of CSP in a Japanese center.

MATERIALS AND METHODS

Study design

This retrospective study was performed at the endoscopy unit of the Osaka Medical Center for Cancer and Cardiovascular Diseases. The study protocol was approved by the center's local ethics committee. Patients with colorectal polyps larger than 5 mm who were recommended to undergo polypectomy and all polyps detected during screening colonoscopies were included in the study. All consecutive patients who underwent colorectal CSP for a subcentimetric polyp between November 2012 and March 2013 were included in a prospectively maintained database. CSP was not performed in patients who were undergoing anticoagulant and antiplatelet therapy. Additionally, CSP was not performed for lesions with suspected intramucosal or invasive carcinomas based on endoscopic assessments. Written informed consent was obtained from all patients upon inclusion.

Procedures

All procedures were performed by nine experienced colonoscopists who had each conducted more than 100 colorectal polypectomies. None of the colonoscopists had performed CSP prior to this trial. A standard type colonoscope (EVIS CF-240I or CF-260DI; Olympus

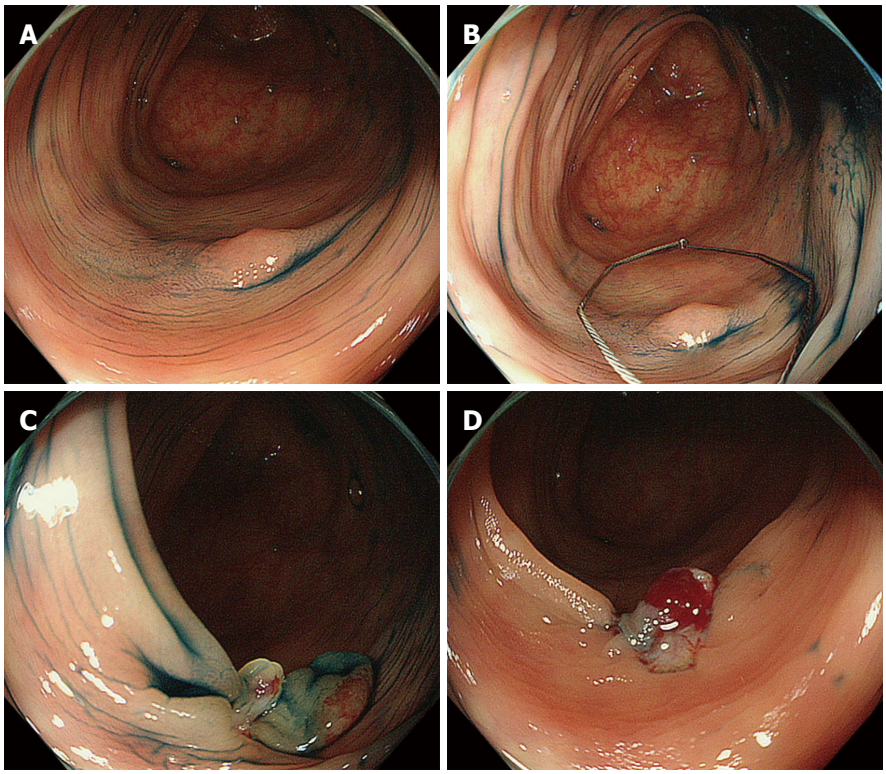

Figure 1 Actual cold snare polypectomy procedure. A: A 5-mm flat adenoma located in the sigmoid colon; B: The electrosurgical snare is opened and pressed against the colonic wall; C: The lesion and surrounding normal non-neoplastic mucosa are grasped and cut without electrocautery; D: Mucosal defect after cold snare polypectomy. Oozing immediately occurred after the procedure but stopped within a few minutes.

Medical Systems, Co., Ltd., Tokyo, Japan) or a high-definition magnifying colonoscope (CF-FH260AZI or CF-H260AZI; Olympus) with a light source (EVIS CLV-260SL; Olympus) and video processor (EVIS LUCERA CV-260SL; Olympus) were used for all patients. A transparent hood (D-201 series; Olympus) was attached to the tip of the colonoscope[14]. All patients were prepared the day before colonoscopy with a low fiber diet and preparatory medicines. Bowel preparation and sedation were administered as previously described in detail[15]. The colonoscope was first inserted into the cecum using the conventional white light mode. In cases of incomplete total colonoscopy (*e.g.*, stenosis with advanced colorectal cancer, pain or discomfort or difficult insertion caused by looping), any detected lesions were recorded and removed within the range of observation. The location, size, and macroscopic type of all of the lesions were documented according to the Paris classification[16,17]. The size was determined using biopsy forceps with a 2.2-mm outer diameter (Radial Jaw 3; Boston Scientific, Natick, MA, United States) or a 13-mm small hexagonal electrosurgical snare (Captivator; Boston Scientific). Magnifying endoscopy was performed to predict the tumor histology when available. CSP was performed using an electrosurgical snare (Captivator; Boston Scientific) without electrocautery (Figure 1, videos). The polyp was snared including normal surrounding mucosa to maintain a non-neoplastic mucosal margin around the lesion. Blood oozing was usually observed immediately after CSP. In the first 10 cases, we observed the resection sites until the oozing stopped. After these 10 cases, oozing wounds were left behind, and endoscopic hemostasis was only performed when spurting or massive bleeding occurred. If the polyps were unresectable with CSP, electrocautery was used for their removal. The removed lesions were suctioned and retrieved after CSP. The retrieved specimens were immersed in 20% formalin without pinning on a plate and examined using standard hematoxylin and eosin staining. Two experienced histopathologists who were blinded to the endoscopic findings evaluated all of the specimens according to the Japanese classification of colorectal carcinomas[18].

Statistical analysis

The procedural details were prospectively recorded in a database, and the medical records were thoroughly investigated. The collected data included patient age, gender, polyp location (*i.e.*, cecum, ascending colon, transverse colon, descending colon, sigmoid colon, or rectum), polyp size, endoscopist (expert or senior resident), morphological type (*i.e.*, protruded/sessile or superficial/elevated), histological diagnosis, incidence of immediate postpolypectomy bleeding requiring endoscopic hemostasis, incidence of delayed bleeding (clinically evident after examination) and any abdominal symptoms. Endoscopic hemostasis was usually performed for delayed postpolpectomy bleeding

Table 1 Baseline data of the participants (n = 61)

Male/female (%)	44 (72%)/17 (28%)
Median age	65
(range, yr)	(40-86)
Total detected lesion	234
Median detected lesion per patient (range)	3 (1-16)
Location	
Cecum	19 (8%)
Ascending colon	61 (26%)

Protruded, sessile	205 (88%)
Superficial, elevated	29 (12%)
Median detected polyp size	4
(range, mm)	(1-9)
Endoscopist	
Expert	79 (34%)
Senior resident	155 (66%)
Histological type	
Not retrieved	28 (12%)
Non-neoplastic polyp	28 (12%)
Neoplastic polyp	176 (76%)
Horizontal margin (neoplastic lesion only)	
HM 0	104 (59%)
HM 1	2 (1%)
HM X	70 (40%)

HM X: Tumor involvement of the lateral margin could not be assessed; HM 0: No tumor identified at the lateral margin; HM 1: Tumor identified at the lateral margin.

when patients experienced repetitive bloody bowel discharges or became hemodynamically unstable. The study investigators assessed the symptoms in the outpatient department during follow-up appointments. Because this was a pilot feasibility study, the sample size was not estimated. The results related to non-parametric data are reported as the medians (ranges) and were compared by Wilcoxon test. The incidence (%) was used for the categorical variables, which were compared using the Yates' χ^2 test. The data analyses were conducted using the statistical package JMP 10 (SAS Institute, Cary, NC, United States).

RESULTS

Baseline data

Two-hundred patients underwent colorectal endoscopic resection (including conventional polypectomy, endoscopic mucosal resection, and endoscopic submucosal dissection) between November 2012 and March 2013. CSP was attempted in 61 patients in this study. The baseline data of the participants are shown in Table 1. The median age (range) of the patients was 65 (40-86) years. The patients comprised 44 (72%) men and 17 (28%) women. In total, 234 subcentimetric lesions were detected during colonoscopy screening. The median and maximum numbers of polyps detected per patient were 3 and 16, respectively. Thirteen (21%) patients presented with only one subcentimetric polyp, and 48 (79%) patients presented with at least two subcentimetric lesions. Two hundred five (88%) of the lesions were protruded/sessile (0-Ⅰs), and 29 (12%) were superficial/elevated (0-Ⅱa). The median (range) size of the polyps was 4 (1-9) mm. Among these lesions, 186 (80%) were diminutive (≤ 5 mm), and 48 (20%) were small (6-9 mm). One hundred and thirty-six (58%) polyps were located proximal to the splenic flexure, and 98 (42%) were situated distal to the splenic flexure. In total, 79 (34%) CSP procedures were performed by four experts, and 155 (66%) were performed by five senior residents.

Procedures for and outcomes of CSP

CSP was attempted for 234 subcentimetric polyps in 61 patients. Two (0.9%) polyps could not be resected without electrocautery and were thus removed by conventional polypectomy with electrocautery. One of these was a 2-mm protruded type inflammatory polyp that was located near a scar from a previous polypectomy in the transverse colon. The other polyp was an 8-mm protruded type adenoma located in the rectum. Thus, CSP was completed for 232 polyps in 61 patients. Immediate postpolypectomy bleeding requiring endoscopic hemostasis occurred in eight lesions (3.4%; 95%CI: 1.1%-5.8%). Although no differences were observed in sex, age, location, morphology, endoscopist or histological type between the lesions with and without immediate bleeding, the median lesion size with immediate bleeding was larger than that of the lesions without immediate bleeding (7.5 mm *vs* 4.0 mm, respectively, P = 0.002), and the incidence of immediate bleeding after CSP was greater for the small than the diminutive polyps (15% *vs* 1%, respectively, P = 0.001) (Table 2). All eight cases of immediate postpolypectomy bleeding were easily managed by endoscopic clipping alone. All patients who underwent CSP visited our outpatient department 7-35 d (median, 14 d) after the procedures. Three (5%) patients complained of minor bleeding after the procedure that stopped without any intervention. Therefore, the incidence of delayed bleeding requiring endoscopic intervention after CSP without prophylactic clipping was 0.0% (95%CI: 0.0%-1.7%). No other complications, such as perforation or postpolypectomy syndrome, were observed. Twenty-eight (12%) of the 232 lesions could not be retrieved after resection for pathological analysis. The remaining 204 (88%) polyps underwent histopathological assessments that revealed 176 (76%) neoplastic polyps (163 low-grade adenomas, 1 tubulovillous adenoma, 4 high-grade adenomas, 5 sessile serrated adenomas/polyps and three serrated adenomas) and 28 (12%) non-neoplastic lesions. The horizontal margins (HMs) of the neoplastic lesions that were removed by CSP underwent pathological assessments. One hundred four (59%) lesions were classified as HM 0 (*i.e.*, no tumor identified at the lateral margin),

Table 2 Procedure-related outcomes

	Immediate bleeding (n = 8)	Non-immediate bleeding (n = 224)	P-value
Male/female	8/0	146/78	0.10[a]
Median age	64.5	68	0.27[b]
(range, years)	(50-76)	(40-86)	
Location			0.40[a]
Proximal to splenic flexure	3 (38%)	132 (59%)	
Distal from splenic flexure	5 (62%)	92 (41%)	
Morphology			0.59[a]
Protruded, sessile (0-Is or Isp)	7 (88%)	196 (88%)	
Flat, elevated (0-IIa)	1 (12%)	28 (12%)	
Median size	7.5 (3-9)	4 (1-9)	0.002[b]
(range, mm)			
≤ 5 mm (%)	2 (22%)	183 (82%)	0.001[a]
> 6 mm (%)	6 (78%)	41 (18%)	
Endoscopist			0.54[a]
Expert	4 (50%)	74 (33%)	
Senior resident	4 (50%)	150 (67%)	
Histological type			
Not retrieved	0 (0%)	28 (12.5%)	
Non-neoplastic polyp	0 (0%)	28 (12.5%)	0.53[a]
Neoplastic polyp	8 (100%)	168 (75%)	

[a]Yates' χ^2 test; [b]Wilcoxon test.

2 (1%) were classified as HM 1 (*i.e.*, tumor identified at the lateral margin), and 70 (40%) were classified as HM X (*i.e.*, tumor involvement at the lateral margin could not be assessed).

DISCUSSION

Although CSP has been reported to minimize the risk of complications when removing subcentimetric polyps in Western countries[19,20], this technique has not yet been widely implemented in Japan. The present study represents one of the largest patient samples regarding CSP from any Japanese institution to date[21-23]. Our results indicate that CSP is a safe and effective method for resecting small colorectal lesions and suggest that CSP is also a feasible method for the removal of subcentimetric polyps in Japan.

Herein, we observed that the incidence of immediate bleeding requiring endoscopic treatment after CSP was 3.4%, which is somewhat higher than that reported in the prospective multicenter study conducted by Repici *et al*[11] (1.8%). However, only 37% of the procedures were CSPs, and the others were CFPs in the study by Repici *et al*[11]. Thus, the incidence of immediate bleeding after CSP might be different from that after CFP. In this context, it should also be mentioned that none of participating endoscopists herein had performed CSP prior to this study, and some of them might have been cautious about oozing that occurred after CSP and unnecessarily used endoscopic clips. Regardless, all cases of immediate CSP-associated bleeding were easily managed endoscopically. Caution might be required when adopting CSP, especially for small (6-9 mm) polyps because these polyps exhibited a higher incidence of immediate bleeding compared to the diminutive (≤ 5 mm) polyps. We observed no CSP cases involving delayed bleeding, perforation or postpolypectomy syndrome that required treatment in this trial, which is perhaps one of the greatest advantages of CSP.

Many Japanese patients who undergo polypectomy are currently hospitalized for a few days, and the number of hospitals that can perform polypectomy is insufficient to treat all of the patients with colorectal polyps. Considering this limited access to polypectomy in Japan and the fact that more than 90% of polyps are subcentimetric, it is possible that the implementation of CSP could increase the availability of a safe and easy procedure for the removal of subcentimetric polyps in outpatients, which could not only the decrease medical expenses associated with hospitalization but also shorten the waiting time for polyp removal in large groups of patients in Japan. Nonetheless, it should be noted that minor bleeding (that did not require endoscopic hemostasis) was observed in 3 patients (5%) after CSP. Although we rarely experience such minor bleeding after conventional polypectomy with electrocautery, this information is important when adopting CSP in daily practice.

Notably, we observed that CSP was associated with a retrieval failure of 12%. Deenadayalu and Rex[24] reported no cases of retrieval failure after CSP in their study, whereas Komeda *et al*[25] reported a retrieval failure of 19% after CSP. The relatively higher incidence of retrieval failure associated with CSP might be an issue of concern for endoscopists who do not currently apply CSP in clinical practice. However, because the indication for CSP is limited to subcentimetric polyps, which have low risks for invasive carcinomas, this aspect is perhaps not a major concern. Additionally, the "resect and discard" policy, which omits formal pathological examination, is now regarded as a promising strategy for decreasing the cost and labor associated with screening and surveillance colonoscopy[26,27]. Therefore, retrieval failure will not be a major obstacle for the generalization of CSP in the future especially if a "resect and discard" strategy is adopted. Of course, careful endoscopic assessment before CSP is essential to avoid removing and discarding invasive carcinomas. Magnifying narrow-band imaging may be a promising tool to secure the safety of both CSP (*i.e.*, by preventing the removal of subcentimetric invasive carcinomas) and the "resect and discard" strategy because pretreatment assessment using magnifying endoscopy allows for the selection of lesions with advanced histologies[28,29]. Therefore, we believe that the combination of CSP and the "resect and discard" strategy using magnifying narrow-band imaging could provide a more efficient (*i.e.*, simple, safe, and cost-effective) strategy for screening and surveillance colonoscopy.

Assessment of the HMs of tumor specimens that have been resected by CSP is also a potential concern for endoscopists who are skeptical about CSP because we cannot expect the thermal burn effect to eradicate

the neoplastic tissue around the electrosurgical snare during CSP. The incidence of HM 1 was only 1.1% in our trial, but the incidence of HM X was 40%. The main indication for CSP is subcentimetric polyps, and for such lesions, doctors do not usually pay attention to HM X statuses because they expect the thermal burn effect to occur and routinely confirm the absence of tumor residue *via* observations of the surrounding mucosa. Although Lee *et al*[30] reported a significantly higher rate of histologic eradication with CSP than with CFP in their prospective randomized controlled trial, the non-inferiority of CSP for tumor residues compared with conventional polypectomy warrants further investigation of the efficacy of CSP. In the meantime, although it is important to pay attention to the presence of tumor residue after CSP, care must be taken to remove the surrounding non-neoplastic mucosa as well as the targeted lesion when implementing CSP. Moreover, careful observation of the surrounding mucosa after CSP using magnifying endoscopy or chromoendoscopy, the washing out of minor bleeding after CSP, and strict surveillance colonoscopy are recommended until the evidence for tumor residue after CSP is considered to be adequate.

This was only a pilot study and therefore has some limitations. First, although the number of CSP procedures was larger than those of previous reports, the small sample size remains still a major limitation of this trial. A large-scale prospective study investigating the actual incidence of delayed bleeding after CSP should be conducted in the future. Second, we used a conventional electrosurgical snare in this trial because the snare developed for CSP was not available during the study period. The use of this snare may have affected the rates of removal failures or insufficient assessments of the HMs of the resected specimens. Finally, although the CSPs in this study were performed by nine endoscopists with no prior experience in CSP, different results might have been obtained if the endoscopists had experienced at least 20-30 CSPs. Specifically, the 70 (40%) HM X lesions should be carefully assessed.

In conclusion, we found that CSP is effective for removal subcentimetric polyps in the colon and rectum. CSP was safe and resulted in no cases of delayed bleeding or perforation and a 3.4% incidence of manageable immediate bleeding. Attention should be given to the potential risk of bleeding immediately after CSP, particularly for small (6-9 mm), lesions as well as to careful endoscopic diagnosis before CSP and the evaluation of tumor residue after CSP. Other areas of concern when implementing CSP might be retrieval failure and incomplete HM assessment. Nonetheless, we conclude that CSP for subcentimetric colorectal lesions is also a feasible procedure for implementation in Japan.

COMMENTS

Background

Although cold snare polypectomy (CSP) using snare resection without electrocautery has been reported to be a safe method for the removal of subcentimetric polyps, CSP is not currently widely used in Japan.

Research frontiers

CSP is a promising procedure, but there are no detailed data about immediate bleeding or the horizontal margins of the histological specimens from Japanese institutions.

Innovations and breakthroughs

The incidence of immediate bleeding after CSP for small polyps (6-9 mm) was significantly higher than that for diminutive polyps (≤ 5 mm). Histopathological diagnoses can be often insufficient because 12% of the resected lesions could not be retrieved for pathological examination, and tumor involvement in the lateral margin could not be histologically assessed in 70 (40%) lesions.

Applications

The authors need to be cautious in the performance of CSP for small (6-9 mm) polyps due to concerns about immediate bleeding and histopathological assessment.

Terminology

Cold forceps polypectomy is a simple procedure that uses endoscopic forceps without electrocautery. CSP is a procedure that uses snare resection without electrocautery.

Peer-review

This is an important manuscript.

Abstract

Portal hypertensive duodenopathy (PHD) is a recognized, but uncommon finding of portal hypertension in cirrhotic patients. Lesions associated with PHD include erythema, erosions, ulcers, telangiectasia, exaggerated villous pattern and duodenal varices. However, duodenal polyposis as a manifestation of PHD is rare. We report a case of a 52-year-old man who underwent esophagogastroduodenoscopy and was found with multiple small duodenal polyps ranging in size from 1-8 mm. Biopsy of the representative polyps revealed polypoid fragments of duodenal mucosa with villiform hyperplasia lined by reactive duodenal/gastric foveolar epithelium and underlying lamina propria showed proliferating ectatic and congested capillaries. The features were diagnostic of polyps arising in the setting of PHD.

Key words: Cirrhosis; Portal duodenopathy; Polyposis; Portal hypertension

Core tip: Duodenal polyposis secondary to portal hypertensive duodenopathy (PHD) is rare. We report a case of PHD presenting as polyposis.

INTRODUCTION

Portal hypertensive duodenopathy (PHD) is a recognized, but uncommon finding of portal hypertension in cirrhotic patients. While other associations of portal hypertension such as portal hypertensive gastropathy and portal hypertensive colopathy have been described and studied, data concerning duodenal alterations is relatively scarce. The lesions described in PHD include erythema, erosions, ulcers, telangiectasia, exaggerated villous pattern and duodenal varices[1]. Recently, there have been emerging reports of polyps as a manifestation of PHD[2-5]. Herein, we report a patient with duodenal polyposis secondary to portal hypertension, review the literature and describe the spectrum of histopathologic changes.

CASE REPORT

A 52-year-old man with compensated alcoholic cirrhosis presented for follow up esophagogastroduodenoscopy. Past medical history includes remote T1N0 colon cancer (status post right hemicolectomy 4 years), low-grade gastrointestinal blood loss, iron deficiency anemia, gastric antral vascular ectasia, portal hypertensive gastropathy and hypertension. He was diagnosed with cirrhosis 13 years ago when he presented with jaundice and ascites and had a recent history of hepatic encephalopathy. Abdominal U/S and magnetic resonance imaging showed a large heterogenous liver, recanalization of the umbilical vein, splenomegaly, splenorenal shunt, additional collateral vessels inferior to the left renal vein and scattered renal cysts. Endoscopy revealed numerous small 1-2 mm polyps extending from the duodenal bulb to the second portion of the duodenum. The three largest polyps included a 6 mm polyp in the mid duodenal bulb (Figures 1A and B), 8 mm polyp distal to this along the anterior wall, and 8 mm polyp in the second part of the duodenum (Figure 1C). The esophagus was normal and no esophageal varices were noted. The stomach showed diffuse "snake skin" appearance, an area of friable mucosa with a polypoid appearance and surface erosions in the antrum and pre-pyloric area with spontaneous oozing of blood. The three duodenal largest polyps were biopsied and histologic examination revealed polypoid fragments of duodenal mucosa with villiform hyperplasia lined by reactive duodenal and gastric foveolar epithelium. The underlying lamina propria showed proliferating ectatic and congested capillaries (Figures 2A and B, D and E). The findings were diagnostic of multiple portal hypertensive duodenal polyps.

DISCUSSION

Common gastrointestinal tract manifestations of portal hypertension include esophageal/gastric/anorectal varices and gastric antral vascular ectasia. In addition, less common features include portal hypertensive gastropathy[6-8], congestive jejunopathy[9,10], portal colopathy[11,12] and PHD[1,13]. PHD is commonly defined as the appearance of patchy or diffuse congestion of the duodenal mucosa associated with friability, erosions or ulcerations[14,15]. The prevalence of PHD in cirrhotic patients with portal hypertension ranges from 8.4%[16] to 51.4%[1]. The lesions described in PHD include erythema, erosions, ulcers, telangiectasia, exaggerated villous pattern and duodenal varices[1]. Coexistence of severe gastropathy and higher hepatic venous pressure gradients are more frequent in PHD patients and features of PHD have been reported to disappear after liver transplantation[16].

Duodenal polyps as a manifestation of PHD, an uncommon event, have been reported previously (summarized in Table 1). These include an ulcerated solitary 3 cm polyp in the descending duodenum[3], multiple sessile polyps in the first portion of the duodenum[2] and a recent report documenting two to "several" duodenal or jejuno-ileal polypoid lesions ranging in size from < 5 mm to 15 mm in 5 patients[4]. The spectrum of histopathologic findings in the polyps includes the presence of numerous capillaries with vascular ectasia/congestion/thrombi as well as fibrosis and smooth muscle proliferation. In addition gastric foveolar metaplasia, reactive atypia and ulceration may be seen. Devadason *et al*[5] reported "duodenal capillary hemagiomatous polyps" in 3 pediatric patients (aged 1, 4 and 6 years old). All these 3 patients presented with multiple duodenal polyps in either the 1st or 2nd portion of the duodenum in the setting of extrahepatic portal venous obstruction. Polyps were biopsied in two patients, both of which demonstrated lobular capillary proliferation within the polyps[5]. Although they favored the term "duodenal capillary hemagiomatous polyps", it appears from their description, as well as accompanying image, that the polyps they described share similar morphological features to the polyps in our case and other reported polyps in the setting of PHD.

To date, including our case, there are 11 documented reports of polyps associated with PHD (Table 1). There is no gender predilection (6 male and 5 female), the ages of patients ranges from 1 to 73 years and in the majority of cases (10/11), multiple polyps are seen. The etiology of portal hypertension in adult patients include alcoholic cirrhosis (37.5%, 3/8), hepatitis C cirrhosis (25%, 2/8) and cryptogenic cirrhosis (37.5%, 3/8), while extrahepatic portal venous obstruction accounts for all cases in the pediatric population (100%, 3/3).

Histologically, the PHD associated polyp surface- and crypt-lining epithelium may focally show cells with

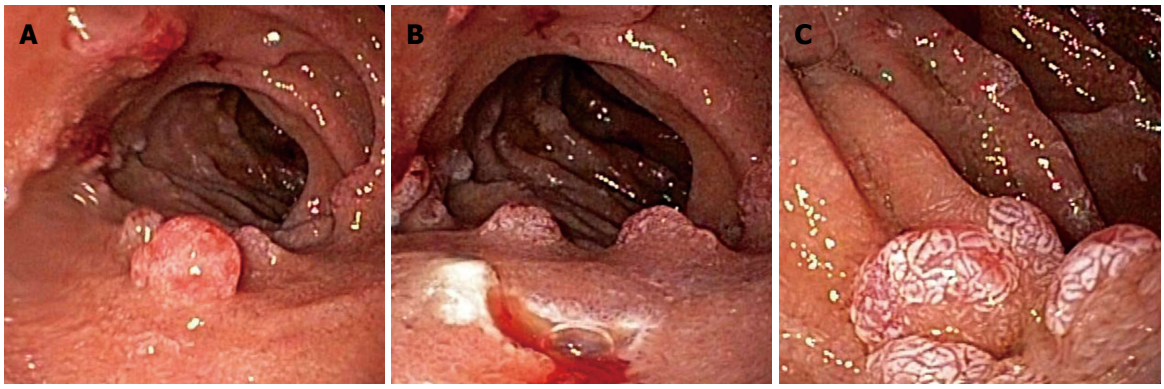

Figure 1 Duodenal polyposis under esophagogastroduodenoscopy. A 6 mm, sessile polyp was seen [prior to removal (A); immediately after removal (B)] in the mid duodenal bulb. A separate 8 mm polyp was seen along the lateral aspect of the second part of the duodenum (C).

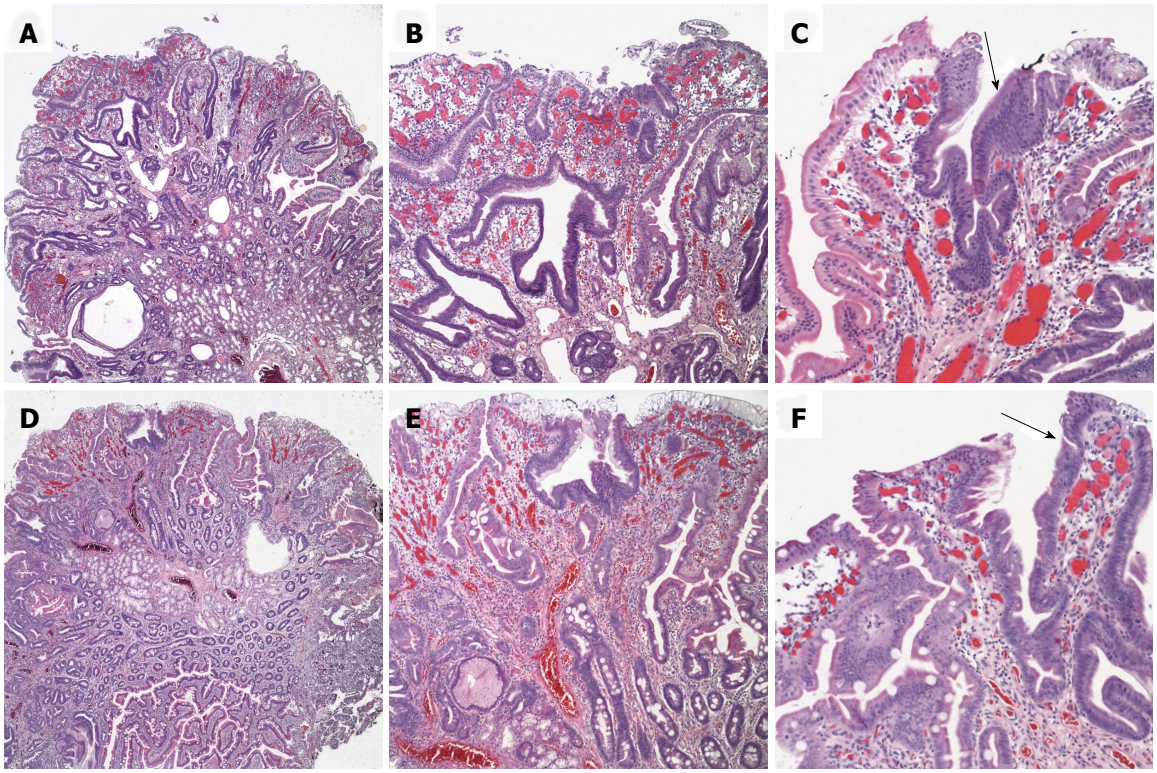

Figure 2 Histopathologic findings. Biopsies from the mid duodenal bulb polyp showed villiform hyperplasia of intestinal and gastric foveolar epithelium with numerous capillaries demonstrating congestion and vascular ectasia (A and B). Similar changes seen in the polyp from the second part of the duodenum (D-E). The epithelium lining the surface and crypts focally (arrows) showing cells with mucin depletion and slightly pencillate nuclei with hyperchromasia (C and F). Representative images of hematoxylin and eosin stained slides taken at 40 × (A, D: 4 × objective and 10 × ocular magnification), 100 × (B, E: 10 × objective and 10 × ocular magnification) and 200 × (C, F: 20 × objective and 10 × ocular magnification).

mucin depletion and contain slightly pencillate nuclei with mild hyperchromasia (Figures 2C and F). These features may mimic duodenal adenomatous polyp, a precancerous lesion in the duodenum. Our current case was previously diagnosed as "duodenal adenomas" at an outside institution. The initial diagnosis of duodenal adenoma in our patient's prior biopsy highlights the challenges that the reactive atypia may pose during histological evaluation. The differential diagnosis of polypoid lesions in the duodenum is diverse (Table 2) and we limit our discussion to more commonly seen and lesions with similar histologically features to PHD associated polyps. While duodenal adenomas with low-grade dysplasia (which are histologically similar to those seen in the colon) are typically composed of mucin depleted cells with hyperchromatic pencillate nuclei, compared to the reactive atypia seen in polyps associated with PHD, nuclei show a greater degree of enlargement, hyperchromasia and stratification. PHD polyps differ from duodenal hamartomatous polyps seen in Peutz-Jegher syndrome as polyps in the latter typically show disorganized mucosa with thick arborizing

Table 1 Reported small intestinal polyps secondary to portal hypertension (including current case)

Ref.	Age (yr)/ gender	Location(s)	Number/sizes of polyps	Pathologic findings	Etiology of portal hypertension
Current report	52/M	Duodenal bulb to second portion	Greater than 7, majority 1-2 mm, largest 8 mm	Villiform hyperplasia of reactive intestinal and gastric foveolar epithelium, proliferating ectatic and congested lamina propria vessels	Alcoholic cirrhosis
Pillai *et al*[2]	55/M	1st portion of duodenum	"multiple sessile polyps", sizes NS	Polypoid muocsa lined by small intestinal and gastric foveolar type epithelium with ectatic capillaries, fibrosis and smooth muscle proliferation of lamina propria	Alcoholic cirrhosis
Zeitoun *et al*[3]	70/M	2nd portion of duodenum	Single polyp, 3 cm	Numerous thick-walled capillaries with vascular ectasia in lamina propria	Alcoholic cirrhosis

IBD: Inflammatory bowel disease.

smooth muscle fibers of the muscularis mucosa. Although there may be histologic overlap between Juvenile polyps, inflammatory bowel disease (IBD) associated inflammatory polyps and PHD associated polyps, Juvenile polyps are characterized by dilated mucin filled crypts, while IBD associated polyps tend to have prominent glandular architectural distortion in the background of IBD.

In summary, duodenal polyps secondary to PHD is uncommon. With our case, the total number of patients reported in the literature to date is 11. The finding of multiple polyps in a patient with portal hypertension should raise suspicion for this entity and careful histopathologic examination is necessary to render the appropriate diagnosis.

COMMENTS

Case characteristics

A 52-year-old man with compensated alcoholic cirrhosis presented for follow up esophagogastroduodenoscopy and multiple duodenal polyps were found.

Clinical diagnosis

Cirrhosis and duodenal polyps.

Differential diagnosis

Duodenal adenomatous polyp, polyposis syndrome, duodenal pancreatic or gastric ectopia, or other benign neoplasms.

Imaging diagnosis

Endoscopy revealed numerous small 1-2 mm polyps extending from the duodenal bulb to the second portion of the duodenum. The three largest polyps

included a 6 mm polyp in the mid duodenal bulb, 8 mm polyp distal to this along the anterior wall, and 8 mm polyp in the second part of the duodenum.

Pathological diagnosis

Portal hypertensive duodenal polyps.

Related reports

Duodenal polyps as a manifestation of portal hypertensive duodenopthy (PHD), an uncommon event, have been reported previously. The prevalence of PHD in cirrhotic patients with portal hypertension ranges from 8.4% to 51.4%. However, manifestation as multiple duodenal polyps is rare.

Term explanation

Portal hypertensive duodenal polyps are seen in patients with cirrhosis and portal hypertension. The spectrum of histopathologic findings in the polyps includes the presence of numerous capillaries with vascular ectasia/congestion/thrombi as well as fibrosis and smooth muscle proliferation. In addition gastric foveolar metaplasia, reactive atypia and ulceration may be seen.

Experiences and lessons

PHD is a recognized, but uncommon finding of portal hypertension in cirrhotic patients. Multiple duodenal polyps can be an endoscopic finding of PHD.

Peer-review

The authors reported a 52-year-old patient with cirrhosis and portal hypertension who underwent endoscopy and was found with multiple portal hypertensive duodenal polyps. This is an interesting case report and literature review. It is very well written with excellent images. The article highlights the clinical characteristics of PHD and provides information about differential diagnosis of portal hypertensive duodenal polyps.

Abstract

Subepithelial lesions (SELs) in the upper gastrointestinal (GI) tract are relatively frequent findings in patients undergoing an upper GI endoscopy. These tumors, which are located below the epithelium and out of reach of conventional biopsy forceps, may pose a diagnostic challenge for the gastroenterologist, especially when SELs are indeterminate after endoscopy and endoscopic ultrasound (EUS). The decision to proceed with further investigation should take into consideration the size, location in the GI tract, and EUS features of SELs. Gastrointestinal stromal tumor (GIST) is an example of an SEL that has a well-recognized malignant potential. Unfortunately, EUS is not able to absolutely differentiate GISTs from other benign hypoechoic lesions from the fourth layer, such as leiomyomas. Therefore, EUS-guided fine needle aspiration (EUS-FNA) is an important tool for correct diagnosis of SELs. However, small lesions (size < 2 cm) have a poor diagnostic yield with EUS-FNA. Moreover, studies with EUS-core biopsy needles did not report higher rates of histologic and diagnostic yields when compared with EUS-FNA. The limited diagnostic yield of EUS-FNA and EUS-core biopsies of SELs has led to the development of more invasive endoscopic techniques for tissue acquisition. There are initial studies showing good results for tissue biopsy or resection of SELs with endoscopic submucosal dissection, suck-ligate-unroof-biopsy, and submucosal tunneling endoscopic resection.

Key words: Gastrointestinal neoplasm; Gastrointestinal endoscopy; Endoscopic ultrasound-guided fine needle aspiration; Endosonography; Gastrointestinal stromal tumors

Core tip: Subepithelial lesions (SELs) of the upper gastrointestinal tract include a broader differential diagnosis, which can range from non-malignant tumors to lesions with malignant potential such as gastrointestinal stromal tumors. The possibility of having a potentially malignant lesion may bring anxiety and discomfort to patients and doctors. Further investigation should be carried out for patients with high-risk lesions after risk stratification. This editorial presents the current

evidence about the diagnostic management of SELs.

Franco MC, Schulz RT, Maluf-Filho F. Opinion: How to manage subepithelial lesions of the upper gastrointestinal tract? *World J Gastrointest Endosc* 2015; 7(18): 1262-1267 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i18/1262.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i18.1262

TYPES AND DIAGNOSIS OF SUBEPITHELIAL LESIONS

Expansive lesions located below the epithelium of the gastrointestinal (GI) tract pose a diagnostic challenge for the gastroenterologist. In most cases, the endoscopic aspect is not diagnostic and lesions are out of reach for conventional biopsy forceps[1].

The differential diagnosis of subepithelial lesions (SELs) encompasses non-neoplastic lesions such as varices, as well as neoplastic lesions with practically no malignant potential, including leiomyoma or lipoma. However, there are neoplastic lesions with a higher malignancy potential, for example gastrointestinal stromal tumors (GISTs) and neuroendocrine tumors[2]. Dealing with patients with SELs is a real exercise in risk stratification.

In a few circumstances, the endoscopic aspect is sufficient to define a low risk lesion, such as a pancreatic rest located at the greater curvature of the antrum, or a large and ulcerated mass like a high grade gastric GIST. The challenge is the inconspicuous SEL clearly located below the mucosa[3].

Some endoscopic maneuvers should be employed to better characterize SELs: Chromoendoscopy and conventional biopsy are useful to rule out true mucosal neoplasms that rise deep in the epithelium, such as myoblastoma and neuroendocrine tumor. Measuring the lesion is also important. Changing patient decubitus and palpation with the biopsy forceps are usually employed to differentiate a true SEL from an extrinsic compression caused by other organs. Generally, these maneuvers have low sensitivity for defining the true nature of the lesions[4].

Sometimes it is relatively easy to make a differential diagnosis using endoscopic ultrasound (EUS), for example between a small gastric carcinoid limited to the deep mucosa and a compression of the GI tract caused by other extrinsic structures, such as a giant splenic cyst. However, in many circumstances the differential diagnosis is not straightforward, even with EUS. When we are dealing with intramural lesions, the EUS image will define the layer of the GI wall where the lesion lies.

Hypoechoic SELs from the fourth layer include a broader differential diagnosis, for example GIST, leiomyoma, and schwannoma, among other mesenchymal tumors.

RISK STRATIFICATION

Thinking about risk stratification, authors looked for some EUS features predictive of SEL malignancy. Larger, heterogeneous lesions with cystic areas and irregular outer margins were proved to harbor a higher risk for malignancy. The presence of at least two of these features had an 80% sensitivity and 80% specificity for detecting malignancy[4,5].

It is noteworthy that the location of the lesion can also predict its behavior. Esophageal SELs rarely harbor any malignant potential (1%), different from gastric and duodenal lesions which have a higher risk for malignancy, in more than 20% of cases[2].

Indeed, when SELs are located in the esophagus, the risk for a potential malignant lesion, such as a GIST, is low (7%). On the other hand, when the lesion is located in the stomach or duodenum this risk is much higher, as some publications reported that subepithelial neoplasms located in the stomach and duodenum were GISTs in more than 70% and 50% of cases, respectively[6,7].

When we looked at our experience[8], we also noticed that location inside the stomach could be useful for risk stratification. From 11 lesions located in the cardia, none were GISTs, while from 17 lesions located at the gastric body, 11 (70%) were GISTs.

Our numbers were confirmed in a larger trial[9], where 144 patients with SELs were endoscopically resected by endoscopic submucosal dissection (ESD). Only 14% of the lesions located at the cardia proved to be GISTs, while 85% were leiomyomas.

EUS is an important tool for the differential diagnosis of SELs. Its features can be diagnostic of extrinsic compressions, lipomas, cysts and varices, and no further investigation is needed.

GIST: ONCOGENESIS AND HISTOLOGIC ASSESSMENT

The concept of GISTs is relatively recent, and refers to a group of mesenchymal lesions that express a transmembrane protein called KIT. This KIT protein is codified by a proto-oncogene called c-kit. In normal conditions, the stem cell factor activates two kit receptors to signal cell proliferation, by activating tyrosine kinase. In GISTs pathogenesis, oncogenic mutations in KIT result in ligand-independent activation of tyrosine kinase. C-kit mutations located at exons 11 and 9 are the most frequent ones. Around 5% of GISTs do not present c-kit mutations; in those cases mutations of the platelet-derived growth factor are seen[10].

GISTs are rare tumors that affect patients in their fifties. In the United States, the estimated incidence of GIST is 7 to 14 new cases per million in the general population[11]. The most frequent locations of GISTs are the stomach and small bowel. The colorectum and esophagus are much less frequent locations, as well as the omentum, retroperitoneum and mesenterium[11].

Histologically, most GISTs are spindle cell type (70%). In the minority of cases, they present as epithelioid (20%) or mixed (10%) types[12]. It is controversial whether the histologic type has prognostic implications. The spindle cell type is practically identical to the histology of leiomyoma. Only an immunohistochemistry panel can make a differential diagnosis between them.

Immunohistochemistry testing at least for C-kit and CD34 is recommended. It is noteworthy that up to 40% of GISTs express smooth muscle actin[12].

GISTs have been included in the 2010 TNM classification, meaning that they should be regarded as malignant neoplasms. However, not all GISTs present invasive or metastatic behavior. Small bowel GISTs present a more invasive behavior when compared to gastric ones. The overall 5-year mortality rate for small bowel GISTs reaches up to 39%, compared to 17% for gastric GISTs[13,14]. Spindle cell GISTs have a higher 5-year disease-free survival rate[15], but these results have not been replicated. In addition, mutations at exon 11 are associated with a better response to target therapy, such as oral imatinib[16].

However, the most important factors that predict GIST behavior are size and mitotic rate[17]. In fact, these features are used for the 2010 TNM classification[18]. In that classification, gastric GISTs up to 2 cm with a low mitotic rate (< 5 mitoses per 50 high-power field), are staged as Ia.

CAN EUS DIFFERENCIATE GISTS FROM OTHER MESENCHYMAL TUMORS SUCH AS LEIOMYOMAS?

The answer is no. At least up to now.

Hunt *et al*[19] found that gastric hypoechoic lesions measuring more than 4 cm, with cystic spaces and ulceration, are probably GISTs. However, most of incidental SELs do not present these features.

Another publication[20] looked at the correlation between EUS and the final histology of small (< 2 cm) resected gastric SELs. It is noteworthy that none of the 22 patients had a GIST, probably because the authors did not resect lesions from the fourth layer, where GISTs usually lie. Most lesions were pancreatic rests, and the presumptive EUS diagnosis was correct in ten of the 22 cases, less than 50%.

In our experience using EUS[8], the presence of flow detected by power Doppler and irregular outer borders had a positive likelihood ratio of 10 for GIST diagnosis. But, from 21 patients with gastric GISTs, power Doppler was positive in only five cases (25%), and irregular outer borders in seven (35%). Therefore, the absence of these features does not rule out the diagnosis of GIST, or in other words, these features have a low negative predictive value for the diagnosis of GIST.

Recently, contrast-enhanced harmonic EUS (CEH-EUS) has been employed for differential diagnosis of gastric SELs. The results were positively convincing in the study by Kannengiesser *et al*[21], but with a limited cohort (fewer than 20 patients). CEH-EUS showed hyperenhancement of gastric lesions from the fourth layer that proved to be a GIST, and no enhancement of gastric leiomyoma.

Computed tomography (CT) and magnetic resonance imaging (MRI) may also be valid tools for GIST diagnosis, especially when a cytological diagnosis is unnecessary. In fact, a meta-analysis[22] that evaluated 4534 patients with GISTs, from 46 studies, showed that CT and MRI had a pooled diagnostic yield of 73% and 91% respectively.

CAN WE PREDICT GIST BEHAVIOR BY ENDOSCOPY OR EUS?

It has been observed that high grade GISTs double in size in 9 mo, while those with benign behavior do it in 18 mo.

Onishi *et al*[23] reported that hypoechoic spots were present in 84% of gastric GISTs which grew in size, and in 52% of gastric GISTs that remained stable in size (84.2% *vs* 51.9%, $P = 0.023$). Again, this is another interesting piece of information but useful only when it is present.

A previous study[24] looked at the use of CEH-EUS to predict GIST grade. Based on enhancement of features immediately after contrast administration (the vessel phase), and a few minutes after (the perfusion phase), gastric GISTs were classified as types Ⅰ and Ⅱ. All type Ⅰ lesions revealed low grade GISTs after resection. On the other hand, all type Ⅱ lesions were high grade GISTs. Once more, this is very interesting data that needs validation in a large cohort of patients.

TISSUE IS THE ISSUE

The bite-on-bite biopsy technique has been described for tissue acquisition of hypoechoic lesions of the fourth layer. However, some reports demonstrated low diagnostic yield of around 17%[25].

EUS-guided fine needle aspiration (EUS-FNA) is the logical procedure for tissue acquisition. A study by Hoda *et al*[26] performed EUS-FNA on gastric lesions with a mean size of 28 mm. They employed a standard 22 G needle, and the diagnostic yield was 62%.

When we remember that during EUS-FNA the GI wall, including the proper muscle layer, is sampled, the first question that comes to our minds is: Is EUS-FNA diagnosis correct? Apparently, the answer is yes. Stelow *et al*[6] reported, in a study of EUS-FNA with sufficient material from 29 patients with SELs and follow-up information, that EUS-FNA diagnosis was correct in 93% of patients, and in almost all cases of mesenchymal tumors.

EUS-FNA diagnosis of SELs may be correct, but the diagnostic yield is not so high for lesions smaller than 30 mm. EUS-FNA had an overall diagnostic yield of 40% to 50% for lesions measuring up to 10 mm, and of 60%

to 70% for lesions measuring from 11 to 30 mm[26]. In conclusion, EUS-FNA has a diagnostic yield of 60% to 70%, with a lower diagnostic yield for small lesions.

The next logical development would be to employ needles that make core biopsy possible. In a prospective study[27], the authors did not find any difference between EUS-FNA and EUS-trucut core biopsy of SELs. They employed the trucut biopsy needle model that was a rigid, 19 G needle. Needle malfunction was relatively common when the scope was in a bent position.

Now, there are new models of core biopsy needle available, such as the 19 G flexible nitinol needle, and the ingenious core trap, which come in different sizes. The first results with these new needles were presented a couple of years ago. In a limited cohort of patients, the diagnostic yield reached impressive figures.

Meta-analysis of 21 studies[28] comparing standard EUS-FNA and the ProCore needle for tissue acquisition of solid masses, including pancreatic masses, lymph nodes and SELs, showed no significant difference in the rates of diagnostic yield, diagnostic accuracy or histologic yield, between the two techniques.

Another meta-analysis[29] focused on diagnostic yield, and on the complication rate of EUS-FNA and EUS-guided core needle biopsy (EUS-CNB), for patients with GIST. The authors reached the same conclusion, *i.e.*, the diagnostic yield of EUS-FNA and EUS-CNB are the same, 65%. The EUS-FNA complication rate was 0.4%, and for EUS-CNB it was 1.1%. Death is rare but may occur after EUS-FNA of GIST, so one must beware of that.

Core biopsy is necessary for GIST diagnosis, and EUS-FNA provides core biopsy in 70% of cases, especially for lesions larger than 2 cm. EUS-core biopsy needles did not prove to be better; therefore, their higher cost is not justifiable. Severe complications and mortality are rare, but may occur after EUS-FNA and EUS-core needle biopsy of SELs.

ENDOSCOPIC TECHNIQUES FOR SEL DIAGNOSIS AND RESECTION

The limited diagnostic yield of EUS-FNA and EUS-core biopsy of SELs prompted the development of more aggressive endoscopic techniques for tissue acquisition. One of them [suck-ligate-unroof-biopsy (SLUB)] consists of placing an endoloop at the base of the lesion with the aid of a cap. After unroofing, biopsies are taken. A few months later, endoscopic and EUS control confirms the complete disappearance of the tumor. Not all fourth layer SELs can be treated by SLUB. The authors suggest that the dimension should not surpass 2 cm and, very importantly, the tumor should have no exophytic growth[30].

ESD is another option for tissue acquisition and treatment of SELs located at the cardia. In a large series[31] of 143 patients, the authors obtained a 95% complete resection rate of leiomyomas and GISTs, with a 4% perforation rate, and no recurrence in 2-year follow-up.

Submucosal tunneling endoscopic resection (STER)[32] involves the creation of a submucosal tunnel in the same fashion as the peroral endoscopic myotomy procedure. The tumor is then resected, and the mucosal incision site is closed, which guarantees the safety of the procedure, even in cases of perforation.

The first published series[32] includes fewer than 20 patients. The majority of them had SELs in the esophagus and cardia. In this paper, only three cases with gastric lesions were treated by STER. It should be remembered that most esophageal SELs are benign leiomyomas.

A word of caution is advised for those interested in these innovative procedures such as SLUB and STER. EUS is absolutely necessary to select lesions suitable for these techniques. In this scenario, a CT scan often demonstrates a smooth outer contour of gastric SELs. However, in the operative field, it is clear that the lesion may project to the serosal surface, making SLUB and STER very dangerous.

CONCLUSION

In conclusion, SELs that are indeterminate after endoscopy and EUS examinations may have a challenging diagnosis. Otherwise, as mentioned before, if the aspect is typical of a neuroendocrine tumor, a pancreatic rest, lipoma, cyst, or varices, management poses no major problems. If EUS demonstrates small hypoechoic tumors of the second and third layers, endoscopic resection is possible and quite safe. For small hyperechoic lesions of the second and third layers, endoscopic resection is a valid alternative. For larger lesions, a tissue diagnosis is necessary. For larger lesions of the fourth hypoechoic layer, EUS-FNA and core biopsy are safe and have a good diagnostic yield. Some authors advocate referring the patient directly for surgery, if the lesion is located in the stomach or in the duodenum. SLUB, STER, and ESD are techniques under investigation for SELs.

Small hypoechoic lesions of the fourth layer should be simply followed (every six months for one year, and then yearly or biannually), especially if EUS features indicate a benign lesion. Oh the other hand, if EUS features are worrisome, EUS-FNA or core biopsy should be tried, but they have a very low diagnostic yield in small lesions. Surgery is a reasonable option especially if the lesion is located in the stomach or duodenum. Again, ESD, SLUB, and STER are under investigation.

Abstract

Endoscopic evaluation of indeterminate biliary strictures (IDBSs) has evolved considerably since the development of flexible fiberoptic endoscopes over 50 years ago. Endoscopic retrograde cholangiography pancreatography (ERCP) was introduced nearly a decade later and has since become the mainstay of therapy for relieving obstruction of the biliary tract. However, longstanding methods of ERCP-guided tissue acquisition (*i.e.*, biliary brushings for cytology and intraductal forceps biopsy for histology) have demonstrated disappointing performance characteristics in distinguishing malignant from benign etiologies of IDBSs. The limitations of these methods have thus helped drive the search for novel techniques to enhance the evaluation of IDBSs and thereby improve diagnosis and clinical care. These modalities include, but are not limited to, endoscopic ultrasound, intraductal ultrasound, cholangioscopy, confocal endomicroscopy, and optical coherence tomography. In this review, we discuss established and emerging options in the evaluation of IDBSs.

Key words: Cholangiocarcinoma; Bile duct diseases; Cholangiopathies; Gastrointestinal endoscopy; Pancreatic adenocarcinoma

Core tip: Indeterminate biliary strictures (IDBSs) remain a considerable challenge for endoscopists, clinicians, surgeons, and other medical professionals as well as patients. The limitations of current technologies have helped drive the search for novel techniques aimed to enhance the evaluation of IDBSs and thus improve diagnosis and clinical care. Here we review existing and emerging techniques and provide a synopsis of current understanding of their strengths, limitations, and role in the evaluation of IDBSs.

Tabibian JH, Visrodia KH, Levy MJ, Gostout CJ. Advanced endoscopic imaging of indeterminate biliary strictures. *World J Gastrointest Endosc* 2015; 7(18): 1268-1278 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i18/1268.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i18.1268

INTRODUCTION

A substantial proportion of biliary strictures cannot be classified as benign or malignant on the basis of non-invasive imaging, endoscopic retrograde cholangiopancreatography (ERCP), and/or routine tissue sampling methods (*i.e.,* biliary brushing, intraductal forceps biopsy)[1]. Although the addition of fluorescence *in situ* hybridization (FISH) to conventional biliary cytology has been useful in assessing strictures with a higher suspicion for malignancy which may benefit from closer follow-up, sensitivity remains low. As a result, these "indeterminate biliary strictures" (IDBSs) remain a clinical challenge, especially when considering the resulting delayed diagnosis, deferred implementation of care, economic impact from repeated evaluations, and resulting angst among patients, clinicians, and endoscopists.

IDBSs may arise *de novo* or in patients with known chronic biliary disease. They typically manifest with (abrupt onset or slowly progressive) jaundice, pruritus, right upper quadrant pain, and/or cholangitis. IDBSs may also be incidentally discovered, often following abdominal computed tomography or magnetic resonance imaging performed for other indications. The differential diagnosis of IDBSs is broad (Table 1), and determination of the underlying etiology and pathobiology is often challenging. Endoscopic evaluation of IDBSs has traditionally consisted of ERCP, but several other ancillary techniques have been developed to help address this common diagnostic challenge.

In this article, we review these ancillary techniques, providing our current understanding of their strengths, limitations, and role in the evaluation of IDBSs.

ERCP

ERCP provides fluoroscopic images of the biliary tree and provides the primary portal for diagnosis and intervention. Cholangiographic features suggestive of a malignant stricture include length (> 14 mm), irregularity, abrupt shelf-like borders, presence of intraductal polypoid or nodular areas, and the presence of simultaneous common bile duct (CBD) and pancreatic duct dilation (*i.e.,* double duct sign)[2,3]. Efforts to improve the sensitivity of cholangiography have led to methods for tissue acquisition; however, conventional methods such as biliary brush cytology, intraductal biopsy, and fine needle aspiration (FNA) have yielded disappointingly low sensitivity for detecting malignancy. For example, a recent review of the literature that identified 16 studies reported an overall biliary brush cytology sensitivity of 42% with a negative predictive value (NPV) of 58%[4]. The poor sensitivity was attributed to sampling error, inadequate specimen (*e.g.,* due to desmoplastic reaction or biliary fibrosis), and/or difficult cytopathologic distinction of subtle differences between malignant and nonmalignant cells[5,6]. Biliary cytopathology interpretation is often challenging, even within high-volume centers. A recent meta-analysis by Navaneethan *et al*[7] compared the effectiveness of brush cytology and intraductal biopsy for evaluating biliary strictures; nine studies were included, and the pooled sensitivity and specificity for brushings was 45% and 99%, respectively, compared to 48% and 99% for intraductal biopsies, respectively. When the two modalities were combined, there was some incremental yield, with sensitivity improving to 59%[7]. Methods tested to potentially further increase the diagnostic sensitivity have included use of longer brush length, initial stricture dilation, and repeated brushing, with repeat brushing appearing to be most effective, albeit still with suboptimal results[8,9]. Intraductal FNA has also been associated with disappointing results, as data from five series (220 patients) demonstrated a sensitivity of 34%, in part perhaps due to technical challenges with performing intraductal FNA[10]. The suboptimal diagnostic performance of conventional tissue sampling techniques has provided the impetus for developing advanced cytologic methods such as FISH, digital image analysis (DIA), and flow cytometry, which are described further in a subsequent section.

A "dominant stricture" is a subtype of IDBS that arises in the setting of underlying primary sclerosing cholangitis (PSC) or other fibrosing cholangiopathies and may be loosely defined as a CBD stenosis of $\leqslant$ 1.5 mm or hepatic duct stenosis $\leqslant$ 1 mm in diameter[11]. Accurately detecting malignancy in the setting of PSC is especially critical given the 1560-fold increased risk of developing cholangiocarcinoma (CCA) in this cohort compared to the general population[12]. However, this imposes an even greater diagnostic challenge, as ERCP-guided approaches to tissue acquisition have performed poorly in this disease, with sensitivity ranging from 18%-40%[11,13,14]. Reasons for low sensitivity include but are not limited to periductal (or submucosal) as opposed to radial growth of some CCAs, desmoplastic reaction, and inadequate access of endoscopic devices and sampling under indirect visualization (chiefly due to the stenotic nature of the disease)[15]. Adjunctive modalities for endoscopic evaluation of IDBSs in this high-risk subset of patients may provide improved diagnostic value and are discussed below in their respective sections.

ADVANCED CYTOLOGIC TECHNIQUES FOR ERCP-ACQUIRED BILIARY BRUSHING SPECIMENS

Fluorescence in situ hybridization

FISH is a cytogenic technique that employs fluorescently labeled DNA probes to chromosomal loci of interest

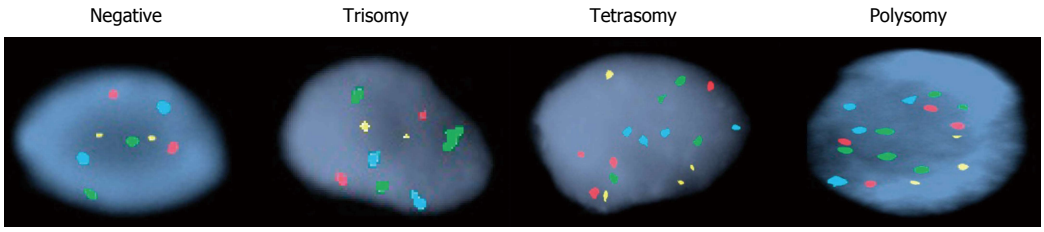

Figure 1 Representative fluorescence *in situ* hybridization microscopic image. Shown above are individual cells from biliary brushings showing distinct fluorescence *in situ* hybridization (FISH) results (arranged from lowest to highest risk of malignancy) using centromere enumeration probes (CEPs) to chromosomes 3 (red), 7 (green), 17 (aqua) and the 9p21 locus (gold). Potential FISH results include negative (two copies of each probe), trisomy 7 (≥ 10 cells with ≥ 3 CEP 7 signals and ≤ 2 signals for the other probes), tetrasomy (≥ 10 cells with four signals for all four probes), and polysomy (≥ 5 cells with ≥ 3 signals for ≥ 2 of the four probes).

Table 1 Potential etiologies of indeterminate biliary stricture

Benign
Primary sclerosing cholangitis
IgG4-associated cholangiopathy
Postoperative stricture (anastomotic, ischemic, cholecystectomy-related)
Ischemia (*e.g.*, hepatic artery thrombosis)
Infections (HIV cholangiopathy, parasites)
Pancreatitis (acute, chronic, autoimmune)
Choledocholithiasis
Mirizzi syndrome
Eosinophilic cholangitis
Vasculitis
Radiation
Portal biliopathy
Malignant
Pancreatic adenocarcinoma
Cholangiocarcinoma
Hepatocellular carcinoma
Lymphoma
Metastatic adenocarcinoma (*e.g.*, compressive lymphadenopathy)

HIV: Human immunodeficiency virus.

and thereby reveals losses or gains in these specific loci (*i.e.,* aneuploidy). Fluorescence microscopy is then used to quantify cells containing nuclei with abnormal probe signal numbers (Figure 1). The presence of ≥ 5 such cells showing gains of ≥ 2 of the (currently four) probes on FISH analysis, *i.e.,* polysomy, has been found to provide improved sensitivity compared to cytology while maintaining comparable specificity[16-20]. Recent studies have reported that incorporating 9p21 (*i.e.,* CDKN2A locus, critical in cell cycle progression and senescence[21,22]) deletion into the diagnostic criteria further improves the sensitivity to 76%-89%[23,24]. In individuals with PSC, detection of polysomy during subsequent ERCPs (*i.e.,* serial polysomy) or detection of polysomy in multiple segments of the biliary tree (*i.e.,* multifocal polysomy) appears to denote even greater risk of CCA[25,26].

DIA

DIA incorporates digital conversion and computer analysis to quantify nuclear DNA content and evaluate nuclear features; when compared to conventional cytology, it has been shown to have a higher sensitivity (39% *vs* 18%) but at the expense of lower specificity (77% *vs* 98%)[27]. In two studies comparing DIA with FISH, DIA appeared to have slightly lower sensitivity (38%-43% *vs* 44%-45%) and specificity (92%-95% *vs* 98%-100%). In one of the studies, routine cytology had a sensitivity of 15% and specificity of 100%, whereas in the other, DIA and FISH were performed only after negative cytology and histology[16,18]. Moreover, multivariable analysis of advanced cytologic methods in the evaluation of IDBSs showed FISH polysomy to be an independent predictor of malignancy, whereas DIA was not[19]. Despite the somewhat enhanced diagnostic sensitivity, the associated decrement in specificity has eliminated the use of DIA in many centers.

Flow cytometry

Flow cytometry relies on the detection of hyperploidy to identify malignant cells; it has similar sensitivity to routine cytology (42%) but has inferior specificity (77% *vs* 92%)[28]. It is not routinely used in the clinical evaluation of IDBSs.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) is increasingly being utilized in the evaluation of biliary strictures since reports of its first application in the mid-1980s[29,30]. Most of the hepatobiliary system can be examined with curvilinear echoendoscopy (EUS) from the gastric antrum (for visualization of the gallbladder), duodenal bulb (for visualization of the mid-CBD up to the confluence of the left and right hepatic ducts), or second portion of the duodenum (for visualization of the periampullary region)[31,32]. In addition, EUS provides other key information, including lymph node (Figure 2A), portal vein, and hepatic artery status for staging and through the detection of malignant ascites, omental deposits, and hepatic metastasis. Furthermore, EUS-guided FNA (Figure 2B) offers a minimally-invasive means for diagnostic tissue sampling (Table 2).

EUS with or without FNA may be useful in distinguishing malignant from benign biliary strictures. EUS findings of a pancreatic head mass (causing a biliary stricture secondary to extrinsic compression), an irregular outer edge of the bile duct wall, or bile duct wall thickness > 3 mm have been associated with malignancy when

Table 2 Comparison of advanced endoscopic imaging modalities

	Advantages	Disadvantages
ERCP	Widely available	Procedural risks
	Workhorse technique with numerous accessories	Fluoroscopic (and endoscopic) images only
	Facilitates other diagnostic modalities (*e.g.*, biliary brushing, biopsy, endomicroscopy) as well as therapy	Low sensitivity of conventional cytology and intraductal biopsies
EUS	Provides staging information	Limited views of the intrahepatic biliary tree (and non-visualization of the right intrahepatic ductal system)
	Permits FNA	Generally nondiagnostic in and of itself without FNA
	Can facilitate difficult biliary cannulation	Risk of tumor seeding if FNA primary tumor
IDUS	Can help direct ERCP-guided tissue acquisition	Limited depth of imaging
		Infrequently used in routine practice
Cholangioscopy	Excellent visualization of the biliary mucosa (with digital cholangioscopes)	High cost (disposable system $2000 per case)
	May improve sensitivity, specificity, and overall accuracy compared to ERCP alone	Likely higher rates of pancreatitis, cholangitis, and perforation compared to ERCP alone
		Time-consuming
		Not widely available
CLE	Excellent sensitivity and negative predictive value	Marginal interobserver agreement
	Provides imaging at a cellular and sub-cellular level (lateral resolution of 3.5 μm)	Contact imaging of a very limited regional surface
		Time-consuming
		Not widely available
OCT	High resolution	Suboptimal sensitivity
	Improved sensitivity compared to ERCP-guided tissue acquisition	Resolution not as high as CLE
	Highly specific	Not widely available
	Permits larger surfaces areas to be examined compared to CLE	Not well-validated

ERCP: Endoscopic retrograde cholangiopancreatography; EUS: Endoscopic ultrasound; IDUS: Intraductal ultrasound; CLE: Confocal laser endomicroscopy; OCT: Optical coherence tomography; FNA: Fine needle aspiration.

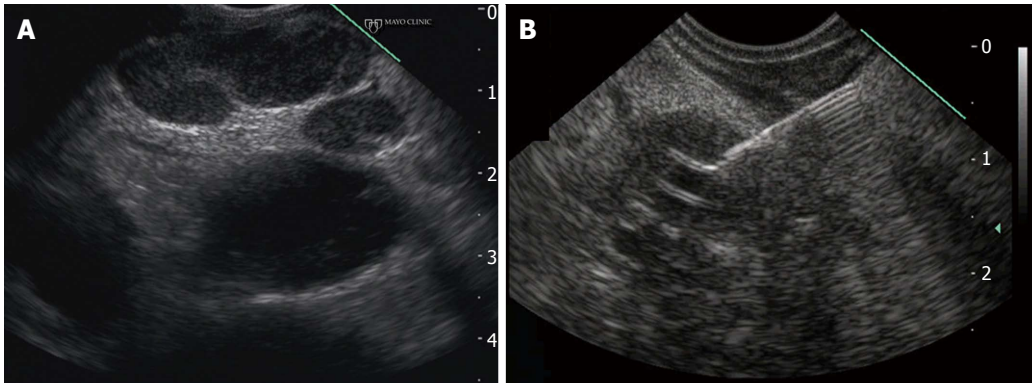

Figure 2 Endoscopic ultrasonographic findings in a patient found to have locally-advanced cholangiocarcinoma. A: Malignant lymphadenopathy; B: Endoscopic ultrasound-guided fine needle aspiration of primary cholangiocarcinoma.

evaluating IDBSs[33]. In a meta-analysis of nine studies including 555 patients, EUS without FNA was found to diagnose a malignant biliary stricture with a sensitivity and specificity of 78% and 84%, respectively[34]. The addition of FNA provides even more encouraging results, as a separate meta-analysis of 9 studies including 284 patients undergoing EUS-FNA demonstrated a sensitivity and specificity of 84% and 100%, respectively[35]. Many of these studies were performed following unsuccessful ERCP diagnosis, thus suggesting the value of EUS-FNA even among this more difficult-to-diagnose cohort.

A factor that appears to influence the sensitivity of EUS-FNA is the location of the stricture: Proximal (intrahepatic or hilar) *vs* distal (extrahepatic). In one study, the sensitivity for distal CCA was significantly higher than that for proximal CCA (81% *vs* 59%)[36]. This is perhaps explained by the greater ease of imaging and sampling of distal lesions as compared to proximal, which may be an important consideration when comparing EUS-FNA to ERCP data. Rösch *et al*[37] found EUS-FNA to be inferior to ERCP in patients with hilar biliary tumors (25% *vs* 75%) but superior for distal malignant strictures (60% *vs* 38%). Another variable that may impact performance of EUS-FNA is the presence of a bile duct stent, which results in acoustic shadowing and may occasionally interfere with sonographic imaging and FNA[38]. However, published data have not found the presence of plastic bile duct stents to lower the yield of EUS-FNA in the evaluation of IDBSs or suspected CCA[39].

A major limitation of EUS-FNA remains the concern for potential seeding of malignant cells along the needle track. This is less problematic for pancreatic head

lesions, as the path of trans-duodenal sampling would be resected during potential subsequent pancreatoduodenectomy. The concern is predominantly for proximal bile duct lesions, which require traversal of the hepatoduodenal ligament portion of the lesser omentum, which may not be resected during potential subsequent surgical intervention. In a series of 191 patients with hilar CCA receiving neoadjuvant chemoradiation followed by liver transplantation, 16 underwent transperitoneal FNA, and of the 6 (38%) that were positive for malignancy, 5 (86%) were later found to have peritoneal metastasis at operative staging *vs* 14/175 (8%) who did not undergo transperitoneal biopsy ($P < 0.01$)[40]. While nearly all patients in this study underwent FNA *via* a percutaneous route, the same concerns exists for EUS-guided FNA. Due to the potential for needle tract seeding, EUS-FNA of a primary bile duct tumor is considered a contraindication to liver transplantation; however, a recent retrospective study showed that preoperative EUS-FNA in patients with CCA did not affect overall or progression-free survival[41]. Until additional studies have further explored this area of uncertainty, biliary specimens to rule out CCA should be acquired intraductally rather than transmurally (*e.g.,* percutaneous or trans-duodenal) if liver transplantation is a consideration.

INTRADUCTAL ULTRASOUND

Intraductal ultrasound (IDUS) employs a thin (2.0-3.1 mm), high frequency (12-30 MHz) wire-guided radial ultrasound probe that is passed through the working channel of a duodenoscope and into the pancreatobiliary system during ERCP. With a radial penetration of 2 cm, IDUS allows for high-resolution characterization of IDBSs. Two to three mural layers are visualized during IDUS: (1) an inner hypoechoic layer representing mucosa, muscularis propria, and the fibrous layer of serosa; (2) an outer hyperechoic layer representing subserosal adipose tissue and serosa; and (3) sometimes an interface layer between bile and the inner hypoechoic layer[42].

IDUS features that have been associated with malignant rather than benign biliary strictures include sonographic disruption of the choledochal wall layers, wall thickening or irregularity, a hypoechoic mass with irregular margins, sessile tumor, infiltration of adjacent tissue or vasculature, or the presence of enlarged lymph nodes[43-45].

The published literature suggests that IDUS, although not often used in routine clinical practice, can be a useful ancillary technique in the evaluation of IDBSs. A retrospective review by Meister *et al*[46] of patients undergoing ERCP with IDUS demonstrated sensitivity as well as specificity of 98%, and a meta-analysis of 5 other studies found that IDUS accuracy for malignancy ranged from 84%-95%. Studies have also demonstrated that adding IDUS to ERCP-guided tissue acquisition improved sensitivity from 41%-68% to 90%-93%[47-49]. Domagk *et al*[50] found a combination of ERCP and IDUS to correctly diagnose malignancy in 88% of patients *vs* 76% and 58% of patients by ERCP alone and MRCP, respectively. Compared to EUS, IDUS has been shown to have greater sensitivity (91% *vs* 76%) and accuracy (89% *vs* 76%) in differentiating a malignant from a benign stricture[51]. IDUS was also found to have superior sensitivity (88% *vs* 63%) and specificity (91% *vs* 53%) in patients with PSC compared to ERCP alone[52].

IDUS, in a single experience reported cancer staging of T1, T2, T3/T4, N0 and N1 to be 84%, 73%, 71%, 69% and 69% accurate, respectively[46]. These results are intriguing; the low accuracy with N staging may be attributable to the limited depth of ultrasonic penetration, which limits IDUS largely to characterizing the mural features of the IDBS[51].

CHOLANGIOSCOPY

Cholangioscopy involves the use of a small-caliber, flexible endoscope to directly inspect the biliary epithelium and facilitate targeted sampling. The cholangioscope (daughter scope) is typically passed either through the working channel of a therapeutic (mother) scope during ERCP (Figure 3) or *via* direct peroral cholangioscopy following endoscopic papillotomy and percutaneous transhepatic cholangioscopy. Early cholangioscopy typically required two skilled endoscopists; this has since evolved to a single endoscopist effort with as-needed nurse assistance. In the last decade, a single-operator cholangioscopy system (SpyGlass Direct Visualization System, Boston Scientific Endoscopy, Marlboro, MA) with capability for 4-way tip deflection, a channel for insertion of a reusable fiberoptic probe, and irrigation and working channels, has been introduced. This system was severely hampered by poor image quality, but recent modifications, including the use of a video chip, has markedly improved image quality. Other cholangioscope options also exist, as alluded to above, but are currently not utilized clinically in the United States[53,54].

Cholangioscopy can help distinguish malignant from benign strictures, particularly *via* examination of epithelial vascular pattern (*e.g.,* irregularly dilated tortuous vessels, *i.e.,* "tumor vessels"), which is 100% specific and 96% sensitive when combined with targeted biopsies[55,56]. The presence of nodules, ulceration, or papillary or villous mucosal projections also suggest malignancy and warrant targeted biopsies[57].

Studies examining direct peroral or percutaneous cholangioscopy with or without biliary mucosal biopsies have demonstrated a sensitivity of 77%-100% and specificity of 79%-100%, with tissue adequacy achieved in 82%-97% of patients[58-63]. Addition of cholangioscopy to ERCP-guided tissue sampling enhances sensitivity for the diagnosis of biliary malignancy. For example, Fukuda *et al*[58] reported the sensitivity and accuracy of ERCP guided cytology and/or forceps biopsy improved from 58% and 78% to 100% and 93%, respectively. In a study by Draganov *et al*[63], sensitivity and accuracy of cytology, forceps biopsy, and cholangioscopy-guided mini-

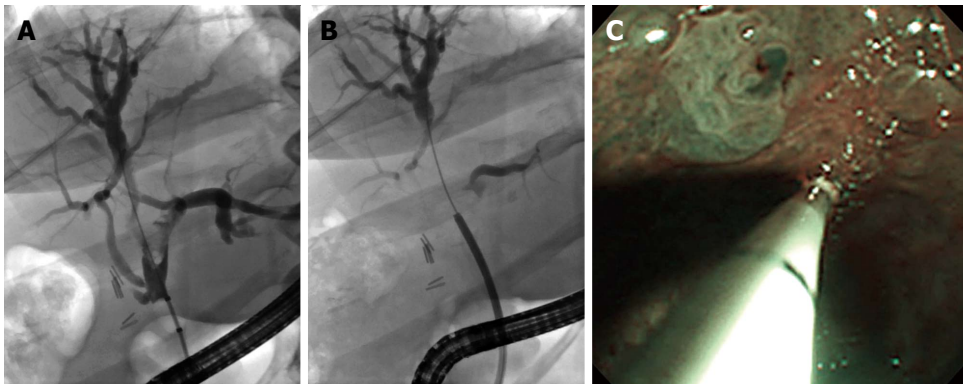

Figure 3 Passage of a SypGlass digital cholangioscope through a therapeutic duodenoscope to better evaluate hilar strictures and filling defects. A: Hilar (primarily right anterior hepatic duct) stricture and filling defects seen during endoscopic retrograde cholangiography pancreatography; B: SypGlass cholangioscope being passed through the working channel of therapeutic duodenoscope to better assess biliary stricturing and filling defects; C: SpyGlass cholangioscopy with narrow band imaging revealing villiform biliary mucosal changes; targeted biopsies were obtained and revealed low grade dysplasia concerning for early cholangiocarcinoma.

forceps biopsy were as follows: 5.8% and 39%, 29% and 54%, and 77% and 85%, respectively; mini-forceps biopsy was significantly more sensitive and accurate than cytology (P = 0.0001) or forceps biopsy (P = 0.0215) alone. Chen *et al*[64] reported the sensitivity and specificity of ERCP, cholangioscopy, and cholangioscopy-directed tissue biopsies to be 51% and 54%, 78% and 82%, and 49% and 98%, respectively, thus demonstrating much greater sensitivity and specificity for cholangioscopy with or without biopsy compared to ERCP alone.

The benefit of cholangioscopy over ERCP in patients with PSC and for distinguishing malignant from benign dominant strictures has also been demonstrated. In a study of 53 patients with PSC and dominant stricture, Tischendorf *et al*[52] used cholangioscopic findings of a polypoid or villous mass or irregularly shaped ulcer to classify malignancy before confirmation with standard tissue acquisition. This cholangioscopic finding provided greater sensitivity (92% *vs* 66%) and specificity (93% *vs* 51%) with a better NPV (97% *vs* 84%) than ERCP alone[52]. Cholangioscopy in the setting of PSC is often severely hampered by the number and severity of biliary stenosis. Cholangioscopy is performed predominantly under water immersion; alternatively, carbon dioxide gas insufflation can be used (predominantly during direct peroral cholangioscopy) and provides a distinctly different appearance to the biliary mucosa. Differences between the two imaging approaches may have individual value, *e.g.,* interpreting subtle surface mucosal change *vs* mucosal surface vascular pattern changes.

Video chip-based cholangioscopes are also equipped with narrow band imaging (NBI) (Figure 3C). NBI is based on the observation that the depth of light penetration depends on wavelength; the longer the wavelength, the deeper the penetration. Standard color video chips provide images based on sequential red-green- and blue illumination. The image is passed directly through selective band filters which highlight the red and blue bands. Blue light penetrates only superficially, whereas red light penetrates into deeper layers. The selective color imaging enhancement highlights mucosal surface detail and more so, mucosal vascular patterns[65-67]. An initial feasibility study involving 21 patients with biliary lesions found visualization of 57% of lesions to be "excellent" using NBI *vs* 9.5% using conventional white-light imaging[68]. A recent, small series of patients with PSC also led to the conclusion that NBI allowed better determination of tumor margins and increased detection of suspicious lesions compared to white-light imaging; the authors could not demonstrate an improved dysplasia detection rate, but this may have been consequent to methodological issues[69].

Relatively few studies have compared the diagnostic yield of cholangioscopy *vs* EUS. In one retrospective series of 66 patients undergoing evaluation of IDBSs with cholangioscopy combined with EUS, sensitivity and specificity for combined modalities was greater than for either modality alone[70]. In another study, 39 patients with negative brush cytology underwent EUS-FNA first and only proceeded to cholangioscopy if EUS was negative; EUS-FNA was diagnostic in 23 patients (58%), and the remainder of the patients required cholangioscopy, thus leading the authors to conclude that cholangioscopy could be reserved for cases where EUS-FNA is nondiagnostic[71].

Potential adverse events of cholangioscopy include pancreatitis, cholangitis, perforation, hemobilia, and sphincterotomy bleeding. A recent retrospective study found that patients undergoing ERCP with cholangioscopy had significantly higher rates of pancreatitis (2.2% *vs* 1.3%), cholangitis (1.0% *vs* 0.2%), and perforation (1.0% *vs* 0.3%) than ERCP alone[72]. However, multivariable analysis did not find cholangioscopy to be associated with an increased rate of adverse events compared to ERCP[73].

CONFOCAL LASER ENDOMICROSCOPY

Confocal laser endomicroscopy (CLE) is an emerging imaging modality that permits high-resolution, *in vivo* assessment of the biliary epithelium. It provides real-time contact imaging at a cellular and sub-cellular

level, offering a lateral resolution of 3.5 μm, optical slice thickness of 30 μm, and optical penetration of 40-70 μm. CLE is based upon the principle of illuminating a tissue with a low-power laser and then detecting reflected fluorescent light. The laser is focused at a specific depth, and only light which is reflected back from that plane is refocused and able to pass through the pinhole confocal aperture; the term "confocal" hence refers to the fact that the reflected light is refocused onto the detection system by the same lens through which the laser light was initially emitted. As a result, scattered light from above and below the plane of interest is not detected, thereby increasing spatial resolution. A focused, scanning light source (*i.e.,* laser) and processor then generate reconstructed grayscale images of the target area, enabling epithelial and subepithelial visualization. Notably, CLE requires administration of intravenous or topical contrast (typically fluorescein) to highlight tissue features and better differentiate normal architecture or inflammatory changes from neoplastic tissue.

A CLE imaging probe (pCLE) can be passed through various ERCP catheters or through the working channel of a cholangioscope. In the first study of pCLE for the evaluation of IDBSs, Meining *et al*[74] reported that the visualization of irregular, dilated ("angiogenic") vessels predicted malignancy with a sensitivity of 83% (compared to 50% for standard histopathology), specificity of 88%, and accuracy of 86% among 14 patients. A subsequent study with 37 patients revealed similar findings[75]. In an effort to more uniformly identify pCLE imaging findings associated with malignancy, a standardized classification system (*i.e.,* Miami classification) was proposed consisting of: (1) the presence of thick, white bands (> 20 pm); (2) thick dark bands (> 40 μm); (3) dark clumps; (4) epithelial structures; and (5) fluorescein leakage[76]. Suggested criteria for benign strictures were: (1) thin, dark (branching) bands; and (2) thin, white bands. In a blinded consensus review that validated this classification schema, combining two or more of the criteria suggestive for malignancy (except fluorescein leakage) provided a sensitivity, specificity, positive predictive value (PPV), and NPV of 97%, 33%, 80%, and 80%, respectively, compared with 48%, 100%, 100%, and 41% for standard tissue acquisition[77]. Interobserver variability was moderate for most of the criteria. A prospective, multicenter study assessing the role of pCLE in the evaluation of 89 patients with IDBSs reported a sensitivity, specificity, PPV, and NPV of 98%, 67%, 71%, and 97% for the detection of malignancy, respectively, compared with 45%, 100%, 100%, and 69% for index pathology[78]. Moreover, when combined with ERCP, pCLE was significantly more accurate than ERCP with tissue acquisition (90% *vs* 73%). Among the subset of patients with PSC, a small retrospective study found that pCLE detected malignancy with a sensitivity, specificity, PPV, and NPV of 100%, 61%, 22.2% and 100%, respectively, compared to 0%, 94.4%, 0% and 89% with standard tissue sampling[79]. Given its high sensitivity and NPV, pCLE may ideally be used to exclude malignancy in this high-risk population. The technique is limited by the need for point contact and by movement. Additional study is needed to optimize image interpretation and to determine the cost benefit.

A limitation of the Miami classification is the suboptimal interobserver agreement. In contrast to the initially reported moderate interobserver variability with most criteria, a subsequent study among 6 experienced endoscopists from 5 institutions reviewed 25 de-identified pCLE video clips of IDBSs and found interobserver agreement for individual criteria to range from poor to fair and for final diagnosis to be slight[80]. Further training and standardization is needed to improve interobserver reliability, as may be expected with most evolving techniques[81].

In an effort to improve the low specificity of pCLE, which has been attributed to inflammatory changes (*e.g.,* chronic inflammation, stent-related changes, previous endoscopic procedures), descriptive criteria (*i.e.,* Paris classification) have recently been proposed[82]. These criteria aim to distinguish benign inflammatory strictures by assessing for vascular congestion, dark glandular patterns, increased interglandular space, and thickened reticular structures, and reportedly have increased the specificity from 64% to 76%[82]. A prospective, multicenter study evaluating 112 patients with IDBSs incorporating the Paris classification found pCLE to be 89% sensitive, 71% specific, and 82% accurate compared with 56%, 100% and 72% with standard tissue sampling alone[83].

OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography (OCT) is analogous to ultrasound but relies on low-intensity infrared light (700 to 1500 nm wavelength range) instead of sound to generate high-resolution, cross-sectional tissue imaging. The delay in time of light back-scattered by the various tissues is measured using a technique known as low coherence interferometry, which has a depth of penetration of 1-3 mm and lateral and axial resolution down to 10 μm. This technology provides much greater spatial resolution than IDUS and, unlike endomicroscopy, does not require contrast administration. OCT achieves visualization of layer architecture similar to histologic sections[84,85]. In doing so, OCT allows visualization of microscopic structures such as blood vessels, lymphoid aggregates, crypts, and submucosal glands and can aid in differentiating malignant from benign tissue in real-time[86-88]. Miniaturization of early OCT probes has enabled insertion into a transparent biliary catheter that can be passed through the working channel of an ERCP scope for biliary cannulation and *in vivo* imaging[89].

OCT has been shown to increase the sensitivity for detecting malignant biliary strictures as compared to biliary brushing cytology alone. Arvanitakis *et al*[90] evaluated 2 OCT criteria, namely unrecognizable layer architecture and presence of large nonreflective areas compatible with tumor vessels, for diagnosing malignant

strictures when compared to the gold standard of tissue acquisition in 35 patients undergoing ERCP for evaluation of IDBSs. Nineteen patients ultimately had malignant strictures, and these 2 OCT criteria were associated with a sensitivity, specificity, PPV, NPV and accuracy of 53%, 100%, 100%, 64% and 74%, respectively. The sensitivity of biliary mucosal brushings and/or biopsy improved from 67% to 84% when at least 1 criterion was added. In another study, the diagnostic utilities of OCT and ERCP-guided brush cytology were compared while evaluating 12 patients with main pancreatic duct stricture. Six patients ultimately had malignancy and OCT demonstrated greater sensitivity (100% *vs* 67%) than cytology while maintaining equal specificity (100%)[91]. OCT, unlike confocal imaging, permits larger surfaces areas to be examined. Improved resolution is paramount. The limited existing data are encouraging, but additional studies are awaited to better define the potential role of OCT in evaluating IBDSs, particularly among patients with high-risk conditions such as PSC.

FUTURE DIRECTIONS

Other technologies may be amenable to use in the evaluation of IDBSs. These include high-resolution endomicroscopy, Raman spectroscopy, EUS elastography, and CLE with chromocholangioscopy or autofluorescence. Each will be challenged by the need for miniaturization and must satisfy value in the face of added cost.

CONCLUSION

IDBSs pose a diagnostic challenge for which more accurate diagnostic tests are critically needed. Although ERCP offers therapeutic options for biliary obstruction, conventional methods of tissue acquisition remain generally insensitive, albeit to a lesser degree with use of advanced cytologic techniques such as FISH. EUS can be of additional benefit in evaluating distal strictures and staging, though concerns remain regarding tumor seeding. IDUS may supplement ERCP and EUS and aid in local staging but, despite its longstanding availability, is seldom employed. Cholangioscopy permits direct visualization and directed sampling; design enhancements may simplify its use and improve performance. Emerging techniques such as pCLE and OCT enable real-time, *in vivo*, endohistologic assessment, but additional study is needed to standardize interpretation, improve inter-rater reliability, and validate performance. The challenges in diagnosis often result in multimodal testing that marginally enhances diagnosis but substantially increases cost. While application of new and innovative technologies is of interest to endoscopists, their use must be tempered by the realization of only marginal improvements in diagnostic sensitivity and frequent decrement in specificity, their potential for adverse events, associated cost, and often limited availability to a small number of diagnostic centers. In addition, more research is needed to determine how to best guide important clinical decisions using these and other established and emerging modalities.

Abstract

Colonoscopy is considered to be the most effective tool for reducing colorectal cancer (CRC) morbidity and mortality. As a result, certifying trainee competence in the performance of colonoscopy is critical to maximizing CRC screening and prevention efforts. Guidelines on training and accreditation around the world have been revised to emphasize the attainment of milestones in the technical and cognitive skills necessary to perform the procedure. To meet this challenge, new evaluation systems have been developed to measure trainee competence through all aspects of colonoscopy training. These changes stem from increased recognition that procedural numbers alone do not necessarily guarantee trainees' proficiency in the performance of colonoscopy. Variability in endoscopic practice and in CRC screening outcomes also point to deficiencies in the current approach towards colonoscopy instruction. However, technological innovations hold great promise in training endoscopists to perform high quality colonoscopy. Furthermore, potential advances in the use of feedback as a training tool provide new avenues for research. This review summarizes the latest evidence on the effort to define, evaluate and promote the achievement of competence in colonoscopy among trainees.

Key words: Competence; Colonoscopy; Colorectal cancer; Core curriculum; Cecal intubation

Core tip: The certification of competence among trainees in the performance of colonoscopy is currently evolving. Recent efforts are shifting the paradigm towards formal evaluation systems that emphasize core skills. Similar innovations in technology and teaching methods provide the push to re-define the future curriculum for colonoscopy training.

INTRODUCTION

The process of determining if medical trainees possess the requisite knowledge and skill to practice the healing arts has played a central role in the evolution of medicine. In the time of the ancient Greeks and Romans, competence was based upon the judgment of the elder physician under whom the trainee served as an apprentice[1]. In 1260, the Mongol Emperor Kublai Khan established the first system of certification based upon the completion of formal written examinations[1]. With the founding of the Royal College of Physicians in London in 1518, a further shift towards formal medical licensure took place with the advent of both written tests and objective assessments of procedural skills[1].

In gastrointestinal endoscopy, the task of certifying competence among trainees is also evolving from an apprenticeship model towards a more objective process based upon the achievement of milestones. With nearly 14.2 million procedures performed in the United States alone[2], colonoscopy represents the most common endoscopic procedure performed by gastroenterologists, surgeons and family practitioners. However, recent studies suggest that the detection of adenomatous polyps and the development of missed interval colorectal cancers (CRCs) may be closely related to the proficiency of the endoscopist[3-5]. Consequently, the process by which trainees are trained and certified to be competent in the performance of colonoscopy has become a high priority.

To approach this vital issue, there are several salient questions to be asked: (1) What is competence; (2) Why does competence matter; (3) How do we determine trainee competence; (4) Do trainees currently attain competence; and (5) How do we help trainees to attain competence.

WHAT IS COMPETENCE?

Competence is defined by the American Society for Gastrointestinal Endoscopy (ASGE) as the "Minimal level of skills, knowledge and/or expertise derived through training and experience that is necessary to safely and proficiently perform a task or procedure"[6]. Competence is determined to be contingent upon: (1) Technical skills to safely perform the procedure; and (2) Cognitive skills to take information gained from a procedure and to place it in the appropriate clinical context[6]. These cognitive and technical skills are further broken down into basic and intermediate competencies (Table 1)[7].

Given that the end-goal of colonoscopy is to reduce CRC-related mortality, competence among trainees can also be defined based upon their ability to surpass quality thresholds. The ASGE defines these benchmarks as: (1) adenoma detection rate (ADR) of $\geqslant$ 30% in male and $\geqslant$ 20% in female patients undergoing average-risk CRC screening; (2) A successful cecal intubation of $\geqslant$ 90% in all colonoscopies and $\geqslant$ 95% for screening colonoscopy; (3) the successful removal of polyps < 2 cm in size; and (4) A colonoscopy withdrawal time of > 6 min[8]. In the United Kingdom, the Joint Advisory Group (JAG) on gastrointestinal (GI) endoscopy requires: (1) Cecal intubation rate of > 90%; (2) > 90% of rate of completing procedures without assistance; (3) Attendance at a basic skills colonoscopy course; and (4) Procedure total of $\geqslant$ 200[9].

WHY DOES COMPETENCE MATTER?

While the answer to this question may seem largely self-evident, the process of certification is salient to many potential interests regarding colonoscopy. First and foremost, endoscopist competence has been shown to have a significant impact on the effectiveness of colonoscopy in detecting and preventing CRC. Baxter *et al*[4] recently questioned the long-standing assumption that colonoscopy decreases CRC-related morbidity and mortality when they demonstrated that the procedure was not protective for right-sided CRC (OR = 0.99, 95%CI: 0.86-1.14). To potentially explain this observation, Singh *et al*[10] in a large population based study in Manitoba, Canada found that colonoscopy with polypectomy, cecal intubation failure and procedures performed by family practitioners were associated with the development of interval CRC within 3 years of an index colonoscopy. This raises the prospect that low levels of competence in polypectomy, cecal intubation and endoscopic training limit the effectiveness of colonoscopy. Furthermore, Kaminski *et al*[11] found that endoscopists with a mean ADR of < 11% had a cumulative hazard rate for the development of interval CRC of 10.94 (95%CI: 1.37-87.01) when compared with physicians who had an ADR of > 20%. A similar study by Corley *et al*[12], found that physicians who increased their ADR from the lowest quintile to the highest quintile prevented 1 interval CRC over the course of 10 years. Furthermore, they found that every 1.0% increase in ADR predicted a 3.0% decrease in the risk of interval cancer (HR = 0.97; 95%CI: 0.96-0.98)[12]. Given that ADR is one of the primary benchmarks for both competence and quality in colonoscopy, it is clear that the process of determining endoscopist proficiency plays a pivotal role in the effort to improve CRC prevention.

Finally, the issue of establishing competence among trainees is important because of recent studies that demonstrate that physician behavior is difficult to alter once an endoscopist is no longer a trainee. Sawhney *et al*[13] found that an institutional mandate to achieve a minimum withdrawal time (time spent from cecal intubation to removal of the colonoscope from the anus) among 42 attending endoscopists failed to produce any significant change in polyp detection rate (PDR). Lin *et al*[14] performed a similar study where they provided periodic feedback of patient satisfaction scores, average withdrawal time, and PDR every 3-6 mo to 10 attending gastroenterologists who were at least 8 years removed from training. One year after the implementation of this feedback mechanism, there was no significant increase

Table 1 American Society for Gastrointestinal Endoscopy Core Curriculum list of core motor and cognitive skills required to be competent in colonoscopy[7]

Motor	Cognitive
Correctly holding the colonoscope	Anatomy
Use of the colonoscopy controls	Patient selection
Colonoscope insertion	Preparation
Colonoscope advancement	Colonoscope selection
Tip control	Informed consent
Torque	Sedation management
Lumen identification	Assessment of indication and risks
Withdrawal/mucosal inspection	Pathology identification
Loop reduction	Therapeutic device settings
Angulated turns	Integration of findings into management plans
Terminal ileum intubation	Report generation and communication
Biopsy	Complication management
Snare polypectomy	Quality improvement
	Professionalism

in either PDR (33.1% *vs* 38.1%, P = 0.04) or ADR (19.6% *vs* 22.7%, P = 0.17)[14]. These observations highlight the potential value of establishing good practices early on in the career of an endoscopist.

HOW DO WE DETERMINE TRAINEE COMPETENCE?

Traditionally, credentialing guidelines have focused primarily on the number of colonoscopies performed to determine procedural competence. In a small study of 7 trainees (4 GI fellows, and 3 surgical residents), Freeman *et al*[15] defined competence based upon independent cecal intubation. They found that trainees were able to intubate the cecum without assistance only 80% of the time after the first 50 procedures and consequently concluded that > 100 cases were likely required to achieve a 90% success rate. Using a cecal intubation time of < 15 min, a cecal intubation rate > 90%, and a 6-point technical skill score as a measure of competence, Chak *et al*[16] found that trainees did not achieve an attending-level of proficiency in colonoscopy even after 120 procedures were performed. These observations form the basis for the Accreditation Council for Graduate Medical Education (ACGME) and ASGE recommendation that a trainee perform a minimum of 140 cases before competency can be assessed in colonoscopy[6,17]. The European Board of Gastroenterology, the Canadian Association of Gastroenterology and the Conjoint Committee for the Recognition of Training in Gastrointestinal Endoscopy in Australia however use the 100 case threshold[18-20]. In the United Kingdom, JAG guidelines recommend a higher threshold (200 independently completed colonoscopies)[9].

Recently, several studies have highlighted the fact that these numbers represent a minimal threshold for competence and that procedural numbers by themselves do not guarantee trainee proficiency. In a large study involving 15 tertiary care centers in South Korea, Lee *et al*[21] found that trainees were able to independently intubate the cecum > 90% of the time, and attain a cecal intubation time of < 20 min only after > 150 procedures were performed. Spier *et al*[22] defined competence as the point at which trainees were able to perform all aspects of colonoscopy (cecal intubation, polypectomy, hemostasis) without the aid of an attending > 90% of the time. Using this definition, the investigators found that all of the 11 GI fellows studied attained these objectives by 500 cases but none attained that goal by the 140 case threshold set by the ASGE/ACGME guidelines[22]. And in a multicenter study[23] of 7 first-year GI fellows at two separate training programs, our own group sought to determine the threshold number of cases at which trainees were able to achieve: (1) Independent cecal intubation rate of $\geqslant$ 90%; (2) Independent ADR of $\geqslant$ 25%; (3) Mean withdrawal time $\geqslant$ 6 min; and (4) Ability to successfully remove polyps without the aid of the attending $\geqslant$ 95% of the time. This study was unique in that nurses were asked to judge whether each of the skills (adenoma detection and removal, cecal intubation) were performed by the fellow without significant assistance by the attending. Consequently, trainees were given credit for adenoma detection only if the adenoma was determined to be independently detected and removed by the trainee in the opinion of the endoscopy nurse. Using these criteria, we found that trainees achieved all of the quality benchmarks only when 201-250 procedures were performed[23].

Recognizing the inherent shortcomings in assigning competence solely based upon procedural numbers, recent efforts have focused on developing evaluation systems that assess both the technical and cognitive skills necessary to perform colonoscopy. In the United Kingdom, the JAG group has developed the Direct Observation of Procedural Skills (DOPS) evaluation for colonoscopy as part of a national system of accreditation for GI trainees[24]. Using a 4 point scoring system ranging from 1-Accepted standards not yet met; frequent errors uncorrected to 4-highly skilled performance, assessors are tasked with grading trainees on both diagnostic and therapeutic skills in colonoscopy. In a study of 111 attending endoscopists, Barton *et al*[24] demonstrated that DOPS had good relative reliability (G = 0.81) and a good correlation with a questionnaire that assessed candidates' knowledge. While the value of DOPS as a method for determining trainee competence is yet to be validated, current JAG guidelines require a total of 10 DOPS evaluations with > 90% of them having no score less than 3 for any given skill. A similar scoring system known as the Direct Observation of Polypectomy Skills (DOPyS) has also been developed by JAG to determine competence in polyp removal using the same four point rating scale with scores of 1-2 considered as failing grades[25]. In a study by Gupta *et al*[25], DOPyS was found to have discriminatory value in differentiating experienced endoscopists with > 1000 procedures from GI trainees who had limited experience in therapeutic

colonoscopy. The added advantage of the DOPyS rating system is that it has been validated to be applied towards video-recordings of procedures.

In the United States, Sedlack[26] have made significant strides in the development of a comprehensive evaluation system for determining trainee competence with the advent of the mayo colonoscopy skills assessment tool (MCSAT). Using a rating system of 1 (Novice) to 4 (Superior), the MCSAT evaluates trainees during live cases[26]. Trainees are assessed in terms of cognitive skills such as knowledge of indication for procedure, use of initial sedation, landmark localization, and pathology identification. They are also are evaluated on procedural abilities such as safe endoscope advancement techniques, loop reduction, mucosal visualization during withdrawal, and polypectomy. In a large study of 41 GI fellows who were evaluated during 4103 procedures, the investigators determined that a mean score of $\geqslant$ 3.5 in all MCSAT parameters along with a cecal intubation rate of 85% and a mean cecal intubation time of less than 16 min best distinguished experienced endoscopists from trainees who had not yet met minimal competence thresholds[27]. Furthermore, they found that GI fellows did not reach these goals until 275 procedures were performed[27]. Because of this work, the most recent ASGE Core Curriculum has endorsed using the MCSAT as a tool for competency assessment throughout colonoscopy training[7].

DO TRAINEES CURRENTLY ATTAIN COMPETENCE?

While there are no formal studies outlining the characteristics of colonoscopy training among Gastroenterology, Surgery and Family Practice programs, it is highly probable that a large degree of variability exists in the educational approaches taken towards teaching trainees how to perform the procedure. Teaching strategies likely vary with the "See one, do one, teach one" approach on one end of the educational spectrum and more didactic and hands-on instruction by an experienced endoscopist on the other. This heterogeneity in training is highlighted by studies that compare GI trainees and surgical residents in achieving benchmarks in quality colonoscopy. In a study of 7 GI fellows and 6 surgical residents, Leyden *et al*[28] found that surgical trainees had lower cecal intubation rates (84% *vs* 93%, $P < 0.0001$), polyp detection rates (14% *vs* 21%, $P < 0.0001$) and ADR (9% *vs* 14%, $P = 0.0065$). A similar study by Spier *et al*[29] found that surgical residents only had a cecal intubation rate of 47% after a mean of 80 procedures were performed.

Even among trainees in recognized GI fellowship programs, recent studies point to potential deficiencies in the approach towards teaching colonoscopy. In an innovative tandem colonoscopy among procedures performed by GI fellows, Munroe *et al*[30] found an overall adenoma miss rate of 27%. Furthermore, the investigators found that there was a 2.2 fold decrease in the risk of missing an adenoma with each 10 fold increase in trainee experience[30]. Thus, to attain a less than 25% adenoma miss rate, a trainee would have to perform 450 procedures, a number that many GI fellows and certainly most surgical and family practice trainees may never reach in the course of training. One potential explanation for this finding is a failure to fully incorporate quality guidelines into the educational curriculum on the part of many training programs[30]. In an online survey on quality guidelines for colonoscopy, GI fellows received a mean score of 55% correct, with only 42% identifying the correct cecal intubation rate goal and 44% indicating the correct ADR benchmark[31].

Finally, feedback from GI trainees themselves highlight the need for improvements in colonoscopy instruction. In a survey of 169 GI trainees in the United Kingdom, Wells *et al*[32] found that only 36% felt that they were "fully" trained in colonoscopy. Furthermore, the respondents estimated than an attending was in the room to provide supervision in only 30% of colonoscopies that were performed[32]. Trainees also cited important aspects of effective teaching which included: (1) Close interaction with a supervisor who has good teaching skills; (2) Systematic approach towards endoscopic techniques; (3) Excellent supervision and discussion-based training; (4) Attendance of a course on quality colonoscopy; and (5) Smaller procedure schedules to allow for training time[32]. These comments point to the need for reforming our current approach toward teaching colonoscopy.

HOW DO WE HELP TRAINEES ATTAIN COMPETENCE?

Advances in both technology and teaching methods clearly point the way towards a new curriculum that is based upon establishing competence in colonoscopy. From a technological standpoint, innovations in simulation present new avenues for trainees to develop and hone cognitive and technical skills away from the time pressures and risks of performing procedures on live patients. Current simulators consist of a mannequin and a modified colonoscope with pressure sensors which mimic the resistance felt with scope advancement and loop formation. Trainers are able to assign specific modules to trainees on the simulators ranging from basic lessons meant to establish hand-eye coordination skills to more realistic scenarios in which full cases are performed on simulated patients.

Several randomized controlled trials have demonstrated a potential benefit to the use of simulation during the early phase of colonoscopy training. Cohen *et al*[33] compared simulation (Simbionix GI Mentor, Simbionix Corporation, Cleveland, Ohio) *vs* non-simulation trained GI fellows in terms of competence measures on colonoscopies performed on live patients. In particular they looked at subjective (rating scale of 1-5 on the part of the trainer) and objective measures such as successful cecal intubation and the ability to correctly identify

Table 2 Median performance scores (25%-75% interquartile range) on live-patient procedures among fellows trained on colonoscopy simulator *vs* trainees with bedside training alone[34]

Fellow performance parameters	Simulator fellow (n = 462)	Traditional teaching (n = 423)	P value
Time to reach maximum insertion (min)	20.0 (14.0-25.0)	20.0 (15.0-29.8)	0.170
Median depth of unassisted insertion (1 = rectum, 6 = terminal ileum)	5.0 (4.0-6.0)	5.0 (4.0-5.0)	0.002
% of colonoscopies completed independently	64.1% (59.7-68.5)	56.3% (51.6-61.0)	0.018
Identifies landmarks (1 = strongly disagree, 7 = strongly agree)	7.0 (6.0-7.0)	6.0 (6.0-7.0)	0.003
Inserts in a safe manner (1 = strongly disagree, 7 = strongly agree)	7.0 (6.0-7.0)	7.0 (6.0-7.0)	0.020
Adequately visualizes mucosa during withdrawal	7.0 (6.0-7.0)	6.0 (6.0-7.0)	0.009
Responds appropriately to patient discomfort	7.0 (6.0-7.0)	6.0 (6.0-7.0)	0.255

cecal landmarks[33]. During the first 80 live cases, the simulator-trained group had higher objective and subjective levels of competence[33]. However after 120 cases, the advantage found with simulation was no longer present and both groups still required a total of 160 live cases to attain 90% competence[33]. In a similar study by Sedlack *et al*[34], GI fellows who received training using the AccuTouch Colonoscopy Simulator (Immersion Medical, Gaithersburg, MD) scored better on all performance measures (Table 2) except for cecal intubation time when compared with trainees who received just bedside instruction on live patients. However, the differences between the two groups also dissipated once greater than 30 procedures were performed[34]. The positive impact of simulation during the early phases of colonoscopy instruction is well summarized in a meta-analysis by Walsh *et al*[35] who found that there was a significant benefit when simulator-based training was compared to no-training at the beginning of fellowship. In contrast, the advantage of simulator-based training was less pronounced when it was pitted against usual training on live patients[35].

Along with simulation, recent advances in technologies designed to be used during live-cases also hold promise in helping trainees to achieve competency in colonoscopy. During training, the formation and reduction of loops that occur with scope advancement represent one of the most important skills that a trainee must acquire in order to safely perform colonoscopy. To assist in this task, magnetic endoscope imaging (MEI) has been developed to provide trainees with a real-time view of scope positioning. With the ScopeGuide (Olympus Corporation, Tokyo, Japan) MEI system, coils embedded within the colonoscope generate an electromagnetic field which is detected by an external receiver dish producing a 3-dimensional image of the location of the colonoscope[36]. In a randomized controlled trial comparing MEI assisted *vs* standard colonoscopy Shah *et al*[37] found that trainees who performed with MEI had a shorter duration of loop formation (median 3 min *vs* 5.4 min, P = 0.0049) and a fewer number of loop straightening attempts (5 *vs* 12, P = 0.0002). In a similar study of trainees who had experience of fewer than 200 procedures, Holme *et al*[36] observed a higher rate of cecal intubation (77.8% *vs* 56%, P = 0.022) and a lower percentage of cases which required attending assistance (18.5% *vs* 40%, P = 0.018) in the MEI group. Thus, MEI may provide a useful role in colonoscopy training if it aids trainees in acquiring the feedback response for recognizing loop formation.

Water immersion colonoscopy also represents another more readily available modality which may assist trainees in their development of procedural competence. In the early stages of training, novices often have difficulty in discerning the direction of the lumen and as a result this leads to prolonged cecal intubation time, the excessive insufflation of air into the colon, looping of the colonoscope and patient discomfort. Addressing these issues, the water immersion technique refined by Leung *et al*[38] involves filling the colonic lumen with room temperature or warm water using a pump connected to the colonoscope. The air pump is turned off during the intubation phase and 30-60 cc of water is instead used to open the collapsed lumen[38]. In a randomized controlled trial by Leung *et al*[39], trainees who used water immersion had shorter cecal intubation times (13 min *vs* 20.5 min, P = 0.0001), lower mean doses of midazolam (mean dose 2.41 mg *vs* 2.9 mg, P = 0.001) and Fentanyl (mean dose 37.9 mcg *vs* 71.7 mcg, P = 0.002) than those who utilized standard air insufflation. More importantly, a recent meta-analysis found that water immersion resulted in higher ADR (RR = 1.16, 95%CI: 1.04-1.30, P = 0.007) and would lead to an additional 68000 colonoscopies in the United States where an adenoma is detected[40].

Along with water immersion, hood-assisted colonoscopy may also aid trainees in determining the direction of the lumen with scope insertion. Because novice endoscopists often have poor control of scope movement and directionality, a significant amount of time is spent with a "redded-out" image because the scope tip is stuck against the colonic wall[41]. This leads to prolonged scope insertion time and excessive air insufflation. A transparent hood that is attached to the instrument tip may help with this problem by maintaining a proper distance between the colonoscope camera and the colonic mucosa. Furthermore, the hood may assist in mucosal inspection and polyp detection upon withdrawal since it helps with depressing and exposing colonic folds. In a randomized trial of hood colonoscopy *vs* standard colonoscopy among Italian trainees, the hood group was found to have a shorter cecal intubation time (4.4 ± 1.8

vs 7.3 ± 3.5, $P < 0.01$), and a higher rate of detecting polyps 5 mm-1 cm in size (72% *vs* 44%, $P = 0.01$)[41]. A similar randomized controlled trial in Japan, found that trainees had a higher cecal intubation rate (60.7% *vs* 37.4%, $P = 0.003$) among female patients and a 17% reduction in cecal intubation time when hood-assisted colonoscopy was used[42]. Consequently, hood-assisted colonoscopy and water immersion both hold promise as future techniques in colonoscopy training if they assist trainees in the sustained acquisition of skills in luminal orientation, safe scope advancement and polyp detection.

While technology may prove to be important in shaping the future of colonoscopy instruction, the role of feedback will remain the central foundation of the colonoscopy core curriculum. The ASGE Training Committee guidelines recommend that: "Regardless of the method ultimately used, it is recommended that some form of continuous assessment be performed and the results used ideally in a formative manner- to give feedback to trainees in areas where further work may be needed-and a summative assessment of skills that can be used for competency assessment"[7].

Despite this directive, the utility of assessment and feedback as teaching tools in colonoscopy remains poorly understood. Koch *et al*[43] developed a self-assessment form (Rotterdam Assessment Form) which asked trainees to rate their own performance after completion of individual procedures. The form consisted of objective data including successful cecal intubation, cecal intubation time, and the amount of time spent without attending assistance along with a subjective rating of various colonoscopy skills using a visual analogue scale and an action plan for improvement[43]. After the implementation of this self-evaluation system, the cecal intubation rate improved from 65% after the first 20 procedures to 85% at 200 procedures ($P < 0.001$)[43]. Cecal intubation time also improved from 13 min, 10 s at 20 procedures to 8 min 30 s after completion of 200 colonoscopies[43]. However, even with these results, it remains largely unclear if the self-evaluation system resulted in an actual improvement on the normal rate of skills acquisition or improvements in polyp detection that one would see in the regular course of training.

While the clinical evidence for using feedback as a training tool in colonoscopy remains limited, this area provides fertile ground for future research endeavors. In a study by Rex *et al*[44] the act of video-recording individual colonoscopies resulted in a 49% improvement in mucosal inspection time and a 31% improvement in withdrawal technique among experienced endoscopists. Relying upon the concept of the Hawthorne effect whereby subjects improve or modify their behavior in response to the fact that they are being studied[45], it is certainly possible that video-recordings can be used to improve technical and cognitive performance among trainees. Furthermore, the addition of the MCSAT to the colonoscopy core curriculum also affords the opportunity to use continuous feedback of competency scores and comparisons with the group average to assist novices in identifying areas that require improvement. Finally, the current JAG certification process also requires trainees to provide a formal assessment of the trainers' performance during individual procedures. Similar "train the trainer" measures that seek to improve the quality of colonoscopy instruction are vitally important from both research and educational standpoints.

CONCLUSION

While the process of certifying competence has clearly evolved away from the apprenticeship model of medical training, the future shape of colonoscopy instruction remains to be determined. With the increasing emphasis on quality benchmarks and recent data questioning the pre-eminent role of colonoscopy in CRC screening due to variability in endoscopic practice, the task of evaluating and teaching competence remains as important as ever. The movement away from concentrating on procedural numbers and towards the attainment of milestones in the development of cognitive and technical skills represents a significant shift in determining competence in colonoscopy. As first steps in this evolution, the MCSAT and the DOPS evaluation systems standout as significant contributions to the process of re-defining the core curriculum. Whether the solution lies in better technology or a feedback-based system of procedural instruction, the approach towards educating trainees will need to adapt to a curriculum that rightfully emphasizes the importance of quality colonoscopy.

Abstract

Recent advancements in virtual reality graphics and models have allowed virtual reality simulators to be incorporated into a variety of endoscopic training programmes. Use of virtual reality simulators in training programmes is thought to improve skill acquisition amongst trainees which is reflected in improved patient comfort and safety. Several studies have already been carried out to ascertain the impact that usage of virtual reality simulators may have upon trainee learning curves and how this may translate to patient comfort. This article reviews the available literature in this area of medical education which is particularly relevant to all parties involved in endoscopy training and curriculum development. Assessment of the available evidence for an optimal exposure time with virtual reality simulators and the long-term benefits of their use are also discussed.

Key words: Virtual reality; Colonoscopy; Sigmoidoscopy; Endoscopy; Endoscopic ultrasound; Medical education; Endoscopic retrograde cholangio-pancreatography; Gastroscopy; Simulation

Core tip: There is good evidence for the use of virtual reality simulation in endoscopy training programmes, with most benefit seen amongst novice trainees. More research is needed concerning the best integration of simulators within a training programme and the optimal exposure needed. Findings are limited by the variety of simulators used and limited power of the studies. More evidence is also needed to support the benefits virtual reality simulators may have within endoscopic ultrasound and endoscopic retrograde cholangio-pancreatography training programmes.

INTRODUCTION

Endoscopy training and skill acquisition conventionally involves observation and feedback on a trainee's performance under the supervision of an experienced endoscopist. This applies to traditional training in a variety of procedures, including oesophagogastroduodenoscopy (OGD), endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasound (EUS) and colonoscopy. More recently, a variety of alternative educational tools have become available that aim to improve trainees' endoscopy skills.

Virtual reality (VR) simulators are an educational modality that has been purposely developed to facilitate endoscopy training in a controlled environment. With improving graphics and technology, medical simulation has advanced from basic mechanical models or animal models to screen-based simulators. Their use and incorporation into endoscopy training curricula has been thought to enhance the speed of trainee skill acquisition, thus improving patients' comfort and safety during candidates' initial phase of learning[1].

This review article aims to evaluate existing evidence on the role of VR simulation in endoscopy training, identify if there is an evidence-based educationally optimal method of incorporating such simulators within endoscopy training programmes and to review the impact that VR simulator training may have upon patient comfort. This article will focus on the impact of virtual reality simulator training for the most common endoscopy modalities, namely OGD, ERCP, EUS and colonoscopy.

LITERATURE STUDY

An extensive bibliographical search was performed *via* the online databases MEDLINE and EMBASE using the following keywords: Simulation, simulator, virtual reality, endoscopy, gastroscopy, OGD, colonoscopy, sigmoidoscopy, endoscopic retrograde cholangio-pancreatography, ERCP, endoscopic ultrasound, EUS. Some of these terms (simulation, simulator, virtual reality), which were relating to simulation, were searched in combination with the remaining keywords, which were relating to endoscopy (*e.g.,* "simulation and endoscopy", "simulation and colonoscopy", "virtual reality and gastroscopy", *etc.*), in order to identify all relevant papers investigating the role of virtual reality simulation in endoscopy training. The results were combined before duplicates were removed and the reference lists from the selected studies were manually examined to identify further relevant reports.

All primary research papers published in full from any year of publication were considered for inclusion in this review, regardless of their design. These papers included internationally conducted studies, but only those written or translated into English were included in the full text assessment. The participants of studies considered in this review ranged from physicians, nurses and medical students and the individuals' endoscopy experience was not taken into account in screening for studies. The intervention sought was that of VR endoscopy against traditional patient-based training methods or where there was no comparison at all.

Screening of these results removed papers which did not have an educational impact focus, as well as discussion papers, in which the title and abstract aimed to legitimise VR simulators (in comparison to traditional training) solely by expert opinion. Papers that included non-VR educational simulators which involved *ex-vivo* parts or mechanical models were also excluded. This demonstrated that a subset of 24 articles were relevant for this review (Figure 1).

RESULTS

Role of VR simulation in OGD training

Table 1 shows the methodology of the eight studies that were included.

Regarding the role of VR simulators in OGD training the available evidence demonstrates that screen-based simulators have a useful role in facilitating training of novice candidates in OGD[2-7], and potentially a place in the continued professional development of more experienced trainees[2,6,8].

Multiple studies have shown that novice trainees who underwent training that included a VR simulator had significantly better performance outcomes than candidates who were traditionally trained in OGD[3-5,7] and Table 2 summarises the various outcomes of studies investigating the role of VR simulation in OGD training. Ferlitsch *et al*[7] furthered support for early use of the VR simulators by showing that there was a continued significant difference in VR simulator-trained candidates' timing, diagnostic and technical accuracy at 60 d. The only study to report a negative outcome comparing simulator training against traditional training stated that the incidence of pain was reported as higher amongst those who used the simulator[9].

Another study showed that a significant proportion of trainees who utilised VR simulators felt that simulator practice would be most useful in early training, with those who were more advanced reporting that some of the modules were not very realistic for their stage of training[6].

Role of VR simulation in ERCP training

Although there have been several studies looking into the role of simulation in ERCP training, the majority of these have used mechanical models and only one has focused on the role of VR simulation. This study enrolled novice and expert endoscopists and aimed to determine the construct and face validity of the simulator. It concluded that the GI Mentor Ⅱ simulator was both realistic and able to differentiate novices and experts based on their performance. In addition, most participants considered it a helpful training tool[10]. Table 3 provides a summary of the design and outcomes of

this study.

Role of VR simulation in EUS training

Only one study could be found that discusses the role of VR simulation in EUS training[11]. Eight experts compared an EUS VR simulator (EUS Mentor) to an animal model, a phantom (EUS FNA box) and a combination model and ranked them by realism, utility as an educational modality, ease of use and ease of incorporation into a training programme. They determined the phantom model to be easiest to use and incorporate into training, whereas animal models were marked as best for realism and utility as an educational tool[11].

Role of VR simulation in colonoscopy training

Table 4 shows the methodology of the thirteen studies that were included.

In assessing the role of VR simulators in colonoscopy training there is more evidence to support its use in training programmes[12-21]. In one survey, 91% of all participating candidates agreed that VR simulators would be useful in their training[12]. Several studies demonstrated that when VR simulator training was compared to traditional colonoscopy training alone, competency parameters were significantly greater amongst simulator trained candidates[13,15-18,20]. The majority of these studies adopted the same methodology, utilising the VR simulator model before candidates started traditional training, which supports the use of VR simulators in this way.

Some studies attempted to determine the amount of exposure with the simulator which is necessary to acquire an "expert" skill base - determined when learning curves plateaued on the simulator modules. While one study reported that the learning curve of novice candidates plateaued on the seventh consecutive attempt[22], another stated that learning curves consistently plateaued at or after the ninth attempt amongst novice candidates[23]. In a separate study which compared learning curves between novice residents and nurses with varying experience in endoscopy the learning curve

Table 2 Results of studies evaluating the role of simulation in oesophagogastroduodenoscopy training

Ref.	Primary outcome	Secondary outcome
Bloom *et al*[6]	Mean time to complete procedure was 224 ± 27.65 s for novice, 171.22 ± 25.43 s for intermediate and 106.40 ± 13.08 s for experienced candidates (P = 0.008) The study demonstrated the construct validity of the simulator	Mean percentage of total surface visualised was 60.56 ± 2.56 for novice, 66.56 ± 2.80 for intermediate and 72.10 ± 0.23 for experienced candidates (P = 0.005) Questionnaire responses suggested that novice and intermediate candidates considered VR simulation an important training tool
Clark *et al*[2]	Efficiency scores (total time to complete procedure divided by percentage of mucosal surface examined) of senior residents were higher than those of junior residents (85% *vs* 59%) demonstrating improved efficiency with continued use of simulator	
Di Giulio *et al*[4]	The simulator-trained group performed a higher number of complete procedures (87.8% *vs* 70%, P < 0.0001) and needed less assistance (41.3% *vs* 97.9%, P < 0.0001) compared to control group. Length of procedure was similar in the two groups	Instructor marked performance as positive more frequently in the simulator-trained group compared to the controls (86.8% *vs* 56.7%, P < 0.0001)
Ferlitsch *et al*[7]	Performance of expert candidates (compared to novices) was better in performance of J-manoeuvre during oesophagogastroduodenoscopy (P < 0.005), complications at colonoscopy (P < 0.02), insertion time (P < 0.001), identification of abnormal findings in gastroscopy and colonoscopy (P < 0.02) and skill performance (P < 0.01). Amongst novices, the simulation-trained group had a better performance compared to the controls in relation to complication rates at virtual endoscopy (P < 0.04), the insertion time during colonoscopy (P < 0.03) and skill performance (P < 0.01)	
Ferlitsch *et al*[3]	The simulation-trained group performed better than the control group in terms of time needed to reach the duodenum [239 s (range 50-620) *vs* 310 s (110-720), P < 0.0001] and technical ability (P < 0.02) in the first ten endoscopic examinations on patients. Diagnostic ability was similar in the two groups After 60 endoscopic examinations, investigation time was still less in the simulation-trained group. Technical and diagnostic ability improved during on-patient training in both groups and differences between groups were no longer seen at that stage	There were no significant differences in pain scores between the groups after 10 and after 60 endoscopies
Sedlack[9]	The control group performed better than the simulation-trained group in terms of patient discomfort (5; IQR, 4-6 *vs* 6; IQR, 5-6; P = 0.015), sedation, independence and competence scores	
Shirai *et al*[5]	The simulator-trained group achieved significantly higher scores than the control group in the following skills: oesophageal intubation, passing from the EGJ to the antrum, pyloric intubation, and examination of the duodenum and the fundus	
Van Sickle *et al*[8]	The study group showed an improvement in endoscopic skills (*e.g.*, Global Assessment of Gastrointestinal Endoscopic Skills scores) after 8 wk of VR simulation training

did not plateau in any group by the tenth attempt[21].

In addition, several studies evaluated the effect of VR simulation training on patient discomfort. Most studies found that this was less during the procedure in simulator trained candidates[13,14,18], but few concluded that there was no significant difference between the two groups[15,24].

Better evidence that simulator training has effective translational skills can be identified by the long-term impact that simulator training has on a candidate's skill base. It has been shown that a simulator trained candidate retains a significant advantage in competence during their first 100 colonoscopies[15] and that these skills are maintained 9 mo after the simulator intervention[19].

Such concordance advocates strong support for the use of simulators in endoscopy training. However, it is important to note the findings in Gerson *et al*[24] which

Table 4 Summary of analysed colonoscopy studies and their design

is the only reported study to find that simulator-based training was inferior to traditional teaching methods. It concluded that simulator candidates had significantly greater difficulty with insertion of the endoscope, a lower ability to reach the splenic flexure and a lower ability for accurate retroflexion, but these findings were not replicated in other studies.

DISCUSSION

This review evaluated the evidence on the use of VR simulation endoscopy training in order to determine its role within modern educational programmes. The skill base acquired during VR simulation-supported training seems to translate into useable skills for patient-based endoscopy. In addition, learning is facilitated and skills acquisition is more effective compared to training with traditional methods alone. This applies to training in OGD (where the evidence was strongest in those who had least experience in OGD), colonoscopy and ERCP despite the small volume of literature available on this topic. There is no strong evidence for the impact of EUS VR simulator use in novice candidates when compared to traditionally trained candidates.

Integration of VR simulation in endoscopy training curricula

Our literature review did not reveal a single optimal method of integrating VR simulator use in endoscopy training programmes. This is in part due to the variety of exposures candidates had with VR simulators within each study. Whilst the majority of studies controlled candidates to a one-time formal exposure with the VR simulator[2-5,14] others allowed unlimited access[8] or optional extra-access[7,15]. The timing of this controlled exposure also varied with some being integrated

within a structured training programme[14] and some randomly during a participant's training. Despite the varied integration within the education programme, study findings were in support of VR simulator use, but further research is needed to show which approach is most effective. The main issue with the available studies is that there are significant differences in their design, in terms of sample size, candidates' prior endoscopic experience, tasks included (*e.g.,* some studies included therapeutic interventions or biopsies of specific lesions as additional tasks[2,6]), training time span, type of training (*e.g.,* some studies included hard-eye co-ordination modules, such as Endobubble/Endobasket, as well as virtual endoscopies[7,14], whereas other studies included virtual endoscopies alone[13]). These differences make comparisons between studies difficult, but there was general agreement in the literature that VR simulation training was effective in improving trainees' endoscopic skills. Therefore, despite differences in the specific interventions and differences in the endpoints of the various studies, the fact that there was an overall trend suggesting an improvement in skill level was sufficient in this review and suggests that institutions can flexibly integrate VR simulation in their endoscopy training curricula.

Optimal exposure to VR simulation

Debate still exists about the optimal exposure time needed with the VR simulator, as this was not apparent within this review. Even within those studies that controlled the exposure within a formalised teaching setting, the time which candidates had with the VR simulator varied from 5-10 h[3,5,7,22], whilst only one study stated that 20 h of exposure was needed on average to reach an expert criteria within colonoscopy[13]. However, its findings were not supported by others and more research is needed to determine the length of exposure needed with the VR simulator. There may be several explanations for the differences in the length of exposure required to achieve an improvement in performance, such as differences in the level of experience of participants, differences in simulator types, differences in the tasks (*e.g.,* some studies included therapeutic interventions or biopsies of specific lesions as additional tasks[2,6]) and collateral learning (*e.g.,* some studies included bedside teaching, educational videos or didactic modules, in addition to VR simulation practice as the main intervention[5,6,24]).

Long-term benefits of VR simulation

Whilst there was some evidence of the long-term benefits of VR simulator use when compared to traditional methods alone[3], the significance of long-term or continued training and the effect on outcomes remains unknown.

Effects of VR simulation on patient comfort

When looking at the reported discomfort or pain, only four studies found that VR simulator training reduced patients' pain significantly[13,16,18,22]. Another four studies found no significant difference between VR simulator trained and traditionally trained candidates[3,15,21,24] and only one found that patients of the VR simulator trained group reported significantly more pain[25]. More evidence is needed to show the true impact that VR simulator training has on patients' reported levels of discomfort.

LIMITATIONS

There are several issues relating to the consistency of the methodology of these studies that limits the comparison and generalisability of their findings. When looking at the studies reviewed, ten of the included studies were single-group intervention studies[2,6,8,10,12,14,19-21,23] without control groups and there were very few larger randomised control trials[15,16] (more than 30 participants). This is impacted further by the variety of different VR simulator models used, as the ability to draw accurate comparisons remains difficult.

Because of the different VR simulator models used, it is hard to accurately compare the mixed competencies used to measure candidates' skills, as measurements made in different simulator models are not truly identical. Recognition of the overall trend suggesting an improvement or reduction in skill level was sufficient in this review, negating the technicalities of the different measures.

Despite the overall trend advocating the use of VR simulators, the power of these findings is also limited by the relatively small study size. Also, as mentioned in the discussion, not all studies actively used VR simulators as part of a structured training programme and it is difficult to assess the impact of each different approach.

Finally, one limitation across all these studies was the varied definition of who was a "novice" or "experienced" candidate and the selection criteria. It was not always clear in the selection criteria how one was defined as being novice, with some studies defining a novice candidate as having no prior endoscopy experience, some as having limited experience in the procedure, whilst others allowed candidates trained in other endoscopy modalities, providing it was not the one under investigation[13,18,21]. For example, having completed less than 200 colonoscopies was defined as being a novice candidate in one study[12] whilst in the majority of studies a novice candidate had to have done no prior colonoscopies. Other studies only excluded those who had prior simulator experience[6,8]. Similarly, there were no uniform criteria among different studies regarding the definition of advanced or expert level. For example, in some studies having done more than 1000 procedures was defined as being an expert[7,13], whereas in other studies having done more than 500 procedures[8,12] or more than 30 procedures in the past 5 years[6] were considered sufficient thresholds for entering the "advanced" group. Clearly using an arbitrary number of previous endoscopies to stratify a candidate's ability and not

standardising a candidate's background experience may impact on the conclusions made in these studies.

CONCLUSION

Given the limitations of the studies, there is consistent evidence advocating the use of VR simulation in endoscopy teaching, stronger still in those who are least experienced. More evidence is needed to strengthen support of VR simulators in ERCP, as many of the models that currently exist to support this field of teaching rely on *ex-vivo* simulators not included in this review. For EUS training, more research is needed into the impact that VR simulators may have.

However, there does not appear to be a clear model in how best to integrate simulators in an educational programme. This is due to the variety of simulator models used and the lack of agreement over the length of exposure needed with any one simulator to obtain a beneficial outcome. A combined curriculum of traditional teaching supplemented with virtual reality simulators is of greater benefit than one without virtual reality simulation. Other considerations, such as the cost-benefit-analysis, although not considered here, would also influence decisions about how best to integrate VR simulators into any endoscopy curriculum.

Abstract

Since laparoscopy was first used in cholecystectomy in 1987, it has developed quickly and has been used in most fields of traditional surgery. People have now accepted its advantages like small incision, quick recovery, light pain, beauty and short hospital stays. In early times, there are still controversies about the application of laparoscopy in malignant tumor treatments, especially about the problems of oncology efficacy, incision implantation and operation security. However, these concerns have been fully eliminated by evidences on the basis of evidence-basis medicine. In recent years, new minimally invasive technologies are appearing continually, but they still have challenges and may increase the difficulties of radical dissection and the risks of potential complications, so they are confined to benign or early malignant tumors. The core value of the laparoscopic technique is to ensure the high quality of tumor's radical resection and less complications. On the basis of this, it is allowed to pursue more minimally invasive techniques. Since the development of laparoscopic colorectal surgery is rapid and unceasing, we have reasons to believe that laparoscopic surgery will become gold standard for colorectal surgery in the near future.

Key words: Laparoscopy; Minimally invasive surgery; Core value; Laparoscopic colorectal surgery

Core tip: This article discusses problems of oncology efficacy, incision implantation and operation security in laparoscopy on the basis of evidence-basis medicine, and also analyzes new minimally invasive technologies, their challenges and their range of application. The core value of the laparoscopic technique is studied and concluded.

Li XX, Wang RJ. Core value of laparoscopic colorectal surgery. *World J Gastrointest Endosc* 2015; 7(18): 1295-1299 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i18/1295.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i18.1295

HISTORY AND CURRENT STATUS

Since 21st century, minimally invasive surgery has got revolutionary successes in more and more fields of

traditional surgery, and has become mainstream of the global surgery developments. Minimally invasive surgery has been not only the belief and pursuit of modern surgeons, but also the compulsory courses as well.

In March 1987, Franch surgeon Phillipe Mouret first used laparoscopy in cholecystectomy, which has unveiled a new era in the development of minimally invasive surgery. Compared with small incision in traditional surgery, modern minimally invasive surgery has a deeper and promoted meaning. Small incision, quick recovery, light pain, beauty, and short hospital stays are all advantages of minimally invasive surgery. People begin to realize that postoperative recovery is mainly related with abdominal incision, exposure duration and extent of damage of the abdominal cavity.

In 1990, American surgeon Jacobs completed the world's first laparoscopic right colon resection. Cutting stapling device (Endo-GIA) has greatly improved the operating conditions of laparoscopic surgery, which has made the cut-off of mesenteric vessels and bowel loops inside abdominal cavity and the lower rectal anastomosis possible. In October 1990, Dennis Fowler operated the first laparoscopic sigmoid resection using Endo-GIA. In November of the same year, Patrick Leahy completed the first laparoscopic ultra-low anterior resection (Dixon) with Endo-GIA. In July 1991, Joseph Uddo completed the first laparoscopic right colon resection. Within one year, almost all types of colon surgeries have been attempted under laparoscopy. In 1992, Kokerling completed world's first abdominoperineal resection (Miles) with laparoscopy. In our country, first laparoscopic colorectal surgery was carried out in 1993, and since then, laparoscopy was gradually used in traditional colorectal cancer surgeries. In the past 20 years, with the continuous development of laparoscopic surgical techniques and the invention and perfection of all kinds of laparoscopic equipments, laparoscopic colorectal surgery has achieved encouraging achievements, and its short and long-term effects have been approved.

With the improvement of the technologies and equipments, laparoscopic colorectal surgery is developing constantly. Mainly, laparoscopic colorectal surgery includes three techniques: Laparoscopic colorectal resection, laparoscopic assisted colorectal resection, and hand assisted laparoscopic colorectal resection. Compared with traditional open surgery, laparoscopic colorectal surgery has following advantages: (1) light postoperative pain; (2) shortened wound healing time, the abdominal incision is relatively small and beautiful; (3) faster recovery of gastrointestinal function; (4) fast-returned normal activities and short hospital stays; (5) reduced complications such as ileus, incision infection; (6) improved patient's intraoperative and postoperative immunity; (7) better operative view in narrow space such as pelvic floor; and (8) precise operation under the magnified view, which is beneficial to vascular skeletonization and lymph-node dissection.

Although laparoscopic colorectal surgery has these advantages, in early time, it did not develop fastly as people expected like laparoscopic cholecystectomy. This is mainly because of the complexity and the long "learning curve" of the laparoscopic colorectal surgery. In recent years, with the development of laparoscopic surgical techniques and the invention of ultrasound knife, Ligasure, and all kinds of intracavitary cutting stapling devices, intraoperative bleeding and operation difficulties are greatly reduced, and the operation time is also notably shortened, which has vigorously promoted the development of laparoscopic colorectal surgery. Since then, laparoscopic colorectal surgery has entered into a rapid developing stage. At present, all the colorectal cancer centers in Shanghai have carried out laparoscopic colorectal surgery, and the proportion of laparoscopic surgeries is rising year by year.

EVIDENCE OF LAPAROSCOPIC COLORECTAL CANCER SURGERY

In the early developing period, laparoscopic colorectal surgery has many controversies. This is mainly because people have a lot of concerns about the application of laparoscopic surgery in malignant tumor treatments: First, whether laparoscopic surgery may increase the incidence of implantation metastasis? And whether laparoscopic surgery can achieve radical resection? Second, whether laparoscopic colorectal surgery may increase surgical complications? Third, since in early time, the learning curve and operation time of laparoscopic colorectal surgery is obviously longer, whether laparoscopic surgery can embody minimal invasion? To answer the above questions, it is necessary to resort to evidence-based medicine for help.

Oncology efficacy

At the end of last century, a series of large randomized controlled trial (RCT) studies comparing laparoscopic and open colorectal surgeries were carried out in Europe and United States (Table 1). In 1993, Lacy *et al*[1] in Spain firstly launched RCT studies comparing laparoscopic and open colon surgeries. From then on, RCT studies such as COST in United States, COLOR in Europe, and CLASICC in United Kingdom were carried out successively[2-4], Leung *et al*[5] in Hong Kong also conducted RCT studies on laparoscopic and open colorectal surgeries. In 2002, Lacy *et al*[1] first published the result of RCT studies on short and long-term effects of laparoscopic colorectal cancer surgery. Since then, the results of RCT studies above have been completed and published one after another. The research contents involve radical resection, long-term curative effects, quality of life and cost effectiveness, *etc.*, which have provided credible clinical evidences for the application of laparoscopic colorectal cancer surgery on the basis of evidence-based medicine.

Since the lack of evidence on laparoscopic rectal

Table 1 Randomized controlled trial studies comparing laparoscopic colorectal surgery and conventional colorectal surgery

Study	No. of patients (laparoscopic *vs* conventional)	Year
Lacy *et al*[1]	219 (111 *vs* 108)	1993-1998
Leung *et al*[5]	403 (203 *vs* 200)	1993-2002
COST	872 (435 *vs* 437)	1994-2001
COLOR	1248 (627 *vs* 621)	1997-2003
CLASSIC	794 (526 *vs* 268)	1996-2002
COLOR Ⅱ	1103 (739 *vs* 364)	2004-2010

cancer surgery, Colon Cancer Laparoscopic or Open Resection Study Group in Europe launched COLORII study[6]. The study began in 2004, a total of 8 countries and 30 centers participated. From January 2004 to May 2010, a total of 1103 cases entered into the group randomly, 59 patients were ruled out for various reasons or incompleted follow-up, 1044 patients were analyzed for statistics finally. In 2013, the study reported the preliminary results. According to the results, the conversion rate of laparoscopic surgery was 17% (91/536). Compared with open surgery, laparoscopic surgery has longer operation time (240 min *vs* 188 min, $P < 0.001$), but less blood loss (200 mL *vs* 400 mL, $P < 0.0001$), faster recovery of gastrointestinal function (2 d *vs* 3 d, $P < 0.036$) and shorter postoperative hospital stays (8 d *vs* 9 d, $P < 0.036$). Postoperative pathological report shows that tumor stage, tumor size, and pathological type have no significant differences between these two groups. No significant differences were also observed in margin distance, positive margin rate and the number of lymph node dissection. The 28-d postoperative complication and mortality rates were close in these two groups. The researchers concluded that for experienced surgeons, laparoscopic rectal cancer surgery can not only meet the radical standard of open surgery, but also enhance postoperative recovery at the meantime.

Implantation metastasis problems of incision

In early times, there were controversies about whether laparoscopic colorectal cancer surgery may cause incision implantation or tumor dissemination. Once upon a time, it was reported that the rate of incision implantation was higher in laparoscopic surgery, the reason may due to the lack of standardization of the operation. In Lacy *et al*[1] study, among these 111 cases, only one had implantation metastasis in trocar puncture hole. More and more reports confirmed that as long as the surgery is operated in accordance with disease-free principles, the rate of incision implantation will not increase. After analyzing 2858 laparoscopic colon cancer cases, Stocchi *et al*[7] reported that the rate of incision implantation is only 0.7% for experienced surgeons. It was also reported, the incision implantation rate is about 0%-1.3% after laparoscopic colon cancer surgery in experienced laparoscopic centers, which has no difference with open surgery[8-11]. Standardized operation can greatly decrease the rate of incision implantation, including: (1) follow the disease-free principles during the surgery and avoid cutting tumor directly using ultrasonic knives; (2) do not stretch or squeeze tumor and simply pursue small incision when removing the tumor, take the tumor out gently with an incision protector or specimen bag, and pay attention to incision flushing at the end of surgery; and (3) before taking the Trocars out, exhaust gases from the vent hole slowly first.

Operation security problems

As the laparoscopic vision is 2-dimensional, it is often difficult to distinguish anatomical structure with spatial perception during the surgery. Moreover, laparoscopic surgery is operated by equipments, as a result, there is no hand feeling, so the laparoscopic colorectal surgery is much more difficult than ordinary laparoscopic cholecystectomy. In early time, complications of laparoscopic colorectal surgery is high, generally reported about 10%-17%. But as the advancement of "learning curve" and improvement of surgical techniques and experience, current literature reports that the incidence of complications will be gradually reduced after operating more than 30 cases. The laparoscopic peculiar complications include: Air embolism and subcutaneous emphysema, *etc*. There are also two Trocar-related complications, one is Trocar infection, but it is very rare, and does not extend hospital stays, and can be treated in outpatient clinics. The other is Trocar hernia, which is also relatively rare, and can be avoided by closing the Trocar holes carefully. Generally, laparoscopic colorectal surgery does not increase mortality, which is usually caused by systemic complications rather than the surgery itself. The life-threatened complications are extremely rare.

Arezzo *et al*[12] analysed all randomized and prospective controlled studies comparing laparoscopic and open rectal cancer surgeries in the Medline and Embase database from 2000 to 2011. Twenty-three studies including 4539 patients meet the criteria. Among them, there are 8 RCT studies, including 1746 patients. Analysis showed that within 30 d after surgery, mortality in laparoscopic group was 1.0%, while in open group was 2.4% (95%CI: 0.21-0.99, $P = 0.048$). The total complication rate was 31.8% in laparoscopic group, while 35.4% (95%CI: 0.76-0.91, $P < 0.001$) in open group. The results of meta-analysis once again prove that laparoscopic surgery has lower complications and mortality rates than open surgery.

INNOVATIVE OR CONSERVATIVE?

In recent years, new technologies in laparoscopy emerge in endlessly, including traditional laparoscopic surgery, robotic surgery, 3-D laparoscopic surgery, single-port laparoscopic surgery (SPA), natural orifice transluminal endoscopic surgery (NOTES) and transanal minimally invasive surgery (TAMIS).

We take Da Vinci Robot as an example, the system not only inherits advantages of traditional laparoscopic surgery, but has many peculiar advantages as well: (1)

there are 4 mechanical arms with the ability of 7 free degrees, which makes it possible to operate precisely in narrow and small space; (2) the thrill of hand can be filtered by computer, which improves the stability of real-time operation picture, and greatly improves the accuracy of operation; (3) high resolution 3-D image gives the operator clear and real stereo visual feedbacks; (4) the good ergonomic design allows the surgeon to operate without standing, which can significantly alleviate fatigues and is more convenient for surgeons to complete complicated and long-time surgeries; and (5) long-distance operation is possible through the robot arm controlled by remote signal transmission. However, so far, the robot's force feedback components are not perfect, because in colorectal surgery, keeping good tension is very important for the quality of operation. Moreover, robots are extremely expensive, their overall cost performance is not high enough for developing countries. So, there is still a long way to go for the popularization of robots.

3-D laparoscopic surgery has the advantages of traditional laparoscopic surgery, its high resolution 3-D image makes the operation more accurate, so it can shorten the learning curves for surgeons, especially for beginners. In order to pay more attention to minimally invasive surgery, techniques such as SPA, NOTES and TAMIS were developed in recent years, the challenges we face are how to operate safely and effectively with only one hole in the case that the surgical instruments are still deficient and how to design instruments with good handling and flexibility, these challenges decide whether these techniques would be epoch-making innovations like the birth of laparoscopy 24 years ago.

In the era of rapid development of new technologies, should a colorectal surgeon be innovative or conservative? It is hard to decide sometimes. As far as I am concerned, the key point is: the feasibility of technology does not mean the rationality of treatment. When treating colorectal cancer, the reliability of radical resection is always in the first place, the second is to minimize surgical complications, finally we may consider to operate minimally invasively. So, we should not put the cart before the horse. We should not pursue less holes and result in increasing difficulties of radical dissection and decreasing of the quality of surgery. For the new techniques like SPA, NOTES and TAMIS, they are now restricted by the existing equipments, which will undoubtedly increase the difficulties of radical dissection and the risks of potential complications. As a result, such technologies should only be confined to benign or early malignant colorectal tumors presently.

As a colorectal surgeon, we should not get lost in the tide of minimally invasive surgery and simply pursue the maximization of minimally invasion. We are delighted to see that since laparoscopic colorectal surgery was developed in China, high-resolution endoscopic vision, high levels of fine anatomy and the establishment of good training plans have made young surgeons more profound in understanding colorectal surgery, which have greatly improved the surgical quality of young surgeons. Therefore, patients are getting better quality of the surgical treatments, and gaining a better survival. Based on the above understanding, we think that the core value of the laparoscopic technique is to ensure the high quality of tumor's radical resection and less complications. On the basis of this, it is allowed to pursue more minimally invasive techniques.

After hundred years of development of colorectal cancer surgery, people's concepts have been greatly changed, the early emphasis of radical resection has been substituted by function preservation and life quality improvements on the basis of radical treatment. Minimally invasive surgery meet these requirements, which reveals the irreversible developments of laparoscopic colorectal surgery. We have reasons to believe that laparoscopic surgery will become gold standard for colorectal surgery in the near future.

Abstract

AIM: To determine compliance to colorectal cancer (CRC) screening guidelines among persons with a family history of any type of cancer and investigate racial differences in screening compliance.

METHODS: We used the 2007 Health Information National Trends Survey and identified 1094 (27.4%)

respondents (weighted population size = 21959672) without a family history of cancer and 3138 (72.6%) respondents (weighted population size = 58201479) with a family history of cancer who were 50 years and older. We defined compliance with CRC screening as the use of fecal occult blood testing within 1 year, sigmoidoscopy within 5 years, or colonoscopy within 10 years. We compared compliance with CRC screening among those with and without a family member with a history of cancer.

RESULTS: Overall, those with a family member with cancer were more likely to be compliant with CRC screening (64.9% *vs* 55.1%; OR = 1.45; 95%CI: 1.20-1.74). The absolute increase in screening rates associated with family history of cancer was 8.2% among whites. Hispanics had lowest screening rates among those without family history of cancer 41.9% but had highest absolute increase (14.7%) in CRC screening rate when they have a family member with cancer. Blacks had the lowest absolute increase in CRC screening (5.3%) when a family member has a known history of cancer. However, the noted increase in screening rates among blacks and Hispanics when they have a family member with cancer were not higher than whites without a family history of cancer: (54.5% *vs* 58.7%; OR = 1.16; 95%CI: 0.72-1.88) for blacks and (56.7% *vs* 58.7%; OR = 1.25; 95%CI: 0.72-2.18) for Hispanics.

CONCLUSION: While adults with a family history of any cancer were more likely to be compliant with CRC screening guidelines irrespective of race/ethnicity, blacks and Hispanics with a family history of cancer were less likely to be compliant than whites without a family history. Increased burden from CRC among blacks may be related to poor uptake of screening among high-risk groups.

Key words: Colon cancer; Health disparities; Screening; Fecal blood test; Colonoscopy

Core tip: It is unclear whether suboptimal screening contributes to the increased risk of cancer within families. We evaluated compliance with colon cancer screening guidelines among adults in the United States. Our study suggested that adults with a family history of any cancer had higher screening rates, but the smallest increase was noted among blacks. Overall, screening was lower among blacks and Hispanics to such an extent that screening among those with a family member with cancer was not higher than screening among whites without a family member with cancer. There is a particular need to improve screening among high risk blacks.

INTRODUCTION

Colorectal cancer (CRC) is a leading cause of cancer-related deaths in the United States[1]. There is ample evidence that screening reduces the burden from this deadly but largely preventable disease[2-4]. Unfortunately, screening rates are suboptimal among the population, particularly among racial/ethnic minorities.

A primary driving factor for the time to initiate CRC screening is the family history of CRC[5]. However, it is well known that malignancies of other organ sites are associated with syndromic CRC such as Lynch syndrome (hereditary non-polyposis colorectal cancer)[6,7]. Lynch syndrome is caused by mutations in mismatch repair gene and is associated with an increased the risk of CRC but other malignancies such as endometrial and urogenital cancers are associated with this syndrome as well.

We hypothesized that CRC awareness should be higher among families with any history of cancer, not just CRC. This awareness should in turn be associated with uptake of CRC screening. The burden of CRC is highest among blacks due to multiple factors related to poorer access, inadequate utilization of healthcare resources even when available and possible biological susceptibility differences[8-10]. Furthermore, blacks are less likely to be aware of cancer diagnosis of their family members[11,12]. We postulated that increased CRC incidence and mortality among blacks may be due to poorer uptake of CRC screening among those at a higher risk of the disease. The aim of the present study was to evaluate compliance with CRC screening guidelines among United States adults with and without a family member with any cancer and investigate differences in compliance by race/ethnicity (whites, blacks and Hispanics).

MATERIALS AND METHODS

We used data from the 2007 Health Information National Trends Survey (HINTS) and the details of the survey have been published[13]. In summary, HINTS was a national survey of adults on health-related information and practices. It was conducted by the National Cancer Institute, National Institutes of Health in the United States between January 2008 and May 2008. The survey is available online at http://hints.cancer.gov/docs/Instruments/HINTS%202007%20CATI%20Instrument%20(English).pdf and http://hints.cancer.gov/docs/HINTS2007FinalReport.pdf.

A total of 7674 people completed the HINTS telephone interview (n = 4092), or mailed survey (n = 3582). Respondents were asked to provide information

Table 1 Comparison of characteristics of respondents with and without a family history of cancer

	Family history of cancer		*P* value
Characteristics	No	Yes	
	n = 1094 (27.4%)	*n* = 3138 (72.6%)	
Mean age, yr (95%CI)	63.4 (62.7-64.2)	63.8 (63.5-64.1)

All percentages are weighted.

on demographic and lifestyle factors, first degree family history of any type of cancer. They were also asked about colon cancer screening with fecal occult blood test, sigmoidoscopy or colonoscopy and when they had the tests. After obtaining approval (IRB-14-MED-28) from the Institutional Review Board of Howard University in Washington DC, we downloaded the dataset. For the present study, our analytical cohort consisted of 4232 respondents (weighted population size = 80161151) who were at least 50 years old and answered questions about their family history of cancer and CRC screening compliance.

Statistical analysis

Our primary outcome was the compliance to CRC screening guidelines defined as the uptake of fecal occult blood testing within 1 year, sigmoidoscopy within 5 years, or colonoscopy within 10 years. We compared the characteristics of respondents with and without family members with a history of cancer. We used survey weights in all analyses and Taylor series linearization was used for variance estimations. Logistic regression analysis was used to estimate OR and 95%CI for the association between family history of cancer and compliance with CRC screening guidelines. We also investigated this association by race/ethnicity. Our final models included age, sex, marital status, highest education achieved, race, health insurance status, smoking status and personal history of cancer. We calculated OR and 95%CI. Statistical analysis was performed by a qualified biostatistician using Stata® statistical software version 11.2 (College Station, Texas) for all analyses. All reported percentages were weighted.

RESULTS

The comparisons of the characteristics of respondents with and without a family history of any cancer are shown in Table 1. Overall, those with a family history were more likely to be female, unmarried, and have health insurance. However, there was no difference in the prevalence of cigarette smoking, body mass index, or personal history of cancer.

When compared to respondents without a family history of cancer, those who had family members with cancer were more likely to be compliant with CRC screening (64.9% *vs* 55.1%; OR = 1.45; 95%CI: 1.20-1.74). Among whites, those with family history of

Table 2 Intra-racial comparison of being up-to-date with colorectal cancer screening by racial distribution of family history of any cancer

	Family history of any cancer	Up-to-date with CRC screening		
		Wt % screened	Unadjusted OR (95%CI)	Adjusted OR (95%CI)
Overall	No (n = 1094)	55.1	Reference	Reference
	Yes (n = 3138)	64.9	1.51 (1.25-1.81)	1.45 (1.20-1.74)

Adjusted for age, sex, education, health insurance, BMI, smoking, marital status and personal history of cancer. CRC: Colorectal cancer; BMI: Body mass index.

Table 3 Inter-racial comparison of being up-to-date with colorectal cancer screening by racial distribution of family history of any cancer

Race	Family history of any cancer	Up-to-date with CRC screening		
		Wt % screened	Unadjusted OR (95%CI)	Adjusted OR (95%CI)
White	No (n = 818)	58.7	Reference	Reference
White	Yes (n = 2560)	66.9	1.42 (1.18-1.72)	1.45 (1.21-1.74)
Black	No (n = 107)	49.2	0.68 (0.39-1.18)	0.96 (0.51-1.80)
Black	Yes (n = 244)	54.5	0.84 (0.54-1.31)	1.16 (0.71-1.90)
Hispanic	No (n = 92)	41.9	0.51 (0.27-0.95)	0.84 (0.48-1.47)
Hispanic	Yes (n = 134)	56.7	0.92 (0.57-1.48)	1.25 (0.72-2.18)

Adjusted for age, sex, education, health insurance, BMI, smoking, marital status and personal history of cancer. CRC: Colorectal cancer; BMI: Body mass index.

cancer had 8.2% absolute higher screening rates than whites without family history of cancer (OR = 1.45; 95%CI: 1.20-1.75; Table 2). Screening rates were generally lower among Hispanics and blacks. Blacks had the lowest increase in screening rates (5.3%) when a family member had a history of cancer which was not statistically different from blacks without a family member with cancer diagnosis (OR = 1.34; 95%CI: 0.61-2.94). Although, Hispanics had the lowest screening rates among those without history of cancer (41.9%), the absolute increase in screening rates was highest among Hispanics (14.7%) when a family member has had a history of cancer.

Despite increase in CRC screening rates among blacks and Hispanics with family history of cancer, their screening rates were still numerically lower than the screening rates among whites without a family history of cancer. However, there were no statistically significant differences in the comparison of interracial screening rates (Table 3).

DISCUSSION

In the present study, we evaluated compliance with CRC screening guidelines among United States adults with and without a family history of cancer overall and by race/ethnicity. Irrespective of race/ethnicity, we found that those with a family history of cancer were more likely to be compliant with CRC screening guidelines compared to those without a family history. This pattern was present among each racial/ethnic group. However, this relationship was statistically significant only among whites. Among blacks, the absolute increase in the compliance with CRC screening among those with a family history of cancer was small. We found that screening rates were so low among blacks that the higher screening rates observed among blacks with family history of cancer were still numerically lower albeit not statistically different from the screening rate among whites without a family history of cancer. This suggests that the increased CRC burden among blacks may be, in part, due to low screening rates among high risk blacks and underscores the need to increase awareness and screening rates among blacks.

Although the Hispanics in this study have the lowest CRC screening rates among those without a family history of cancer, they exhibited the highest absolute increase in CRC screening among those with a family history of cancer. This suggests an appropriate response in uptake of preventive services among Hispanics, but the screening rates were still lower than that among whites without a family history of cancer. This finding indicates that increased education about CRC screening is needed among Hispanics.

We are not aware of any other study that has examined the association of a family history of any

cancer with CRC screening for a direct comparison to our study. However, prior studies have examined the CRC screening among persons with a family history of CRC. Using data from the 2005 California Health Interview Survey (CHIS), Ponce *et al*[14] reported that screening rates were lower among Hispanics in general when compared with whites, but disparities were more pronounced among respondents with a family history of CRC (OR = 0.28; 95%CI: 0.11-0.60) as compared to disparity among those without family history of CRC (OR = 0.74; 95%CI: 0.59-0.92). However, CRC screening rate was comparable among blacks and whites among those with (OR = 0.92; 95%CI: 0.31-1.34) or without a family history of CRC (OR = 1.08; 95%CI: 0.84-1.40). In another study which used the 2009 CHIS, Almario *et al*[15] investigated CRC screening among respondents with a family history of CRC in California. The authors reported that there was no difference in overall screening rate among blacks when compared to whites (OR = 1.03; 95%CI: 0.81-1.27). However, among individuals who were 40-49 years old (when early screening should have started because of the increased risk of CRC), blacks were 71% less likely to have had a colonoscopy (OR = 0.29; 95%CI: 0.04-0.87). Taken together, these two studies suggest lower rates of appropriate CRC screening among blacks and Hispanics at an increased risk of CRC. However, the studies focused only on residents of the state of California. Nonetheless, these findings were comparable to our findings that are based on nationally representative data of United States adults.

It is unclear why the rates of CRC screening was lower among these minority populations, but we speculate that known factors such as health literacy, access and utilization differences may be playing important roles. In a previous study using the 2007 HINTS data, Orom *et al*[16] reported differences in perceived cancer risk by race. The authors reported that Hispanics were less likely to perceive themselves at higher risk of cancer even when they have family members with cancer. This disconnect may be related to health literacy or communication challenges. It is well known that blacks are less likely to discuss their chronic health problems with family members[17,18] and often hold fatalistic beliefs which negatively correlate with uptake of preventive services such as CRC screening[19].

There are some notable strengths of our study. We examined compliance with CRC screening guidelines among a nationally representative large sample of United States adults and two modes of survey was used (mail and telephone), thereby increasing the reach of the survey. Furthermore, the survey was conducted in English and Spanish to ensure broader participation. However, our study has important limitations. Although we do not suspect that respondents would have any motivation not to tell the truth, but our study was based on self reports and we could not abstract medical records to verify CRC screening uptake and the time they took place. Also, the race designation in the HINTS survey was by self-identification. Furthermore, our study did not capture other factors which may influence CRC screening compliance such as accessibility to healthcare facilities, availability of culturally sensitive care providers and type of health insurance coverage.

In conclusion, while being up-to-date with CRC screening is generally higher among those with a family history of cancer, blacks and Hispanics with a family history of cancer were less likely to be compliant with CRC screening guidelines compared with whites without a family history of cancer. There is a need to improve cancer education among blacks and Hispanics and increase CRC screening rates, especially among higher risk groups.

COMMENTS

Background

The risk of cancer is higher among families when a member has been diagnosed with cancer. The current study evaluated compliance with colorectal cancer (CRC) screening guidelines among adults with and without a family member with a history of cancer.

Research frontiers

The CRC screening rates were higher among United States adults with family members with cancer diagnosis. By race, CRC screening rates among blacks and Hispanics were lower than whites. The screening rates among blacks and Hispanics with family history of cancer did not even reach the level of screening among whites without family history of cancer.

Innovations and breakthroughs

The current study examined whether United States adults with a family history of cancer were more likely to be compliant with CRC screening guidelines. This has not been thoroughly investigated previously.

Applications

Blacks and Hispanics have lower screening rates than whites even when they have family members with history of cancer. This study suggests that the low absolute increase in CRC screening rates among blacks when a family member has a history of cancer may represent inadequate CRC screening uptake among high risk blacks. This may be playing a role in the observed CRC disparity by race in the United States.

Terminology

Screening for CRC reduces the incidence and mortality from the disease.

Peer-review

The manuscript is a well-designed observational study that addressed a major issue about health behavior among different races. The authors managed to reveal this issue through extensive research and thorough statistical analysis.

Abstract

Methods to assess, access and treat pathology within the gastrointestinal tract continue to evolve with video endoscopy replacing radiology as the gold standard. Whilst endoscope technology develops further with the advent of newer higher resolution chips, an array of adjuncts has been developed to enhance endoscopy in other ways; most notable is the use of magnets. Magnets are utilised in many areas, ranging from endoscopic training, lesion resection, aiding manoeuvrability of capsule endoscopes, to assisting in easy placement of tubes for nutritional feeding. Some of these are still at an experimental stage, whilst others are being increasingly incorporated in our everyday practice.

Key words: Magnet; Endoscopy; Training; Therapeutic; Capsule; Nutrition; Child; Paediatric; Colonoscopy; Imaging

Core tip: Magnetic technology is being incorporated into many aspects of endoscopy from diagnostic procedures to assisting in therapeutic interventions. Here we summarise some of the more exciting innovations and the potential future roles magnets will play in this field.

INTRODUCTION

Magnets were traditionally viewed with great scepticism by the endoscopy community due to the potentially hazardous consequence that ingestion of this material

led to. However the property of magnets, notably the ability to be sensed and also exert a force from a distance, began to be recognised as a solution to many emerging problems faced by an endoscopist. Magnetic technology is now incorporated within many areas of endoscopy.

Endoscopic training

Colonoscopy is undertaken worldwide, with variations in reported caecal intubation rates. Although there are several reasons for this, a common factor elucidated in quality assurance audits is the consequence of recurrent colonic looping leading to a consequent lack of advancement of the endoscope tip, and subsequent patient discomfort[1]. Measures to appreciate colonoscopic positioning in the past required fluoroscopy, however, its use was cumbersome and posed a radiation risk[2,3]. In 1993, the technique of magnetic endoscopic imaging (MEI) of the colonoscope was described by Bladen *et al*[4]. This was then further developed by Olympus® into a mobile unit known as "Scopeguide". This technology provides a real time three-dimensional image of the colonoscope as it passes through the colon. The basic principle relies on the generation of pulsed low intensity magnetic fields generated from electromagnetic generator coils positioned at regular intervals within the colonoscope. This is then picked up by a receiver dish which allows calculation of the precise position and orientation of the colonoscope. It enables loops to be visualised and loop resolution to be performed under direct vision as well as assisting in identifying the location of the tip of the scope.

It has been proposed that this device can improve caecal intubation rates, times and patient comfort. This was demonstrated in the first randomized controlled trial (RCT) of MEI on colonoscopy performance in adults[5]. However, more recent studies have demonstrated conflicting results in those with enough statistical power to show a difference in the two groups. Two studies have shown higher caecal intubation rates, one study has shown shorter intubation times and two showed patient comfort scores were better with MEI, although one of the latest studies looking into its role in unsedated colonoscopy failed to show any statistical difference in any of these outcome measures[5-8]. The largest RCT on MEI to date (n = 810) did however reveal that in less experienced endoscopists the performance, measured by caecal intubation rate, was significantly better than with standard colonoscopy without MEI[9]; also demonstrated by Chen *et al*[10] in a meta-analysis collating 8 RCT. This may lead to the conclusion that the benefit of the device may be more of a training tool for trainee endoscopist through identification of loops, as shown by similar performance improvements in this group in other cohort studies[11-13].

These devices are not in general routine practice on all endoscopy sessions, in part because they are expensive to purchase and require the use of Olympus® equipment. However, what studies have not recorded is the current trainee and trainer satisfaction with this equipment. As the dynamics of the colon can be visualised, there can be a more logical discussion between the trainer and trainee, to resolve an issue of lack of tip advancement or patient discomfort. In practice, trainees appear to be more satisfied with the use of MEI during colonoscopy. One explanation for this is that it allows the trainer to explain the decision making required to facilitate tip advancement without taking the colonoscope over from the trainee. With the growing pressure to train a greater number of generic healthcare endoscopists, the additional cost may thus be justified. With other endoscope manufacturers, such as Pentax®, incorporating MEI into their equipment in the near future it is likely this technology becomes increasingly embedded in day to day colonoscopy practice.

Therapeutic endoscopy

Going beyond the realms of basic diagnostic endoscopy, into an era where the endoscopist has now developed the proficiency to undertake therapy, comes an explosion of technology. Endoscopic polypectomy has evolved since its first undertaking by Hiromi Shinya in 1969, from the basic "lassoing" of a polyp to endoscopic mucosal resection (EMR) to endoscopic submucosal dissection (ESD) which allows en-bloc resection of large lesions[14]. ESD is however a technically demanding procedure with relatively longer procedure times compared with EMR, and significant complication rates with perforation risk as high as 18% in some series[15]. A common reason for this difficulty is the limited field within which the endoscopist, with his "one handed knife", is operating in. Current standard technique requires the use of a combination of submucosal fluid injection and utilisation of gravity. However, these methods often lead to difficulty in maintaining a safe field of dissection due to a lack of elevation to expose the submucosal plane. To overcome this issue, Gotoda *et al*[16] designed a magnetic anchor device to apply counter-traction. The anchor consisted of a small magnetic weight that was attached to an endoclip with a thread. Once the standard circumferential incision had been made for ESD, the anchor, which was loaded on the end of a standard endoscope, was deployed by attaching the clip to one end of the flap of the lesion[16]. Initially, an extracorporeal magnetic control system of a C-arm type was used to attract the anchor away from the lesion to allow sufficient counter-traction of the flap by the endoclip, which behaved as micro-forceps. The external magnet has since been miniaturised by other investigators to a smaller hand held magnet which is positioned over the torso of the patient. This method has been shown to be feasible as well as reduce procedural times, with no reported complications on 25 gastric lesions[17,18]. This is a promising method and adds to the arsenal of ways to allow possible endoluminal triangulation.

At a more endoscopic surgical level, the use of magnets has been used to create suture free anastomoses. The concept relies on a pair of identical magnetic rings being applied to each end of the intestinal segments to be joined.

When they are then brought into close proximity, the magnets align and mate together. Over a period of about 5 d the inner area necroses off while the surrounding non compressed tissue heals and remodels itself. The coupled magnets then fall off into the created lumen leaving a magnetic compression anastomosis. Initial animal model experiments have shown encouraging safety and efficacy. But unfortunately this did not transpire into the clinical setting, with reports of serious adverse events[19-21]. Further disadvantages in this technique were the inevitable delay in anastomotic formation as well as a restriction on the circumference of the anastomosis due to the initial fixed size magnets used. To get over this drawback, more recent research has looked into using "nano-magnets" delivered *via* an endoscopic catheter device. These self-assemble at the two opposing desired sites to occupy a larger perimeter. The lumen of the anastomosis is then created with the aid of a needle knife. An early proof of concept studys on live porcine models, as well as a human cadaver, has shown the successful formation of gastro-jejunostomies[22]. Although currently not commercially available, magnetic compression anastomosis seems a viable option to aid in the formation of a secure gastro-enteric anastomosis during future natural orifice transluminal endoscopic surgery, replacing the standard methods of suturing or stapling which has its associated complications of leakage and stricture formation.

Capsule endoscopy

The demand for capsule endoscopes has grown exponentially, and it is unlikely that even Paul Swain when he took it upon himself to swallow this first "pill" in 1999 would have envisaged that over 2 million of these would have been ingested worldwide subsequently. The market is well established in the small bowel, and beginning to grow in force progressively for the colon. The upper GI tract seemed to have eluded this technology, firstly due to the speed of travel down the oesophagus and secondly because the larger more capacious stomach really necessitated capsule maneuverability. This has led to several investigators trialling various methods for capsule control, with magnetic assisted capsule endoscopy (MACE) being the most promising. Four systems have been developed, all of which have incorporated magnetic inclusion bodies into the capsule endoscope and controlled externally either by a magnetic field generated by a guidance system or more simply by a fixed magnet on a hand held device. The largest comparative trial to date (n = 189) comparing MACE to standard upper GI endoscopy was undertaken in France using a system developed jointly by Olympus® and Siemens®. The mean examination time was 11 min compared to the 6 min for standard gastroscopy, with the specificity and sensitivity of 94% and 62% respectively for major lesions[23]. However, the magnetic guidance system was similar in size to that of an MRI scanner and was limited to the examination of the stomach.

A simpler system which utilises a hand held magnet has recently been developed by Intromedic Ltd®, the MiroCam-Navi, and which for the first time was capable of exploring the entire upper GI tract. Although awaiting a randomised comparison trial the first feasibility study undertaken on volunteers showed promising visualisation of all the landmarks of the upper GI tract from the GOJ, cardia, fundus, body, incisura, antrum and pylorus of 92%, 88%, 100%, 96%, 96% and 100% respectively[24]. This system even has the possibility to aid in small bowel examination by reducing gastric transit time, through manoeuvring the capsule across the pylorus. Due to the simplicity of its use and high patient acceptance this technology certainly seems a true prospect for the future of upper GI tract examination, with the possibility of accurate capsule localisation and even targeted drug delivery being a distinct likelihood in the future[25,26]. The opportunity to support a community based screening programme, if one was to ever occur for upper GI tract pathology, is an attractive proposition with this technology. This MACE system would not require the expensive set-up costs or decontamination equipment needed with standard endoscopy. However, the current cost of this capsule would need to drop considerably, which should be within the realms of the manufacturers should mass use occur.

Nutritional feeding

In recent times there has been a growing demand for endoscopically placed naso-gastric/jejunal tubes largely due to increase demand for enteral feeding in those unable to maintain an adequate oral intake[27,28]. Jejunal tube placement is often undertaken at the bedside blindly, although this approach is associated with a significant failure rate. The alternative of direct endoscopic or radiological placement requires significantly resources. To attempt to solve these issues, two "bedside magnetic" devices have been developed; the Syncro-Blue tube and the Cortrak system. The Syncro-Blue tube uses a magnetic stylet placed at the end of the feeding tube which is then maneuvered into position *via* attraction of a hand held magnet. This system was evaluated in a case series of 288 critically ill patients, with successful post pyloric placement in 89% and a mean procedure time of 15 min[29]. Each tube costs approximately 95 dollars, which is likely to be cost saving given the associated expense of endoscopic or radiologically placed tubes. The more widely used Cortrak system, which has an electromagnetic transmitting stylet and a receiver placed in the epigastrium, allows real time tracking of the feeding tube as it is passed down the upper GI tract to its desired position. Although the Cortrak system does not allow external control, a recent systematic review has shown that procedure times as well as tube related adverse events are significantly lower compared to endoscopy with similar successful insertion rates[30]. The advantage of this system over the former is that it does not need X-ray imaging to confirm its position, with studies demonstrating 99.5% correlation with X-ray positioning[31]. In addition, there is the benefit of re-inserting the tube if accidental

dislodgement to the stomach was to occur.

CONCLUSION

So it seems that magnets are truly an ally to GI endoscopy, with several establishing methods. Those that are in an experimental stage are growing in momentum with even newer concepts being conceived. With more and more collaborations being undertaken between scientists, physicians and surgeons this seems to be an innovating field and the application of magnets is and will remain an attractive proposition enhancing endoscopy.

Abstract

Recent advances in the endoscopic treatment of dysplasia in Barrett's esophagus (BE) have allowed endoscopists to provide effective and durable eradication therapies. This review summarizes the available endoscopic eradication techniques for dysplasia in patients with BE including endoscopic mucosal resection, endoscopic submucosal dissection, photodynamic therapy, argon plasma coagulation, radiofrequency ablation and cryotherapy.

Key words: Dysplasia; Barrett's esophagus; Endoscopic therapy; Endoscopic mucosal resection; Radiofrequency ablation; Endoscopy; Photodynamic therapy

Core tip: Endoscopic treatment of high-grade dysplasia in Barrett's esophagus (BE) has become the standard of care for patients with this premalignant condition. In this review, we highlight the efficacy, durability and safety of the available endoscopic therapies for BE with high-grade dysplasia.

INTRODUCTION

Barrett's esophagus (BE) is defined by the "American Gastroenterological Association" (AGA) as "a condition in which any extent of metaplastic columnar epithelium that predisposes to cancer development replaces the stratified squamous epithelium that normally lines the distal esophagus", (Figure 1)[1]. The existence of intestinal metaplasia (IM) in the esophagus predisposes to development of esophageal adenocarcinoma and BE

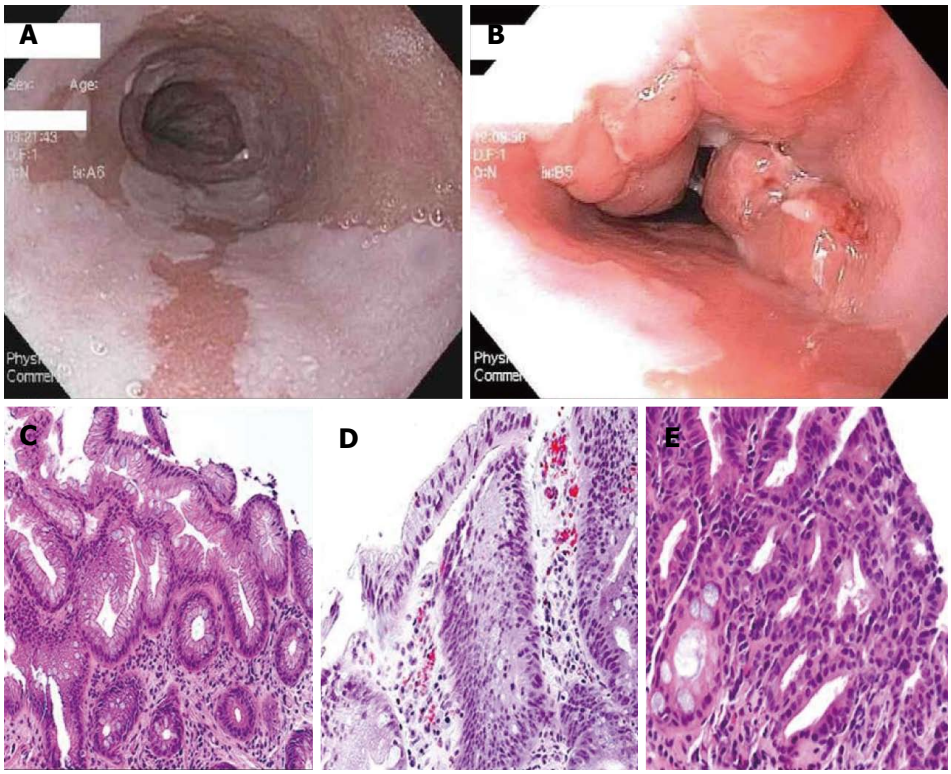

Figure 1 Histopathology pictures. A: White-light endoscopic image of long segment BE; B: White-light endoscopic image of BE with nodular mucosa found to be HGD; C: Hematoxylin and eosin (HE) stain of Barrett's mucosa; D: HE of Barrett's mucosa with LGD; E: Barrett's mucosa with HGD. HGD: High-grade dysplasia; LGD: Low-grade dysplasia; BE: Barrett's esophagus.

has become a well-recognized and treatable condition. The estimates of progression of non-dysplastic BE to adenocarcinoma are variable but uniformly low, ranging from 0.12% to as high as 2.9% per year, with more recent studies reporting lower rates of progression, generally less than 0.5% per year[2,3]. However, the incidence of progression to adenocarcinoma in patients with BE with dysplasia is up to five times as high as in non-dysplastic BE[2]. The presence of high-grade dysplasia (HGD, Figure 1) in BE portends a significant risk of progression to adenocarcinoma, calculated to be up to a 6% annual risk in one meta-analysis[3].

The need for non-invasive strategies to treat dysplasia in patients with BE has become an impetus for gastrointestinal endoscopists to develop new and effective endoscopic techniques. In this paper, we review the different options for treatment of dysplasia in BE, with a focus on endoscopic treatment of HGD.

SURGICAL TREATMENTS

In the past, the gold standard of therapy for HGD was esophagectomy, a procedure with well-recognized morbidity and perioperative mortality as high as 10%[4,5]. More recently, laparoscopic approaches and techniques such as the transhiatal esophagectomy have become more common. These techniques have lower morbidity than some of the older surgical techniques, including reduced hospital length of stay, fewer major complications, and less post-operative dumping syndrome[6,7]. Surgical therapy is a valid curative option for patients in whom there is suspicion of cancer invading the submucosa or if lymph node metastases are present. In patients with early esophageal adenocarcinoma, up to 20% of patients with cancer involving the submucosa will have lymph node metastases, with the risk increasing further with growth of the tumor into the deeper submucosa. In contrast, the risk of lymph node metastases in patients with intramucosal adenocarcinoma (*i.e.*, not invading the submucosa) is much lower at less than 2%[8].

While endoscopic therapy of HGD has become increasingly common, esophagectomy is still an option for patients. The AGA and American Society of Gastrointestinal Endoscopists (ASGE) still acknowledge esophagectomy as a therapeutic option in appropriate patients with BE and HGD, while the American College of Gastroenterology (ACG) guidelines on BE state that esophagectomy is no longer the necessary treatment response to HGD[1,9,10].

ENDOSCOPIC TREATMENTS

For patients with HGD limited to the esophageal mucosa, endoscopic eradication has become the mainstay of therapy. Multiple modalities compatible with endoscopy have been studied including both mechanical removal of tissue and ablative techniques. Methods that involve tissue resection include endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD).

The ablative techniques include several older techniques such as photodynamic therapy (PDT), laser therapy with Nd:YAG (neodymium-doped yttrium aluminum garnet; Nd:$Y_3Al_5O_{12}$) or potassium titanyl phosphate (KTP) lasers, multipolar electrocoagulation (MPEC), argon plasma coagulation (APC), and newer techniques such as cryotherapy and radiofrequency ablation (RFA). These therapies are tailored to the type of HGD present, specifically whether the dysplasia is visible, raised, discolored or nodular; features which have been associated with higher rates of malignancy compared to flat mucosa[11]. It is important to note that all the endoscopic treatments described below require acid suppression therapy for success, namely proton pump inhibitor (PPI) therapy.

EMR AND ESD

EMR, initially developed in Japan for treatment of superficial squamous cell esophageal carcinoma, is now the treatment of choice for nodular HGD in the esophagus[12]. It is also considered helpful diagnostic tool to evaluate for adenocarcinoma invading the submucosa, as well as to determine whether mucosal nodules harbor dysplasia. EMR is useful in staging, as illustrated by Wani *et al*[13]'s study which found that in patients with BE and dysplasia or early cancer, EMR resulted in upstaging of the diagnosis in 10% of patients and downgrading of the diagnosis in 21%. The two main EMR techniques are use of an endoscopic resection cap (ER-cap) (Olympus, Tokyo, Japan), which varies in terms of shape and texture and a multi-band ligator (Wilson-Cook, Indianapolis, United States) used for multiband mucosectomy (MBM). A diathermic snare is used for resection in both techniques. A submucosal lift with saline or a more viscous solution such as hydroxypropyl methylcellulose (artificial tears) can also be employed prior to resection when using the ER-cap method and is sometimes used with MBM. Pouw *et al*[14] performed a randomized controlled trial comparing of ER-cap and MBM and found that MBM was less costly and resulted in fewer acute complications without any significant difference in the depth of tissue resected.

EMR has been shown to be safe and effective as monotherapy for eradication of HGD in several studies. The reported rates of remission from HGD after EMR range from 87%-96% with median follow-up of 22-28 mo[15-17]. The long term remission rate and the durability of EMR as a solo modality for treatment are not currently known; therefore, these patients should be maintained in a surveillance endoscopy program. Complications of EMR include bleeding, perforation, and most commonly stricture formation. The frequency of stricture development reported in EMR studies varies widely, from 12.5% to 88%, depending on the extent of EMR and number of sessions[15-17]. For the majority of patients, post-EMR strictures are easily treated with endoscopic dilation techniques. In general, the smaller the area of resection, the lower the likelihood of stricture formation[17].

ESD is a safe and effective therapy for early gastric cancers and large dysplastic colon polyps[18,19]. Technically, the procedure differs from EMR in that a specialized ESD knife is used to access the submucosal space and dissect the superficial lesion away from the submucosa. As with EMR, a cushion of fluid is first injected to lift the lesion of interest and protect the esophageal wall from deeper penetration of the ESD knife. This fluid typically contains a viscous agent to allow for a sustained lift and a dye to help identify tissue planes for appropriate dissection[20]. The rationale for using ESD is that this technique can allow for a larger and more precise area of dysplastic tissue removal than EMR can safely target.

ESD has recently been evaluated in the management of BE with HGD and early adenocarcinoma. A German group reported a 77% curative resection rate in a small group of patients with a recurrence rate of 5.9% in two years follow-up. The complication rate was 27% for this group of patients and included one perforation and three strictures[21]. A retrospective analysis of 70 Belgian patients who underwent ESD reported a curative resection rate of 64% for patients with HGD and 85% for patients with early adenocarcinoma. At a median follow-up of 20 mo, 92% of patients retained remission from neoplasia. Strictures formed in 60% of patients and these were managed endoscopically[22]. The technique of ESD requires specific training and is only safe in qualified hands in high volume centers. At this time, the ASGE is the only major United States GI society that recognizes ESD as a potential treatment for visible HGD[10].

PDT

PDT is a technique for endoscopic ablation using either 5-aminolevulinic acid or porfimer sodium as a photosensitizing agent followed by exposure to laser light, which causes a photochemical reaction, damaging both mucosal and deeper tissues. The largest study of PDT was a randomized clinical trial evaluating PDT plus omeprazole *vs* omeprazole alone, which showed that patients treated with PDT had a HGD eradication rate of 77% compared to 39% in the omeprazole-alone group. With 5-year follow-up 15% of patients treated with PDT had progressed to cancer, compared to 29% in the omeprazole group[23]. In one longer-term follow-up study of 66 patients with HGD and early adenocarcinoma who underwent PDT, in the calculated 5-year survival was 97% in patients with HGD and 80% in those with early adenocarcinoma without significant long-term complications[24]. Currently, all three major United States societies mention PDT as an option for ablating HGD in BE[1,9,10].

LASER THERAPIES

Nd:YAG and KTP laser-derived thermal therapies have also been evaluated as a treatment tool for HGD in BE. Both Nd:YAG and KTP are crystals that when used in lasers produce wavelengths of light that can damage

tissue, such as dysplastic BE. These lasers have typically been studied in tandem with one another or combined with another mode of therapy. Sharma *et al*[25] reported a series of seven patients with BE and HGD who were not surgical candidates who underwent combination therapy with Nd:YAG laser and monopolar electrocautery. The dysplasia was eradicated in all seven with only residual metaplasia in three patients over a mean follow-up of 3.4 years. Nd:YAG-enhanced KTP laser was also shown to be safe and effective in pilot study of 10 patients with 100% eradication of dysplasia on follow-up esophageal biopsies and no recurrence on average follow-up of 10 mo[26]. Laser treatment is rarely used at this time as other therapies have become more popular.

APC AND MULTIPOLAR ELECTROCOAGULATION

APC is another form of endoscopic thermal therapy using the medium of argon gas to conduct electrical current leading to tissue destruction. The therapy is performed *via* a catheter that fits through the endoscope working channel. MPEC utilizes electrical current through an endoscopic catheter to cause localized tissue destruction. One prospective trial compared APC and MPEC for treatment of dysplastic BE and found no statistical difference in either endoscopic or histologic eradication of dysplasia[27]. However, MPEC required significantly fewer endoscopic therapy sessions with a trend toward better histologic eradication. There were no serious adverse events but 8% of patients treated with MPEC and 13% of patients treated with APC experienced transient upper GI symptoms. While APC is not typically used as a solo modality for treatment of BE and dysplasia, APC can be used to treat small areas of residual BE. In one study of patient with BE and HGD who underwent mucosectomy, treatment of residual disease with APC was found to prolong recurrence-free survival[28].

CRYOTHERAPY

The goal of this endoscopic therapy is to use freeze-thaw cycles for the destruction of tissue. Cryotherapy is performed using low-pressure liquid nitrogen (CSA Medical, Maryland, United States) or carbon dioxide (GI Supply, Pennsylvania, United States) delivered *via* spray catheter. One of the earlier prospective studies of cryotherapy found a 94% eradication rate for HGD with complications including chest pain and dysphagia, as well as one gastric perforation[29]. Recently, a prospective cohort study of 96 patients (two-thirds of whom had HGD) underwent cryotherapy, resulting in a complete eradication rate of 81% for HGD. Only three patients developed a stricture in the 37 mo of follow-up[30]. The durability of cryotherapy in preventing disease recurrence has come into question. Halsey *et al*[31] published data suggesting that up to 30% of patients treated with cryotherapy experienced disease recurrence at a median of 6.5 mo, and 10% had a second recurrence. However, a more recent single center retrospective cohort reported a HGD eradication rate of 100% with sustained remission in 97% of patients with previous HGD over a range of 24-57 mo[32]. At this time, only in the ASGE guidelines is cryotherapy specifically mentioned as a treatment option for dysplasia in BE[10].

RFA

RFA has emerged as the ablative technique of choice for BE with HGD because of the quality of evidence to support the ease of its administration, its efficacy, and safety profile. The procedure involves the direct application of radiofrequency energy to the esophageal mucosa, using either a balloon for circumferential treatment and more focal treatment through an attachment to the end of the endoscope or a small catheter that can pass through the working channel (Barxx/Covidien, Dublin, Ireland). With these tools, RFA can be applied to the mucosa circumferentially or focally. In the landmark multicenter sham-controlled randomized controlled trial by Shaheen *et al*[33], RFA resulted in eradication of dysplasia in 81% of patients with HGD. The treatment also decreased the progression of dysplasia to cancer. Complications were rare in this study, with only a 6% rate of stricture formation over 12 mo of follow-up[33]. RFA has also been shown to be successful in eradicating persistent dysplasia after initial therapy with PDT. In one study, RFA used as rescue therapy after PDT treatment successfully eradicated residual HGD in 86% of patients[34].

For some patients with BE, multiple endoscopic therapies are required for treatment. RFA is most effective on smooth BE mucosa, and is not adequate treatment for nodular dysplasia. As a result, endoscopists have been combining endoscopic eradication therapies, most commonly EMR and RFA. With combination therapy, visible or nodular dysplasia can be precisely removed with EMR, and any residual dysplasia or metaplasia can be systematically treated with RFA, typically performed after the EMR site has healed. One retrospective study of combination therapy reported an 86% complete eradication rate of HGD, but complete eradication of only 62% of nondysplastic intestinal metaplasia[35]. More recently, a multicenter prospective trial in Europe (EURO Ⅱ) evaluated the efficacy and safety of such a treatment strategy. EMR was performed on visible abnormalities within the BE segment and the remaining visible Barrett's mucosa was treated with RFA 6 wk later. Patients underwent a median of two RFA sessions. This combination of procedures achieved a 92% complete eradication rate for HGD and neoplasia and complete eradication of intestinal metaplasia in 87% of patients. At 36 mo of follow-up, only 4% of patients had recurrence of neoplasia. There were no major complications from the procedures and the rate of esophageal stenosis rate was 6%[36].

The existing evidence for treatment of low-grade dysplasia (LGD, Figure 1) in BE (most often with RFA) is

less abundant than studies of patients with BE and HGD. However, a recent randomized clinical trial (the SURF trial) showed a significantly lower rate of progression of LGD to either HGD or adenocarcinoma over three years after RFA[37]. Complicating the decision to ablate LGD is the fact that there is significant disagreement between pathologists on the definition of LGD. Several studies have highlighted the discrepancy in pathologist interobserver agreement when evaluating specimens with LGD. In one such study, expert pathologist confirmed only 15% of previously diagnosed LGD[38]. The AGA recommends RFA as therapy for BE with LGD based on high quality evidence while the ASGE dictates that RFA should be considered as therapy for LGD, and ACG acknowledges the effectiveness of RFA for LGD[1,9,10].

RISK OF RECURRENCE AFTER ENDOSCOPIC THERAPY

Recurrence after endoscopic therapy is a concern for gastroenterologists treating patients with dysplastic BE and the rates of recurrence vary widely depending on the study. Gupta *et al*[39] noted that IM returned in up to 33% of patients at 2 years after endoscopic therapy including RFA. A smaller percentage of recurrent IM was dysplastic (22%). The investigators were unable to identify any predictors for recurrence in this particular population of patients[39]. Other groups have tried to define predictors for recurrence of IM after definitive ablative therapy. In one recent large retrospective analysis, researchers found a slightly lower recurrence rate of 20% at 2.4 years for either IM or dysplasia. These investigators were able to identify risk factors for recurrence of BE and neoplasia, which included a worse pre-treatment histology, older age, and longer BE segments[40]. A single-center retrospective analysis of patients who achieved complete eradication of both IM and dysplasia with RFA found the one-year recurrence rate of IM to be 25% while dysplasia recurred in 8.5% of patients[41]. In contrast, a systematic review and meta-analysis of prospective and retrospective studies of RFA found that recurrence of dysplasia and IM was much lower after RFA treatment, with a 0.9% pooled recurrence rate for dysplasia and a 13% rate of recurrence for IM with an average follow-up of 1.5 years. There was wide range of IM recurrence rates reported in this study, ranging from 8% to 21%[42].

ENDOSCOPIC THERAPY OF NON-DYSPLASTIC BE

The debate rages on in the world of BE whether ablation of non-dysplastic Barrett's esophagus (NDBE) should be performed. Endoscopists advocating ablation of NDBE extrapolate the success of RFA in patients with HGD and LGD, applying these findings to non-dysplastic metaplasia. Another argument favoring ablation of NDBE is the lack of randomized controlled trials showing that surveillance of BE reduces mortality from esophageal adenocarcinoma, and thus other interventions should be considered[43,44]. Endoscopists who argue against ablation of NDBE focus on the lack of high quality evidence available to support such a notion and the very low rates of progression to cancer reported for non-dysplastic BE. Other issues proposed in the argument against ablation of nondysplastic BE include issues related to subjecting large numbers of patients to multiple endoscopic procedures, and the associated costs of the procedures and risk of complications[45]. One other argument against ablation of non-dysplastic BE is the possibility of missing subtle nodularity or mucosal changes that would be optimally treated with EMR, and instead burying it with suboptimal RFA therapy[45,46]. More prospective randomized controlled trials are needed to study the utility of RFA and other endoscopic therapies to treat NDBE. The AGA and ASGE mention that RFA could be considered for selected patients with NDBE thought to be at increased risk of progression to HGD and cancer[1,10].

CONCLUSION

The treatment options for HGD in BE have evolved into less-invasive therapies. There are now highly effective endoscopic therapies that are less morbid than esophagectomy. Most patients are treated with a combination of endoscopic resection and RFA with good outcomes. However, it is the job of the gastrointestinal endoscopist to be vigilant in surveillance for possible dysplasia recurrence in these patients. We have not yet reached the point where a patient can be told he or she has experienced complete eradication with no possibility of recurrence, and all patients should remain in surveillance. Until that time comes, we will continue to sharpen the endoscopic tools that will help us along the way to a durable cure.

Abstract

Benign esophageal strictures refractory to the conventional balloon or bougie dilatation may be subjected to various adjunctive modes of therapy, one of them being endoscopic incisional therapy (EIT). A proper delineation of the stricture anatomy is a prerequisite. A host of electrocautery and mechanical devices may be used, the most common being the use of needle knife, either standard or insulated tip. The technique entails radial incision and cutting off of the stenotic rim. Adjunctive therapies, to prevent re-stenosis, such as balloon dilatation, oral or intralesional steroids or argon plasma coagulation can be used. The common strictures where EIT has been successfully used are Schatzki's rings (SR) and anastomotic strictures (AS). Short segment strictures (< 1 cm) have been found to have the best outcome. When compared with routine balloon dilatation, EIT has equivalent results in treatment naïve cases but better long term outcome in refractory cases. Anecdotal reports of its use in other types of strictures have been noted. Post procedure complications of EIT are mild and comparable to dilatation therapy. As of the current evidence, incisional therapy can be used for management of refractory AS and SR with relatively short stenosis (< 1 cm) with good safety profile and acceptable long term patency.

Key words: Endoscopic incisional therapy; Esophageal strictures; Anastomotic strictures; Needle knife; Radial incision and cutting

Core tip: Benign esophageal strictures refractory to conventional balloon or bougie dilatation can be subjected to endoscopic incisional therapy. The technique entails the use of needle knife or scissors for radial incision and cutting off of the stenotic rim. Adjunctive therapies with balloon dilatation or intralesional steroids may be needed for prevention of re-stenosis. Current evidence suggests use of incisional therapy for refractory short segment (< 1 cm) anastomotic strictures and Schatzki's rings with good safety profile and acceptable long term patency.

INTRODUCTION

Benign esophageal strictures are a frequent challenge for the endoscopist. Peptic injury secondary to chronic acid exposure accounts for 80% of all benign esophageal strictures[1]. However, the remaining 20%-30% may be associated with Schatzki's rings (SR), esophageal webs, post radiation injury, anastomotic strictures (AS) and caustic ingestion. Based on anatomical complexity the strictures are classified as either simple or complex[2]. Simple are those with short, straight strictures, usually allowing passage of normal diameter endoscopes and are easy to treat (webs, rings and peptic strictures). The difficult to treat complex strictures are longer (> 2 cm), angulated or with severely stenosed lumen, a consequence of fibrosis with cicatricial narrowing. AS, caustic strictures and radiation strictures are known to be complex strictures[2]. Dilatation by bougie or balloon dilators has been the age old technique for management of benign esophageal strictures and generally the simple ones respond adequately to 1-3 dilatations[3]. The more difficult ones require more sessions of dilatations or the need for additional modes of treatment. Henceforth, Kochman *et al*[4] have defined strictures as: (1) refractory, when there was a persisting dysphagia score of 2 or more, as a result of inability to successfully achieve a diameter of 14 mm over 5 sessions at 2 wk intervals; and (2) recurrent, when there was inability to maintain a satisfactory luminal diameter for 4 wk once the target diameter of 14 mm had been achieved.

Although dilatation is a time tested, safe and effective mode of therapy for esophageal strictures, 10% of patients may require repeated dilatations[4,5] and 90% of those who have a single recurrence will eventually develop further recurrence. Moreover, dilatation failure group will require adjunctive modes of therapy. The various endoscopic options (Table 1) besides dilatation are intralesional steroid injection[6-8] or topical mitomycin C[9,10], esophageal stenting (self-expanding metal stents[11-13], self-expanding plastic stents[14,15] and biodegradable stents[16-19]), rendezvous procedure (antegrade and retrograde dilatation)[20,21] and incisional therapy.

Limited literature exists on endoscopic incisional therapy (EIT) and this review will deal with indications, techniques and the outcome of this modality in the management armamentarium of benign esophageal strictures.

DESCRIBED USES OF EIT

After the first description of its utility by Raskin *et al*[22] for Schatzki's ring in 1985, incisional therapy has been found to be useful in a number of other causes such as AS[23-25], strictures after esophageal endoscopic sub mucosal dissection (ESD) or endoscopic mucosal resection (EMR)[26,27], corrosive strictures[28], upper esophageal webs[29] and a host of other benign strictures.

TECHNICAL DETAILS OF INCISIONAL THERAPY

Pre procedure assessment

Before subjecting a patient to EIT a proper assessment of the indication, the suitability of the procedure and the safety of the patient has to be done. The baseline symptom profile including the grade of dysphagia has to be recorded. Usually, strictures refractory to conventional modes of therapy are subjected to EIT as use of EIT for naive strictures (without prior dilatation therapy) has not been found to be superior to the conventional dilatation[30]. Active inflammation or underlying malignancy has to be ruled out with histology. Contrast esophagography and cross sectional imaging are needed for proper delineation of the stricture anatomy. The diameter of the stricture can be roughly estimated on endoscopy as: (1) size of 10 mm or more if a standard endoscope tip can be passed (GIF-H180 with insertion tube diameter of 9.8 mm; Olympus Medical Systems, Tokyo, Japan); (2) size of 5-10 mm if standard ultrathin scope can be passed (GIF-N180 with insertion tube diameter of 4.9 mm); (3) size of 2-5 mm if the ultrathin scope cannot be passed; and (4) less than 2 mm (pin point strictures) if the outer sheath of the needle-knife catheter (1.7-mm needle diameter) (Wilson Cook Medical Inc, Winston-Salem, NC) can just be passed or not pass through. The depth of the lesion is assessed by comparing with the length of the needle knife (approximately 4 mm). This documentation will help in outcome assessment post therapy. Finally, patients with bleeding diathesis, respiratory failure, severe or unstable cardiac disease and anastomotic leakage or infection need correction of these risk factors before therapy.

Instruments required

EIT has been carried with a host of electrocautery and mechanical devices including polypectomy snares and

argon plasma coagulation[31]. However, the most widely used are the needle knives that are nothing but "naked" diathermy wires[32]. The standard needle knife designed for endoscopic retrograde cholangio-pancreaticography is a diathermy wire that protrudes out of the catheter sheath by a handle mechanism and electrocautery is done powered by electrosurgical generators. This free hand technique is a cause of concern for fear of perforation. To minimize this risk, a modification has been made with the addition of an insulated ceramic tip (insulated tip needle knife, IT knife) allowing only cutting at the side. Other modifications such as the hook tip knife can also be used[32].

Mechanical devices that have been used are the Heiss-Device flexible endoscopic scissors (Telemed Systems, Hudson, Mass) and the FS-3L-1, endoscopic suture scissors (Olympus America Corp, Melville, NY).

A combined mechanical and electrocautery device, originally devised for ESD, known as SB Knife Jr (Sumitomo Bakelite Co., Tokyo, Japan) has also been used. It is a scissor-type knife with rotatable monopolar scissors and insulated coating for enhanced incision power while protecting surrounding tissues. A comprehensive table of the various instruments with their specifications has been depicted in Table 2 and Figure 1.

The technique

First applied to SR, the most commonly used incisional therapy is the needle knife electroincision and will be dealt with in detail here. Although most commonly the standard needle knife is used, with the advent of various modifications, the IT-knife is preferred for short strictures[32]. The basic principle of this modality is the same as dilatation, *i.e.*, disruption or displacement of the fibrotic tissue to help restore a satisfactory lumen diameter and prevent the reorganization of the fibrotic tissue.

The electroincision requires use of radial incisions with the knife attached to an electrosurgical unit such as UES-30 generator (Olympus, Tokyo, Japan) or more commonly ERBE generator (Elektromedizin GmbH, Tübingen, Germany) with software controlled fractionated cuts either in the pure cut or blended cut modes.

The technique used has been essentially the application of radial incision of the stricture area and was rechristened with the term of "radial incision and cutting" (RIC) method by Muto *et al*[25] RIC is carried out in the following steps (Figure 2): (1) The stricture area is incised under direct vision with the needle knife in a radial fashion parallel to the longitudinal axis of the esophagus. Usually a virtual line connecting the cranial and the caudal sides of the lumen is presumed and the incision line is guided accordingly. Precise movement is imperative for appropriate use of needle knife and can be achieved better with the endoscope tip movement rather than the needle itself; (2) The length and the number of incisions are guided by the need to completely remove the rim of stenosis. On an average, 8-12 radial incisions are needed[24]. The incision depth is assessed using the needle-knife length as a comparator; (3) While for short segment strictures, the

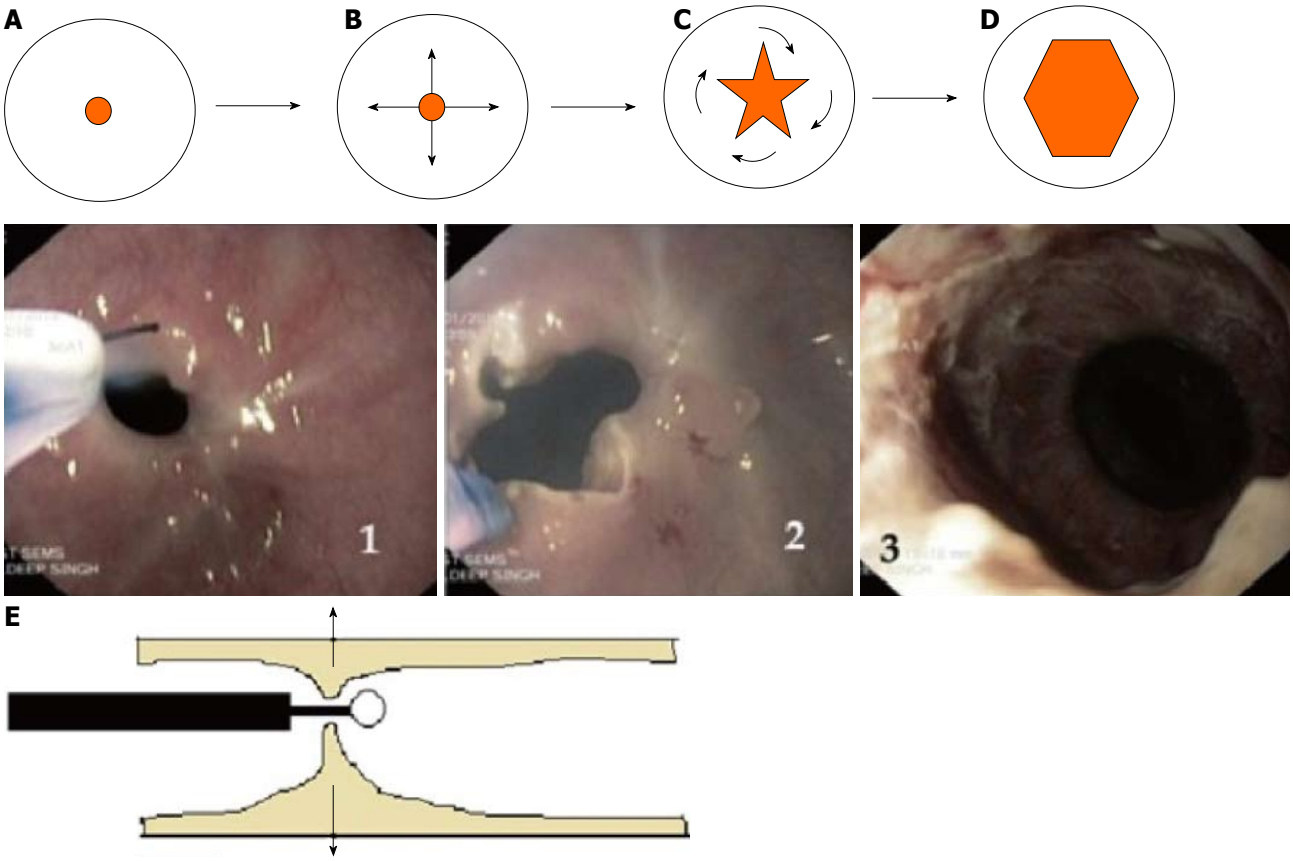

Figure 2 The technique of endoscopic incisional therapy procedure. A-D: Schematic front view of stricture site; B: Arrows depict the radial direction of incision; C: Curved arrows depict the slicing off of the intervening areas; D: Final outcome at the end of procedure; E: Lateral view of stricture site depicting the transverse working domain of the needle knife (arrows); 1: Use of needle knife for incision; 2: After radial incision; 3: At the end of EIT and balloon dilatation. EIT: Endoscopic incisional therapy.

technique is pretty straight forward, but for long segment ones, many times an opening needs to be created with multiple, short radial incisions before the scope can be negotiated for distal segments. Thus, technically difficult as it is for long segment ones, complete removal of the stenosed rim may not always be feasible; and (4) The parts of the strictured site in between the incision lines are then sliced off using the knife and the procedure is usually terminated once the scope can be easily passed across the strictured segment.

A modification to the technique proposed by Lee *et al*[24] was the use of a transparent hood attached to the scope tip for better visualization of the work field.

Post-procedure the patients are observed for immediate complications such as pain, significant bleeding or perforation. Once these have been ruled out, the patients can be discharged and assessed on a regular basis for recurrence of symptoms, grade of dysphagia or weight loss for which repeat assessment and redo of the therapy may be needed. Similar to the needle knife used for EIT various other devices such as the polypectomy snare[31] or scissors[28,33] have also been used.

Adjunctive measures

In the post-procedure phase, when the tissue has been freshly incised and chances of re-formation of stenosing fibrotic scar are high, various adjunctive measures have been described. Endoscopic balloon dilatation (EBD) with CRE balloon dilators (Boston Scientific, Natick, MA) have been done post-procedure and repeated frequently till the scarring of the cut surface[23,25,27]. Nonaka *et al*[28] have described the use of oral steroids for the prevention of re-stenosis. Yamaguchi *et al*[34] also demonstrated prevention of stricture after ESD with prednisolone. It has already been established in literature that use of intralesional steroids can prevent stricture recurrence[6-8]. The study of the efficacy of the same after EIT is currently being carried out in a large multi-center randomized control trial in Japan (UMIN Clinical Trials Registry: UMIN000014017). Argon plasma coagulation use has also been described along with incision for stepwise reduction of the scar tissue[31].

Evaluation of the treatment outcome

Recurrence of symptoms with dysphagia more than grade Ⅱ or the inability to pass a standard endoscope (9.5 mm) across the stricture site is considered as recurrent stenosis. If this condition arises even after 5 sessions of EIT, it is considered as treatment failure[30]. Post-procedure relief of symptoms, need for repeat procedure and the long term patency are factors assessed for the efficacy assessment of the procedure.

OUTCOME OF INCISIONAL THERAPY

The incisional therapy has been an alternate modality for the management of benign refractory strictures. The average time required for the procedure ranges from 6-14 min[24,25]. The majority of the published studies describe its use primarily in SR and AS. Anecdotal case reports have been found of its use in other conditions.

SR

After the first description of electrosurgical incision of SR by Raskin *et al*[22] in 1985, various studies have used it. When used as the initial intervention modality for SR (*i.e.*, without prior dilatation therapy), Guelrud *et al*[35] produced excellent results with 14 out of 17 patients (82.4%) becoming asymptomatic after a single session of EIT during a follow up of 46 mo. In the dilatation unresponsive group, Burdick *et al*[36] showed improvement in dysphagia in 6 out of 7 patients (85.7%) after a single session of EIT over a 36 mo follow-up, however later studies failed to replicate a similar outcome. DiSario *et al*[37] conducted EIT on 11 patients, who had a median of 3 dilatations prior to incision, out of whom 4 (36%) remained symptom free but 7 (64%) required further incisions or dilatations during a median follow-up of 55 mo. However, they found that there was a significant increase in the mean duration of improvement immediately after incision as compared with that of dilatation (17 mo *vs* 5 mo; $P = 0.034$).

In a prospective randomized study, comparing bougie dilatation with EIT as the initial therapy for symptomatic SR, Wills *et al*[38] demonstrated that both modalities had similar efficacy in symptom control, dysphagia and GERD, during a 12 mo follow-up period. However, the EIT group had longer symptom free survival time compared with the bougie dilatation group (7.99 mo *vs* 5.86 mo; $P = 0.03$).

AS

The most common esophageal stricture variant where EIT has been studied is the anastomotic stricture, mostly esophago-gastric anastomosis. Esophageal AS develops in 5%-46% of patients after surgical resection[2,39] and is secondary to post-operative complications such as bleeding, fistulization, leak development, anastomotic site infection and ischemia of the gastric anastomosis[2,39,40]. The success of balloon dilatation ranges from 70%-90% while 40% require more than 3 dilatations for optimal result[39-41]. A viable alternate management option has been the use of EIT as demonstrated in various studies (Table 3).

In cases of treatment naïve patients, after a single session of EIT, recurrence free course over a 6-24 mo follow up has been found to be 80.6% to 93%[24,30,31]. Thus, it is quite an effective therapy compared to dilatation without the need for repeated sessions for a considerable period of time. In fact, in a comparative trial with bougie dilatation, Hordijk *et al*[30] demonstrated that both EIT and dilatation were equally efficacious (80.6% *vs* 67.7%) at 6 mo follow-up.

In the more difficult group of refractory strictures, the symptom free rate dropped to 60% to 65%[25,42] with 44% requiring re-treatment. However, when

Table 3 Various studies of incisional therapy in esophageal anastomotic stricture

Ref.	Type of stricture	No. of patients	Length of stricture	No. of pre-procedure dilatations[1]	Follow-up duration (mo)	Outcome of single session
Schubert *et al*[31], 2003	Treatment naive	15	6.1 mm (3-10 mm)	NA	23	No recurrence - 14/15 (93%)
Simmons *et al*[23], 2006	Refractory	9	--	6	3-14	No dysphagia - 4/9 (44.4%) No response - 1/9 (11%)
Hordijk *et al*[42], 2006	Refractory	20	< 1 cm - 12 cm > 1 cm - 8 cm	8	12	No dysphagia - 12/20 (60%) Recurrence - 8/20 (40%) Treatment failure - 2/20 (10%)
[2]Hordijk *et al*[30], 2009	Treatment naive	EIT arm - 31	EIT arm - 1.35 cm	N/A	6	No difference in the success rate (80.6% *vs* 67.7%)
		SB arm - 31	SB arm - 0.55 cm (mean)			Treatment failure- EIT arm - 1; SB arm - 5
Lee *et al*[24], 2009	Treatment naive	24	< 1 cm - 21 cm > 1 cm - 3 cm	N/A	24	No recurrence - 21/24 (87.5%) Restricture - 3/24 (12.5%)
Muto *et al*[25], 2012	Refractory	EIT - 32	⩽ 5 mm - 49 mm	10	EIT - 14.8	Short term - 93.8% improvement
		EBD - 22	> 5 mm - 5 mm		EBD - 17.2	Long term - EIT better than EBD

[1]Mean number of dilatations; [2]Randomized prospective study. Treatment naïve: No previous dilatation; EIT: Endoscopic incisional therapy; SB: Savary bougienage; EBD: Endoscopic balloon dilatation; NA: Not applicable.

compared to continued dilatation therapy, EIT performed better than dilatation with significantly higher patency rates at 6 mo (65.3% *vs* 19.8%, $P < 0.005$) and 12 mo (61.5% *vs* 19.8%, $P < 0.005$) follow-up[25].

The other most important contributor of EIT response is the length of the stricture. Hordijk *et al*[42] had demonstrated that while patients with stricture length less than 1 cm had recurrence free course, all patients with stricture length greater than 1 cm had recurrence. Similar finding has been shown by Lee *et al*[24] wherein only 4.8% patients with stricture < 1 cm had re-stricture as compared to 66.7% in the group with stricture > 1 cm. This has been attributed to the increased amount of fibrosis in the longer strictures and hence decreased response.

Other strictures

In a retrospective study of 8 patients with post chemo-radiotherapy, ESD or EMR induced strictures, EIT improved dysphagia in all patients in the immediate post-procedure phase but 3 mo lumen patency was seen in only 3 (37.5%) patients[26].

Anecdotal case reports of use of endoscopic scissors have been used for management of corrosive strictures[28] and fibrous scar in proximal esophagus[33]. Stricture after surgery for esophageal atresia in a 4-year-old child has also been reported to be managed with EIT along with stenting[43].

Author's experience

A total of 14 patients with benign esophageal strictures (AS 5, corrosive strictures 4) have been subjected to incisional therapy along with balloon dilatation. Incisional therapy was done with Microknife™ XL Triple lumen knife (Boston Scientific, Natick, United States) followed by balloon dilatation with CRE™ Balloon Dilator (Boston Scientific, Natick, United States). Successful dilatation was achieved in 11 of the 14 after 3-9 sessions. No complications were noted.

COMPLICATIONS

Complications of EIT include pain, bleeding or perforation. Perforation is the most dreaded complication and can occur because of inability to gauge the depth of the esophageal wall or the length of the stricture during the incision therapy. Bleeding is usually self-limited and lesser known complication as the fibrotic strictures subjected to incisional therapy are relatively avascular. The complication rate of EIT appears to be mild comparable to dilatations with bougies or balloons, which can have perforation or significant hemorrhage at a rate of 0.1% to 0.4%[3]. For EIT, the reported perforation rate ranges from 0%-3.5%[24,25,30,37,42] with no reported evidence of significant bleeding. Perforation can be managed essentially with conservative treatment and if it fails, can be subjected to stent placement or surgery. Bleeding can be easily managed with methods such as balloon tamponade. Thus, EIT is a safe therapeutic option for stricture management.

CURRENT STATUS OF INCISIONAL THERAPY

As of the current evidence, EIT can be used as a treatment modality for refractory SR and AS with relatively short stenosis (< 1 cm). A suggested algorithm for the management of benign strictures has been shown in Figure 3.

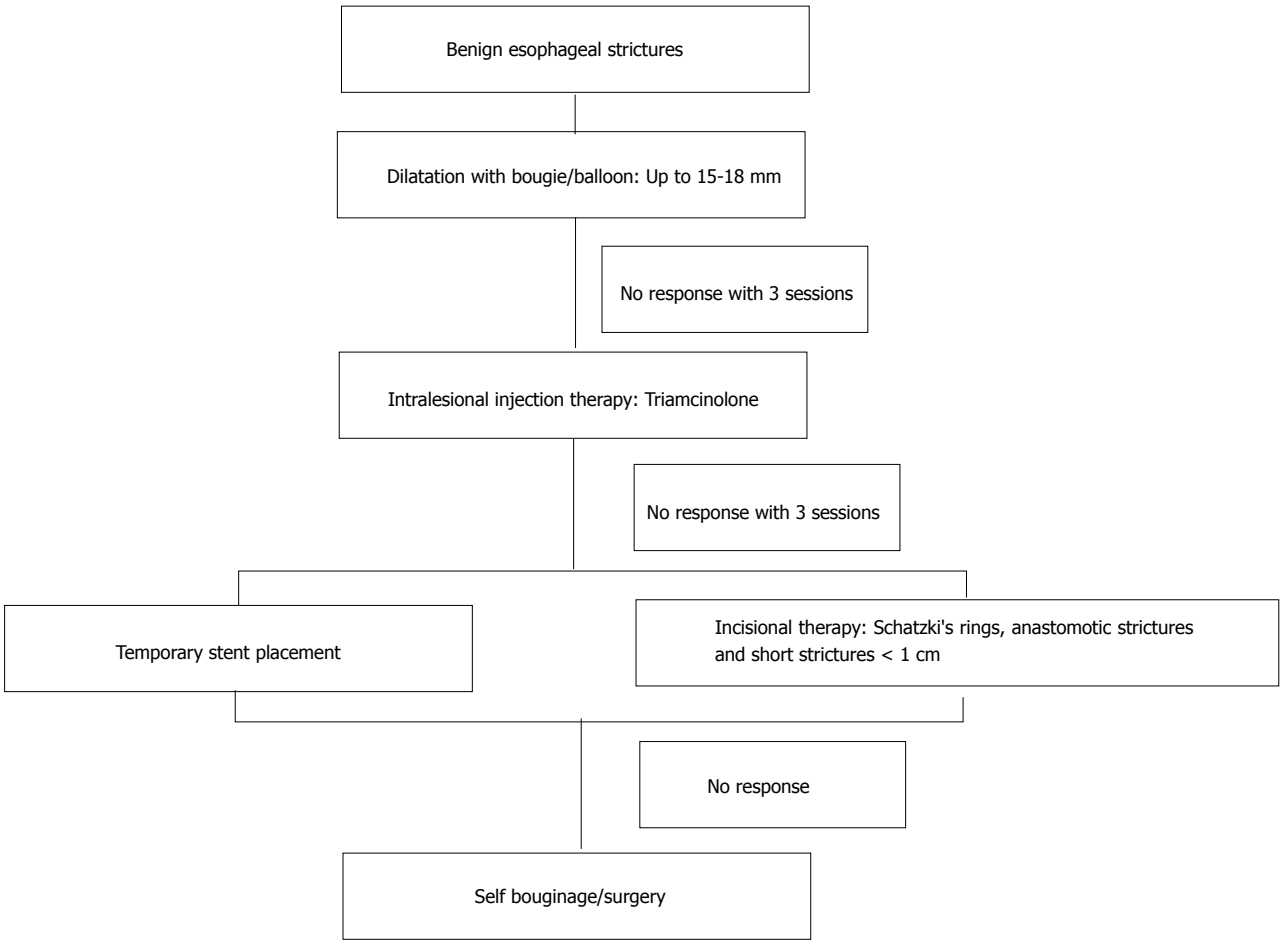

Figure 3 Algorithm for the management of benign esophageal strictures.

AREAS OF FUTURE RESEARCH

A number of questions need to be answered through larger trials before a standardized recommendation can be made regarding the use of incisional therapy in esophageal stricture management: (1) it can be used for all refractory strictures; (2) number of balloon or bougie dilatations before considering EIT; (3) cumulative risk of the procedure; (4) efficacy and applicability of instruments other than needle knife; (5) the choice of adjunctive therapy to prevent re-stenosis; (6) cost effectiveness of the therapy in the long run; and (7) technical expertise and applicability issues in day-to-day practice.

CONCLUSION

EIT is a feasible, safe and effective treatment modality for benign short refractory esophageal strictures with established evidence in SR and AS. It has good immediate symptom improvement with acceptable long-term patency.

Abstract

AIM: To assess the safety of single-incision laparoscopic cholecystectomy (SILC) for acute cholecystitis.

METHODS: All patients who underwent SILC at Sano Hospital (Kobe, Japan) between January 2010 and December 2014 were included in this retrospective study. Clinical data related to patient characteristics and surgical outcomes were collected from medical records. The parameters for assessing the safety of the procedure included operative time, volume of blood loss, achievement of the critical view of safety, use of additional trocars, conversion to laparotomy, intraoperative and postoperative complications, and duration of postoperative hospital stay. Patient backgrounds were statistically compared between those with and without conversion to laparotomy.

RESULTS: A total of 100 patients underwent SILC for acute cholecystitis during the period. Preoperative endoscopic treatment was performed for suspected choledocholithiasis in 41 patients (41%). The mean time from onset of acute cholecystitis was 7.7 d. According to the Updated Tokyo Guidelines (TG13) for the severity of cholecystitis, 86 and 14 patients had grade Ⅰ and grade Ⅱ acute cholecystitis, respectively. The mean operative time was 87.4 min. The mean estimated blood loss was 80.6 mL. The critical view of safety was obtained in 89

patients (89%). Conversion laparotomy was performed in 12 patients (12%). Postoperative complications of Clavien-Dindo grade Ⅲ or greater were observed in 4 patients (4%). The mean duration of postoperative hospital stay was 5.7 d. Patients converted from SILC to laparotomy tended to have higher days after onset.

CONCLUSION: SILC is feasible for acute cholecystitis; in addition, early surgical intervention may reduce the risk of laparotomy conversion.

Key words: Acute cholecystitis; Single-port access surgery; Single incision laparoscopic cholecystectomy; Single incision laparoscopic surgery; Laparo-endoscopic single-site surgery

Core tip: Single-incision laparoscopic cholecystectomy (SILC) has attracted attention as a minimally invasive procedure. A scar-less operation can be achieved by making a skin incision at the umbilicus. However, the safety of this procedure for acute cholecystitis has not been established. We reported 100 consecutive cases of SILC for acute cholecystitis and their surgical outcomes. SILC was safely performed in approximately 80% of cases in this series. We believe that the results of this study indicate the feasibility of SILC for acute cholecystitis.

Feasibility of single-incision laparoscopic cholecystectomy for acute cholecystitis. *World J Gastrointest Endosc* 2015; 7(19): 1327-1333 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i19/1327.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i19.1327

INTRODUCTION

Cholecystectomy is widely performed as a basic treatment for acute cholecystitis. In the Updated Tokyo Guidelines issued in 2013 (TG13), early cholecystectomy is recommended as the first treatment choice, except for severe cases with organ failure[1]. Laparoscopic cholecystectomy (LC) is now a mainstream procedure. When performed by skilled surgeons, LC is considered a safe procedure even for acute cholecystitis[2].

In recent years, single-incision laparoscopic surgery (SILS) has attracted attention as a minimally invasive procedure. In SILS, multiple devices are inserted from a single skin incision into the abdominal cavity to reduce the length and number of incisions. In particular, scarless operations can be achieved by making skin incisions at the umbilicus[3]. Because cholecystectomy is performed in a nearly fixed visual field and because it does not require wide-range maneuvers, SILS is easily incorporated into cholecystectomy. SILC is becoming established as a procedural option.

However, there are limited reports on surgical outcomes of SILC for acute cholecystitis. Because maneuverability is limited in SILC compared with that in conventional LC, the safety of this procedure for acute cholecystitis has not yet been established. If SILC is as safe as conventional LC, SILC will become the procedure of choice for patients who desire better aesthetic outcomes. Although successful completion of SILC is a prerequisite for better aesthetic outcomes, data on acute cholecystitis are limited. At our hospital, we have focused on SILC and cases of acute cholecystitis. Thus, in order to address these clinical questions, we conducted a retrospective study of past cases. The objectives of this study were to assess the safety of SILC for acute cholecystitis and to investigate requirements for successful completion of SILC.

MATERIALS AND METHODS

This study included all patients who underwent SILC for acute cholecystitis at Sano Hospital (Kobe, Japan) between January 2010 and December 2014. Although SILC is, in principle, performed for all patients requiring cholecystectomy, four patients for whom laparoscopy had not been selected at the discretion of their attending physicians and one patient suspected to have concomitant gallbladder cancer were excluded. According to TG13[4], acute cholecystitis was diagnosed in patients who met all the following diagnostic criteria: (1) local inflammatory signs; (2) systemic inflammatory findings; and (3) characteristic imaging findings. Data were collected from medical records and analyzed. The parameters used to assess the safety of the surgery included operative time, volume of blood loss, achievement of the critical view of safety, use of additional trocars, conversion to laparotomy, intraoperative and postoperative complications, and duration of postoperative hospital stay.

Surgical technique

We performed SILC using a standard technique with conventional trocars and instruments. A 20-mm incision was first made at the umbilicus. An optical port, a 5-mm trocar, and 5-mm forceps were inserted in the incision. These three instruments were placed in a triangle to maximize their spacing. In addition, a 3- or 5-mm instrument was inserted beside the optical port. We did not use any devices specialized for SILS.

It is feasible to perform nearly the same surgical procedure as conventional LC because the potential interference of each device is minimized by direct insertion of two instruments without trocar. We made every effort to create the critical view of safety, as described by Strasberg. To prevent bile duct injury, we converted to open surgery when we could not create the critical view of safety or could not identify the cystic duct.

Drainage tubes were not routinely placed, even in

Table 1 Patient characteristics

	Acute cholecystitis (n = 100)
Mean age (yr ± SD)	66.8 ± 14.4
Sex	
Male	51
Female	49
Mean BMI (kg/m^2 ± SD)	23.9 ± 3.3
History of abdominal surgery	26 (26%)
Suspected choledocholithiasis	41 (41%)
Mean time from onset (d ± SD)	7.7 ± 4.1
TG13 severity grading	
Grade Ⅰ (mild)	86 (86%)
Grade Ⅱ (moderate)	14 (14%)

SD: Standard deviation; BMI: Body mass index; TG13: Updated Tokyo Guidelines.

Table 2 Surgical outcomes

	Acute cholecystitis (n = 100)
Mean operative time (min ± SD)	87.4 ± 39.3
Mean estimated blood loss (mL ± SD)	80.6 ± 162.4
Achievement of critical view of safety	89 (89%)
Additional trocar insertion	9 (9%)
Conversion to laparotomy	12 (12%)
Postoperative complication	4 (4%)
Bile leakage	(2)
Stone passage into the CBD	(2)
Mean duration of postoperative hospital stay (d ± SD)	5.7 ± 5.1

SD: Standard deviation; CBD: Common bile duct.

cases of severe inflammation. However, we placed a drainage tube from the right lateral abdomen to the liver bed in cases of suspected remnant abscess or bile leakage.

Statistical analysis

The *t* test was used to assess differences in patient age, body mass index (BMI), and days from onset. The Fisher exact test was used to assess differences in all other factors. All tests were two-sided, and *P*-values less than 0.05 were considered to indicate a statistically significant difference. All statistical analyses were performed with EZR (Saitama Medical Center, Jichi Medical University, Saitama, Japan), a graphical user interface for R (The R Foundation for Statistical Computing, Vienna, Austria)[5].

RESULTS

Patient characteristics

During the study period, 100 patients underwent SILC for acute cholecystitis. Their mean age was 66.8 years. The male-to-female ratio was 51:49. Their mean BMI was 23.9 kg/m^2. A history of some type of abdominal operation was found in 26 patients (26%). Choledocholithiasis was suspected in 41 patients (41%), based on imaging studies, and endoscopic lithotomy was performed before SILC. The mean time from the onset of acute cholecystitis to cholecystectomy was 7.7 d. According to TG13[4] guidelines for the severity of cholecystitis, 86 patients and 14 patients had grades I and II acute cholecystitis, respectively (Table 1).

Table 3 Histological diagnoses of resected gallbladder for acute cholecystitis

	n = 100
Edematous cholecystitis	9
Necrotizing cholecystitis	8
Suppurative cholecystitis	5
Chronic cholecystitis	74
(Acute on chronic cholecystitis)	(61)
Xanthogranulomatous cholecystitis	1
Adenocarcinoma	3

Surgical outcomes

The surgical outcomes are shown in Table 2. The mean operative time was 87.4 min, and the mean estimated blood loss volume was 80.6 mL. The critical view of safety was achieved in 89 patients (89%), although anterograde dissection of the gall bladder starting from the fundus was required for 42 of these patients. Additional trocar insertion was required in 9 patients (9%). SILC was converted to laparotomy in 12 patients (12%). A drainage tube was placed in 13 patients (13%), including 4 patients with necrotizing cholecystitis. Postoperative complications of Clavien-Dindo grade III or greater were observed in 4 patients (4%). The complications included leakage of bile from the stump of the cystic duct and passage of stones into the common bile duct in two patients each. These complications were resolved in all four patients using only endoscopic treatment. The mean postoperative hospital stay was 5.7 d.

Histological diagnosis

Histological diagnoses of the resected gallbladders included acute-on-chronic cholecystitis in 61 patients, edematous cholecystitis in 9 patients, necrotizing cholecystitis in 8 patients, suppurative cholecystitis in 5 patients, and xanthogranulomatous cholecystitis in 1 patient. Incidental adenocarcinomas were founded in 3 patients (Table 3).

Comparison of patients with and without conversion to laparotomy

The results of comparison between patients with and without conversion to laparotomy are shown in Table 4 and Figure 1. Despite the lack of statistical significance, the number of days after onset tended to be higher in patients who were converted from SILC to laparotomy.

Learning curve

The mean operative times of every five consecutive cases of SILC performed by a chief surgeon are shown

Table 4 Comparison of patients with and without conversion to laparotomy

	Without conversion (n = 88)	With conversion (n = 12)	P value
Mean age (yr ± SD)	66.1 ± 14.5	71.6 ± 13.3	NS
Sex			
Male	44	7	NS
Female	44	5	
Mean BMI (kg/m^2 ± SD)	23.9 ± 3.1	24.1 ± 4.7	NS
History of abdominal surgery	22 (25%)	4 (33.3%)	NS
TG13 severity grading			
Grade I (mild)	82 (93.2%)	4 (33.3%)	P < 0.001
Grade II (moderate)	6 (6.8%)	8 (66.7%)	
Mean time from onset (d ± SD)	7.5 ± 4.0	9.1 ± 4.4	NS

SD: Standard deviation; NS: Not significant; BMI: Body mass index; TG13: Updated Tokyo Guidelines.

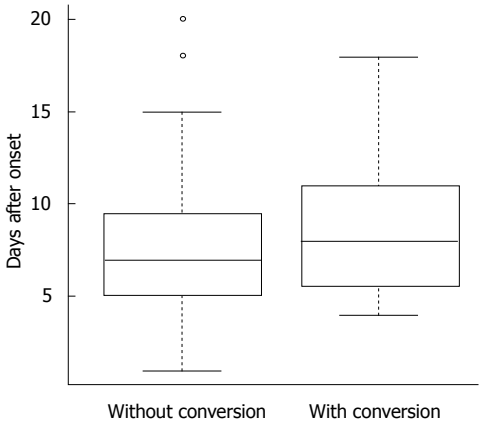

Figure 1 Time after onset of acute cholecystitis. Patients with conversion to laparotomy show a tendency toward increased preoperative days from onset.

in Figure 2. There were no obvious trends suggestive of a learning curve.

DISCUSSION

Although Navarra *et al*[6] first reported SILC in 1997, it did not initially attract much attention. However, SILC has been rapidly adopted since 2009, with improvements to platforms and devices dedicated for SILS[7-11]. Since then, SILS has been increasingly used, mainly because of its excellent aesthetic outcome; it has been widely applied not only to cholecystectomy, but also to appendectomy, colectomy, gastrectomy, urologic procedures, and gynecologic procedures[12-16]. LC in particular is relatively easy to perform with SILS, and SILC is routinely performed. The reasons for this include: (1) the surgical field is limited to the liver bed; (2) the direction of scopes and devices remains almost constant; (3) the procedure is mainly indicated for benign conditions; and (4) many patients undergoing the procedure are young. However, the drawbacks of SILS include: (1) the limited maneuverability of scopes and devices that may interfere with one another; and (2) difficulty in setting devices at different angles, as all devices are oriented in the same direction. Compared with conventional LC, SILC is technically more difficult. Because advanced endoscopic surgical techniques are required to perform SILC, it is a difficult procedure for less experienced surgeons. However, these obstacles have been gradually eliminated owing to advances such as the innovation of techniques appropriate for SILS, development of dedicated platforms, and introduction of pre-bending forceps[7,17-20].

Several randomized controlled trials (RCTs) have revealed that SILC is as safe as conventional LC[21-23]. However, to our knowledge, no RCT has assessed only patients with acute cholecystitis, for which SILC is technically more difficult, and the safety of SILC for acute cholecystitis has not been established. Thus, we reviewed 100 consecutive cases of SILC performed for acute cholecystitis and reported their surgical outcomes. The operative time tended to be longer in patients with cholecystitis; this likely reflects the difficulty of operative maneuvers. Moreover, the volume of intraoperative blood loss also tended to be higher; this may be attributable to the facts that (1) the gallbladder and its surrounding tissue affected by acute inflammation are more likely to bleed because they are congested and become edematous; and (2) the hepatic parenchyma is easily damaged because of inflammatory adherence of the gallbladder to the liver bed. These findings suggest that SILC for acute cholecystitis involves some level of difficulty. Thus, application of SILC should require careful consideration.

However, we performed SILC in all patients with acute cholecystitis who were judged to require cholecystectomy, and SILC was successfully completed without additional trocars in approximately 80% of cases. These findings indicate that SILC is applicable to many patients, even those with acute cholecystitis. Moreover, because the complication rate in this study is not higher than that reported in another study[23], we believe that SILC for acute cholecystitis is as safe as other surgical procedures under the conditions described in this study. In other words, the results of our study suggest that SILC can be performed in patients with acute cholecystitis without compromising safety. At minimum, there appears to be no need to exclude patients with acute cholecystitis from SILC.

New procedures typically have learning curves. However, there was no evidence of a learning curve for SILC

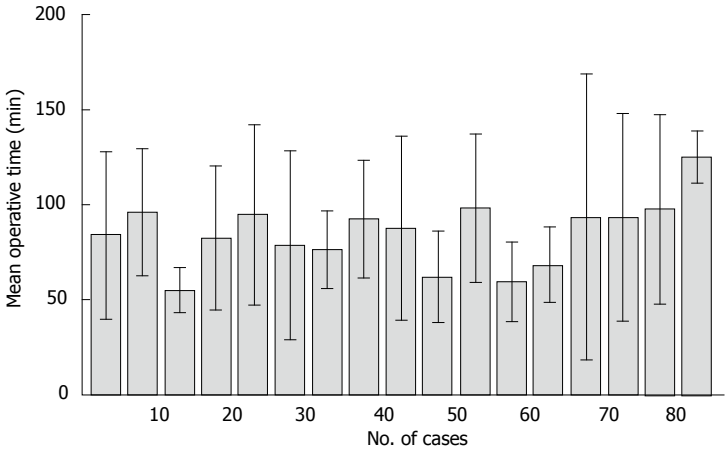

Figure 2 Mean operative time for every five consecutive cases of single-incision laparoscopic cholecystectomy for acute cholecystitis. All 85 cases performed by a chief surgeon are shown above. The standard deviation of each group is also shown. There are no obvious trends suggestive of a learning curve.

for acute cholecystitis in this study. This observation may be owing to the quality of the surgeons in our study. All surgeons who participated in this study were experienced and skilled in laparoscopic surgery and had each experienced more than 10 cases of SILC. Moreover, our SILC surgical procedure can be learned in a short time because of its similarity to conventional LC. However, the learning curve may be more obvious in less experienced surgeons.

SILC was introduced in our hospital in 2009. It was performed only in select patients during the early period after introduction while accumulating knowledge and standardizing the techniques used during the surgical procedure. Since January 2010, SILC has been applied to all patients, except those with gallbladder cancer. When the procedure is performed, we place the most emphasis on safety. Our policy is to convert SILC to laparotomy without hesitation when any difficulties present during the laparoscopic operation. The rate of conversion to laparotomy in the present study was slightly higher in patients with acute cholecystitis, likely owing to this policy. Consequently, no serious complications occurred, and excellent safety was demonstrated. Although the incidence of complications related with the bile duct was slightly high, this is likely because our institution specializes in endoscopic treatment. Many patients with suspected common bile duct problems seek treatment at our hospital. In fact, 41% of patients in this study were recommended to our facility for suspected choledocholithiasis and they underwent endoscopic treatment before cholecystectomy. This factor may have contributed to the increased incidence of these complications. Although bile leakage occurred in two patients with acute cholecystitis, it was not caused by damage during a laparoscopic operation, as neither case had been converted to laparotomy. While the common bile duct was not damaged in any of the patients, leakage was resolved by endoscopic biliary drainage after surgery. To maintain the safety of SILC, surgeons should never perform reckless operative maneuvers and convert to laparotomy before performing risky maneuvers.

However, a desire to avoid conversion to laparotomy is reasonable without compromising safety in terms of aesthetic outcome. In this study, SILC was converted to laparotomy in 12 patients (12%). The main reason for conversion was difficulties during the laparoscopic operation because of severe inflammatory fibrosis (10 patients). Operation difficulties owing to inflammation are reported related to the elapsed time between disease onset and operation[24]. The results of this study indicate that the number of preoperative days after onset tended to be higher in patients who were converted from SILC to laparotomy. Based on these findings, SILC performed as early as possible may permit resection before development of inflammatory fibrosis, and thus reduce the risk of laparotomy conversion. Avoiding laparotomy results in a less invasive procedure, less postoperative pain, and shorter postoperative hospital stay, making the merits offered by SILC more attractive. The TG13 recommends performing cholecystectomy within 72 h[25]. Unfortunately, we could not perform early surgery in many cases because of the lack of smooth cooperation with the first-contact physicians, limited availability of operation theater space, and lack of anesthetist availability. Despite our efforts to overcome these issues, some patients were unable to undergo early cholecystectomy. Conversely, in patients for whom early operation is not feasible, conservative treatment and elective SILC after complete suppression of inflammation may be preferable.

In conclusion, the results of this study suggest that SILC is feasible for acute cholecystitis and that early surgical intervention may reduce the risk of conversion to laparotomy. Although an aesthetic outcome is important, the decision to convert to laparotomy should be made based on other factors. We hope that SILC will be considered a safe procedure and be more widely used.

COMMENTS

Background

Cholecystectomy is widely performed as a basic treatment for acute cholecystitis. Laparoscopic cholecystectomy (LC) is considered a safe procedure and widely performed for acute cholecystitis.

Research frontiers

Recently, single-incision laparoscopic cholecystectomy (SILC) has been rapidly

adopted over conventional LC. SILC is considered a less invasive procedure with better aesthetic results. However, the safety of this procedure for acute cholecystitis has not yet been established.

Innovations and breakthroughs

In this study, the authors reviewed 100 consecutive cases of SILC for acute cholecystitis and reported their surgical outcomes. The authors focused on SILC as well as accumulated cases of acute cholecystitis. This study is based on single-institution and consecutive experiences.

Applications

The results of this study suggest the safety and difficulty of SILC for acute cholecystitis. SILC is feasible for acute cholecystitis. However, surgeons should not hesitate to convert to laparotomy when difficulties arise.

Terminology

SILC is also called single-port access surgery or laparo-endoscopic single-site surgery. It is a minimally invasive surgical procedure with a single skin incision. Scarless operations can be achieved by making a skin incision at the umbilicus. However, SILC is technically more difficult because of the limited maneuverability. Advanced laparoscopic surgical skills are required for SILC.

Peer-review

The authors retrospectively assessed the safety of SILC for acute cholecystitis. They concluded that SILC is feasible for acute cholecystitis and that early surgical intervention may reduce the risk of conversion to laparotomy. This article is of interest for further clinic practice.

Abstract

AIM: To evaluate the methodology, feasibility, safety and efficacy of a novel method called cap-assisted endoscopic sclerotherapy (CAES) for internal hemorrhoids.

METHODS: A pilot study on CAES for grade Ⅰ to Ⅲ internal hemorrhoids was performed. Colon and terminal ileum examination by colonoscopy was performed for all patients before starting CAES. Polypectomy and excision of anal papilla fibroma were performed if polyps or anal papilla fibroma were found and assessed to be suitable for resection under endoscopy. CAES was performed based on the requirement of the cap, endoscope, disposable endoscopic long injection needle, enough insufflated air and sclerosing agent.

RESULTS: A total of 30 patients with grade Ⅰ to Ⅲ internal hemorrhoids was included. The follow-up was more than four weeks. No bleeding was observed after CAES. One (3.33%) patient claimed mild tenesmus within

four days after CAES in that an endoscopist performed this procedure for the first time. One hundred percent of patients were satisfied with this novel procedure, especially for those patients who underwent CAES in conjunction with polypectomy or excision of anal papilla fibroma.

CONCLUSION: CAES as a novel endoscopic sclerotherapy should be a convenient, safe and effective flexible endoscopic therapy for internal hemorrhoids.

Key words: Sclerotherapy; Hemorrhoids; Cap-assisted endoscopic sclerotherapy; Colonoscopy; Colon; Papilla fibroma; Hemorrhoidal disease

Core tip: Sclerotherapy is the most effective therapy for grade Ⅰ or Ⅱ internal hemorrhoids. Traditional sclerotherapy may cause iatrogenic risk due to misplaced injections. We designed a novel technique called cap-assisted endoscopic sclerotherapy (CAES) for hemorrhoids by flexible endoscopy. Our study demonstrated that CAES is a safe, effective and convenient endoscopic therapeutic strategy for grade Ⅰ, grade Ⅱ and partial grade Ⅲ internal hemorrhoids. The colon preparation and colonoscopy before CAES brought more benefits for patients, including possible polypectomy and excision of anal papilla fibroma under colonoscopy. This study implies the future contribution of endoscopists on hemorrhoidal disease.

Cap-assisted endoscopic sclerotherapy for hemorrhoids: Methods, feasibility and efficacy. *World J Gastrointest Endosc* 2015; 7(19): 1334-1340 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i19/1334.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i19.1334

INTRODUCTION

Hemorrhoidal disease is one of the most common anorectal disorders that affects mainly adults of any age and sex[1-4]. The etiology of hemorrhoids remains controversial. Nowadays, the most widely accepted theory is that hemorrhoidal disease is the abnormal dilatation and distortion of the vascular channel, together with destructive changes in the supporting connective tissue of the anal cushion[5]. The submucosal vascular cushions are a normal anatomical structure of the anal canal and their existence with symptoms such as bleeding, prolapse, pain, thrombosis, mucus discharge and pruritus indicates hemorrhoidal disease[6]. The true incidence of hemorrhoids is difficult to estimate as many patients are reluctant to seek medical suggestions for various personal, cultural and socioeconomic reasons[7]. Approximately 50% of individuals require treatment for hemorrhoids in their 50s or older, and 10%-20% of patients need surgical therapies[8].

Hemorrhoids have been well described for thousands of years. However, the treatment of hemorrhoids has only substantially evolved during the past few decades[1]. The current therapies for hemorrhoids can be grouped into conservative management, office-based procedures and surgical treatment[8-10]. Increased fiber intake, medical therapies and lifestyle changes are included in the conservative treatment options for non-thrombosed hemorrhoids[10]. If conservative management is unsuccessful, several office-based modalities could be options, including rubber-band ligation, injection sclerotherapy, laser photocoagulation, bipolar diathermy, cryotherapy, Dopplerguided hemorrhoidal artery ligation and infrared coagulation[8,9,11]. When an office-based therapy is still ineffective, patients may consider further intervention, such as hemorrhoidectomy, thrombectomy of external hemorrhoids and stapled hemorrhoidectomy[7,9].

As an crucial component of many non-surgical practices, sclerotherapy is most effective for grade I and Ⅱ internal hemorrhoids, especially for patients who have an increased risk of bleeding[2]. However, traditional sclerotherapy is performed by physicians through an anoscope. This method may cause iatrogenic risk and complications due to misplaced injections[2]. Therefore, there is scope for improvement in the field of sclerotherapy for hemorrhoids.

With the development of interventional flexible endoscopy and in order to solve the problems above, we designed a novel method called cap-assisted endoscopic sclerotherapy (CAES) for internal hemorrhoids. This article presents our pilot study on the methodology, feasibility, safety and clinical findings using CAES for internal hemorrhoids.

MATERIALS AND METHODS

Patient inclusion and exclusion criteria

This observational study was carried out in the Second Affiliated Hospital of Nanjing Medical University. All eligible patients with symptoms and signs of grade Ⅰ, grade Ⅱ or grade Ⅲ internal hemorrhoids requiring further interventional procedures after failure of conservative treatment were included in the study. Internal hemorrhoids are graded based on protrusion and reducibility (grade Ⅰ, hemorrhoids characterized by prominent vasculature with engorgement but no prolapse; grade Ⅱ, hemorrhoids prolapse only with straining but spontaneously reduce; grade Ⅲ, hemorrhoids prolapse beyond the dentate line with straining and require manual reduction; grade Ⅳ, hemorrhoids prolapse beyond the dentate line with straining but cannot be reduced manually)[12,13]. All included cases for analysis were followed up for at least four weeks.

Acute thrombosed hemorrhoids with anal pain, stricture, fissure, fistula, fecal incontinence, ulcerative colitis, Crohn's disease and any bleeding risk condition were excluded. Patients with acute diarrhea in the last

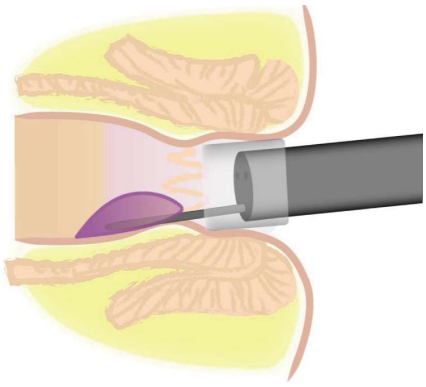

Illustration: Jacob Peichuan Ji

Figure 1 Illustration of cap-assisted endoscopic sclerotherapy.

12 h, severe complications, cancer, stroke, pregnancy, puerperium, mental disorders and portal hypertension were also excluded. Colon and terminal ileum examination by colonoscopy was performed for all patients before starting CAES. Polypectomy was performed if polyps were found and assessed to be suitable to be resected under endoscope. Informed consent was obtained from all participants.

Concept and methods of CAES

As shown in Figure 1, the regular cap used in endoscopic submucosal dissection was fixed on the top of the colonoscope. This cap is used to maximize visibility of the endoscopic view with enough insufflated air through the channel within the endoscope. A disposable endoscopic long injection needle (*e.g.,* the specially designed long needle: DT-EN-W322, 10/15/20 mm length, 22 g, Detian Medical, Changzhou, China) through the operating channel is used for the injection of the sclerosing agent. The needle is advanced into the submucosa of the targeted area of the hemorrhoids. The injecting points are above the dentate line. The sclerosing agent (Lauromacrogol injection, Tianyu Pharmaceutical, Xi'an, China), 1-2 mL for each injecting point, is injected while retracting the needle slowly. During the procedure, enough air is given for exposure of the endoscopic view. Before the complete retrieval of the needle from the tissue, as a suggestion, it is found to be helpful if you do not withdraw and stop the needle from moving for 5 s to prevent bleeding. The same procedure is performed for each targeted site under endoscopic view. Before taking out the endoscope, enough suction of air in the colon and visible rectal contents should be carried out to avoid or relieve abdominal distention and the feeling of defecation after the procedure.

Preparation and education

Although antibiotic prophylaxis was suggested for predisposing valvular heart disease because of the possibility of bacteremia after sclerotherapy[14], antibiotics were not used before and after CAES in this study. Besides, for safety considerations and observational requirements in this study, patients were required to rest in bed on the first night after the procedure. All individuals were required to follow medical instructions for avoiding constipation and diarrhea. Medicines were prescribed to soften the stools after the procedure if the patient had constipation.

Safety and satisfaction survey

Complications were recorded during and four weeks after CAES. The intensity of CAES and the relationship between the complications and CAES were described using the Common Terminology Criteria for Adverse Events (version 3.0). Intensity of complications was classified as mild, moderate, severe and disabling. The relationship between the complications and CAES was categorized as unrelated, possible, probable and definitely related to CAES. All patients were required to have a face to face communication at the doctor's office for the assessment of safety, efficacy and degree of satisfaction of the CAES. The level of satisfaction was classified into two degrees: positive, satisfied and pleased to introduce the CAES to other patients; negative, not satisfied and did not like this procedure. The second colonoscopy would be performed if the patient had bleeding or any other anorectal symptoms.

RESULTS

Patient characteristics

Table 1 shows the characteristics of the patients, including gender, age, classification of the internal hemorrhoids, grade of prolapse, previous hemorrhoidectomy history and other related information. A total of 30 patients with grade Ⅰ, grade Ⅱ or grade Ⅲ internal hemorrhoids was included for analysis in this study.

Clinical findings

Colon and terminal ileum examination by colonoscopy before CAES was performed in all patients for differential diagnosis of other possible diseases related to intestinal bleeding. No complications were observed during the procedure. However, we have to highlight that the needle could not be retrieved immediately when the injection was finished. It is suggested to keep the needle stable within the tissue for 5 s. If the needle was taken out from the tissue too quickly, bleeding would occur and the endoscopic view was affected by the blood. Figure 2 shows the procedures of CAES for internal hemorrhoids and the excision for anal papilla fibroma.

The patients were required to stay in hospital for 12 h after the procedure for safety considerations in this pilot observational study. No complications were observed during and after the procedure of polypectomy, CAES, excision of anal papilla fibroma and biopsy of polyps on the hemorrhoid lesion. All patients could return to normal activities after they were discharged from hospital. One (3.33%) patient claimed mild tenesmus within four days after CAES. This adverse event was finally confirmed as the result of one injection site that was chosen below the dentate line by an endoscopist who performed this procedure for the first time. One hundred percent

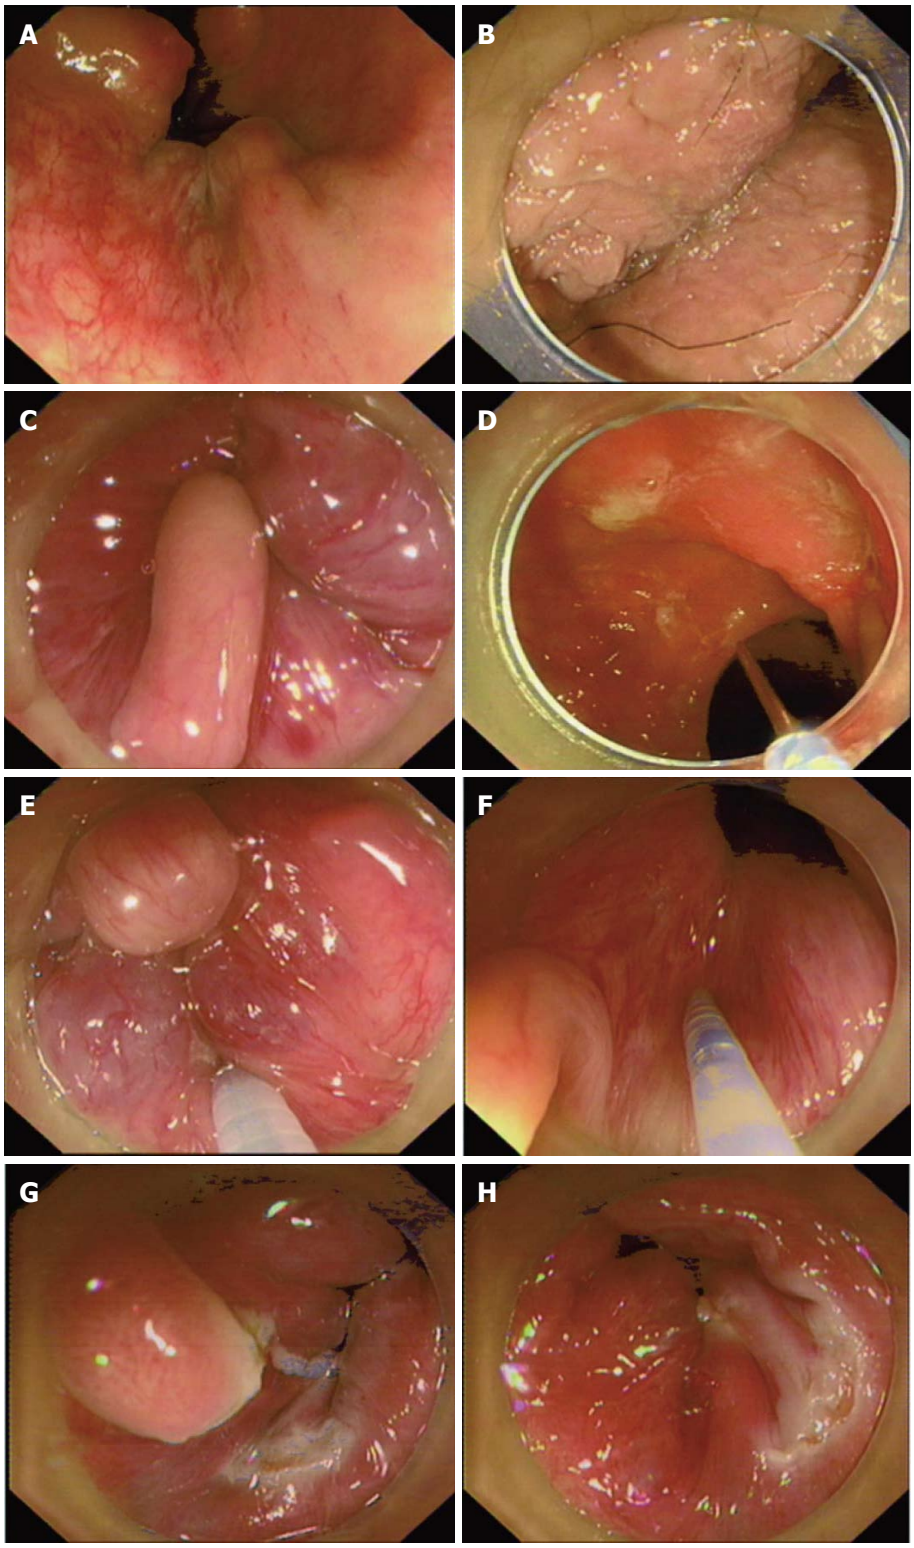

Figure 2 Procedures of cap-assisted endoscopic sclerotherapy for internal hemorrhoids and the excision for anal papilla fibroma. A: Internal hemorrhoids with retroflection of the endoscope; B: The anal region under cap-assisted endoscopic view; C: Internal hemorrhoids and anal papilla fibroma under cap-assisted endoscopic view with enough insufflated air; D: The disposable endoscopic long injection needle through operating channel; E: Injection of lauromacrogol into submucosa of internal hemorrhoids with the cap-assisted endoscopic view; F: Injecting of lauromacrogol into submucosa of internal hemorrhoids close to papilla fibroma before dissection; G: Dissection of anal papilla fibroma (confirmed by the followed pathology) after cap-assisted endoscopic sclerotherapy (CAES); H: No bleeding after CAES and dissection of anal papilla lesion before ending all procedures.

of patients were satisfied with this novel procedure. Those patients who underwent CAES in junction with polypectomy or excision of anal papilla fibroma expressed strong feeling of satisfaction for the therapeutic strategy.

DISCUSSION

Sclerotherapy dates back at least one century[15] and has been regarded as traditional therapy for grade Ⅰ and Ⅱ internal hemorrhoids. A variety of sclerosing agents, including ethanolamine, quinine, hypertonic saline solution, 5% phenol in oil, aluminum potassium sulfate and tannic acid, have been used in injection sclerotherapy for treating hemorrhoids[16-19]. Traditionally doctors had to use an anoscope during the sclerotherapy procedure. Misplacement of the sclerosing injection may result in potential complications, including pain, impotence, prostatitis, mucosal ulceration or necrosis

Table 1 Patient demographics and clinical results

Patient demographics	*n* (%)
Total included cases	30
Classification of internal hemorrhoids	
Grade Ⅰ	7 (23.33)
Grade Ⅱ	21 (70.0)
Grade Ⅲ	2 (6.67)
Grade Ⅳ	0
Male	22 (73.33)
Age (mean ± SD)	45.5 ± 4.2
With hemorrhoidectomy history	6 (20.0)
With rectal mucosal prolapse	4 (13.33)
With polyps on hemorrhoid lesions	1 (3.33)
With external hemorrhoids	0
Colon and terminal ileum examination before CAES	30 (100)
Polypectomy during colonoscopy before CAES	7 (23.33)
Excision of anal papilla fibroma after CAES	1 (3.33)
Biopsy for the polyps on hemorrhoids before CAES	1 (3.33)
Complications during and post-CAES	0
Post-CAES rectal bleeding	0
Post-CAES rectal mild pain or tenesmus	1 (3.33)
Positive satisfaction on CAES	30 (100)

Data are frequency counts (percentage of total) or the mean ± SD. CAES: Cap-assisted endoscopic sclerotherapy.

and prostatic abscess[10]. These complications emphasize the importance of precise placement of the injection with the sclerosing agent. In order to avoid the above complications, this prospective study was designed to evaluate the feasibility and efficacy of CAES for internal hemorrhoids under colonoscopy.

The preliminary results based on 30 cases demonstrated that CAES should be an effective interventional flexible endoscopic therapy for selected candidates with grade Ⅰ to grade Ⅲ internal hemorrhoids. After CAES, 100% of patients achieved the expected clinical response. The follow-up within 4 wk showed sustained clinical efficacy. No severe or obvious complications were observed and none of the suffered complications were definitely related to CAES in the study. These results indicated that CAES was safe and helpful to prevent iatrogenic risk from misplaced injections. The length of a common commercial endoscopic injection needle was not suggested in CAES because of its short length (*e.g.,* 4 or 5 mm), which seems to require more sites for injection and induce more mucosal injury and potential inflammation. Our specially designed needle, with a 15-20 mm length, is an important tool for enough submucosal injection with the sclerosing agent. Based on our experience, this CAES technique with the transparent cap is able to treat all hemorrhoids in a forward view fashion. There might be no need to have retroflection for the CAES procedure. Importantly, it is impossible for endoscopist to have retroflection in all cases.

In the present study, a high level of patient satisfaction (100%) and the convenience from adequate medical health or psychophysical protection for doctors also provide evidence to support CAES to be promising for the future. Actually, CAES brought additional benefits for patients, such as colonoscopy, possible polypectomy, excision of anal papilla fibroma and biopsy of polyps on hemorrhoid lesions under endoscopy.

Another advantage of doing an endoscopic procedure before CAES to that of using a plain disposable anoscope is that bleeding and other anorectal symptoms related to different colorectal diseases could be better differentiated[20]. A population-based study in the United States[21] reported in the hematochezia cohort showed significantly higher rates of diverticulosis, polyp or multiple polyps, mucosal abnormality/colitis, tumor and solitary ulcers on colonoscopy findings. Anorectal diseases, including hemorrhoids, are frequent in patients with intestinal disease. Hemorrhoids have been reported to occur in 20% of patients with UC[22] and approximately 7% of patients with CD[23]. In these selected cases, lesions in the colon and terminal ileum were observed during the examination by colonoscopy before CAES, which should be an effective way to have an early diagnosis of CD and UC with hemorrhoids. Therefore, colon preparation and colonoscopy is important when dealing with hemorrhoids as it would save the related medical cost and colon preparation for patients.

The cap, endoscope, air, long needle, sclerosing agent and endoscopic view should be the key points for the endoscopist to perform the CAES. This CAES technique is simple but the possible risk should be considered for physicians. One patient claimed mild tenesmus within four days after CAES. This complication was finally confirmed as the result of one injection site chosen below the dentate line by an endoscopist who performed this procedure for the first time. This lesson highlighted the importance of training for CAES. With the necessary training, the angle, direction and depth of injection under endoscopic view could be controlled very well and it would be easy to avoid the risk of injuring deeper tissues or injecting outside of the hemorrhoid.

All cases were required to be hospitalized for bed rest on the first night after the procedure, according to the design of this observational study. However, this hospitalization would not be required if the patient has no other condition except hemorrhoids. For prevention of recurrence of hemorrhoids, medicines and health education are important to maintain soft defecation within the first week after CAES if necessary.

There are some limitations in the present study. The sample size of this pilot study was small but a larger prospective study based on these preliminary results is ongoing. This was not a controlled study with the comparison of other traditional interventional therapies. Therefore, a rigorous randomized clinical trial should be designed to provide more evidence for the practice of CAES. Although CAES and the required preparation of colon and colonoscopy showed advantages and low medical costs for the diagnosis and therapy of anorectal diseases related to hemorrhoidal disease, a cost-effective analysis is needed for further study.

In conclusion, CAES is an innovation of endoscopic

sclerotherapy. It should be a convenient, safe and effective flexible endoscopic therapy for internal hemorrhoids. Traditionally, hemorrhoids are commonly treated by surgeons. However, the present study implies the future contribution of endoscopists for hemorrhoidal disease.

COMMENTS

Background

The current therapies for hemorrhoids can be grouped into conservative management, office-based procedures and surgical treatment. As a crucial component of many non-surgical practices, sclerotherapy is most effective for grade I and II internal hemorrhoids. However, traditional sclerotherapy is performed by physicians using an anoscope. This method may cause iatrogenic risk and complications due to misplaced injections. Additionally, an anoscope has the limitation of only being used within the anus. Therefore, there is scope for improvement in the field of sclerotherapy for hemorrhoids.

Research frontiers

With the development of interventional flexible endoscopy, the authors designed a novel method called cap-assisted endoscopic sclerotherapy (CAES) for internal hemorrhoids. This article presents the authors' pilot study with the methodology, feasibility, safety, clinical findings and their experience using CAES for internal hemorrhoids.

Innovations and breakthroughs

This study demonstrated CAES is a safe, effective and convenient endoscopic therapeutic strategy for grade Ⅰ, grade Ⅱ and partial grade Ⅲ internal hemorrhoids. The colon preparation and colonoscopy are the steps before the final sclerotherapy. The colon preparation and colonoscopy before CAES brought more benefits for patients, including possible polypectomy and excision of anal papilla fibroma under endoscopy. Besides, in these selected cases, lesions in the colon and terminal ileum were observed before CAES during the colonoscopy itself, which should be an effective way to have an early diagnosis of Crohn's disease and Ulcerative colitis with hemorrhoids. Therefore, it would save the related medical cost and colon preparation for patients. This study implies the future contribution of endoscopists on hemorrhoidal disease.

Applications

This pilot study based on 30 cases demonstrated that CAES should be an effective interventional flexible endoscopic therapy for selected candidates with grade Ⅰ to grade Ⅲ internal hemorrhoids. After CAES, 100% of patients achieved the expected clinical response. The follow-up within 4 wk further showed the sustained clinical efficacy. No severe or obvious complications were observed and none of the suffered complications were definitely related to CAES in the study. These results indicated that CAES was safe and helpful in preventing iatrogenic risk from misplaced injections. The authors' specially designed needle, 10/15/20 mm in length, is an important tool to ensure enough submucosal injection with the sclerosing agent. Based on the authors' experience, this CAES technique with the transparent cap is able to treat all hemorrhoids in a forward view fashion. There may be no need for retroflection for the CAES procedure. Importantly, it is impossible for endoscopist to have retroflection in all cases. In the present study, a high level of patient satisfaction (100%) and the convenience of adequate medical health or psychophysical protection for doctors also provide evidence for supporting CAES to be promising for the future. Actually, CAES brought additional benefits for patients, such as colonoscopy, possible polypectomy, excision of anal papilla fibroma and biopsy of polyps on hemorrhoid lesions under endoscopy.

Terminology

The concept and methods of CAES: The regular cap used in endoscopic submucosal dissection was fixed on the top of the colonoscope. This cap is used to maximize visibility of the endoscopic view with enough insufflated air through the channel within the endoscope. A disposable endoscopic long injection needle through the operating channel is advanced into the submucosa of the targeted area of the hemorrhoids. The injecting points are above the dentate line. The sclerosing agent for each injecting point is injected slowly while retracting the needle slowly. During the procedure, enough air was given for exposure of the endoscopic view. Before the complete retrieval of the needle from the tissue, as a suggestion, it is helpful if you do not withdraw and stop the needle from moving for 5 s to prevent bleeding. The same procedure is performed for each targeted site under endoscopic view.

Peer-review

The authors describe a modification of the band ligation technique of hemorrhoid therapy by using ESD caps with sclerotherapy. The use of a cap mounted on the tip of an endoscope was useful to stabilize its position for precise injection of a sclerosing agent through a long needle. Overall, the model is elegant and the results seem to be promising. In addition to a novel technique, their analysis is rigorous, including the use of a post-procedure questionnaire. The images and diagram are also excellent.

Abstract

AIM: To critically appraise the published randomized, controlled trials on the prophylactic effectiveness of the non-steroidal anti-inflammatory drugs (NSAIDs), in reducing the risk of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis.

METHODS: A systematic literature search (MEDLINE, Embase and the Cochrane Library, from inception of the databases until May 2015) was conducted to identify randomized, clinical trials investigating the role of NSAIDs in reducing the risk of post-ERCP pancreatitis. Random effects model of the meta-analysis was carried out, and results were presented as odds ratios (OR) with corresponding 95%CI.

RESULTS: Thirteen randomized controlled trials on 3378 patients were included in the final meta-analysis. There were 1718 patients in the NSAIDs group and 1660 patients in non-NSAIDs group undergoing ERCP. The use of NSAIDs (through rectal route or intramuscular route) was associated with the reduced risk of post-ERCP pancreatitis [OR, 0.52 (0.38-0.72), P = 0.0001]. The use of pre-procedure NSAIDs was effective in reducing approximately 48% incidence of post-ERCP pancreatitis, number needed to treat were 16 with absolute risk reduction of 0.05. But the risk of post-ERCP pancreattis was reduced by 55% if NSAIDs were administered after procedure. Similarly, diclofenac was more effective (55%) prophylactic agent compared to indomethacin (41%).

CONCLUSION: NSAIDs seem to have clinically proven advantage of reducing the risk of post-ERCP pancreatitis.

Key words: Non-steroidal drugs; Pancreatitis; Diclofenac; Indomethacin; Endoscopic retrograde cholangiopancreatography

Core tip: Current meta-analysis of 13 randomized controlled trials on 3378 patients successfully demonstrates the usefulness of non-steroidal anti-inflammatory drugs (NSAIDs) in the prevention of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis. Post-procedure use of NSAIDs by any route has clinically proven advantage of reducing 55% risk of post-ERCP pancreatitis. Diclofenac (55%) compared to indomethacin (41%) was more effective prophylactic agent.

Systematic review and meta-analysis on the prophylactic role of non-steroidal anti-inflammatory drugs to prevent post-endoscopic retrograde cholangiopancreatography pancreatitis. *World J Gastrointest Endosc* 2015; 7(19): 1341-1349 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i19/1341.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i19.1341

INTRODUCTION

Since its introduction into the field of gastroenterology, hepatology and hepato-pancreatico-biliary surgery, the endoscopic retrograde cholangiopancreatography (ERCP) has advanced to be an important and essential diagnostic and therapeutic tool. The introduction of magnetic resonance cholangiopancreatography and endoscopic ultrasound with several technological developments has sidelined ERCP into a largely a therapeutic tool in the management of sphincter of Oddi disorders, choledocholithiasis, pancreatic duct pathologies, and benign or malignant strictures of the common bile duct. However, ERCP carries significant risk, with post-ERCP pancreatitis being the most frequent and dreaded of these. The reported prevalence of post-ERCP pancreatitis is as high as 10%[1-4] in the medical literature. Nevertheless, it may exceed up to 30% in certain high-risk cluster of female patients with sphincter of Oddi dysfunction[5]. Post-ERCP pancreatitis may result in prolonged hospital stay, pancreatic oedema, pancreatic necrosis, pancreatic pseudocyst, systemic inflammatory response syndrome and mortality up to 1% in addition to adding a significant financial burden on health-care resources[6].

Considering the morbidity, mortality and financial burden related to post-ERCP pancreatitis, it is vital to consider every preventive strategy to reduce its incidence. Risk-benefit analysis and then right patient selection may be the best way to avoid un-necessary ERCP and its subsequent complications. Several studies have reported promising modalities of prophylaxis including pancreatic duct stenting of patients with sphincter of Oddi dysfunction, administration of NSAIDs of various types by various routes and other diverse measures. The evidence of these prophylactic measures is conflicting and so far has failed to demonstrate the accurate effectiveness[7-11]. Based upon the available evidence, NSAIDs are the most commonly used modality for post-ERCP pancreatitis prevention. The possible advantages of NSAIDs use are cost-effectiveness, easily accessible and effortlessly administrable. The aim of this systematic review is to critically appraise the published randomized, controlled trials in the clinical effectiveness of the NSAIDs in reducing the risk of post-ERCP pancreatitis.

MATERIALS AND METHODS

Electronic medical databases such as the Medline, EMBASE, Cochrane Colorectal Cancer Group Controlled Trial Register, the Cochrane Central Register of Controlled Trials (CENTRAL) in the Cochrane Library and Science Citation Index Expanded were explored until May 2015 to find published randomized, controlled trials. The MeSH terms related to the NSAIDs and post-ERCP pancreatitis were retrieved from the search engine of PubMed and were used to search electronic databases. Attempts to include additional studies were also made by the hand searching of the citations of published studies. The statistical analysis of the extracted data was conducted according to the guidelines provided by the Cochrane Collaboration including the use of RevMan 5.3® statistical software, random-effects model analysis, heterogeneity testing by χ^2 test, heterogeneity quantification by I-squared test and the use of forest plots for the graphical display of the combined outcomes[12-18]. The critical appraisal tool to score the quality of included trials was adopted from the published guidelines of Jadad *et al*[19] and Chalmers *et al*[20]. The short summary of the resulting evidence was presented in a tabulated form by using tool GradePro®[21], provided by the Cochrane Collaboration.

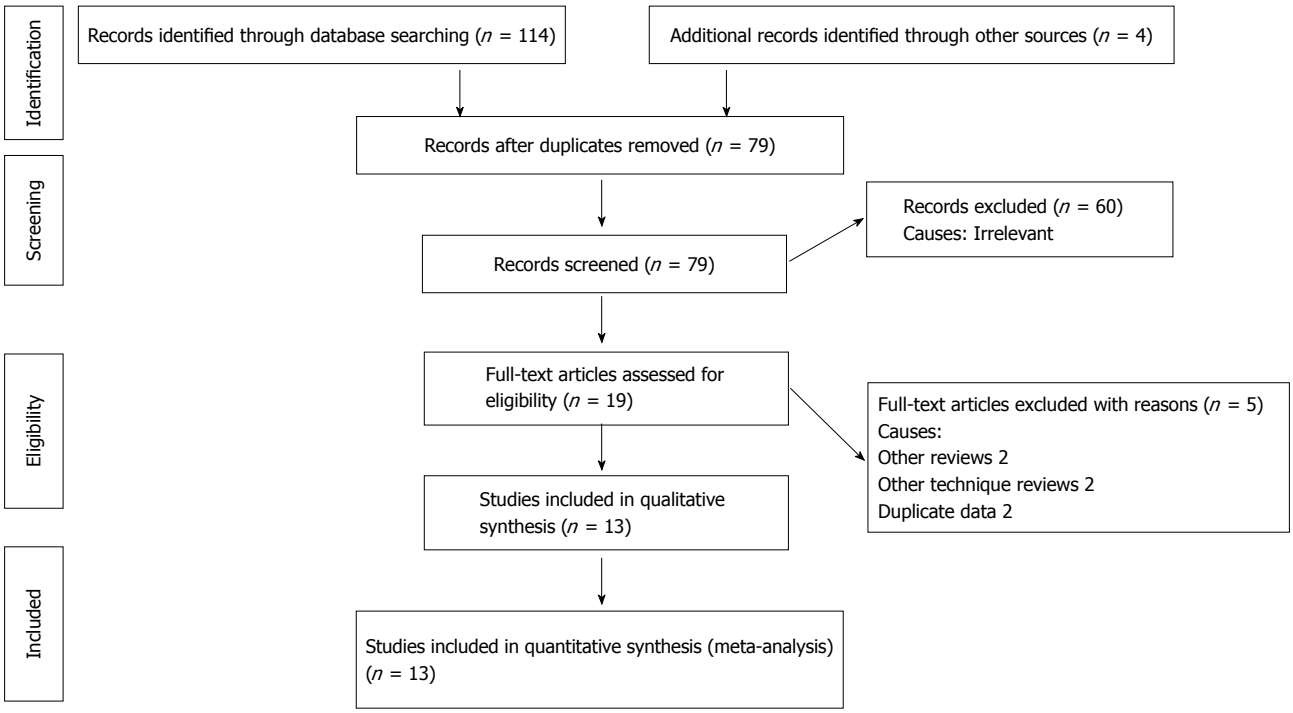

Figure 1 PRISMA flow chart.

RESULTS

Number of studies on first hit in search engines and their subsequent shortlisting is given in the PRISMA flow chart (Figure 1). Thirteen randomized, controlled trials[22-34] on 3378 patients undergoing ERCP were analysed in this study. Some 1718 patients were assigned in NSAIDs group whereas 1660 patients were in no-NSAIDs group. The characteristics of included studies are given in Table 1. The short summary on the quality of evidence generated from the combined analysis of trials used in this meta-analysis is given in Table 2. The study quality based scores of included trials were graded adequate based upon the reporting of four quality indicator variables, *i.e.*, optimum randomization technique, power calculations, concealment and intention-to-treat analysis.

Incidence of post-ERCP pancreatitis in NSAIDs vs placebo trials

As shown in Figure 2A, there was minimal and non-significant heterogeneity [Tau^2 = 0.11, χ^2 = 18.60, df = 12, (P = 0.10); I^2 = 35%] among trials. In the random effects model (OR, 0.52; 95%CI: 0.38, 0.72; Z = 4.02; P < 0.0001) analysis, the risk of post-ERCP pancreatitis was significantly lower (48% lower) following the use of NSAIDs. The NNT was 16 with absolute risk reduction of 0.05.

Incidence of post-ERCP pancreatitis in per rectal NSAIDs vs placebo trials

As shown in Figure 2B, there was no heterogeneity [Tau^2 = 0.11, χ^2 = 9.86, df = 7, (P = 0.20); I^2 = 29%] among trials. In the random effects model (OR, 0.43; 95%CI: 0.28, 0.67; Z = 3.77; P = 0.0002) analysis, the risk of post-ERCP pancreatitis was significantly lower (57% lower) following rectal administration of NSAIDs.

Incidence of post-ERCP pancreatitis in diclofenac vs placebo trials

As shown in Figure 2C, there was significant heterogeneity [Tau^2 = 0.38, χ^2 = 14.49, df = 6, (P = 0.02); I^2 = 59%] among trials. In the random effects model (OR, 0.45; 95%CI: 0.24, 0.83; Z = 2.55; P = 0.01) analysis, the risk of post-ERCP pancreatitis was significantly lower (55% lower) following the use of diclofenac.

Incidence of post-ERCP pancreatitis in indomethacin vs placebo trials

As shown in Figure 2D, there was no heterogeneity [Tau^2 = 0.00, χ^2 = 3.81, df = 4, (P = 0.43); I^2 = 0%] among trials. In the random effects model (OR, 0.59; 95%CI: 0.39, 0.88; Z = 2.61; P = 0.009) analysis, the risk of post-ERCP pancreatitis was significantly lower (41% lower) following the use of indomethacin. Based upon this finding it seems like diclofenac is more effective NSAIDs compared to indomethacin for the prevention of post-ERCP pancreatitis.

Incidence of post-ERCP pancreatitis if NSAIDs are administered before procedure

As shown in Figure 2E, there was no heterogeneity [Tau^2 = 0.05, χ^2 = 5.96, df = 5, (P = 0.31); I^2 = 16%] among trials. In the random effects model (OR, 0.52; 95%CI: 0.34, 0.80; Z = 2.93; P = 0.003) analysis, the risk of post-ERCP pancreatitis was significantly lower (48% lower) if NSAIDs are administered before the

procedure of ERCP compared to placebo.

Incidence of post-ERCP pancreatitis if NSAIDs are administered after procedure

As shown in Figure 2F, there was minimal heterogeneity [Tau^2 = 0.21, χ^2 = 10.30, df = 5, (P = 0.07); I^2 = 51%) among trials. In the random effects model (OR, 0.45; 95%CI: 0.27, 0.77; Z = 2.90; P = 0.004) analysis, the risk of post-ERCP pancreatitis was significantly lower (55% lower) if NSAIDs are administered after the procedure of ERCP compared to placebo.

DISCUSSION

Summary of main results

Results of this meta-analysis demonstrate that the use of NSAIDs (by any route of administration) meaningfully reduces the incidence of post-ERCP pancreatitis; rectal administration is slightly more effective; diclofenac seems to be clinically better than indomethacin and post-ERCP administration has shown superior results. The use of pre-procedure NSAIDs was effective in reducing approximately 48% but the risk of post-ERCP pancreatitis was reduced by 55% if NSAIDs were administered after the procedure.

Overall completeness and applicability of evidence

The findings of current study are pertinent to only those groups of patients which may require either therapeutic or diagnostic ERCP and fit enough to undergo the procedure. Despite the reporting of several systematic reviews and meta-analysis[35-46] evaluating the role of NSAIDs in reducing

the risk of consequent pancreatitis resulting from ERCP, this is the only study providing evidence on the role of NSAIDs, route of NSAIDs administration, type of NSAIDs being more effective and the timing of the NSAIDs administration to reduce the incidence of post-ERCP pancreatitis.

Quality of evidence

This study reports a total of 3378 participants from 13 randomized, controlled trials undergoing ERCP reporting post-ERCP pancreatitis as primary outcome preferentially. The risk of bias in the included trials was low to moderate when scores against the standard quality guidelines and therefore, the quality of resulting evidence may be considered adequate (Table 2). The variable experience of endoscopists might have influenced the outcomes. Other confounding factors which might have influenced the final outcome of the ERCP include the use of different endoscopes, type and dosage of sedation, variable use of scope-guide technique, indications of ERCP, sundry patient selection and diverse biochemical measuring tools for the diagnosis of post-ERCP pancreatitis.

Potential biases in the review process

Authors adopted the standard Cochrane Collaboration methodology to perform the statistical analysis, interpretation as well as to present the quality of evidence. The quality of included (Table 3) randomized, controlled trials was assessed for risk of bias in one of the six domains (blinding) and at unclear risk of bias in another domain (allocation concealment). The low risk of bias was mainly attributable to the presence of blinding in all the trials and presence of allocation concealment in the majority of the studies. Presence of adequate randomization technique and optimum utilization of the power calculations in all included trials provided adequate strength to generate higher level of evidence to support the conclusion. There are no trials comparing pre-procedure *vs* post-procedure prophylactic use of NSAIDS. This inference was made based upon their comparisons against placebo. Same limitation also applies on the effectiveness of diclofenac *vs* indomethacin. However, the conclusion in terms of an individual agent *vs* other agent effectiveness and timing of NSAIDS administration may reluctantly be drawn from the available studies comparing effectiveness against placebo.

Agreement and disagreement with other published evidence

The findings of current meta-analysis are in accordance with the conclusions of the previously published reviews[35-46]. However, this study provides up to date, comprehensive and cumulative evidence on the use of NSAIDs (by any route of administration) meaningfully reducing the incidence of post-ERCP pancreatitis, suggesting the rectal administration of NSAIDs being more effective, indomethacin proven to be clinically better than diclofenac and pre-ERCP administration of NSAIDs showing superior results.

Implications for practice and research

This study quite successfully validates that NSAIDs may

routinely be used to prevent the post-ERCP pancreatitis. However, the aforementioned confounding factors influencing the final outcomes must be acknowledged and attempts must be made to generate less biased evidence by removing these limitations. This study categorically reports the superiority of rectal administration of NSAIDs, diclofenac over indomethacin and post-ERCP administration of NSAIDs to reduce post-ERCP pancreatitis. However, these results cannot be generalized because the preventative strategy for post-ERCP pancreatitis in group of patients with known peptic ulcer disease, asthma, and allergy to NSAIDS needs also to be formulated. In addition, NSAIDs cannot be used in patients with chronic kidney disease. Other measures to prevent post-ERCP pancreatitis must not be completely abandoned and may be applicable in these situations. In addition, there are no reported trials comparing pre-procedure *vs* post-procedure prophylactic use of NSAIDS. This inference was made based upon their comparisons against placebo. Same limitation also applies on the effectiveness of diclofenac *vs* indomethacin. Trials targeting these questions must be considered for a validated conclusion from direct evidence instead of the presented indirect inference. Current review is unable to quantify the potential complication of bleeding following the prophylactic use of NSAIDs in ERCP patients, especially in patients undergoing sphincterotomy simultaneously. Although this is beyond the scope of this study but reported incidence of bleeding is almost negligible. Neither the length of incision nor the pre-procedure use of aspirin or other NSAIDs appear to be important predictors of ERCP-sphincterotomy linked bleeding[47].

COMMENTS

Background

Post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis can be a serious complication resulting in increased mortality and morbidity in already sick patients. Therefore, the preventative strategies for post-ERCP are vital to reduce its consequences. The use of non-steroidal anti-inflammatory drugs (NSAIDs) is simple, economical and reported to be effective to reduce the incidence of post-ERCP pancreatitis. This article highlights the evidence in the form of meta-analysis to define the role of NSAIDs.

Research frontiers

Other preventive measures to reduce the incidence of post-ERCP pancreatitis include sphincterotomy of the sphincter of Oddi and pancreatic duct stenting. However, the use of NSAIDs seems to be less invasive and most economical. Several studies have reported its effectiveness and current study is an attempt to advance this evidence further.

Innovations and breakthroughs

Current meta-analysis of 13 randomized controlled trials on 3378 patients successfully demonstrates the usefulness of NSAIDs in the prevention of post-ERCP pancreatitis. Post-procedure use of NSAIDs by any route has clinically proven advantage of reducing 55% risk of post-ERCP pancreatitis. Diclofenac (55%) compared to indomethacin (41%) was more effective prophylactic agent.

Applications

Based upon the findings of this study the use of NSAIDs has clinical advantage in the reduction of post-ERCP pancreatitis and may routinely be used.

Terminology

ERCP: Endoscopic retrograde cholangiopancreaticography; NSAIDs: Non-steroidal anti-inflammatory drugs; MRCP: Magnetic resonance cholangio-pancreaticography.

Peer-review

The manuscript is overall well written.

Abstract

Endoscoic variceal ligation (EVL) by the application of bands on small bowel varices is a relatively rare procedure in gastroenterology and hepatology. There are no previously reported paediatric cases of EVL for jejunal varices. We report a case of an eight-year-old male patient with a complex surgical background leading to jejunal varices and short bowel syndrome, presenting with obscure but profound acute gastrointestinal bleeding. Wireless capsule endoscopy and double balloon enteroscopy (DBE) confirmed jejunal varices as the source of bleeding. The commercially available variceal banding devices are not long enough to be used either with DBE or with push enteroscopes. With the use of an operating gastroscope, four bands were placed successfully on the afferent and efferent ends of the leads of the 2 of the varices. Initial hemostasis was achieved with obliteration of the varices after three separate applications. This case illustrates the feasibility of achieving initial hemostasis in the pediatric population.

Key words: Endoscopic variceal ligation; Endoscopic hemostasis; Pediatrics; Gastrointestinal hemorrhage; Varices; Variceal banding

Core tip: Banding jejunal varices in the pediatric population is feasible, safe and can achieve initial hemostasis in complex surgical patients.

Belsha D, Thomson M. Challenges of banding jejunal varices in an 8-year-old child. *World J Gastrointest Endosc* 2015; 7(19): 1350-1354 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i19/1350.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i19.1350

INTRODUCTION

Ectopic varices are defined as large porto-systemic venous collaterals occurring anywhere in the abdomen except in the cardio-esophageal region[1].

Figure 1 Computed tomography angiography with multiple serpiginous vessels in the left side of the bowel mesentery.

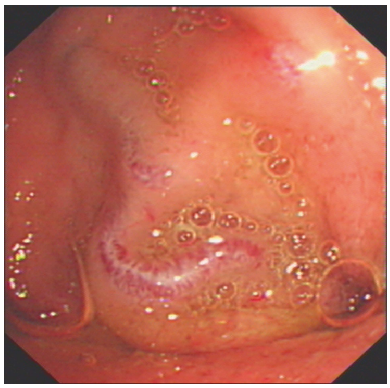

Figure 2 Suspicion of varices.

They account for up to 5% of all variceal bleeding[2]. Ectopic varices have been reported to occur at numerous sites, including 18% in the jejunum or ileum, 17% in the duodenum, 14% in the colon, 8% in the rectum, and 9% in the peritoneum[3]. Jejunal variceal bleeding, although rare, can be life threatening. There are only a few reports on the managements of jejunal varices in the paediatric population[4]. We present a rare case of severe and recurrent gastrointestinal bleeding secondary to jejunal varices in an 8-year-old patient. The management strategies including the use of endoscopic variceal ligation (EVL) are discussed.

CASE REPORT

An 8-year-old male patient was transferred from another tertiary hospital for assessment for obscure but profound acute gastrointestinal bleeding (AGIB).

He had a complex background of gastroschisis at birth associated with duodenal and colonic atresia. He had a repair of gastroschisis on day 1 of life and subsequently underwent a duodenojejunal anastamosis with right hemicolectomy and ileostomy formation, followed by ileo-colonic anastamosis and closure of the stoma. He had short gut syndrome and received nutritional supplementation *via* a balloon gastrostomy.

He had had multiple episodes of GI bleeding since he was 18 mo of age, which were thought to be associated with a superior mesenteric vein thrombosis. These were intermittent in nature and managed conservatively. The patient had a period of two years without a GI bleed prior to this presentation.

In 2014 however, the patient had 17 episodes of AGIB. Seven episodes were significant, mainly of hematochezia with clots or large melena. His lowest recorded hemoglobin was 22 g/L. The patient had multiple blood transfusions and was given 4 weekly iron infusions. He underwent computed tomography (CT) angiography which revealed distorted adjacent vascular structures around the pancreas with the splenic vein looping over the superior edge of the pancreas.

Normal enhancement was noticed in the portal vein, its left and right branches, the splenic vein (SV) and the superior mesenteric vein (SMV). However; there is unusual prominent venous structure draining in to the right side of the confluence of the SMV and the SV. There were multiple serpiginous vessels in the left side of the bowel mesentery with in particular a clump of varices/collaterals in the small bowels mesentery (Figure 1). All connections from these apparent varices couldn't be established, however; there was at least a connection to a looping vessel which extends into the left side of the SMV. Further looping vessels were seen in the anterior aspect of the mesentery from a proximal loop of the jejunum. Theses dilated blood vessels and collaterals around the mesentery of the small bowel raised the suspicion of mesenteric varices in the upper abdomen, but no active bleeding source was recognised. The patient was put intermittently on octreotide infusion but wasn't given primary or secondary prophylaxis as it was felt that the varices were more confined to some areas and secondary to mesenteric venous obstruction/abnormalities rather than strong evidence of generalised portal hypertension.

On arrival to our hospital in the same year, upper GI endoscopy revealed no esophago-gastric varices but identified portal gastropathy. Ileo-colonoscopy was normal apart from an erythematous ileo-colonic anastamotic rim. WCE identified a suspicious area (around 50 cm from the pylorus) of nodular shaped lesions with bluish discoloration, suspicious of varices. Two days later, further profound hematochezia occurred and therefore octreotide infusion (5 mcg/kg per hour) was commenced. Trans-oral double balloon enteroscopy (DBE) confirmed a normal esophagus, mild evidence of portal gastropathy, a normal duodenum, and jejunal examination revealed 4 moderately large isolated jejunal varices around 40-50 cm post-pylorus (Figures 2 and 3). Four bands were placed successfully on the afferent and efferent ends of the leads of the 2 of the varices using an operating gastroscope (Figure 4). The commercially available variceal banding devices are not long enough to be used either with DBE which was initially used diagnostically. Trans-anal DBE was performed and showed a small potential varix

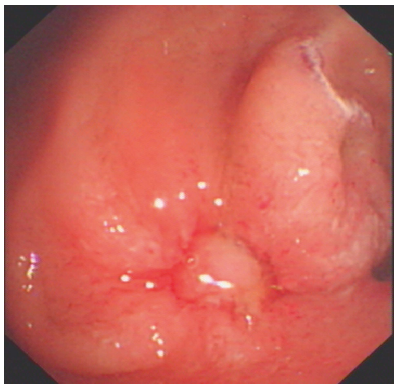

Figure 3 Appearance of jejunal varices using the double balloon enterosocpy.

approximately 120 cm proximal to the ileo-colonic anastamosis and this was not considered a risk and was not bleeding therefore was not banded. This area was marked for future reference with methylene blue tattoo injection. One week later a further endoscopy revealed the 2 banded varices to be thrombosed and now absent and sloughing within the bands was noted which were beginning to fall off the mucosa. The remaining 2 variceal vessels were then also banded. Two weeks subsequently the patient was well with no further bleed and a further endoscopy revealed friable variceal beds but no active bleeding. One further varix was banded at that time with hemostasis identified.

However the patient developed recurrence of bleed two weeks later possibly from an ileo-colonic source. The patient had shunting procedure few weeks later (mesenterico-caval shunt).

DISCUSSION

Our patient presented with the classical clinical signs reported previously in the literature for jejunal varices, evidence of abnormal vasculature in the mesentery with or without portal hypertention, a history of abdominal surgery, and hematochezia with or without hematemesis[5].

The exact pathology for developing jejunal varices in our case is not fully understood. It is likely to be a combination of superior mesenteric vein thrombosis (subsequently re-canalised however) and adhesions. A history of abdominal surgery appears to predispose to the development of ectopic varices around adhesions[6]. It seems that small-bowel anastomotic and adhesion-related varices can form within adhesions in the setting of mesenteric venous obstruction with or without portal hypertension[5].

Collateral formation within adhesions from previous surgery is the usual mechanism for the development of ectopic varices[3], with a likely mechanism that adhesions bring the parietal surface of the viscera in contact with the abdominal wall and portal hypertension results in the formation of varices below the intestinal mucosa[7].

The mainstay for the diagnosis of jejunal varices in our case was a combination of CT angiography and

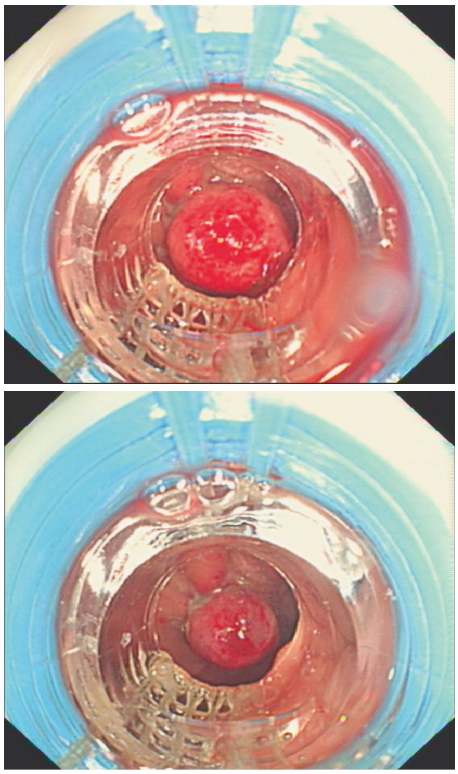

Figure 4 Banding of the jejunal varices using the operative gastroscope.

wireless capsule endoscopy.

Jejunal varices in wireless capsule endoscopy appear as serpiginous or nodular shapes, with or without a bluish discoloration. The variceal mucosa appears mosaic-like, shining, or normal compared with surrounding mucosa[8].

Capsule endoscopy is invaluable for the diagnosis of small-bowel varices. It is highly sensitive for detecting fresh blood in the small bowel. Clinical suspicion, capsule endoscopy image recognition, and alertness during capsule endoscopy interpretation are keys to diagnosis[8].

Several approaches for the treatment of jejunal varices have been described including surgery[9], portal venous stenting[10-12], percutaneous embolisation[13,14] and thne endoscopic options[5,15-18].

Surgical treatment options for small bowel variceal bleeds include resection of the afferent area of bowel and re-anastomosis[13]. However this can be challenging in patients with short gut and multiple adhesion as in our case.

Transjugular intrahepatic portal-systemic shunt or a decompressive shunting procedure is recommended in patients with overt systemic portal hypertension[13,19,20]. With the addition of coil or embolization has been reported to be particularly useful for ectopic varices, as these can continue to bleed despite successful portal pressure reduction[21].

The effectiveness of beta-blockers for primary prophylaxis and octreotide treatment for acute hemorrhage of anastomotic and segmental varices is uncertain[5].

It has been reported that endoscopic treatment including sclerosing agents can be used for treatment

of actively bleeding duodenal or jejunal varices or to prevent re-bleeding from focal varices with hemorrhage. However, while hemostasis is feasible, ulceration and re-bleeding rates can be high[5]. The use of N-butyl-2-cyanoacrylate (Histoacryl®) injection has been described in several case reports, for hemostasis of actively bleeding duodenal varices[15,22,23]. In one series all the varices had developed around the anastamotic sites and only two had elevated systemic portal pressure[18]. Another case report describes successful treatment of bleeding jejunal varices using cyanoacrylate sclero-therapy *via* enteroscopy in an adult patient[16].

EVL has a theoretical increased risk of complications in the small bowel because of its thin wall, *e.g.*, perforation. However, there are several reports of successfully treated duodenal varices by EVL in adults without complications. In a review of 19 cases (all adults) with duodenal EVL only 3 (15.8%) rebled after treatment with no deaths reported due to complications or rebleeding[16]. In a report of 4 patients with duodenal EVL, 2 achieved complete resolution of varices after one treatment session, one had remaining varices on surveillance endoscopy but no bleeding in a 9 mo period and one case required surgical resection after several banding sessions[17].

The standard ligation balloon devices available are too short to be adapted for an enteroscope or a colonoscope but are applicable to standard upper GI endsocopes. The operating gastroscope (GIF-2TQ260M) allowed 3 way tip deviation and is stiffer than conventional upper GI endsocopes allowing successful banding to occur.

In this case, EVL was used successfully to achieve initial hemostasis with obliteration of the varices after three separate applications, however bleeding subsequently occurred from an ileo-colonic source.

Frequently ectopic variceal bleeding is difficult to manage and traditionally surgery or shunting is required depending on the underlying disease and the patency of the portal vein.

Endoscopic treatment as a minimally invasive approach is feasible and safe in this case and represents a viable alternative.

To the best of our knowledge, this is the first reported case in the literature describing EVL in the management of jejunal variceal bleeding in the pediatric population.

This case illustrates the technical feasibility and apparent safety of EVL in the management of jejunal variceal bleeding in children.

COMMENTS

Case characteristics
Recurrent severe gastrointestinal bleeding.

Clinical diagnosis
Jejunal varices.

Differential diagnosis
Upper gastrointestinal endoscopy ruled out esophageal and gastric variceal bleeding. Ilio-colonosconoscopy and wireless capsule ruled out other diagnosis like polyps or other vascular malformation. Wireless capsule showed features suggestive of ectopic varices.

Laboratory diagnosis
Extensive investigations including complete blood count, Lipase, liver enzymes, kidney function, radiological images with computed tomography (CT) angiography. The diagnosis was confirmed with wireless capsule endoscopy and endoscopy of the affected small bowel.

Imaging diagnosis
Imaging study using CT scan demonstrated thickening and irregularity of the mesentery surrounding in keeping with the diagnosis of mesenteric panniculitis.

Pathological diagnosis
Variceal bleeding was the diagnosis as per the wireless capsule endoscopy and the endoscopic finding.

Treatment
The patient was treated with pharmacological agents including octreotide. Blood transfusion was needed frequently to stabilise the patient. Endoscopic variceal ligation was successfully applied to achieve initial hemostasis.

Related reports
Clark *et al* reported successful endoscopic ectopic variceal ligation: A series of 4 cases and review of the literature in adult population.

Experiences and lessons
Jejunal varices is a rare disorder that can present with recurrent severe gastrointestinal bleeding in complex surgical paediatric patient, the authors describe a novel intervention in paediatric using endoscopic variceal ligation to achieve initial hemostasis.

Peer-review
In this case report the authors present the case of an 8-year-old child treated with endoscopic band ligation for jejunal varices. This kind of pathology is rare and the therapeutic options could be challenging.
